articulation to tension and applying rhythmic oscillations to the joint to qualify the resistance to movement. The normal joint end-feel is initially soft and resilient and gradually becomes more restrictive as maximal joint range of motion is reached. A pathologic or restrictive end range of motion is palpable earlier in passive joint movement and has an abrupt, restrictive end-feel when compared with normal joint end-feel. The paraphysiologic zone of movement occurs outside the joint's normal elastic barrier and is the site of joint cavitation and manipulation. The anatomic barrier of the joint marks the junction of the paraphysiologic and pathologic zones of movement. The pathologic zone of movement lies outside the limits of normal anatomic joint integrity and is characterized by joint injury (e.g. sprain, subluxation or luxation).

Combining the evaluation of segmental joint range of motion and the presence or absence of pain at the extremes of motion, diagnostic interpretations can be implied.[54] Normal joint motion is painless, suggesting that articular structures are intact and functional. Normal joint mobility that has a painful end range suggests that a minor sprain of the associated articular tissues is present. Painless joint hypomobility suggests that a contracture or adhesion is present. Painful hypomobility suggests an acute strain with secondary muscle guarding. Painless hypermobility may indicate a complete rupture and a painful hypermobility suggests a partial tear of the evaluated structure.

Motion palpation Motion palpation is used to evaluate each individual vertebral and pelvic articulation for loss of normal joint motion and overall resistance to induced motion. The goal of palpating joint movement is to evaluate the initiation of motion resistance, the quality of joint motion and end-feel, and the overall joint range of motion (ROM). Similar palpatory findings can be noted in other soft tissues such as skin, connective tissue, muscles or ligaments.[46] Each vertebral segment is evaluated for altered motion palpation findings in flexion and extension, right and left lateral flexion and right and left rotation. Segmental causes of vertebral movement restrictions include soft tissue (e.g. capsular fibrosis, muscle spasms or contractures) and osseous (e.g. malformations, osteoarthritis, ankylosis) pathologies. Vertebral segments with altered motion palpation findings (i.e. joint stiffness) can occur with or without localized muscle hypertonicity and pain. Comparisons of motion palpation findings before and after manipulation or stretching exercises are made to evaluate the vertebral motion segment response to treatment.

Wither motion palpation Lateral forces are applied to individual dorsal spinous processes of the withers (T3–T12) to assess lateral bending and rotation of individual thoracic vertebral motion segments. The practitioner stands facing the withers. To stabilize the cranial and caudal vertebral segments, the bases of both hands are applied to the ipsilateral surface of the spinous processes adjacent to the vertebra being evaluated. The index fingers contact the contralateral surface of the dorsal spinous process to be assessed. A compressive force is applied between the index fingers and base of the hands to induce slight rotation of an individual thoracic spinous process. Normally, 3–4 mm of spinous process movement is palpable, without any evidence of pain or muscles spasms in response to the applied force. In horses with wither discomfort due to poor saddle fit, an obvious pain response (e.g. a rapid elevation of the head, depression of the withers) and local muscle hypertonicity will be precipitated with the applied pressure. In chronic forelimb lameness (e.g. laminitis), individual spinous process motion will not be detectable and the entire withers will move as a unit due to presumed chronic fibrosis and muscle guarding.

Trunk lateral bending motion palpation Lateral forces are applied to individual dorsal spinous processes of the trunk (T13–L6) to assess lateral bending and rotation of individual thoracolumbar vertebral motion segments. The practitioner stands facing the trunk. The base of the tail is grasped in the caudal hand, which provides side-to-side motion during the procedure. The base of the cranial hand is positioned against or between the spinous processes of interest. A lateral bending moment (i.e. wiggle) is induced as the cranial hand rhythmically pushes laterally and the caudal hand pulls laterally. The cranial hand is repositioned at the sequential dorsal spinous processes from cranial to caudal in order to assess lateral bending and rotation at individual thoracolumbar vertebral segments. Normally, a slight springy end-feel of joint motion is palpable at each motion segment, without any evidence of pain or muscle spasms in response to the applied force. In horses with back problems, restricted vertebral motion or stiffness is palpable and there is evidence of local pain and muscle spasms in response to the applied pressure. In general, acute or primary back problems produce segmental stiffness, pain and muscle hypertonicity. Chronic or secondary back problems produce regional stiffness, pain and muscle hypertonicity or atrophy.

Rib motion palpation Lateral compressive forces are applied to the individual ribs and costochondral junctions to assess pain and mobility. The base of the hand is positioned over individual ribs as a medial motion is induced, similar to expiration. The hand is repositioned at the sequential ribs and costochondral junctions from cranial to caudal. The amount of rib motion, resentment and secondary muscle spasms are noted during the induced movements. Normally, a slight springy feel is palpable at each rib, without any evidence of pain or muscle spasms. In horses that are girthy or have back problems, restricted rib motion or stiffness is palpable and there is evidence of local pain, resentment and muscle spasms in response to the applied pressure.

Trunk flexion-extension motion palpation While standing on an elevated surface, ventrally directed forces are applied rhythmically over individual dorsal spinous processes to assess flexion and extension of individual thoracolumbar (T13–L6) vertebral motion segments. The palm of one hand is placed over the dorsal aspect of the spinous process of interest. The other hand grasps the wrist and both hands apply a ventral force equally. An extension moment and rebound flexion (i.e. bounce) is induced as the hands rhythmically push ventrally. The hands are repositioned at sequential dorsal spinous processes from cranial to caudal. Normally, a slight springy end-feel of joint motion is palpable at each motion segment, without any evidence of pain or

muscle spasms. In horses with back problems, restricted motion or stiffness is palpable and there is evidence of local pain and muscle spasms in response to the applied pressure.

Lumbosacral flexion-extension motion palpation Ventrally directed forces are also applied rhythmically over the tuber coxae to induce extension of the sacroiliac and lumbosacral articulations. The practitioner stands facing the pelvis. The fingers are placed over the dorsal aspect of the tuber coxae to induce the ventral motion. A normal response to the induced movement is fluid vertical motion of the lumbosacral region with 1–2 cm of dorsoventral displacement over the lumbar dorsal spinous processes. Horses with pelvic or lumbar dysfunction will have a noticeable pain response, resent the induced movement or will have protective gluteal or sublumbar muscle spasms that limit the induced movement. The vertically directed force primarily induces movement at the lumbosacral junction, but sacroiliac joint motion and potential injury must also be differentiated with this procedure.

Sacroiliac ligament stress tests The sacroiliac ligaments are not readily palpable in horses. However, specific forces applied to the pelvic prominences (i.e. tuber sacrale, tuber coxae or tuber ischii) or the sacral apex can provide an indirect method to assess the structural and functional status of the supporting ligaments.

Dorsoventral sacroiliac ligament stress tests Sacroiliac ligament injury can be identified by rhythmically applying a ventrally directed force over the lumbosacral dorsal spinous processes in an effort to stress the supporting sacroiliac ligaments. This procedure requires the practitioner to get up on an elevated surface (i.e. mounting block) so that the two separately applied forces can be directed vertically over the L6 and S2 dorsal spinous processes, respectively. Horses with sacroiliac ligament injuries would be expected to resent the induced movement over the L6 dorsal spinous process since it specifically stresses the interosseous sacroiliac ligament (i.e. ligamentous sling of the sacropelvic junction). Horses with lumbosacral vertebral joint dysfunction (i.e. localized pain, reduced joint motion and muscle hypertonicity without structural pathology) may also resent this procedure. Rhythmically applied ventrally directed forces over the dorsal spinous processes at the sacrocaudal junction would be expected to specifically stress the dorsal portion of the dorsal sacroiliac ligament. A positive response to this test combined with positive ultrasound findings of desmitis of the dorsal sacroiliac ligament would be highly suggestive of clinically significant dorsal sacroiliac ligament injury.

Lateral sacroiliac ligament stress test Sacral apex deviation can be assessed by applying simultaneous, but opposite directed, lateral forces to the tuber sacrale and the sacrocaudal junction (Fig. 21.9). Sacroiliac joint or ligament injuries can also be localized by evaluating pain and ligamentous laxity in the sacroiliac joint. These procedures are similar to valgus-varus stress tests used to evaluate the collateral ligaments of the distal limb articulations. Care should be taken not to apply excessive force due to the long lever arm action of the sacral apex on the sacroiliac ligaments, which can unduly stress unstable or partially torn ligaments or aggravate an acutely inflamed sacroiliac joint. The proposed mechanism of action of these tests is to use the base of the tail and sacrum as a handle to apply a lateral (horizontal plane) stress to the sacroiliac joint as the wing of the ilium is stabilized.

The technique involves two parts. First, the base of the hand closest to the horse's head is placed over the lateral aspect of the tuber sacrale. The hand closest to the tail grasps the base of the tail head (Cd2–3). The sacroiliac joints are then evaluated as firm pressure is simultaneously applied by both hands, pushing with the hand at the tuber sacrale away from the examiner and pulling with the hand at the tail head toward the examiner (Fig. 21.9A). Theoretically, this maneu-

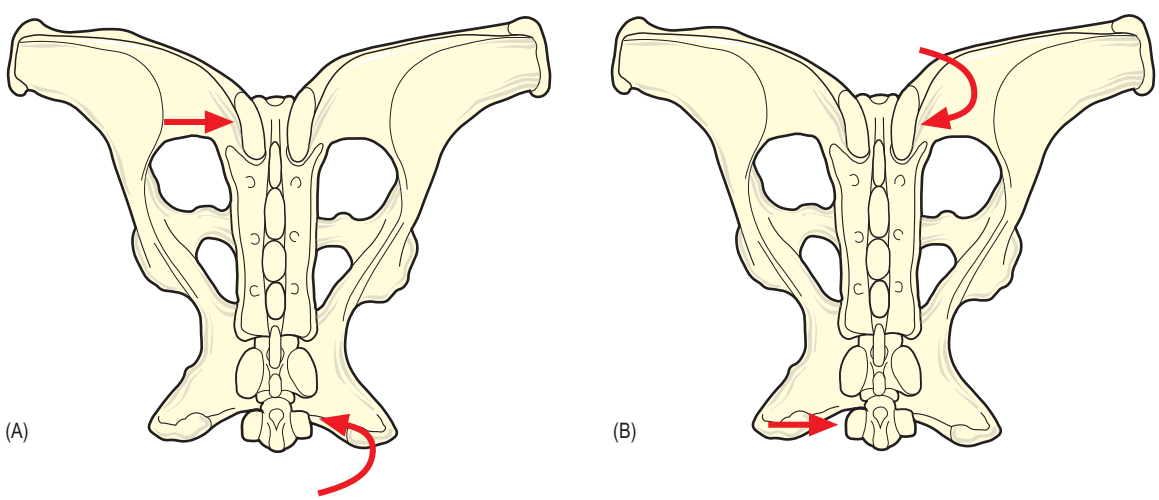

Fig. 21.9
Forces applied during a sacroiliac ligament stress test (dorsal view). (A) Firm pressure is applied by both hands, pushing with the hand at the ipsilateral tuber sacrale away from the examiner while simultaneously pulling with the hand at the tail head toward the examiner. (B) Firm pressure is applied by both hands; pulling with the hand at the contralateral tuber sacrale toward the examiner while simultaneously pushing with the hand at the tail head away from the examiner.

ver produces compression of contralateral and distraction of ipsilateral sacroiliac articular surfaces.

The second portion of the technique involves repeating the procedure and reversing the direction of the applied forces (Fig. 21.9B). The fingers of the hand closest to the horse's head are placed over the contralateral tuber sacrale and the base of the hand closest to the tail is placed against the ipsilateral base of the tail head (Cd2–3). The sacroiliac joints are again evaluated as firm pressure is applied by both hands, pulling with the hand at the tuber sacrale toward the examiner and pushing with the hand at the tail head away from the examiner. Theoretically, the contralateral sacroiliac articular surfaces are distracted and the ipsilateral sacroiliac articular surfaces are compressed. A pain response to the induced movements may be identified either unilaterally or bilaterally, depending on the extent of inflammation or injury present. In general, sacroiliac joint compression would be expected to aggravate osteoarthritic changes, whereas joint distraction would be expected to stress any injured or inflamed sacroiliac ligaments.

Proximal limb evaluation

In horses with back or pelvic problems, the proximal limbs are often affected either primarily or secondarily. Primary thoracic or pelvic girdle muscle or joint dysfunction is often evident as lameness in the affected limb. However, back or pelvic problems can also induce secondary proximal limb dysfunction that needs to be differentiated. Muscular or osseous asymmetry of the shoulder or pelvic regions are often indications of limb dysfunction or lameness. The pectoral region is viewed cranially to assess muscular symmetry. The dorsal scapula and wither region are viewed caudally from an elevated surface to assess bilateral symmetry and muscle development related to proper saddle fit. The croup or gluteal region is also viewed caudally to assess symmetry and muscle development. Horses with pelvic lameness or EPM often have noticeable gluteal muscle atrophy or asymmetry. The tuber sacrale are assessed for osseous asymmetry associated with pelvic fractures, sacroiliac joint subluxation or developmental factors. Changes in the height of the tuber sacrale should be assessed relative to the apex of the second sacral spinous process (S2).

Abnormal tonicity of the thoracic or pelvic girdle muscles is identified by hypotonicity or flaccidity, and hypertonicity associated with local trigger points or regional muscle spasms. The proximal limbs are also evaluated for normal ranges of motion or flexibility. In the forelimb, the scapulothoracic and shoulder joints are evaluated. In the hindlimb, the sacroiliac and coxofemoral joints are assessed. The fore and hindlimbs are individually examined in protraction, retraction, abduction, adduction and flexion for resistance to the applied movements, joint stiffness or muscle hypertonicity. Horses with back or pelvic problems will resent certain movements, have reduced limb motion and will not actively extend and stretch the limbs. Normally, horses will actively stretch their fore and hindlimbs when positioned in protraction and retraction. Extension of the hindlimb caudally will apply a stretch to the hindlimb protractor muscles, which include the iliopsoas, rectus femoris and tensor fascia latae. Injury to these muscles will produce resentment to passive stretching of the hindlimb. Iliopsoas muscle injury or hypertonicity can also be confirmed with rectal palpation.

Diagnostic injections

The use of injections of local anesthetics into painful or inflamed musculoskeletal structures is the basis of lameness evaluation. Fortunately, the same principle can be applied to painful soft tissue, articular or osseous structures of the back and pelvis.

Muscle

Injection into areas of perceived muscle pain or reactive acupuncture points helps to assess the contribution of muscle pain to the observed back problem, cause of poor performance, vague gait abnormalities or resentment to placement of the saddle.[27] Before and after comparisons of the muscle response to applied pressure (i.e. algometry) or changes in gait help to confirm the clinical significance of the muscle pain to the primary presenting complaint. In humans, trigger point therapy relies on the use of intramuscular injections of local anesthetic to reduce focal areas of muscle pain and hypertonicity. Similar techniques have been applied in horses with mixed results, which are mostly related to the inability to adequately define and measure muscle pain and dysfunction.

Interspinous spaces

Injections of local anesthetics into narrowed interspinous spaces or areas of interspinous pseudoarthrosis can be used diagnostically and therapeutically to assess the influence of over-riding or impinged spinous processes on back pain. The clinical significance of impinged spinous processes is often difficult to assert based solely on radiographic findings, since impinged spinous processes are often diagnosed in horses without obvious back pain. Firm digital palpation of affected dorsal spinous processes often produces a localized painful response (e.g. cutaneous trunci reflex or active extension of the back). Confirmation of the clinical significance of potential impinged spinous processes can be achieved with injections of local anesthetics. At sites of severe impingement or proliferation, it is often impossible to pass a needle directly on midline into the interspinous space. In this instance, a paramedian approach to the interspinous space provides lateral access to the area of pathology, which reduces the need to advance a needle through a collapsed interspinous space, although bilateral injections of the affected interspinous spaces are required. Nuclear scintigraphy is also an important adjunct in the definitive diagnosis and localization of impinged spinous processes as a contributing cause to back pain. Therapeutically, interspinous injections with anti-inflammatories (i.e. corticosteroids) provide variable

effectiveness and durations of pain relief and normal spinal function.

Articular processes

Articular process osteoarthritis is a common pathology and an important contributor to back pain. Like articular limb lameness, intra- or periarticular injections of the articular processes can assist in the localization and treatment of the presumed back pain. Periarticular injections of articular processes in the thoracolumbar spine can be used both diagnostically and therapeutically. Ultrasound guidance is recommended due to the deep location and close proximity to the spinal neurovascular structures that exit the intervertebral foramen.[35] Intra-articular injections of the articular processes are difficult due to the small articulation and sparse joint capsule; therefore periarticular injections are often performed. A 15 cm spinal needle can be used with ultrasound guidance to assess the articular process joint capsule in most horses.

Sacroiliac joint

The ante-mortem diagnosis of sacroiliac osteoarthritis is often frustrating and based on exclusion of other possible causes of hindlimb lameness.[33,55] In humans, periarticular injections of the sacroiliac joint are easy to perform, safe and seemingly effective in controlling pain associated with sacroiliac joint osteoarthritis.[56–58] The deep overlying croup musculature and seemingly inaccessible anatomic location of the sacroiliac joint has limited the clinical application of intra-articular or periarticular sacroiliac joint injections in horses.[33,55,59] Injection of the general sacroiliac region for diagnostic and therapeutic purposes has been performed, but inappropriate needle placement or the use of too short needles explain why most techniques have had suboptimal diagnostic or therapeutic effects.[38,60,61]

A medial approach to the sacroiliac joint provides the most direct, safe and consistent periarticular injection technique (Fig. 21.10).[62] Periarticular injections are made as close as possible to the caudomedial sacroiliac joint margin due to the high prevalence of degenerative changes affecting the caudomedial sacroiliac joint margin.[52,63] Important neurovascular structures to be avoided include the sciatic nerve and the cranial gluteal nerve, artery and vein that pass through the greater sciatic foramen, directly caudal to the sacroiliac joint.[64] Osseous topographic landmarks used to identify the needle entry site and the direction of needle advancement include the contralateral tuber sacrale and the ipsilateral tuber coxae and greater trochanter of the femur. The midpoint of the distance from the cranial aspect of the tuber coxae and the cranial aspect of the greater trochanter is used as a target for needle advancement. The needle entry site is 2 cm cranial to the contralateral tuber sacrale. The needle entry site and the midpoint of the tuber coxae and greater trochanter are connected with white tape to indicate the direction of needle advancement. A 25 cm, 15 gauge spinal needle is bent slightly in the direction of the bevel of the needle to match the medial curvature of the iliac wing. The needle is inserted with the bevel facing toward the targeted sacroiliac joint and advanced along the medial aspect of the iliac wing until it firmly engages the dorsal surface of the sacral wing, near the medial border of the sacroiliac joint. Poor performance or vague proximal hindlimb lameness associated with sacroiliac osteoarthritis can be diagnosed and treated with this reliable and easy-to-use injection technique.[62]

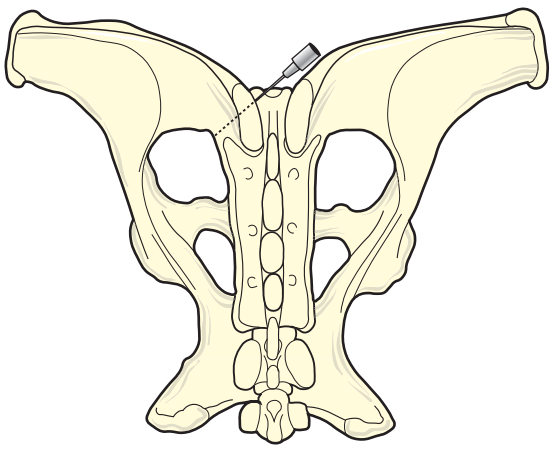

Fig. 21.10
Diagram of a medial approach to the sacroiliac joint for diagnostic or therapeutic purposes (dorsal view). The needle is directed from the cranial aspect of the contralateral tuber sacrale toward the caudomedial aspect of the affected sacroiliac joint.

Diagnostic imaging

Radiographic examination

For diagnosing lower limb lameness, radiographs are usually the first imaging modality used. However, due to difficulties associated with radiographing the equine back, other diagnostic imaging modalities may be used initially to localize the presumed inciting cause of back pain or dysfunction.

Standing position It is possible to take good-quality lateral views of the thoracic (T1–T18) and cranial lumbar spine (L1–L4) in the standing position.[65] Using portable equipment, the dorsal apexes of the spinous processes for T2–L3 can usually be visualized. Powerful equipment is necessary for radiographic examination of the horse's vertebral column, because exposures of up to 150 kV and 500 mA may be required in large horses.[66] Exposure values will vary according to the system employed, but a few suggested radiographic techniques are given in Table 21.4.[67]

One of the major problems encountered in radiography of such a thick subject is the inevitable production of secondary radiation. However, there are a number of ways to minimize scatter. The tube can be mounted on an overhead gantry system and linked to a cassette holder on the far side of the horse. The primary beam can then be automatically directed to the center of the cassette and the beam size can be care-

Table 21.4 Suggested radiographic techniques for imaging the thoracolumbar spine

Vertebral structures or region	Kilovolt (peak)	Milliamps	Grid
Spinous processes			
Withers (T3–T8)	75	30	No
Midthoracic (T9–T15)	70	55	Yes
Thoracolumbar (T16–L4)	85	80	Yes
Articular processes			
Midthoracic (T9–T15)	100 +	200–300	Yes
Vertebral bodies			
Thoracic (T5–T18)	75	55	Yes
Lumbar (L1–L5)	100 +	200–300	Yes

fully collimated to the size of the film. This system makes it possible to use high-ratio and crosshatch grids with confidence to effectively reduce scatter. The fastest possible system of intensifying screens and film (e.g. rare earth screens) should be employed so that exposures can be kept to a minimum. Most radiographic film cassettes contain lead in the backing, but at exposures over 100 kVp, it is advisable to place an additional lead sheet behind the cassette to absorb backscatter. As the scatter is oriented perpendicular to the ground with a film-focus distance of 150 cm, an air gap exists between the spine and the cassette and this helps to reduce the amount of scatter reaching the film. There is a considerable difference in tissue attenuation between the tips of the spinous processes and the vertebral bodies; thus, at least two radiographs of the same region at different exposures must be taken or some form of beam filtration is necessary. Considerable improvement in radiographic quality can be obtained by filtering (dodging) part of the primary beam to help compensate for the marked variation in thickness of the horse's spine.[66]

The horse should be sedated prior to radiography to reduce the degree of movement and to allow the handler to stand well out of range of the beam. Stocks are also useful to prevent movement. Lead markers placed midline on the horse's back are useful for orientation on the radiographs. The horse must be standing completely square, as the spine rotates to some extent if one leg is non-weight bearing. For the dorsal apexes of the spinous processes, the beam should be centered 5 cm ventral to the dorsal skin surface; for the region of the vertebral bodies, it should be centered 15–20 cm below the dorsum depending on the size of the horse. The beam should normally be horizontal but for visualization of the dorsal articular facets in the cranial lumbar region, it is useful to angle the beam from a ventral to dorsal orientation at an angle of 20–30° to avoid superimposition by the transverse processes. As a grid is being used, the cassette must be tilted accurately at the same angle of 20–30°.[67]

Under general anesthesia It is not possible to take radiographs of diagnostic quality of the caudal lumbar (L3–L6) and sacroiliac regions in a standing horse. The horse must be anesthetized and placed on its back in the frog-legged position so that the cassette can be inserted beneath the pelvis for a ventrodorsal view. Even in very large horses (i.e. weighing over 700 kg), exposures above 150 kV are not required, although up to 500 mA have been used on some occasions. To limit scattered radiation, it is necessary to use crossed, high-ratio grids and to put additional lead on the back of the cassette to prevent backscatter.

Normal radiographic anatomy The thoracolumbar spine of the newborn foal has a more pronounced curvature (i.e. dorsally convex) in the midthoracic region than does the adult horse.[67,68] The dorsal spinous processes appear short in relation to the length of the vertebral bodies, and in the midthoracic region they are blunt ended or spatula shaped, with wide interspinous spaces. The vertebral bodies have well-defined cranial and caudal epiphyses, but all the other ossification centers in the vertebral bodies and neural arch have fused before birth. During the first few months of life the thoracolumbar spine straightens out to some extent. In the mid and caudal region there is some alteration in shape of summits as well as a general lengthening and reduction in size of the interspinous spaces. At about 12 months of age, calcification of separate ossification centers on the summits of the cranial spinous processes occurs, and these persist without fusion into old age (i.e. 15 years or older). The tallest point of the vertebral column is at the withers, usually T4–T6. Areas of periosteal irregularity are frequently seen in the midportion of the thoracic spine, but these are of no clinical significance. The spines beneath the saddle region, T11–T17, are considerably shorter and more upright; the anticlinal vertebra is usually T15. Caudal to this, the spinous processes are increasingly slanted forward and the interspinous spaces are considerably narrowed. The summits are variable in shape, but they have cranially directed, often beak-shaped tips.

In the adult the thoracolumbar spine lies horizontal when the horse stands squarely on a level surface. The ventral portions of the vertebral bodies are clearly visible radiographically as far back as T16, because they form the roof of the thoracic cavity. It is difficult to see the articulations of the ribs and the articular and transverse processes unless oblique views are taken. Behind the diaphragm, the lumbar vertebrae as far back as L3 can be defined, as well as the articular and transverse processes. Closure of the vertebral epiphyses occurs at 3–3.5 years of age. In the region of the midback the width of the interspinous spaces varies and some impingement or over-riding of the spinous summits may occur. This is more often seen in Thoroughbreds than in other breeds and seems to be related to the conformation of the back; it is more common in stocky, short-coupled horses. The reduction or obliteration of the interspinous spaces, chiefly in the region from T13 to T18, is associated with local periosteal reaction and focal areas of radiolucency. The spinous summits sometimes overlap one another and become misshapen presumably because of the continued pressure from the adjacent spines. In one survey of clinically normal horses, 34% showed some degree of spinous process impingement.[68] There are few variations noted in the normal radiographic anatomy apart from the changes associated with impingement or over-riding dorsal spinous processes in the midback

region. Other osseous findings (e.g. abnormal spinal curvature, osteoarthritis, vertebral fracture or spondylosis) are incidental or are rarely encountered.

Primary indications for radiography of the pelvis include acute or severe pelvic asymmetries, upper hindlimb lameness and pelvic crepitus or fractures.[69] Ilial wing overlap and the deep anatomic location of the sacroiliac joint make radiographic imaging difficult at best. The radiographic features of chronic sacroiliac joint disease are minimal and include nonspecific increases in the joint space and apparent enlargement of the caudomedial aspect of the sacroiliac joint.[33] Linear tomography has also been used to examine the lumbosacral and sacroiliac regions of horses, but limited access to equipment has restricted its clinical usefulness.[70] Positive findings include widening of the sacroiliac joint and irregular joint outlines with osteophyte formation at the caudal aspect of the joint. Osseous changes are common bilaterally, but may be more pronounced on the clinically affected side.[70]

Scintigraphic examination

A useful adjunct to clinical diagnosis in recent years has been the advent of nuclear scintigraphy for horses.[71–74] The technique involves intravenous injection of a radionuclide and detection of 'hotspots' of increased radioactivity in the bone phase by use of a gamma camera. Scintigraphy is helpful in detecting over-riding or impinged spinous processes, vertebrae fractures, osteoarthritis, spondylosis, stress fractures of the wing of ilium and some sacroiliac osteoarthritis. Scintigraphy is particularly valuable in identifying bony lesions at sites not accessible with conventional radiography.

The radiopharmaceutical most commonly used for equine scintigraphy is 99 m technetium-labeled methylene diphosphonate (^{99m}Tc-MDP). A weight-dependent dose between 3 and 6 GBq (100–150 mCi) of ^{99m}Tc-MDP is injected intravenously and images of the bone phase are obtained 2–3 hours later. Due to the initial high renal and bladder radioactivity, vascular phase and soft tissue phase images of the thoracolumbar spine cannot be obtained. Damaged skeletal muscle can be detected by abnormal soft tissue uptake of ^{99m}Tc-MDP during bone-phase imaging, but usually only if the horse has been strenuously exercised before the scintigraphic examination.[75]

For a complete examination, the horse should be imaged from both the left and the right; otherwise some subtle lesions, for example those located at the articular processes, can easily be missed. A high-resolution, low-energy, parallel-hole collimator should be used; this gives a geometrical resolution of 4.4 mm at a distance of 5 cm from the collimator face. For the caudal thoracic and lumbar regions, the camera is positioned obliquely at an angle of 50–65° to the horizontal. This allows the distance between the camera and spine to be minimized. Positioning the camera horizontally above the spine results in superimposition of all the vertebral structures. The camera can be oriented perpendicular to the floor for views of the cranial thoracic spine. When the camera is positioned over the lumbar spine, the image quality may be improved by shielding the kidney using a lead sheet.

The images are acquired on the basis of either counts or time. One million counts or more are optimal for maximal resolution of the caudal regions of the equine back and the pelvis. This large number of counts requires several minutes of immobility on the part of the horse, however, and thus generally cannot be achieved without general anesthesia. Movement of the standing horse can be minimized by appropriate sedation and quiet handling of both the horse and camera. Blinders and cotton earplugs for the horse may help. Nuclear medicine software that is able to correct for motion is now available and this compensates for the slight swaying of the horse and respiratory movements.

Normal scintigraphy findings In normal horses, regions of bone close to the skin surface such as the tuber sacrale and tuber coxae appear 'hotter' (i.e. increased radiopharmaceutical uptake) than adjacent bone structures, as there is less soft tissue attenuation. Other superficial sites that appear slightly 'hot' are the apices of the spinous processes, particularly at the withers. In good-quality images, the individual vertebra can be clearly distinguished. The spinous processes and articulations have a slightly higher uptake, but this should be equal for all joints in the region. On lateral oblique views, each rib is located cranial to its respective vertebra. As an aid to orientation, on left lateral views the 16th rib usually overlies the cranial pole of the right kidney.

Any scintigraphic abnormality appears as increased radiopharmaceutical uptake (a 'hotspot'), whereas areas of diminished uptake are difficult to detect due to poor image resolution. The most common sites for increased uptake are at the apices of the spinous processes, the articular processes or the sacroiliac region.

Nuclear scintigraphy is considered by some authors to be an accurate and diagnostically useful technique for identifying acute and chronic sacroiliac joint injuries.[53] Subjective evaluation or quantitative analysis of bone scans are typically able to identify asymmetric radioisotope uptake over the affected tuber sacrale. However, presumed normal horses, without a history of hindlimb or sacroiliac joint injuries, may also have asymmetric uptake over the tuber sacrale. A dorsal view of the sacrum is considered the most diagnostic image for evaluating and comparing the sacroiliac joints.[53] However, there is usually extensive overlap of uptake in the tuber sacrale and the sacroiliac joints on the dorsal view. Oblique views of the ilial wings are recommended to confirm left-to-right asymmetries in radioisotope uptake and to separate the tuber sacrale dorsally from the sacroiliac joint region ventrally,[76] although oblique views may be difficult to interpret due to inconsistent camera positioning on the left and right sides. The thick overlying gluteal musculature may also attenuate radiopharmaceutical uptake from an affected sacroiliac joint. Stress fractures of the ilial wing may be difficult to differentiate from sacroiliac joint injuries due to the common location and extension of the incomplete fracture line into the sacroiliac joint.[53,77,78]

Ultrasonographic examination

There has been considerable interest in recent years concerning the value of ultrasonography for evaluation of the

epaxial structures, particularly the supraspinous and dorsal sacroiliac ligaments.[35,79]

Supraspinous ligament A 7.5 or 10 mHz linear array transducer is used to examine the supraspinous ligament that runs dorsal to the thoracic and lumbar spinous processes. It is necessary to clip the hair over an area of approximately 20 cm in width extending from the withers to the base of the tail. The ligament has an echogenic, striated appearance similar to tendon. It is thinner and wider in the caudal withers region and becomes narrower and thicker in the lumbar region. It is always thinner as it runs over the spinous processes. The dorsal convex surface of the spinous processes can be clearly seen and impinged or over-riding spinous processes can be identified by visualizing narrowed interspinous spaces. There may also be evidence of false joint formation between impinging spines. The echogenicity of the ligament may vary somewhat and a more clearly defined fibrous pattern seen in the caudal thoracic and lumbar regions. In the withers (T6–T9) it is sometimes possible to see hyperechogenicity that may cast acoustic shadows. These are associated with the secondary centers of ossification on the dorsal tips of the spinous processes. A little caudal to this (T9–T12) it is possible to see hypoechoic areas that may be associated with cartilage metaplasia adjacent to the ligament insertion into the dorsal spinous process. This does not usually have any clinical significance.

Dorsal sacroiliac ligament The dorsal portion of the dorsal sacroiliac ligament can be visualized with a 7.5–10 mHz linear array transducer as it runs from the tuber sacrale to the summits of the sacral spinous processes.[80] The sacroiliac region is first viewed on midline in transverse section. The tuber sacrale are seen as hyperechoic convex lines on either side of the sacral spinous processes. The transducer is then moved laterally over the tuber sacrale so that the dorsal portion of the dorsal sacroiliac ligament appears as a crescent-shaped echogenic structure. Longitudinal views of the dorsal sacroiliac ligament are then examined. The ligaments are examined for alterations in echogenicity and fiber orientation, but particularly for any increase in size.

Additional pelvic and vertebral structures It is possible to examine the dorsal surface of the iliac wing and caudal margin of the sacroiliac articulation to identify dorsal cortex irregularities associated with incomplete and complete ilial wing fractures.[81,82] Denoix has elegantly demonstrated the visualization of the thoracolumbar articular processes, transverse processes, lumbosacral and caudal lumbar intervertebral disk spaces and the sacroiliac joint.[35] The ventral sacroiliac ligament and the ventral joint margins of the sacroiliac joint can also be visualized on transrectal ultrasonography.[79] Ventral periarticular remodeling of the sacroiliac joint has been observed with transrectal ultrasound approaches. Muscle injuries are more difficult to detect ultrasonographically, although in severe cases of muscle strain an increased echogenicity with thickening of the connective tissue septae within the muscle may be identified.

Thermographic examination

Thermography has been used successfully as an aid to diagnose back problems. However, it is important to have the right equipment and to establish normal thermal profile parameters. Even so interpretation of infrared thermography imaging can be difficult. A single thermal study has little or no prognostic value. Von Schweinitz concludes:

> Thermal imaging reveals important information about the neural outflow of the spine in terms of sympathetic tone. The thermal findings are a compilation of local tissue factors and vasomotor tone requiring care in interpretation. The relevance of disturbed vasomotor tone, especially persistent vasoconstriction, is well established in chronic back pain syndromes in man. Many of these syndromes involve disturbing sensory faults (e.g. allodynia, burning, aching) which can neither be directly communicated by our patients nor readily described by any other current diagnostic test.[83]

Thermography provides quick, safe and non-invasive assessment of the whole patient. It takes into account a major aspect of homeostasis and prompts one to investigate all other thermally abnormal sites. With current diagnostic technologies, it often provides the only objective evidence confirming cases of equine back disease. Routine use of thermal imaging in equine poor performance syndromes confirms that thoracolumbar and sacral neuromuscular disease is a common condition.[83] Thermography has been used to diagnose muscle strain or inflammation in the sacroiliac and croup regions.[84] Horses with sacroiliac joint injuries are expected to have protective muscle spasms in the adjacent musculature. Palpation of muscle sensitivity has been correlated with abnormal thermographic images in most cases.[84]

Magnetic resonance imaging (MRI) and computed tomography (CT)

These are emerging modalities that have not yet been applied to the problems involving the thoracolumbar spine. However, the detail and quality of both skeletal and soft tissue structures elsewhere in the horse's body mean that once the technological difficulties have been overcome there is great potential for improved diagnostic ability for the thoracolumbar and lumbosacral spine.

Specific pathologic conditions

Clinical signs associated with spinal muscle pathology include atrophy, focal swelling and palpable tenderness of the epaxial muscles. Spinal muscle biopsies help to evaluate suspected back disorders, but are best used with a complete physical examination and imaging procedures. Spinal ligament injuries affect the supraspinous and sacroiliac ligaments. Osseous pathology has been observed at the vertebral processes, intervertebral articulations and sacroiliac joints in horses. Degenerative changes are common in many articular processes, intertransverse, lumbosacral and sacroiliac

articulations. Osseous spinal lesions tend to affect multiple vertebral locations.

Vertebral anomalies and deformities

Developmental variations in the morphology of thoracolumbar vertebral bodies, processes and joints in horses are known to occur, but usually result in secondary rather than primary back problems.[14–16,28,51] Congenital abnormalities that affect the normal spinal curvature include scoliosis, lordosis and kyphosis. In newly born foals signs of scoliosis and lordosis are sometimes seen in association with other in utero postural deformities (e.g. limb contractures, bent face and torticollis). These may be severe and necessitate euthanasia or be mild when they show an apparent complete recovery. The condition of kyphosis (i.e. roach-back) is most frequently seen during the period of active growth after weaning although the underlying cause does not appear to be in the vertebral column. The problem may be associated with a progressive straightening of the hindlimb conformation during a growth spurt or perhaps be secondary to a stifle or hock problem (e.g. osteochondrosis). The condition of congenital lordosis (i.e. dipped or sway-back) has been associated with hypoplasia of the cranial and caudal intervertebral articular processes in the cranial thoracic region T5–T10.[85] There is overextension of one or more of these articulations leading to the ventral curvature of the midthoracic spine. In older horses acquired lordosis is sometimes seen, particularly in brood mares after a number of pregnancies, but usually no clinical problems are associated with it.

All these vertebral deformities predispose to some weakness of the thoracolumbar spine, leading to poor performance and soft tissue injuries. Diagnosis can be confirmed by radiography revealing abnormal curvature of the vertebral column, principally in the cranial thoracic region (T5–T10) with lordosis, mid- to caudal thoracic region with scoliosis and the cranial lumbar region (L1–L5) with kyphosis.

Soft tissues injuries

Muscle strain

Damage to the epaxial tissues is undoubtedly the most common cause of back injury in the horse.[4] The main action of the longissimus muscle is to extend the back (i.e. to dorsiflex) or, if acting singly, to laterally bend the spine. The primary role of these muscles is to control the stiffness of the back rather than to actively assist locomotor movements. Strain or injury to all or part of the longissimus muscles most frequently occurs during ridden exercise because of a slip, fall or poorly executed jump. It may be caused through fatigue or inadequate fitness. The clinical signs are an acute onset of poor performance often accompanied by a change of temperament. Local swelling and heat of the muscles may occur, particularly in the lumbar region. The back is kept rigid and there is a restriction in the hindlimb gait at exercise, often with a wider than normal rear limb stance. There may be difficulty in maintaining normal tracking action of the hindlimbs. Disunited canter and frequent breaking of stride are also frequently seen. Stiffness of the hindlimb and back is seen particularly in short turns, but no clear signs of lameness are evident. There is obvious pain on palpation and a marked reduction in flexibility of the thoracolumbar spine. In the acute stages some elevation (i.e. 2–4 times baseline levels) in the plasma levels of muscle-derived enzymes (CK and AST) will be noted after mild exercise. If the sublumbar muscles are involved pain will be easily elicited on rectal palpation.

Classic signs of exertional myopathy (i.e. rhabdomyolysis) are not difficult to differentiate from muscle strain of the back. However, the atypical low-grade form of exertional myopathy is more difficult to diagnose as it can occur after varying amounts of exercise, but is more commonly seen in horses on a high-protein diet and in highly strung fillies or mares in excellent bodily condition. Diagnosis can usually be confirmed by determination of muscle-derived enzymes after exercise. In exertional myopathy, levels will be increased greater than five times over baseline values.

Polysaccharide storage myopathy (PSSM) has been recently diagnosed from longissimus muscle biopsies in showjumpers, dressage and draft horses.[44] The horses showed typical signs of a soft tissue back injury and biopsies from the longissimus lumborum muscles revealed high glycogen levels with abnormal deposits of amylase-resistant polysaccharide. This study indicates that muscle biopsy may be an important diagnostic aid in some chronic back problem cases.

Ligamentous damage

Clinical conditions affecting the spinal ligaments include mild, moderate or severe sprains. Severe injuries are characterized by complete ligamentous disruption and joint laxity (i.e. joint luxation). A fairly common site of thoracolumbar injury in Thoroughbred gallopers and jumpers is the supraspinous ligament which runs all the way down the middle of the back and is adherent to the summits of the thoracic and lumbar dorsal spinous processes. It is made up of a continuous ligament to which the multiple tendon insertions of the longissimus muscles contribute. The composite structure is subject to strain in the same way as the muscle injuries just described. The clinical signs are essentially similar, but tend to persist for longer and the ultimate prognosis is less favorable. The cranial lumbar region is the most common site of injury. The ligament is often visibly thickened above the spinous summits and pain is easily elicited on palpation. Reduced lateral flexion of the thoracolumbar spine is seen in one or both directions. By taking low-exposure radiographs, the soft tissue thickening and some focal radiodensity in the ligament may be seen in long-standing cases. Detached flakes from the spinous summits are also noted on occasion and are associated with periosteal irregularity and sclerosis on the dorsal surfaces of the spinous summits. This may also be seen in the caudal withers' regions, but care must be taken not to confuse elevated periosteum with a vestigial center of ossification on the dorsal tips of the T3–T12 spines. Diagnosis can be assisted by ultrasonographic examination.[35,36] The prognosis for supraspinous ligament strain is usually guarded, largely because of the likelihood of recurrence. Some

horses do recover but go on to develop signs of a 'cold back', which is defined as temporary stiffness and a dipped back, without affecting their competitive performance.

Other soft tissue lesions

These include such disorders as skin lesions (e.g. wounds, scars, warbles, pruritic conditions), which may cause secondary signs of back pain. Pressure or chaffing from an ill-fitting saddle, particularly in endurance competitions, may also be observed.

Thoracolumbar osseous pathology

Spinal disorders and sacroiliac joint injuries have been identified as significant causes of chronic poor performance in horses.[4,33,86] In humans, the most common known sources of back pain are related to the intervertebral disks, zygapophyseal joints and sacroiliac articulations.[87] Intervertebral disk disease is uncommon in horses, but significant and widespread degenerative changes of the thoracolumbar zygapophyseal joints and sacroiliac articulations have been reported, even in active race horses.[52]

Articular pathophysiology

The zygapophyseal joints are synovial articulations that undergo joint capsule pathology and joint degeneration similar to other synovial joints. Articular degeneration usually progresses through three phases of pathology: dysfunction, instability and degeneration. Joint dysfunction is characterized by restricted joint motion, localized pain and inflammation, and abnormal paraspinal muscle hypertonicity. Restricted articular motion stimulates local biochemical alterations and the release of inflammatory products. The inflammatory process can alter the intra-articular environment and further contribute to joint capsule pathology and periarticular fibrosis. Muscle hypertonicity may restrict joint motion and contribute to adhesion formation. Joint immobilization also produces bone demineralization, capsular adhesions and loss of ligamentous strength. Restoring joint motion can lead to normal joint function, depending on the amount and duration of the immobilization. Joint motion is essential for the prevention of joint contracture and adhesion formation. Progressive joint immobilization is characterized by initial musculotendinous contractures, followed by capsular and periarticular adhesions and eventual intra-articular adhesions.

Joint degeneration progresses as the dysfunctional joint is unable to distribute normal biomechanical stresses. The instability phase of joint degeneration is characterized by cartilaginous, meniscal, capsular and ligamentous deformation and degeneration. Abnormal joint and paraspinal tissue biomechanics induce additional subchondral bone changes and joint derangement. Reduced or asymmetric motion in one vertebral motion segment may induce compensatory hypermobility in adjacent vertebral segments due to injuries to the joint capsule or ligamentous laxity. The increased joint mobility results in joint instability, joint derangement and secondary muscle hypertonicity. Joint instability also affects the neurologic influences of proprioception and the central neuromotor control of movement and posture. Potential radiographic findings of articular instability may include osteophyte formation or vertebral instability (i.e. listhesis). The spinal degenerative phase is characterized by attempts at stabilization of the degenerative tissues. Chronic joint immobilization can lead to fibrocartilaginous replacement of the joint cavity and eventual ankylosis. Radiographic signs of advanced osteoarthritis and osteophyte formation, spinal ligament ossification and spinal ankylosis can be visualized at this stage.

Articular process degenerative joint disease

As with any synovial articulation, loss of motion or aberrant joint physiology can be a primary source of pain.[21] Jeffcott states that degenerative joint disease of the articular processes (i.e. zygapophyseal joints) is common in older horses but

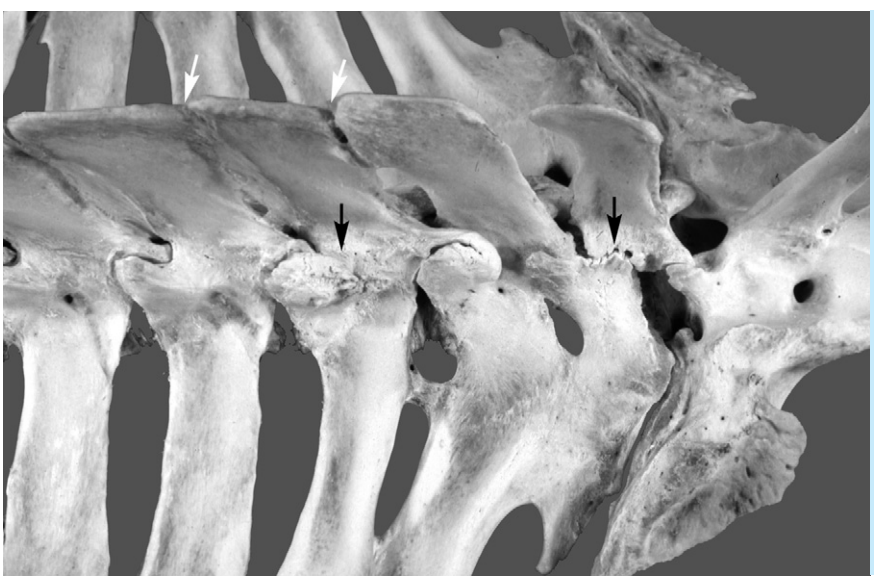

Fig. 21.11
Dorsolateral view of the lumbosacral vertebral region (L2–S2) of a 4-year-old racing Thoroughbred that fractured the right front sesamoids during a race. Varying degrees of spinous process impingement (white arrows), vertebral lamina stress fractures (black arrows), articular process ankylosis (L4–L6) and bilateral intertransverse joint ankylosis (L5–L6) are present.

probably not clinically significant.[88] However, Denoix reports that zygapophyseal joint pathology at the thoracolumbar junction and lumbar vertebral region is one of the most common spinal disorders associated with back pain.[89] In a necropsy survey of 36 Thoroughbred race horses, severe articular process degenerative changes were reported in 25% of specimens (Fig. 21.11).[52] Articular surface lipping, osteophytes, periarticular erosions, intra-articular erosions and ankylosis (in order of increasing severity) were noted. Articular surface lipping and periarticular erosions of the articular processes were common at the thoracolumbar junction and cranial lumbar spine. Intra-articular erosions and ankylosis were restricted to the caudal lumbar vertebral segments, where vertebral mobility is normally limited.[90] Additional studies may help to show that the zygapophyseal joints are a clinically significant source of back pain in horses, as has been shown in humans.[87]

Impinged or over-riding spinous process

Spinous process overlap, without any evidence of osseous impingement, has been noted in horses.[52] In humans, isolated spinous process deviation is a common finding and can be related to vertebral rotation (i.e. scoliosis) or developmental asymmetries in the neural arch, but rarely is it associated with spinous process fracture or malposition of the entire vertebra.[91] Impinged or over-riding spinous processes (i.e. kissing spines) are reported to be the most common osseous cause of back pain in horses.[4]

Spinous process impingement in the thoracic spine occurs most commonly between T13 and T18, reportedly related to altered spinous process morphology.[51,92] Thoroughbreds have a higher prevalence of spinous process impingement or overriding compared with other breeds due to misshapen dorsal apices and narrower interspinous spaces.[4,51] Competitive jumping or dressage horses reportedly have a higher prevalence of thoracolumbar spinous process impingement related to ventroflexion or demanding spinal maneuvers.[4] However, dorsoventral vertebral mobility in the caudal thoracic spine has not been reported to differ from other adjacent vertebral regions, therefore increased dorsoventral movement may not fully account for the vertebral distribution of spinous process impingement.[90,92] Additional weight-carrying requirements have also been implicated because this vertebral region is covered by the saddle while being ridden,[41] although thoracolumbar spinous process impingement has been reported in Standardbreds and an extinct equine species, *Equus occidentalis*, which presumably have not had extraneous weight placed on their backs.[93] Aging has not been found to be a factor in the pathogenesis of thoracolumbar spinous process impingement.[4,51,92]

The diagnosis of impinged or over-riding spinous processes is difficult since apparently normal horses often have a high prevalence of osseous changes radiographically.

Vertebral lamina stress fractures

Stress fractures are usually characterized by bone-specific predilection sites, periosteal and endosteal callus, an incomplete fracture line that may progress to complete fracture, tendency to occur bilaterally, a predominance in athletes undergoing strenuous or repetitive activities, and a patient history of periodic, recurrent, low-grade lameness.[78,81,94] In a necropsy sample of Thoroughbred race horses, 50% (18 of 36) of specimens had incomplete fractures and focal periosteal proliferation of the vertebral lamina, characterized as vertebral stress fractures (see Fig. 21.11).[77] Incomplete fractures of the vertebral lamina occurred consistently at the cranial aspect near the junction of a cranial articular process and the spinous process. Most vertebral stress fractures were continuous with vertical articular clefts of the cranial articular processes, which may provide a site for stress concentration and may contribute to the etiopathogenesis of equine vertebral stress fractures.[95] Thoracolumbar articular process morphology may also contribute to the development of vertebral lamina stress fractures. The articular processes of the caudal thoracic and lumbar portions of the spine (T16–L6) are deeply interlocking and restrict axial rotation.[16,92] Complete articular process fractures in this vertebral region are thought to result from excessive axial rotation.[92] Most specimens had one vertebra affected unilaterally, but several specimens had multiple vertebral lamina stress fractures and some were bilateral. Bilateral complete fractures of the vertebral lamina were noted in one specimen, so that the dorsal L6 vertebral arch and spinous process could be removed.

Spondylosis

Spondylosis is a degenerative disease of the vertebral joints that produces large osteophytes that bridge the ventral vertebral bodies. The exact cause of vertebral body osteophytes is unknown but biomechanical and biochemical mechanisms have been proposed.[96] Abnormal joint loading produces microtrauma and degeneration of the annulus fibrosis and periarticular tissues. Portions of the annulus fibrosis and ventral longitudinal ligaments become ossified and produce partial bridging of the involved joints. As the osteophytes increase in size, nerve roots may be compressed at the intervertebral foramen or spinal cord compression occurs if the proliferation extends dorsally into the vertebral canal. The cycle of altered joint biomechanics and inflammatory mediators may continue until complete ankylosis and obliteration of the joint occurs. The forming vertebral osteophytes and the ankylosed vertebral bodies are susceptible to fracture due to the reduced ability to absorb or transfer normal locomotor forces through the ossified ligaments and fused vertebral joints. Several vertebral bodies are usually involved, especially in advanced stages.

Vertebral fractures

Spinous process fractures of the withers (T2–T9) are usually due to falling over backwards and landing on the highest point of the back. Conservative care is usually recommended. Proper saddle fit is difficult following fracture due to lateral displacement of the multiple fracture fragments. Spinous

process fractures do not typically cause spinal cord compromise.[97]

Vertebral end-plate fractures occur more commonly in foals and are usually related to a fall or significant trauma. Vertebral body compression fractures have been reported in the thoracolumbar vertebral region (T1–T3, T9–T16 and T18–L6) and are frequently due to physical trauma, electric shock or lightning strike.[97–100] Depending on the severity of the vertebral fracture, minimal fracture displacement is usually found. A complete neurologic examination will help to localize the fracture site if spinal cord compromise is present.[101,102] Isolated hindlimb paresis or paralysis with normal forelimb function suggests a spinal cord lesion caudal to T2.

Sacral fractures are a common cause of cauda equina injury. Horses that forcefully back into a solid object or fall backwards can fracture the sacrocaudal vertebral region and produce abnormal perineal neurologic signs. Careful palpation may help to localize a site of pain or vertebral asymmetry.

Neurologic diseases

Conditions that are primarily neurologic in origin must always be considered in differential diagnosis of a back problem. However, there are few disorders that can be specifically related to the thoracolumbar vertebral column.

Ataxia

The most common group of conditions are those that cause ataxia and proprioceptive deficits. These conditions include cervical vertebral stenosis (CVS or wobbler disease), equine protozoal myeloencephalitis (EPM), equine degenerative myeloencephalopathy (EDM) and equine herpesvirus 1 vasculitis (EHV-1). Some of the signs in these conditions will be similar to back problems mainly because of ataxia or incoordination resulting in stiffness or splinting of the back muscles. The hind action with varying degrees of proprioceptive deficit will cause stiffness (hypomelia), weakness and toe dragging. Horses with EPM may also exhibit some lameness and neurogenic atrophy of skeletal muscles. Other causes of ataxia that are usually seasonal are associated with ingestion of certain types of grass (e.g. rye grass, Bermuda and Dallis grass). For more information see Chapter 24.

Lower motor neuron diseases

The condition of stringhalt can produce severe and bizarre signs affecting the hindlimbs.[103] However, in milder cases stiffness and exaggerated action of one or both hindlimbs may be seen. The specific etiology of this condition is not known, but morphologically it appears to be distal axonopathy.[104] Another long-established but little understood condition is that of 'shivering'. It is assumed to be of neurologic origin, but its etiology is completely unknown. The clinical signs involve muscle fasciculations of the back and hindquarters, particularly if a hindlimb is picked up and fully flexed. The condition rarely affects performance and does not appear to be the cause of a genuine back problem. 'Shivers' may also be confused with polysaccharide storage myopathy (see Chapter 6).

Other neurologic diseases

Lyme disease (borreliosis) may need to be considered in some locations where various species of ticks are present. The infective agent is a spirochete, *Borrelia burgdorferi*, which may cause neurologic signs of lethargy or aggression due to low-grade meningitis. Musculoskeletal pain is usually due to polyarthritis or intermittent lameness. Serological confirmation (i.e. IFA, ELISA and Western blot) is possible and response to treatment with amoxicillin or tetracycline for 2 weeks may support a diagnosis of Lyme disease.

Sacropelvic pathology

The ante-mortem diagnosis of sacroiliac joint injury in horses is difficult and often based on a diagnosis of exclusion.[53] Based on a review of the literature, osteoarthritis of the sacroiliac joint is the most prevalent disease process affecting horses with sacroiliac joint pain or dysfunction, although its clinical significance remains uncertain.[33,52,63,105] Degenerative changes tend to be bilaterally symmetric and localized to the medial aspect of the sacroiliac joint (Fig. 21.12).

Sacroiliac ligament desmitis has been documented ultrasonographically in the dorsal portion of the dorsal sacroiliac ligament.[36,79,80] A diagnosis of sacroiliac ligament desmitis is based on loss of normal echogenicity on a short-axis view and a decrease in parallel fiber pattern on the long-axis view. Complete sacroiliac ligament disruption is most likely due to substantial trauma, such as flipping over backwards or catastrophic musculoskeletal injuries associated with race training.[52] However, few cases of complete rupture of the sacroiliac ligaments have been reported in the veterinary literature.[52,106]

The pathogenesis of apparent spontaneous or insidious differences in tuber sacrale height needs to be further researched.[33] The presumed diagnosis of sacroiliac joint subluxation based solely on the presence of tuber sacrale height asymmetry is inappropriate.[56] Variable degrees of tuber sacrale height asymmetry occur frequently and may be due to chronic asymmetric muscular or ligamentous forces acting on the malleable osseous pelvis and not direct sacroiliac ligament injury.[107] Horses with chronic sacroiliac problems and presumed sacroiliac joint subluxation have not had identifiable changes in the sacroiliac ligaments at necropsy.[33] In addition, Standardbred trotters with substantial tuber sacrale height asymmetries did not have significant increases in sacroiliac pain compared to horses with lesser degrees of asymmetry.[108] An ante-mortem diagnosis of sacroiliac joint luxation can only be supported if an acute change in tuber sacrale height asymmetry due to substantial trauma has been documented or if sacroiliac joint instability (i.e. crepitus or independent tuber sacrale movement) is evident during physical examination.

Fig. 21.12
Ventral view of the lumbosacral vertebral region (L5–S2) of a 23-year-old Thoroughbred used for dressage. The horse had a clinical history of psoas muscle soreness and chronic pain localized to the lumbosacral junction. Bilateral intertransverse joint ankylosis (L4–L6), a large osteophyte at the right ventral lumbosacral intervertebral foramen (white arrow) and proliferative changes of the sacral articular surface of the sacroiliac joints (black arrows) are present.

Table 21.5 Techniques used in the treatment of back problems in horses

Category	Specific methods
Rest	Stall rest
	Paddock turnout
	Restricted or controlled exercise
Management	Replace or reflock saddle
	Therapeutic saddle pads
	Change stable and work routine
	Attempt reschooling or try another training approach
	Graduated exercise program
	Assess or modify rider's equitation
Pharmaceuticals	NSAIDs (oral, parenteral or local injection)
	Corticosteroids (oral or local injection)
	Muscle relaxants
	Sclerosing agents (local injection)
	Sweats or counterirritants
	Hormonal therapy
	RVI injections
Surgery	Compound or comminuted fracture of the withers
	Impinged dorsal spinous processes
Physiotherapy	Heat (hot packs, infra-red heat lamp, poultice, short-wave diathermy)
Thermal	Therapeutic ultrasound
Mechanical	Hydrotherapy and swimming
Electrical	Electrical muscle stimulation
	Magnetic therapy (static and pulsed)
	Shock-wave therapy
Manual therapy	Osteopathic techniques
Articular techniques	Chiropractic techniques (high velocity, low amplitude)
Soft tissue techniques	Physical therapy techniques (mobilization, soft tissue techniques)
	Manipulation under general anesthesia (MUA)
	Massage therapy
	Stretching exercises
Acupuncture	Dry needle, aquapuncture, low-level laser puncture
	Moxibustion
Nutraceuticals	Chondroitin sulfate
	Glucosamine
	Glycosaminoglycans
	MSM
Botanicals	Western herbs
	Chinese herbs
Homeopathy	Arnica montana

Pelvic stress fractures also need to be ruled out in horses with sacroiliac pain or dysfunction.[41] A high prevalence of occult pelvic stress fractures has been reported in Thoroughbred race horses.[77,78,94,109] Pelvic stress fractures occur in consistent locations on the caudal border of the ilium adjacent to the sacroiliac joint.[76,81,94] The incomplete fracture lines extend into the caudomedial aspect of the sacroiliac joint, which could possibly produce concurrent sacroiliac joint inflammation and degradation. Complete ilial wing fractures (the most common type of pelvic fracture) typically produce a palpably depressed tuber sacrale on the affected side.[78]

Treatment and management

Medical management

The basic principles of medical management are to reduce pain and muscle spasms to permit better healing, followed by a program of rehabilitation and measures to prevent further injury or stress to the back. It is therefore necessary in many cases to use a combination of medications (e.g. NSAIDs, muscle relaxants, corticosteroids, local irritants or analgesics) in addition to physiotherapy or manipulative therapies (Table 21.5).

Non-steroidal anti-inflammatory drugs (NSAIDs)

For acute and severe pain from muscle strain, fractured withers and acute sacroiliac injury, intravenous NSAIDs followed by oral doses are beneficial. Phenylbutazone (1–2 g, p.o., b.i.d.) is still the drug of choice for many equine practitioners. Other NSAIDs include ketoprofen (2.2 mg/kg (1 mL/100 lb), i.v., s.i.d. for up to 5 days) or naproxen (5–10 mg/kg, p.o., b.i.d. for up to 14 days). If severe muscle spasms are present then diazepam (0.08 mg/kg, i.v. or p.o.) may also be administered.[110] In mild or chronic cases, oral naproxen once or twice daily (5–10 mg/kg) is recommended. Phenylbutazone in low doses (1 g, p.o., s.i.d.) for mild aches and stiffness can be beneficial, but may mask signs of developing tendinitis or other musculoskeletal injuries with long-term use.[110] In chronic cases with low-grade bone pathology (e.g. over-riding dorsal spinous processes or osteoarthritis) a course of NSAIDs can be useful in conjunction with a progressive exercise program. Exercise should begin with a graduated program of lunging to build up and loosen the back and hindquarter muscles. Once the horse is fairly fit on the lunge line, riding work may begin. At this time oral phenylbutazone (i.e. 4 g/day for 4 days; 3 g/day for 4 days; 2 g/day for 4 days; 1 g/day for 4 days and 1 g every other day for 8 days) can be given as the exercise is gradually increased.

Muscle relaxants

Muscle relaxants such as dantrolene sodium (2 mg/kg, p.o., s.i.d.) and methocarbamol (15–44 mg/kg, p.o., s.i.d.) have been advocated for many years, but their effectiveness does not seem to be uniform in all horses.[111] These drugs may not have any specific effects other than reducing muscle tension or spasm in order to allow natural healing to progress. Thiocolchicoside (2–4 mg/100 kg, i.m., twice weekly for 4 weeks) and repeated injections of methocarbamol (10 mg/kg, i.v.) have also been advocated in Europe.[112]

Corticosteroids

The systemic use of corticosteroids is rarely indicated for primary back problems because of the possible side effects of laminitis, arthropathy and alimentary problems. NSAIDs are usually more effective and are associated with fewer adverse effects. The use of local injections into the interspinous spaces for the diagnosis or treatment of impinged or over-riding dorsal spinous processes has been successful.[110] The injection mixture includes methylprednisolone acetate, isoflupredone acetate and serapin with approximately 5 mL injected at each interspinous space of concern. Improvement usually takes 2–6 days and repeated treatment is sometimes necessary. Occasionally, a local infection at the injection site can be a complication, which needs to be treated immediately with antibiotics. Denoix & Dyson recommend local injections of corticosteroids (flumethasone, 0.5–1 mg per injection site with a maximum total dose of 4 mg; dexamethasone 1.5–2.5 mg per injection site, with a maximum total dose of 10 mg; methylprednisolone acetate, 40–60 mg per injection site, with a maximum total dose of 200 mg), sometimes in association with muscle relaxants or serapin.[112] Injections of corticosteroids around the sacroiliac joint region have been used quite extensively, but currently there are no well-designed or controlled trials reported in the literature. Larger doses of corticosteroids (20 mL) mixed with serapin have been advocated for sacroiliac joint injections.[110]

Additional medications

This is another controversial area and one where there is really only anecdotal information on efficacy of a range of different preparations. However, they have been widely used in practice, often in combination with acupuncture or physical therapy.

Serapin Serapin is an aqueous solution derived from the pitcher plant (*Sarraseniaceae*), which is said to block selectively the C fibers that carry pain sensation in peripheral nerves. Serapin is used alone or in combination with other drugs (i.e. corticosteroids) and may be used for both soft tissue (muscle and ligament injuries) and osseous problems (e.g. over-riding dorsal spinous processes). Small doses of 1–2 mL of serapin are given at multiple sites.

Sclerosing agents Again a number of proprietary agents have been used particularly around the sacroiliac joint and in the region of the ventral sacroiliac ligament. Horses are reported to improve their performance, but no scientific reports of their use are available.

Iodine For chronic muscle soreness, multiple injections of 2% iodine in oil (Hypodermin or McKay's solution, 3–4 mL, i.m., at multiple sites) within the sore muscle (e.g.

longissimus and middle gluteal muscles) have been recommended.[110] The injection area is massaged and the horse walked out the next day. Light work can then be resumed. Scientific reports on the beneficial action of iodine on muscle soreness are not currently available.

Hormones The estrus-suppressing drug altrenogest (0.044 mg/kg (1 mL/110 lb), p.o., s.i.d.) has been useful in some mares that exhibit apparent back pain when they are in estrus. Also in young Thoroughbreds that show signs of 'cold back' the use of estrone sulfate (0.1–0.15 mg/kg, i.m., every 2 weeks) may be beneficial.

Rubeola virus immunomodulator (RVI) Some practitioners have promoted RVI injections to assist in the reduction of chronic muscle soreness in some horses. RVI (2 mL, SQ, s.i.d. for 6 or more days) is an inactivated rubeola virus that is reported to have immunomodulatory effects that reduce chronic myofascial inflammation. However, the exact mechanism of action and extensive clinical reports are not currently available.

Mesotherapy

Mesotherapy is a technique that has been used for more than 30 years in France.[113] It consists of multiple intradermal injections with fine 5 mm needles into the dermatomes corresponding to the site of the lesion. The mechanism of action apparently involves type I and II nerve fibers coming from the skin which have collateral fibers that can inhibit pain transmission in the spinothalamic fasciculus, from deep structures of the same spinal segment to the thalamus and cerebrum.[112]

Mesotherapeutic injections are made using a mixture of local anesthetic solution (7 mL of lidocaine, 140 mg), short-acting corticosteroid (7 ml of dexamethasone, 15 mg), and muscle relaxant (8 ml of thiocolchicoside, 20 mg). The injections are made at the level of the lesion and caudal to it, taking into account the caudal orientation of the segmental nerves. For example, if treating over-riding dorsal spines between T10 and T15, the treated region extends from T10 to L1. Two to three rows of injections are made on each side of the median plane. The horse is restricted to light work on the lunge for 3 days. Normal training is progressively resumed over 5 days. A substantial improvement is anticipated within 7–14 days. The expected duration of action varies between 3 and 12 months.

Surgical management

There are few surgical indications for treatment of back problems except for impinged or over-riding dorsal spinous processes. In young horses that fracture the dorsal spines in the withers (T3–T10) surgery is not necessary unless the fractures are highly comminuted, when it may be necessary to debride the site to prevent infection or osteomyelitis.

Resection of dorsal spinous processes

Surgery for over-riding spinous processes was first reported by Roberts[114] and since then there have been a number of modifications to the technique.[34,115,116] However, the principle is the same, which is to remove the parts of the spinous processes that impinge. We believe that it is absolutely essential to confirm the correct diagnosis and select the most appropriate spines to alleviate the condition. There are many horses that show radiographic findings of over-riding spinous processes that do not exhibit clinical signs of a back problem.[68] Furthermore, many milder cases of over-riding spinous processes will respond to medical and conservative therapy.[51]

A recent paper reported by far the largest series to date and recorded a good response to surgery in those horses that failed to respond to conservative management.[34] The surgical technique involved placing the horse in lateral recumbency. A midline incision is made through the skin, subcutis and supraspinous ligament. The incision extends from one spinous process cranial to those identified for resection to one process caudal to them. The dorsal 4–5 cm of the dorsal spinous processes are dissected free of the supraspinous ligament, the interspinous ligaments and adjacent muscle tissue. Partial resection of the processes is performed with an oscillating saw to a depth that ensures that there is a minimum gap of 5 mm between the remaining bodies of each process resected. The minimum number of processes are resected in each case (e.g. if two processes are affected then one is removed, and if three are affected only the middle one is removed). One centimeter of the dorsal apex of the adjacent spinous process is also removed so that the change from resected to unresected processes is less abrupt. The supraspinous ligament and muscles are sutured and a simple interrupted suture placed between these sutures. The subcutis is sutured using three metric polyglycolic acid sutures and the skin is closed. The wound is protected by a stent bandage sutured over it. In the series, 72% of horses returned to full work and a further 9% improved sufficiently to be used for some athletic work.[34]

Chiropractic

Mechanism of action

Chiropractic evaluation focuses on evaluating and localizing segmental vertebral dysfunction (i.e. chiropractically defined 'subluxation') which is characterized by localized pain, muscle hypertonicity and reduced joint motion.[117] A thorough knowledge of vertebral anatomy, joint physiology and biomechanics is required for proper chiropractic evaluation and treatment. Alterations in articular neurophysiology from mechanical or chemical injuries can affect both mechanoreceptor and nociceptor function via increased joint capsule tension and nerve ending hypersensitivity.[118] Mechanoreceptor stimulation induces reflex paraspinal musculature hypertonicity and altered local and systemic neurologic reflexes. Nociceptor stimulation results in a lowered pain threshold, sustained afferent stimulation (i.e. facilitation), reflex paraspinal musculature hypertonicity and abnormal neurologic reflexes.

The goal of chiropractic treatment is to restore normal joint motion, stimulate neurologic reflexes and to reduce pain and muscle hypertonicity. Multiple theories have been proposed and tested over the years to explain the pathophysiol-

ogy of vertebral segment dysfunction and its interactions and influences on the neuromusculoskeletal system.[117,119] Chiropractic treatment is thought to affect mechanoreceptors (i.e. Golgi tendon organ and muscle spindles) to induce reflex inhibition of pain and reflex muscle relaxation and to correct abnormal movement patterns.[45,120] Anecdotal evidence and clinical experience suggest that chiropractic is an effective adjunctive modality for the diagnosis and conservative treatment of select musculoskeletal-related disorders in horses. However, therapeutic trials of chiropractic manipulations are often used since we currently have limited formal research available about the effectiveness of chiropractic procedures in equine practice.

During treatment, a 'release' or movement of the restricted articulation is often palpable. An audible 'cracking' or 'popping' sound may also be heard during chiropractic treatment as the applied force overcomes the elastic barrier of joint resistance.[121,122] The rapid articular separation produces a cavitation of the synovial fluid.[123] In humans, radiographic studies of synovial articulations after manipulation have shown a radiolucent cavity within the joint space (i.e. vacuum phenomenon) that contains 80% carbon dioxide and lasts for 15–20 minutes. A second attempt to recavitate the joint will be unsuccessful and potentially painful until the intra-articular gas has been reabsorbed (i.e. refractory period). The static position of the vertebral or sacroiliac joints in humans has been studied before and after manipulation by roentgen stereophotogrammetric analysis, which allows precise measurements of three-dimensional articular movement.[124] Static palpation changes were noted before and after manipulation but no changes were seen with the roentgen stereophotogrammetric analysis. Therefore, soft tissue responses such as joint capsules, muscles, ligaments, tendons and postural neuromuscular reflex patterns should be the focus of future spinal manipulative studies and not articular malpositioning (i.e. bone out of place).[124]

Indications

The principal indications for equine chiropractic evaluation are back or neck pain, localized or regional joint stiffness, poor performance and an altered gait that is not associated with overt lameness. A thorough diagnostic work-up is required to identify soft tissue and osseous pathology, neurologic disorders or other lameness conditions that may not be responsive to chiropractic care. The primary clinical signs that equine chiropractors look for are localized musculoskeletal pain, muscle hypertonicity and restricted joint motion. This triad of clinical signs can be found in a variety of lower limb disorders, but is most evident in neck or back problems. Chiropractic care can help manage the muscular, articular and neurologic components of select musculoskeletal injuries in performance horses. Musculoskeletal conditions that are chronic or recurring, not readily diagnosed or are not responding to conventional veterinary care may be indicators that chiropractic consultation is needed. Chiropractic care is usually contraindicated in the acute stages of soft tissue injury. However, as the soft tissue injury heals, chiropractic has the potential to help restore normal joint motion, thus limiting the risk for future reinjury.[40] Chiropractic care may provide symptomatic relief in early degenerative joint disease if related to joint hypomobility and subsequent joint degeneration. Chiropractic is usually much more effective in the early clinical stages of disease versus end-stage disease where reparative processes have been exhausted.

Contraindications

Chiropractic is not a 'cure all' for all back problems and is not suggested for treatment of fractures, infections, neoplasia, metabolic disorders or non-mechanically related joint disorders. Acute episodes of sprains or strains, degenerative joint disease or impinged spinous processes are also relative contraindications for chiropractic treatment. All neurologic diseases should be fully worked up to assess the potential risks or benefits of chiropractic treatment. Serious diseases requiring immediate medical or surgical care need to be ruled out and treated by conventional veterinary medicine before routine chiropractic treatment is begun. However, chiropractic care may contribute to the rehabilitation of most postsurgical cases or severe medical conditions by helping in the restoration of normal musculoskeletal function. Chiropractic care cannot reverse severe degenerative processes or overt pathology.

Acupuncture

Mechanism of action

Acupuncture involves the insertion of fine needles into specific predetermined locations (i.e. acupuncture points) to produce therapeutic effects.[125] Acupuncture points are often chosen within the same dermatome as the lesion or condition being treated, as well as local tender or painful sites, points cranial or caudal, proximal or distal to the localized lesion.[126] Additional methods of stimulation include acupressure, aquapuncture, electrostimulation and low-level laser therapy. Theoretically, each acupuncture point, or combination of points, has specific therapeutic actions when stimulated.

The primary benefit of acupuncture for back problems is pain management via opioid (i.e. enkephalin and β-endorphin) and non-opioid (e.g. serotonin) pathways.[126] Pain relief is often immediate, but may have variable durations of effectiveness, depending on the type and severity of musculoskeletal dysfunction. Acute injuries often respond rapidly and require fewer treatment sessions, whereas chronic musculoskeletal conditions may require periodic or long-term treatment. Acupuncture is often the treatment of choice for trigger points, which are localized tight, painful bands of muscle at characteristic locations within large muscle groups, particularly the middle gluteal muscle.

Indications

Clinical studies and experimental reports indicate that acupuncture is a safe and effective modality for specific musculoskeletal conditions if used properly.[125] Disease conditions managed by acupuncture include trauma, osteoarthritis and

muscle hypertonicity. Pain is the primary indication for acupuncture in horses with back problems. Acupuncture does not have any known direct effects on reducing joint stiffness, as do manual therapies. Therefore, synergistic effects are often obtained with combined chiropractic and acupuncture treatment that cannot be obtained consistently with either modality by itself. The immediate pre-race use of acupuncture is banned by many racing jurisdictions and athletic organization regulations due to its potential misuse of analgesic properties.

Contraindications

There are few specific contraindications for acupuncture since the majority of medical and surgical conditions have associated indications for acupuncture. Fractures, active infections and bleeding tendencies are relative contraindications. Risks and complications associated with needle placement include infection, puncture of organs or pneumothorax. Solid needles or aquapuncture are often recommended over the thoracolumbar region due to the risk of breaking off a portion of the needle within the epaxial muscles from the action of the thoracolumbar fascia on the needle.

Physical therapy

Mechanism of action

Physical therapy modalities that may have direct application to back problems in horses include devices that apply electrical currents for pain control or neuromuscular rehabilitation; thermal modalities (i.e. superficial and deep heat or cold applications) for influencing inflammatory mediators, collagen extensibility and altering nerve conduction; and mechanical approaches (e.g. massage, vibration, stretching and training exercises) for maximizing musculoskeletal rehabilitation.

Indications

In the absence of trauma or documented pathologic findings, the primary goal of treatment should address restoration of function and prevention of future disability.[40] Management should be systematically and methodically directed toward developing co-ordination and proprioception, flexibility, strength and endurance. The negative effects of immobilization and deconditioning should be minimized with early mobilization and controlled activity. Increased mobility is addressed with joint mobilization and muscle stretching.[127] Altered movement patterns are addressed with co-ordination via proprioceptive retraining, postural re-education, muscle strengthening and endurance training.[40]

The primary indications of physical therapy for back or pelvic problems include localized or generalized pain, joint motion restrictions and altered back muscle tonicity.[128] Pain modulation can be provided by influencing inflammatory mediators, altering pain perception and transmission, and increasing β-endorphin levels. Physical therapy modalities involved in pain control include electrical stimulation (i.e. muscle stimulation, transcutaneous electrical nerve stimulation (TENS)), the application of hot or cold, mechanical vibration and electromagnetic modalities. Soft tissue and articular motion restrictions (i.e. stiffness) can be directly addressed with specific stretching exercises to induce creep and stress relaxation within fibrotic or shortened periarticular soft tissues. With minimal training, horses and their owners can be taught how to do simple but effective passive joint mobilization and active stretching exercises (i.e. carrot stretches) to improve both axial skeleton and limb flexibility. Cryotherapy (i.e. ice packs or ice massage) is indicated in the first 24–48 hours post injury to reduce pain, induce muscle relaxation and reduce inflammation. The application of heat or electrical stimulation can provide increased soft tissue extensibility, reduced inflammation and adhesion formation, and pain control to help facilitate the restoration of normal joint motion.[118]

Abnormal muscle tone can be addressed with modalities that increase or decrease muscle contractility or coactivation and nerve conduction or inhibition. Some of these modalities include hydrotherapy, electrical stimulation and rehabilitative exercises that specifically address issues of reduced flexibility, co-ordination, strength and endurance. In humans, anti-inflammatories and other drugs can be delivered into superficial soft tissues via electrical currents (i.e. iontophoresis) or via mechanical sound waves (i.e. phonophoresis). However, preliminary equine research indicates that a heavy hair coat, thick skin and deep articular structures may limit the overall effectiveness of these novel drug delivery systems for back problems.

Contraindications

Contraindications for massage include active skin lesions, open wounds, acute inflammation or persistent muscle hypertonicity (i.e. exertional rhabdomyolysis).[129] Contraindications for electrical modalities include active skin lesions, open wounds, pain of unknown origin or pain conditions where masking the pain may be detrimental (e.g. pre-race).[130] Contraindications for superficial or deep heating modalities include acute injury or inflammation, open wounds, recent or potential hemorrhage, neoplasms or impaired sensation.[118] Precautions or contraindications for cryotherapy include open wounds, vascular compromise or peripheral vascular disease due to the induced vasoconstriction produced by the ice.[118]

Future areas of research

In horses with back pain, specific functional pathologies that need to be addressed in addition to initial pain relief include trigger points, hypertonic muscles, weak muscles, abnormal movement patterns and joint dysfunction. Compared to their human counterparts, veterinarians and equine athletes often have a very limited selection of options for the treatment of musculoskeletal disorders. Currently, we do not have objective measurement or rehabilitation tools to specifically assess soft tissue or articular pain, reduced flexibility and joint stiffness,

muscle hypertonicity, trigger points or alterations in proprioception or co-ordination associated with musculoskeletal or nerve dysfunction. Normal kinematics of the thoracolumbar spine have been investigated[8,9,11,131,132] but continued work needs to be done to assess segmental vertebral motion and its response to specific and defined articular and soft tissue injuries. Objective measures of spinal stiffness have been investigated[133] but the effects of pain, muscle hypertonicity, articular process osteoarthritis and concurrent lameness have not been explored.

Functional outcome measures assess how well a horse is able to do the job asked of it (e.g. speed, flexibility, co-ordination, strength and endurance). Quantitative assessments of pain include the use of a 0–10 pain scale, algometry or pain pressure threshold measurements, and mapping areas of pain. A 0–10 visual analog scale or pain scale is easy to use and provides a semi-objective means of following pain, dysfunction, performance or any other musculoskeletal parameter either immediately before and after treatment or over several days or weeks of treatment. Measurements can be compiled independently by both the owner and the veterinarian, with similarities or differences evaluated.

Other areas of musculoskeletal treatment that need further scientific investigation include well-defined, scientifically validated strength and endurance training programs tailored for the unique athletic demands of the various equestrian events. It is hoped that new insights into measuring musculoskeletal dysfunction and the pathophysiology of chronic pain syndromes will assist in assessing the effectiveness of many of the traditional and complementary modalities currently applied to horses with the rationale of reducing morbidity and improving overall performance in our elite equine athletes.

CHAPTER 22

Prevention of orthopedic disease in athletic horses

Antonio Cruz

Introduction

The science of injury prevention in equine sports medicine is still underdeveloped. Although there exists valuable and scientifically obtained information regarding the characterization of horses' gaits and the influence of conformation and environment (shoeing, surface, etc.) on the incidence of injuries, it appears that practical recommendations towards injury prevention are not very commonly implemented nor regulated within the equine industry across the world. Largely, riders and trainers may still believe that traditional training methods and good horsemanship will produce sound horses and the implementation of scientific findings in the daily equestrian routine has not found a resounding echo amongst equestrians. In contrast, in the human literature there are a large number of studies pertaining to injury prevention, mostly driven by the rising cost of healthcare and liability associated with sport-induced injuries. In addition, the approach to training human elite athletes is mostly multidisciplinary, including exercise physiologists, kinesiologists, physicians, physiotherapists, nutritionists and biomechanical engineers.

In the last decade a significant thrust has occurred in the area of sport-induced injuries in horses. As a result there is a body of information describing risk factors, incidence of injuries and preventive measures for exercise-induced injuries. Despite a higher number of horses enrolled in equestrian disciplines other than racing, most of the investigative efforts have been directed to the racing industry due to the greater socioeconomic impact that it represents. The racing industry also, concerned about horse welfare and its public perception, has funded most of this research as an effort to improve racing conditions. In the United Kingdom a comprehensive approach to preventing race horse injuries[1] has been warmly welcomed by the racing industry. A close partnership amongst owners, trainers, jockeys, veterinarians, epidemiologists and regulatory bodies is producing relevant information regarding the incidence of race horse injuries and associated risk factors and should serve as a role model for other racing jurisdictions and equestrian disciplines (Fig. 22.1).

The identification of injuries and risk factors and the understanding of injury pathophysiology are the first steps towards preventing orthopedic injuries. In most cases injuries occurring in performing horses are highly correlated with their equestrian discipline. Each athletic activity places stresses in specific anatomic regions. The identification of injury patterns associated with different equestrian sports (Table 22.1) has led veterinarians to recognize lesions promptly to prevent further damage. For instance, condylar fractures are recognized mainly in race horses or pastern fractures in barrel racing Quarter Horses.

Recognizing musculoskeletal structures at risk, such as cannon bone, superficial digital flexor (SDF) tendon or suspensory ligament (SL), has prompted the study of their

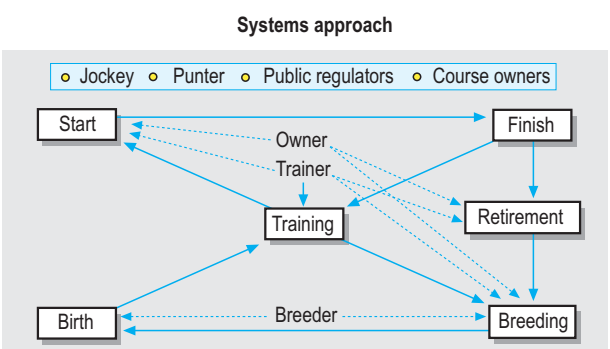

Fig. 22.1
A systems approach to reducing musculoskeletal injuries. (Courtesy of Professor KL Morgan, University of Liverpool, UK.)

Table 22.1 Common injuries seen in horses by sport activity. A soundly conformed horse with adequate and balanced feet is essential to prevent many of these injuries

Activity	Common injuries
Flat racing	Bucked shins, stress fractures (humerus, tibia, pelvis), condylar fracture, osteochondral (chip) fragmentation (carpus/fetlock), SDF tendinitis, suspensory breakdown, P1 fracture, DJD
Harness racing	Bucked shins, stress fractures, condylar fracture, osteochondral (chip) fragmentation (carpus/fetlock), SDF tendinitis, suspensory breakdown, DJD
Hurdle racing	Catastrophic fracture, interosseous muscle desmopathy
Barrel racing	SDF tendinitis, P2 fracture (hind leg)
Rodeo	Navicular disease, 'Ringbone', bone 'spavin', P2 fracture
Cutting/reining	Navicular disease, interosseous muscle desmopathy, bone 'spavin', stifle injuries
Team roping	Bone 'spavin', interosseous muscle desmopathy, P2 fracture, back/pelvic problems
Showjumpers/ eventers	Interosseous muscle desmopathy, SDF tendinitis, stifle/fetlock injuries, P1 fractures, back problems
Dressage	Interosseous muscle desmopathy, SDF tendinitis, back problems
Polo ponies	SDF tendinitis, proximal interosseous muscle desmopathy, back problems, fetlock DJD
Endurance	Myopathies, SDF tendinitis

biomechanical behavior under different conditions. However, the scientific study of incidence of injury and associated risk factors has occurred to a large extent only in the racing industry. In racing horses there is information available through different studies in different racing jurisdictions (Table 22.2). A comparison amongst these studies must be done carefully due to the different study designs and conditions under which they were carried out. We must accept that in the current competition environment we will not succeed in totally eliminating injuries. The goal is therefore not to eliminate them, but to significantly reduce their risk and incidence to a level that is just the result of unforeseen accidents. It is important to define an injury, measure the extent of its risk and to identify modifiable factors associated with such risk. These risk factors can then be seen as highly preventable, preventable, non-preventable or unforeseen risks.

In other equestrian disciplines the prevention of orthopedic injuries is mainly based on the practice of good horsemanship combined with generally applied physiology and biomechanics as well as good old common sense developed through previous experiences. The use of different training surfaces and programs, exercise intensity, jump or course design is based mostly on tradition and experience rather than on scientific findings of the biomechanical behavior of the horse's locomotor system under different circumstances. Most of the research efforts have been made to characterize horse locomotion and loads transmitted to the appendicular skeleton during different types of exercise. A comprehensive universal analysis of injury incidence and risk factors in equestrian disciplines other than racing is lacking at the present time.

The making of a champion athlete capable of outperforming its competition in extreme conditions, sustaining minimal or no injuries, starts long before it is born. In the equine industry, earnings are the measure of success. To generate earnings a horse must enter competition and the sounder and fitter the horse, the higher the likelihood of success. Although selection of breeding stock is based on a few traits, such as speed, it is also possible that those successful horses that become part of the breeding pool are not only transmitting the desired trait but perhaps some superior biomechanical qualities, likely associated with conformation.[2]

This chapter will focus on the training and performing horse but we must recognize that choosing the optimal genetic lines, normal pregnancy and adequate management of the horse during growth and development can provide the future trainer with an outstanding 'diamond in the rough'. Genetics, nutrition and exercise play a crucial and somewhat unknown role in the development of an athlete. All of them need to be investigated more fully to determine the optimal management of a growing horse to prevent performance-limiting injuries.

Thoroughbred, Standardbred, Arabian or Quarter Horse racing generates a significant economic activity in many countries.[3] There are several modalities of racing. In North America most of the racing is flat and harness racing while in other countries other modalities such as steeplechasing, hunterchase or hurdling exist. Most of the scientific work related to characterization and prevention of exercise-associated injuries has been carried out in race horses. Aspects of horse selection, management, training and competition have been investigated. Race horses are usually started into training at an early age (1–3 years of age), as most of the competition occurs when the horse is 2 or 3 years old. Considerable debate has centered round the optimal training age as the North American system has been criticized for starting horse training at a very early age.[4,5] The central point of disagreement has been the perceived notion that horses trained at an early age tend to have an increased risk of catastrophic injury and certain industry groups have lobbied to change actual training practices. In order to understand the risk of training a young race horse, several investigations have focused on the effects of early exercise in musculoskeletal development.

The training period represents a time of intensive psychological and physical challenges for a horse. Training not only achieves the development and maintenance of cardiovascular fitness and musculoskeletal strength but it also improves the neuromuscular co-ordination and mental aptitude of the horse. One of the objectives of training is to decrease the risk of injury during athletic competition by adapting the musculoskeletal and cardiovascular systems to the rigors of competition. The term 'functional adaptation' is used to describe the response of the body to accommodate an imposed

Table 22.2 Studies reporting injury risk factors and potential strategies to diminish them. Note that most of the studies are conducted in race horses under different racing jurisdictions. Comparison amongst studies must be done with caution as study design will vary (MS, musculoskeletal; N/A, no preventive measures offered; QH, Quarter Horses; TB, Thoroughbreds)

Risk factor	Injury	Pop.	Country	Prevention strategies	Reference
Speed, distance	Bucked shins	TB	USA	Increase speed, decrease distance, introduce high-speed sprints	43
Age at first race, racing history, race distance, sand gallops, woodchip gallops, zero gallop work	Catastrophic	TB	UK	Introduce schooling races, shorten National Hunt racing distance, gallop at least 1 furlong for every 7 furlongs cantered	1
Track conditions	Fracture	TB	Japan	Decreased sharp turns, change banking %, change vertical profile, change composition of ground	31
Firm turf tracks Heavy dirt tracks	Fracture	TB	Japan	Regulate racing according to track conditions	37
Location on the track	Fracture	TB	Japan	Map hardness distribution on track and water track to maintain adequate water content, automatic rakes to remove sand accumulation and eliminate excessive water content on the track surface	38
Increased cumulative high-speed exercise	Catastrophic	TB	USA (California)	Decreased cumulative high-speed exercise	52
Pre-existing injury	MS injury	TB	USA (Kentucky)	Pre-race inspection	29
Pre-existing injury	MS injury	QH	USA (Texas)	Pre-race inspection	53
Jockey's use of whip	Fracture	TB	Japan	Regulate use of whip	38

mechanical environment in a way which optimizes the mass and distribution of the tissues.[6] It is important to understand that this adaptation occurs in a timeframe that varies with different tissues.

Specific activity-oriented training will help develop the relevant muscle groups and strengthen the skeleton and other supporting structures in areas of higher demands, according to the type and intensity of a specific exercise. It will also develop the co-ordination required to maintain an adequate balance during the different stages of competition and the competitive attitude required to succeed at equestrian disciplines. Maintaining an adequate body balance will ensure the proper loading of the musculoskeletal system and will decrease the incidence of orthopedic injuries.[7] Intense training also separates horses with moderate physical aptitude from those with outstanding physical and psychological qualities, which will finally enter elite athletic competition. Training programs should focus on speed, strength, precision (mental focus) and stamina. It is during training that the musculoskeletal system is allowed to adapt to a particular exercise intensity characterized by cyclic loading to increase the fatigue life and therefore minimize the risk of injury. During training an evolution in the intensity and complexity of exercise occurs which allows the supporting musculoskeletal structures to develop the necessary strength to sustain performance. In addition, other less well-investigated factors, such as proprioceptive adaptation, will adjust to provide an adequate body and joint balance such that the loading conditions under which performance occurs do not result in an injury.

Musculoskeletal changes occurring during training are time dependent and vary with exercise intensity, age of the horse and quite possibly with each individual horse. Therefore, training programs must adjust to these biological characteristics of different tissues to optimize their results. In race horses most of the injuries occur during training.[8,9] Since training management will determine conditions such as shoe wear, foot angles, training speed, cumulative distance and frequency, racing intervals and racing surface, training constitutes the largest single element influencing risk of athletic injuries. Training regulations vary with racing jurisdictions and no formal education or rigorous testing is required to become a trainer in many racing jurisdictions. Trainers have the ability to affect a horse's performance and they are largely responsible for the success that a horse may enjoy. In a study carried out by Verheyen and Wood at the Animal Health Trust in Newmarket, England, where data were collected on 1178 horses in training and 13 trainers, it was found that fracture risk was significantly affected by trainer.[10] Training methods are jealously guarded by many trainers afraid of disclosing their methodology. However, the enforcement of regulations regarding training guidelines needs to be investigated as a method to reduce injury risk.

Functional adaptation of the musculoskeletal system

The adaptive response of bone may be summarized in Wolf's Law and its behavior is well described and understood.[11,12] Bone responds to loads (exercise) by depositing new bone in those areas where the loads imposed are higher. The bone response occurs at a certain rate determined by bone remodeling, which involves osteoclastic and osteoblastic activity. Intense repetitive loading, which occurs at a faster rate than bone remodeling, will increase the risk of bone damage and

catastrophic fracture.[13] McCarthy & Jeffcott evaluated the third metacarpal bone responses to treadmill exercise and found that exercised horses had less cortical porosity, larger subperiosteal osteogenesis and increased bone stiffness, showing a significant adaptive response.[14]

Responses of suspensory ligament and proximal sesamoid bones to exercise have also been evaluated. In a study by Bramlage et al, two groups of six horses each, trained versus untrained, were tested for the load to failure response of the suspensory apparatus. The load to failure was higher in trained horses (1340 kg versus 1100 kg) and most of the trained horses (83%) suffered rupture of the suspensory apparatus by sesamoid fracture, showing also a response to exercise.[15]

Tendon functional adaptation is less well defined. Superficial digital flexor tendon responds to exercise by increasing the cross-sectional area, decreasing echogenicity and increasing the modulus of elasticity.[16] Exercise also induced histomorphologic changes in the SDF tendon by diminishing crimp angle and length in its central region in relation to the periphery, where the crimp angle was greater than in control (unexercised) horses. In this study, the authors concluded that the changes observed in the core region of the SDF tendon of exercised horses were indicative of microtrauma.[17,18] From these studies it appears that although there are some changes associated with exercise, it is difficult to determine if they are responses to microtrauma or adaptations to exercise.

It has been hypothesized that the adaptive capacity of tendon is reduced with increased age. To test this hypothesis, a series of experiments were conducted to evaluate the effects of exercise in young horses. The results are summarized in a paper by Smith et al.[5] The authors conclude that immature tendon can respond to exercise by synthesizing and maintaining the integrity of the matrix, while mature tendon has a limited response capacity. It is therefore possible that exercising the horse as a foal may allow for a functional adaptation response, which provides the horse with a tendon that is more resistant to injury (Fig. 22.2). Additional evidence of a hypertrophic response to exercise at an early age is offered by Kasashima et al.[19] This opens up the possibility of using early training as a measure to reduce the incidence of tendon injuries at a later time. The necessary training strategies and the optimal age at which to achieve such a goal require further investigation before making practical recommendations.

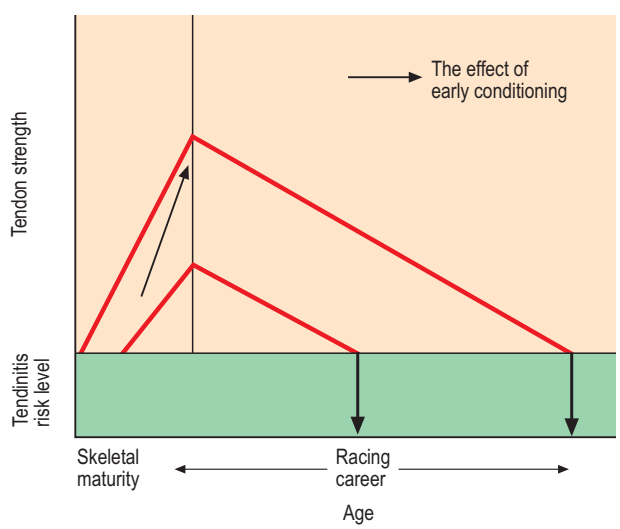

Fig. 22.2
Effect of early conditioning resulting in increased tendon strength and diminishing incidence of tendinitis. (Courtesy of Dr Roger Smith, The Royal Veterinary College, North Mimms, UK.)

As the horse gets older, exercise induces histomorphologic changes in the digital flexor tendons that do not seem sufficient to sustain the demands associated with high-speed racing. Since the mechanical behavior of the tendon in response to loads has been well defined,[20] exercising conditions, which repetitively overcome the tendon's biomechanical properties, will likely result in pathologic damage or even tendon breakdown. During galloping at racing speed the strain sustained by the SDF tendon has been calculated to be about 16%.[21] Under experimental conditions SDF tendons reached failure point at strains of 12–20%.[20,22] The high rate of tendon injuries in race horses may therefore be associated with the inability of current training programs or the tendon itself to modify their biomechanical properties to tolerate the high loads occurring during exercise.

In jumping horses, forelimb tendon injuries are an important cause of lameness and wastage.[23] The study of the effect of jump height in landing forces in these structures has revealed that fence height significantly increases the forces in the SDF tendon but not in the deep digital flexor (DDF) tendon or SL. In vitro experiments have shown the rupture forces of the DDF and SDF tendons to be around 13 and 12 kN respectively.[23,24] In addition, peak force in the SDF tendon slightly exceeds the in vitro failure force.[23] Comparison between in vitro and in vivo experiments must be done carefully but there is evidence to suggest that the in vivo peak landing force of the SDF approaches in vitro rupture forces. From this study it was concluded that the higher the fence, the higher the landing force on the SDF, therefore increasing the risk of SDF injury. The effect of jump height cannot be evaluated by itself as the quality of the horse, jumping technique and fatigue have been shown to have an effect on the forelimb landing forces. In a study by Schamhardt et al, experienced horses could clear higher fences than inexperienced horses with minimal effect on the ground reaction forces at landing.[25] In trotting horses, for example, SL loading increases during fatigue by an increase in fetlock hyperextension.[26] Therefore proper conditioning, training and selection of a horse with natural aptitude to clear fences are also important to limit the incidence of injuries in this equestrian discipline. Trainers and riders must be coached and understand that to push a horse beyond its capabilities will significantly increase the risk of musculoskeletal injury.

The equine industry must ensure that the conditions under which a horse is exercised do not impose further stress on the soft tissue structures. Since certain performing conditions such as fatigue, inadequate surfaces or shoeing,

Table 22.3 Studies reporting incidence of injuries and the main findings during the study, by year of study and country (OR, odds ratio; TB, Thoroughbreds; QH, Quarter Horses)

Country	Population	Year	Main findings	Reference
UK	Race horses (flat and National Hunt)	96–98	Fatal injuries 0.29% of all starts, non-fatal injuries 0.76% National Hunt > flat racing Injuries ↑ as surfaces became firmer Lowest incidence of injuries on turf surfaces	1
UK	Race horses (flat and National Hunt)	90–99	55% on injuries: lower limb fracture and tendon breakdown Risk factors: ↑ age, surface firmness and race distance	1
USA (New York)	Thoroughbreds	1986	Fracture injuries: dirt > turf Other injuries: dirt = turf 2 yr olds had more fracture injuries than other injuries	33
USA (Minnesota)	Thoroughbreds	1987	57% soft tissue injuries, 36% bone injuries, 7% other ↑ breakdown in horses > 4 yr old OR: Dirt (1.6) vs turf	32
USA (New York)	Thoroughbreds	1991	OR: Dirt (3) vs turf Risk of injury ↓ with racing season and no. of starts Risk of breakdown ↑ with horse's age	34
USA (New York)	Thoroughbreds	86–88	Risk factors: track, dirt > firm track, ↑ with track distance Worst surfaces: muddy dirt and firm turf OR: Hindlimbs severe injury (4) vs forelimb	61
USA (Kentucky)	Thoroughbreds	92–93	Injury prevalence per start: 0.33% Catastrophic injuries: left forelimb, sesamoid, third metacarpal Injuries: 90.2% affected forelimb, 44.7% affected suspensory apparatus	55
USA (California)	All race horses	90–92	Fatal injuries: 42% (racing), 39% (training) QH: fatal injuries 82% (racing) TB: fatal injuries 48% (racing) TB (racing injuries): prox. sesamoids and third metacarpal QH (racing injuries): prox. sesamoids and carpal bones	50
USA (California)	Thoroughbreds (post-mortem)	92–94	Toe-grabs ↑ risk of injury OR Low toe-grabs for fatal injury (1.8), for suspensory app. failure (6.5), for condylar fracture (7) OR regular toe-grabs for fatal injury (3.5), for suspensory app. failure (15.6) for condylar fracture (17.1)	54
South Africa	Thoroughbreds	93–94	8.1% of available training days were lost (72.1% due to lameness) Wastage amongst trainers: 0.1 to 23.7%	59

Table 22.3 cont'd

Country	Population	Year	Main findings	Reference
USA (Kentucky)	Thoroughbreds	94–96	87% of injuries in the lower limb (carpus to fetlock) 94.4% of injuries in the forelimbs (left > right) Risk factors identified: age > 5 yr old; stumbling; changing leads; interfering with another horse; > 60 days interval between races; positive pre-race inspection findings	29
Australia	Thoroughbreds	85–95	0.24% incidence of breakdown injuries per start 0.04% of fatal injuries per start Risk factors identified: ↑ horse age; Change distance from previous race; lower class of race; barrier position	39
Australia	Standardbreds	92–95	Injury rate ↓ 22% after elevating banks from 4.8° to 5.7°	60
USA (California)	Thoroughbreds (post-mortem)	94–96	↓ difference between toe and heel angle ↓ risk of suspensory app. failure ↑ toe angle helps diminish risk of suspensory app. failure	54
USA (Kentucky)	Thoroughbreds	96–97	Incidence of injury: 0.44% Risk factors: abnormality of suspensory ligament during pre-race inspection; claiming race < 25,000$; < 7 furlongs distance	29
USA (Texas)	Quarter Horse	95–98	Catastrophic injuries: 0.8/1000 starts Non-catastrophic: 2.2/1000 starts 73% of injuries in distances of 330–400 yards	53
USA (Florida)	Thoroughbreds	95–98	Injury incidence: 1.2/1000 starts Turf injury incidence: 2.3/1000 starts Dirt injury incidence: 0.9/1000 starts Risk factors: geldings; > 33 days since last race; turf surface	34
USA (California)	Thoroughbreds	98	Risk factors: pre-existing subclinical suspensory injury; toe-grabs	33
UK	Thoroughbreds	2000–01	78% of fractures occurred during training Fracture rate: 1.18/100 horses/month; 50% are stress fractures; 20% affect 3rd Mtc.; 30% affect pelvis; 20% affect knees Fracture risk is affected by trainer	1

improper conditioning or metacarpo(tarso)phalangeal hyperextension may be associated with an increase in the load sustained by structures of the appendicular skeleton, it would seem logical to avoid or modify conditions that would promote such motion without jeopardizing other structures.

Once we have recognized the adaptive nature of the musculoskeletal system, and the value of training in taking advantage of this, it is important to analyze which risk factors are involved in orthopedic injuries in exercising horses.

Risk factors

It has been shown that many of the injuries occurring in race horses are not the result of random accidental events but the end-point of a chronic process associated with the overuse of the body's biomaterials.[27] The most common biological structures injured in equine disciplines are the bones, tendons and ligaments of the appendicular skeleton. In order to prevent

the wear of these structures to the point of breakdown, it is of paramount importance to understand the concept of fatigue and the biomechanical behavior of those structural components under different conditions.

Fatigue of a material refers to a process by which the material reaches the breakdown point by cyclic loading above the endurance limit, similar to repetitively bending a paper clip until it breaks.[28] Fatigue represents a significant risk factor for musculoskeletal injuries and avoiding the onset of fatigue should significantly decrease the risk of a catastrophic injury.[13] Muscle fatigue reduces the muscle's ability to store energy and neutralize the stresses imposed on the bone, potentially resulting in a fracture. Fatigue of the cardiovascular system may lead to exhaustion and a reduced ability to quickly respond to changes in the body's spatial orientation. Accurate and timely control of body movements is essential to prevent body injuries resulting from high inertial forces associated with high-speed exercise. An inadequate response to motion changes may place uncommon forces on supporting structures which may not be prepared to support them. These forces could overwhelm a musculoskeletal structure, resulting in breakdown. For instance, stumbling during racing has been linked to the occurrence of catastrophic injuries in Thoroughbred horses.[29] The gait co-ordination required in certain sports trains a specific set of psychomotor skills and muscle activity. The sudden change imposed on a system by an inaccurate motion could potentially jeopardize certain supporting structures, increasing the risk of musculoskeletal injury. The severity of this injury will vary depending on the forces applied.

There are several studies identifying injury risk factors associated with racing (Table 22.3). It is a difficult challenge to define the incidence of injuries and to identify the different risk factors in each equestrian discipline. Most of the scientific efforts have been directed to the investigation of catastrophic injuries occurring to race horses. Although these are devastating incidents, they only represent a minimal part of the industry wastage due to musculoskeletal problems. Other less 'visible' problems, such as tendon or suspensory ligament damage and arthritis, have a larger impact on the economics and welfare of horses.[30] It must be understood that many equestrian disciplines, and in particular racing, represent an activity where horses reach and sustain exercise intensities capable of overwhelming the musculoskeletal system's response capacity, potentially ending in a severe or catastrophic injury. Musculoskeletal injuries represent an occupational hazard for the athletic horse. Veterinarians, trainers and riders must remain vigilant and proactive to design strategies to reduce incident rates amongst exercising horses.

Characterization of sport horse injuries has occurred over time and considerable advance has been made in describing injury patterns, risk factors, treatment modalities and outcomes. This has helped us to understand the pathophysiology of athletic injuries and to put in place the necessary mechanisms to prevent or minimize the risk of injuries. There is a trend towards seeing injuries as an inherent risk to the sport horse but it has been shown that implementation of the appropriate measures will reduce injury rates significantly.[31]

In North America, the main investigation into the causes of equine racing injuries was established by the California Horse Racing Board in 1990, although other studies, such as the racetrack breakdown pilot study in Minnesota[32] or those conducted in New York,[33,34] Florida[35] and Kentucky,[36] have contributed to our current body of knowledge. In other countries where racing constitutes an important sport activity, similar studies have been undertaken, such as in Japan,[37,38] the UK[1] and Australia.[39] Because of the different racing conditions in different parts of the world, it is difficult to extrapolate results across continents. However, one thing is clear: musculoskeletal injuries represent the leading cause of wastage in the racing industry across the world.

Early detection of subtle injuries leads to effective prevention of further injury and catastrophic breakdown and it has been suggested that adequate monitoring of horses is critical to prevent further damage to an already injured structure.[29] Minimally invasive techniques are currently being developed to identify biomechanical changes related to exercise and identify high-risk horses.

As veterinarians investigate the trend of training-related injuries, further study of the methods of training will likely reveal a cause–effect relationship. In this respect, the excellent work carried out by Nunamaker's group at the University of Pennsylvania is important, investigating the pathophysiology of the 'bucked shin' complex, where a clear relationship has been found between methods of training and the occurrence of 'bucked shins'.[13] It has been reported that 70–92% of race horses will develop 'bucked shins' at some point in their careers.[40,41] An investigation showed that 'bucked shins' are produced by an excessive cycling of the dorsal cortex of the metacarpus and its pathophysiology is discussed in Chapter 17. Modification of training regimes by introducing shorter high-speed (breeze) workouts has decreased the incidence of 'bucked shins'.[42]

The most common orthopedic injuries suffered by performing horses as a result of exercise are indicated in Table 22.1.

Soft tissue injuries

The main soft tissue structures affected during exercise are the SDF tendon, the SL and the accessory ligament (AL) of the DDF tendon. Although they seldom produce a catastrophic breakdown, a study has shown their importance in the North American racing industry.[43] In the UK a 30% incidence of tendinitis has been reported,[44] although a more recent report quotes an incidence of 43% amongst National Hunt horses.[45]

Considering that the SDF tendon strain associated with racing approximates the strain associated with tendon failure, it is not surprising that some horses will eventually damage their tendons as the safety margin at peak performance is very small.[46] During post-mortem examinations of clinically normal equine flexor tendons, the morphology, biochemistry and histology of the tendon were investigated.

Abnormal macroscopic appearance, increase in total sulfated glycosaminoglycans, increase in total proportion of type III collagen and decrease in collagen-linked fluorescence were the main findings. The results suggested that this was a healing response to microdamage.[47] It has also been postulated that tendon fiber microdamage often precedes catastrophic tendon breakdown.[48] The response to galloping exercise was evaluated in another study. Young Thoroughbreds were exercised for 18 months and compared to a group exercised only with walking. Crimp angle and length were evaluated. The results indicated that galloping exercise modifies normal age-related changes in crimp morphology consistent with microtrauma.[18] The effects of different training regimes have not been investigated at this time. Since the healing response of tendons is a slow process, in those horses that have suffered from tendinitis, it is crucial to monitor tendon health and to allow proper healing to occur before reintroduction to exercise.

Before the introduction of tendon ultrasonography, one of the problems associated with tendon injuries was reinjury of the affected tendon, caused by premature return to exercise. Today we recognize that appropriate monitoring of tendon healing should be done by ultrasound and return to exercise should ideally be delayed until there is ultrasonographic evidence of healing. Sonographic indications of early tendinitis include an enlargement of cross-sectional area and a decrease in tendon echogenicity. The recent advances in ultrasound imaging suggest an important role for it as a method of routine monitoring during training. By combining monitoring and new training strategies, the incidence of tendinitis and associated wastage should be reduced.[49] There is a need for a scientifically based approach to training horses for peak athletic performance with minimal risk of injuries. However, the reduction in tendinitis should not be at the expense of other tissues and therefore the responses of all tissues and systems contributing to high-speed locomotion must be optimized.[5]

Pre-existing pathology has emerged as a culprit for many racing injuries. The California post-mortem study has described stress fractures occurring to humerus, pelvis and tibia previous to catastrophic breakdown.[50] In addition, soft tissue injuries leading to inadequate support of the skeletal system have also been implicated in the occurrence of certain racing injuries. LeJeune and co-workers recently presented the results of an investigation where damage to the medial suspensory ligament branch increased the load placed on the lateral metacarpal condyle, speculating that damage to the suspensory branch may play an important role in the occurrence of condylar fractures.[51] This study seems to support the clinical impression and the results of another study where early detection of soft tissue lesions (pre-race examination) decreased the incidence of severe musculoskeletal injury.[29] Published injury risk factors and prevention strategies are summarized in Table 22.2.

We must persevere with the investigation of the pathophysiology of sport injuries and the identification of risk factors. In addition, the industry has to be willing to compromise or perhaps change the spectacle in order to reduce injury rates. Design of different performing surfaces, jumping courses, racetrack profiles, length of races, speed of races or training programs may need to be reviewed and potentially altered without jeopardizing the essence of the competition.

CHAPTER 23

Pharmacotherapy of joint and tendon disease

Rustin M. Moore and Honor A. Walesby

Introduction

The reality of pharmacology is that there are no silver bullets or magical cures. No one drug or therapeutic substance can be placed into a syringe, administered as a powder or given as a pill that will cure all of the musculoskeletal conditions affecting the equine athlete. Pharmacotherapeutic agents are designed to assist the body in the healing process. Combination therapy that utilizes rest, physical therapy, pharmacotherapeutics and possibly surgery is necessary to ensure proper healing and restore function. An effective therapeutic plan is based on careful assessment of patient signalment, the history and duration, location, type and severity of the injury, as well as the economics.

The common denominator in all equine athletic injuries is inflammation. The cellular mediators and biochemical processes associated with inflammation are responsible for the clinical signs of heat, pain, and swelling, as well as ongoing tissue destruction. The goal of pharmacotherapeutic intervention should be to control the cellular mediators and biochemical processes of inflammation, prevent ongoing tissue destruction, relieve pain, restore function and return the horse to normal work conditions with minimal loss of fitness. A sound understanding of the mechanism of action, indications for use, effective dosages, drug interactions, toxicity and expected results for the available veterinary drugs is necessary.

The goal of this chapter is to provide information pertaining to drugs used to treat the equine athlete. The knowledge gained from this chapter should help facilitate the optimum selection and application of pharmacotherapeutic agents in the treatment and maintenance of the athletic horse. This chapter will focus on anti-inflammatory drug therapy and other medications used in the treatment of joint and tendon disease in horses.

Anti-inflammatory drug therapy in horses

Anti-inflammatory medications are commonly administered to horses for the treatment of inflammatory and infectious diseases, and for traumatically or surgically induced injuries of the musculoskeletal system. The most commonly used anti-inflammatory drugs include non-steroidal anti-inflammatory drugs (NSAIDs) and corticosteroids, but other drugs such as polysulfated glycosaminoglycans, dimethylsulfoxide and hyaluronate are also believed to have anti-inflammatory effects. The NSAIDs are commonly administered systemically for their analgesic and inhibitory effects on inflammation, fever and edema. Numerous NSAIDs are available, but phenylbutazone (PBZ) and flunixin meglumine (FLM) are currently the most commonly used. Aspirin (acetylsalicylic acid) has limited use in the treatment of musculoskeletal disease in horses due to its poor analgesic effects. Ketoprofen (KTP), carprofen (CRP), dipyrone, meclofenamic acid (MFA) and naproxen (NPX) are other NSAIDs used in horses.

Although corticosteroids are rarely used systemically to treat musculoskeletal disease in horses, they are commonly administered locally within joints affected by synovitis and arthritis. Knowledge of the mechanism of action, pharmacologic properties, pharmacokinetic behavior and therapeutic

and toxic effects of these medications will enable veterinarians to select the optimum anti-inflammatory pharmacotherapeutic regimen for the treatment of horses affected with musculoskeletal disease.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs represent a class of drugs that inhibit one or more of the pathways involved with the synthesis of prostaglandins (PGs) and thromboxanes (TBXs) from arachidonic acid. The principal mechanism of action is through inhibition of cyclo-oxygenase (COX). Prostaglandins, particularly those of the E-series, are involved in synovial inflammation and depletion of proteoglycan from articular cartilage matrix.[1,2] There is substantial evidence to suggest that PGE_2 is the principal PG involved in joint degeneration. Synoviocytes and chondrocytes synthesize PGE_2 in response to exposure to lipopolysaccharide (LPS) and other inflammatory mediators, and increased concentrations of PGE_2 have been reported in the synovial fluid of horses with osteoarthritis.[3] Additionally, there is also evidence to suggest that PGs may modulate latent matrix metalloprotease release with resultant cartilage matrix degradation.[4,5]

Classification and mechanism of action

Non-steroidal anti-inflammatory drugs are classified, based upon their chemical structure, into carboxylic and enolic acids. A majority of NSAIDs belong to the carboxylic acid group, whereas few are enolic acids. Additionally, NSAIDs can be further divided into five major categories.[6] These categories include pyrazolones (phenylbutazone, dipyrone), salicylic acids (aspirin), acetic acids (etodolac), fenamic acids (meclofenamic acid, flunixin meglumine) and propionic acids (naproxen, ketoprofen, carprofen).[7] The acidic nature of the NSAIDs facilitates their accumulation at sites of inflammation (acidic pH), enabling them to be more effective in inflamed versus normal tissues.[6,8]

Most NSAIDs have a similar mechanism of action and physical and chemical properties.[9,10] NSAIDs inhibit the synthesis of PGs and TBXs from arachidonic acid by inhibiting COX. All NSAIDs, other than aspirin, are competitive COX antagonists; this mechanism of action requires the continued presence of the active drug to exert the effect. Aspirin is an irreversible antagonist that deactivates COX by acetylation. Because platelets are non-nucleated and thus do not have the capacity to synthesize new COX, it has a profound effect on platelet function.

A relatively recent discovery expanding knowledge of the COX pathway is that there are at least two COX isomers, namely the constitutive (COX-1) and inducible (COX-2) isoforms.[6] The COX-1 isomer is believed to be the 'housekeeping' enzyme responsible for basal synthesis of PGs necessary for physiologic functions, including maintenance of vasomotor tone (intestinal mucosal and renal blood flow), prevention of platelet aggregation and adhesion and maintenance of gastric cytoprotection.[6] The COX-2 isomer is responsible for increased eicosanoid synthesis associated with inflammation and is induced by LPS, cytokines and other inflammatory mediators. The affinity for the two COX isoforms varies among NSAIDs. Some are more potent inhibitors of COX-1, while some are relatively equipotent for their effects on COX-1 and COX-2, and others have a greater selectivity for COX-2. A COX-1/COX-2 ratio is useful to measure the selectivity of an NSAID for the COX isomers.[6] Unfortunately, many of the NSAIDs currently used in horses have a ratio ≥ 1, which means they inhibit COX-1 as much or more than the COX-2. A COX-1/COX-2 ratio < 1 is preferable in order to maximize the anti-inflammatory effects of the NSAID while minimizing the potential for toxic side effects.

Many of the actions attributed to NSAIDs are dose dependent. Greater doses are necessary to reduce inflammation than are required to actually inhibit eicosanoid synthesis. At lower doses, many NSAIDs inhibit PG-mediated fever, pain and vasomotor tone.[9,10] However, the dose required to decrease edema formation and leukocyte accumulation at inflammatory sites is substantially greater than the dose required to reduce PG synthesis. Therefore, the NSAIDs currently available are likely to be more effective in inhibiting pathologic processes involving PGE_2 (pain, fever), compared with those involving other mediators.

Greater doses of NSAIDs also inhibit non-PG dependent processes, such as enzyme activity, transmembrane ion flux and proteoglycan synthesis by chondrocytes.[9] Ketoprofen was originally reported to also block the lipoxygenase (LPX) pathway, thus reducing synthesis of leukotrienes from arachidonic acid. However, studies using carrageenan-induced inflammation in subcutaneous tissue chambers in horses revealed that ketoprofen decreased PGE_2 synthesis, but not leukotriene B_4 synthesis.[11,12] Thus, these studies have demonstrated that ketoprofen does not inhibit the LPX pathway in horses.

Research into the development of NSAIDs with dual COX and LPX inhibitory activity should offer a more balanced approach to inhibiting the synthesis of arachidonic acid-derived inflammatory mediators. Because COX inhibition may cause preferential metabolism of arachidonic acid via LPX, a dual COX-LPX inhibitor may improve the anti-inflammatory effects of NSAIDs. Additionally, the development of more specific COX-2 inhibitors with a COX-1/COX-2 ratio < 1 will help improve the therapeutic effectiveness of these compounds while minimizing their potential toxic side effects.

Potency and selectivity of NSAIDs in horses

An in vitro study evaluating the potency and selectivity of commonly used NSAIDs in horses revealed that FLM and

indomethacin were more potent than PBZ and CRP in inhibiting prostacyclin and thromboxane synthesis.[12] Flunixin meglumine and indomethacin appeared to be selective COX-1 inhibitors in the horse whereas PBZ and CRP were non-selective COX inhibitors. Carprofen was the weakest COX-2 inhibitor tested. Preliminary in vitro selectivity assays indicate that etodolac, a potential COX-2 inhibitor, is approximately 5–10-fold selective for COX-2 in horses.[14] However, etodolac was nowhere near as selective as some of the experimental COX-2 inhibitors that have been tested in horses.[13] Etodolac was shown to be as effective as PBZ at reducing LPS-induced synovitis and lameness in horses, and it exhibited relative COX-2 selectivity in that it inhibited PGE_2 but not $TBX\text{-}B_2$.[15]

Pharmacokinetics

Absorption

Peak plasma concentrations and the onset of action for NSAIDs after oral administration vary with the timing of administration with regard to eating. Mean time to peak plasma concentration for PBZ (4.4 mg/kg p.o.) in ponies with access to hay was delayed 6–12 hours, compared with fasted ponies.[16] Phenylbutazone and other NSAIDs appear to bind to hay and other digesta, thus delaying time to peak plasma concentration. Fermentative digestion of roughage in the large intestine releases the bound drug, which possibly contributes to the propensity of NSAIDs to cause ulcerative disease in the large intestine.[9] The time to reach peak plasma concentration and the elimination half-life can be dramatically prolonged by the timing of administration relative to feeding. This has important clinical implications with regard to the therapeutic efficacy of an orally administered NSAID as well as potential problems related to horses in sanctioned competitive events.

There are conflicting data regarding the effects of feeding versus fasting on the absorption of MFA.[6,17] Horses with free access to feed had delayed absorption, decreased maximal plasma concentration and delayed time to peak concentration, compared with fasted horses, administered FLM. Although it may not be practical, NSAIDs should be administered to horses that have not eaten for at least 2 hours before and are withheld from feeding for 2 hours after dosing in order to control absorption, time to peak plasma concentration and elimination half-life.

Metabolism and elimination

Most NSAIDs undergo hepatic metabolism and either renal or biliary excretion. NSAIDs administered to lactating mares are not excreted in milk in concentrations yielding measurable plasma levels in foals. Phenylbutazone undergoes hepatic metabolism to yield oxyphenbutazone, the pharmacologically active metabolite, and γ-hydroxyphenylbutazone, an inactive metabolite. The parent compound and the two metabolites are excreted into the urine and, due to their acidic nature, excretion is more rapid in alkaline than acidic urine.[18,19] Aspirin (acetylsalicylic acid) is rapidly deacetylated to salicylate, the active metabolite of the parent drug. A paucity of data regarding metabolism of MFA exists for horses; it is known that conjugation occurs and between 10% and 14% is excreted in the urine after oral administration.[10] Although little is known regarding the elimination of FLM, it does not accumulate in the body and approximately 14% is excreted in urine.[10]

Naproxen undergoes hepatic metabolism and along with its principal metabolite, 2-(6-hydroxynaphthyl)propionic acid, is excreted in the urine in high concentrations.[20] Ketoprofen is used clinically as a racemic mixture of the R(–) and S(+) enantiomers with half-lives of 1.1 hours and 1.5 hours, respectively, after i.v. administration.[21] Ketoprofen accumulates in inflammatory exudates, resulting in substantially prolonged exudate half-lives of 19.7 hours and 22.6 hours for the R(–) and S(+) enantiomers, respectively. Similar to KTP, CRP is used clinically as a racemic mixture of the R(–) and S(+) enantiomers, each with different potencies and pharmacokinetics. There is evidence that the COX inhibitory and anti-inflammatory effects of carprofen are primarily attributable to the S(+) form. However, recent evidence suggests that the R(–) enantiomer may be equipotent to the S(+) form as an analgesic and in some other activities such as inhibition of β-glucuronidase release.[22,23] Coincident with decreases in plasma concentrations, CRP accumulates in inflammatory exudates, resulting in exudate levels exceeding plasma levels from 2 to 48 hours.[24]

Plasma protein binding

NSAIDs are highly (90–99%) bound to plasma proteins; thus, the free active fraction of these drugs is extremely small.[6] Concurrent administration of another highly protein-bound drug (i.e. chloramphenicol, rifampin, barbiturates) can cause displacement of the NSAID, resulting in an increased free active fraction.[6]

Effect of age on pharmacokinetics

The pharmacokinetics of NSAIDs varies with the age of the horse. The plasma half-life of i.v. PBZ (4.4 mg/kg) was longer for 8–10-year-old adult horses and ponies (5.5 hours) than for 3-year-old ponies (3.9 hours).[16] NSAIDs have substantially different pharmacokinetic profiles in neonatal (< 24 hours of age) foals compared with adult horses. In general, neonates have a reduced ability to eliminate NSAIDs, compared with adult horses, after a single i.v. dose.[25–27] The large volumes of distribution of NSAIDS in neonatal foals may necessitate larger initial doses; however, the relatively long half-lives suggest that the dosing interval should be extended to prevent accumulation of these drugs with resulting potential toxic side effects.

Effect of dose on pharmacokinetics

Unlike most NSAIDs, PBZ can have dose-dependent kinetics, with the half-life increasing from 4 to 8 hours when adminis-

tered at a dose of 10 mg/kg.[28] This effect is likely due to saturation of hepatic enzymes responsible for PBZ metabolism. Taken together, the effect of dose and age on the pharmacokinetics of PBZ emphasizes the need for caution in the dose and dosing interval when administering this drug to older horses, especially those that are systemically ill or dehydrated.

Tissue kinetics

Phenylbutazone, like many NSAIDs, has dramatically different kinetic values for tissue compared with plasma.[6] The acidic nature and high protein binding of NSAIDs causes them to accumulate at sites of inflammation. For example, the plasma half-life for PBZ is between 4 and 8 hours, whereas the half-life in exudates is approximately 24 hours.[8] Ketoprofen accumulates in inflammatory exudates and thus the half-lives of the R(–) and S(+) enantiomers are prolonged from 1.1 hours and 1.5 hours to 19.7 hours and 22.6 hours, respectively.[29] Similarly, CRP accumulates in exudates and yields substantially greater concentrations than in plasma between 2 and 48 hours after administration.[24]

Drug interactions

Concurrent administration of chloramphenicol reduces the clearance and increases the half-life of PBZ, which may accentuate both therapeutic and toxic effects. A single dose (25 mg/kg i.v.) of chloramphenicol prior to PBZ administration resulted in a significant decrease in the elimination rate and this effect was accentuated by additional dosing of chloramphenicol.[30] Rifampin induces hepatic biotransformation processes and has been shown to increase the elimination rate of PBZ in horses.[30]

There are anecdotal reports that when PBZ is administered to horses anesthetized with thiobarbiturates, increased depth and duration of anesthesia may occur due to competitive plasma protein binding.[31,32] A study evaluating administration of PBZ (8.8 mg.kg IV) 9 minutes after thiamylal (11 mg/kg i.v.) demonstrated no effects of PBZ on thiamylal pharmacokinetic parameters or depth or duration of anesthesia.[33] However, there were changes in PBZ pharmacokinetics, including increased serum concentrations and decreased percentage protein-bound PBZ. In another study, administration of PBZ (6.6 mg/kg i.v.) for 4 days prior to thiamylal anesthesia did not

Table 23.1 Recommended dosage regimens for non-steroidal anti-inflammatory drugs in horses†

Drug	Route	Formulation	Dose	Duration	References
Acetylsalicylic acid (aspirin)	PO	Tablets, powder	25–35 mg/kg BID 5–50 mg/kg SID		35 36
Dipyrone	IV, IM	Injectable	5–22 mg/kg 11.1 mg/kg QID		35 10

Etodolac	IV	Injectable	23 mg/kg BID		14

PO = per os, IV = intravenous, IM = intramuscular, SID = once daily, BID = twice daily, TID = three times daily, QID = four times daily, QOD = every other day

† Dosages are based on normal horses; may need to adjust dosages if horses are ill, dehydrated, volume depleted, or if administering NSAIDs in combination. Ponies may require lower dosages.

Modified from Kallings P. Nonsteroidal anti-inflammatory drugs. Vet Clin North Am Equine Pract 1993; 9: 523–541.

have a significant effect on recumbency time.[30] Therefore, it seems unlikely that perianesthetic administration of PBZ would alter the intensity or duration of anesthesia. It also seems unlikely that thiamylal administration would have a clinically important effect on the disposition of PBZ.

A study evaluating the pharmacokinetics of steady-state PBZ and single-bolus gentamicin administered together revealed that gentamicin pharmacokinetics are altered by concomitant PBZ therapy. However, no effect of gentamicin was found on the pharmacokinetics of PBZ.[34] Gentamicin was administered as a 2.2 mg/kg i.v. bolus on the fourth day of once-daily treatment with PBZ (4.4 mg/kg i.v.). Phenylbutazone induced a 49% increase in the rate of gentamicin return to the central compartment from peripheral tissues and the half-life and volume of distribution of gentamicin decreased 23% and 26%, respectively. There were no changes in PBZ pharmacokinetics induced by gentamicin. Because PBZ induces changes in the rate and extent of distribution and elimination of gentamicin, caution should be exercised when using this drug combination in horses.

Dosage regimen

The dose, interval and route of administration for NSAIDs commonly used in horses are given in Table 23.1.[7,10,14,17,24,35–39]

Therapeutic uses

NSAIDs are indicated in horses with inflammatory conditions of the musculoskeletal system including myositis, tendinitis, desmitis, laminitis, osteoarthritis, synovitis/tenosynovitis, osteitis/osteomyelitis, septic arthritis and surgically or traumatically induced injury. They are commonly administered perioperatively to control postoperative pain and fever and prevent excessive edema formation.

Although the mechanism of action is the same, there are apparent differences in the efficacy of different NSAIDs depending upon the type of condition being treated. For example, clinical and experimental data suggest PBZ is more efficacious in providing analgesia for most horses with musculoskeletal disease, whereas FLM is more effective in providing visceral analgesia in horses with colic.[40] These differences in effect may be due to the specificity of certain NSAIDs for different COX isomers or for COX within different tissues. Ketoprofen is reported to be effective in decreasing inflammation and pain associated with musculoskeletal disease and colic.[41–43] Acetylsalicylic acid (aspirin) is rarely used as an anti-inflammatory drug in horses because of its extremely short half-life and low potency. However, it is frequently administered to horses with thromboembolic disorders to decrease platelet aggregation.[10,44] Dipyrone is a potent antipyretic agent, but has only mild analgesic properties.[40] Other currently less commonly used NSAIDs include CRP, MFA and NPX. Newer, more specific COX-2 inhibitors, such as etodolac, are currently being developed and evaluated in horses.[13,15,45,46]

Analgesic effects

NSAIDs appear to mediate their analgesic effect in part by their inhibitory effects on COX, thus preventing or modulating PGE_2 synthesis locally at sites of inflammation.[9] However, because there are several clinically effective NSAIDs that are relatively weak COX inhibitors, anti-inflammatory mechanisms other than inhibition of PG synthesis are believed to be involved. PGE_2 is believed to bind to sensory nerve receptors and promote the discharge of impulses with a consequent increase in pain.[9] Prostaglandin E_2 also sensitizes nerve endings to the effects of numerous physical and chemical stimuli. Overall, PGs amplify peripheral pain by decreasing the nociceptor threshold.[9] Although PGE_2 does not cause pain itself, it can amplify the nociceptive pathway by affecting the pain-inducing properties of other mediators such as histamine and bradykinin.[9] It also seems to affect the body's ability to distinguish between different types of nociceptive stimuli. There is evidence to suggest that PGs are involved in nociceptive pathways within the spinal cord and that NSAIDs have at least some action in inhibiting this cascade. NSAIDs do not exert a direct effect on normal pain perception, but rather reduce hypersensitivity to pain caused by inflammation and this effect is mediated by a reduction in PGE_2. The analgesic effects of NSAIDs apparently can be dissociated from the anti-inflammatory effects and require a lower dose. The analgesic effects of NSAIDs are variable depending upon the source of pain and the specific drug. There are limited controlled clinical trials or experimental studies comparing the analgesic effects of commonly used NSAIDs in horses with musculoskeletal disease.

A study evaluating the analgesic effects of PBZ, FLM and CRP administered at the end of surgery, prior to anesthetic recovery, demonstrated that there were no differences in the pain scores or number of horses requiring additional analgesia among the three groups of horses.[47] In horses requiring additional analgesia after surgery, there was a significant difference in the time after surgery between the groups receiving FLM and PBZ. Horses treated with FLM required additional drug 12.8 ± 4.3 hours after surgery whereas those given PBZ required it at 8.4 ± 4.6 hours after surgery. Horses treated with CRP were intermediate in requiring additional drug 11.7 ± 6.9 hours after surgery. A study evaluating and comparing the inhibition of peripheral pain by FLM and CRP in horses demonstrated that there was no demonstrable analgesic effect for either drug when tested using an external skin stimulation test for nociception.[48] However, when the heating element model of nociception was used, a 1.1 mg/kg i.v. dose of FLM failed to inhibit peripheral pain whereas a dose of 0.7 mg/kg i.v. of CRP inhibited the peripheral pain response for approximately 24 hours.[48]

In another study evaluating the analgesic effects of PBZ in horses after arthroscopic surgery, no difference was shown between PBZ-treated and placebo-treated horses regarding plasma β-endorphin or catecholamine concentrations.[49] However, horses treated with PBZ had a lower total postoperative pain severity index, which suggests that perioperative treatment with PBZ did exert some analgesic effects.[49]

Pretreatment of horses with PBZ prior to carrageenan-induced synovitis was more effective in reducing lameness, joint temperature, synovial fluid volume and synovial fluid PGE_2 concentrations than pretreatment with KTP.[50] Additionally, KTP administered at the PBZ equimolar dose (3.63 mg/kg) to horses with chronic laminitis reduced chronic hoof pain and lameness to a greater extent that did 2.2 mg/kg PBZ. This effect was still present 24 hours after drug administration.[51] Therefore, it was recommended that a dosage rate of 1.65 times the recommended therapeutic dose is more potent than PBZ in alleviating chronic hoof pain and lameness in horses.

In a study of experimentally induced carpitis in horses, the effects of eltenac reached a plateau at a dose of 0.5 mg/kg, but its effects were not different from those of FLM administered at a dose of 1.1 mg/kg.[39] Both drugs at these doses caused a reduction of carpal circumference, joint hyperthermia and carpal pain and increased carpal flexion angle and stride length, demonstrating their analgesic, antipyretic and anti-inflammatory effects.

Anti-inflammatory and chondroprotective effects

Inflammation can lead to pain and edema formation. Inhibition of PG synthesis perioperatively can reduce the inflammatory response secondary to surgery or the primary disease, thus decreasing pain and edema. NSAIDs are commonly administered perioperatively to horses for these reasons. For example, PBZ is often administered for several days after arthroscopic surgery in horses with synovitis secondary to osteochondral chip fractures or osteochondrosis in order to decrease synovitis arising from primary joint disease and from the surgery.

Prostaglandins of the E-series seem to be involved with increased metabolic activity in cartilage, whereas those of the F-series are chondroprotective.[9] Prostaglandin E_2 is responsible for the majority of bone resorption associated with osteomyelitis.[9] NSAIDs are therefore useful in acute synovitis and osteomyelitis to decrease PG-mediated synthesis of destructive enzymes and reduce cartilage degradation and bone resorption. However, prolonged administration can accelerate cartilage degeneration. In general, NSAIDs have a suppressive effect on proteoglycan synthesis.[52] In vivo and in vitro studies have investigated the chondroprotective and potentially deleterious effects of NSAIDs, often with contradictory and confusing results. Additionally, the clinical relevance of these effects is not fully known. NSAIDs appear to have a varying ability to inhibit catabolic events in cartilage matrix with several noted differences in their inhibitory effects on the activity of degradative enzymes. Some of the potential beneficial effects of NSAIDs may not result from direct inhibition of these degradative enzymes, but rather suppression of other inflammatory mediators involved in cartilage degeneration.

A study evaluating the effects of orally administered PBZ to horses on proteoglycan synthesis and chrondrocyte inhibition of IL-1β in articular cartilage explants revealed that administration for 14 days caused a significant decrease in proteoglycan synthesis.[53] The investigators concluded that PBZ should be used judiciously in athletic horses with osteoarthritis because prolonged administration could suppress proteoglycan synthesis and potentiate cartilage damage.

Both the R and S enantiomers and the racemic mixture of CRP attenuated the increased IL-6 production induced by LPS in equine synoviocytes whereas the S enantiomer had a similar effect on chondrocytes.[54] Neither enantiomer of the racemic mixture suppressed the LPS-induced IL-1 production in synoviocytes or chondrocytes.

A study evaluating the effect of FLM, tolfenamic acid and both the R and S enantiomers of KTP on the response of equine synoviocytes to LPS demonstrated that all four compounds inhibited β-glucuronidase in a concentration-dependent manner, with tolfenamic acid being the most potent.[55] Tolfenamic acid and FLM caused an increased production of IL-6 induced by LPS, but only at their highest concentration (1000 μmol/L). Flunixin, tolfenamic acid and the S enantiomer of KTP caused a significant and concentration-dependent increase in IL-1 release. All four drugs caused a marked, concentration-dependent inhibition of PGE_2 synthesis. These findings suggest that by removing the regulator role of PGE_2 on IL-1 synthesis, the long-term use of NSAIDs in horses with arthropathies could potentially enhance cartilage degeneration. In another study evaluating the effect of commonly used NSAIDs on LPS-stimulated equine synovial membrane explants, it was demonstrated that PBZ, FLM, KTP and CRP suppressed PGE_2 production without causing a detrimental effect on viability of function as measured by hyaluronan synthesis.[56]

Administration of PBZ (4.4 mg/kg p.o. every 12 hours) for 30 days caused a significant decrease in mineral apposition rate in the tibia and appeared to decrease the healing rate of unicortical defects in horses.[57]

Antipyretic effects

Cytokines such as TNF, IL-1 and IL-6 increase in response to LPS and other inflammatory stimuli and result in the increased production of PGE_2 in the hypothalamus. The net effect of this hypothalamic increase in PGE_2 is to reset the body's thermal set point at a higher temperature, resulting in fever. NSAIDs inhibit endogenous PGE_2, which raises the threshold level of the thermoregulatory center in the hypothalamus[9], thereby preventing or limiting the febrile response. Different NSAIDs seem to have varying antipyretic effects; empirically, dipyrone seems to be the most effective antipyretic in horses. The antipyretic effects of NSAIDs are observed with doses that inhibit PG synthesis, which is usually much lower than those needed for anti-inflammatory effects.

Antiendotoxic effects

NSAIDs are effective in inhibiting endotoxin-induced prostanoid release and thus are used to pretreat horses

predisposed to develop endotoxemia or to treat horses with suspected endotoxemia to prevent endotoxic shock. Some horses with infectious conditions of the musculoskeletal system such as septic arthritis/tenosynovitis, septic cellulitis, myositis and other potential infectious conditions involving Gram-negative bacteria are predisposed to the adverse effects of endotoxemia. Flunixin meglumine reportedly is more effective in ameliorating the cardiovascular effects of endotoxin, whereas PBZ is more selective in blocking the inhibitory effect of endotoxin on gastrointestinal motility.[58] Pretreatment with FLM (0.25 mg/kg i.v.) decreases the synthesis of TBX-B_2 and 6-ketoprostaglandin $F_{1\alpha}$, the stable metabolites of TBX-A_2 and prostacyclin respectively, and improves hemodynamic status in experimentally induced endotoxemia in equids. Flunixin meglumine prevents endotoxin-mediated pregnancy loss in mares during the first 60 days of gestation only if administered in the early stages of endotoxemia (often before clinical signs are present).[59]

Hemostatic and antithrombotic effects

Aspirin and other NSAIDs are sometimes used in horses for treatment or prophylaxis of diseases with a thromboembolic component, including thrombophlebitis, laminitis, navicular disease, intestinal ischemia and non-strangulating infarction. Aspirin is recommended because of its irreversible inhibition of platelet COX leading to inhibition of TBX-A_2 synthesis, which is a proaggregatory and vasoconstrictor substance released during blood clotting.[9,10] A single oral dose of aspirin (20 mg/kg) prolongs bleeding time and decreases platelet adhesiveness in horses.[60] Aspirin (19 mg/kg) causes complete blockade of serum TBX-B_2 synthesis for 7 days; 74% inhibition remains at 24 days.[44] This indicates that aspirin causes complete, irreversible inhibition of platelet COX and this action probably extends to megakaryocytes in the bone marrow.[44] In vitro studies of equine platelets demonstrate that FLM, PBZ and NPX also have potent antiaggregatory properties.[61] Flunixin meglumine and PBZ cause reversible inhibition of platelet COX, with serum TBX-B_2 concentrations returning to normal within 48 hours.[44] Because microthrombi and platelet–platelet or platelet–neutrophil aggregates have been shown to form during laminitis,[62] some clinicians administer aspirin to horses as a preventive or therapeutic agent; however, the efficacy of this treatment is unknown.

Laminitis

Horses with acute gastrointestinal tract disease, other infectious or inflammatory diseases and horses with severe lameness are predisposed to the development of laminitis. Therefore, NSAIDs are often considered crucial in horses for the prevention and/or treatment of laminitis. Providing analgesia disrupts the pain–vasoconstriction cycle induced by the release of catecholamines and other vasoconstrictive substances. This may help attenuate the decreased digital blood flow and laminar perfusion characteristic of the early stages of acute laminitis. Phenylbutazone is believed by many to be more effective in reducing pain associated with laminitis; however, FLM, MFA and KTP are also effective.[9,10,41] Aspirin may also be useful in decreasing platelet aggregation in the laminar microvasculature, which should improve laminar blood flow. A PBZ equimolar dose of KTP (3.63 mg/kg), which is 1.65 times the recommended therapeutic dose, was more potent than PBZ in alleviating chronic hoof pain and lameness.[41] Whether or not the commonly used NSAIDs are effective in reducing the inflammatory cascade involved in laminitis or whether they simply provide analgesia by inhibiting PGE_2 synthesis is currently unknown. Regardless, they are a vitally important component of the medical management of acute laminitis.

Clinical applications

Clinical and experimental evidence suggests that PBZ be used at 4.4 mg/kg once daily or 2.2 mg/kg once to twice daily for its analgesic and anti-inflammatory properties in musculoskeletal disease.[6] Additionally, clinical experience suggests PBZ also exerts anti-inflammatory effects in reducing surgical wound edema; however, this has not been demonstrated experimentally. Clinically, dipyrone is not a very effective analgesic for musculoskeletal pain and is usually administered i.v. in horses principally for its antipyretic effects. Aspirin is a poor analgesic, but its irreversible effect on platelets at low doses makes it potentially useful for horses with laminitis and navicular disease. Meclofenamic acid is apparently most useful for treatment of chronic musculoskeletal pain. In a clinical trial, MFA was shown to improve lameness in 78% of horses with navicular disease, 76% with chronic laminitis and 61% with osteoarthritis.[63] Another clinical trial comparing 7-day treatment regimens of MFA (2.2 mg/kg) to PBZ (4.4 mg/kg) in horses with navicular disease and osteoarthritis demonstrated that 60% of those treated with MFA responded favorably compared with 36% treated with PBZ.[10]

Flunixin meglumine is effective and useful in the treatment of lameness in horses, but because of its high cost in comparison to PBZ, it is usually not the first NSAID administered. In one clinical trial of horses with various musculoskeletal diseases, FLM alleviated clinical signs in 74%.[64] Naproxen is somewhat unique in the relative closeness of the doses required for its analgesic and anti-inflammatory effects. When administered at a dose of 4–8 g/day for 7 days, NPX markedly improved lameness and stride length in horses with experimentally induced myositis.[65] Naproxen was also reported to be particularly effective in the treatment of inflammatory swelling and lameness.[66] Clinically, 90% of horses with myositis treated with NPX responded favorably within 5 days. Ketoprofen has been shown to decrease synovial fluid PGE_2 concentrations, joint effusion and lameness in a carrageenan-induced synovitis model in horses.[51] Some veterinarians prefer KTP to FLM or PBZ in the treatment of musculoskeletal inflammation and pain in foals due to its decreased propensity for gastrointestinal ulceration. Carprofen has been shown to decrease inflammatory exudate

PGE_2 levels for up to 8 hours and ex vivo TBX-B_2 generation for 15 hours after a single i.v. dose.[24] Additionally, it reduced the swelling in an experimental model of soft tissue inflammation in the necks of ponies. Carprofen has also been shown to alleviate cutaneous pain caused by application of a heating element for 24 hours and was equally effective to PBZ and FLM for postoperative analgesia.[47] Ketoprofen and CRP are particularly effective in decreasing inflammation-associated edema and joint effusion in horses.[10,51]

Combination NSAID therapy

Because all NSAIDs have a similar mechanism of action, it is believed that there is no apparent benefit of administering NSAIDs in combination. However, combination NSAID therapy is becoming increasingly common. Although it is true that all NSAIDs inhibit COX, it is currently unknown if there is greater affinity of NSAIDs for COX in certain tissues. Likewise, it is assumed that there is a differential affinity of the COX isoforms by the same NSAID. Thus, because NSAIDs have a similar mechanism of action, combination therapy can increase the potential for toxicity. Therefore, it is important to adjust the dose of each NSAID if administered in combination and it is imperative to maintain hydration in order to reduce the potential for toxicity.

Combination NSAID therapy may be useful perioperatively in certain horses. For example, those with ischemic bowel requiring intestinal resection and anastomosis are predisposed to the development of endotoxemia, postoperative ileus, laminitis and thrombophlebitis. Flunixin meglumine appears to be superior in blocking the effects of endotoxin on hemodynamic variables and decreasing eicosanoid synthesis.[67–71]

Phenylbutazone is anecdotally reported to be more effective in controlling pain in horses with laminitis and has been shown to be more selective in decreasing the inhibitory effects of endotoxin on intestinal motility.[58] Aspirin, often administered for its antithrombotic effects, may help prevent or reduce laminitis, thrombophlebitis and intestinal adhesion formation. Concurrent administration of FLM (1.1 mg/kg i.v.) and PBZ (2.2 mg/kg i.v.) does not alter the disposition or clearance of either drug; therefore, it should not result in increased concentrations of either drug.[72] However, concurrent administration of FLM and PBZ prolongs the pharmacologic effect (TBX-B_2 suppression) and may increase the potential for toxicity.[72] Experimental or controlled clinical studies are necessary to evaluate the therapeutic efficacy and toxicity of combination NSAID regimens before they can be recommended.

Adverse effects of NSAIDs

Inhibition of the COX pathway accounts not only for the therapeutic effects of NSAIDs, but also for the potential toxic effects. Gastrointestinal ulceration and renal papillary necrosis associated with NSAIDs are believed to occur secondary to decreased PGE_2 synthesis, which is important in maintaining mucosal blood flow and other cytoprotective effects and renal medullary blood flow. There may be breed, age and idiosyncratic differences in the susceptibility to NSAID toxicity. For example, ponies are reportedly more susceptible than horses to the toxic effects of PBZ[73] and young animals are also believed to be especially sensitive to the adverse effects of NSAIDs.[74–77] Horses that are aged, systemically ill and/or dehydrated also appear to be predisposed to the toxic effects of NSAIDs. The toxic potential of the three most commonly used NSAIDs in horses was greatest for PBZ, less for FLM and least for KTP.[7] Naproxen did not cause clinically apparent toxicity in horses at three times the recommended dose.[20] Although data are scarce, MFA and CRP seem to have minimal toxic effects when used at the recommended dosing regimen.[6,38] Therefore, veterinarians should use caution when selecting and administering NSAIDs to young, aged, systemically ill or dehydrated animals because of a greater susceptibility to the toxic side effects.

Gastrointestinal tract ulceration

Administration of NSAIDs in excessive doses, for prolonged periods or in the presence of dehydration or volume depletion can lead to a number of serious side effects. Gastrointestinal ulceration (gastric glandular and small and large intestinal mucosa) is a relatively common side effect of NSAID administration in horses. Additionally, horses administered NSAIDs (especially PBZ orally) can develop ulcerations of the oral mucosa as a result of a local irritant effect, which could account for the effects observed on the cecal and large colon mucosa of horses treated with orally administered PBZ. Phenylbutazone binds to hay, which delays its absorption. Once the hay reaches the large intestine (cecum and colon), PBZ is released after digestion and fermentation, resulting in relatively high concentrations that could have a local irritant effect on the cecal and colonic mucosa. However, this local irritant effect cannot account for all of the toxic effects since similar lesions are noted in horses with parenterally administered NSAIDs.

The ulcerogenic effects of NSAIDs are believed to result from an NSAID-mediated decrease in mucosal PGE_2, leading to vasoconstriction, hypoxia and necrosis. Prostaglandins are normally cytoprotective in the gastrointestinal tract. Prostaglandin E_2 and PGI_2 decrease the volume, acidity and pepsin content of gastric secretions and also stimulate bicarbonate secretion by epithelial cells, produce mucosal vasodilation, increase mucus production and stimulate turnover and repair of gastrointestinal epithelial cells.[78] NSAIDs disrupt these normal cytoprotective effects in the gastric mucosal barrier and contribute to the development of gastric glandular mucosal ulceration. Gastrointestinal ulceration is often accompanied by secondary anemia, hypoproteinemia and hypoalbuminemia owing to blood and plasma protein loss. Additionally, horses with NSAID toxicity often demonstrate neutropenia, which has been suggested to be due to suppression of granulopoiesis in the bone marrow. However, this effect is most likely secondary to intestinal inflammation, disruption of the mucosal barrier and subsequent absorption of endotoxin into the circulation.

In recent studies, PBZ did not decrease gastric or intestinal mucosal PG concentrations in horses 48 hours after

administration.[79] There is evidence to suggest that PBZ causes direct injury to the intestinal microvasculature.[79] Juvenile horses are especially predisposed to the ulcerative effects of these drugs on the gastric mucosa, while adult horses are more commonly affected with right dorsal colon ulceration, resulting in abdominal pain, diarrhea and a protein-losing enteropathy.[7] Most reported cases of ulcerative colitis have been in adult horses administered PBZ but other NSAIDs can contribute to the development of this disease. The relative ulcerogenic effect of three commonly used NSAIDs in clinically normal adult horses is PBZ > FLM > KTP.[7]

Non-selective COX-1 inhibitors or those with combined COX-1 and COX-2 inhibitory effects delay the recovery of ischemic-injured intestinal mucosa.[45] This finding demonstrates that constitutively synthesized PGs are important for mucosal recovery. Etodolac, a potential COX-2 inhibitor in horses, partially inhibited PG synthesis, but had no effect on recovery of ischemic-injured equine jejunal mucosa in vitro, which is in contrast to FLM, which almost fully inhibited PGs and inhibited mucosal recovery.[45] Etodolac behaved similar to a COX-2 inhibitor in that it partially inhibited PGE_2 and PGI_2, but had no effect on TBX-B_2, a COX-1 metabolite.[45]

Renal toxicity

Papillary necrosis is the major nephrotoxic effect of NSAIDs observed in horses but tubular nephritis can also occur. Renal synthesis of PGs occurs primarily in the medulla.[80] Conditions resulting in renal vasoconstriction (dehydration, volume depletion, shock) induce PG synthesis and secondary compensatory vasodilation.[80] Under normal circumstances, vasodilatory PGs play a minor role in maintaining renal blood flow and controlling renal function. However, during certain pathophysiological conditions, vasodilatory PG synthesis is required to maintain adequate renal perfusion and function. Renal medullary ischemia is considered the initiating factor in the development of renal papillary necrosis. This occurs when horses are administered NSAIDs either in excessive doses, for prolonged periods, or concomitant with dehydration or volume depletion.[74,75,81] Without concurrent dehydration, PBZ does not reportedly result in renal papillary necrosis.[75] However, concurrent administration of NSAIDs and aminoglycoside antibiotics can also potentiate the risk of nephrotoxicity.[10] If possible, horses that are dehydrated or volume depleted should have their fluid volume normalized prior to beginning NSAID therapy.

Hemostatic effects

Although NSAIDs impair platelet adhesion and can either lead to or exacerbate bleeding tendencies owing to their inhibition of platelet TBX-B_2 synthesis, these are not frequently observed complications in horses.[40]

Decreased wound healing

Administration of NSAIDs has been reported to contribute to an increased incidence of abdominal incisional complications in horses.[82] Although NSAIDs reportedly have no clinically significant effect on wound healing, their use in horses has been reported to contribute to the development of abdominal incisional complications.[82] Experimentally, the administration of FLM (1.1 mg/kg i.v. b.i.d) for 7 days caused decreased strength in skin, linea alba and small intestinal enterotomy wounds at 7 days in ponies.[83] Another retrospective study reported no association between the administration of NSAIDs and the development of abdominal incisional complications.[84] Clinically, the use of NSAIDs does not appear to affect wound healing.

Thrombophlebitis

Perivascular injection of PBZ causes intense phlebitis and tissue necrosis. Administration of excessive doses of PBZ has been demonstrated to cause degeneration and dilation of the walls of small veins and microvascular phlebitis, which may contribute to some of the toxic effects on the intestinal mucosa and kidney.[79] Fifty percent of horses administered PBZ develop pulmonary vascular thrombosis observable at necropsy.[85] The clinical significance of these changes is unknown.

Corticosteroid therapy

Corticosteroids are administered systemically and locally for their anti-inflammatory properties in horses. These drugs are often administered either parenterally or orally for their systemic anti-inflammatory effects or locally within joints for local anti-inflammatory effects. Despite the potential untoward effects on articular cartilage, corticosteroids are commonly administered intra-articularly in horses with non-septic joint disease because of their potent anti-inflammatory properties. Intra-articular injection of corticosteroids into inflamed joints depresses the initial inflammatory events, including capillary dilation, leukocyte margination and migration, inflammatory cell accumulation, enzyme and inflammatory mediator liberation and cytokine, prostaglandin and thromboxane synthesis.[86]

Classification and mechanism of action

Glucocorticoids are produced synthetically and are often classified according to their onset and duration of action, and route of administration.[87] Corticosteroids commonly administered parenterally in horses with rapid onset (< 1 min) and short duration ($t_{1/2}$ = 1–2 h) include prednisolone sodium succinate (Solu-Delta-CORTEF, Upjohn), methylprednisolone acetate (Depo-Medrol, Upjohn) and methylprednisolone sodium succinate (Solu-Medrol, Upjohn). Those corticosteroids with rapid onset (5–45 min) and intermediate duration ($t_{1/2}$ = 3–4 h) include dexamethasone sodium phosphate or dexamethasone in propylene glycol (Azium SP and Azium, Schering). Corticosteroids with slow onset and long duration

include triamcinolone acetonide (Vetalog, Solvay), methylprenisolone acetate (Depo-Medrol), and flumethasone (Flucort, Syntex). Parenteral formulations of corticosteroids with rapid onset are usually used in emergency situations such as anaphylaxis and circulatory shock, whereas those with slow onset and long duration are used for synovitis, arthritis or intralesional therapy. Orally administered corticosteroid formulations are categorized as rapid onset and short duration (prednisone tablets); rapid onset and short-to-intermediate duration (triamcinolone tablets or powder); and slow onset and long duration (dexamethasone tablets or powder).[87] These formulations are usually used for subacute to chronic inflammatory or allergic conditions.

Corticosteroids are 21-carbon molecules that contain three 6-carbon rings and a 5-carbon ring.[88] Pharmacological activity depends upon the presence of a hydroxyl group at the C-11 location. The corticosteroids available for intra-articular use are 11β-hydroxyl compounds that do not require biotransformation and are generally ester salts prepared as suspensions. The duration of effect appears to be inversely correlated with the water solubility of the corticosteroid and the rate of absorption. Triamcinolone is the most insoluble and has the longest duration of action. Other factors believed to determine the duration of action of intra-articular corticosteroids include the rate of hydrolysis of the drug by enzyme in the synovial cavity as well as the binding affinity of the steroid for the steroid receptors in the target cells of the joint.[88]

The local effect of a corticosteroid in the joint is dependent on the rate of hydrolysis within the joint. Methylprednisolone acetate (MPA) is considered a long-acting ester when given i.m. because of the slow rate of absorption from the site of injection with subsequent hydrolysis in the plasma. However, when injected into a joint, it is rapidly hydrolyzed to the active drug (methylprednisolone, MP) with high local synovial fluid concentrations detectable within 2 hours post injection.[89,90] Measurable concentrations of MP were detectable for 5–39 days, whereas MPA was detectable for only 2–6 days post injection. Although MPA was not detectable systemically after intra-articular injection, it was detectable in the synovial fluid for 24 hours. This resulted in depression of endogenous hydrocortisone for 3–4 days, but the adrenal gland remained responsive to corticotrophin.[89]

The biologic potency or activity of corticosteroids is dependent upon many factors, including the total dose administered, the duration of action, duration and frequency of treatment, rate of conversion to biologically active metabolites, crystal size of the suspension and numerous other cell and tissue variables.[88] Corticosteroids exert their effect on cells by binding to plasma membrane and steroid-specific cytosolic receptors of steroid-responsive tissues.[87,91] The corticosteroids apparently passively diffuse into the cytosol of steroid-responsive tissues and bind to cytosolic receptors, which leads to a change in the allosteric nature of the receptor–steroid complex. The activated cytosolic receptors are then translocated to the nucleus where they bind to the steroid response element on nuclear DNA. This results in modulation of gene transcription and mRNA coding for specific proteins that ultimately causes the hormonal effect. Glucocorticoids exert their anti-inflammatory effects via stimulating production of lipocortin, which inhibits the activity of plasma membrane-bound phospholipase A_2 (PLA_2) and thereby inhibits release of arachidonic acid and indirectly the de novo synthesis of inflammatory mediators including PGs, TBXs, LTs and platelet-activating factor. The onset of action at the cellular level is likely immediate, but completion of the necessary steps in this cascade likely takes from a few to several hours, which delays the biologic effect.

Corticosteroids exert their local anti-inflammatory effects by:

- stabilizing lysosomal membranes and the concomitant release of lysosomal enzymes
- decreasing vascular permeability
- inhibiting leukocyte adherence to microvascular endothelium and subsequent diapedesis
- suppressing leukocyte superoxide synthesis
- inhibiting platelet aggregation
- inhibiting PG synthesis by inhibiting the release of arachidonic acid from membrane phospholipids
- reducing inflammatory effects of the healing process that result in fibrosis.[91]

Glucocorticoid receptors have been identified in neutrophils, lymphocytes and eosinophils. Corticosteroids typically have greater effects on cellular rather than humoral processes and on movement rather than function of leukocytes.[88] One of the predominant mechanisms of their anti-inflammatory properties is their inhibitory effect on the migration of neutrophils and macrophages into sites of inflammation. When administered systemically, corticosteroids cause a neutrophilic leukocytosis owing to a prolonged half-life, increased bone marrow synthesis of neutrophils, decreased margination and subsequent egress into sites of inflammation. Corticosteroids also have been shown to exert a dose-dependent effect on neutrophil function but this occurs to a lesser degree than the effect on leukocyte movement. Higher doses inhibit the release of lysosomal enzymes from neutrophils and neutrophilic phagocytosis is similarly suppressed. Poor correlation has been reported between neutrophil numbers and PGE_2 concentrations in synovial fluid after corticosteroid treatment of chronic inflammatory joint disease in people, which suggests a likely alternative source of prostaglandins and/or differential effects of these drugs on cellular function.[92]

Pharmacokinetics

Clearance

Corticosteroid suspensions generally have a relatively short intra-articular half-life. Considerable variation has been reported for the clearance of corticosteroid suspensions from the synovial cavity after intra-articular administration. Triamcinolone acetate has a reported synovial fluid half-life ranging from 1 to 5 days.[93] The median synovial fluid half-life of MPA and MP in the tarsocrural joint space of normal

horses as detected with high-performance liquid chromatography was 10.3 and 10.4 hours, respectively.[94] Another study has demonstrated that MPA can liberate its active principle in the synovial cavity for up to 1 month after intra-articular injection.[89]

Therapeutic uses

Joint disease

Although there is appreciable information in the literature regarding the untoward effects of intra-articular corticosteroid therapy, much of this has been shown more recently to be overgeneralization; there appear to be distinct differences in the effect of steroids on articular cartilage and synovial membrane depending upon the type and dose used. Intra-articular injection of corticosteroids remains a useful treatment for traumatic, degenerative and non-septic joint disease in the horse. Steroids effectively suppress the pain, heat and swelling associated with inflammatory joint disease and thus are effective in treating synovitis and arthritis. Aseptic technique is essential to prevent joint infection.[91]

Several drug formulations are approved for intra-articular administration, such as triamcinolone acetonide (TMA), isoflupredone acetate, betamethasone acetate (BMA), MPA and flumethasone.[87]

Experimental and clinical effects of intra-articular corticosteroids

Numerous in vivo and in vitro experimental and clinical investigations have reported on the therapeutic and deleterious effects of intra-articular corticosteroids in horses.

Methylprednisolone

Intra-articular injection of MPA into the joints of normal horses has shown some regressive effects on articular cartilage.[95,96] However, questions remain regarding the minimal effective dose and the effect this would have in arthritis/synovitis and the effect in joints of exercised horses.

Injection of 100 mg of MPA into the middle carpal joint of horses with experimentally induced osteochondral fragmentation of the distal radial carpal bone did not reduce lameness, but did cause a decrease in synovial fluid PGE_2 concentrations and lowered scores for synovial membrane intimal hyperplasia and vascularity, when compared with polyionic fluid-treated joints.[97] These potential beneficial effects must be weighed against the detrimental findings of articular cartilage erosion and morphologic lesions associated with MPA treatment. The deleterious effects of MPA in this model are in contrast to the favorable effects of TMA on clinical lameness, synovial fluid, synovial membrane and articular cartilage morphologic and biochemical parameters in the same model.[98]

A study of acute synovitis of the radiocarpal and middle carpal joints induced by four injections of lipopolysaccharide (0.5 ng) at 2-day intervals in ponies demonstrated that intra-articular injection of MPA (0.1 mg/kg) concomitant with the last dose of LPS 2 days before euthanasia had substantial effects on proteoglycan, protein and collagen synthesis in harvested cartilage explants.[99] Methylprednisolone alone caused a decrease in proteoglycan synthesis and increased protein and collagen synthesis in cartilage explants. Synovial membrane protein synthesis was also increased by MPA. However, there were no differences in protein or proteoglycan synthesis in explants from horses with synovitis whether or not they were treated with MPA. Acute synovitis appeared to prevent changes induced by intra-articular MPA alone. The effects of intra-articular MPA are different in inflamed versus normal joints.

A study evaluating the effects of LPS-induced acute synovitis and the effects of MPA on transcription of cartilage matrix proteins in ponies demonstrated that articular chondrocytes increase type II procollagen and aggrecan synthesis in response to synovitis and that MPA alters chondrocyte function in both inflamed and normal joints.[100]

In another study, synovial fluid samples were collected weekly from the radiocarpal joints of normal horses and MPA (60 mg) was injected into the radiocarpal joints at 2-week intervals, beginning on week 3, to quantify synovial fluid volume and keratan sulfate, cartilage aggrecan, C-propeptide and cartilage type II procollagen.[101] Synovial fluid volume was significantly reduced by MPA at weeks 4, 6, 7 and 8 but had returned to pretreatment values by week 9, which corresponded to 2 weeks after the last injection of MPA. It is known that corticosteroids suppress synovial membrane hyaluronic acid synthesis in vitro and this may contribute to the reduction in synovial fluid volume in normal joints. Keratan sulfate and cartilage aggrecan were significantly increased in the synovial fluid of joints treated with MPA, when compared with non-treated controls. C-propeptide was significantly decreased in synovial fluid of MPA-treated joints. These results suggest that repeated use of intra-articular MPA leads to potentially deleterious inhibition of procollagen II synthesis and increased release of degradation products of proteoglycan aggrecan from articular cartilage. This study also demonstrated that MPA did not influence articular cartilage aggrecan metabolism in the contralateral joint, which is in contrast to remote-site effects of TMA on articular cartilage GAG content.[98]

In an in vitro study, equine articular cartilage explants were treated with methylprednisolone sodium succinate (MPS) at various concentrations ranging from 0.001 to 10 mg/mL for one day and then in fresh medium without MPS.[102] Proteoglycan synthesis was severely depressed by 10 mg/mL MPS for 24 hours in normal cartilage. Cartilage treated with 5 mg/mL had pyknotic chondrocyte nuclei and empty lacunae. MPS concentrations of 1.0 and 0.1 mg/mL depressed proteoglycan synthesis in normal cartilage but concentrations recovered within 2 days after MPS removal from the medium. Concentrations of MPS of 0.01 and 0.001 mg/mL did not have a significant effect on proteoglycan synthesis in normal cartilage explants. MPS concentrations of 1.0 and 0.1 mg/mL alleviated articular cartilage

degradation in explants cultured in monocyte-conditioned medium, which suggests that it is possible to identify an intra-articular concentration of corticosteroid that will protect articular cartilage from cytokine-induced matrix degradation, but will not have a prolonged or permanent deleterious effect on chondrocyte matrix synthesis.

Equine chondrocytes cultured in monolayer were stimulated with IL-1β and cultured either with or without dexamethasone or MPA.[103] The stimulatory effect of IL-1β on matrix metalloproteinase (MMP) 13 (collagenase 3) gene expression in articular chondrocytes was decreased by dexamethasone, and reduced in a dose-dependent manner by MPA. These in vitro results parallel in vivo studies in other species and indicate that in vivo use of corticosteroids reduces the rate of progression of experimentally induced osteoarthritis.[104–106] In another study, the effects of MPA, BMA and dexamethasone in inhibiting equine MMP-2 and MMP-9 were assessed using gelatinase and casein degradation assays.[107] Betamethasone had no effect on MMP-2 or -9. Dexamethasone and MPA had no effect on MMP-9, but MMP-2 was significantly inhibited at the highest dose tested for dexamethasone (1 mg/mL) and the higher concentrations of MPA (1.2 and 5 mg/mL). Corticosteroids affect MMP levels in disease by preventing synthesis at the transcriptional level, which has been documented in the horse.[108]

Articular cartilage explants and chondrocyte monolayer cultures obtained from young adult horses were cultured to determine the effect of differing concentrations of MPA on chondrocyte function and viability in vitro.[109] Steady-state levels of type II procollagen mRNA decreased without concomitant decreases in type I procollagen expression as the concentration of MPA in the culture medium increased from 1×10^1 to 1×10^8 pg/mL. Cytotoxicity occurred as MPA concentrations increased to 1×10^8 and 1×10^9 pg/ml. The cartilage-specific fibronectin was suppressed in normal and inflamed joints with a single intra-articular injection of 0.1 mg/kg MPA. Collectively, this study demonstrates that MPA suppresses matrix protein markers of chondrocyte differentiation. The investigators speculate that a decreased and altered expression of matrix proteins in chondrocytes likely contributes to corticosteroid-induced cartilage degradation.[109]

An in vitro study evaluating the effect of MPA on proteoglycan and collagen metabolism in cartilage explants from normal equine joints revealed several important findings.[110] Proteoglycans were not lost to the media in response to MPA treatment over a 72-hour period, but there was a decrease in the size of some aggrecan monomers as well as the proteoglycan aggregate. The lowest doses of MPA stimulated protein synthesis and there was a trend for a similar pattern for proteoglycan and collagen synthesis. A protective effect of MPA against proteoglycan degradation in the explants was observed with higher doses (0.04–4.0 mg/mL) as demonstrated by reduced GAG being released into the media. The investigators speculate that MPA may affect post-translational modification of the core protein with the addition of smaller and fewer GAG chains.[110]

Methylprednisolone acetate reduced proteoglycan loss in cartilage explant cultures from the middle carpal joint of horses but this effect was not seen at clinically relevant concentrations.[111] MPA caused a dose-dependent inhibition of proteoglycan synthesis at all concentrations tested but chondrocyte viability was deleteriously affected only at the 2000 μg/mL dose. These results suggest that the therapeutic effect of MPA is not restricted to the anti-inflammatory effects on soft tissues of the joint.

Betamethasone

Horses were administered either 2.5 mL of betamethasone (3.9 mg betamethasone sodium phosphate and 12 mg betamethasone acetate per mL) or an equivalent volume of saline intra-articularly 14 and 35 days after experimentally induced osteochondral fragmentation of the distal radial carpal bone.[112] Some horses were exercised on a high-speed treadmill and others were kept in a box stall, and all horses were evaluated serially and then euthanized 56 days after fragmentation. The BMA did not cause any histologic, histochemical or biochemical evidence of articular cartilage alterations in horses with or without exercise.[112] The exercised horses also had comparable glycosaminoglycan concentrations as the saline-treated control joints. Therefore, the intra-articular injection of BMA in the middle carpal joint did not cause any consistently observable detrimental effects in exercised or non-exercised horses.

Triamcinolone

Recent work has suggested that intra-articular TMA (12 mg) may exert chondroprotective effects in the horse with experimentally induced osteochondral fragmentation.[98] Horses treated with TMA were less lame than horses with osteochondral fragments treated with polyionic fluids and horses without osteochondral fragments injected with polyionic fluids. Joints treated with TMA had less synovial membrane inflammatory cell infiltrate, intimal hyperplasia and subintimal fibrosis. Additionally, TMA-treated joints had better articular cartilage morphologic scores and increased hyaluronic acid concentrations. These findings support a chondroprotective effect of TMA with no observable detrimental effects. Despite previous reports of non-detectable corticosteroid levels in the contralateral joint of horses,[94] there was an observable beneficial remote-site effect in the non-treated joints of these horses. This remote-site effect of TMA in joints contralateral to the treated joints suggests a possible treatment effect perhaps unrelated to detectable levels of the drug and involving a mechanism of action that may not be pharmacologically mediated.[98]

In another report of the effects of intra-articular TMA (12 mg) on subchondral bone in horses with experimentally induced osteochondral fragmentation of the distal radial carpal bone, it was demonstrated that treated horses were significantly less lame than non-treated ones.[113] Additionally, there were no observable detrimental effects of TMA on any parameter measured, indicating there were no deleterious effects on the dynamics of bone remodeling and fragility in horses with experimentally induced osteochondral

fragmentation of the middle carpal joint.[113] However, the investigators mentioned their concern that the treated horses, which were less lame, did not have increased subchondral bone formation as expected from their improved weight bearing and increased loading. They speculate that TMA might have caused a slight reduction in the normal subchondral bone remodeling response.[113]

Dosage regimen

The formulation and dose of corticosteroid suspensions commonly used for intra-articular administration in horses is given in Table 23.2.

Adverse effects of intra-articular corticosteroids

Administration of corticosteroids into joints can have both therapeutic and detrimental effects.[91] The detrimental effects include decreased cartilage elasticity and glycosaminoglycan content with progressive cartilage degeneration; formation of calcium deposits on the surface of hyaline cartilage; cartilage thinning and fissure formation; and decreased synovial fluid viscosity and hyaluronic acid content. The predominant adverse effects include 'steroid arthropathy', postinjection flare, septic arthritis and osseous metaplasia.[91] These deleterious effects have been shown to be both drug and dose dependent.

Because of the intense reduction in inflammation and associated pain caused by intra-articular injection of corticosteroids, there is some concern that horses may overuse an injured, 'pain-free' joint, thus accelerating joint degeneration. This concern has been substantiated by at least some studies showing that corticosteroids can have deleterious effects on chondrocyte metabolism. However, the beneficial effects on reducing inflammation and the associated degradative mediators released from inflammatory cells versus the potential direct deleterious effects must be weighed when considering the use of corticosteroids in an inflamed joint. At high concentrations, corticosteroids inhibit proteoglycan synthesis and have a negative influence on the structure of collagen in the articular cartilage.[95,114] However, there is debate over the clinical importance of decreased proteoglycan content, particularly when lower doses of steroids are used. More recently, BMA or TMA injected into the joints of horses with experimentally induced cartilaginous lesions followed by exercise on a treadmill did not cause any exacerbation of cartilage damage beyond that observed in control animals.[112,113] Therefore, it appears that worsening of cartilaginous damage in horses undergoing strenuous exercise may not be as much of a concern as has been reported previously. This is particularly true when using lower doses of corticosteroids, particularly TMA and BMA.

Corticosteroids can lead to steroid arthropathy by delaying fracture healing and reducing synovial inflammation and associated pain, which enables the horse to continue strenuous exercise, thereby exacerbating the degenerative joint disease.[91] Steroid arthropathy is characterized by an accelerated rate of joint damage, radiographic evidence of severe degenerative joint disease, joint enlargement owing to capsular distension and osteophytic new bone growth, decreased range of motion and crepitation. This condition usually occurs following intra-articular injection of corticosteroids into joints with pre-existing cartilage damage or those not rested appropriately after injection. Recommended doses of corticosteroids injected into a normal joint may not lead to corticosteroid-induced arthropathy, even with strenuous exercise. However, injured joints should be allowed to rest following corticosteroid injection in order to allow the hyaluronic acid content to return to normal levels. Despite the fact that hyaluronic acid content increases with prolonged corticosteroid use, the catabolic effect on cartilage matrix increases the vulnerability of cartilage to traumatic injury. Corticosteroids administered at higher doses or at more frequent intervals than recommended can lead or contribute to steroid arthropathy.

Table 23.2 Corticosteroid suspensions for intra-articular use in horses

Corticosteroid suspension	Trade name	Concentration (mg/mL)	Dose (mg)	Potency relative to hydrocortisone	Relative duration of action
Betamethasone	Celestone soluspan	6*	3–18	30	Medium–Long
Flumethasone	Flucort	0.5	1.25–2.5	120	Short–Medium
Isoflupredone 'acetate'	Predef 2X	2	5–20	50	Short–Medium
Methylprednisolone 'acetate'	Depo-Medrol	40	40–120	5	Long
Triamcinolone 'acetonide'	Vetalog	6	6–18	5	Medium

* Each mL contains 3 mg betamethasone acetate and 3 mg betamethasone sodium phosphate.

Modified from Caron JP. Principles of treatment of joint disease. In: Auer DE, Stick JA, eds. Equine surgery, 2nd edn. Philadelphia, PA: Saunders; 1999: 678–696.

Injection of some corticosteroids can lead to a non-septic inflammatory response ('steroid flare') characterized by heat, swelling and pain.[91] This inflammatory response can begin as early as a few hours following injection and may last from a few hours up to several days. The reaction is believed to be in response to the microcrystalline suspension of the corticosteroid ester, and occurs in approximately 2% of injected joints.[91]

Septic arthritis can occur subsequent to any intra-articular injection secondary to inadvertent contamination of the joint during arthrocentesis.[91] Because corticosteroids suppress the local immune response in the joint following intra-articular injection, the environment is conducive for infection to develop.

Inadvertent deposition of long-acting corticosteroids in periarticular soft tissues can cause idiopathic metaplastic bone formation.[91] This condition does not occur with short-acting steroids, which suggests a reaction to the vehicle in the long-acting formulations. The ossification may take several months to develop and mechanical interference can occur if the lesions become sufficiently large.

Systemic effects of intra-articularly administered corticosteroids

Once intra-articularly administered corticosteroids are absorbed from the synovial cavity they undergo hepatic biotransformation and renal excretion.[88] Corticosteroids administered intra-articularly are absorbed and can have systemic effects, which has been shown by suppression of the endogenous cortisone levels.[89] Serum concentrations of TMA after injection of 6 mg into three joints of horses peaked 4 hours post injection and became undetectable by 48 hours post injection.[115] Only extremely small concentrations of isoflupredone became measurable in serum 24 hours post injection of 4 mg despite concentrations of both drugs remaining detectable in the synovial fluid of treated joints for up to 10 days after injection.[94] Neither drug was detected in the synovial fluid of the contralateral joint despite detectable quantities in serum. Concentrations of the parent drug or metabolites of both MPA and isoflupredone were detected in urine for 24 and 72 hours, respectively. The study demonstrates the rapid elimination of these two corticosteroid preparations from the synovial fluid and serum of horses.

Sodium hyaluronate

Mechanism of action

Hyaluronate (HA) is endogenously synthesized by synoviocytes and chondrocytes. The viscoelasticity of the synovial fluid and the boundary lubrication function of the synovial membrane are directly proportional to the concentration and polymerization of the hyaluronate synthesized and present within the joint.[116–119] HA incorporated into the extracellular matrix of articular cartilage forms the nucleus for proteoglycan aggregates within the equine joint.[120] Exogenous hyaluronate is thought to supplement the actions of depleted or depolymerized endogenous hyaluronate and modulate the increased synthesis of endogenous hyaluronate.[121–130] The half-life of intra-articular HA injected into the normal equine joint is estimated to be 96 hours.[131] The half-life of intra-articular HA injected into the arthritic joints of sheep decreased from 20.8 hours to 11.5 hours.[132] The short half-life suggests that a majority of the exogenous hyaluronate is rapidly cleared from the joint and that a portion remains within the joint associated with the synovial tissues, influencing the metabolic activity of these cells.[131–133]

The anti-inflammatory effects of exogenous hyaluronate have been demonstrated in numerous in vitro studies. These effects include inhibition of macrophage and granulocyte chemotaxis, inhibition of lymphocyte migration, and reduction of granulocyte and macrophage phagocytosis.[132,134–142] HA is thought to interact with the CD44 cell receptor of neutrophils in inhibiting neutrophil-mediated degradation and PGE_2 production; this interaction is concentration and molecular weight dependent.[143] HA has an indirect effect upon articular cartilage mediated through the HA-binding domain of the proteoglycan molecule at the chondrocyte cell surface.[144] High concentrations of intra-articular HA bind the domain and suppress IL-1β and TNF-α induced proteoglycan degradation, thus reducing inflammation and inhibiting cartilage degeneration and early osteoarthritis.[145–148] Although HA has been shown to have no effect on the healing of intracartilaginous and osteochondral joint lesions, a study using partially meniscectomized rabbit stifles demonstrated the ability of high molecular weight HA to inhibit cartilage degeneration and early osteoarthritis in the femoral condyle and tibial plateau of the treated joints.[145,149] Despite research results, clinical reports and anecdotal success, the exact mechanisms by which HA exerts its beneficial effect upon diseased joints remain speculative.

Indications for use

The concentration of synovial fluid HA within normal equine joints does not differ significantly from the concentrations measured in joints affected with acute synovitis or acute and chronic arthritis; however, joints affected by septic arthritis or with radiographic evidence of osteoarthritis had significantly lower concentrations than normal controls.[150,151] The use of HA for the treatment of joint disease in the horse was first reported in 1970.[128] Since that time, clinical reports have supported the use of HA for the treatment of equine joint disease. However, a majority of the evaluations are subjective, the criteria for successful treatment are absent, the duration of post-treatment observation is highly variable and the specific diagnosis for the condition being treated is lacking.[122,124,126,130,131,136,137,152–155] A recent more objective report, utilizing a bilateral osteochondral fracture model created with an arthrotomy, concluded that intra-articular HA had a protective effect on the articular cartilage and resulted in reduced lameness. However, both treated and non-treated limbs returned to preoperative weight-bearing

values.[129,153] In a double-blind study using intra-articular hylan, an HA derivative, gait analysis found no beneficial effect in the treatment of acute amphotericin-induced synovitis.[154]

The most recent investigation evaluated the effect of intravenous HA on carpal joints in exercising horses after arthroscopic surgery and osteochondral fragmentation. The investigators concluded that intravenous HA appears to alleviate signs of lameness by interacting with synoviocytes, and by decreasing the production and release of inflammatory mediators. Treated horses had lower lameness scores, significantly better synovial membrane histologic scores and significantly lower concentrations of total protein and PGE_2 within the synovial fluid when compared to placebo-treated horses. No significant effects were noted for glycosaminoglycan content, synthetic rate or morphologic score in articular cartilage or other synovial fluid measurements.[155]

Hyaluronic acid has been shown to improve tendon healing with naturally occurring tendinitis and was proposed to have prevented scar formation along the damaged tendon tissue.[156] In an experimental study of collagenase-induced tendinitis, peritendinous injections of HA improved tendon healing in areas not associated with a tendon sheath.[157] Intrathecal injections of HA improved tendon healing as measured by ultrasound, increased the HA content of tendon sheath synovial fluid and reduced the number of adhesions formed between the tendon and sheath. Histologically, the HA reduced inflammatory cell infiltrate, improved tendon structure and minimized intratendinous hemorrhage.[158] Another study of collagenase-induced tendinitis examined the effect of subcutaneous peritendinous HA upon lameness, ultrasonographic healing, biochemical indices, biomechanical strength and inflammation.[159] The study did not reveal significant benefits of HA treatment outside the synovial sheath on tendon repair in collagenase-induced tendinitis.[159]

Effective dose

Early in vitro work demonstrated that HA at a molecular weight greater than 5×10^2 kDa stimulated the synthesis of HA in a concentration-dependent manner, and that hyaluronate preparations with a molecular weight below 5×10^2 kDa had little or no effect except at high concentrations when HA synthesis was depressed.[160] Therefore in vitro, the effect of molecular weight has been clearly demonstrated, but the correlation between molecular weight and clinical effect remains less clearly defined. A comparative study, utilizing five sodium hyaluronate products for the treatment of traumatic arthritis, found that horses treated with HA of a molecular weight greater than 2×10^3 kDa were sound significantly longer than those treated with HA with a molecular weight less than 2×10^3 kDa.[161] A study utilizing 77 trotters with moderate to severe joint injuries investigated the comparative effect of HA, polysulfated glycosaminoglycan and a placebo in a double-blind, randomized design. No difference was detected between treatment groups with regard to prevalence or cumulative incidence of soundness; however, the treatment groups did have reduced lameness scores and significantly better results than the placebo.[162] To add to the controversy, another blinded study looked at the clinical effect of HA in the treatment of 69 Thoroughbreds with carpitis and found no therapeutic response or clinically significant difference between HA with molecular weights of 0.13×10^3 kDa and 2.88×10^3 kDa.[163] The molecular weight and manufacturers' dosage recommendations for the currently available HA formulations are given in Tables 23.3 and 23.4, respectively.

The HA formulations currently available for intravenous injection are Legend® (Bayer) in the United States and Hyonate® (Bayer) elsewhere. The manufacturer recommends that Legend® 40 mg sodium hyaluronate (4 mL) be administered i.v. once weekly for a total of three treatments.

Drug interactions

Hyaluronate is frequently combined with corticosteroids for intra-articular treatment of degenerative joint disease in horses. Retrospective studies have shown that intra-articular administration of corticosteroids may suppress effective microbial killing, reducing the immune status within the joints of horses and increasing the potential for low numbers of bacteria to establish an infection within the injected joint.[164–167] A prospective study, utilizing intra-articular HA in carpal joints inoculated with *Staphylococcus aureus*, showed no difference in the development of sepsis between HA-injected joints and controls.[168] Therefore, the potential for septic arthritis and the incidence of 'synovial flare' may be increased for combination drug therapy utilizing corticosteroids.[169]

Toxicity

No contraindications to HA use are noted on the label and acute toxicological studies performed in horses demonstrate no evidence for systemic toxicity secondary to acute and chronic overdose.[170] Intra-articular and intravenous HA at one, three and five times the recommended dose were admin-

Table 23.3 The average molecular weight of currently available sodium hyaluronate formulations for intra-articular use

Trade name	Manufacturer	Average molecular weight in daltons (Da)
Hyalovet	Fort Dodge	$4.0–7.0 \times 10^5$
Hyvisc	Boehringer Ingelheim	2.1×10^6
Synacid	Shering-Plough	$0.15–0.20 \times 10^6$
Hylartin V	Pharmacia & Upjohn	3.5×10^6
HY-50	Bexco Pharma	Not available
Equron	Solvay Animal Health	$1.5–2.0 \times 10^6$
Equiflex	Chesapeake Biological	1×10^6
Legend	Bayer Corporation	3×10^5

Table 23.4 Manufacturers' recommendations for intra-articular use of sodium hyaluronate in horses

Trade name	Concentration	Packaging	Recommended dose
Hyalovet	10 mg/mL	2 mL syringe	20 mg hyaluronate sodium (2 mL) should be administered aseptically in small or medium-sized joints not more than twice weekly for a period not to exceed 4 weeks.
Hyvisc	10 mg/mL	2 mL syringe	22 mg hyaluronate sodium (2 mL) should be administered aseptically in small and medium-sized joints and a double dose or 44 mg hyaluronate sodium (4 mL) once weekly for a total of three treatments.
Synacid	10 mg/mL	5 mL vial	50 mg of hyaluronate sodium (5 mL) should be given intra-articularly in carpal and fetlock joints. Synacid should be injected under strict aseptic conditions and effusion should be removed prior to injection.
Hylartin V	10 mg/mL	2 mL syringe	20 mg sodium hyaluronate (2 mL) should be administered aseptically in small and medium-sized joints and a double dose or 40 mg hyaluronate sodium (4 mL) once weekly for a total of three treatments.
HY-50	17 mg/mL	3 mL syringe	Not available.
Equron	5 mg/mL	2 mL syringe	The dose of Equron in small and medium-sized joints (fetlock, carpal) is 2 mL (10 mg) administered intra-articularly. In larger joints (hock), the dose is 4 mL (20 mg). Depending on the clinical response and medical judgment of the veterinarian, the treatment may be repeated weekly for a total of four treatments. Strict aseptic measures should be taken to prepare the site for injection and during the intra-articular administration of Equron. Care should be used while injecting to avoid scratching the cartilage surfaces. Such trauma can result in diffuse, transient swelling lasting 24–48 hours, but will have no detrimental effect on the ultimate clinical response. For best results, the horse should be given 2 days of stall rest before gradually resuming normal physical activity.
Equiflex	5 mg/mL	5 mL vial	Not available.
Legend	10 mg/mL	2 mL vial	20 mg sodium hyaluronate (2 mL) should be administered aseptically in small and medium-sized joints once weekly for a total of three treatments.

Note: Sterile preparation of the injection site accompanied by the use of a single-dose preparation with the addition of a water-soluble antibiotic is standard practice.

istered at weekly intervals for a total of 9 weeks. Clinical, hematologic and clinical chemistry parameters remained unchanged. Transient slight to mild postinjection swelling of the joint capsule occurred in horses treated with HA, as well as with the saline control. Neither gross nor histological lesions were noted in either the soft tissues or the articular cartilage of the treated and control joints.[170] The safety of using HA in breeding animals has not been established and manufacturers caution against its use in these animals.[171]

Polysulfated glycosaminoglycans

Mechanism of action

Polysulfated glycosaminoglycans (PSGAGs) are highly sulfated polysaccharides derived from the extract of bovine lung and trachea. The principal glycosaminoglycan present in PSGAGs is chondroitin sulfate. PSGAGs are known to inhibit many of the enzymes associated with osteoarthritis and connective tissue degradation. In vitro studies have shown that PSGAGs are capable of inhibiting lysosomal elastase, cathepsins G and B, lysosomal hydrolases, keratin sulfate glycoanhydrolase, serine proteases, neutral metalloproteinase (e.g., proteoglycanase, stromelysin, gelatinase and collagenase), β-glucuronidase, α-glucosidase, β-N-acetylglucosaminidase and hyaluronidase.[132,172–175] In addition, PSGAGs have been reported to inhibit prostaglandin E synthesis, influx of leukocytes into inflammatory sites and the production of superoxide radicals and interleukin-1 and to have a dose-related effect on fibroblast and tenocyte metabolism resulting in increased production of collagen, non-collagen proteins and sulfated glycosaminoglycans.[132,176]

PSGAG has been shown to have a greater affinity for proteoglycans and non-collagenous proteins than for collagen.[173] Fibronectin, which is increased in osteoarthritic cartilage, forms complexes with collagen, which are then stabilized by PSGAG.[173] PSGAGs exert their chondroprotective effect by reducing proteoglycan breakdown, stimulating HA synthesis and enhancing the production of glycosaminoglycan, proteoglycan (glucosamine) and colla-

gen (proline).[176–179] In vitro studies on equine cartilage indicate that PSGAG increases collagen and glycosaminoglycan synthesis, and inhibits glycosaminoglycan and collagen degeneration in normal and osteoarthritic articular cartilage explants and cell cultures.[180] However, in vitro work using smaller PSGAG dosages found a dose-dependent inhibition of proteoglycan synthesis, minimal effect on proteoglycan degradation, no effect on proteoglycan monomer size and no change in monomer aggregation.[181,182] Thus the exact mechanism by which PSGAG exerts its effect remains unclear.

Indications for use

PSGAG is believed to have chondroprotective properties, which make its use preferable when cartilage damage is present in addition to acute synovitis. PSGAGs have been classified as disease-modifying osteoarthritis drugs in that therapy is meant to prevent, retard or reverse the morphologic cartilaginous lesions associated with osteoarthritis.[183]

In vivo work utilizing chemically and physically induced models of intercarpal joint osteoarthritis of horses demonstrated less articular fibrillation and erosion, less chondrocyte death, markedly improved safarin-O staining, but no change in the partial- or full-thickness articular cartilage lesions.[184,185] Investigators concluded, first, that intra-articular PSGAG (250 mg every 7 days for five treatments) could markedly decrease the development of osteoarthritis, but was of no benefit in healing cartilage lesions present at the time of initial therapy, and second, that intramuscular PSGAG (500 mg every 4 days for seven treatments) had an insignificant effect upon physical cartilage defects and only a limited effect upon chemically induced osteoarthritis as evidenced by a slight degree of improvement in safarin-O staining.[184,185] Another study investigated the effect of PSGAG, with or without exercise, on the repair of articular cartilage defects and on the development of osteoarthritis in the carpi of ponies. Investigators concluded that PSGAG was effective in ameliorating clinical, radiographic and scintigraphic signs associated with joint disease, but that repair tissue was more fibrous in the PSGAG-treated joints and the synovium of the PSGAG-exercised joints had a greater degree of cellular infiltration.[186,187]

Negative charges conferred by sulfate groups cause PSGAG to bind to connective tissues.[172,173,175] In rabbits, radioactively labeled PSGAG is distributed to knee joint articular cartilage, patellar cartilage, meniscus and intervertebral disk tissue following intramuscular administration.[172–175] The widespread distribution of PSGAG to connective tissue has proven useful in the treatment of tendinitis. In rabbits with collagenase-induced tendinitis, treatment with PSGAG resulted in diminished loss of tendon mechanical properties, an increased number of large-diameter collagen fibrils, improved organization of repair tissue at the cellular level and suppression of inflammation.[188] In horses with collagenase-induced tendinitis, those treated with PSGAG had earlier sonographic development of echogenic patterns, a more rapid decrease in core defect size and less severe lameness, compared with a control group of untreated horses.[189]

Effective dose

The PSGAGs are most commonly administered by the intramuscular route. Previous work investigating the distribution of radiolabeled PSGAG after intramuscular administration found PSGAG concentrations within the synovial fluid and joint tissues of the carpus consistent with other non-equine studies. No significant difference was found between carpi containing osteochondral fragments and the control joints, suggesting that distribution is not influenced by inflammatory changes. Investigators concluded that intramuscular therapy (500 mg every 4 days) was effective in maintaining anti-inflammatory levels in the joints.[172] Another study, using intramuscular radiolabeled PSGAG in rabbits, demonstrated PSGAG within the superficial digital flexor tendon at concentrations shown to inhibit inflammatory mediators in vitro.[190] Investigators used the label dose for the horse, and concluded that PSGAG may be useful in the treatment of acute tendinitis.[190]

The PSGAG formulations currently available for intra-articular and intramuscular use are Adequan I.A.® (Luitpold) and Adequan I.M.® (Luitpold), respectively. Manufacturers recommend that Adequan I.A.® (250 mg, 1 mL) be injected aseptically into the affected joint once a week for 5 weeks and that Adequan I.M.® (500 mg, 5 mL) be injected aseptically into the muscles of the neck every 4 days for 28 days or seven treatments. The initial treatment with Adequan I.M.® at manufacturer's recommended dose and frequency is often followed with one intramuscular dose every 30 days while the horse is in training. Sterile preparation of the injection site accompanied by the use of a single-dose preparation with the addition of 125 mg of amikacin sulfate (Amiglyde-V®, Fort Dodge) is standard practice for intra-articular administration of Adequan I.A.®.[191]

Drug interaction

PSGAG is frequently combined with corticosteroids for intra-articular treatment of degenerative joint disease in horses. Retrospective studies have shown that intra-articular administration of corticosteroids may suppress effective microbial killing, reducing the immune status within the joints of horses and increasing the potential for low numbers of bacteria to establish an infection within the injected joint.[164–167] A prospective study, utilizing intra-articular PSGAG in carpal joints inoculated with *Staphylococcus aureus*, demonstrated significant increase in the potential for sepsis between PSGAG-injected joints and controls.[168] Previous in vitro work has shown PSGAG-mediated inhibition of the equine complement activity. Inhibition of the complement cascade within the joint may increase the potential for subinfective doses of bacteria to colonize the synovium, resulting in sepsis.[192] Therefore, the potential for septic arthritis and the incidence of 'synovial flare' may be increased with the use of

intra-articular PSGAG alone or in combination with corticosteroids.[193]

There is some concern regarding the potential anticoagulant effect of PSGAG. PSGAG is classified as a heparin analog and has been known to cause local hematomas and heparin-associated thrombocytopenia in humans.[194] Although it has been suggested that PSGAG not be used in conjunction with other NSAIDs or other anticoagulants, there have been no reports of hemarthrosis, thrombocytopenia or coagulopathies in horses despite its widespread use both alone and in combination with NSAID administration.[195]

Toxicity

Toxicology studies were conducted in horses: doses as high as 1250 mg were administered intracarpally to six horses once a week for 18 weeks. This dosage is five times the recommended dosage and 3.6 times the recommended therapeutic regimen. Clinical observations revealed mild, self-limiting swelling and soreness at the injection site in 1.8% of the horses. Dose-related increases in partial thromboplastin time, creatinine and glucose were noted. Toxicological doses as high as 2500 mg were administered intramuscularly to six horses twice a week for 12 weeks. This dosage is five times the recommended dosage and three times the recommended therapeutic regimen. None of the animals in this study showed any adverse effect on clinical, hematologic or clinical chemistry parameters.[193] Studies have not been performed to establish reproductive safety in horses and manufacturers caution against its use in breeding animals.

Chondroitin sulfate

Mechanism of action

Chondroitin sulfate (CS) is the predominant glycosaminoglycan found in adult articular cartilage. CS is similar to polysulfated glycosaminoglycan (PSGAG) in that both contain repeating chains of galactosamine and glucuronic acid disaccharide units, but CS contains only one sulfate group per disaccharide unit compared with the three or four sulfate groups per disaccharide unit for PSGAG.[196] The presence of sulfate groups is critical to the pharmacology and pharmacokinetic activity of both PSGAG and CS.[196] Chondroitin sulfate has been classified as a slow-acting, disease-modifying agent (SADMA) and as a slow-acting drug in osteoarthritis (SADOA).[197–199] It has been shown to inhibit degradative enzymes such as leukocyte elastase and N-acetylglycosaminidase in vitro. However, it must be noted that these inhibitory activities refer to intact polymeric CS molecules and the efficacy of unsulfated monomeric forms and other degradation products is unknown and untested.[200,201]

Chondroitin sulfate marketed for use as a dietary supplement in horses is usually in combination with glucosamine with or without added vitamins and minerals. The bioavailability of oral CS remains speculative and scientific literature provides conflicting results. Absorption of radiolabeled CS has been reported for man, dogs and rats; however, less than 15% of the molecules were absorbed as high molecular weight fractions. Investigators concluded that a majority of the CS was absorbed only after degradation to smaller molecular weight products and the loss of the sulfate group.[202–205] The absence of absorption of oral CS has been reported for several studies in humans and rabbits in which a dimethylene blue assay was unable to detect the presence of smaller sulfated glycosaminoglycan molecules.[205,206]

Large intestinal bacteria utilize CS directly as an energy source while bacterial sulfatases remove the active sulfate groups from the disaccharide units, thus allowing radio-active inorganic sulfate to be present in the body after oral administration of $^{35}SO_4$-labeled CS.[207] This has led some researchers to conclude that CS is not absorbed following oral administration, but rather a low molecular weight desulfated degradation product of the disaccharide polymer is absorbed instead. However, absorption of CS and dermatan sulfate from the gastrointestinal tract has been reported in humans. Treated patients had reduced N-acetylglycosaminidase and granulocyte activity, as well as an increase in HA concentrations.[203] Skeptics would conclude that the existence of a polymer chain and the presence of sulfate groups are necessary for the biologic activity of CS; therefore any positive clinical response to oral administration of CS is secondary to the biologic activity of its low molecular weight degradation products or from the activity of other substances present in the supplement, such as glucosamine.[208]

Indications for use

Several studies report positive responses to oral CS therapy for the management of osteoarthritis in the human knee.[209–214] One human study utilizing oral treatment with *Perna canaliculus* extract for a period of 6 months reported that 19 of the 28 rheumatoid and 15 of the 38 osteoarthritis patients felt that they benefited from the oral therapy.[213] Positive results associated with oral CS therapy have been reported for a rabbit model of osteoarthritis, as well as for a chemically induced canine synovitis model. Dogs with chemically induced synovitis pretreated with CS combined with glucosamine had reduced soft tissue and bone-phase scintigraphic activity as well as reduced lameness scores. However, treatment after the induction of synovitis (without pretreatment) showed no beneficial effects.[215]

Effective dose

A plethora of choices exists regarding oral supplement for the treatment and prevention of joint disease in the horse. Each brand contains varying concentrations of CS with or without glucosamine as key ingredients. These ingredients are then combined with a variety of vitamins, minerals and frequently a 'secret' compound. The supplements are usually recommended as daily top dressing for feed and manufacturers provide a measuring device specific to their product. Because

these products are classified as dietary supplements and neutraceuticals, the efficacy, safety and quality assurance programs put forth by the United States Food and Drug Administration do not apply.

Recommendations regarding effective dose, long-term toxicity, drug interaction and teratogenicity are anecdotal or based on manufacturers' claims.[200,203,205,216–218] One product, Cosequin®, has been clinically and scientifically evaluated. One trial consisted of 25 clinical cases of horses with joint pain treated with oral Cosequin® for a period of 6 weeks.[219] In this study, lameness, response to flexion and stride length improved with Cosequin therapy but there were no controls. In another study utilizing the Freund's complete adjuvant model of inflammatory joint disease, 12 horses were treated with oral Cosequin® for a total of 36 days.[220] Therapy began 10 days prior to induction of arthritis and continued for 26 days afterward. No benefit was observed for lameness, stride length, carpal circumference or response to carpal flexion and synovial fluid protein concentration did not improve.[220] Due to the widespread use and popularity of these products, controlled studies and scientific validation are needed to address the controversy regarding enteral absorption, pharmacokinetics, toxicity, drug interaction and clinical efficacy.

Glucosamine

Mechanism of action

Chondrocytes manufacture glucosamine from glucose as a precursor for the glycosaminoglycan units found within articular cartilage.[221,222] Glucosamine has been classified as a slow-acting, disease-modifying agent, a slow-acting drug in osteoarthritis and as a chondroprotective. When available, glucosamine becomes the preferred substrate over glucose for chondrocyte synthesis of glycosaminoglycans.

Glucosamine is a small, water-soluble molecule that is absorbed from the small intestine and across biological barriers in the body.[223,224] It undergoes gastric dissociation to yield non-ionized glucosamine.[223,224] Glucosamine hydrochloride yields greater quantities of the active non-ionized form of glucosamine than glucosamine sulfate. It is the non-ionized form of glucosamine that directly determines the bioavailability of the glucosamine compounds.[223,224] Labeling with [^{14}C] in rats and the use of specific ion exchange chromatography in dogs and humans have demonstrated almost complete bio-availability with only 5% fecal loss.[223]

In vitro work has shown a dose-dependent increase in the synthesis of hyaluronic acid, glycosaminoglycan and proteoglycan in response to exogenous glucosamine.[222,224] Exogenous glucosamine inhibits superoxide radical generation, lysosomal enzyme production, nitric oxide production, proteoglycan loss, gelatinase activity and collagenase activity in equine cartilage explants exposed to lipopolysaccharide and recombinant interleukin-1β.[225,226] The anti-inflammatory activity of glucosamine is achieved through a prostaglandin-independent mechanism, which is thought to contribute to cartilage preservation as well as provide protection against metabolic impairment induced by NSAIDs.[223,227,228]

In vivo studies have demonstrated uniform incorporation of [^{14}C]-labeled glucosamine into newly synthesized proteoglycans located within articular cartilage.[229,230] The anti-inflammatory effect of glucosamine does not influence or interfere with PG synthesis in rat and dog models and has been shown to improve experimentally induced morphological damage to articular cartilage.[229–231] In rats, glucosamine counteracts metabolic and morphologic chondrocyte damage produced by intra-articular dexamethasone.[232] A study using human subjects affected with osteoarthritis looked at cartilage biopsies taken before and after 4 weeks of treatment with either oral glucosamine sulfate or placebo. Glucosamine therapy correlated with reduced use of joint pain analgesics and improved joint function. Electron microscopy performed on biopsy samples taken before treatment confirmed the presence of chronic osteoarthritis. Electron microscopy performed on biopsy samples taken after 4 weeks of treatment demonstrated evidence for an increase in cartilage matrix production and a mild decrease in inflammatory activity, giving the affected cartilage an appearance more similar to healthy cartilage.[218,232]

Indications for use

Oral supplements, such as glucosamine, were initially developed as an alternative to the practical and financial limitations associated with intra-articular and intramuscular HA and PSGAG. Oral glucosamine administration has been associated with decreased pain and an increased range of motion when compared with placebo in a well-controlled clinical trial in people with osteoarthritis of the knee.[218] Oral glucosamine has been shown to alleviate the symptoms of chronic arthritis with daily dosing over a 6–8-week period.[233] The first of two double-blind studies comparing ibuprofen to oral glucosamine in humans with unilateral osteoarthritis of the knee showed a faster reduction in pain and swelling for ibuprofen during the first 2 weeks, but the difference was found to favor glucosamine at week 8 of therapy.[234] The second study reported a similar difference in response at 2 weeks, but from 3 weeks onwards there was no significant difference in response between ibuprofen and glucosamine, with the exception of a significantly lower incidence of adverse side effects for glucosamine than ibuprofen.[217] Glucosamine proved superior to PBZ in the management of back pain and to a placebo in the treatment of spinal osteoarthritis.[235,236] Researchers investigating combination therapy in humans concluded that the use of oral glucosamine significantly decreased the effective dose of NSAIDs needed to control chronic pain.[237]

Effective dose

Two forms of glucosamine are available for oral administration: glucosamine hydrochloride and glucosamine sulfate. Both disassociate within the stomach, but the hydrochloride

salt yields a greater amount of the active, non-ionized glucosamine, which has direct bio-availability. The oral products currently available for horses are numerous and seem to be increasing on a monthly basis. Unfortunately, there is a dearth of clinical and scientific studies in horses. Information regarding efficacy and dosage for oral glucosamine is anecdotal or based on manufacturers' claims. Given the consistency demonstrated for absorption, distribution and elimination studies in humans, rats and dogs, the assumption is that a similar effective dose rate of at least 10 g per day is necessary to treat a 500 kg horse.[208]

Toxicity

Oral glucosamine is a neutraceutical and as such is not regulated by the United States Food and Drug Administration for purity, efficacy or safety. As a result, safety trials have not been performed prior to these products being released onto the market. To date, investigations into long-term use, placebo controlled, and retrospective evaluation of combination therapy with other medicaments have failed to demonstrate toxicity or adverse effects different from placebo controls associated with the use of oral glucosamine in man.[223,224,236,238,239]

Dimethyl sulfoxide

Mechanism of action

Dimethyl sulfoxide (DMSO), a byproduct of the lumber industry, was originally used as an industrial solvent. DMSO was first employed as a therapeutic agent in the treatment of interstitial cystitis and arthritis during the early 1960s.[240] Since that time, it has been widely used within the equine industry either alone or mixed with corticosteroids to reduce soft tissue swelling, inflammation and edema secondary to acute trauma.[241,242]

The pharmacologic effects of DMSO and its metabolite, dimethyl sulfide, are diverse. DMSO has been shown to possess superoxide dismutase activity. As a result, it can inactivate superoxide radicals, inhibit hydroxyl radical-mediated depolymerization of hyaluronan and suppress PG synthesis by oxygen-derived free radicals.[240,242–245] DMSO is believed to possess analgesic properties secondary to the inhibition of prostaglandins E_2, $F_{2\alpha}$, H_2 and G_2. The analgesic effect of DMSO has been compared to that produced by narcotic analgesics and been found to be efficacious for both acute and chronic musculoskeletal pain.[246]

In addition to its anti-inflammatory effects, DMSO possesses the ability to rapidly and easily penetrate the skin. It serves as a carrier to enhance the penetration of various agents through the skin into underlying synovial, connective and interstitial tissues.[242,246,247] DMSO has been shown to enhance the penetration of percutaneous steroids three-fold and the ability of cortisone to locally stabilize lysosomes 100-fold.[242] In addition, DMSO increases the local antiarthritic effect of hydrocortisone 10-fold when used as a carrier.[248]

DMSO has an antiarthritic effect independent of its ability to promote corticosteroid absorption.[249] Topical application of the gel formulation of DMSO decreased the mean synovial white blood cell concentrations in an equine synovitis model.[250] DMSO has been shown to help resolve tissue inflammation through increased blood flow and promotion of vascular dilation.[242] It causes collagen dissolution, which may help to restore pliability to fibrosed tissues.[242] Topical application of DMSO solution, in rabbits, reduced ankle stiffness in a fracture model of arthritis.[251] Both the anti-inflammatory and antiarthritic effects of DMSO appear to be more effective when used to treat acute versus chronic inflammatory conditions.[246]

Both DMSO and dimethyl sulfide are extensively and rapidly distributed to all areas of the body after oral, intravenous and topical administration.[246] The half-life of the parent compound and its metabolite is 9 hours.[246] DMSO is primary excreted through the kidney, but secondary elimination through the respiratory tract and bile does occur.[246]

Indications for use

DMSO has been used intra-articularly for its anti-inflammatory and free radical scavenging properties in the management of equine inflammatory joint disease.[245,247,252–254] Several equine studies reporting the use of DMSO in intra-articular lavage solutions have shown a decrease in total synovial leukocyte counts and a decrease in synovial inflammatory response in DMSO-treated joints without evidence of gross, histological or histochemical cartilage degradation.[255–257] Juvenile bovine articular cartilage explants repeatedly exposed to a 10% DMSO solution showed a significant time-dependent decrease in the rate of proteoglycan synthesis after 3 or more hours of exposure. Histologically, chondrocyte viability and cartilage matrix water content were decreased.[258] A recent study, evaluating the effect of DMSO on equine articular cartilage metabolism in an explant culture environment, examined proteoglycan synthesis and degradation, lactate metabolism (general indicator of cellular metabolism) and chondrocyte viability after exposure to various concentrations of DMSO for predetermined time intervals.[259] Proteoglycan and lactate metabolism were inhibited in a dose- and time-dependent manner after exposure to DMSO concentrations in excess of 5%. Proteoglycan release and chondrocyte viability were not affected, and the changes in proteoglycan synthesis and lactate metabolism returned to baseline after the exposure period. Investigators concluded that DMSO concentrations in excess of 5% suppress equine articular cartilage matrix metabolism by direct inhibition of chondrocyte metabolism without a decrease in chondrocyte number. Thus DMSO induces a state of metabolic dormancy in the chondrocytes but these effects are reversible and chrondrocyte viability is not affected.[259]

Effective dose

Domoso® (Fort Dodge) is commercially available as a 90% DMSO veterinary gel for topical use. Manufacturer recommendations are for liberal application to skin over affected area 2–3 times per day. The total daily dosage is not to exceed 100 g and the duration of therapy is not to exceed 30 days. Domoso® is also available as a 90% veterinary solution. The recommended dose for the solution is 0.25–1.0 g/kg diluted in saline or 5% dextrose solution at a concentration of not more than 10%. The 10% solution is to be given at a slow rate once daily for 3 days. The solution can be administered orally through a nasogastric tube at a dose of 1.0 g/kg diluted in 1 liter of water.

Current treatment protocol for equine septic arthritis includes joint lavage with lactated Ringer's solution containing 5% to 40% DMSO. Lavage solutions containing DMSO concentrations in excess of 5% have been shown to have detrimental effects upon articular cartilage matrix metabolism. Until further investigation and pharmacokinetic studies can be performed, the concentration of DMSO contained within intra-articular lavage solutions should not exceed 5%.[259]

The manufacturer cautions against the use of non-medical grade DMSO products, which may contain harmful impurities secondary to the distillation process.[246] Washing of the hands and wearing protective rubber gloves before handling DMSO is strongly recommended in order to avoid transcutaneous penetration of potentially harmful substances.

Drug interactions

DMSO possesses anticholinesterase activity and therefore should not be combined or used in conjunction with organophosphates or other cholinesterase inhibitors.[170,246] Death secondary to mercury intoxication has been reported when DMSO was mixed with mercury salts (red blister) and applied topically to the legs of a horse.[246] Caution should be exercised when mixing DMSO with any drug due to enhanced percutaneous absorption and the potential for toxicosis. DMSO potentiates effects of heparin, insulin, corticosteroids and atropine both topically and systemically.[170,246]

Toxicity

When used at the label dose, DMSO is safe. Local effects such as dermal irritation, exfoliation, erythema and vesiculation are common even at recommended dosages and are exacerbated by the use of sweat wraps, blistering agents, heavy bandages and occlusive dressings. These effects are transient and resolve when therapy is discontinued. When in contact with room air, DMSO will self-dilute to a concentration of 66–67%, causing an unpleasant garlic smell and taste to which some individuals are highly sensitive.[170,246]

Hemolysis and secondary hemoglobinuria have been reported to occur in horses following rapid intravenous administration of concentrations in excess of 20%. This effect can be prevented by slowing the administration rate and diluting the DMSO with isotonic fluids to a concentration ≤ 10% or by administering the product orally via a nasogastric tube.[246] DMSO is known to be teratogenic and hepatotoxic in laboratory animal species, including rats and rabbits, and has been shown to cause intravascular erythrocyte hemolysis and nephritis.[260] DMSO should therefore be used with caution in pregnant mares and individuals suffering from dehydration and renal or liver disease.[193,246]

Pentosan polysulfate

Mechanism of action

Pentosan polysulfate (PPS) is derived from beechwood hemicellulose and is similar to PSGAG in that it is highly sulfated. PPS does not possess analgesic activity, but rather works through modification and correction of pathological imbalances associated with osteoarthritis to provide symptomatic relief.[261] Tritiated PPS has been shown to preferentially distribute to the urinary tract after i.v. administration, the large intestine, liver and urinary tract after oral administration and to the articular cartilage and meniscal fibrocartilage after intra-articular administration in rats and rabbits.[262–264] Human studies, using intra-articular administration of tritiated PPS, demonstrated the formation of complexes with the protein components of articular cartilage while similar rat studies showed localization to cartilage and binding with synoviocytes.[264,265] A new calcium derivative of pentosan polysulfate (CAPPS) has been developed that is absorbed more effectively after oral administration than the sodium salt of pentosan polysulfate (NAPPS).[266]

Pentosan polysulfate is a potent inhibitor of human granulocyte elastase, testicular and arterial hyaluronidase, lysosomal chondroitin-4-sulfatase, N-acetylglucosaminidase, cathepsin B_1 and cathepain G.[261,264,267–272] PPS was able to stimulate the synthesis of proteoglycans by bovine chondrocytes cultured in the presence and absence of interleukin-1.[273] PPS in a concentration range of 0.1–1.0 μg/mL was able to stimulate the production of HA by cultured synoviocytes obtained from rheumatoid and osteoarthritic joints with maximum stimulation occurring at concentrations of 0.25 μg/ml.[274,275] PPS at concentrations of 0.1–10.0 μg/mL was shown to consistently stimulate proteoglycan synthesis in an in vitro lapine chondrocyte injury model. Synthesis increased to 25% above control level occurred at 1.0 μg/mL after 2–4 days in culture. This concentration is similar to the concentration achieved in articular cartilage after intramuscular injection of the recommended therapeutic dose; therefore, the in vitro effect could be achieved in vivo.[197,275,276]

An experimental model for joint disease in rabbits demonstrated the ability of oral CAPPS to maintain a ratio of aggrecan to dermatan sulfate similar to normal articular

cartilage.[277] A rabbit atrophy model for arthritis showed that PPS given intramuscularly at 10 mg/kg every other day prevented proteoglycan depletion from articular cartilage.[278] An anterior cruciate transection model and a joint atrophy model for canine osteoarthritis demonstrated significant reductions in active stromelysin levels concomitant with increased levels of tissue inhibitor metalloproteinase in the articular cartilage of treated dogs associated with intramuscular PPS given at 2 mg/kg once weekly.[279,280] A sodium iodoacetate-induced model of arthritis reported amelioration of radiographic and histologic indexes of joint degeneration for chickens treated with 1–5 μg of PPS.[261]

Indications for use

Pentosan polysulfate has been found to abrogate the deleterious effects of chronic administration of hydrocortisone when injected simultaneously into the knee joints of rabbits.[281] An owner- and clinician-blinded study of 40 dogs with osteoarthritis found significant improvement in stiffness, mobility and pain on joint manipulation for dogs treated weekly with intramuscular NAPPS at 3 mg/kg for 4 weeks. The overall responses were measured with a validated scoring system and the effects were evident for a period up to 4 weeks after the first treatment. Placebo-treated dogs did not improve and dogs treated with NAPPS doses of 1 mg/kg or 5 mg/kg did not show any significant effect.[281] NAPPS was evaluated in a randomized prospective study to determine its applicability in the treatment of fragmented coronoid process and osteochondritis dessicans of the elbow compared with conventional surgical management of these disorders in dogs. Dogs treated with intramuscular NAPPS at 3 mg/kg had more rapid improvement of limb function relative to surgically treated dogs as determined by force plate analysis. At 9 months, no detectable difference between NAPPS-treated and surgically treated dogs was detected. Investigators concluded that NAPPS injections are a valid alternative to surgery for the management of fragmented coronoid process and osteochondritis dessicans in dogs.[282]

Effective dose

An open clinical trial in human osteoarthritis patients described improved symptoms of pain, increased function and reduction in the consumption of NSAIDs for up to 12 weeks after intramuscular administration of CAPPS at 2 mg/kg.[283] A double-blind placebo-controlled study of humans with hip or knee osteoarthritis reported that NAPPS administered intramuscularly at 3 mg/kg every 7 days for four consecutive treatments was associated with significantly improved measurements for rest pain, walk pain, early morning stiffness and improved lifestyle scores for up to 3 months when compared with placebo-treated patients.[175] Although there are no published equine studies describing the application of PPS for the treatment of joint disease in the horse, the dosage regimen used corresponds to that recommended for the dog and for humans, i.e. 2–3 mg/kg intramuscularly every 7 days for four treatments, repeated every 3 months as required. Note: this product is not available in North America.

Atropine sulfate

There is anecdotal evidence for the use of atropine in synovial structures of the horse. Atropine is believed to decrease synovial secretions and thus alleviate the gross clinical signs of clinical conditions, such as bog spavin and idiopathic tenosynovitis. Intra-articular and intrasynovial use of atropine alone and in combination with steroids or HA has been reported with the atropine dosages ranging from 4 mg to 20 mg. The primary indication is distension of synovial structures refractory to drainage and intra-articular treatment with either HA or steroids. There are no anecdotal accounts regarding the use of atropine in osteoarthritis or septic arthritis and there are no clinical or scientific studies to support the use of atropine in the synovial structures of the horse.

CHAPTER 24

Neurologic causes of gait abnormalities in athletic horses

Bonnie R. Rush

Introduction

Performance horses often present for evaluation of neurologic gait deficits. Many owners interpret the abnormal gait as lameness, wherein the source of the gait abnormality is actually neurologic dysfunction. In some cases, neurologic gait deficits will be immediately obvious to the examining veterinarian and the owner learns to recognize the signs of spinal ataxia during the neurologic examination. In other cases, the source of the gait abnormality is obscure and may require extensive evaluation by an experienced clinician. Gait evaluation of horses with spinal ataxia may be confounded by an existing lameness that has been exacerbated by weakness or traumatic injury. A few neurologic diseases will present as a single limb lameness that fails to respond to regional anesthesia (i.e. equine protozoal myelitis). Systematic physical and neurologic examination will clarify a difficult gait analysis and determine whether the primary source of abnormal gait is lameness or neurologic dysfunction. Physical examination will identify concurrent problems related to neurologic disease such as traumatic injury to the musculoskeletal system, developmental orthopedic disease, focal muscle atrophy or multisystemic disease. Neurologic examination provides neuroanatomic lesion localization and allows the clinician to develop a list of differential diagnoses.

Head shaking is also common in performance horses and, in many cases, is neurogenic in origin. Head shaking was previously attributed to behavior and training, but is now recognized to result from numerous medical conditions. The most common cause of head shaking is trigeminal neuritis, which produces neuropathic pain upon exposure to natural sunlight. Head shaking is often performance limiting and can be career ending for individual horses.

Neurologic examination

- Neurologic examination should be performed in a systematic manner to avoid overlooking subtle abnormalities.
- Gait abnormalities are accentuated by manipulation such as inclines, circling and blindfolding.
- The goal of the neurologic examination is to determine grading of deficits, symmetry and neuroanatomic localization.
- Cranial nerve examination is normal with the majority of diseases producing spinal ataxia.

Gait evaluation

Neurologic gait deficits are graded on a scale of 0–5: grade 0 – normal, grade 1 – mild deficits detected by trained eye; grade 2 – deficits detected by most observers; grade 3 – prominent deficits detected by all observers; grade 4 – marked deficits (may fall during examination); grade 5 – recumbent.[1] Evaluation of gait for neurologic deficits is performed predominantly at the walk. Circling, head elevation and manipulation over obstacles accentuate neurologic gait abnormalities. Circles should begin large and slowly decrease in diameter until the horse is moving forward in a tight circle around the examiner. Symmetry and severity of weakness, ataxia and spasticity are evaluated during manipulation. Strength is assessed by the sway test, tail pull and manipulation on an inclined plane. Weakness is manifested by toe

dragging, muscle fasciculations, dipping of the trunk during weight bearing and inability to resist tail pull. Horses with ataxia will demonstrate delayed responses to proprioceptive positioning, stumbling, knuckling, circumduction (excessive flexion and abduction of the outside hindlimb during protraction), posting (pivoting on the inside hindlimb) and truncal sway. Spasticity (hypermetria) is characterized by excessive anterior phase of stride and failure to flex the hocks and carpi (tin soldier gait).

Observe the horse from the front, rear and side to assess muscle mass symmetry. Focal sweating or focal muscle mass loss indicates damage to focal gray matter in the spinal cord. Spontaneous movement, such as tremors, muscle fasciculations or myoclonia, indicates lower motor neuron dysfunction or primary muscle disease. The cervical vertebrae are palpated for pain and bony abnormalities. Gently pricking or pinching the neck, trunk and limbs in a caudal to cranial direction is performed to evaluate cutaneous sensation. Decreased cutaneous sensation will be observed caudal to a focal lesion in the spinal cord or nerve root. Hyperesthesia manifests as twitching, tensing of the abdomen, noxious behavior or self-mutilation and may indicate nerve root pain or neuritis.

Cranial nerve examination

A cranial nerve (CN) examination should be performed on horses with spinal ataxia to identify brain and brainstem dysfunction. Neurologic disorders that are most likely to result in cranial nerve abnormalities are equine protozoal myelitis, traumatic injury, cauda equina syndrome (polyneuritis equi) and viral encephalitides. Cervical stenotic myelopathy and equine degenerative myeloencephalopathy will not produce cranial nerve abnormalities.

The olfactory nerve (CN 1) is evaluated by determining the horse's interest in feed. The menace response is performed by stimulating the horse to blink by visual stimulation with your hand and assesses the optic nerve (CN 2, afferent) and the facial nerve (CN 7, efferent). The palpebral response is elicited by touching the patient's eyelid to stimulate blinking (Fig. 24.1), and this test evaluates the trigeminal nerve (CN 5, afferent) and the facial nerve (CN 7, efferent). The papillary light reflex produces bilateral miosis in response to a unilateral light source. The afferent response is induced by the optic nerve (CN 2), and the efferent response reflects activity of the oculomotor nerve (CN 3).

The eyes should be examined for evidence of strabismus (abnormal eye position) and nystagmus (rapid, rhythmic eye movement). Elevation of the head facilitates detection of strabismus in large animal patients. The oculomotor nerve (CN 3) controls the majority of extraocular muscles and dysfunction results in ventrolateral strabismus (in addition to failure of the papillary light response). Damage to the trochear nerve (CN 4) or trochlear nucleus paralyzes the dorsal oblique muscle of the globe, resulting in dorsal deviation of the medial angle of the iris. The abducens nerve (CN 6) controls the lateral rectus and retractor bulbi muscles and paralysis results in medial deviation of the globe and failure to retract the globe. The vestibulocochlear nerve (CN 8) provides upper motor neuron input to the extraocular muscles via the medial longitudinal fasciculus and vestibular dysfunction results in ipsilateral, ventrolateral strabismus (Fig. 24.2). The doll's eye response is performed by turning the patient's head in a horizontal plane to elicit physiologic nystagmus. Physiologic nystagmus requires normal f unction of the oculomotor, trochlear, abducens and vestibulocochlear nerves. Pathologic nystagmus is observed in horses with vestibulocochlear or cerebellar dysfunction without manipulation of the head. Peripheral vestibular damage (CN 8) produces horizontal nystagmus with the fast phase away from the lesion, whereas central damage (vestibular nuclei, cerebellum) produces horizontal, vertical or rotary nystagmus and the direction of nystagmus may change with head position.

Facial symmetry depends on function of the muscles of facial expression (facial nerve, CN 7) and the muscles of mas-

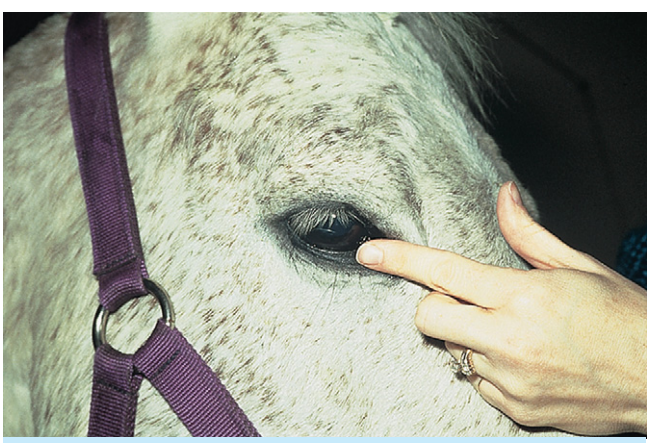

Fig. 24.1
Palpebral response elicited by touching the patient's eyelid to stimulate blinking (sensation – trigeminal nerve; motor response – facial nerve).

Fig. 24.2
Ventrolateral strabismus of the left eye in a horse with left vestibular dysfunction. Note the elevated head position to accentuate abnormal ocular position.

Fig. 24.3
Paralysis of the lips and nostrils in a horse with traumatic injury to the right buccal branch of the facial nerve (over the masseter muscle). The ipsilateral nostril is collapsed and the muzzle is pulled away from the lesion. The ear and eye are not affected by this peripheral lesion.

tication (trigeminal nerve, CN 5). Atrophy of the muscles of mastication (masseter and temporalis) is often accompanied by loss of facial sensation (failure to respond to digital pressure on the nasal septum). A dropped jaw is only observed in horses with bilateral trigeminal nerve damage. Damage to the facial nerve results in muzzle deviation away from the affected side, lack of palpebral response, ear droop, decreased nostril flare and buccal impaction of feed. Corneal ulceration is common due to inability to blink and decreased tear production due to damage to parasympathetic fibers to the lacrimal gland. Damage to the buccal branches of the facial nerve (over the masseter muscle) causes paralysis/paresis of the lips and nostrils only (Fig. 24.3). Tongue tone is controlled by the hypoglossal nerve (CN 12) and the gag reflex reflects function of the glossopharyngeal (CN 9) and vagus (CN 10) nerves.

Clinical signs of vestibular dysfunction (CN 8) include head tilt, nystagmus, falling, circling, reluctance to move and asymmetric ataxia with preservation of strength.[2] Horses prefer to lie on the side of the lesion and may lean on the wall towards the affected side when standing. When forced to move, the horse will take short, inco-ordinated steps in a circle toward the direction of the lesion. Extensor hypotonia ipsilateral to the lesion and hyper-reflexia of the extensor muscles of the contralateral side result in asymmetric ataxia. Nystagmus usually appears with the onset of other peripheral vestibular signs, but may last only 2–3 days due to central compensation. Other signs of vestibular disease may improve 2–3 weeks after onset due to visual and central compensation. Blindfolding a horse with compensated disease will result in ataxia and a head tilt (Romberg test).

Horner's syndrome results from damage to the sympathetic nerve and produces the classic clinical signs of miosis, ptosis, third eyelid prolapse and enophthalmos. Horner's syndrome in horses is unique in that they develop transient, ipsilateral sweating of head and neck (Fig. 24.4) and poor airflow through the ipsilateral nostril, in addition to the four classic signs.[3] The sympathetic nerve originates in the intermediate gray column from T1 to T3 and travels through the cranial mediastinum to the vagosympathetic trunk, to the cranial cervical ganglion caudomedial to tympanic bulla and guttural pouch, and travels with the ophthalmic branch of CN 5 to the periorbita. The most common sites of damage to the sympathetic nerve in horses are the jugular furrow (vagosympathetic trunk) and guttural pouch (internal carotid nerve). Lesions of the cervical intumescence and brachial plexus (avulsion) may produce Horner's syndrome in horses.

Fig. 24.4
Sweating of the head and neck in a horse with Horner's syndrome. Ipsilateral miosis, ptosis, enophthalmos and third eyelid prolapse are also present.

Differential diagnosis of spinal ataxia

- Cerebrospinal fluid (CSF) analysis and plain film radiography are often indicated for preliminary evaluation of horses with spinal ataxia.
- Cytologic evaluation of CSF obtained from the lumbosacral site most accurately reflects pathology of the spinal cord.
- The reference range for CSF white blood cell count is 0–6 cells/μL.
- The reference range of CSF total protein is 50–100 mg/dL.

There are numerous differential diagnoses for neurologic gait abnormalities in athletic horses, but the most common disorders in horses presenting for poor performance are cervical stenotic myelopathy (CSM), equine protozoal myeloencephalitis (EPM), spinal cord trauma and equine degenerative myeloencephalopathy (EDM). Plain film radiography, myelography and CSF analysis are indicated to evaluate horses with spinal ataxia. Horses with vertebral injuries usually demonstrate pain during manipulation of the neck and can be differentiated from CSM by plain film radiographic examination.

Abnormalities in CSF are rarely pathognomonic, but often are suggestive of the pathologic process. It is not unusual for horses with severe neurologic deficits to have normal CSF analysis due to the distance of the lesion from the sampling site, stage of the disease process or presence of non-exfoliative or extradural lesions.

Cerebrospinal fluid analysis

Cerebrospinal fluid flows in a cranial to caudal direction so cytologic evaluation of CSF obtained from the lumbosacral site more accurately reflects a pathologic process in the spinal cord.[4] Collection of CSF from the lumbosacral site is performed in standing, sedated horses and the conus medullaris can be penetrated without complication. Landmarks are the point of intersection of the dorsal midline and a line connecting the caudal border of the tuber coxae. A slight depression may be palpated caudal to L6, cranial to S2 and axial to the tuber sacrale. Upon penetration of the dura, some horses will react by flagging their tail, kicking or dropping in the hindlimbs. An 18 gauge, 15 cm needle with a stylet is recommended and CSF is collected passively or with gentle aspiration. Aggressive aspiration will result in blood contamination of the sample. Cerebrospinal fluid is submitted for analysis in a red top clot tube for cytologic analysis, immunoblot analysis and viral titers. If CSF fluid is bloody or discolored, the sample should be submitted in EDTA for cytologic evaluation.

Intracranial lesions are better represented in CSF samples obtained from the atlanto-occipital (AO) site. Atlanto-occipital collection of CSF requires general anesthesia and accidental penetration of the brainstem may result in death or neurologic dysfunction. The advantages of collection of CSF at the AO site include decreased risk of traumatic blood contamination of the sample and the ability to obtain CSF pressure with a water manometer.

Cerebrospinal fluid should appear clear, colorless and non-viscous and should not clot.[5] Cerebrospinal fluid can appear red from traumatic (iatrogenic) blood contamination or pathologic hemorrhage. Traumatic blood contamination is non-homogenous during collection and may clot. The CSF will appear clear following immediate centrifugation of a blood-contaminated sample. Pathologic hemorrhage appears homogenous during collection and the sample rarely clots. The supernatant is often xanthochromic following immediate centrifugation of the sample (see Fig. 24.13). Xanthochromia, or yellow discoloration of CSF, indicates the presence of bilirubin in the CSF due to peripheral hyperbilirubinemia or red blood cell lysis, within the central nervous system, secondary to hemorrhage or vasculitis. Turbidity of CSF can result from increased white blood cells, red blood cells, bacteria, fungi or epidural fat.

Cytologic examination should be performed within 30 minutes of sample collection. If expedient sample processing is not feasible, cells can be preserved by the addition of 40% ethanol to the sample at a 1:1 dilution. The range of total white blood cell count is 0–6 cell(s)/μL in normal horses. Differential cell count is determined from slides prepared by cytocentrifugation. Normal CSF consists of predominantly small lymphocytes and mononuclear cells. Neutrophils are not present in normal CSF and usually indicate an infectious disease process. Bacterial culture and Gram stain are recommended in cases with increased neutrophils in the CSF. Eosinophils in CSF samples may be associated with migrating parasites, fungal or protozoal infections. The reference range for protein content in equine CSF is 50–100 mg/dL. Increased protein in CSF can occur with blood contamination, hemorrhage, increased permeability of the blood–brain barrier, local immunoglobulin production or tissue degeneration.

Cervical stenotic myelopathy (Wobbler's syndrome, cervical vertebral malformation)

- Typical cases are characterized by symmetric ataxia with the hindlimbs more severely affected than the forelimbs.
- Plain film radiography provides an indication of the likelihood of spinal cord compression.
- Myelography determines the site(s) of spinal cord compression and characterizes the lesion as dynamic or static.
- CSM is likely a manifestation of developmental orthopedic disease and is primarily observed in young horses.
- Surgical intervention improves neurologic deficits by approximately two grades if performed within 1 month of onset of clinical signs.

Recognition

History and presenting complaint

Cervical stenotic myelopathy (CSM) is a common cause of symmetric spinal ataxia in horses from 6 months to 3 years of age.[6] In most instances, the rear limbs are more severely affected than the forelimbs by one neurologic grade. The clinical signs of spinal cord compression often progress for a brief period and then stabilize.

Physical examination

At rest, CSM-affected horses may have a basewide stance and demonstrate delayed responses to proprioceptive positioning. When prompted to back, horses may stand basewide, lean backward, drag their hindlimbs and/or step on their hindfoot with a forelimb. Moderate to severely affected horses will have lacerations on the heel bulbs (wobbler heels) and medial aspect of their forelimbs from over-reaching and interference. Horses with prolonged clinical signs of CSM will have hooves that are chipped, worn or squared at the toe. The muscula-

ture of the neck may appear disproportionately thin compared to the rest of the body and prominent articular processes of the fifth and sixth cervical vertebrae may be evident in some horses.[7]

Occasionally, forelimb ataxia may be more severe in horses with stenosis of the caudal cervical vertebrae (C6–C7) due to compression of the cervical intumescence. Alternatively, arthropathy of the caudal cervical vertebrae may produce cervical pain and forelimb lameness due to peripheral nerve compression, without producing clinical signs of spinal cord compression.[8] Affected horses typically travel with a short cranial phase of the stride and a low foot arc of their forelimb(s), and may stand or travel with their head and neck extended. Rarely, diskospondylosis of the cervical vertebrae will produce a short strided gait and cervical pain, with or without spinal ataxia. Horses with diskospondylosis or arthropathy of the caudal vertebrae may demonstrate increased rate and depth of respiration with cervical manipulation due to pain.

Owners often report a traumatic incident with the onset of clinical signs of CSM.[6] The traumatic incident may be the result of mild neurologic deficits with the injury exacerbating the clinical signs of spinal cord compression. Asymmetric ataxia and paresis may be occasionally observed in horses with dorsolateral compression of the spinal cord by proliferative, degenerative articular processes and periarticular soft tissue structures.[9] Infrequently, clinical signs of nerve root compression are seen such as cervical pain, atrophy of the cervical musculature, cutaneous hypalgesia and hyporeflexia of cervical reflexes adjacent to the site of spinal cord compression. These signs are more commonly observed in horses over 4 years of age with severe arthropathy of the caudal cervical vertebrae (C5–C7), and result from peripheral nerve compression by proliferative articular processes as the nerve root exits the vertebral canal through the intervertebral foramen.[7]

Special examination

Plain film radiography Equine protozoal myelitis and equine degenerative myeloencephalopathy are the most difficult diseases to differentiate from CSM. Cerebrospinal fluid analysis, radiographs of the cervical spine and myelography may be performed to differentiate these diseases. Cytologic analysis of cerebrospinal fluid is usually unremarkable in horses with CSM. In instances when cerebrospinal fluid analysis is abnormal, the alterations are consistent with acute spinal cord compression, such as mild xanthochromia or mild increases in protein concentrations.

Evaluation of standing cervical radiographs can determine the likelihood of CSM.[12] Radiographs of the cervical vertebrae can be obtained in standing, sedated horses. Three views, centered on C2, C4 and C6, are necessary in adult horses to obtain sufficient overlap for an adequate image of each cervical vertebra. A radiographic machine with a capacity of 1000 mA, 150 kV is required to obtain suitable radiographic quality. With the exception of ponies and neonatal horses, portable radiographic machines are inadequate for radiographic examination of the vertebral column. Radiographic cassette size for spinal studies is 35 × 43 cm and rare-earth intensifying screens, medium- to high-speed radiographic film, and aluminum interspaced focused grids are typically used. The standard focal spot to film distance for standing radiography and myelography is 100 cm. Long-scale (low mAs, high kVp) techniques may be used for survey radiographic examination to preserve resolution of soft tissues and vertebrae. Short-scale (high mAs, low kVp) techniques allow visualization of the contrast column and are used for myelographic examination.

Light sedation is sufficient for obtaining lateral projections of the cervical vertebrae in standing horses. Minimizing the distance of the neck to the cassette (minimize object–film distance) will diminish magnification artefact. In standing

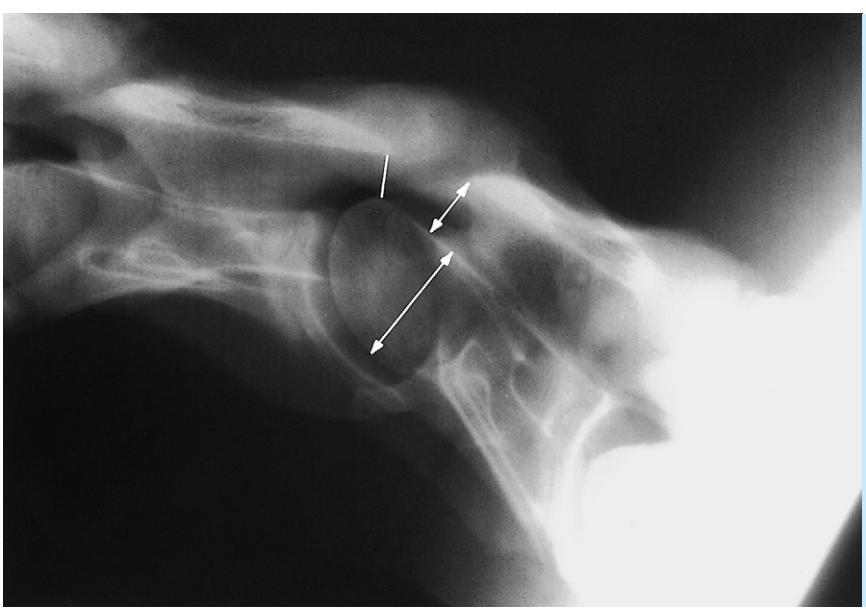

Fig. 24.5
Survey radiograph of the fifth and sixth cervical vertebrae in a horse with cervical stenotic myelopathy. The intervertebral canal diameter of the C5–C6 articulation is indicated by the solid line, and the intravertebral canal diameter of C6 is denoted by the double arrow. Sagittal ratio is calculated by dividing these measurements by the width of the vertebral body as shown on C6 (intravertebral sagittal ratio = 47%). Bony malformations include malalignment of the C5–C6 articulation, flare of caudal physis of C5 and caudal extension of the dorsal lamina of C5.

horses, only neutral views can be obtained. Precise positioning is imperative for interpretation of lateral radiographic projections of the cervical vertebrae. Rotation of the spine results in superimposition and distortion, which interfere with quantitative assessment of vertebral canal diameter.

Cervical radiographs are evaluated by subjective assessment of vertebral malformation and objective determination of vertebral canal diameter.[12] The five categories of bony malformation which are subjectively assessed in horses with CSM are degenerative joint disease of the articular processes, subluxation between adjacent vertebrae, flare of the caudal physis of the vertebral body, abnormal ossification patterns and caudal extension of the dorsal laminae (Figs 24.5–24.7). Although the presence of characteristic vertebral malformations supports the diagnosis of CSM, subjective evaluation of survey radiographs does not reliably discriminate between CSM-affected and unaffected horses.[10,13] Degenerative joint disease of the articular processes of the caudal cervical vertebrae is the most frequent and severe malformation observed in CSM-affected horses (Fig. 24.7). However, degenerative

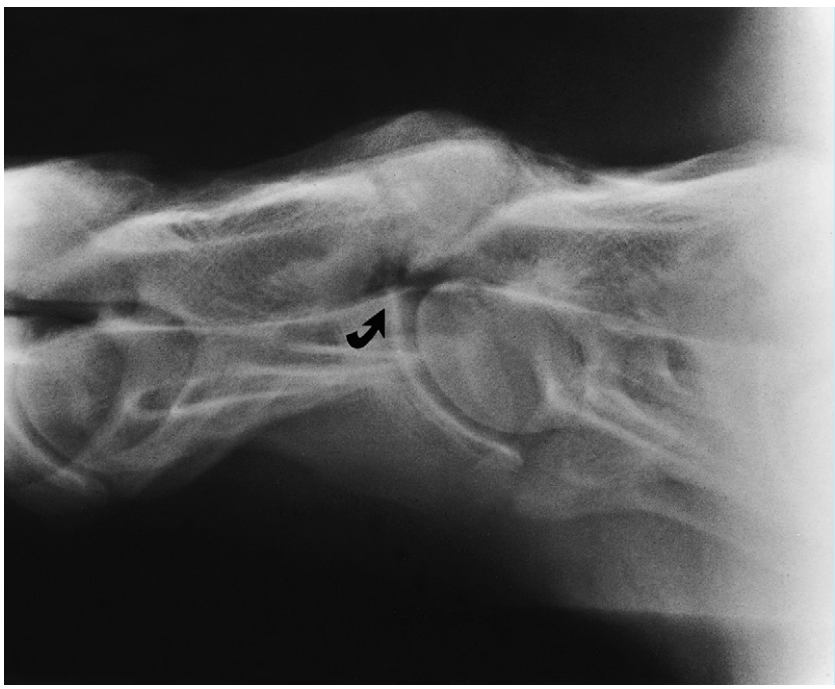

Fig. 24.6
Survey radiograph of the fifth and sixth cervical vertebrae. There is malalignment of the C5–C6 articulation, flare of caudal physis of C5 and mild degenerative joint disease on the articular processes of the C5–C6 articulation (arrow).

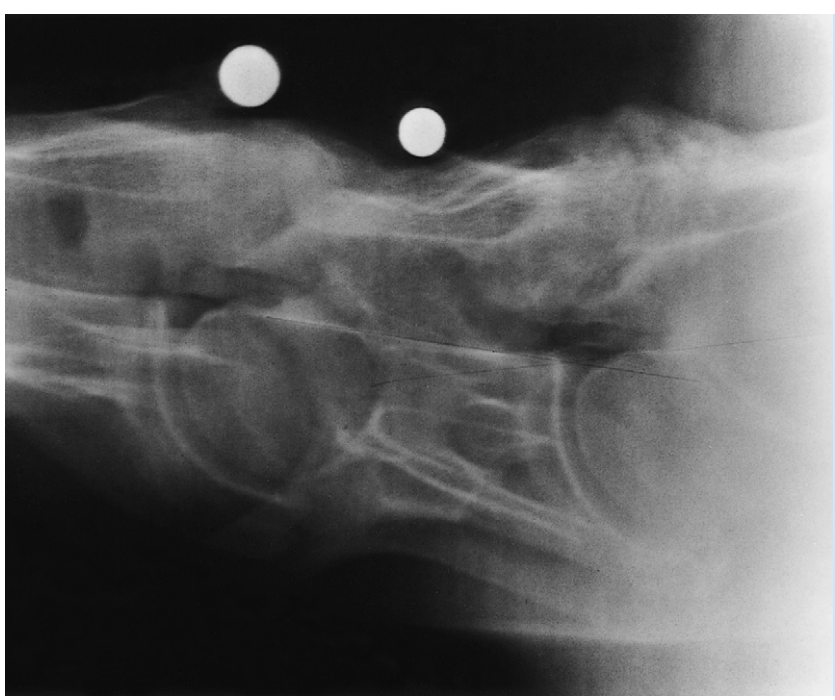

Fig. 24.7
Survey radiograph of the sixth and seventh cervical vertebrae demonstrating marked degenerative joint disease of the C6 (large dot) and C7 (small dot) articulation.

arthropathy occurs in 10–50% of non-ataxic horses and is the most frequent and severe vertebral malformation in horses without CSM.[12,13] Subjective evaluation of degenerative arthropathy of the articular processes without consideration of vertebral body diameter may lead to false-positive diagnosis of CSM.

The vertebral canal diameter is objectively assessed by determination of the sagittal ratio.[12] The sagittal ratio is obtained by dividing the minimum sagittal diameter of the vertebral canal by the width of the corresponding vertebral body (Fig. 24.5). The minimum sagittal diameter is measured from the dorsal aspect of the vertebral body to the ventral border of the dorsal laminae and the vertebral body width is measured perpendicular to the vertebral canal at the widest point of the cranial aspect of the vertebral body. The sagittal ratio eliminates error due to magnification because the vertebral canal and vertebral body are in the same anatomic plane. The sagittal ratio should exceed 52% from C4 to C6 and 56% at C7 in horses greater than 320 kg. The sensitivity and specificity of the sagittal ratio for identification of CSM-affected horses are approximately 89% for vertebral sites C4 through C7.

The semiquantitative scoring system developed by Mayhew should be used in foals less than 1 year of age to assess cervical radiographs for diagnosis of CSM.[14] The scoring system combines objective measurement of vertebral canal diameter and subjective evaluation of vertebral malformation. Stenosis of the vertebral canal is assessed by determination of the inter- and intravertebral minimum sagittal diameters which are corrected for radiographic magnification by dividing these values by the width of the vertebral body (Fig. 24.5). Foals that measure below the mean are allotted 5 points and foals that measure 2 SD below the mean or fall below the mean at multiple sites are allotted from 6 to 10 points. Cervical vertebral malformation is determined by subjective assessment of five categories: encroachment of the caudal epiphysis of the vertebral body dorsally into the vertebral canal, caudal extension of the dorsal lamina to the cranial physis of the next vertebra, angulation between adjacent vertebral bodies, abnormal ossification of the physis and degenerative joint disease of the articular processes. The maximal score allotted for each category of bony malformation is 5 points. A total score of 12 or higher (maximal total score 35) confirms the radiographic diagnosis of CSM. Stenosis of the vertebral canal and malalignment between adjacent vertebrae are the most discriminating parameters in this semiquantitative scoring system to differentiate CSM-affected from normal foals.

Survey radiographic examination of the cervical vertebrae determines the likelihood of spinal cord compression. Myelographic examination is required for the definitive diagnosis of CSM, identification of the location of affected vertebral sites and classification of spinal cord compressive lesions.[15] The clinician should use radiographic interpretation to classify the patient into one of the following categories:

1. Low sagittal ratio (< 48% at C4 through C6), moderate to severe bony malformation – perform myelographic examination to identify sites of spinal cord compression and classify lesions as static or dynamic
2. Marginal sagittal ratio (48% through 56%) mild to moderate bony malformation – perform myelographic examination to confirm or rule out CSM
3. High sagittal ratio (> 56%), minimal bony malformation – pursue other differential diagnoses.

Myelographic examination Myelography is performed under general anesthesia in lateral recumbency.[15] The landmarks for cisternal puncture at the AO site are the cranial border of the wings of the atlas, the caudal border of the occipital protuberance and the dorsal midline. The poll region is aseptically prepared and the head flexed at a 90° angle with the cervical vertebral column. The spinal needle (3.5 inch, 18 gauge with stylet) is introduced and directed towards the

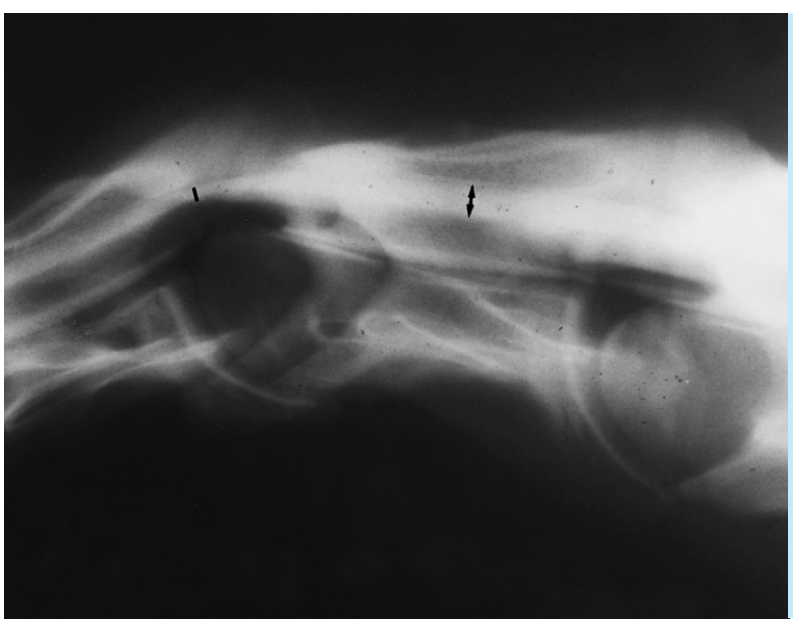

Fig. 24.8
Myelographic examination of C4 through C6 with the cervical spine in ventroflexion. Dynamic instability and spinal cord compression are present at C4–C5. The '50% rule' is determined by dividing the dorsal contrast column of the C4–C5 articulation (black line) to the midvertebral, dorsal contrast column caudal to the intervertebral space (double black arrow).

lower jaw. The spinal needle is advanced until the dura mater is penetrated, which often produces a 'popping' sensation. Clear cerebrospinal fluid should drip rapidly or flow from the hub with successful placement of the spinal needle. Twenty to 40 mL of contrast medium produces sufficient positive-contrast opacity to identify spinal cord compression in adult horses. The bevel of the spinal needle is directed caudally and contrast medium is injected at a constant rate over a 5-minute period. The head and neck are elevated under a wedged platform for 5 minutes at 30–45° to facilitate caudal flow of contrast medium. Iohexol (350 mg iodine/mL) is the most popular non-ionic, water-soluble contrast medium used for equine myelographic studies. This second-generation agent produces less neurotoxicity and meningeal irritation than metrizamide.

A complete myelographic examination should include neutral and stressed (flexed and extended) views of the cervical vertebrae.[15] Horses with obvious sites of spinal cord compression on neutral myelographic views, excessive flexion and extension of the neck should be avoided while obtaining dynamic views to prevent exacerbation of spinal cord injury. Spinal cord compression can be dynamic or static in horses with CSM.[6] Dynamic compression occurs due to vertebral instability and produces intermittent spinal cord compression during ventroflexion of the neck (Fig. 24.8); spinal cord compression is relieved when the neck is in the neutral position. Pathologic changes most commonly observed in horses with dynamic compression are instability between adjacent vertebrae, malformation of the caudal vertebral epiphysis (caudal epiphyseal flare) and malformation/malarticulation of the articular processes. Osteochondrosis of the articular processes is not always present at the site of spinal cord compression in horses with dynamic compression. The intervertebral sites most commonly affected by dynamic compression are C3–C4 and C4–C5. Static compression is defined as continuous spinal cord impingement, regardless of cervical position, and occurs predominantly in the caudal cervical region, C5–C6 and C6–C7 (Fig. 24.9). Static spinal cord compression is exacerbated by thickening of the dorsal lamina, hypertrophy of the ligamentum flavum and degenerative joint disease of the articular processes. Static and dynamic spinal cord compression are both associated with narrowing of the vertebral canal from C3 to C6, regardless of the site of spinal cord compression, indicating that generalized vertebral canal stenosis is an important factor in the pathophysiology of CSM.[12]

The ventral contrast column is often obliterated at the intervertebral space in normal myelographic studies, particularly when the neck is in the flexed position. A decrease of 50% or greater of the dorsal and ventral columns or less than 2 mm dorsal contrast column (or smaller) have been used previously as diagnostic criteria for CSM but have recently been discredited due to frequent false-positive diagnosis. Some investigators prefer to use a 20% reduction in the dural diameter compared to an adjacent midbody site to diagnose spinal cord compression. The decrease in the sagittal diameter of the contrast column is determined by comparing the value at the intervertebral space to a midvertebral site, cranial or caudal to the suspected intervertebral space.

Horses should be monitored for 24 hours after the myelographic procedure for depression, fever, seizure and worsening in neurologic status.[15] Worsening of neurologic status after myelography may result from spinal cord trauma during hyperflexion, iatrogenic puncture of the spinal cord or chemical meningitis. Administration of phenylbutazone (4.4 mg/kg, p.o., q.o.d.) from 1 day before to 1 day after myelographic examination will attenuate fever and depression associated with chemical meningitis.

Treatment and prognosis

Medical therapy

Conservative management of CSM-affected horses consists of anti-inflammatory therapy (glucocorticoids, dimethylsulfoxide, non-steroidal anti-inflammatory drugs) and exer-

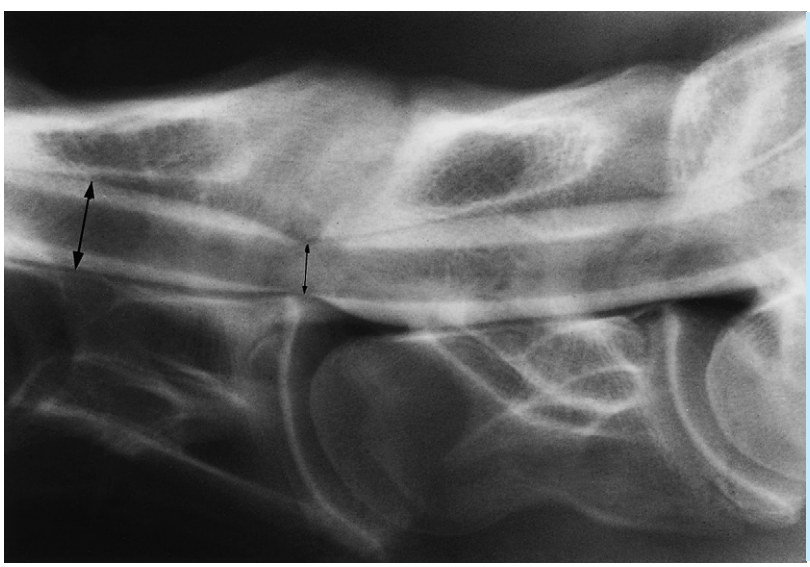

Fig. 24.9
Myelographic examination of C6–C7 with the cervical spine in neutral position. Static spinal cord compression is demonstrated by obliteration of the dorsal and ventral contrast columns. Percent reduction in dural diameter is determined by comparing the intervertebral space (small black arrow) to the midvertebral site cranial to the intervertebral space (large black arrow). Twenty percent or greater is diagnostic of compression (40% reduction in this case).

cise restriction. Anti-inflammatory therapy alone may decrease edema associated with spinal cord compression but full recovery without dietary or surgical intervention is unlikely. The most successful conservative treatment option for CSM-affected foals (< 1 year) is the 'paced diet' program[16] which is designed to correct endocrine imbalance associated with a high carbohydrate diet. This dietary program is restricted in energy and protein (65–75% NRC recommendations), but maintains balanced vitamin and mineral intake (minimum 100% NRC recommendations). Vitamins A and E are provided at three times NRC recommendations and selenium is supplemented to 0.3 ppm. Roughage is provided by pasture or low-quality (6–9% crude protein) grass hay. Stall confinement is recommended to minimize repetitive spinal cord compression from dynamic instability.

Horses with cervical pain and forelimb lameness due to cervical vertebral arthropathy may benefit from intra-articular administration of corticosteroids and/or chondroprotective agents.[17] Arthrocentesis of the cervical vertebral articulations (facets) is performed with ultrasound guidance using a 6″, 18 gauge spinal needle in the standing, sedated or recumbent horse. The cranial facet of the caudal vertebrae will appear superficial to the caudal facet of the cranial vertebrae. The articular space is accessed at the cranioventral opening of the articular facet, which is angled approximately 60° from the ultrasound beam. The needle should be introduced 5 cm cranial to the facet and inserted at a 30° angle to the skin surface. Joint penetration should be confirmed by aspiration of synovial fluid. If the neck is extended, the transverse process of the cranial vertebrae may obscure the path to the articulation. Intra-articular triamcinolone (6 mg/joint) or methylprednisolone (100 mg/joint) have produced a positive clinical response in approximately 50% of horses with arthrosis of the articular processes. The goal of intra-articular anti-inflammatory therapy should be to improve cervical mobility, reduce cervical pain and/or eliminate forelimb lameness. It is unlikely that intra-articular therapy will significantly improve clinical signs of spinal ataxia.

Surgical intervention

Surgical intervention is the most widely reported treatment for CSM.[18–20] The goals of surgical intervention are to stabilize the cervical vertebrae and decompress the spinal cord. Cervical vertebral interbody fusion (ventral stabilization) provides intervertebral stability for horses with dynamic spinal cord compression. Affected cervical vertebrae are fused in the extended position to provide immediate relief of spinal cord compression and prevent repetitive spinal cord trauma.

Dorsal laminectomy (subtotal Funkquist type-B) is performed to decompress static lesions by removing portions of the dorsal lamina, ligamentum flavum and joint capsule at the compressed site.[20] This procedure provides immediate decompression of the spinal cord but fatal postoperative complications may occur.[18] Ventral stabilization in horses with static compression induces remodeling of the articular processes and soft tissue structures, resulting in delayed decompression of the spinal cord over a period of weeks to months. Decompression is immediate with dorsal laminectomy but because of its relative safety, ventral stabilization is the technique of choice for dynamic and static compressive lesions for many equine surgeons.

Ventral stabilization improves the neurologic status of horses with CSM by one to two neurologic grades, with 12–62% of horses returning to athletic function. Dorsal laminectomy results in improvement in neurologic status in 40–75% of horses with static compression. The most important patient factor for determination of postoperative prognosis is duration of clinical signs prior to surgical intervention. Horses with clinical signs less than 1 month prior to surgery are more likely to return to athletic function than are horses with clinical signs of greater than 3 months' duration.[18] Subtotal laminectomy and ventral stabilization for static compression of the caudal cervical vertebrae are associated with fatal postoperative complications including vertebral body fracture, spinal cord edema and implant failure.

Postoperatively, horses should be maintained with strict stall rest for 3 weeks and fed from a hay net to minimize motion at the surgery site. The duration of convalescence and rehabilitation following cervical vertebral interbody fusion is approximately 6–12 months. An individualized exercise program, determined by projected use and neurologic status of the horse, should be designed for promotion of muscular strength. Extended exercise at slow speed, including ponying and lunging on inclines, is recommended during rehabilitation. Neurologic examination should be performed to determine ability to return to athletic function following surgery. It is unlikely that significant improvement in neurologic status will occur beyond the 1 year postoperative time period.

Etiology

Cervical stenotic myelopathy appears to be a manifestation of developmental orthopedic disease. Developmental orthopedic disease of the appendicular skeleton, such as physitis, joint effusion, osteochondrosis and flexural limb deformities, occurs more frequently in young horses with CSM.[11] A direct cause-and-effect relationship between osteochondrosis and CSM has not been identified; however, the association between the frequency of occurrence of osteochondrosis and CSM indicates that the pathophysiology of these two conditions is similar. It is unlikely that CSM is heritable by simple Mendelian dominant/recessive patterns. The mode of inheritance more likely involves multiple alleles and variable penetrance which determine genetic predisposition to CSM. A high plane of nutrition, micronutrient imbalance, rapid growth, trauma and abnormal biomechanical forces are environmental factors that appear to contribute to the development of CSM in genetically predisposed individuals.

Epidemiology

Cervical stenotic myelopathy typically produces spinal ataxia in young horses from 6 months to 3 years of age. Cervical

stenotic myelopathy has been reported in most light and draft breeds. Thoroughbreds are particularly predisposed, wherein the prevalence is approximately 2% of the population. Approximately 10–50% of Thoroughbreds have characteristic developmental malformations of the cervical vertebrae without spinal cord compression.[10] Male horses are more frequently affected than females. The majority of CSM-affected horses are less than 3 years of age at presentation, although middle-aged horses are occasionally diagnosed with acute-onset CSM.[6]

Equine protozoal myeloencephalitis

- EPM may manifest a variety of neurologic deficits including single limb dysfunction, spinal ataxia or cranial nerve abnormalities.
- The definitive host of EPM is the opposum, and numerous small mammals can serve as intermediate hosts.
- Diagnosis is primarily based on neurologic examination, history and disease progression; immunoblot analysis of CSF provides supportive evidence of EPM.
- Ponazuril is the first FDA-approved drug labeled for treatment of EPM.

Recognition

Presenting complaint

Clinical EPM is often reported in well-maintained, young (3–6 years) performance horses.[22] The onset of clinical signs can vary from acute to insidious and distribution of neurologic deficits may be focal or multifocal. Horses may progress from normal to recumbent over a period of hours. Conversely, an owner of an EPM-affected horse may describe an obscure lameness of weeks' to months' duration.

Physical examination

The clinical signs are dependent on the location of the organism within the central nervous system. The spinal cord is most frequently affected (85%) and the most recognizable manifestation of EPM is asymmetric spinal ataxia with focal muscle mass loss or focal sweating. Asymmetric gluteal muscle atrophy is particularly common (Fig. 24.10). Horses may present with a single limb lameness, which does not originate from a musculoskeletal disorder. Symmetric spinal ataxia without muscle mass loss is also frequently observed. Horses with EPM rarely demonstrate pain or response to analgesic medication. Administration of analgesic medication may help distinguish traumatic injury from EPM. Horses with damage to the brainstem and cerebral cortex by EPM are less frequently observed (15%), and clinical signs of parasites within these regions of the central nervous system reflect the neuroanatomic localization of the organisms, including cranial nerve deficits, proprioceptive deficits, weakness, altered mentation and/or seizures. Dysphagia, vestibular dysfunction, facial nerve paralysis and atrophy of the masseter and temporalis muscles and tongue are frequently reported clinical signs in horses with EPM of the brainstem. Vital parameters are typically unremarkable in affected horses.

Fig. 24.10
Asymmetric gluteal muscle atrophy in a horse with equine protozoal myelitis.

Diagnosis

In most instances, CSM is the most difficult disease to differentiate from EPM. Asymmetric ataxia, focal sweating and focal muscle mass loss should direct diagnostic efforts towards EPM. However, symmetric spinal ataxia does not preclude a diagnosis of EPM. Horses with symmetric ataxia due to EPM are differentiated from CSM on the basis of standing radiographic evaluation, CSF immunoblot analysis for *Sarcocystis neurona*, and myelographic evaluation. Horses with EPM of the brain and brainstem may be difficult to distinguish from those with viral encephalitis (Eastern equine encephalitis, Western equine encephalitis, West Nile virus and rabies). Viral encephalitides may be differentiated from EPM by viral serology, CSF cytology and antibody detection and clinical course of disease.

Hematologic and biochemical analysis are unremarkable in horses with EPM. Cytologic analysis of CSF may reveal mild, non-specific inflammation characterized by mononuclear pleocytosis and mild protein elevation. However, CSF analysis is often unremarkable in horses with EPM. Immunoblot analysis (Western blot analysis) identifies antibody against the organism in serum and CSF. Positive immunoblot analysis of serum samples cannot be used to definitely diagnose EPM because it simply indicates exposure to the organism and not necessarily the presence of disease (poor positive predictive value). A negative immunoblot analysis test of serum from a horse with neurologic disease does indicate that the diagnosis of EPM is unlikely (high negative predictive value).[26]

Positive immunoblot analysis of cerebrospinal fluid may indicate intrathecal production of antibody to the organism. The sensitivity and specificity of immunoblot analysis for diagnosis of EPM are approximately 90%.[22] The most

common cause of false-positive diagnosis is iatrogenic hemorrhage during CSF tap. However, damage to the blood–brain barrier due to a pathologic process (i.e. trauma, vasculitis) may also result in false-positive test results from CSF of seropositive horses. It is important to recognize that immunoblot analysis of CSF is frequently false positive in CSM-affected horses if they live in a geographic area with a high EPM seroprevalence. Therefore, differentiation of CSM and EPM should not be determined on the basis of immunoblot analysis alone.

Treatment and prognosis

Prompt initiation of antiprotozoal treatment is warranted in suspect cases of EPM, often prior to obtaining results of immunoblot analysis on CSF. Ponazuril (Marquis®, Bayer Animal Health) is the first FDA-approved drug for treatment of EPM. It is a coccidiacidal drug, belonging to the triazine family, and is a primary metabolite of toltrazuril.[27] Ponazuril is readily absorbed from the gastrointestinal tract and penetrates the CSF to attain therapeutic drug concentrations. Serum concentrations are approximately 25 times CSF concentrations. The label treatment regimen is 5 mg/kg orally, once a day for 28 days. If a horse does not improve on this dose within 2 weeks of initiation of therapy, 10 mg/kg per day can be prescribed for an additional 28 days. Some horses relapse after a 28-day course of therapy indicating a longer period of drug administration may be warranted.[27] Sixty percent of horses with EPM improve one neurologic grade during the 28-day treatment period with 5 mg/kg, and approximately 65% of horses improve one neurologic grade with 10 mg/kg.[28] During the safety phase of the approval process, the following adverse effects were recorded in horses receiving either 1×, 2× or 6× the recommended dosage: blisters on the nose and mouth, hives, loose stools, mild colic, sporadic inappetance and edema of the lamina propria of the uterine epithelium.[29] Ponazuril has not been approved for use during pregnancy or lactation and has not been evaluated for drug interactions.

Traditional therapy consists of a combination of sulfa antimicrobials and pyrimethamine (1.0 mg/kg s.i.d.).[30] Sulfadiazine (20 mg/kg s.i.d.) appears to be superior to sulfamethoxazole for treatment of EPM, on the basis of volume of distribution, protein binding, longer $t_{1/2}$, lower MIC for *Toxoplasma* and higher mean plasma concentrations. Potential adverse effects associated with administration of pyrimethamine and sulfa antimicrobials include anemia, leukopenia, abortion, antibiotic-induced colitis and treatment crisis. Hay and grain inhibit intestinal absorption so EPM therapy should be administered on an empty stomach. Sulfadiazine and pyrimethamine inhibit protozoal replication but are not cidal, which relies on an immunologic response to destroy the organism.[22] The recommended treatment period is 90–120 days, and the prognosis for return to normal neurologic function is approximately 60%. Poor prognostic indicators include recumbency, focal muscle mass loss and prolonged duration of clinical signs prior to administration of antimicrobial therapy. The decision to discontinue therapy is determined by significant improvement in clinical signs of EPM. Premature discontinuation of therapy may result in relapse of neurologic signs. The neurologic signs of relapse are similar to the first episode, and the incidence of relapse is approximately 10–15%.

Immunostimulant therapy has been suggested as ancillary therapy for EPM, although efficacy of these products has not been rigorously tested in horses with clinical signs of disease. Corticosteroids should be avoided in horses suspected to have EPM due to the immunosuppressive effects. *Sarcocystis neurona* organisms are more likely to be observed at necropsy examination of the central nervous system of horses receiving corticosteroids for treatment of EPM. However, administration of a single dose may be beneficial in a recumbent horse with EPM.

Epidemiology

Equine protozoal myeloencephalitis is the most common cause of neurologic disease in horses in most regions of North America. Protozoal myeloencephalitis has been recognized in horses since the 1970s but it was not until 1991 that the primary parasite responsible for EPM was cultured from a horse and given the name *Sarcocystis neurona*. Opossums are the definitive host of *S. neurona* and several small mammals (skunk, armadillo, domestic cat, raccoon) are capable of serving as intermediate hosts to complete the lifecycle.[21] The role of each of these potential intermediate hosts in the natural lifecycle of *S. neurona* is not clear. Transmission of the parasite from the above-mentioned intermediate hosts to the definitive host is probably accomplished by ingestion of dead intermediate hosts by the opossum, rather than the typical prey-predator lifecycle observed with most *Sarcocystis* spp.

Horses appear to be dead-end, aberrant hosts (not capable of transmitting infection from horse to horse).[22] The sporocyst in opossum feces appears to be the infectious form of the organism for horses. The route of migration of the parasite from the time of ingestion of sporocysts to parasitism of the central nervous system is unknown. Control of the disease should be centered on limiting exposure of horses to opossum feces; approximately 20% of opossums excrete infectious sporocysts in the wild.[23] Disposal of skunk, raccoon, armadillo or cat carcasses from equine premises will prevent opossums from eating carrion, which may remove the primary source of infection for the definitive host. The most important form of contaminated equine feeds (i.e. hay, pasture, grain, water) is currently unknown.

Recent studies estimate 44–55% of horses in North America have been exposed to *S. neurona*, based on seroconversion.[24] Variability in seroprevalence across the United States appears dependent on environmental factors such as number of freezing days (decreased incidence) and relative humidity (increased incidence). Despite the high exposure rate, clinical disease remains infrequent (approximately 2%) in horses exposed to the parasite. Evidence suggests that some horses may clear the organism from the central nervous

system routinely, which may explain the relatively high number of normal horses with CSF antibodies to *S. neurona* compared to the prevalence of clinical disease. Individual risk factors for development of clinical disease are suspected to be stress, corticosteroid administration, general anesthesia, strenuous exercise, long-distance transport and natural individual susceptibility. Most commonly, a single horse on a farm will develop clinical signs of disease. Epizootics with > 50% clinical attack rates have been reported on farms with large resident opossum populations with access to the feed sources.[25]

Vertebral trauma

- The most common sites of vertebral injury in horses vary with the age.
- Diagnosis of vertebral fracture is determined by plain film radiography or nuclear scintigraphy.
- Medical therapy is indicated in ambulatory patients with stable fractures.
- Surgical therapy is indicated in unstable fractures of the cervical or sacral vertebrae.

Cervical fractures

Traumatic spinal cord injury is a common etiology of spinal ataxia in performance horses, and can be difficult to diagnose. The most common site of traumatic spinal cord injury is dependent on age of the horse.[31] Cervical fractures are more common in foals and result from hyperextension, hyperflexion and luxation. Adult horses are more likely than foals to develop fractures of the caudal thoracic and lumbar spine. Regardless of the site of the fracture, the prognosis is dependent on the severity of the initial injury.

Fig. 24.11
Cervical radiograph from a weanling that reared over backward and impacted on the pole. One wing of atlas (C1) is displaced ventrally. The odontoid process (dens) of the axis (C2) is fractured and the entire axis is displaced ventrally. The foal demonstrates grade 2 symmetric ataxia and a mechanical head tilt.

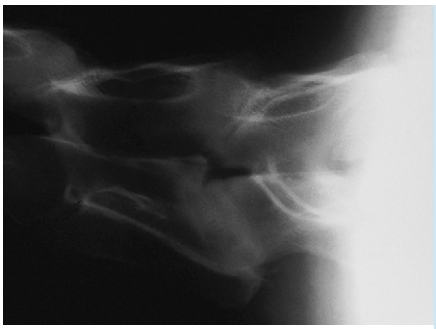

Fig. 24.12
Cervical radiograph of C4 through C7 from an adult horse after a head-on collision with a tree. A vertebral body compression fracture is present at C6. The horse was recumbent.

The most common cervical vertebral fracture in foals is axial dens fracture and atlantoaxial subluxation (Fig. 24.11).[32] Atlantoaxial subluxation may result from resisting head restraint (hyperextension) or somersault (hyperflexion) injuries in young horses. Foals with atlantoaxial subluxation will have a stiff, splinted neck and, in some instances, audible crepitation with manipulation of the head. Neurologic gait deficits range from none to marked tetraparesis and ataxia. Foals may have a head tilt, without other signs of vestibular dysfunction, due to mechanical malalignment of the C1–C2 articulation. Radiograph views of the cervical spine reveal widening of the cranial physis of the axis. In foals with neurologic gait deficits, cranioventral luxation of axis usually occurs with increased distance between the spine of the atlas and axis and between the floor of the atlas and the axial dens.

In adult horses, compression fractures of the vertebral body and articular facet fractures are the most common fractures of the cervical vertebrae and occur with head-on collision and falling, rolling injuries in horses (especially jumping and steeplechasing), respectively (Fig. 24.12).[31] Cervical vertebral fractures are associated with pain, resistance to manipulation and splinting of the neck. Focal sweating, loss of cutaneous sensation and torticollis may be observed if exiting nerve roots are damaged by the fracture. The severity of neurologic gait deficits will range from none to tetraplegia dependent on the degree of vertebral luxation and spinal cord injury.

Thoracic fractures

Thoracic fractures are more common in adult horses than foals and result from falling over a jump or flipping over backwards.[31] The first three thoracic vertebrae are most likely to fracture, followed by T12. Fracture of the thoracolumbar junction is observed in horses that fall and roll down an embankment. Clinical signs in horses with T12 or thoracolumbar fractures include paraparesis and tracking or drifting of the hindlinbs to one side. Dorsal spinous process fractures of T4 to T8 occur in horses that flip over backwards. These fractures are not usually associated with fracture of

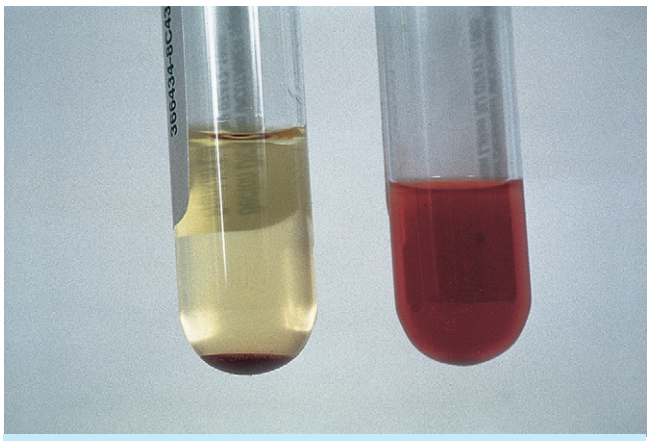

Fig. 24.13
Cerebrospinal fluid from a horse with head trauma. CSF appears hemorrhagic prior to centrifugation (right) and xanthochromic (supernatant) with a red cell pellet after centrifugation (left).

the vertebral bodies, although neurologic gait deficits may result from contusion of the spinal cord. Sacral fractures occur with dog-sitting incidents and may result in loss of tail function, urinary incontinence, loss of anal tone and fecal retention.

Diagnosis of vertebral fractures can be difficult. Despite the presence of a fracture, overlapping structures and surrounding muscle mass render radiographic projections of the vertebrae difficult to interpret.[33] Vertebral fracture should be investigated in horses that have a history of a traumatic event, pain on palpation, clinical signs of tetra- or paraparesis and/or hyperesthesia or loss of cutaneous sensation. Plain film radiography may identify cervical, sacral and thoracic fractures. Fractures of the lumbar vertebrae are not amenable to radiographic examination due to the soft tissue mass surrounding the vertebral bodies in this region.[31] Nuclear scintigraphy may enable the clinician to identify non-displaced cervical fractures and fractures of the lumbar spine which are inaccessible to radiographic examination. Cerebrospinal fluid is often hemorraghic in horses with CNS trauma. The supernatant will appear xanthochromic after centrifugation if the hemorrhage is pathologic in origin (as opposed to iatrogenic) (Fig. 24.13).

Treatment and prognosis

Medical therapy

Conservative management, consisting of stall rest and anti-inflammatory therapy, may be rewarding in horses that are ambulatory after vertebral fracture.[33] The therapeutic approach for foals with atlantoaxial subluxation is dependent upon the severity of neurologic deficits and the degree of malalignment and instability of the vertebrae. Stall rest and conservative anti-inflammatory therapy may be successful in foals with relatively stable, non-displaced fractures.

Early medical therapy (less than 8 hours after injury) to prevent edema formation consistently produces a more favorable outcome than does late intervention.[33] Glucocorticoids (dexamethasone 0.1–0.2 mg/kg, i.v., q 8–12 h) minimize cerebral edema and secondary injury by prevention of membrane lipoperoxidation and inhibition of arachidonic acid metabolites. Dimethyl sulfoxide (1 g/kg, i.v., s.i.d. to b.i.d.) may prevent or reduce cerebral edema. Rapid administration of the 10% DMSO solution may result in intravascular hemolysis and hemoglobinuria. Mannitol (0.25–1 g/kg, i.v. over 20 minutes as a 20% solution, b.i.d. to t.i.d.) reduces existing CNS edema via hyperosmolar dehydration and may reduce CSF pressure within 30 minutes of administration. Non-steroidal anti-inflammatory drugs have limited ability to reduce CNS edema and inflammation but analgesic properties may relieve malaise and reduce depression. Liberal administration of anti-inflammatory drugs may permit excessive movement by the horse and loss of muscular splinting of the fracture, which may promote displacement of fracture fragments.

Surgical intervention

Surgical intervention is recommended for foals with unstable cervical fractures and severe neurologic gait deficits.[32] Surgical approaches for correction of atlantoaxial subluxation in foals includes compression plating, Steinmann pin fixation, dorsal laminectomy of the caudal atlas and ventral cervical fusion.[31] Surgical stabilization of vertebral fractures is rarely attempted in adult horses. Successful lag screw fixation of vertebral body fracture and dorsal decompression of a transverse, ventrally displaced sacral fracture have been reported.[34] Surgical intervention has not been reported in horses with thoracic or lumbar vertebral fractures. Dorsal spinous process fractures may require surgical removal if sequestration of bone fragments occurs.

Exuberant callus formation may impinge on the spinal cord and produce neurologic gait deficits months after the injury. Therefore, the ultimate usefulness of a horse with traumatic spinal cord damage may not be determined for a prolonged period of time after injury. Nonetheless, response to therapy within the first few days is a good prognostic indicator.

Equine degenerative myeloencephalopathy

- EDM produces symmetric spinal ataxia in young (6 mo to 2 yr) horses.
- There is no ante-mortem diagnostic test so EDM is a diagnosis of exclusion.
- Vitamin E supplementation may prevent or stabilize disease in predisposed individuals.
- Predisposing factors include heredity and environmental factors that reduce or inhibit dietary vitamin E.

Recognition

Neurologic examination

Horses with EDM demonstrate symmetric ataxia, spasticity and weakness.[35] Hypermetria and weakness are particularly prominent. During neurologic examination, affected horses demonstrate circumduction, posting, abnormal proprioceptive positioning and abnormal sway test. The severity of forelimb ataxia may equal that of the hind limbs.[40] Most horses with EDM have difficulty backing and may dog-sit or fall when forced to back. Horses with chronic disease may develop signs of lower motor neuron dysfunction such as decreased cutaneous truncal, cervical, cervicofacial and laryngeal adductory slap reflexes.[40] The typical clinical course of EDM is characterized by insidious progression of neurologic gait deficits, followed by stabilization of clinical signs. Clinical signs do not progress after maturity and affected horses rarely develop quadriparesis or tetraplegia.

Diagnosis

Equine degenerative myeloencephalopathy is a diagnosis of exclusion.[41] There is no ante-mortem diagnostic test so lumbosacral CSF analysis, cervical radiographs and/or myelography are performed to eliminate other potential causes of spinal ataxia in young horses.[36] The results of these tests are unremarkable in horses with EDM. Plasma α-tocopherol concentration may be low (< 1.0 μg/mL) or normal (1.5–3.0 μg/mL) in horses with EDM depending on the stage of the disease process. A single sample reflects the current status of the horse and cannot detect a deficiency that may have existed prior to or during the degenerative process.[41] Therefore, plasma α-tocopherol provides supportive evidence, but cannot be used to diagnose or rule out EDM. The clinician may suspect EDM based on neurologic signs (hyporeflexia, forelimbs and hindlimbs equally affected, weakness and hypermetria) and familial history. Foals of dams that have previously produced an EDM-affected foal are 25 times more likely to develop EDM.[37] Nonetheless, the definitive diagnosis is determined by necropsy examination.

There are no gross lesions of EDM. The caudal medulla oblongata and midthoracic spinal cord demonstrate the most severe histopathologic lesions of EDM.[40] Findings include neuroaxonal dystrophy of brainstem nuclei (nucleus cuneatus, nucleus gracilis and the lateral cuneate nucleus) and throughout the spinal cord.[40] The most prominent gray matter lesions in the spinal cord are in the nucleus of the spinocerebellar tracts of the thoracic spinal cord. The most prominent white matter lesions are spheroid formation (swollen dystrophic axons – Fig. 24.14) and lipofuscin accumulation in the dorsal and ventral spinocerebellar tract in the lateral funiculus and ventromedial funiculus of the cervicothoracic spinal cord. The lipofuscin pigment is believed to represent malonaldehyde, the end-product of lipid peroxidation of degenerating spinal cord.[40]

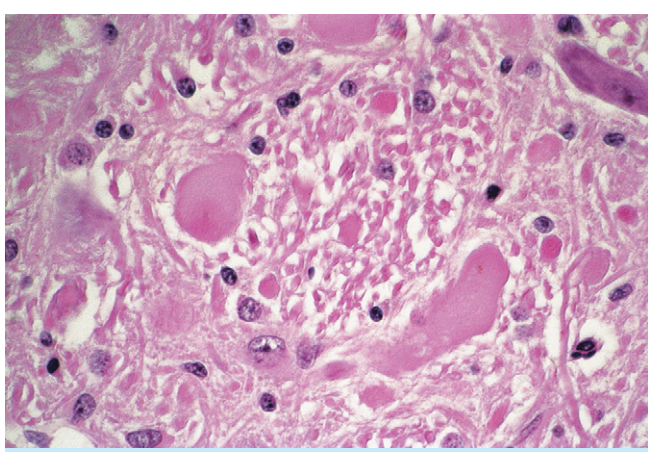

Fig. 24.14
Photomicrograph from the brainstem of a 6-month-old colt with equine degenerative myeloencephalopathy. Spheroids, representing swollen dystrophic axons, are characteristic of EDM. H&E ×100.

Treatment and prevention

Dietary vitamin E supplementation may be used to prevent or treat EDM. The current recommendation for treatment of horses with clinical signs of disease is 6000 IU of d,l-α-tocopherol acetate (with 60 mL corn oil) daily through the third year of life. This dose has been reported to improve the neurologic status of affected horses.[41] For prevention of EDM in genetically predisposed horses, α-tocopherol acetate is supplemented in the diet at 1000–2000 IU/day during pregnancy and through the first year of life. Horses with access to pasture or properly cured hay ingest adequate amounts of vitamin E and do not require supplementation. Supplementation is recommended for all horses eating hay that has been improperly cured or stored for an extended period of time. Combination vitamin E/selenium products can produce selenium toxicity at doses required to achieve the recommended level of vitamin E supplementation.[41]

Epidemiology and pathophysiology

Equine degenerative myeloencephalopathy is a diffuse degenerative disease of young horses affecting the brainstem and spinal cord. Ataxia typically develops between 3 and 12 months of age.[35] Equine degenerative myeloencephalopathy has been reported in most light breeds of horses and appears familial in Standardbreds, Appaloosas, Paso Finos and zebras.[36] There is no gender predilection. Equine degenerative myeloencephalopathy has been reported most frequently from the north-eastern United States, wherein up to 45% of ataxic horses have a histopathologic diagnosis of EDM. Predisposing factors for development of EDM include use of insecticides, exposure to wood preservatives and turnout in dirt lots. Access to green pasture appears protective.[37]

Vitamin E is suspected to play a pivotal role in the pathophysiology of EDM. The histopathologic lesions of EDM are similar to experimentally induced vitamin E deficiency in other

species. Low plasma α-tocopherol concentrations are observed in clinical cases of EDM and prophylactic administration of vitamin E to genetically predisposed foals and pregnant mares decreases the incidence of EDM.[38] Low plasma α-tocopherol concentration from 6 weeks to 10 months of age appears to be a critical factor in the development of EDM in hereditarily predisposed foals. Low α-tocopherol values do not reflect a primary defect of gastrointestinal absorption in this population of foals, but may reflect inappropriate assimilation of vitamin E.[39]

Head shaking

- Head shaking is seasonal and may be triggered by exposure to sunlight.
- Affected horses are suspected to experience neuropathic pain in the form of a burning sensation around their muzzle.
- Response to medical therapy is variable and may be transient.
- Surgical therapy should be considered a salvage procedure and should only be performed in horses demonstrating a consistent response to diagnostic nerve blocks.

Recognition

Presenting complaint

Horses with head shaking disorder toss their heads in the absence of obvious external stimuli. Some horses will head shake with such violence that they are dangerous to the handler or rider. Photo-induced horses attempt to avoid direct sunlight by seeking shade or hiding their heads in unusual places. Clinical signs are often seasonal, abating during winter months and returning in spring. The condition affects adult horses, and geldings and Thoroughbreds appear to be over-represented.[45] The behavior is exhibited at rest and during exercise. Violent head shaking at the beginning of exercise is common and can render the horse unusable for riding. A change in environment may result in some horses failing to exhibit the behavior on the day of examination so the owner should obtain a videotape of the head shaking behavior prior to their appointment.

Physical examination

Head shakers demonstrate sudden, violent jerking movements of the head in the absence of obvious external stimuli.[44] Quick vertical flips or jerking movements (as if stung by a bee on the end of the nose) are characteristic, but some horses may intersperse horizontal and rotary activity.[42] Affected horses often snort, sneeze and rub their nose. Horses that demonstrate head shaking behavior due to other etiologies usually perform intentional, head tossing behavior, rather than rapid, bee-sting vertical flips characteristic of photic head shaking.

Diagnosis

There are numerous differential diagnoses for head shaking in horses. Next to trigeminal neuritis, otitis, dental disease, TMJ osteitis and foreign body may be the most common causes of head shaking. Ophthalmologic, otic, oral and endoscopic examination of the upper respiratory tract (including guttural pouches) and radiographic examination of the skull may be performed in horses demonstrating head shaking behavior to rule out these differential diagnoses. Findings are unremarkable in horses with photic head shaking. To determine if the behavior is induced by natural light, the horse should be placed under the following conditions: direct sunlight, blindfolded, night-time outdoors, dark lenses in direct sunlight. If sunlight has been identified as the stimulus for infraorbital pain, reduced sunlight exposure by providing shelter or a mask is indicated.[42]

Treatment and prognosis

Medical therapy

The response of photic head shakers to medical therapy is variable. Favorable, transient and non-response to therapy are commonly reported outcomes of medical management. Cyproheptidine (0.3–0.6 mg/kg, p.o., b.i.d.) is an antihistamine, serotonin antagonist with anticholinergic effects. The mechanism of action for treatment of photic head shaking is unknown.[44] A 7-day course of cyproheptidine is recommended to determine response to therapy and horses that respond should be treated during the season in which they exhibit head shaking behavior. Approximately two-thirds of photic head shakers will respond to cyproheptidine.[45] Clinical signs typically recur 24 hours after discontinuation of cyproheptidine. Transient lethargy, depression, colic or anorexia may be observed in some horses with cyproheptidine administration. Carbamazepine (3–4 mg/kg, p.o., t.i.d. to q.i.d.) is the drug of choice for treatment of trigeminal neuritis in humans. This drug may be administered alone or in combination with cyproheptidine to horses that fail to respond to cyproheptidine alone.[46] The response to carbamazepine is approximately 80% of cases. Melatonin (12 mg p.o. between 1700 and 1800 h) has been reported to diminish clinical signs in some head shaking horses. Transient relief may be obtained with topical EMLA cream (lidocaine 2.5% and pilocarpine 2.5%) applied to the muzzle. Cover the topical cream with plastic wrap (make holes for nostrils) and leave on for 45 minutes. Administration of topical therapy prior to exercise may facilitate riding, training and showing of affected horses. The ideal combination of drug therapy is tailored to the individual horse, based on trial and error response to therapy. Corticosteroids, NSAIDs and antihistamines are ineffective in the treatment of photic head shaking.

Surgical intervention

Surgical intervention should be considered for horses that cannot be controlled with medical therapy. Bilateral infra-

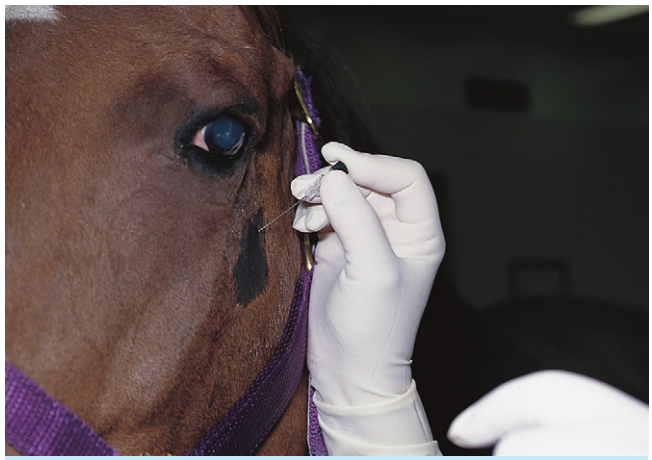

Fig. 24.15
The bilateral posterior ethmoidal nerve block is performed for diagnostic purposes in horses with head shaking. A 7 cm, 18 gauge spinal needle is inserted below the zygomatic arch and directed rostral ventral towards the upper sixth cheek tooth (approximately 5 cm). Local anesthetic is infused at the level of the maxillary foramen.

orbital neurectomy is a salvage procedure for refractory cases. Surgical candidates must demonstrate a consistently positive response to serial infraorbital nerve blocks.[44] Bilateral infraorbital nerve block is performed by infusion of mepivicaine (10 mL) over and within the infraorbital canal. Approximately 30–40% of photic head shakers improve after bilateral infraorbial neurectomy, and successful outcome may be improved by careful case selection (i.e. consistent response to infraorbital nerve block). Postoperative complications may include nasal pruritus (common, temporary), reinnervation and neuroma formation.

An alternative procedure to infraorbital neurectomy is bilateral sclerosis of the posterior ethmoidal branch of the trigeminal nerve.[46] Prior to considering the procedure, horses should respond favorably to bilateral posterior ethmoidal nerve block. This block is performed using a 7 cm, 18 gauge spinal needle inserted below the zygomatic arch and directed rostral ventral towards the upper sixth cheek tooth (approximately 5 cm) (Fig. 24.15). Five milliliters of mepivacaine is infused at the level of the maxillary foramen. Bilateral sclerosis of the posterior ethmoidal branch of the trigeminal nerve is achieved by perineural injection (5 mL) of 10% phenol in almond oil.[46] This procedure is performed under anesthesia, by inserting a 20 cm stiletted needle up the infraorbital nerve to the level of the maxillary foramen. Proper positioning of the needle at the maxillary foramen is confirmed by fluoroscopy. Approximately 65% of horses demonstrate a 90–100% improvement after bilateral sclerosis of the posterior ethmoidal branch of the trigeminal nerve.

Pathophysiology

Prior to the 1990s, the cause of head shaking was rarely identified and the condition was largely unresponsive to therapy. In 1995, Madigan and co-workers presented a series of photic head shaking horses in which head shaking was triggered by natural sunlight and darkness provided relief from the condition.[42] Photic head shaking horses are suspected to experience a burning sensation or tingling of the muzzle (neuropathic pain) in response to bright sunlight. The mechanism of photic head shaking may be similar to photic sneezing in humans, in which exposure to bright light triggers sneezing episodes. Photic sneezing in humans is a heritable, non-allergic disorder. Photic head shaking may represent a form of referred pain in which stimulation of one of the cranial nerves enhances irritability of the other, in this instance optic-trigeminal summation. This may be associated with convergence between optic and trigeminal tracts in the brainstem. Some clinicians suspect trigeminal ganglioneuritis, due to latent equine herpesvirus infection, may contribute to irritability of the infraorbital nerve. Bright sunlight is the most common trigger for neuropathic head shakers but other stimuli, including specific feeds (gustatory head shaking), may also serve as a trigger for infraorbital nerve irritability.[43] In some horses, the triggering stimulus is not identified but their head shaking behavior appears characteristic for neuropathic pain and they respond to medical therapy. Many other disorders besides neuropathic pain may induce head shaking behavior in horses. A thorough diagnostic evaluation is indicated to eliminate other etiologies of head shaking behavior.

CHAPTER 25

Physical treatment of the equine athlete

Andris J. Kaneps

Introduction

Physical treatment is the application of non-pharmacologic techniques and methodologies for the treatment of musculoskeletal disorders. Thermal, sound and light treatments, manual techniques and controlled exercise will be described in this chapter.

Accurate localization and diagnosis of the injury or lameness must precede the choice of appropriate physical treatment methods. Treatments should be chosen based on the goals of the therapy program and the circumstances of treatment, such as a hospital setting or a competition, the availability of trained people to apply treatments, and available technology.

Physical treatment of horses is often a major adjunct to surgical or medical therapy. It may also be the primary therapy where a horse is competing under Federation Equestre Internationale (FEI) or other competition regulations that prohibit use of medications. Some of these treatment techniques have undergone scientific scrutiny, while others have not. It therefore behoves the attending veterinarian to carefully review available current literature before using some of these methods.

Table 25.1 Aspects of thermal therapy

Therapy type	Indications	Methods of application	Responses to treatment
Cold	Acute injury (first 24–48 hours) Pain reduction	Ice water immersion Ice surface application Cold packs	Restricts blood flow Reduces metabolism Reduces activity of inflammatory enzymes Reduces pain
Heat	Chronic injury (after 72 hours) Enhance tissue stretching Enhance healing response	Warm water from hose Hot packs Leg sweat Therapeutic ultrasound	Increases blood flow Increases metabolism Increases activity of tissue enzymes Relaxes muscle spasm Reduces pain Increased tissue extensibility

Thermal therapy

Physiological effects of heat application

One of the most accessible and time-tested methods of physical treatment is thermal therapy. The major physiological benefits of heat therapy are increased local circulation, decreased pain, reduction of muscle spasm resulting in muscle relaxation, and increased tissue extensibility.[1–3]

The primary effect of local heat application is stimulation of local circulation by dilation of blood vessels. Increased local blood flow helps mobilize tissue metabolites, increases tissue oxygenation and raises the metabolic rate of cells and enzyme systems. As a rule, an increase in tissue temperature of 10°C increases the metabolic rate 2–3 times.[1] These factors are especially beneficial for wound healing or other soft tissue injuries.

Increased local blood flow may be initiated by three mechanisms. The axonal reflex is a direct response of the blood vessels to local increases in tissue temperature. Local

inflammatory mediators such as histamine, prostaglandins (such as PGE_2 and prostacyclin) and bradykinin may also initiate vasodilation and increase capillary permeability. Local spinal reflexes are stimulated by afferent impulses from the thermoreceptors at the site of heating and result in decreased postganglionic sympathetic adrenergic nerve activity, which decreases smooth muscle tone of vessels, allowing them to dilate.[1]

Edema reduction is a common reason for heat application in horses. Increased blood flow and vascular permeability may promote resorption of edema. However, vasodilation of a dependent limb, such as in a standing horse or human, may actually lead to edema in the limb(s) by the same mechanisms that cause edema, specifically increased blood flow and vascular permeability. Application of heat at one location may also cause reflex vasodilation at a distant site. For example, when heat is applied to the lower back of humans, the vessels of the distal limb dilate in response.

Heat application is also recognized to decrease pain. Stimulation of heat receptors may result in closing of the neural gate, which blocks afferent stimuli from peripheral pain receptors. Heat may also act as a counterstimulus to pain, making the afferent impulses of pain less noticeable.[1–3]

Muscle spasms are decreased following heat application. Increased muscle temperature results in decreased firing of muscle spindles, which helps to break the cycle of pain–spasm–pain. The same sort of cycle may be partially responsible for flexural contractures in foals with physitis. The flexor muscles are the largest group of forelimb muscles in the foal. Severe physeal pain results in reflex increased muscle spindle firing and muscle spasm leads to flexural contracture.

Soft tissues may be stretched most effectively when they are heated. Heat decreases tissue viscosity and increases tissue elasticity. Low-load, prolonged stretching of tissues heated to 40–45°C (104–113°F) results in increased extensibility of tendon, joint capsule and muscle.[1–3]

Indications for heat therapy

Heat is best applied after the acute inflammation has subsided, usually no sooner than 48–72 hours after an injury. It is also useful for reducing muscle spasm and pain due to musculoskeletal injuries. Heat therapy can be used to increase joint and tendon mobility, particularly by heating before active stretching. Heat application may be beneficial for accelerating the healing response of localized soft tissue injuries.

Heat: methods of application

Superficial heat may be applied with hot packs, hydrotherapy, paraffin baths or moist air. These methods provide heat penetration to approximately 1 cm from the skin surface.[1–3] This is often sufficient for many distal limb injuries because of the lack of an insulating fatty subcutaneous tissue layer in horses. Deep heat may be applied using therapeutic ultrasound.

The most profound physiological effects of heat occur when tissue temperatures are raised to 40–45°C (104–113°F).[1,3,4] Tissue temperatures above 45°C may result in pain and irreversible tissue damage.[4] Skin and subcutaneous tissue temperature increases approximately 5°C after 6 minutes of treatment and maintains that temperature for up to 30 minutes.[5] For deeper tissues, 15–30 minutes heating is required to elevate tissue temperature into the therapeutic range.[1,3]

Direct contact of the skin to temperatures over 45°C (115°F) may cause thermal injury and tissue damage. Heat sources warmer than 45°C must be wrapped in several layers of moist towels before application.[4] Superficial heat using hydrocollator packs, which are heated to 71–79°C, or rechargeable hot packs is usually applied for 15–20 minutes, but timing depends on the warmth of the heat source.

Warm water is probably the most accessible method of heat therapy. Methods of application may be from a hose or with wet towels, or water immersion in a bucket, therapy tub or turbulator boot. A rule of thumb is that water as hot as one's hand can comfortably endure is about 38–41°C (101–105°F). Tissue heated by water at this temperature may only reach the lowest tissue therapeutic range. To make warm hydrotherapy most effective, a thermometer should be used to determine water temperature. Horses will commonly experience pain with water 45°C and higher.

In a study of hot water hose therapy applied to the metacarpal region in a horse, it was found that water as warm as a human could comfortably endure resulted in skin surface temperatures on the horse of 39.5–41°C.[5] Temperature of subcutaneous and deep tissues stabilized at 39–40°C approximately 9 minutes after therapy was started. Tissue temperatures returned to baseline approximately 15 minutes after therapy ceased.[5] Heating the equine digit by standing in a 47°C water bath for 30 minutes resulted in significant increases in soft tissue perfusion and laminar temperatures.[6] Vascular perfusion increased, but not significantly.[6]

Commercial hot packs provide marginally effective treatment temperatures, yet they are very simple to use. The packs consist of a chemical that rapidly changes from a gel to a crystalline structure in an exothermic reaction. The packs attain temperatures of about 54°C (130°F) within minutes of activation. Heat is maintained for 20–30 minutes. The packs are either single use and disposable or rechargeable in a microwave by immersion in near-boiling water. Hot packs of this type are available from Tempra Technology, Bradenton, Florida, USA (single-use disposable) or Cyan Massage Products, Edmonton, Alberta, Canada (rechargeable).

Hydrocollator packs are commonly used in human physical therapy practices. Heat is retained by blocks of silica gel encased in a flexible canvas cover. Hydrocollator packs are heated to 71–79°C (160–174°F).[4] They are somewhat heavy for use in standing horses, but the weight helps maintain good contact with the treatment area. Moist towels should be wrapped around the packs to prevent thermal injury.

Therapeutic ultrasound (US) may be used for superficial or deep heating of tissues. In horses, treatment is usually conducted at 1.5 W/cm^2 for 10 minutes. Ultrasound selectively heats tissue with high protein and/or collagen content.[4] Tendon, muscle, fibrous connective tissue and bone may be effectively heated to 45°C, while adipose tissue is relatively

transparent to the effects of therapeutic US. The greatest heating occurs at tissue interfaces, similar to the sharp image delineations between tissue interfaces of skin, tendon and fluid seen with diagnostic US. Ultrasound effectively heats tissues to a depth of more than 7 cm (3″). In dog thigh muscles, US treatment at 1.5 W/cm^2 resulted in temperature increases of 4.6°C, 3.6°C and 2.4°C at 1 cm, 2 cm, and 3 cm depths, respectively.[7] An additional benefit of US is the deep massage of tissues because the sound waves compress and expand tissues and tissue fluids.[7] Fibrous connective tissue scars may be loosened and reabsorbed to a certain degree with therapeutic US. Treatment is usually performed once or twice daily for 10–14 days. Ultrasound coupling gel must be used to provide good contact between the US transducer and the skin.

Physiological effects of cold application

The major physiological benefits of cold therapy are decreased local circulation, decreased pain and decreased tissue extensibility.[1–3,8,9] The viscoelastic properties of soft tissues are reduced with cold therapy, which may be an undesirable effect.[1–3]

The primary effect of local cold application is to constrict blood vessels. Local reflexes and central nervous system responses mediate vasoconstriction. Reduced blood flow may help reduce edema, hemorrhage and extravasation of inflammatory cells. Just 10 minutes of ice pack application to the stifle of dogs resulted in a 56% decrease in local tissue blood flow.[8] Reduced tissue metabolism may inhibit the effect of inflammatory mediators and enzyme systems. Because of these effects, cold therapy is often indicated within the first 48 hours of injury.

Cyclical rebound vasodilation is another response of cold therapy.[10] Following a minimum of 15 minutes of cold therapy that results in tissue temperatures of 10–15°C, cycles of vasoconstriction and vasodilation occur. An example of this effect is the warm, tingling sensation in one's fingers after long-term exposure to cold.

Pain is reduced by mechanisms similar to that described for heat therapy. Small myelinated nerve fibers are more sensitive to cold therapy and reduce conduction earlier than similar sized unmyelinated fibers. Application of an ice pack for 20 minutes over the ulnar nerve in cats reduced nerve conduction velocity by 29%.[9]

Indications for cold therapy

Cold therapy is indicated in acute musculoskeletal injuries and is particularly effective during the first 24–48 hours after injury.[11] Distal limb injuries are the most easily and effectively treated.

Cold: methods of application

Cold may be applied by ice water immersion, ice packs or cold packs and Freon or ice water-charged circulating bandages or boots.

Therapeutic effects of cold occur at tissue temperatures between 15° and 19°C (59–66°F).[1–3] Tissue temperatures of 10°C and less may cause cold thermal damage. Average time of cold application is 15–20 minutes. Treatments should be repeated every 2–4 hours during the first 24–48 hours of injury if the goal is to reduce tissue inflammation and edema.

Cold therapy is effective to a depth of 1–4 cm from the skin surface, depending on the amount of adipose tissue and the local blood supply.[1–3] Cold treatment is rapid and effective in the distal limbs of horses because they lack an adipose layer and target tissues such as tendons, ligaments and joint capsules are close to the skin surface.

Direct contact of ice water with the skin is the most effective method of cold therapy. In human physical therapy, ice baths are maintained at temperatures of 13–18°C (55–64°F).[1] In a study of ice water immersion therapy applied to the metacarpal region of a horse, skin surface temperatures stabilized at 9–10°C approximately 10 minutes after therapy was started.[5] Temperature stabilized at 17–19°C in subcutaneous tissue and at 20–24°C between the deep and superficial flexor tendons approximately 10 minutes after therapy was started. Tissue temperatures had not returned to baseline by 10 minutes after therapy was stopped.[5] Ice water immersion of the equine digit for 30 minutes resulted in significant decreases in soft tissue perfusion and laminar temperatures.[6]

Cold packs saved from shipments of pharmaceutical supplies are easily adapted for therapeutic use. They may be applied directly to the treatment site or wrapped in a wet or dry towel and held in place with a bandage. The cold packs maintain their cold temperatures well and are easily reused. One disadvantage is that these types of cold packs do not conform well to the limbs. Even a small air gap between the pack and the skin often results in subtherapeutic tissue temperatures. The cold packs may be thawed, shaped to the anticipated site using a form such as a cardboard tube or plastic pipe, and refrozen. Commercial products such as cold leg wraps have the same gel substance as cold packs. The gel is formed as a tape that may be wrapped on a limb and held in place with a wet bandage. Cold packs may be applied for greater than 30 minutes, but the intensity of cold is less than that of ice. Cold packs developed primarily for equine use are also available in sizes that conform specifically to the cannon bone, carpus or tarsus (Dura*Kold Corporation, Oklahoma City, OK, USA).

Manipulative therapy

Stretching and massage are physical methods of treatment that may be applied without the need for sophisticated equipment. Stretching is useful for maintaining or increasing the range of motion of an injured joint and for increasing a horse's flexibility and elasticity to improve performance. Stretching is especially beneficial following joint injury or surgery. This technique should not be used on limbs that may have acute tendon or ligament injuries.

Evaluating the flexibility of a horse's joints, including joints of the neck, is often carried out during a lameness or

neurologic examination. Being familiar with the normal ranges of motion of these structures is necessary to determine if there is a restriction in the range of motion. Comparisons can be made to the contralateral joint or structure if there is uncertainty.

Limb mobility is usually easy to evaluate during flexion tests for lameness. Head and neck flexibility may be evaluated with gentle manipulation using the halter or by encouraging the horse to reach for a carrot. Evaluation of back and trunk mobility is described in Chapter 21.

Stretching exercises should begin 24 hours after joint surgery or after a joint injury, providing that the injury has been accurately diagnosed. Flex and extend the joint to the point of mild discomfort and hold at that point for 10–15 seconds. Repeat the sequence up to 12 times twice daily.

Massage may be used to warm muscles prior to exercise and for soothing tired muscles after exercise. Experience with human athletes has shown that pre- and postexercise massage makes athletes more comfortable and helps decrease stiffness following competition.[12]

There are variations in massage therapy techniques that focus on specific mechanisms of action. Trigger point massage focuses on relaxing tight bands of muscle or fascia that are sensitive to manipulation, thereby reducing sensitivity of the affected areas. This type of massage has been found to reduce heart rate and blood pressure and to significantly relax human patients.[13] The technique also aims to decrease the sensitivity of active myofascial zones that may cause discomfort in a distant area.[14] Acupressure massage results in stimulation of regions that are connected to Chinese meridians similar to acupuncture points.[15]

Massage therapy should be considered palliative. Few of the claimed advantages of the techniques have been scientifically evaluated.[16] Using a trained therapist with a close professional relationship with the attending veterinarian is imperative for safe and effective treatment.

Exercise

Controlled exercise regimens may be used during the rehabilitation period after injury or surgery. Controlled exercise protocols have been established for rehabilitation of tendon and ligament injuries (see Chapter 20). Gradually increasing the time and intensity level of exercise is beneficial for healing of soft tissues and bone as both become stronger with use, particularly in growing horses.[17–19] Harness race horses may enter a controlled exercise program by designating the number of jogging miles at a given pace for each exercise session.

Swimming or underwater treadmill exercise is another method of providing controlled exercise with the advantage of minimal concussion. These methods spare the musculoskeletal system, but enhance cardiorespiratory fitness. Swimming should not replace conditioning for fitness under normal weight-bearing conditions. Swimming is also an excellent method for increasing joint mobility after injury or surgery. Horses do not use the same muscle groups during swimming that are used during weight-bearing exercise and may cause hyperextension of the back muscles.[14,20] Because of this, swimming should be combined with regular ring or track work to condition the muscles, bones and joints that are used for normal weight-bearing activities.

Treadmills, although not often readily available, are a good intermediate step between exercise with minimal concussion and the horse's regular exercise. Most treadmills have a rubber running surface that reduces concussion during weight-bearing exercise. Speed and inclination of the treadmill can be adjusted to the level of exercise intensity that is appropriate for the horse.

Control of the exercise program may be useful during and after rehabilitation is complete.[21] Treadmill exercise was used in one study to establish a base level of fitness, then regular track workouts were gradually added.[21] Regular exercise over the track eventually made up 50–70% of the total work for each horse. Horses trained in this fashion had fewer training and racing injuries and better race times than conventionally trained horses.[21]

Ultimately horses must train under the same conditions they will encounter in competition. This means that riding or driving with a gradual increase in duration and intensity of exercise will be needed. The key to retraining a horse is to realize that cardiovascular fitness declines significantly after 4–6 weeks of rest[22] and that bone strength decreases significantly within 12 weeks of rest.[23] Retraining will result in noticeable improvement of cardiac measurements within 6 weeks, increased bone mineral density within $16\frac{1}{2}$ weeks and tendon dimensions within 16 weeks.[18,24,25] Published studies on bone and tendon response to exercise do not identify the earliest time that significant strength returns to these tissues after reintroduction of exercise. Three to 4 months may be the minimum time required to re-establish musculoskeletal tissue strength following 2 or more months of complete rest.

Light therapy

Light of any type emits energy, as evidenced by the heat given off by a light bulb. Specialized sources of light energy have been used to enhance tissue healing, reduce swelling and increase local circulation.[26–29] Light therapy has also been used to produce analgesia and to stimulate acupuncture points.[26] Many of these effects have been verified in laboratory animal-based research, but other studies have failed to measure effects of this modality.[27–29] Light therapy is not universally accepted in mainstream veterinary medicine.

Laser is an acronym for Light Amplification by Stimulated Emission of Radiation. Lasers produce coherent, monochromatic light. Indications for laser therapy in equine practice include tendinitis, desmitis, soft tissue bruising, wounds, myofascial injuries and burns. Helium-neon, gallium-arsenide and gallium-aluminum-arsenide are common sources of laser light used for treatment purposes in equine

practice.[26] Monochromatic infrared light sources have also been used to enhance wound healing in humans and horses.[30] Laser energy at a dose of 2–8 J/cm^2 is recommended for treatment of soft tissue injuries and 0.5–1 J/cm^2 is recommended for acupuncture point stimulation.[26,31] Treatment protocols are different for each device and manufacturers' instructions should be carefully followed.

No deleterious effects of light therapy have been reported. Lasers have the potential to cause eye injury so operators need to wear eye protection when using certain laser devices that emit a concentrated, high-power beam.

Extracorporeal shockwave therapy

A new application of sound wave energy is currently undergoing critical evaluation in clinical and scientific settings. Extracorporeal shockwave therapy (ESWT) consists of short-duration (5 μs), high-pressure shockwaves (up to 80 MPa) that stimulate tissue. Originally these devices were used for non-invasive lithotripsy of cystic and renal calculi in humans.[32]

Focused and non-focused ESWT devices are currently marketed for use in horses. Reports of positive treatment effects have been made for both types of devices.[32–34] Each treatment usually consists of 2000 pulses. The intensity of shockwave therapy is set in a range of 0.9–1.8 mJ/mm^2 or according to the atmospheric pressure at the output probe (2.5–4 bar), depending on the manufacturer's recommendations.[32,34] Horses must be sedated and often need to have regional anesthesia proximal to the site of application. Each treatment lasts 10–15 minutes and is repeated at 1–4-week intervals. Treatment protocols require 1–4 separate treatments depending on the nature of the injury and response to initial therapy.

As the shockwaves pass through tissue interfaces, compression and shear loads occur within the tissues, resulting in stimulation of healing of bone and soft tissue injuries. Bone healing and remodeling have been enhanced and an analgesic effect has been noted for 2–4 days following treatment.[32,35,36] Use of ESWT to treat arthritis of equine distal tarsal joints (bone spavin) resulted in improvement of lameness grade in 59 of 74 horses treated.[33] Chronic suspensory desmitis was successfully treated in 24 of 30 horses after three ESWT treatments.[34]

Extracorporeal shockwave therapy is indicated for treatment of tendinitis and insertional desmopathies. Injuries of the origin or insertion of the suspensory ligament, dorsal cortical stress fractures, incomplete fractures of the proximal sesamoid bone(s), arthritis and navicular disease have been successfully treated with ESWT.[32–34] Continuing clinical experience and research using this therapeutic modality will ultimately identify effective applications in the near future.

CHAPTER 26

Upper airway function of normal horses during exercise

Susan J. Holcombe and Norm G. Ducharme

The horse is a magnificent athlete that can run in excess of 30 miles per hour. In order to accommodate the tremendous oxygen demand of skeletal muscles during such intense exercise, the horse increases its minute ventilation nearly 50-fold. High airflow rates required to meet this ventilatory demand are created principally by diaphragmatic contraction, which produces driving pressures within the upper airway exceeding -30 cmH_2O. Because the horse is an obligate nasal breather and rarely breathes orally, the horse's upper airway must quickly prepare for these large changes in airflow and pressures by dilating and becoming more rigid (less compliant). Such accommodation is achieved by synchronous and coordinated contraction of upper airway muscles and constriction of capacitance vessels within the mucosa of the upper airway.[1,2] These remarkable and somewhat unique

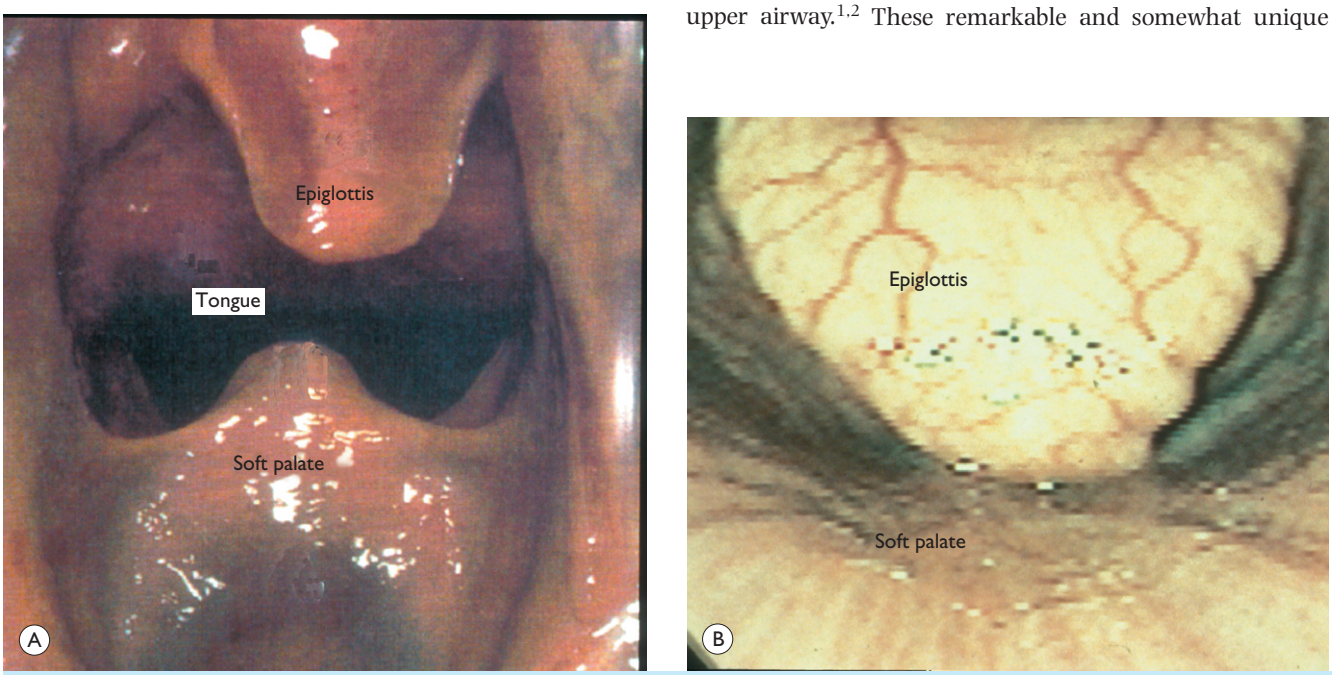

Fig. 26.1

Notice the space between the epiglottis and the soft palate, which forms the communication between the oropharynx and nasopharynx in people. (B) Endoscopic image of the equine epiglottic and soft palate apposition. There is no communication between the oropharynx and nasopharynx in the horse due to the tight apposition of the soft palate and epiglottis.

adaptations of the equine upper airway to exercise are the subject of this chapter.

Obligate nasal breathing

Teleologically, obligate nasal breathing is thought to be advantageous to a fight or flight creature, because obligate nasal breathers can graze and masticate while moving air through the nasal passages, maintaining olfaction and the ability to sense predators.[3] To accomplish this, the soft palate is tightly apposed to the base of the larynx, such that there is no communication between the oropharynx and the nasopharynx, as exists in people (Fig. 26.1A,B). In people, the 'switch point' from nasal to oronasal breathing during exercise is determined by the flow resistance in the nasal airway and the turbulence of the airflow.[4] Estimated airflow rate associated with the switch from nasal to oronasal breathing is variable and reported to be between 22 and 44 L/min.[4–6] Horses maintain nasal breathing, normally, throughout exercise and rely on capacitance vessel constriction and contraction of upper airway dilating muscles to minimize airflow resistance.[1] Exactly at what level of exercise intensity these factors occur in exercising horses is not known.

Basic upper airway mechanics

The upper airway begins at the nares and includes the nasal passages, the nasopharynx, and oropharynx, guttural pouches, larynx, and trachea. Some segments of the upper airway, such as the larynx, are supported by cartilage, and some portions such as the nasal passages, are supported by bone. The pharyngeal region is formed principally by skeletal muscle and relies on the contraction of these muscles and muscles of the hyoid apparatus and tongue for stability.

At rest, the average 450 kg horse breathes 12 times per minute with a tidal volume of 5 liters and peak inspiratory flow of 5.09 ± 0.34 L/s, making its resting minute ventilation approximately 60 L/min.[7] During intense exercise, respiratory frequency increases to 120 breaths per minute, peak inspiratory airflow increases to 75 ± 9.35 L/s, tidal volume increases to 12–15 Ls, and minute ventilation increases to approximately 1400–1800 L/min.[7] All the upper airway segments are exposed to varying degrees of negative pressure as the diaphragm contracts during inhalation, creating negative driving pressure for airflow to the lungs. These pressures range from –1.9 ± 0.2 cmH_2O during normal tidal breathing to –38.6 ± 3.9 cmH_2O while running at speeds that result in maximal heart rate (HR_{max}).[8] The ratio of the peak pressure that occurs to produce a given peak airflow is the airway impedance and impedance is a measure of how the airflow is opposed by the airway.[9] The determinants of airway impedance include resistance, which is dependent on the airway geometry, and the elastance and inertance of the tissues.[9] The most important component of airway impedance is resistance, which is principally determined by the radius of curvature of the airway or its diameter. Resistance is defined by the formula $R = (8\eta l)/\pi r^4$, where η is the viscosity of the air, l is the length of the airway, and r is the radius.[10] The viscosity of air does not change and the length of the airway changes minimally with head and neck flexion and extension. The diameter of the airway, however, does change during inhalation and exhalation. In the resting horse, two-thirds of the total resistance to airflow resides in the upper airway.[1] As the horse inhales, the largest pressure changes occur at the nares and larynx due to narrowing in these areas.[1] During exercise, upper airway resistance increases to 80% of total airway resistance, because the tissues of the upper airway tend to collapse dynamically as airway pressures become more negative.[1] Positive pressure tends to dilate the upper airway during exhalation and therefore upper airway resistance to airflow during exhalation is only 50% of total expiratory airway resistance.[1] Static or dynamic obstructive airway disease can result in large changes in airway resistance. For example, if the diameter of the airway decreases by 20% due to a small amount of granulation tissue on the left arytenoid cartilage, airway resistance would double. Therefore, throughout the respiratory cycle, the horse relies on neuromuscular mechanisms to dilate and stabilize the airway during intense exercise to expand and stabilize the airway in order to accommodate such high flow rates and pressure changes while minimizing resistance to airflow.

Head position

The position of the horse's head and neck does affect upper airway flow mechanics in exercising horses.[11] Measurements of airway mechanics made in six horses with the head and neck in neutral, extended, and flexed positions confirmed that head and neck position significantly increases inspiratory impedance.[11] The induced obstruction is typical of a dynamic upper airway obstruction because inspiratory values but not expiratory values are altered. Head and neck flexion may cause the airway to be more compliant, because tissues, such as the pharyngeal walls and soft palate, bulge into the airway, or because the nasopharynx shortens with this maneuver. Horses with most types of obstructive upper airway dysfunction show more severe signs of respiratory distress and exercise intolerance while exercising with the head and neck flexed rather than in a neutral or extended position. Posture or head position alters upper airway muscle activity such that head flexion, or cervical spine flexion increases genioglossus nerve activity in other species.[12,13] Therefore, altered upper airway muscle activity may result from postural changes in head and neck position in exercising horses and these changes may be due to stimulation of local upper airway receptors that sense changes in tissue tension, pressure, and airflow.

Neuromuscular control of upper airway function

During intense exercise multiple stimuli trigger contraction of upper airway dilating muscles, including chemical stimuli such as hypercapnia and hypoxia, limb movement, central locomotor-linked cortical influences, receptors located in the lower airways, and upper airway sensory receptors.[14–21]

The laryngeal mucosa has an abundant supply of sensory receptors that control a complex pattern of respiratory reflexes that influence the patency of the upper airway and the pattern of breathing.[22] These receptors are mechanoreceptors or temperature sensing receptors and include pressure, flow, and drive receptors that line the mucous membranes and deeper tissues of the nose, nasopharynx, and larynx.[22] They receive afferent innervation from branches of the trigeminal, glossopharyngeal, and vagus nerves.[23,24] Receptors in the nasopharynx are innervated by branches of the glossopharyngeal and trigeminal nerves.[22] These receptors are principally tactile receptors and stimulate the gag response, important in airway protection.

Especially relevant to dilation and stability of the upper airway during exercise are the pressure receptors. Pressure receptors account for 60% of the sensory receptors within the laryngeal mucosa in horses, which is similar to other species.[22,25] These receptors are innervated by the superior laryngeal branches of the vagus nerve.[23] They are stimulated during upper airway obstruction, when large collapsing pressures are produced in the upper airway, and they provide afferent information to the central nervous system, signaling contraction of upper airway muscles to resist dynamic collapse in the upper airway. For example, studies in dogs, cats, rabbits, monkeys, and people have shown that reflex augmentation of muscle contraction by application of negative pressure in the upper airway occurs in the genioglossus and other tongue muscles, muscles of the hyoid apparatus, and the soft palate.[16,18–21,26,27] In horses, negative pressure stimulates increased electromyographic activity in the cricoarytenoideus dorsalis muscle, the primary laryngeal abductor.[25] During incremental exercise testing the palatinus, palatopharygeus, hyoepiglotticus, sternohyoideus and sternothyroideus, geniohyoideus, and genioglossus muscles all had increasing levels of electromyographic activity as treadmill speed increased, and upper airway pressures became more negative.[28–30]

In species other than horses, it has been noted that the time of application of negative pressure during the breathing cycle is an important variable in determining the magnitude of the response of upper airway muscles. Specifically, upper airway motor neurons are more responsive during early inspiration to pressure changes in the airway than during later stages of inspiration.[27] The onset of inspiratory upper airway muscle activity often precedes that of the diaphragm, and is modulated by chemical drive, and mechanical afferent input from the upper airways that is, primarily, vagally mediated.[31] Many of the upper airway muscles are maximally active during early to mid inspiration, with a subsequent decrement in activity during the remainder of inspiration. Inspiratory activation of upper airway muscles prior to the diaphragm will dilate or stiffen the upper airway, promoting upper airway patency, prior to the onset of inspiratory airflow and hence produce an early inspiratory stabilization of upper airways.[31] The degree of negative pressure established in the upper airway will increase the amount of muscular preactivation.[21]

Topical anesthesia of the luminal surface of the larynx or bilateral superior laryngeal nerve sectioning markedly reduces the response to changes in upper airway pressure and upper airway muscle activity in laboratory species and people.[24,32] In horses, topical anesthesia of the laryngeal

mucosa results in increased inspiratory upper airway and nasopharyngeal impedances, and decreased respiratory frequency and minute ventilation.[33] The dynamic upper airway obstruction was caused by nasopharyngeal collapse due to decreased skeletal muscle support. Following topical anesthesia of the laryngeal mucosa, horses exhibit dorsal displacement of the soft palate and nasopharyngeal collapse during endoscopic examination at rest (Fig. 26.2) and varying degrees of nasopharyngeal collapse during incremental treadmill exercise (Fig. 26.3).[33] These results suggest that local sensory receptors in the upper airway of horses, as has been shown in laboratory species, contribute to upper airway patency and that disrupting the sensory component of the local reflex that controls contraction of upper airway muscles can cause dynamic upper respiratory obstruction in horses.

Nasal occlusion

Because negative pressure induces contraction of upper airway muscles, a nasal occlusion test was developed in horses in order to mimic pressure changes that might occur during intense exercise to challenge the upper airway with more negative pressures during resting videoendoscopic examination. Peak tracheal inspiratory pressure during nasal occlusion (-24.9 ± 3 cmH_2O) is not significantly different from peak inspiratory pressure while horses exercise at HR_{max} (-25.6 ± 2.7 cmH_2O), and peak pharyngeal inspiratory pressure is significantly more negative (-28.9 ± 4.9 cmH_2O) during nasal occlusion than while horses exercise at HR_{max} (-17.5 ± 2.1 cmH_2O).[34] These data indicate that nasal occlusion in standing horses results in pharyngeal and tracheal inspiratory pressures that equal or exceed those that are generated during exercise at HR_{max}, making it a potentially useful test for evaluating the activity of laryngeal and pharyngeal muscle function. However, anecdotally, horses that exhibit varying degrees of nasopharyngeal collapse at rest frequently have normal airway function during treadmill exercise. As well, horses that readily displace their soft palates at rest frequently displace during treadmill exercise, but the correlation between displacement at rest and during treadmill exercise is not a strong one.

Other sensory receptors within the upper airway include flow and drive receptors. Drive receptors represent 20% of laryngeal sensory receptors in horses.[22,25] These receptors respond to changes in airway deformation, such as collapse, muscle contraction and movement of the laryngeal cartilages.[22] Flow receptors are temperature-sensing receptors.[22] These receptors sense cool air temperatures, which occur as airflow increases. The majority of these receptors are responsive during inspiration, but some (approximately 20%) respond during exhalation, and a small population of the airway sensory receptors is active during both inspiration and expiration.[22]

In addition to afferent sensory receptor stimulation in the upper airway, chemical stimuli such as hypercapnia and hypoxia also increase the activity of upper airway dilator muscles.[16,17] Horses exercising at HR_{max} become hypercarbic ($Paco_2$ of 50.2 mmHg) and hypoxemic (Pao_2 of 56.1 mmHg).[35] Hypoxia and hypercarbia stimulate inspiratory and expiratory motor neuron activity.[36,37] The neural mechanism by which central and peripheral chemoreceptors affect cranial motor neuron activity and signaling upper airway dilating muscles, and the role of vagal afferents in these responses are unknown.

Measurement techniques for upper airway mechanics in exercising horses

Evaluating upper airway function in exercising horses requires a combination of qualitative and quantitative measurement techniques. Videoendoscopic evaluation of the upper airway in exercising horses has proven invaluable in assessing both normal and abnormal airway function. Sometimes combined with visual observations of airway function, upper airway mechanics measurements are made by measuring airway pressures and airflows. Using the data, calculations can be made to determine respiratory frequency, tidal volume, minute ventilation, and impedance. Tidal breathing flow volume loops can be constructed if airflow is quantitatively measured and appropriate computer software is available.[38] As well, pressure volume curves can be constructed if both airway pressure and tidal volume are measured, permitting work of breathing to be calculated.[10] Muscle activity can be assessed by measuring the electromyographic activity of muscles.[16–19] Finally, because many upper airway abnormalities cause the horse to produce unique respiratory related sounds during exercise, sound analysis can be used to evaluate upper airway function and dysfunction.[39]

The goal when measuring tracheal pressures in exercising horses is to obtain accurate measurements in a minimally invasive manner. Error in measurements can occur due to the high tracheal airflow velocities in running horses and the presence of the measurement apparatus.[40] Trancutaneous placement of tracheal catheters minimizes airflow obstruction and provides excellent measurement of tracheal static pressure.[41,42] However, percutanous tracheal catheterization, especially repeated catheterization, causes tissue trauma that may be unacceptable. Therefore, nasotracheal catheters are frequently used for measuring tracheal static pressures.[40] These catheters are constructed using polyethylene tubing with a series of side ports created for pressure measurement.[40] The catheter is then connected to a differential pressure transducer (Model DP/45, Validyne, Northridge, CA) and recordings can be made on chart recorders or computers capable of recording respiratory function measurements.

Airflow can be measured qualitatively or quantitatively. Qualitative measurement can be performed using temperature sensors.[43] Temperature sensors, such as thermisters can be placed at the nostril or within the trachea. Respiratory rate and respiratory:stride coupling can be assessed, but quantitation of the airflow is not possible. Facemask systems are used to quan-

titate airflow measurements.[43,44] The facemask must cover the horse's nose and mouth, be airtight, and allow for unimpeded nostril dilation. In addition, the mask should be light enough and comfortable for the horse to wear while running. Pneumotachographs are instruments used to measure instantaneous rate of volume flow of respired gas.[43,44] Briefly, the pneumotachograph is attached to the end of the facemask and as the horse breathes through the pneumotachograph, it creates a resistance to airflow. The pneumotachograph is calibrated prior to the experiment using a rotameter such that a given pressure, measured using a pressure transducer, is proportional to the airflow. Therefore, the difference in pressure measured across the pneumotachograph is proportional to the airflow rate. A pneumotachograph facemask system imposes added resistance to airflow, and may alter upper airway pressures, respiratory frequency, ventilation, and respiratory pattern in exercising horses.[45,46] Alternatively, quantitative airflow measurements can be made by ultrasonic flow determination, using ultrasonic pneumotachometers.[43] These flow meters impose low resistance and have a high frequency response, but are prone to baseline drift.[43]

Pressure and airflow can be recorded on chart recorders or computers, allowing calculation of various indices that describe the patterns of the airflow. Peak inspiratory and expiratory pressures and flows are determined by measuring from baseline to the peak of the curve. Impedance (Z) is calculated by dividing peak pressure by peak flow. Tidal volume (V_T) can be determined by measuring the area under the airflow curve during exhalation. Respiratory frequency (f_R) is determined by counting the number of breaths per minute. Minute ventilation ($\dot{V}_E$) is the product of respiratory frequency and tidal volume. Respiratory timing can also be determined by measuring the inspiratory time (T_I) and expiratory time (T_E) for each breath.[10]

Tidal breathing flow volume loops can be constructed by plotting airflow and tidal volume. Indices used to describe the loop and the pattern of breathing include peak inspiratory and expiratory flow, and inspiratory and expiratory flows at various tidal volumes, including 50, 25, and 12.5% of tidal volume.[38] Tidal breathing flow volume loop analysis is a very sensitive method for detecting airway obstruction in exercising horses because airflows are so high.[38] Pressure volume curves can also be constructing by plotting pressure and volume. Work of breathing can then be calculated by determining the area under the pressure volume curve.[10]

Sound analysis or spectrum analysis of respiratory sounds has been used to help identify the source of specific airway obstructive diseases and to evaluate the effect of various surgical procedures on airway noise. Respiratory sounds can be recorded using a dynamic, unidirectional microphone positioned in front of the horse's nose.[39] Recordings can be made while the horse exercises freely or on a treadmill. The respiratory sounds are then analyzed using a computer-based spectrum analysis program (Spectrogram version 6.0 (shareware), available at: http://www.monumental.com/rshorne/gram.html). Spectrograms of horses with laryngeal hemiplegia and dorsal displacement of the soft palate have been described.[39]

Electromyographic measurements of muscles can be made using unipolar or bipolar fine wire or surface electrodes, if the muscle is superficial. Electromyography provides information about the timing of muscle activity and relative increases and decreases in electrical activity, but does not provide information about muscle lengthening or shortening.[47] Sonomicrometry can be used to assess muscle lengthening and shortening.[48]

Muscular anatomy and function of the upper airway

The nose

The horse's nose includes the paired external nares, the nasal cavities, and the paranasal sinuses. The nostril has two compartments: a dorsal blind sac called the nasal diverticulum and the ventral part, which is the true nostril.[49] The alar fold divides the nostril into the dorsal and ventral parts. The nasal cavity is divided in half by the nasal septum and vomer bone. Each nasal cavity has a dorsal and ventral nasal concha, which divide the cavity into dorsal, ventral, middle, and common meatus (Fig. 26.4).[49] The ethmoid turbinates project from the ethmoid bone in the caudal part of the nasal cavity (Fig. 26.5). The nasal valve is the narrowest point in the nasal cavity and, thus, is a major contributor to nasal resistance.[1] This region is caudal to each nostril and immediately rostral to the nasoincisive notch within the dorsal meatus. It is bound medially by the nasal septum, ventrally by the concha, and dorsolaterally by the skin and dorsal conchal fold (Fig. 26.6).[49] Expansion of the nasal valve during exercise occurs by constriction of capacitance vessels and contraction of

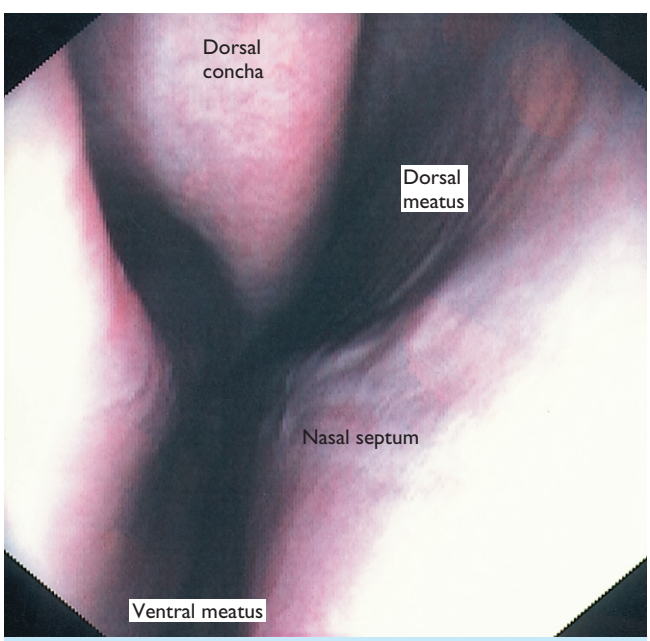

Fig. 26.4

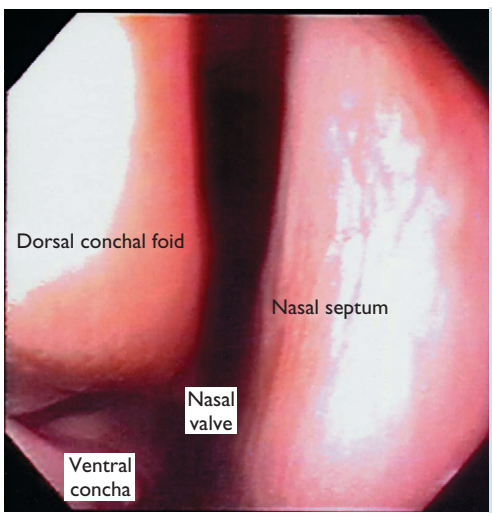

Fig. 26.6 Endoscopic image of the nasal valve region.

muscles that pull the skin taut at the dorsal aspect of the notch. The respiratory portion of the nasal cavity has a vascular submucosa, which contains a rich vascular plexus. This plexus is concentrated on the ventral portion of the nasal septum and ventral meatus and is important for warming and humidifying air. The capacitance blood vessels in the airways, especially those lining the nasal mucosa, are innervated by sympathetic, parasympathetic, and peptidergic systems that regulate blood flow.[50] This extensive vasculature is responsible for warming and humidifying inspired air. When these vessels are dilated, the sinuses and nasal passages become engorged with blood, resulting in airway narrowing and increased airway resistance. Such nasal congestion is a cause of airway obstruction and poor performance in horses with Horner's syndrome. During exercise, sympathetic stimulation causes vasoconstriction, increasing airway dimensions and decreasing resistance to airflow.[50]

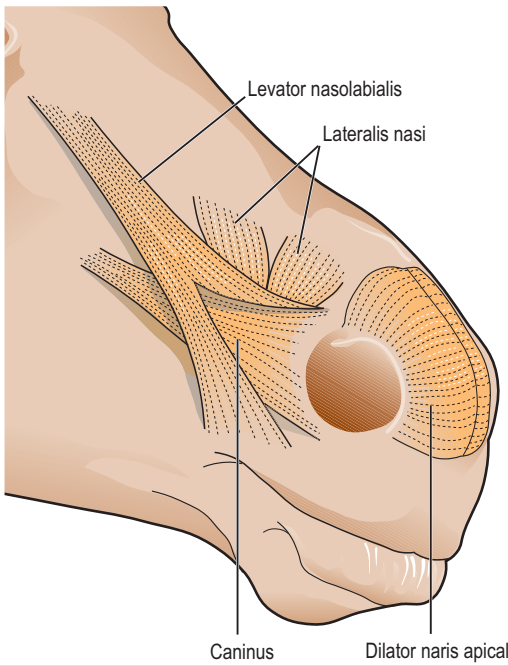

Fig. 26.7 Illustration of the dilating muscles of the nares.

In obligate nasal breathers such as the horse, increasing nasal patency during exercise is critical to minimizing work of breathing. At rest, the horse's nostril is shaped like a comma, but as the horse increases its respiratory effort the nostril dilates and becomes circular in shape. Horses can actually decrease their nasal resistance during exercise by increasing nasal volume and flaring their nostrils. Nostril dilation is accomplished by the contraction of four different muscles (Fig. 26.7).[49] Contraction of the lateralis nasi dilates the nostril, rotates the conchal cartilages laterally, and expands the nasal vestibule, which forms the floor of the nasal valve.[49] Other muscles involved in dilatation of the nostrils include the caninus, dilator naris apicales, and levator nasolabialis. Contraction of the caninus or dilator naris lateralis muscle helps expand the lateral aspect of the nostrils.[49] Dilator naris apicales is an unpaired muscle that lies between the nostrils and aids in dilatation of the nostrils.[49] Levator nasolabialis dilates the nostrils and also elevates the maxillary lip and commissures.[49] Horses with dysfunction, weakness, or lack of contraction of one or more of these muscles will likely have dynamic nasal obstruction that may limit performance.

The nasopharynx

The nasopharynx is a musculomembranous unit that functions during breathing, deglutition, and vocalization and connects the nasal cavity to the larynx. It is attached to the pterygoid, palatine, and hyoid bone, and to the arytenoid, cricoid, and thyroid cartilages by nasopharyngeal muscles that cause pharyngeal dilation and constriction.[51] The nasopharynx is not directly supported by cartilage or bone, yet contraction of these pharyngeal muscles allows the nasopharynx to withstand large

changes in intraluminal pressures that occur during tidal breathing at rest and during exercise. Such activation of these muscle groups is synchronous with breathing and this synchronization is coordinated by multiple stimuli.[17,27] These same muscles are also important during deglutition. This dichotomy of action, contracting the pharyngeal walls during swallowing and dilating the airway during breathing, seems contradictory. But these muscles are uniquely situated to perform both activities, because the pharynx is a conduit for both food and air. Muscles responsible for altering the size and configuration of the nasopharynx include the muscles that alter the shape and position of the tongue, the muscles that control the position of the hyoid apparatus, a constrictor group of muscles located in the dorsal pharynx, and a group of muscles that regulate the position of the soft palate.

Soft palate

The soft palate completely divides the pharynx into nasal and oral compartments in the horse. Because the horse is an obligate nasal breather, it is critically important that the soft palate remains ventral to the epiglottis, except during swallowing, to allow unimpeded nasal breathing. The soft palate extends caudally from the hard palate to the base of the larynx and consists of the oral mucous membrane, which contains ductile openings of the palatine glands, the palatine glands, the palatine aponeurosis, palatinus and palatopharyngeus muscles, and the nasopharyngeal mucous membrane.[51] The caudal free margin of the soft palate continues dorsally, on either side of the larynx, forming the lateral pillars of the soft palate. These pillars unite dorsally, forming the posterior pillar of the soft palate or the palatopharyngeal arch.

The position of the soft palate is determined by the coordinated activity of groups of antagonistic muscles which include the levator veli palatini, tensor veli palatini, palatinus, and palatopharyngeus muscles (Fig. 26.8).[52,53] The *levator veli palatini* muscle attaches to the petrous part of the temporal bone and the lateral lamina of the guttural pouch. It travels along the lateral wall of the nasopharynx and terminates within the soft palate. A branch of the pharyngeal branch of the vagus nerve innervates this muscle.[51] It acts to elevate the soft palate during swallowing and vocalization. The action of the levator veli palatini muscle can be seen during endoscopic examination of the upper airway when the gag reflex is stimulated (Fig. 26.9). A 'sling' forms within the nasopharynx as the nasopharynx contracts into a sphincter.

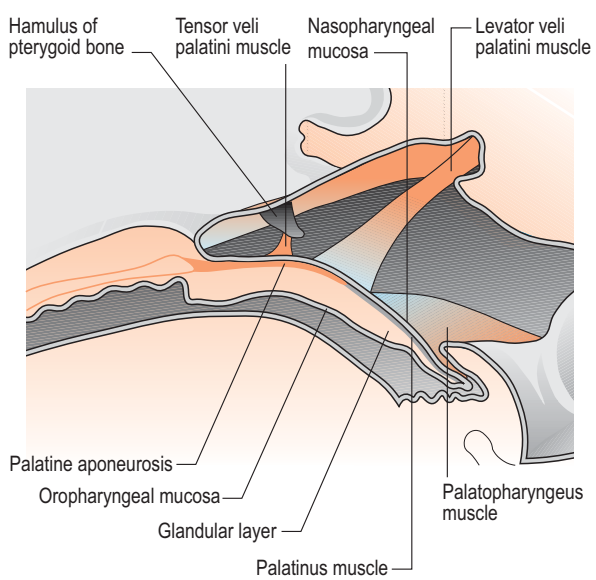

Fig. 26.8
Illustration of the muscles of the soft palate.

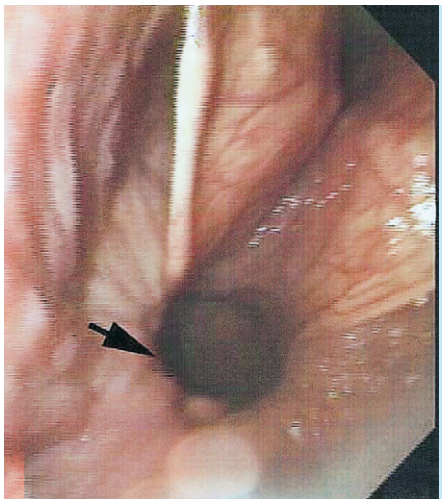

Fig. 26.9
Endoscopic image of the nasopharynx during a 'gag' reflex. Notice the 'sling' formed by partial contraction of the levator veli palatini muscles (arrow).

The *tensor veli palatini* is a flat, fusiform muscle that, like the levator, attaches to the petrous part of the temporal bone, the pterygoid bones, and the lateral lamina of the guttural pouch.[51] Its tendon is reflected around the hamulus of the pterygoid bone, where it is lubricated by a bursa. The tendon then ramifies in the palatine aponeurosis.[51] It receives motor innervation from the mandibular branch of the trigeminal nerve. Contraction of this muscle tenses the palatine aponeurosis and, therefore, the rostral portion of the soft palate, and depresses this portion of the soft palate toward the tongue.[51–53] Contraction of the tensor veli palatini muscle also aids in opening the pharyngeal opening of the guttural pouch.[54] Bilateral transection of the tendon of the tensor veli palatini muscle in horses causes instability of the rostral portion of the soft palate resulting in inspiratory obstruction during intense exercise (Fig. 26.10A–C).[55] The rostral portion of the soft palate is more compliant and its action dependent on airway pressures, such that during inspiration the rostral portion of the soft palate billows dorsally in the airway and during expiration it is depressed toward the tongue by the positive pressure within the airway.[55]

The *palatinus* muscle (uvula retractor muscle) consists of two fusiform muscles that lie on either side of midline of the soft palate, beneath the nasopharyngeal mucosa, extending caudally from the hard palate.[51] The muscles attach to the caudal aspect of the palatine aponeurosis and terminate near the caudal free margin of the soft palate. A small muscle bundle arising from the lateral aspect of each muscle continues a short distance caudodorsally into the palatopharyngeal arch.[51] It receives motor innervation from a branch of the

pharyngeal branch of the vagus nerve.[51] Contraction of the palatinus muscle shortens the soft palate.[51–53]

The *palatopharyngeus* muscle originates from the palatine aponeurosis and the lateral border of the palatinus muscle.[51] It travels caudally along the lateral wall of the nasopharynx to the pharyngeal raphe, forming part of the superior constrictor muscle group. A branch of the pharyngeal branch of the vagus nerve innervates it.[51] Contraction of this muscle shortens the soft palate and draws the larynx and esophagus toward the root of the tongue.

Contraction of both the palatinus and palatopharyngeus muscles shortens the soft palate and depresses the caudal portion toward the tongue.[52,53,56] Both the palatinus and palatopharyngeus muscles receive efferent motor innervation from the pharyngeal branch of the vagus nerve.[51] This nerve branches from the parent vagus nerve at the level of the cranial cervical ganglion and courses cranioventrally along the medial wall of the guttural pouch to the dorsal wall of the pharynx where it ramifies in the pharyngeal plexus. Bilateral local anesthesia of the pharyngeal branches of the vagus nerve induced persistent dorsal displacement of the soft palate and dysphasia in horses.[57] Horses can become dysphasic, with or without persistent soft palate dysfunction, following guttural pouch lavage with caustic solutions, guttural pouch empyema, trauma, or mycosis.[58,59] Based on this information, there was convincing evidence to suggest that dysfunction of the neuromuscular group, including the pharyngeal branch of the vagus nerve, palatinus and palatopharyngeus muscles, might be involved in the pathogenesis of intermittent dorsal displacement of the soft palate in exercising horses.

Electromyographic measurements of the palatinus and palatopharyngeus muscles in normal horses exercising on a treadmill showed that these muscles are active, synchronous with respiration, and their activity increases as exercise intensity and inspiratory pressures increase (Fig. 26.11).[60] Phasic expiratory activity of the palatinus muscles increases 310 ± 67%, whereas phasic expiratory activity of the palatopharyngeus muscles increases 120 ± 30% as the treadmill speed increases from 6 m/s to 13 m/s (or until exhaustion).[60] Palatinus muscle EMG activity is diminished in horses with dorsal displacement of the soft palate and does not significantly increase as treadmill speed increases.[60]

The palatinus muscle is composed of principally type IIA fast twitch fibers (5–25% type I and 75–95% type IIA) with darkly staining mitochondria, which suggests that these fibers have increased endurance relative to most skeletal muscle fast-twitch fibers.[61] The palatopharyngeus muscles are also principally composed of type IIA fibers (10–25% type I and 75–90% type IIA fibers).[61] Pathologic abnormalities are

NADH stained section of the palatinus muscle from a horse with intermittent dorsal displacement of the soft palate. Notice the moth-eaten fibers and areas of increased amounts of connective tissue.

also observed in the palatinus muscle of horses with intermittent dorsal displacement of the soft palate (DDSP). These abnormalities are consistent with chronic denervation and include fiber type grouping, mild atrophy, moth-eaten fibers and target fibers (Fig. 26.12A–D).[61]

Muscles of the hyoid apparatus

The hyoid apparatus in horses consists of an assembly of bony rods, some of which articulate together.[62] Several muscles are attached to this apparatus, and the contraction of theses muscles alters the shape and position of the apparatus, which in turn, changes the position and shape of the larynx and nasopharynx.[63,64] The hyoid apparatus consists of the paired stylohyoid, epihyoid, ceratohyoid, thyrohyoid bones, and the central basihyoid bone (Fig. 26.13). The stylohyoid bone articulates with the petrous part of the temporal bone, allowing the stylohyoid bones to move cranial to caudal, in a pendulous manner. The ceratohyoid bone attaches to the distal end of the stylohyoid bone (by way of the epihyoid bone), and movement at this articulation lengthens the stylohyoid–ceratohyoid unit (Fig. 26.14). The base or root of the tongue is attached to the lingual process of the basihyoid bone. The tongue is located on the floor of the mouth between the rami of the mandible. The base of the tongue is attached to the hyoid apparatus, soft palate, and pharynx.[51] Folds of mucous membrane pass dorsally on either side of the base of the tongue to form the palatoglossal arches, which attach the tongue to the soft palate.[51] The genioglossus, hyoglossus, and styloglossus muscles are extrinsic muscles of the tongue that, in part, control the position and function of the tongue and provide attachments to the hyoid apparatus.[51]

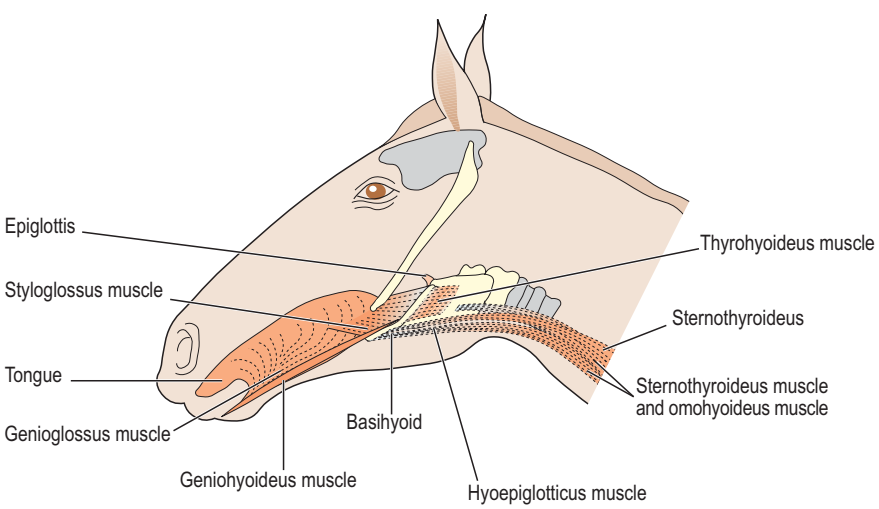

Fig. 26.13
Illustration of some of the muscles that control nasopharyngeal function.

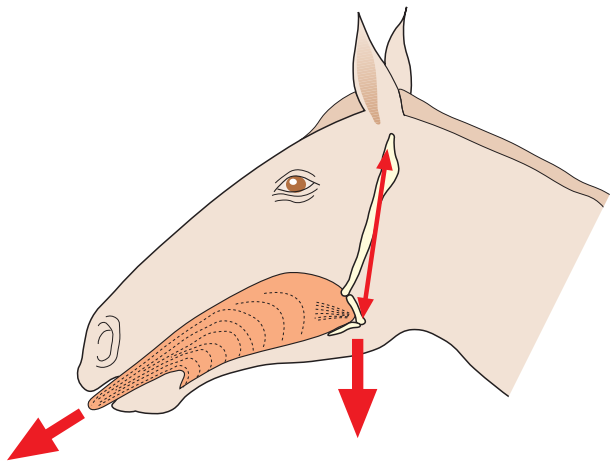

Fig. 26.14
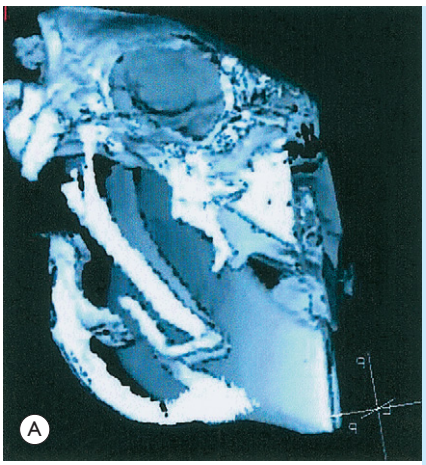
Illustration showing the effect of various muscles on hyoid length and position.



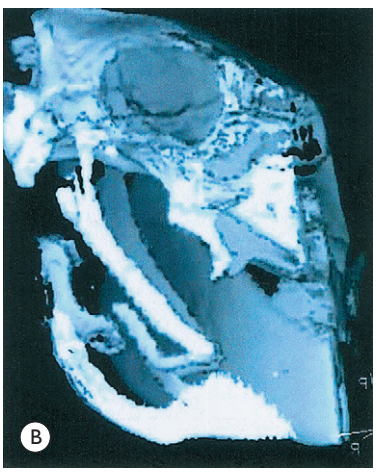


Fig. 26.15
(A) Computed tomographic image of the hyoid apparatus of a horse with its tongue tied out of its mouth under general anesthesia. (B) Computed tomographic image of the hyoid apparatus of a horse under general anesthesia with the tongue in a neutral position.

The genioglossus is a fan-shaped muscle that lies within and parallel to the median plane of the tongue.[51] The genioglossus muscle originates from the medial surface of the mandible, just caudal to the symphysis, and is innervated by the medial branch of the hypoglossal nerve.[51] A large tendon runs throughout the muscle. Muscle fibers radiate rostrally toward the tip of the tongue, dorsally, and distally toward the root of the tongue. The hyoglossus is a flat wide muscle that lies in the lateral portion of the root of the tongue.[51] The hyoglossus originates from the lateral aspect of the basihyoid bone and from portions of the stylohyoid and thyrohyoid bones and is innervated by the lateral branch of the hypoglossal nerve.[51] The styloglossus muscle originates at the distal lateral aspect of the stylohyoid bone and travels the length of the tongue, along its lateral aspect.[51] Near the tip of the tongue the paired muscle meets and ramifies with fibers of intrinsic tongue muscles. Styloglossus contraction retracts the tongue. Contraction of the genioglossus muscle protracts the tongue and pulls the basihyoid bone rostrally. Genioglossus also acts with the hyoglossus muscle to depress and retract the tongue. Hyoglossus and genioglossus activity are synchronous with respiration and activity of these muscles correlates well with increases in pharyngeal airway size during breathing.[63–68] Hypoxia, hypercapnia, and airway occlusion caused parallel increases in electrical activity of the protrudor and retractor muscle of the tongue, consistently inducing net retraction and depression of the tongue, improved airflow function and enhanced pharyngeal stability.[64,65] Therefore, it seems that tongue depression may be the critical force needed to dilate and stabilize the nasopharynx.

Many horses perform or race with their tongues tied to the mandible or out of the mouth to stop the horse from getting the tongue over the bit, and in an attempt to improve performance, decrease airway noise, and improve airway function. Tying the tongue out of the horse's mouth does not influence the position of the hyoid apparatus or dimensions of the nasopharynx in anesthetized horses (Fig. 26.15A,B).[69,70] In addition, application of a tongue-tie does not alter airway mechanics in normal, exercising horses, suggesting that application of a tongue-tie does not improve upper airway function or alter position of the hyoid apparatus in normal horses.[69,70] The passive action of pulling the tongue out of the horse's mouth is very different from active muscle contraction. Also, the tongue-tie may cause protrusion of the tongue but not depression of the tongue, and depression of the tongue may indeed be the critical action of the extrinsic tongue muscles that creates upper airway stability and dilation.

Other muscles that attach to the hyoid apparatus include the geniohyoideus, sternohyoideus and sternothyroideus, omohyoideus, and thyrohyoideus. The geniohyoideus muscle is a fusiform, paired muscle that lies on the ventral surface of the tongue.[71] The geniohyoideus originates from the medial surface of the mandible (near the genioglossus' origin) caudal to the symphysis and inserts on the basihyoid bone. The hypoglossal nerve innervates it, and its action is thought to move the hyoid bone rostrally.[71] The omohyoideus, sternohyoideus and sternothyroideus muscles are accessory respiratory muscles that insert on the manubrium and extend cranially. The sternothyroideus inserts on the caudal abaxial aspect of the thyroid cartilage, and the sternohyoideus inserts on the basihyoid bone and the lingual process of the hyoid apparatus. Contraction of these muscles results in caudal traction of the hyoid apparatus and larynx, resulting in dila-

tion of the upper airway.[71] These muscles are innervated by branches of the first and second cervical nerves.[71] Both the sternothyroideus and sternohyoideus muscles are sometimes transected as palliative therapy for horses with dorsal displacement of the soft palate. Following myectomy, translaryngeal and tracheal inspiratory pressures and resistance measurements increase, suggesting that these muscles may act to dilate and stabilize the nasopharynx in normal horses.[72] The effects of myectomy on airway mechanics in horses with upper airway obstructive disease are yet unknown. The omohyoideus muscles originate on the subscapular fascia near the shoulder joint and also insert on the basihyoid bone and the lingual process of the hyoid apparatus. Contraction of these muscles results in caudal traction of the hyoid apparatus and tongue movement other than retraction.[73] The omohyoideus muscles are innervated by branches of the first and second cervical nerves. The omohyoideus muscles have also been transected for treatment of soft palate displacement in conjunction with the sternohyoideus and sternothyroideus muscles but no experimental data exist to investigate the result of omohyoid transection alone or in conjunction with the sternohyoideus and sternothyroideus muscles in horses during exercise.[74]

The *thyrohyoideus* is a flat rectangular muscle attached to the lateral surface of the thyroid cartilage lamina that inserts on the caudal part of the thyrohyoid bone.[71] It is innervated by the hypoglossal nerve and moves the hyoid bone caudally or the larynx rostrally and dorsally.[71] In studies evaluating the electromyographic activity of some 'extrinsic' nasopharyngeal muscles during exercise, Ducharme and co-workers observed decreased thyrohyoideus muscle activity prior to soft palate displacement in one horse. Investigations by Tsukroff et al[75] reveal that transection of a combination of the following muscles results in dorsal displacement of the soft palate in horses: thyrohyoideus, omohyoideus, sternohyoideus and hyoepiglotticus muscles.[75] The displacement observed was associated with a more caudal positioning of the basihyoid bone. In subsequent studies thyrohyoideus muscle resection caused intermittent dorsal displacement of the soft palate in exercising horses.[76] As well, thyrohyoideus muscle prosthesis, created by placing a suture through the basihyoid bone and the thyroid cartilage, alleviates dorsal displacement of the soft palate.[76] These data clearly suggest that thyrohyoideus muscle dysfunction is the likely etiology of intermittent dorsal displacement of the soft palate in horses.

Dorsal pharyngeal constrictors

The action of the dorsal pharyngeal constricting muscles and the stylopharyngeus muscle is responsible for stiffening and dilating the nasopharynx.[77–80] The inferior pharyngeal constrictor (thyropharyngeus muscle), middle pharyngeal constrictor (hyopharyngeus muscle), and superior pharyngeal constrictor (palatopharyngeus and pterygopharyngeus muscles) form the dorsal and caudolateral pharyngeal walls.[78,79] Contraction and shortening of these muscles forms a sphincter, moving the food bolus caudal into the esophagus during swallowing. During breathing, these muscles have tonic and phasic expiratory activities, which helps to support the nasopharynx.[79,80] The major dilating muscle of the dorsal nasopharynx is the stylopharyngeus muscle.[79] This muscle originates on the axial aspect of the distal portion of the stylohyoid bone and courses rostroventrally to ramify in the wall of the dorsal nasopharynx, by passing between the pterygopharyngeus and palatopharyngeus muscles (Fig. 26.16A,B). Contraction of the stylopharyngeus muscles pulls the pharyngeal wall dorsally, to receive the bolus during swallowing.[81] In a similar manner, during breathing, contraction of the stylopharyngeus muscle pulls the nasopharyngeal wall dorsally, thereby supporting the dorsal wall of the nasopharynx and preventing dynamic collapse of this area during inspiration.[82] The glossopharyngeal nerve provides motor innervation to the stylopharyngeus muscle.[81] Bilateral glossopharyngeal nerve anesthesia produces stylopharyngeus muscle dysfunction, dorsal pharyngeal collapse both during nasal occlusion and exercise, and airway obstruction in horses (Fig. 26.17A,B).[83] Therefore, the stylopharyngeus muscle is an important nasopharyngeal dilating muscle in horses and dysfunction of this muscle may be implicated in clinical cases of dorsal nasopharyngeal collapse.[83]

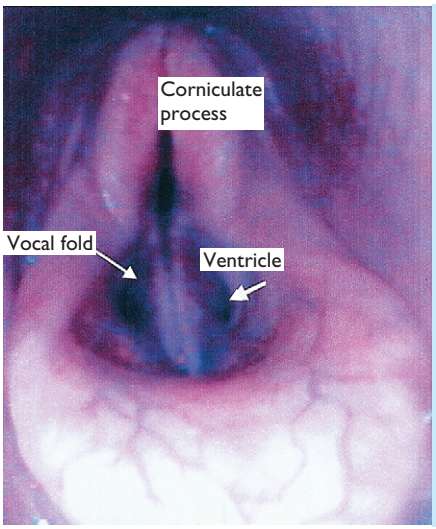

Fig. 26.18 Endoscopic image of the larynx during adduction.

The larynx

The larynx forms the communicating channel between the pharynx and the trachea and functions during breathing, vocalization, and deglutition. The larynx is composed of cartilage and muscle and is covered with a mucous membrane. The laryngeal cartilages include the cricoid, thyroid, and epiglottic cartilages, which are unpaired, and the arytenoid cartilages, which are paired.[84] The cricoid cartilage is shaped like a signet ring and is positioned rostral to the first tracheal ring and connected to the trachea by the cricotracheal membrane. The thyroid cartilage is the largest of the laryngeal cartilages and is situated just rostral to the cricoid cartilage.[84] The arytenoid cartilages form the dorsal border of the rima glottidis. They are triangular in shape with a dorsal muscular process, which serves as the origin for the cricoarytenoideus dorsalis muscle, a ventral vocal process serving as the attachment of the vocal ligament, and the rostral apex which forms the corniculate process.[84] The arytenoid cartilages are positioned on either side of the cricoid cartilage and are connected to it by the cricoarytenoid articulations. The articulation is a diarthrodial joint that allows the arytenoid cartilage to rotate dorsolaterally during abduction and axially during adduction.[84] The mucous membrane covering the epiglottic cartilage reflects off the lateral border of the epiglottis and blends with the mucous membrane covering the corniculate processes of the arytenoid cartilages, forming the aryepiglottic folds. The mucous membrane covers the vocal ligament, forms the vocal folds, and lines the lateral ventricles, forming the laryngeal saccules (Fig. 26.18). These saccules are 2.5 cm deep with a capacity of 5 to 6 ml. They extend between the medial surface of the thyroid cartilage and the ventricularis and vocalis muscles.

The intrinsic laryngeal muscles produce changes in caliber of the rima glottidis by abducting and adducting the corniculate processes of the arytenoid cartilages and the vocal folds and hence altering airway resistance. These actions are accomplished by the contractions of the intrinsic laryngeal muscles. The cricoarytenoideus dorsalis is the principal abductor muscle that widens the laryngeal aperture by abducting the corniculate process of the arytenoid cartilage and tensing the vocal folds. The thyroarytenoideus, arytenoideus transversus, and the cricoarytenoideus lateralis muscles adduct the corniculate processes of the arytenoid cartilages, narrowing the rima glottidis and protecting the lower airway during swallowing.[84] The cricothyroideus muscle receives efferent motor innervation from the external branch of the superior laryngeal nerve, a branch of the vagus nerve, while all other intrinsic laryngeal muscles receive motor innervation from the recurrent laryngeal nerve, which is also a branch of the vagus nerve.[84] Crushing or transection of the left recurrent laryngeal nerve, or perineural anesthesia of the left recurrent laryngeal nerve, results in grade IV laryngeal hemiplegia in horses.[85] However, following experimental crush of the left recurrent laryngeal nerve in ponies, reinnervation of some intrinsic laryngeal muscles is evident.[85] In ponies, recovery of movement of the vocal folds occurred between 2.5 and 8 months, following recurrent laryngeal nerve crush.[85] Electromyographic examinations of the laryngeal muscles and microscopic evaluation of the muscles and the recurrent larygneal nerve reveal that return of function is due to reinnervation.[85] At times, there is evidence of aberrant reinnervation in abductor and adductor muscles.[85]

The epiglottis is principally composed of elastic cartilage and rests on the dorsal surface of the body of the thyroid cartilage and is held there by the thyroepiglottic ligaments. The position of the epiglottis is controlled by the position of the larynx, and hyoid apparatus, and by contraction of the hyoepiglotticus muscle, which is the only muscle that attaches to the epiglottis.[84] The hyoepiglotticus is a bilobed extrinsic laryngeal muscle that originates on the basihyoid bone in horses, and inserts on the ventral body of the epiglottis.[84] In horses, contraction of the hyoepiglotticus muscle pulls the epiglottis toward the basihyoid bone, depressing it against the soft palate, enlarging the airway.[28] The hyoepiglotticus muscle has respiratory-related electromyographic activity in horses that increases with exercise intensity and breathing effort.[28] Furthermore, electrical stimulation of the hyoepiglotticus muscle depresses the epiglottis ventrally against the soft palate, changing the conformation of the epiglottis in some horses (Fig. 26.19A,B).[28] The hyoepiglotticus muscle is likely an upper airway dilating muscle, which functions to enlarge the airway, thereby decreasing airway resistance in exercising horses. In addition to dilating the aditus laryngis, contraction of the hyoepiglotticus muscle stabilizes the epiglottis during inspiration, preventing its prolapse through the rima glottidis. Retroversion of the epiglottis is described clinically in exercising horses and can be created experimentally by anesthesia of the hypoglossal nerves.[86,87] Blockade of these nerves creates hyoepiglotticus dysfunction, and dysfunction of other hyoid muscles including geniohyoideus and genioglossus, and suggests that the clinical problem may be due to paresis of the hyoepiglotticus muscle or other muscles involved in controlling the position of the basihyoid. Active control of epiglottis position by the hyoepiglotticus muscle apparently stabilizes the epiglottis and vigorous recruitment of the muscle activity during inhalation dilates the airway and maintains the nasal breathing route in horses during intense exercise. Conformational changes in the epiglottis that occur during exercise, respiratory stimulation, sedation, or nasal occlusion may not be abnormal, but may be the result of normal activity of the hyoepiglotticus muscle.

Guttural pouches

Physiology

The guttural pouch, or diverticulum of the auditory tube, is unique to the horse and other Perissodactyla. Each pouch has a volume of 300 to 500 mL and communicates with the nasopharynx through the pharyngeal opening of the auditory tube. The guttural pouch is lined with a thin mucous membrane composed of pseudostratified, ciliated epithelium interspersed with goblet cells.[88] Mucous glands and lymphatic nodules are found deep to the epithelial layer. Various immunoglobulin isotypes, including IgGa, IgM, and IgA, have been detected in the guttural pouch mucosa, submucosa, and lymph nodules, suggesting that the guttural pouch has phylactic ability.[89]

Recently, investigators determined that the equine guttural pouches function during selective brain-cooling to maintain blood carried by the internal carotid arteries at a temperature below the core body temperature during hyperthermia, induced by exercise.[88] Blood is supplied to the brain, principally, by the internal carotid arteries, with contributions from the cerebral and occipital arteries. The extracranial portion of the internal carotid artery travels through the medial compartment of the guttural pouch. The temperature of the air within the guttural pouch was fairly constant (37.5 ± 0.05°C) during exercise, and was responsible for cooling the blood within the internal carotid artery by 2°C.[88] The heat transfer from the internal carotid artery to the guttural pouch was minimal at rest but became more efficient with exercise.[88] Therefore, the function of the guttural pouches in the horse seems to be to cool the brain during periods of hyperthermia.[89]

Because of the position of the nasopharyngeal openings of the guttural pouches, changes in nasopharyngeal pressures during inspiration and expiration also affect pressures within the guttural pouches.[90] When airflow through the nasopharynx is 0 L/s the pressure within the guttural pouches is negative, similar to measurements made in the middle ear of humans.[90] After swallowing the nasopharyngeal aperture opens and pressures within the guttural pouches equilibrate with the nasopharynx. Both at rest and during exercise the guttural pouch static pressures are similar to

nasopharyngeal pressures, but slightly out of phase with the respiratory cycle.[90] Movement of the head, chewing, snorting, or swallowing causes changes in pressures simultaneously in both guttural pouches. Therefore, the elevated compliance of the guttural pouch makes it susceptible to pressure changes in the nasopharynx associated with airflow but also with head movement.[90]

Anatomy

The openings of the guttural pouches are within the nasopharynx. The floor of the pouches forms the dorsal aspect of the nasopharynx, and the caudal extent of the guttural pouch is at the level of the parotid salivary glands. The guttural pouches are bordered dorsally by the base of the skull and the atlas, ventrally by the nasopharynx and rostral esophagus, medially by the longus capitis muscle, the rectus capitis ventralis muscle and the median septum, and laterally by many blood vessels and muscles, including the digastric muscles. Retropharyngeal lymph nodes can be identified beneath the guttural pouch membrane on the floor of the medial compartment (Fig. 26.20).

The guttural pouch is divided into medial and lateral compartments by the stylohyoid bone. The caudal portion of the stylohyoid bone articulates with the petrous temporal bone at the base of the skull (Fig. 26.21). Cranial nerves VII (facial) and VIII (vestibulocochlear) exit the cranium near this articulation. The opening from the middle ear into the guttural pouch is with the dorsolateral compartment, near the articulation of the stylohyoid and petrous temporal bones. The medial compartment is approximately twice as large as the lateral compartment and cranial nerves IX (glossopharyngeal), X (vagus), XI (accessory), and XII (hypoglossal), the sympathetic trunk, the cranial cervical ganglion, and the internal carotid artery lie beneath the lining of the medial compartment (Figs 26.22 and 26.23). Cranial nerve X, the sympathetic trunk, and the cranial cervical ganglion are

closely associated with the internal carotid artery. The pharyngeal branch of X is given off near the cranial cervical ganglion and can be seen as it runs rostroventrally in the guttural pouch toward the wall of the dorsal pharynx, where it ramifies with the pharyngeal branch of IX in the pharyngeal plexus. The pharyngeal branch of IX can be identified as it runs rostrally across the ventral aspect of the stylohyoid bone (Fig. 26.24). The maxillary artery is a continuation of the external carotid artery, beyond the origin of the superficial temporal artery, and runs dorsally in the lateral compartment of the guttural pouch. The maxillary vein can be seen lateral to and slightly deep to the external carotid artery. A portion of the digastric muscle can be seen along the ventrolateral wall of the lateral compartment (Fig. 26.25). The levator veli palatini and the tensor veli palatini muscles arise, partially, from the lateral lamina of the auditory tube, and

CHAPTER 27

Abnormalities of the upper airway

Susan J. Holcombe and Norm G. Ducharme

Upper airway obstructive diseases can limit athletic performance by decreasing minute ventilation, exacerbating exercise-induced hypoxemia, decreasing maximal oxygen consumption and increasing airway resistance. Such lesions can be dynamic and only apparent during exercise, or static and evident at rest. In concert with a complete history, signalment, and physical examination, endoscopic examination of the upper airway, both at rest and during treadmill exercise, will establish the etiology of the airway obstruction. In addition, imaging modalities such as radiography, ultrasonography, computed tomography, sound analysis, and nuclear medicine can be valuable in diagnosing performance-limiting lesions of the upper airway.

Redundant alar folds (alar fold collapse)

- The alar fold is formed by a thick fold of skin and mucous membrane extending rostrad from the ventral nasal concha.[1]
- Redundant alar folds are an uncommon cause of exercise intolerance and respiratory noise in performance horses.[2,3]
- The diagnosis is made by securing the alar folds dorsally to document decreased respiratory noise and improved exercise intolerance.[2]
- Treatment includes tying the alar folds out of the airway during exercise or alar fold resection.[2,3]

Recognition

History and presenting complaint

Most horses with redundant alar folds make an expiratory fluttering noise during exercise and may be exercise intolerant. Horses exhibit no clinical signs at rest.[2]

Physical examination

No abnormalities are apparent at rest.

Special examination

Other causes of respiratory noise and exercise intolerance should be eliminated by performing an endoscopic examination of the upper airway and evaluating both nasal passages. Confirmation that redundant alar folds are the cause of the airway noise is made by placing a temporary suture through the skin of each nostril, the alar folds, and tying it over the bridge of the nose while the horse exercises (Fig. 27.1).[2] The alar folds may also be held out of the nasal passage manually or with clips. Alleviation of the upper airway noise suggests that redundant alar folds are the cause.[2]

Fig. 27.1
The nose of a horse with rings through the alar folds. The string is used to tie the rings together, pulling the alar fold out of the airway.

Laboratory examination

None is indicated.

Diagnostic confirmation

Absence of noise and improved exercise tolerance during exercise with the alar folds secured out of the nasal passage confirms the diagnosis.[2,3] Differential diagnoses for alar fold collapse include obstructive airway diseases that cause exercise intolerance and abnormal respiratory noise during exercise (Table 27.1).

Treatment and prognosis

Therapeutic aims

The goal of treatment is to remove or secure the alar folds during exercise. The alar folds can be tied out of the airway during exercise or surgically resected.

Therapy

The horse is anesthetized and placed in lateral or dorsal recumbency. The alar fold is exposed by dilating the nostril or incising the lateral ala of the external naris. The alar fold is excised along the lateral margin of the alar cartilage and nasal septum, ending ventral to the ventral concha.[2,3] Usually, 1–2 cm of the cartilaginous portion of the ventral concha is excised. Hemostasis is achieved by placing ligatures and apposing the nasal mucosa and the skin of the nasal diverticulum. If the lateral nasal ala is incised to expose the alar fold, it is closed in two layers.[2,3]

Prognosis

Reportedly, respiratory tract noise improves in 71% of horses following alar fold resection and 88% of horses race after

surgery.[3] Horses with small nares and narrow nasal passages have a poorer prognosis for performance.[2,3]

Prevention

There is no known prevention.

Etiology and pathophysiology

Etiology

The etiology of redundant alar folds is unknown, but may involve narrow nasal passages and inappropriate function of the transversus nasi muscles.

Pathophysiology

A thick fold of skin forms the alar fold and mucous membrane extending rostrad from the ventral nasal concha.[1] The space dorsal to the alar fold is the false nostril or diverticulum of the nostril while the true nostril that continues caudally to the nasal passage is ventral to the alar fold. When the nostril is dilated, the alar fold is tensed, obliterating the nasal diverticulum.[2] Excessive alar fold tissue or inappropriate nostril dilation may cause the alar fold to collapse across the nostril, causing airway obstruction and exercise intolerance during inhalation, and a fluttering noise during exhalation.

Epidemiology

Standardbred horses and American Saddlebreds may be predisposed to this condition.[3]

Mycotic rhinitis

Recognition

History and presenting complaint

Mycotic rhinitis is rare in horses and occurs most frequently in warm, humid climates. The most common clinical signs include nasal discharge that may or may not be foul smelling, sneezing, and intermittent epistaxis.[2,4] Horses with nasal granulomas may make an abnormal respiratory noise during exercise and show signs of exercise intolerance. If the fungal infection is invasive and involves the paranasal sinuses, extension to the brain and meninges can occur, resulting in cerebral signs such as depression, dementia, ataxia, and recumbency.

Physical examination

Horses with mycotic rhinitis generally have nasal discharge that may be malodorous, and if chronic, they may have alopecia along the ventral aspect of the affected naris.[2] If a nasal granuloma is causing airway obstruction, decreased airflow through the affected nostril is detected by holding the hands over each nostril.

Special examination

Endoscopic examination of the affected nasal passage reveals fungal plaques or granulomas affecting the mucocutaneous junction of the nostril, or mucous membrane of the nasal septum and concha.[2,4,5] Ulceration of the mucosa surrounding the plaque or granuloma may also be seen.[5] If the primary site of infection is the paranasal sinus region, exudate at the nasomaxillary opening within the middle meatus may be evident.

Laboratory examination

Laboratory tests are generally not warranted, but if the infection is chronic, hyperfibrinogenemia may be detected.

Diagnostic confirmation

The diagnosis of fungal rhinitis is confirmed by biopsy and culture of the plaque or mass.[2–6] Fungi that have been reported to cause mycotic rhinitis in horses include *Conidiobolus coronatus*, *Cryptococcus*, *Rhinosporidium*, *Aspergillus fumigatus* and *A. boydii*, *Coccidioides*, and *Pseudallescheria*.[2–7] The presence of septate hyphae or fungal mycelium on cytological examination is indicative of fungal infection.

Treatment and prognosis

Therapeutic aims

The goal of therapy is to eradicate the fungus from the nasal passage.

Therapy

Surgical excision of granulomas and topical as well as systemic antifungal therapy are effective in the treatment of mycotic rhinitis.[2] *Aspergillus fumigatus* is sensitive to natamycin solution applied topically.[4] Nystatin can be added to the natamycin and used topically or intralesionally.[4] Oral itraconazole, 3 mg/kg, orally, twice daily, for 3.5 to 4 months also results in the resolution of *Aspergillus* sp. infection.[6] Topical and intralesional injection of amphotericin B and intravenous sodium iodide or oral potassium iodide is used to treat *Conidiobolus coronatus* infection, but recurrence has been reported.[5]

Prognosis

Mycotic rhinitis due to *Aspergillus* sp. resolves with treatment and recurrence is low.[2,4,6] *Conidiobolus coronatus* resolves with surgical and medical treatment, but does recur.[5,6]

Cryptococcus sp. is an invasive fungus that can infect the paranasal sinuses and invade the brain and meninges.[2,7] Because of the aggressive nature of this fungus, the prognosis is generally poor for resolution, unless a single, non-invasive granuloma is excised.[2,7]

Prevention

No method of prevention is known.

Etiology and pathophysiology

Etiology

Fungi isolated from the nasal cavity of affected horses include *Conidiobolus* spp., *Cryptococcus* spp., *Rhinosporidium*, *Aspergillus* spp., *Coccidioides*, and *Pseudallescheria*.[2–7]

Pathophysiology

Inhalation of fungal spores and colonization of the nasal mucosa is the most likely route of infection, resulting in mycotic rhinitis.

Epidemiology

Mycotic rhinitis is rare, but is most commonly seen in hot, humid climates, such as the southeastern USA and tropical areas.

Progressive ethmoid hematoma (PEH)

- Clinical signs include unilateral epistaxis and respiratory stridor.
- Endoscopy of the nasal passage and inspection of the ethmoid region demonstrates ethmoid hematoma.
- The diagnosis is confirmed by histopathology of the mass.
- Most ethmoid hematomas originate at the ethmoid turbinate, but can originate from the paranasal sinuses.
- Treatment options include surgical excision, either sharply or with a laser, or chemical ablation.
- Recurrence is approximately 43%.

Recognition

History and presenting complaint

Horses with progressive ethmoid hematoma (PEH) have unilateral or bilateral epistaxis, respiratory stridor, variable facial deformity depending on the duration of the condition, and decreased airflow through the affected nostril.[8]

Physical examination

Unilateral nasal obstruction may be diagnosed by holding the hands over each nostril and detecting reduced airflow from the affected nostril. Decreased airflow will generally be detected from the nostril with the most nasal discharge. Facial deformity may also be observed as asymmetric convexity of the facial bones, medial and rostral to the orbit.

Special examination

Endoscopic examination of the upper airway, including both nasal passages, is frequently diagnostic for progressive

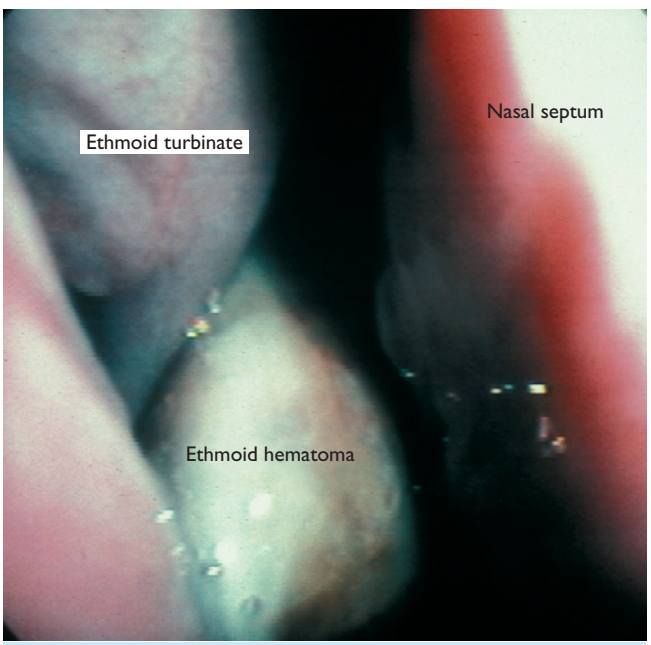

Fig. 27.2
Endoscopic image of an ethmoid hematoma.

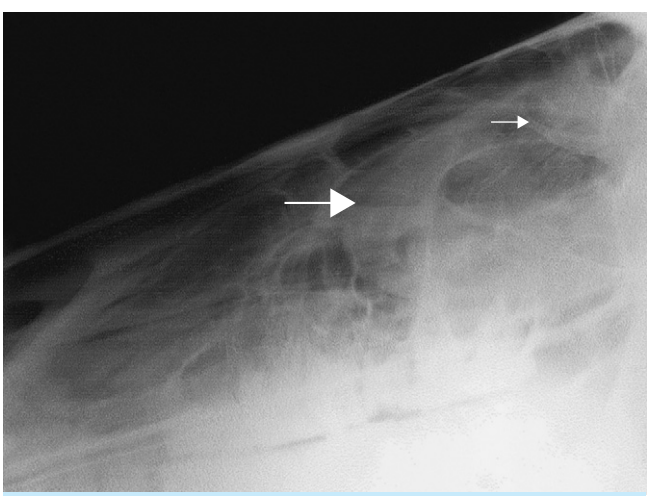

Fig. 27.3
Lateral radiograph of the paranasal sinus region of a horse. The large arrow points to the ethmoid hematoma and the small arrow points to the ethmoid turbinates.

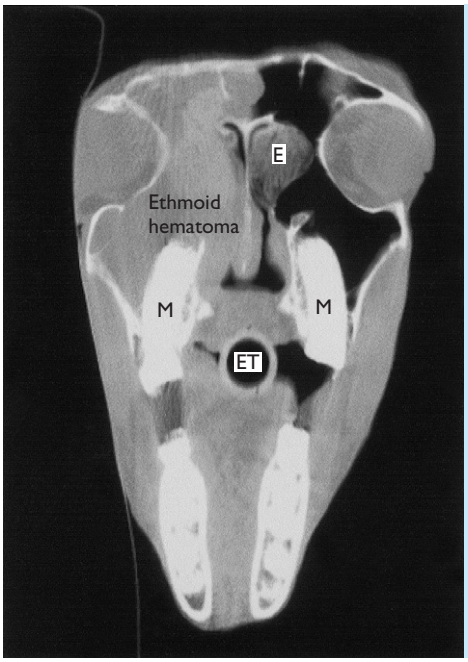

Fig. 27.4 Coronal slice of a computed tomographic image of a horse with an ethmoid hematoma. Notice the left sinus region is occupied by the ethmoid hematoma. E, normal ethmoid turbinate; ET, endotracheal tube; M, molars.

ethmoid hematoma. Ethmoid hematomas originate from the ethmoid turbinate region or paranasal sinuses (Fig. 27.2). The masses are smooth, green to purple in color and may be small and discrete or expansile, invading the entire nasal passage, nasopharynx, or paranasal sinus region.[8,9] If the mass is confined to the maxillary or frontal sinus, serosanguineous fluid will be evident at the nasomaxillary opening, but the mass may be obscured from view.[8,9] Differential diagnoses for progressive ethmoid hematoma include fungal granulomas, neoplasia, and nasal polyps. Biopsy and histopathology is warranted if the etiology of the mass is unknown.

Lateral, dorsoventral, and oblique radiographic projections of the paranasal sinus region are taken to define the anatomic limits of the expansile mass (Fig. 27.3).[10] A discrete, round density overlying the ethmoid labyrinth or within the maxillary or frontal sinus is suggestive of progressive ethmoid hematoma.[10] Fluid lines in the sinuses may be present if secondary sinusitis has occurred. Computed tomography is useful to define the extent of the mass prior to surgical excision (Fig. 27.4).[10]

Laboratory examination

Rarely, horses have evidence of mild, regenerative anemia, though generally blood loss from ethmoid hemotoma is minimal. Depending on the duration, size of the mass, and inflammatory reaction, hyperfibrinogenemia may be present.[11]

Diagnostic confirmation

Differential diagnosis for PEH includes neoplasia, fungal granuloma, nasal polyp, sinus cyst or abscess. Definitive diagnosis is made based on the histopathology of the mass. Ethmoid hematoma is a non-neoplastic angiomatous mass covered by respiratory epithelium and fibrous tissue.[8,9] The parenchyma of the mass is composed of blood, fibrous tissue, hemosiderin laden macrophages, neutrophils and necrotic debris, especially in large, chronic masses, with occasional calcareous deposits.

Treatment and prognosis

Therapeutic aims

The goal of treatment is elimination of the mass. This can be achieved by surgical excision, laser photo ablation, or chemical ablation.[8,9,11,12] Surgical excision of progressive ethmoid hematoma is performed by placing the horse under general anesthesia, in lateral recumbency, with the affected side up.[8,9] Depending upon the location of the mass, a maxillary bone flap or frontal nasal bone flap may be performed to provide access to the maxillary sinuses, or frontal sinuses and nasal cavity, respectively.[8] The mass is resected at its origin by sharp dissection or using Nd:YAG laser.[8,9] Copious hemorrhage is expected and controlled using cold saline and pressure applied with sterile gauze packing. Prior to surgery, it is prudent to have a blood donor available in case blood loss is excessive enough (packed cell volume < 20% following volume resuscitation) to warrant blood transfusion. Photo ablation of the mass using the Nd:YAG laser can be performed in the standing, sedated horse if the mass is accessible via the nasal passage.[9] Treatments are generally performed weekly until the mass has resolved. Alternatively, progressive ethmoid hematomas can be chemically ablated by intralesional injection of formalin.[11,12] In the standing, sedated horse, the mass is injected with 4% formaldehyde or neutral buffered 10% formalin using a transendoscopic 23-gauge retractable needle (Mill-Rose Laboratories, Inc., Mentor, OH) or through an injection apparatus constructed from polyethylene tubing and a 22- or 25-gauge needle.[11,12] The injection apparatus is inserted into the biopsy channel of the endoscope and the mass is injected with formalin until the mass distends.[12] Treatments are repeated every 3–4 weeks until the lesion is obliterated, requiring a mean of 5 treatments, ranging from 1 to 18 treatments.[12]

Complications from surgical excision include severe hemorrhage, chronic sinusitis, surgical site infection, and osteomyelitis of the bone flap.[8] Complications following formalin injection include laminitis, dysphagia, and neurologic disease, if the ethmoid hematoma has eroded through the cribiform plate.[11,12]

Prognosis

Recurrence following surgical excision is 43%, necessitating periodic re-evaluation should the mass recur. Recurrence is slightly higher in horses with bilateral progressive ethmoid hematomas.[8,9,12]

Prevention

There are no known preventive measures.

Etiology and pathophysiology

Etiology

The etiology of PEH is unknown.

Pathophysiology

Progressive ethmoid hematoma is an expanding angiomatis mass originating from the mucosa of the ethmoid conchae or paranasal sinuses. Progressive expansion of the mass occurs due to recurrent hemorrhage and local invasion of tissues. Masses may expand rostroventrally into the nasal passage or nasopharynx, or within the paranasal sinuses.

Epidemiology

Progressive ethmoid hematomas have been reported in horses from 6 months to 20 years old, but are most commonly diagnosed in middle-aged and older horses.[8] Thoroughbred horses are over-represented in case series, though the disease has been reported in many breeds. Bilateral lesions occur 15% of the time.[8]

Sinusitis

- The paranasal sinuses include the frontal, maxillary, sphenopalatine, and dorsal and ventral conchal sinuses.
- Sinusitis can be primary or secondary, and is most commonly associated with dental disease, masses, and trauma.
- Clinical signs of sinusitis include nasal discharge and facial swelling.
- Surgical debridement of the sinus is frequently recommended for treatment of primary or secondary sinusitis.

Recognition

History and presenting complaint

Horses with sinusitis frequently have unilateral or bilateral nasal discharge. If the sinusitis is due to dental disease or fungal infection the discharge may be foul smelling.[13] Horses with primary sinusitis frequently have a history of recent upper respiratory tract infection. If the sinusitis is secondary to a cyst or neoplastic mass, facial swelling and deformity of facial bones may be detected as the mass expands within the sinus.[13,14]

Physical examination

Rarely are horses febrile. Facial swelling may be detected and may be painful to palpation.[13] Deformity of facial bones overlying the sinus may be evident, especially in chronic cases of expansile masses such as sinus cysts and neoplasia.[13,14] Increased respiratory rate and effort is detected if the airway is obstructed. This occurs when the ventral cochal sinus is affected and compresses the ventral meatus.[14] Airflow obstruction may occur if the mass expands into the ventral meatus and is diagnosed by holding the hands over each nostril and detecting reduced airflow from the affected nostril. Epiphora occurs in horses with sinusitis if the nasolacrimal duct is compressed by a mass or swelling in the surrounding tissues.[13] Hair loss may be detected on the horse's face if the epiphora is chronic.

Special examination

Techniques used to diagnose sinusitis include radiography, computed tomography, sinoscopy, endoscopy, and nuclear medicine.[13,14] Generally at least four views of the skull are taken if sinusitis is expected, including the left and right oblique, lateral, and dorsoventral views. The left and right oblique views help to confirm which side of the head is affected. Fluid lines (Fig. 27.5), masses within the sinuses (Fig. 27.6) and periapical tooth root abscessation and abnormal alveolar bone can frequently be detected radiographically. Computed tomography is performed to localize the lesion more accurately in cases of secondary sinusitis. Sinus cysts, dental disease, neoplasia, ethmoid hematoma, mycotic granulomas, polyps, and epidermal inclusion cysts can cause secondary sinusitis and frequently require surgical removal.[13,14] The information gained from the computed tomographic scan aids in surgical planning and the surgical approach. Sinoscopy is performed in the sedated, standing horse by inserting a flexible endoscope or arthroscope through a trephine in the frontal, rostral maxillary, or caudal maxillary sinus.[15] Fluid is aspirated from the sinus and submitted for culture and cytology and the

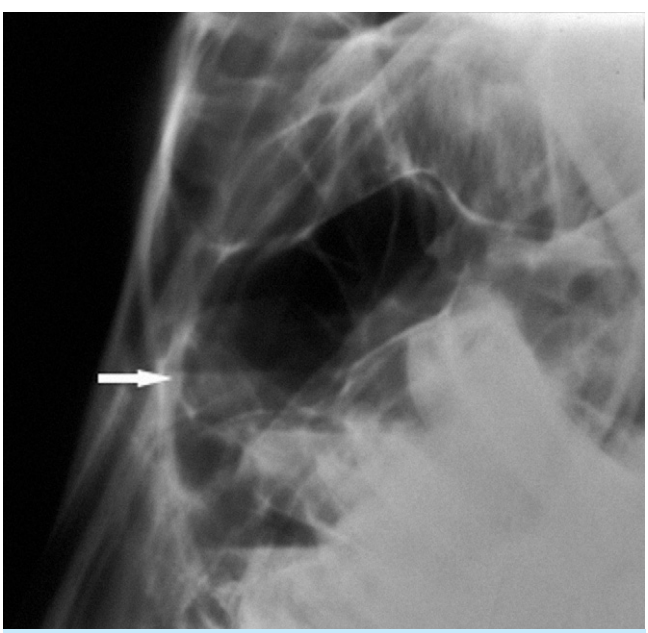

Fig. 27.5

Lateral radiograph of the paranasal sinus region of a horse with a mass (arrow) within the maxillary sinus.

sinus can be irrigated to evacuate exudate. The sinuses can be explored and masses or tooth root abscesses identified and biopsied by use of this technique. Endoscopic examination of the nasal passages is useful in cases of sinusitis to confirm that the exudate is coming from the nasomaxillary opening of the middle meatus. The specific origin of the exudate and inciting cause cannot be determined by endoscopy alone. Nuclear medicine is rarely used in cases of sinusitis, but can be used to confirm infected apical tooth roots. Despite radiography and computed tomography, identifying the affected tooth can at times be difficult. White blood cell scan is performed to help localize the infected tooth because the radiolabeled white blood cells can be imaged surrounding the infected tooth root.

Laboratory examination

The results of laboratory tests on blood are generally normal. Fluid aspirates are submitted for culture and sensitivity.

Diagnostic confirmation

The diagnosis of primary sinusitis is made based on a history of previous upper respiratory tract infection, nasal discharge originating from the paranasal sinus region, evidence of fluid within the sinuses on radiographs or computed tomography, and the absence of a secondary cause of the sinusitis.[13,14] Secondary sinusitis is diagnosed based on the presence of an inciting cause of the sinusitis, such as apical tooth root abscess, sinus cyst, neoplastic mass, ethmoid hematoma, mycotic granuloma, polyp, or trauma and facial bone fracture into the sinus.[13,14] Conformation of the etiology of secondary sinusitis is made by sinoscopy, biopsy, or surgical exploration of the sinus.

Treatment and prognosis

Therapeutic aims

The goal of therapy is to rid the sinus of infection and remove the inciting cause in cases of secondary sinusitis.

Therapy

The results of culture and sensitivity of fluid aspirated from the sinus dictate the appropriate antimicrobial therapy necessary to treat the sinusitis. Because primary sinusitis frequently is a sequela to upper respiratory tract infection, *Streptococcus* spp. are frequently isolated. Penicillin or trimethoprim sulfonamides are appropriate antibiotics to use in the treatment of primary sinusitis, prior to receipt of culture results. In addition to systemic antibiotics, repeated lavage of the sinus with balanced polyionic solution decreases the exudate and dilutes the organisms and inflammatory mediators within the sinus.[13,14] A chronic irrigation system can be placed following sinus centesis. Sinus centesis can be performed at the cranial or caudal maxillary sinus or frontal sinus. A point 2.5–3 cm dorsal to the facial crest and 3 cm rostral to the medial canthus marks the placement for centesis of the caudal maxillary sinus;[14] 2.5–3 cm dorsal to the facial crest and 3 cm caudal to the infraorbital foramen permits access to the cranial maxillary sinus.[14] Centesis of the frontal sinus is performed at a site midway between the medial canthus of the eye and the midline of the head.[14] Following aseptic preparation, a 2–3 mL bleb of local anesthetic is injected subcutaneously at the chosen site. A stab incision is made through the skin and subcutaneous tissue and a 2 mm Steinmann pin in a Jacob's chuck is used to drill a hole into the sinus. Sterile polyethylene tubing is fed through the centesis site and fluid is aspirated using a needle and syringe attached to the tubing. Next, a chronic irrigation system can be placed through the centesis site into the sinus and sutured in place. An extension set works well. The chronic irrigation system permits irrigation of the sinus with 1–3 liters of solution two to four times daily until there is no longer production of exudate.

The goal of treating secondary sinusitis is to treat the primary cause. Depending upon the location, sinus cysts, ethmoid hematomas, neoplasia, polyps, and infected teeth can be approached surgically through a maxillary bone flap or frontal nasal bone flap.[14,16] Because the sinuses are highly vascular, copious hemorrhage can occur. Hemorrhage is controlled during surgery by lavaging the site with cold saline and applying pressure to the bleeding area. Occasionally, but rarely, vessels can be located and ligated. After the mass has been removed, continuous pressure is applied to the area using stallion gauze packing placed within the sinus. The end of the packing is exited through a hole in the dorsal or ventral conchal sinus and then out the nose. The packing is pulled in 36 to 48 hours.

Prognosis

The prognosis for recovery from primary sinusitis, sinus cysts, trauma, and dental disease is good.[13,17] Complications can include chronic drainage from the sinus, recurrence of the cyst if a portion of the cystic lining was left within the sinus, oral nasal fistulas from tooth extraction, incisional infection and sequestration of the bone flap overlying the sinus. Prognosis for most neoplastic masses within the sinus resulting in sinusitis is poor due to the expansile, invasive, and metastatic nature of the tumors. Recurrence of ethmoid hematoma is 43%.[2]

Prevention

There is no known prevention.

Etiology and pathophysiology

Etiology

Sinusitis can result from a primary infection within the sinus, frequently secondary to an upper respiratory tract infection. Sinusitis can also occur secondary to an apical tooth root abscess, sinus cyst, neoplasia, trauma and fracture of facial bones, ethmoid hematoma, and fungal granuloma.[13,14]

Epidemiology

The prevalence of sinusitis is approximately 1.06%.[18]

Rostral and dorsal pharyngeal collapse

- Horses with nasopharyngeal collapse usually are normal at rest.
- The diagnosis of nasopharyngeal collapse is made during treadmill endoscopic examination.
- There is no known treatment for nasopharyngeal collapse.
- Clinical signs of nasopharyngeal collapse, in some horses, will resolve with time.
- Horses with hyperkalemic periodic paralysis are at risk for developing nasopharyngeal collapse.

Recognition

History and presenting complaint

Various degrees of nasopharyngeal collapse may cause exercise intolerance and respiratory noise in exercising horses.

Physical examination

This is normal in the resting horse.

Special examination

Endoscopic examination of the nasopharynx and larynx is generally normal. If the nares are manually occluded during the examination, the lateral walls, dorsal aspect of the nasopharynx, or rostral portion of the soft palate may collapse into the airway to an abnormal degree in affected horses, especially horses with hyperkalemic periodic paralysis (HYPP).[19,20] In normal horses, the roof of the nasopharynx projects into the

Fig. 27.7 Endoscopic images of the nasopharynx of an exercising horse showing progressive nasopharyngeal collapse. Collapse is apparent in the first frame (A) and increases with increasing duration of exercise on the treadmill (B, C).

lumen of the nasopharynx minimally at the end of expiration due to positive end-expiratory pressure within the guttural pouches. The floor of the guttural pouch forms the roof of the nasopharynx. At rest, the pressure in the guttural pouches is in phase with the pressure in the nasopharynx.[21] During exercise, the pressures are not in phase, such that peak expiratory pressure within the guttural pouch lags behind peak expiratory nasopharyngeal pressure, resulting in some degree of dorsal pharyngeal collapse at end expiration.[21] Nasopharyngeal collapse is most accurately diagnosed during treadmill endoscopic examination. Some horses show signs of nasopharyngeal collapse during resting endoscopic examination, but have normal nasopharyngeal function during exercise. Similarly, horses with exercise intolerance and respiratory noise during exercise may be normal at rest, exhibiting signs of disease during treadmill endoscopy (Fig. 27.7).

Laboratory examination

None is indicated.

Diagnostic confirmation

Differential diagnoses for nasopharyngeal collapse include dynamic upper respiratory diseases that cause exercise intolerance and abnormal respiratory noise during exercising, such as dorsal displacement of the soft palate. Evaluating the horse's airway function during exercise can lead to a definitive diagnosis of nasopharyngeal collapse.

Treatment and prognosis

Therapeutic aims

The goal of treatment is to resolve the nasopharyngeal collapse.

Therapy

There is no current treatment for nasopharyngeal collapse. Horses are exercised with their tongues tied and wearing figure eight nosebands in an attempt to help 'stabilize' the airway. Occasionally, the disease is self-limiting and horses recover normal function without treatment. If the horse has suffered from a respiratory viral infection or pharyngitis, alleviating the airway inflammation may improve nasopharyngeal function within a few weeks to months. Horses that are HYPP positive respond to acetazolamide therapy.[19,21]

Prognosis

The prognosis is usually unfavorable, especially in horses with underlying disease such as HYPP. The condition resolves in some horses.

Prevention

There is no known prevention.

Etiology and pathophysiology

Etiology

The disease is associated with HYPP in some horses. However, in most cases the etiology of pharyngeal collapse is not known.

Pathophysiology

Nasopharyngeal collapse may result from some form of exercise-induced guttural pouch tympany or neuromuscular lesion involving the muscles that support the dorsal nasopharynx.[19] Horses should be evaluated for neuromuscular or primary muscle disorders, such as equine protozoal neuropathy, selenium and vitamin E deficiency, hyperkalemic periodic paralysis, or upper respiratory inflammatory disease.[19,20]

Epidemiology

The epidemiology of this condition has not been described. However, this disease is most frequently diagnosed in young race horses, which may be due to the speed and intensity at which they compete. As well, nasopharyngeal collapse is frequently recognized in horses with HYPP, and rather than being a distinct entity, represents a muscle group affected by the disorder.

Retropharyngeal abscesses

Recognition

History and presenting complaint

Horses with retropharyngeal abscessation frequently have palpable swelling in the throat region, nasal discharge, abnormal respiratory noise during exercise, dorsal displacement of the soft palate, and exercise intolerance. If the airway obstruction is severe, horses may show signs of

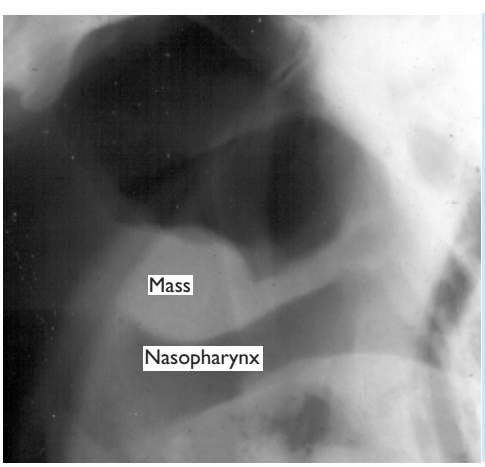

Fig. 27.8 Lateral radiograph of the pharyngeal region of a horse with an abscessed retropharyngeal lymph node causing collapse of the dorsal nasopharynx.

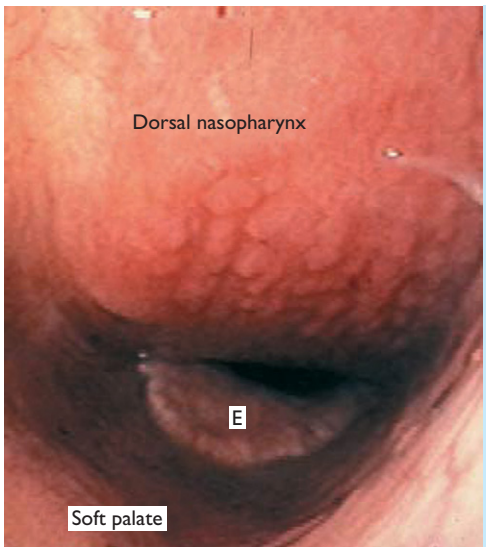

Fig. 27.9 Endoscopic image of the nasopharynx of a horse with abscessed retropharyngeal lymph nodes. Notice how the dorsal nasopharynx is collapsed, such that the larynx cannot be seen. E, epiglottis.

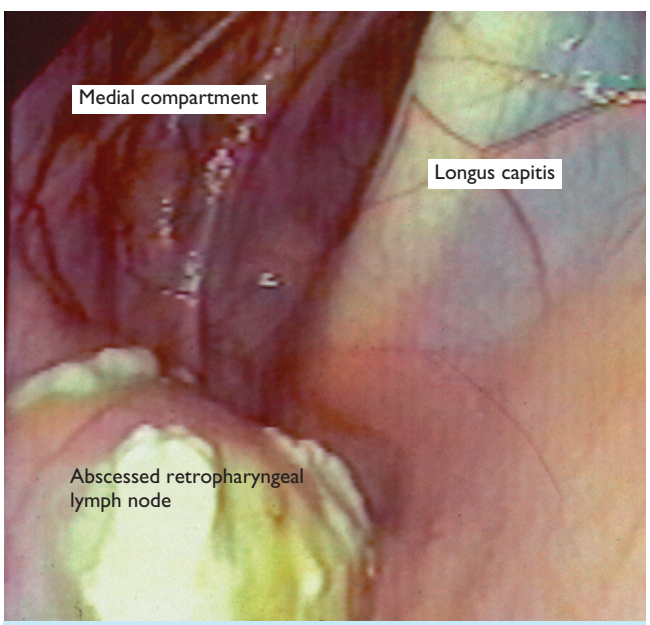

Fig. 27.10 Endoscopic image of the medial compartment of the guttural pouch. Notice the abscessed retropharyngeal lymph node.

respiratory distress at rest, including respiratory stridor, increased respiratory rate and effort, and anxiety. Additional clinical signs include dysphagia, inappetance, and depression.

Physical examination

Palpation of the throat in the area of Viborg's triangle may reveal swelling that can be painful. Pressure in this area can cause the horse to make stridorous upper airway noise. If the horse is dysphagic, feed material and saliva may be seen at the nares. If the horse is in respiratory distress, stridorous breathing and increased respiratory effort may be apparent.

Special examination

Radiography of the throat area reveals soft tissue density in the retropharyngeal region, dorsal to the pharynx and on the floor of the guttural pouch (Fig. 27.8). Compression of the dorsal nasopharynx by the abscessed retropharyngeal lymph node is evident during endoscopic examination of the upper airway (Fig. 27.9). Depending upon the size and location of the abscess, the enlarged lymph node may be best seen within the guttural pouch, on the floor of the medial compartment (Fig. 27.10) Ultrasonographic examination of the throat will show increased soft tissue density containing hyperechoic fluid, or purulent exudates.

Laboratory examination

Results of complete blood count frequently show leukocytosis and neutrophilia with regenerative left shift, and lymphocytosis. Some horses will have hyperfibrinogenemia.

Diagnostic confirmation

The diagnosis is confirmed by aspiration of material from the affected lymph node and culture of the exudate. Retropharyngeal lymph node abscesses are most frequently caused by *Streptococcus* spp., particularly *Streptococcus equi*.

Treatment and prognosis

Therapeutic aims

The goal of therapy is resolution of the abscess.

Therapy

If the horse is in respiratory distress an emergency tracheotomy is performed. Briefly, an area 20 cm long and 15 cm wide at the junction of the proximal and middle thirds of the trachea is clipped and aseptically prepared. Tracheal rings can be palpated in this area. The skin is anesthetized by subcutaneous injection of local anesthetic (lidocaine (lignocaine) or mepivacaine hydrochloride) in a linear pattern in the area of the incision or in a curved pattern proximal to the incision. A 10–12 cm linear incision is made through the skin, subcutaneous tissue, and cutaneous trunci sharply with a scalpel along the midline. The fascial plane dividing the right and left sternohyoid muscles is sharply incised with a scalpel, Metzenbaum scissors, or the muscle bellies can be moved to the side, exposing the tracheal rings. A scalpel is inserted between two tracheal rings, in the middle of the incision, by stabbing the blade through the tracheal ligament, attaching the two tracheal rings. Without removing the blade, the ligament is cut 50% to the left, turned within the trachea, and cut 50% to the right, taking care to only transect the ligament. Before removing the scalpel blade from the tracheal lumen, a Kelly hemostat is inserted into the tracheal lumen, identifying the opening in the tracheal lumen. As the hemostat is removed from the lumen, the tracheostomy tube is inserted. The tube must be secured such that when the

horse moves its head and neck, the tube lumen is not obstructed and the tube is not dislodged from the trachea.

Because most retropharyngeal lymph node abscesses are caused by streptococcal species, penicillin, 22 000–44 000 IU/kg, or sulfamethoxazale-trimethoprim, 15 mg/kg, is administered for 7 to 10 days. Judicious use of non-steroidal anti-inflammatory medication is appropriate. If the lymph nodes are large, surgical drainage may be required. Following general anesthesia, the horse is positioned in dorsal recumbency. A modified Whitehouse approach is performed on the affected side, exposing the abscessed lymph node. Confirmation of the abscess is made by inserting a needle into the mass and aspirating material from the lymph node that can be submitted for culture and antibiotic sensitivity. A stab incision is then made in the lymph node and the purulent material evacuated. The incision is left open, to heal by second intention, and the site is lavaged with saline or dilute tamed iodine solution twice daily.

Prognosis

The prognosis for return to normal function within 4 to 5 months following retropharyngeal lymph node abscess is excellent, or approximately 90%.[22]

Prevention

Decreased exposure to horses infected with *Streptococcus equi* minimizes the occurrence of retropharyngeal lymph node abscess formation. Prophylactic vaccination against *S. equi* may limit retropharyngeal lymph node abscess formation, but vaccination is not without risk.

Etiology and pathophysiology

Etiology

Most retropharyngeal lymph node abscesses are caused by streptococcal species, principally *S. equi.*

Epidemiology

Retropharyngeal lymph node abscesses are most commonly seen in horses less than 1 year old, and in horses infected with *S. equi.*

Dorsal displacement of the soft palate (DDSP)

Recognition

History and presenting complaint

Horses with intermittent dorsal displacement of the soft palate (DDSP) are exercise intolerant and make an abnormal expiratory noise during exercise. The displaced soft palate

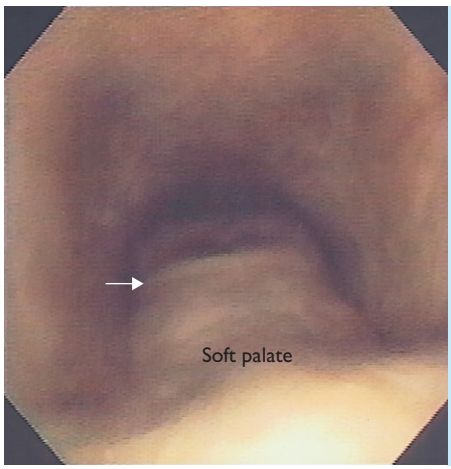

Fig. 27.11 Endoscopic image of a horse with dorsal displacement of the soft palate while exercising on a treadmill. Notice how the soft palate billows dorsally in the airway, obstructing the rima glottidis. Arrow, caudal free margin of the soft palate.

billows dorsally during exhalation as air flows beneath the soft palate (Fig. 27.11). The noise associated with DDSP is a 'snoring noise', and is caused by fluttering of the caudal margin of the soft palate. In approximately 30% of horses with DDSP, noise is not reported.[23,24] The importance of either noise production or exercise intolerance is dependent on the activity of the horse. This is an uncommon disease of show horses and generally affects the horse's performance because of the noise production. However, horses that perform with the head and neck flexed, such as upper level dressage horses and Saddlebreds, suffer exercise intolerance with DDSP due to the more negative inspiratory pressure and airway resistance that occurs with head and neck flexion.[25] Dorsal displacement of the soft palate is more common in race horses, especially 2–4-year-olds.[26–28] The exercise intolerance is often described by trainers and riders or drivers as 'choking down' or 'hitting a wall' because DDSP causes significant expiratory obstruction that limits minute ventilation. Mouth breathing during exhalation is recognized by fluttering of the cheeks as air is diverted underneath the soft palate through the mouth, and is a specific sign that a horse has displaced its soft palate dorsal to the epiglottis. Occasionally coughing during exercise is reported in association with the disease. Coughing is a symptom of upper respiratory infection and these types of infection have been associated with the onset of DDSP in some cases.

Physical examination

Because intermittent DDSP is a dynamic obstructive airway disease that occurs during exercise, most horses are normal at rest. If the soft palate displacement is persistent and associated with dysphagia, feed material may accumulate in the airway, the horse may cough, and have clinical signs of aspiration pneumonia. The primary complaint in these horses is dysphagia and aspiration, which is quite different from the population of horses with intermittent DDSP, exercise intolerance, and respiratory noise.

Some horses with intermittent DDSP have a history of upper respiratory infection. These horses may have nasal discharge, coughing, and enlarged retropharyngeal and submandibular lymph nodes. If the horse had previous surgery in an attempt to treat the DDSP, evidence of such surgery

includes indentation in the cervical musculature, where a sternothyrohyoid myectomy was performed. It is more difficult to identify horses that have excision of the caudal margin of the soft palate or sternothyroid tenectomy and myectomy at the muscle's origin. Clipping the hair over the ventral aspect of the cricoid cartilage may permit identification of a surgical scar indicative of prior laryngotomy procedure.

Special examination

Watching and listening to the horse exercise at a racetrack and witnessing the described abnormal noise and exercise intolerance of the horse may be helpful in diagnosing DDSP. The noise is somewhat specific in that it occurs during expiration and has a snoring character, quite different from inspiratory noises associated with laryngeal hemiplegia and other dynamic inspiratory airway abnormalities. Endscopic examination of the nasopharynx and larynx at rest is important to assess nasopharyngeal function and rule in or out other causes of abnormal airway noise and exercise intolerance, such as laryngeal hemiplegia or epiglottic entrapment. Initially, the nasopharynx is examined in the unsedated horse as the horse breathes normally. Examination of both guttural pouches may be helpful if upper airway infection is suspected. Stimulating the horse to swallow permits assessment of the function of nasopharyngeal muscles and may cause the horse to displace its soft palate. Dorsal displacement of the soft palate is recognized by the dorsal position of the caudal edge of the soft palate obstructing the view of the epiglottis (Fig. 27.12). Occluding the horse's nares for 20–60 seconds, forcing the horse to breathe against the obstruction, may stimulate increased activity in upper airway muscles and induce DDSP. The interpretation of induced DDSP during nasal occlusion is difficult because a percentage of horses that displace the soft palate during nasal occlusion show no evidence of DDSP during endoscopic examination while the horse runs on the treadmill.[26,27] As well, horses that do not displace at rest do displace during treadmill examination. The caudal aspect of the soft palate can be examined by passing the scope in the proximal trachea which induces DDSP in most horses. After withdrawing the endoscope, the caudal edge of the soft palate can be examined for evidence of cyst, masses or prior staphylectomy. During endoscopy, the most important signs indicative of DDSP are (1) the ease with which DDSP can be induced by nasal occlusion, (2) how readily the horse is able to correct it by swallowing, and (3) how many attempts (swallows) are required to replace the caudal edge of the soft palate in its subepiglottic position. Endoscopic examination of the nasopharynx while the horse runs on the treadmill permits identification of DDSP as it occurs during exercise. Some horses will make the characteristic 'snoring' noise and open mouth breathing during exhalation can also be detected.

In some horses, permanent displacement of the soft palate is present such that the epiglottic cartilage cannot be examined. It is important to evaluate the epiglottis morphology as well as its function; for instance, subepiglottic masses and epiglottic deformity can result in DDSP. If permanent displacement is present, there are a few techniques that can be used to evaluate the structure and integrity of the epiglottis. Sometimes removing the twitch will relax the horse and allow it to reposition the soft palate appropriately. Sedation may permit replacement of the soft palate.[29] In the standing, sedated horse, following application of local anesthetic to the nasopharynx, bronchoesophageal forceps can be passed in one nostril and used to un-entrap the epiglottis from the soft palate. Evaluation of the epiglottic cartilage and the position of the soft palate can be performed using radiography (Fig. 27.13). Finally, an oral endoscopic examination can be performed on the horse following sedation or general anesthesia and application of a mouth speculum. If the horse is anesthetized, manual palpation of the epiglottic cartilage and soft palate can also be performed.

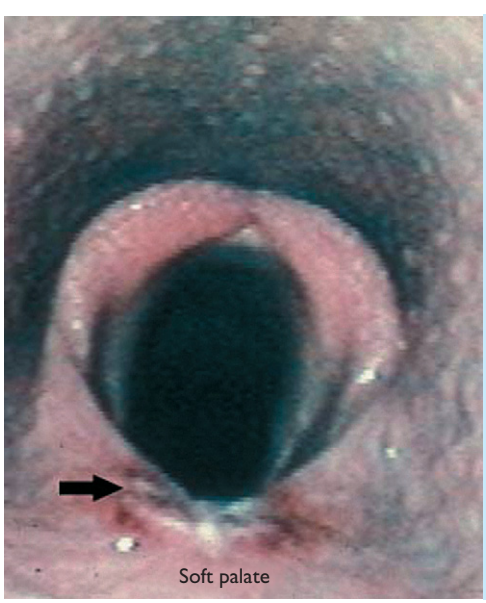

Fig. 27.12 Endoscopic image of the nasopharynx of a horse with dorsal displacement of the soft palate. Notice the ulcer (arrow) at the caudal free margin of the soft palate.

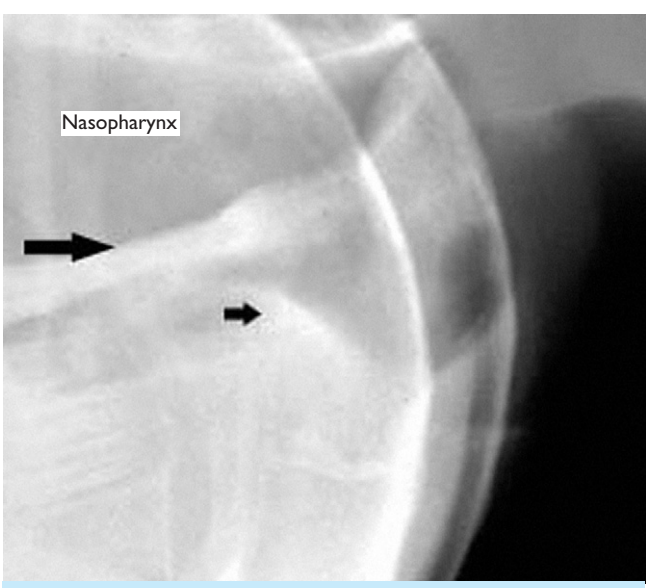

Fig. 27.13 Lateral radiograph of the pharyngeal region of a horse with persistent dorsal displacement of the soft palate. Notice the epiglottis (small arrow) positioned ventral to the soft palate (large arrow).

Diagnostic confirmation

Because horses with DDSP are normal at rest, with clinical signs occurring only during exercise, the diagnosis can be very difficult to confirm. The best way to diagnose DDSP is during endscopic examination of the nasopharynx while the horse runs on the treadmill. However, not all horses exhibit signs of DDSP during treadmill exercise. As well, because the clinical signs are similar to many other obstructive upper airway diseases, DDSP can be easily missed or overdiagnosed.

Treatment and prognosis

Therapeutic aims

The goal of therapy is to prevent DDSP from occurring. Because the etiology of DDSP is unknown, this can be a difficult task.

Therapy

In 2-year-old horses or any horse that has active or previous upper airway inflammation, the initial therapy should focus on decreasing the upper airway inflammation. Medical therapy can be instituted unless a structural abnormality, such as epiglottic deformity, entrapment, or soft palate cyst or mass, is present. If bacterial upper airway infection is diagnosed, systemic antibiotics (usually penicillin G, ceftiofur or sulfamethoxazole-trimethoprim) may be administered with non-steroidal anti-inflammatory drugs. Upper airway inflammation is treated in a plethora of different ways, including systemic administration of corticosteroids (dexamethasone), non-steroidal anti-inflammatory medication, topical anti-inflammatory throat sprays such as glycerin, dimethyl sulfoxide, and nitrofurazone, systemic administration of interferon, and guttural pouch lavage with balanced polyionic solutions with or without dimethyl sulfoxide and corticosteroids. Oral interferon alpha (50–200 IU/day for 10 days to 2 weeks) is sometimes prescribed. An appropriate treatment regimen for moderate to severe nasopharyngeal inflammation, without bacterial infection, might include treatment first with systemic corticosteroids such as prednisolone or dexamethasone and topical anti-inflammatory throat spray for 2 to 4 weeks. A common throat spray administered at the rate of 20 cc, orally, every 12 hours consists of: glycerin 250 mL, 250 mL DMSO 90%, nitrofurazone 500 mL, prednisolone 50 mL (25 mg/mL). Horses should be rested (light training without fast speed work) for 10–30 days and the upper airway function re-evaluated periodically. Normal function may not return for 3–4 months, if the cause of the DDSP was neuromuscular dysfunction related to airway inflammation.

Tack modifications such as the use of a bit that keeps the tongue under it (i.e., a 'W' bit, Serena bit), tongue-ties and the figure eight noseband are traditional approaches (although unproven) that might be of value in reducing the occurrence of DDSP. There is no evidence to support the use of a tongue-tie in the prevention of DDSP or improvement of airway mechanics in exercising horses.[30–32]

Owners and trainers of 2-year-old horses should consider waiting until the following year before pursuing any surgical treatment as maturity may alleviate the need for treatment. In addition, 2-year-olds have a high prevalence of pharyngitis that has been associated with DDSP due to inflammation of the nerves and perhaps muscles that stabilize the soft palate.[33]

Surgical treatment alternatives are numerous and include staphylectomy or trimming the caudal free margin of the soft palate, various strap muscle resections (sternohyoid, sternothyroid, and omohyoid alone or in combination), epiglottic cartilage augmentation, and various tension palatoplasty procedures.[34–40] These procedures are performed by some surgeons alone or in various combinations.

The goal of staphylectomy is to remove a thin section of the caudal free edge of the soft palate.[40] If an ulcer is present at the caudal margin of the soft palate, resection of the ulcerative tissue via staphylectomy is recommended. The mechanism by which this procedure is therapeutic is unknown. Some suggest that staphylectomy stiffens the free edge of the soft palate or perhaps enlarges the pharyngeal ostium.[40] Following the surgical procedure, systemic antibiotic therapy is continued for 7 days and anti-inflammatory medication is continued for 3–7 days. The laryngotomy incisions should be cleaned twice daily until they are healed (approximately 3 weeks). The horse can begin training 2–3 weeks later. Some surgeons close the thyrohyoid membrane at the time of surgery, which dramatically decreases the discharge from the incision. Others close the entire laryngotomy incision, eliminating the need for postoperative wound care.[41] Complications following primary closure of a laryngotomy incision include subcutaneous emphysema, incisional discharge, postoperative fever, incisional abscessation, seroma, and subcutaneous edema.[41]

Complications of staphylectomy include dysphasia, coughing, aspiration, pneumonia, and permanent DDSP.[40] The most common complication is infection at the laryngotomy site, which usually responds to wound care and antibiotics. Staphylectomy is traditionally done through a laryngotomy, but can be performed with the horse standing by use of a laser. The section of soft palate removed should be minimal as the major complication of this procedure is nasal regurgitation of feed and water. If resection is too extensive, the soft palate no longer contacts the ventral surface of the epiglottis, forming a communication between the oropharynx and nasopharynx, such that feed material from the oropharynx reaches the nasopharynx prior to or during swallowing. Furthermore, if the caudal free edge of the soft palate is rostral to the epiglottic cartilage, expiratory airflow reaches the ventral surface of the soft palate, lifting the soft palate and leading to displacement.

The goal of the resection of the sternothyroideus and sternohyoideus muscles is to prevent caudal retraction of the larynx from the caudal edge of the soft palate.[34] The most common myectomy is the sternothyrohyoid myectomy, which can be performed in the standing, sedated horse with local anesthetic applied at the surgical site.[34] Additionally, some surgeons also resect a section of the omohyoid muscles. Complications are usually minor and include incisional seromas or abscesses requiring appropriate drainage. There is a report of one horse exsanguinating following this

procedure.[34] This latter complication is more common if the omohyoid muscles are removed. Long-term complications were thought to be only cosmetic in nature associated with the lack of strap muscle at the surgery site. However, in experimental horses with normal airway function, resection of the sternothyroid and sternohyoid muscles has been observed to result in a less dynamically stable nasopharynx at exercise as measured by an increase in inspiratory tracheal pressure.[42]

The Llewellen procedure combines the staphylectomy and myectomy, but the sternothyroideus tendon is transected through the laryngotomy site, as it inserts on the thyroid cartilage.[35] Following the staphylectomy portion of the Llewellen procedure, some surgeons elect to remove 4–7 cm of the sternohyoideus muscles that are easily accessed via the laryngotomy incision.

Epiglottic augmentation was developed because epiglottic flaccidity is implicated in the pathogenesis of DDSP. The purpose of the procedure is to stiffen the horse's epiglottis.[36,43] With the horse under general anesthesia, the subepiglottic tissue is injected with Teflon paste (Mentor Polytef paste for injection, Mentor O&O, Inc., 3000 Long Water Dr, Norwell, MA 02061) as the epiglottis is retroverted through a laryngotomy incision. Postoperatively, the resulting fibrosis and granulomatous reaction in response to the Teflon contributes to a thicker and less flaccid epiglottis.[43] The frequent lack of availability of the Teflon paste in recent years has diminished the use of this technique, which is usually performed in combination with a sternothyroid myectomy and a staphylectomy. For 5–7 days following epiglottic augmentation, the epiglottis may look swollen and red, and may, in fact, be entrapped. Some horses have persistent soft palate displacement for 5–14 days following surgery. Horses are treated with systemic antibiotics and anti-inflammatory medication for 2 weeks after surgery and can begin training within 6–8 weeks. Complications include dysphasia, permanent soft palate displacement, coughing, Teflon granulomas, and epiglottic entrapment.

Tension palatoplasty was introduced during the 1990s to reduce the dorsal billowing of the soft palate by stiffening the ventral aspect of the soft palate.[37–39] Rostral stability of the soft palate might be important in the overall stability of the soft palate during exercise and in the prevention of intermittent dorsal displacement of the soft palate. The popularity of these procedures has diminished because of the finding that, in experimental horses, rostral palate stability may not be important in prevention of DDSP.[44] Furthermore, results in clinical patients were comparable to that of other techniques.

Three techniques have been described to stiffen the soft palate. In the original technique, under general anesthesia using an oral approach with long-handled scissors, a section of oral palatine mucosa and submucosa (starting 1–2 cm caudal to the hard palate) is resected.[37] Care must be taken not to invade the entire palate as a palatal fistula could occur. Tension on the palate is obtained by re-apposing the edges of the palatal mucosa and closing the defect created. Stiffening has also been done using thermal cautery applied at the same location.[38] Alternatively, the procedure can be done with the horse standing, applying thermal cautery to the nasopharyngeal mucosa of the rostral palate.

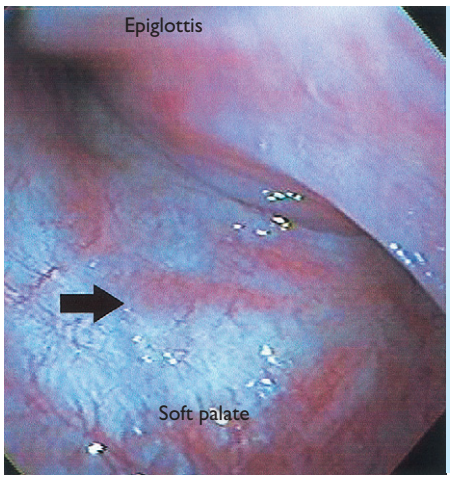

Fig. 27.14 Endoscopic image of the soft palate of a horse following laser surgery. Notice the white, scarred area (arrow).

Tension palatoplasty has also been performed at the caudal aspect of the soft palate using the laser.[39] This procedure was proposed as an alternative for staphylectomy and performed in conjunction with a sternothyroid myectomy and tenectomy. Briefly, horses are restrained in stocks and sedated. Using endoscopic guidance, the caudal margin of the soft palate is anesthetized by use of topical local anesthesia. A 600 μm bare fiber is passed through the biopsy channel and directed at the caudal free edge of the soft palate. Using 15 watts of power and contact technique, the fiber was applied for 1–2 seconds at 2–4 mm intervals along the entire free edge of the palate and extending approximately 1.5 cm rostrally.[39] Horses are treated intraoperatively with phenylbutazone (6 mg/kg intravenously) and topical throat spray, and discharged with instructions to hand walk for 3 days prior to returning to jogging or galloping. Postoperative medications consisted of intranasal throat spray for 14 days, phenylbutazone (4 mg/kg by mouth) for 5 days, and a decreasing regime of oral prednisolone for 14–21 days. If an endoscopic examination at 1 week indicated normal healing of the soft palate, horses were returned to full training (Fig. 27.14).[39]

Finally, a new procedure is being developed based on the finding of the results of experimentally created dysfunction of the thyrohyoid muscle.[45] The surgical procedure restores the function of the thyrohyoid muscles using sutures as prostheses to displace the larynx rostrally and slightly dorsal to the basihyoid bone. A clinical trial is currently underway and further discussion is pending validation of the surgical procedure in a clinical population with naturally occurring DDSP (Ducharme NG, Cornell University, personal communication).

Prognosis

The prognosis following treatment is approximately 60 ± 10%. According to trainers and veterinarians recurrence frequently occurs 3–6 months after surgery. Reported success rate for epiglottic augmentation is 66%.[46] Staphylectomy has a 59% success rate, defined as improved racing performance.[40] Horses will have their first race start approximately 16 weeks after surgery.[40] Reported success for the sternothyrohyoid myectomy is 58–60%.[34,40] Horses have their first

race start approximately 10 weeks following surgery. Reported success rate for the Llewellen procedure is 60%.[35] Following transendoscopic laser cauterization of the caudal margin of the soft palate, combined with sternothyroid myectomy and tenectomy, 92% of horses raced successfully.[39]

Etiology and pathophysiology

Etiology

The cause of intermittent DDSP is unknown. However, many theories exist to explain the etiology of this condition, some based on research and data and others on speculation. Dorsal displacement of the soft palate occurs when the soft palate displaces dorsal to the epiglottis, billowing in the nasopharynx creating expiratory obstruction. This event occurs during inspiration, expiration, and swallowing and probably has multifactorial etiology.[47] Some theories focus on dysfunction of the nerves and muscles controlling the soft palate function, and others are directed at the stability and proximity of the epiglottis and larynx to the soft palate. The stability of the nasopharynx is obtained by complex coordination of skeletal muscles and a multitude of conditions affecting these muscles, such as hyperkalemic periodic paralysis and equine protozoal myeloencephalopathy, can result in DDSP during exercise.[20]

The thyrohyoideus is a flat rectangular muscle attached to the lateral surface of the thyroid cartilage lamina that inserts on the caudal part of the thyrohyoid bone. It is innervated by the hypoglossal nerve and moves the hyoid bone caudally or the larynx rostrally and dorsally. In studies evaluating the electromyographic activity of some 'extrinsic' nasopharyngeal muscles during exercise, Ducharme et al observed decreased thyrohyoideus muscle activity prior to soft palate displacement in one horse. Bilateral resection of the thyrohyoideus muscles causes intermittent DDSP during exercise in horses.[45] The specific function of the thyrohyoideus muscle in preventing DDSP is not well understood, but because contraction of the thyrohyoideus muscles apposes the larynx and basihyoid bone, the position of the larynx relative to the soft palate is probably important in the pathogenesis of DDSP.

Neuromuscular dysfunction of the structures controlling the position of the soft palate has been implicated as a cause of this disease, and may occur due to inflammation of the upper airway. The pharyngeal branch of the vagus nerve, and other nerves important in the coordination of nasopharyngeal function, course through the guttural pouch. Specifically, the pharyngeal branch of the vagus nerve provides motor innervation to the palatinus and palatopharyngeus muscles, two muscles that control the position of the caudal portion of the soft palate. Desensitizing the pharyngeal branch of the vagus nerve bilaterally causes persistent DDSP and dysphagia in horses.[48] Biopsies taken of the palatinus muscle from horses with DDSP showed evidence of chronic denervation included fiber type grouping, mild atrophy, moth eaten fibers and target fibers.[49]

Epiglottic hypoplasia may cause DDSP because the epiglottis is not rigid enough to maintain its position dorsal to the soft palate.[49] No conclusive evidence exists to support epiglottic hypoplasia as the cause of DDSP, and its association with DDSP and poor racing performance has not been confirmed.[50] However, epiglottic malformation or chondritis may result in permanent or persistent DDSP.

Pathophysiology

Dorsal displacement of the soft palate is an expiratory obstructive syndrome that causes increased expiratory impedance, decreased minute ventilation, hypoxia, and hypercarbia (Table 27.1).[48,51] When the soft palate displaces dorsal to the epiglottis during exercise, it billows dorsally and ventrally during the respiratory cycle. During inhalation, the soft palate is located ventrally (still dorsal to the epiglottis). During exhalation, the soft palate displaces dorsally, thus diverting the flow of air through the oropharynx and mouth. This flow pattern is associated with more negative peak tracheal pressure and increased expiratory impedance.[47,48,51] During inhalation, it is less clear whether the less negative atmospheric pressures are associated with decreased airway resistance due to oral breathing as two studies revealed different results.[47,48,51]

Prevention

Preventing DDSP is difficult because the etiology of this disease is unknown. However, aggressive, timely treatment of upper airway inflammation and appropriate vaccination against upper respiratory tract viruses may decrease the chances of horses developing intermittent DDSP.

Epidemiology

Dorsal displacement of the soft palate (DDSP) is a performance-limiting upper airway condition in horses that was identified in 1.3% of 479 horses examined endoscopically at rest.[52] The prevalence of this disease is likely to be higher because DDSP is a dynamic condition that occurs during intense exercising, making the diagnosis at rest and, even during treadmill exercise, difficult.

Epiglottic entrapment

- Epiglottic entrapment occurs when redundant aryepiglottic tissue envelops the epiglottis.
- Epiglottic entrapment can be an incidental finding during endoscopic examination of the larynx and not associated with clinical signs.
- The entrapping aryepiglottic tissue can be smooth or edematous and ulcerated.

Recognition

History and presenting complaint

Horses with epiglottic entrapment may have exercise intolerance and make an abnormal respiratory noise during exer-

cise but rarely cough or are dysphagic. Some affected horses do not display any abnormalities.

Physical examination

This is generally normal. Horses with severely ulcerated, swollen entrapping aryepiglottic membrane may be dysphagic and have signs of aspiration pneumonia, though this is rare.

Special examination

Endoscopic examination reveals that the epiglottis is in its normal position dorsal to the soft palate but is encased in aryepiglottic tissue. The normal serrated edge of the epiglottis and its vascular pattern are obscured by the entrapping membrane. The aryepiglottic tissue can be smooth, fitting tightly around the epiglottis, or swollen and ulcerated (Fig. 27.15A, B). Occasionally, the epiglottis is entrapped by the aryepiglottic tissue intermittently, during exercise or swallowing. In these cases, the diagnosis may be made during endoscopic examination with the horse running on a treadmill or may be apparent on a lateral projection radiograph of the larynx. Radiographically, the entrapment appears as excessive soft tissue density surrounding the epiglottis. Radiography can be useful if the soft palate is persistently displaced, due to the entrapment, and the epiglottis and entrapping aryepiglottic membrane cannot be seen during endoscopic examination performed transnasally.

Laboratory examination

Laboratory examination is normal, but none is usually indicated.

Diagnostic confirmation

Differential diagnoses for epiglottic entrapment include dynamic upper airway lesions that cause exercise intolerance and abnormal respiratory noise during exercise. A definitive diagnosis of epiglottic entrapment is made by endoscopic examination.

Treatment and prognosis

Therapeutic aims

The goal of treatment is to relieve the entrapment.

Therapy

Transaxial division of the entrapping aryepiglottic membrane can be performed by use of a hooked bistoury through the mouth with the horse under general anesthesia (Fig. 27.16).[53] This same procedure is sometimes performed transnasally on standing, sedated horses, but is not recommended because of the risk of soft tissue damage.[54] Lacerations of the nasopharynx, soft palate, and epiglottis have occurred during transaxial division of the entrapping aryepiglottic tissue performed

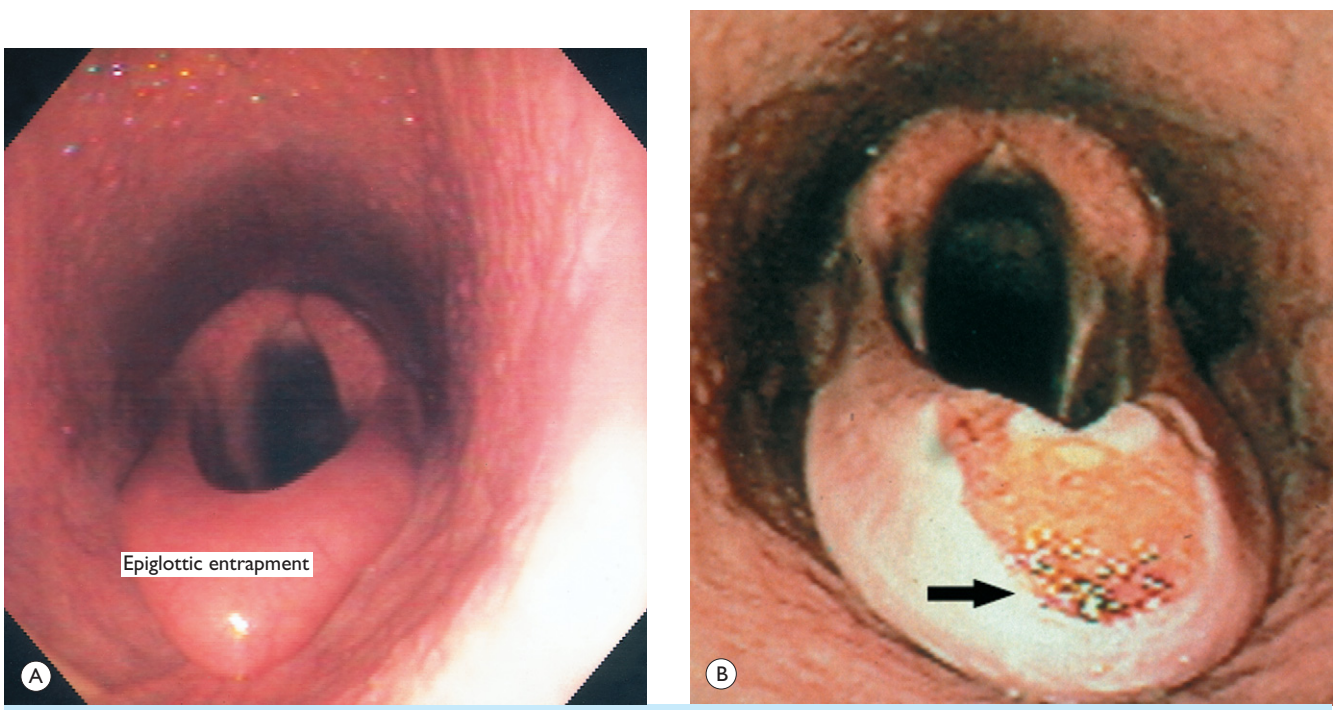

Fig. 27.15
(A) Endoscopic image of the larynx of a horse with epiglottic entrapment. Notice that the epiglottis is encased in the aryepiglottic membrane such that the vascular pattern on the dorsal surface of the epiglottis and the serrated margin of the epiglottis is not visible. (B) Endoscopic image of the larynx of a horse with an epiglottic entrapment. Notice the ulcerated area (arrow) of the entrapping aryepiglottic tissue.

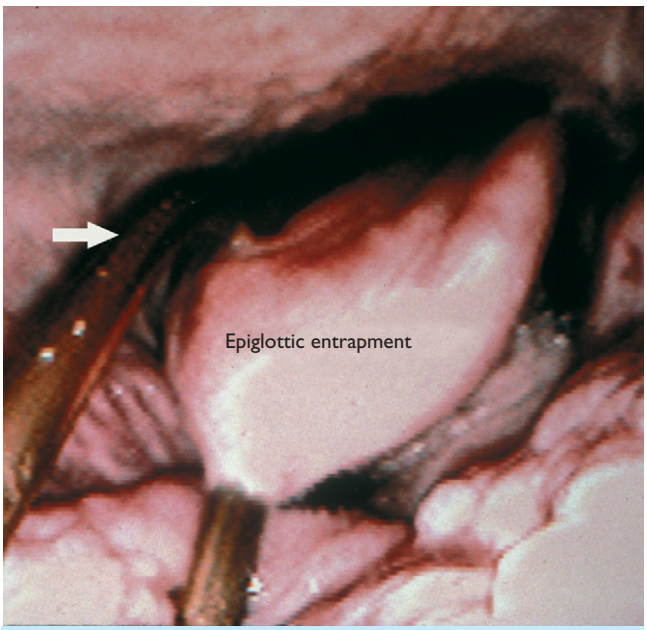

Fig. 27.16
Endoscopic image through the mouth of a horse where an entrapping aryepiglottic membrane is being excised using a hooked bistoury (arrow) with the horse under general anesthesia.

through the nose in standing horses if the horse swallows or moves. Such complications can be career or life ending. The entrapping membrane can also be divided by use of the Nd:YAG laser in standing, sedated horses.[55] Following axial division of the aryepiglottic membrane, topical and systemic anti-inflammatory therapy are recommended in an attempt to prevent re-entrapment of the epiglottis. A topical anti-inflammatory solution (furacin, dexamethasone, DMSO, glycerin) can be sprayed into the throat twice daily using an infusion pipette and judicious use of oral phenylbutazone or flunixin meglumine is recommended for 7 to 10 days. If the aryepiglottic membrane is ulcerated and swollen, the membrane can be resected through a laryngotomy incision, following general anesthesia of the horse.[53]

Prognosis

Eighty-two percent of horses have a positive outcome following transoral axial division of the aryepiglottic tissue; 5–10% of horses have recurrence of the entrapment after surgery, and 10–15% of horses develop dorsal displacement of the soft palate following correction of epiglottic entrapment.[53,55] The prognosis for a positive outcome following resection of the aryepiglottic tissue through a laryngotomy incision is 27%. The large discrepancy in outcome compared to horses with simple axial division may be due to the severity of the ulceration of aryepiglottic tissue and possible epiglottic deformity or chondritis of the epiglottic cartilage that may develop secondary to the entrapment.

Prevention

There is no known preventive measure.

Etiology and pathophysiology

Etiology

The etiology is unknown.

Pathophysiology

Aryepiglottic tissue is areolar, mucous membrane that attaches along the free margin of the epiglottis and continues between the lateral edges of the epiglottis to the corniculate processes of the arytenoid cartilages. This mucous membrane is somewhat redundant along the ventral surface of the epiglottis. The manner by which the entrapment occurs is unknown, but it may be precipitated by airway inflammation and specifically inflammation of the aryepiglottic tissue. It has been suggested that horses with epiglottic hypoplasia, diagnosed by use of endoscopy or radiographic measurement of the thyroepiglottic length, are predisposed to epiglottic entrapment.[49] Standardbred and Thoroughbred horses with epiglottic entrapment have a shorter epiglottis than do horses of the same breed without entrapment.[49]

Epidemiology

Between 0.74 and 2.1% of race horses have epiglottic entrapment.[52,56] As many as 8% of horses with a complaint of upper airway obstruction have epiglottic entrapment.[57]

Epiglottic retroversion

- Epiglottic retroversion is a rare cause of exercise intolerance and abnormal respiratory noise in horses.
- Epiglottic retroversion is diagnosed during treadmill examination with the horse running on a treadmill.
- When the epiglottis retroverts, it prolapses through the rima glottidis, causing airway obstruction.
- Epiglottic retroversion is probably due to damage to the hyoepiglotticus or geniohyoideus muscle, or branches of the hypoglossal nerve.

Recognition

History and presenting complaint

Epiglottic retroversion is a rare condition that causes abnormal respiratory noise during exercise and exercise intolerance.[58,59]

Physical examination

The physical examination is normal.

Special examination

Epiglottic retroversion is diagnosed during treadmill endoscopic examination.[58,59] At rest, the nasopharynx and larynx of af-

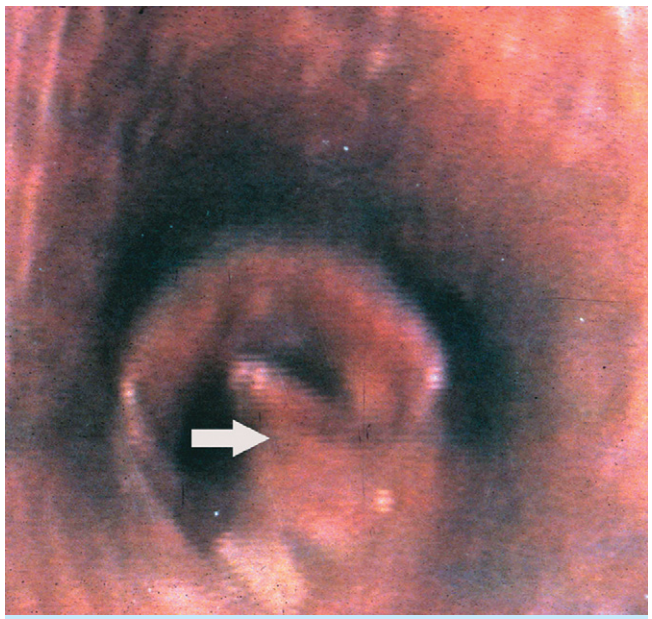

Fig. 27.17
Endoscopic image of the larynx of a horse running on a treadmill. Notice that the epiglottis (arrow) is retroverted through the rima glottidis, exposing the ventral surface of the epiglottis.

fected horses is normal during endoscopic examination. During treadmill endoscopy, the epiglottis lifts dorsally off of the soft palate during inspiration such that the ventral surface of the epiglottis faces rostrally and is readily seen on endoscopic examination. As airflows increase as treadmill speed increases, the epiglottis retroverts through the rima glottidis, such that the ventral surface of the epiglottis is seen (Fig. 27.17). Epiglottic retroversion causes dynamic airway obstruction in affected horses (Table 27.1).

Laboratory examination

Laboratory examination is normal; though none is usually indicated.

Diagnostic confirmation

Differential diagnosis of epiglottic retroversion includes those diseases that cause abnormal respiratory noise during exercise and exercise intolerance (Table 27.1). The diagnosis of epiglottic retroversion is definitively made during treadmill endoscopic examination.

Treatment and prognosis

Therapeutic aims

The goal of treatment is to stabilize the epiglottis and prevent it from obstructing the airway during inspiration.

Therapy

Little is described of treatment for epiglottic retroversion. Treatment of two horses is described, with one horse racing successfully after epiglottic augmentation with polytetrafluoroethylene (Teflon), and another horse showing no improvement.[59]

Prognosis

Prognosis is excellent for life, but guarded for athletic endeavors.[58,59]

Prevention

There are no known preventive measures, though care should be taken when performing surgery ventral to the epiglottis so as not to damage nerve supply or muscles in this area.

Etiology and pathophysiology

Etiology

The cause of epiglottic retroversion is unknown.

Pathophysiology

Epiglottic retroversion has been produced experimentally by bilaterally anesthetizing the hypoglossal nerves and by anesthesia of the geniohyoideus muscle, suggesting that trauma or dysfunction of the hyoepiglotticus or geniohyoideus muscle are implicated in the pathogenesis of epiglottic retroversion.[60]

Epidemiology

Because so few cases have been reported, the epidemiology of this disease is unknown.

Subepiglottic cyst

Recognition

History and presenting complaint

Coughing, abnormal respiratory noise, and exercise intolerance are clinical signs of subepiglottic cyst in mature horses. Dysphagia may occur in younger horses or horses with a very large cyst.[58]

Physical examination

Physical examination is usually normal. If the horse is dysphagic, coughing and aspiration pneumonia may be evident.

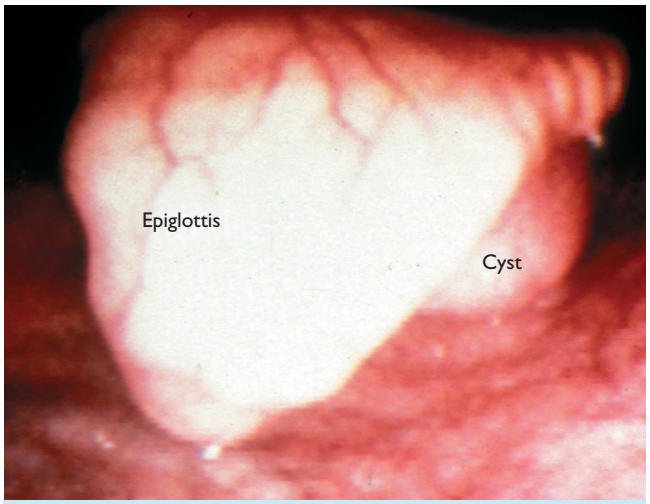

Fig. 27.18
Endoscopic image of the epiglottis of a horse with a subepiglottic cyst.

Special examination

Endoscopic examination of the larynx and nasopharynx is generally diagnostic for subepiglottic cyst (Fig. 27.18) The cyst is round, pale pink to red, covered with mucosa, and generally seen beneath the epiglottis. Occasionally, the cyst can only be seen in the nasopharynx during swallowing or intermittently during exercise, and remains beneath the soft palate in the oropharynx.

Laboratory examination

None is indicated unless there is a suspicion of aspiration pneumonia.

Diagnostic confirmation

Endoscopic examination is diagnostic for subepiglottic cyst. Following resection, the cyst can be submitted for histopathologic analysis if there is any concern that the cyst may instead be a neoplastic mass.

Treatment and prognosis

Therapeutic aims

The goal of treatment is removal of the cyst.

Therapy

Subepiglottic cysts can be excised through a laryngotomy incision with the horse in dorsal recumbency under general anesthesia.[58] The cyst is positioned beneath the laryngotomy incision by retroverting the epiglottis. The aryepiglottic mucosa is incised and the cyst is dissected free and removed. The incision in the aryepiglottic tissue is allowed to heal by second intention. Alternatively, the cyst can be excised along with the overlying mucosa by application of a snare device made with obstetrical wire threaded through an infusion pipette in an anesthetized horse.[58] Care must be taken to remove the entire cyst and minimal amount of aryepiglottic tissue. Subepiglottic cysts can also be excised using an Nd:YAG or diode laser in standing, sedated horses or horses under general anesthesia.[58]

Prognosis

The prognosis for return to function and resolution of coughing is good to excellent. Recurrence is rare, unless the entire cyst is not removed.

Prevention

There is no known preventive measure.

Etiology and pathophysiology

Etiology

Subepiglottic cysts may be either acquired, especially in older horses, or congenital in foals. The cysts may develop from remnants of thyroglossal ducts, but this has not been substantiated.

Pathophysiology

Airway obstruction and abnormal respiratory noise result from the cyst flipping dorsally across the rima glottidis, causing airway obstruction.

Epidemiology

Subepiglottic cysts are most frequently diagnosed in young racing horses, both Standardbreds and Thoroughbreds, but have been identified in foals and older horses. There is no known breed predisposition.[58]

Axial deviation of the aryepiglottic folds

- Axial deviation of the aryepiglottic folds has been diagnosed in racing Thoroughbreds, Standardbreds, and Arabians.[61]
- This disease is probably associated with racing because of the high speeds at which the horses perform.
- Diagnosis of axial deviation of the aryepiglottic folds is made during endoscopic examination of the horse running on a treadmill.
- Treatment includes rest and anti-inflammatory therapy or surgical removal of the aryepiglottic folds.

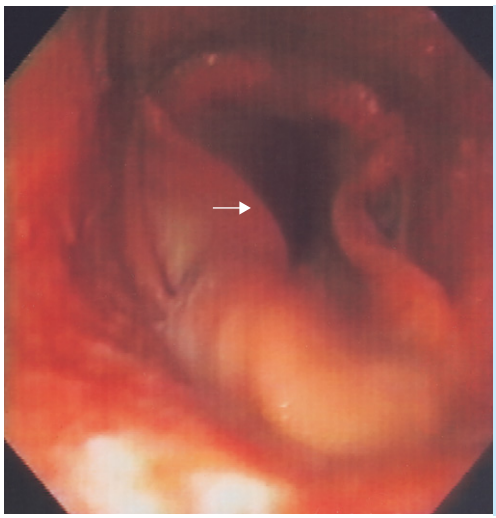

Fig. 27.19 Endoscopic image of the larynx of a horse with aryepiglottic fold collapse (arrow). This image was taken while the horse was running on the treadmill.

Recognition

History and presenting complaint

Horses with axial deviation of the aryepiglottic folds are exercise intolerant and make an abnormal respiratory noise during exercise.[61]

Physical examination

Physical examination is normal.

Special examination

Axial deviation of the aryepiglottic folds is only diagnosed during endoscopic examination of horses running on a treadmill (Fig. 27.19). During intense exercise, the aryepiglottic tissue that connects the corniculate portions of the arytenoid cartilages to the lateral edge of the epiglottis collapses axially across the rima glottidis during inspiration.[61]

Fig. 27.20 Endoscopic image of the larynx of a horse following resection of the aryepiglottic folds.

The obstruction is dynamic and worsens as exercise intensity increases.

Laboratory examination

Laboratory examination is normal; none is usually indicated.

Diagnostic confirmation

Differential diagnosis of axial deviation of the aryepiglottic folds includes dynamic obstructive upper airway diseases that cause abnormal respiratory noise and exercise intolerance. The definitive diagnosis of axial deviation of the aryepiglottic folds is made during endoscopic examination with the horse running on a treadmill.[61]

Treatment and prognosis

Therapeutic aims

The goal of treatment is to alleviate the dynamic airway obstruction by stabilizing the aryepiglottic folds.

Therapy

Treatment for axial deviation of the aryepiglottic folds includes surgical resection of the aryepiglottic tissue between the lateral edge of the epiglottis and the corniculate processes of the arytenoid cartilages (Fig. 27.20). This can be accomplished using an Nd:YAG or diode laser, with the horse sedated and standing or under general anesthesia.[61] Alternatively, horses can be rested and treated with topical anti-inflammatory throat spray and systemic anti-inflammatory medication.[61]

Prognosis

Seventy-five percent of horses that had surgery and 50% of horses that were rested had objective improvement in performance.[61]

Prevention

There is no known method of prevention.

Etiology and pathophysiology

Etiology

The cause of this condition is unknown.

Pathophysiology

The aryepiglottic tissue that attaches the lateral aspect of the corniculate process of the arytenoid cartilage to the lateral edge of the epiglottis collapses dynamically across the rima glottidis during intense exercise, resulting in inspiratory airway obstruction.

Epidemiology

Axial deviation of the aryepiglottic folds has been diagnosed in racing Thoroughbreds, Standardbreds, and Arabians.[61] This disease is likely associated with racing because of the high speeds at which the horses perform.

Epiglottitis

- Epiglottis is inflammation of the epiglottic mucosa, and at times, the tip of the epiglottic cartilage.
- Treatment includes rest and systemic and topical anti-inflammatory therapy.
- Complications of epiglottitis include epiglottic entrapment and deformity of the epiglottic cartilage.
- The prognosis for return to athletic endeavors following epiglottitis is excellent.

Recognition

History and presenting complaint

Most horses have a history of exercise intolerance, abnormal respiratory noise during exercise, and coughing. Occasionally, horses have evidence of airway obstruction at rest, dysphagia, and anorexia.[62]

Physical examination

Generally, physical examination is normal, unless the horse is dysphagic or coughing. Coughing can be easily elicited by laryngeal palpation. Dysphagic horses may have clinical signs of aspiration pneumonia or rhinitis.[62]

Special examination

Epiglottitis is diagnosed by endoscopic examination of the horse's larynx at rest. The epiglottis is swollen and dark pink to purple. The mucosa on the surface of the epiglottis and the aryepiglottic tissue beneath the epiglottis is frequently swollen and may be ulcerated. Frequently, the tip of the epiglottic cartilage is visible and may be surrounded by granulation tissue.[62]

Laboratory examination

Complete blood count and serum chemistry values are usually normal.

Diagnostic confirmation

Differential diagnosis of epiglottitis includes epiglottic entrapment, subepiglottic cyst and other dynamic airway diseases that cause exercise intolerance, abnormal respiratory noise during exercise, and coughing.

Treatment and prognosis

Therapeutic aims

The goal of treatment is to resolve inflammation of the epiglottis.

Therapy

Horses should be rested for a minimum of 14 days. Topical administration of furacin-DMSO-glycerin-prednisolone solution is applied transnasally twice daily for 10 days to 2 weeks.[62] Systemic anti-inflammatory medication such as phenylbutazone, flunixin meglumine, or dexamethasone is recommended for 10 to 14 days. If aspiration pneumonia is suspected, broad-spectrum antimicrobial therapy is recommended.[62] Endoscopic examination of the airway should be repeated in 2 weeks.

Prognosis

Prognosis for return to performance is excellent. Complications resulting from epiglottitis occur in approximately 28% of cases and include epiglottic deformity, which can occur if the epiglottic cartilage is exposed and chondritis occurs.[62] Also, epiglottic entrapment can occur following epiglottitis due to the subepiglottic inflammation.[62]

Prevention

There is no known prevention.

Etiology and pathophysiology

Etiology

The etiology of epiglottitis is unknown, though speculative causes include trauma due to poor quality hay, dorsal displacement of the soft palate, and the presence of a foreign body, respiratory tract infection, and allergic reaction.

Pathophysiology

Respiratory noise and dysphagia are caused by swelling of the epiglottis with subsequent partial occlusion of the airway and abnormal function of the epiglottis.

Epidemiology

Epiglottitis is diagnosed frequently in race horses but has been seen in older brood mares.[62]

Laryngeal hemiplegia

- Laryngeal hemiplegia almost always affects the left side of the larynx and its cause is unknown.

- Laryngeal hemiplegia is frequently diagnosed during endoscopic examination of the larynx at rest, but treadmill endoscopy may be required.
- Horses with laryngeal hemiplegia may cough due to aspiration of food material because the laryngeal adductor function is compromised.
- The current surgical therapy of choice includes laryngoplasty with ventriculocordectomy.

Idiopathic laryngeal hemiplegia (ILH) has been recognized in horses for several centuries. Much of the information about this disease was obtained from anatomic and histopathologic studies as well as dynamic and airway mechanics studies during exercise. Despite what is known, there remains a great deal of speculation and controversy concerning the etiology of ILH and the diagnosis and treatment of horses affected with this disease.

Recognition

History and presenting complaint

Horses with ILH or 'roarers' have a history of making an inspiratory noise during exercise and/or poor performance. The term 'roaring' describes an unnatural sound 'rattling, snoring, and whistling' during inspiration.[63] The noise is heard only during exercise, immediately after exercise during hyperpnea, or when the horse is startled (grunt test). These horses also have abnormal vocalization. Many horses are unaffected until 5–6 years of age such that a history of normal breathing during exercise followed by progressively more noisy breathing is often reported. The noise starts as a hoarse whistling which increases to a louder roaring as exercise intensity increases and the condition progresses. Exercise intolerance experienced by horses with ILH is associated with decreased ventilation due to laryngeal collapse.[64,65] The degree of impairment reflects a combination of factors such as degree of laryngeal collapse, athletic capacity, and the length and intensity of competition. Horses performing lower levels of work, such as show hunters and trail horses, may not experience exercise intolerance. The presence of the inspiratory noise during exercise may be the major complaint for this group of horses.

Physical examination

A thorough examination may help to identify the causes of the disease, though the majority of cases of laryngeal hemiplegia are idiopathic. The throat area is visually inspected for signs of trauma or deformity. Horner's syndrome can accompany laryngeal hemiplegia that results from perivascular injection of caustic substances or trauma involving the jugular furrow, due to the close proximity of the jugular vein, recurrent laryngeal nerve, and sympathetic trunk. Horner's syndrome is recognized based upon clinical signs of unilateral ptosis, miosis, dropped eyelid and sweating near the base of the ear, due to loss of sympathetic innervation. An important characteristic of Horner's syndrome is dilation of the vascular bed of the ipsilateral nasal cavity. Sympathetic nerve damage causes the horse to lose its ability to constrict the nasal vascular bed leading to reduced airflow that can be detected manually.

Fig. 27.21
Illustration of laryngeal palpation technique.

The larynx is palpated for evidence of atrophy of the cricoarytenoid dorsalis muscle. This is best done by standing at the shoulder of the horse and using the index fingers to palpate the dorsal aspect of the cricoid cartilage for symmetry (Fig. 27.21), then moving one finger to the muscular process and determining again the symmetry between the left and right side. If the cricoid and/or muscular processes of the arytenoid cartilage are more prominent on one side (usually the left), atrophy of the cricoarytenoid dorsalis muscle and ILH is suspected. This test is somewhat crude, and those inexperienced at palpating this area may find it inaccurate.

Historically, the absence of arytenoid cartilage adductor movement can be identified by the thoracolaryngeal reflex ('slap test').[66] While standing on the left side of the horse, one could place two to three fingers of the left hand on the lateral aspect of the larynx, and using the right hand, slap the wither area. A positive slap test will elicit a contraction of the adductor muscles and a 'twitching' can be felt over the side of the larynx. The procedure is then reproduced on the contralateral side. This test can also be performed during endoscopic examination of the larynx, but the slap test has a poor correlation with laryngeal function.[66]

Listening to the abnormal respiratory sounds that the horse makes during exercise can be helpful in the diagnosis of the ILH. Horses with ILH tend to make a 'grunt' sound and/or a hoarse whistling noise during inspiration. Occasionally ILH

is followed by dorsal displacement of the soft palate so open mouth breathing and a 'gurgling noise' is heard, but this is rare.

Special examination

The diagnosis of ILH is made by endoscopic examination of the larynx at rest, although in a proportion of horses, treadmill videoendoscopy is necessary to confirm the diagnosis. Alternatively, the horse's larynx can be assessed endoscopically immediately after cessation of exercise, though this type of examination is not as specific as treadmill endoscopy. Endoscopic examination permits assessment of the laryngeal anatomy as well as function. Laryngeal function, including adduction and abduction of the corniculate processes of the arytenoid cartilages and vocal folds, can be assessed during nasal occlusion and after swallowing. The ability of the arytenoid cartilages to abduct normally is critically assessed to determine signs of idiopathic laryngeal hemiplegia/hemiparesis. At least 40% of Thoroughbred and other large breed horses have movements of the laryngeal cartilages that are not consistently symmetrical or synchronous. Terms such as 'weak', 'paretic', 'partially paralyzed', 'flutter', and 'hesitation' have been applied to the arytenoid function of these horses. These variations in arytenoid movements are classified in unsedated horses at rest using the grading system (Table 27.2).[67] During exercise, the laryngeal grade can also be classified (Fig. 27.22). The results of studies correlating the grade of laryngeal function at rest with function during exercise suggest that horses with resting grade I or II laryngeal function have full arytenoid abduction at exercise and are normal. Approximately 75% of grade III horses have partial or complete collapse during exercise.[68,69] All horses with resting grade IV laryngeal function have significant collapse of the left hemilarynx during treadmill exercise (Fig. 27.23).[68,69] Therefore, the asynchrony of arytenoid cartilage movement is inconsequential and should not be used as the basis for diagnosis of laryngeal dysfunction or surgical intervention. The diagnosis of idiopathic

Table 27.2 Laryngeal grading system for horses examined at rest

Laryngeal grade	Description
I	Synchronous full abduction of both arytenoid cartilages during inspiration or breath holding or after swallowing
II	Asynchronous full abduction of the left arytenoid cartilage (hesitation, flutter or delay) can be achieved and maintained during inspiration or breath holding or after swallowing
III	Asynchronous abduction of the left arytenoid cartilage (hesitation, flutter or delay). Substantial movement is present but full abduction cannot be achieved and maintained during inspiration or breath holding or after swallowing
IV	No appreciable abduction of left arytenoid cartilage

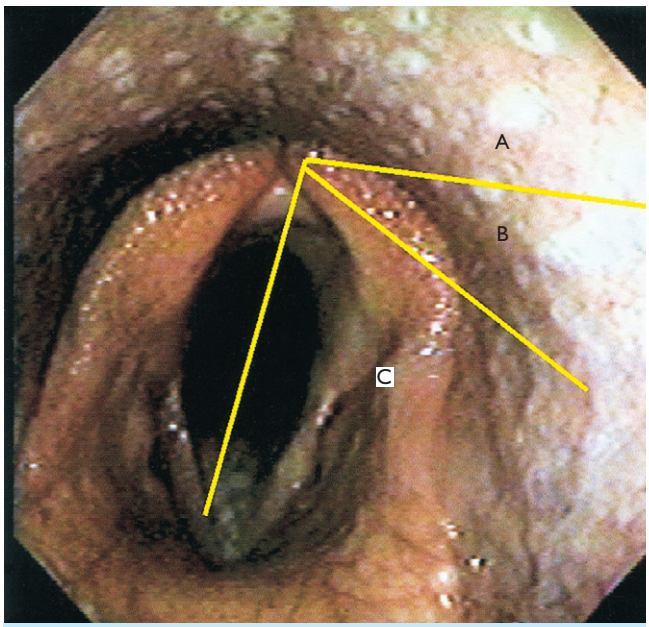

Fig. 27.22
Endoscopic image of a larynx showing the position of the corniculate process of the arytenoids cartilage for each grade of laryngeal position. Zone A represents the position (maximal abduction) for grades I and II; Zone B represents the position for grade III (partial abduction); Zone C represents the position for grade IV laryngeal hemiplegia, or complete paralysis with no abduction.

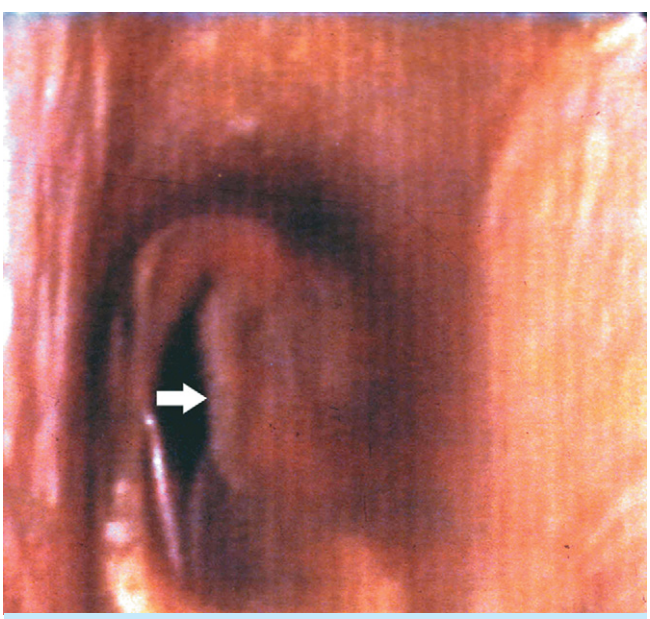

Fig. 27.23
Endoscopic image of the larynx of a horse with grade IV idiopathic laryngeal hemiplegia while the horse is running on the treadmill. Notice how the left arytenoid collapses across the rima glottidis (arrow).

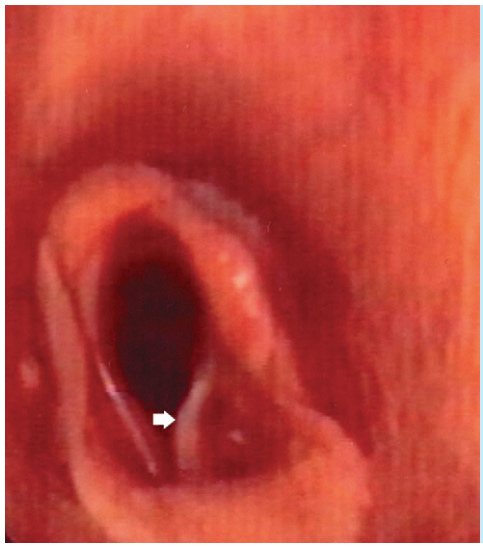

Fig. 27.24 Endoscopic image of the larynx of a horse with grade III idiopathic laryngeal hemiplegia and vocal fold collapse. Notice how the left vocal fold collapses across the rima glottidis (arrow).

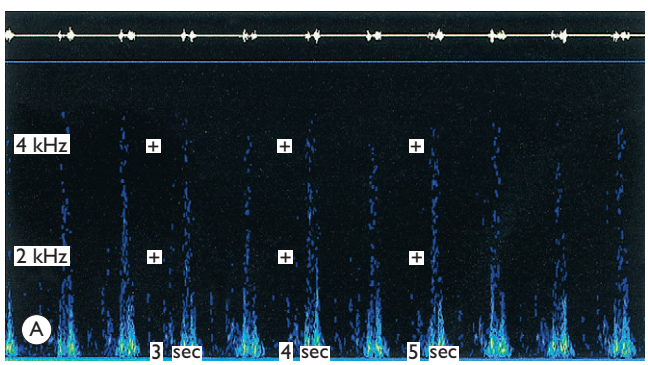

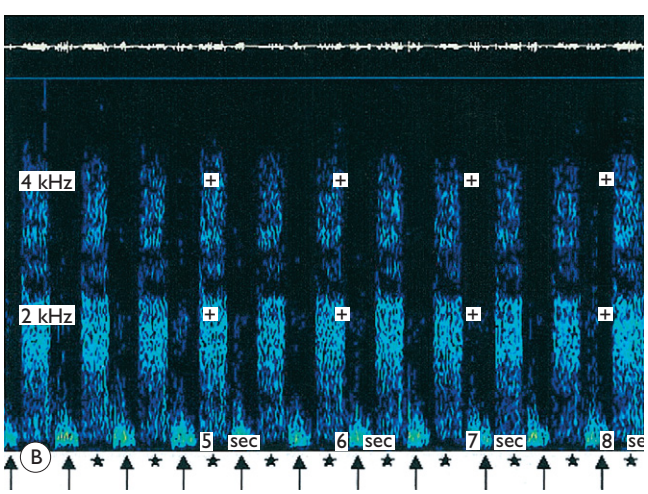

Fig. 27.25
(A) Spectrogram of respiratory sounds from a horse with normal upper airway function. Time is on the abscissa, frequency on the ordinate. Sound level increases with brightness of the color (black indicates no sound). Inspiration is indicated by a star, expiration by an arrow. The top line of the graph is sound pressure level, a measure of sound intensity. (B) Spectrogram of respiratory sounds for a horse with laryngeal hemiplegia. Notice the formants of inspiratory noise centered at 0.3, 1.6, and 3.8 kHz.

laryngeal hemiplegia is made based upon the inability of the horse to abduct the arytenoid cartilages and maintain abduction during exercise.

Treadmill endoscopic examination is useful in horses with grade III ILH because the degree of arytenoid abduction can be assessed and the optimum treatment prescribed. Horses with partial arytenoid collapse during exercise often have the same or better degree of arytenoid abduction than that obtained after a laryngoplasty.[70] These horses frequently have vocal cord collapse (Fig. 27.24), obstructing the ventral aspect of the rima glottidis, with little collapse of the arytenoid cartilage. Therefore, sacculectomy or vocal cordectomy, or ventriculocordectomy, rather that laryngoplasty, might more accurately alleviate the obstruction.

Sound analysis can be helpful in the diagnosis of laryngeal hemiplegia.[24,71] Joint time-frequency analysis of airway sounds during exercise may help quantitate the upper airway sounds of horses such that ILH can be diagnosed during exercise without access to videoendoscopy. From sounds recorded during exercise, laryngeal hemiplegia is identified by the presence of sound throughout inhalation and exhalation and the presence of three frequency bands centered on 0.3 kHz, 1.6 kHz and 3.8 kHz are seen during inhalation (Fig. 27.25A, B).[24]

In the laboratory, airway mechanics can be measured, accurately assessing the degree of laryngeal function and dysfunction.[64,65,72] In addition, blood gas measurements can help to determine the degree of ventilation compromise caused by laryngeal hemiplegia.[65] Typically, horses with laryngeal hemiplegia develop worsening exercise-induced hypoxemia (Pao_2 = 53 torr) and hypercapnia ($Paco_2$ = 53 torr) compared with control values (Pao_2 = 69 torr and $Paco_2$ = 44 torr).[65]

Electrodiagnostic testing of the thoracolaryngeal reflex latency and velocity has been shown to have no correlation with endoscopic examination, and therefore, is not useful in the assessment of laryngeal function.[6]

Treatment and prognosis

Therapeutic aims

The goal of therapy is to restore the diameter of the rima glottidis and to prevent dynamic collapse of the vocal cord and arytenoid cartilage during inspiration, minimizing resistance to airflow. The problem resides in the fact that the larynx has both digestive and respiratory functions. The arytenoid cartilage must fully abduct (larynx must be fully dilated) during strenuous exercise and fully adducted (larynx must fully close) during swallowing. Therefore, treatments aimed at permanently increasing the diameter of the rima glottidis tend to interfere with laryngeal adduction during swallowing and protection of the airway.

Therapy

The treatment of laryngeal hemiplegia was first described by Günther in 1866. He evaluated the effects of various types of arytenoidectomy and ventriculectomy.[63] These treatments

were failures, probably due to surgical techniques that were state-of-the-art at the time. In 1907, Williams introduced the ventriculectomy.[73] This treatment was later modified by Sir Hobday who improved the technique by creating a laryngotomy that did not invade (incise) the thyroid and/or cricoid cartilage and performed the ventriculectomy bilaterally.[73] Quinlan and Morton (1957) further modified the technique by adding the cordectomy to the procedure.[74] The current laryngoplasty technique was first described in 1970.[75] Although some minor variations in the surgical technique have been developed since its original description, the basic principle remains the same. Specifically, one or two prosthetic sutures are placed between the caudodorsal aspect of the cricoid cartilage and the muscular process of the arytenoid cartilage, mimicking the action of the dorsal cricoarytenoid muscle. Various types of arytenoidectomies, both partial and subtotal arytenoidectomy, were introduced in the early 1980s.[76] Partial arytenoidectomy, or removal of all parts of the arytenoid cartilage except the muscular process, achieves the best mechanical result, optimizing the area of the rima glottidis.[76,77] The neuromuscular pedicle graft procedure is the most recent surgical treatment for ILH and is performed by grafting neuromuscular bundles composed of the first cervical nerve and omohyoideus muscle to the atrophied cricoarytenoideus dorsalis muscle or by anastomosing branches of the first cervical nerve to the abductor branch of the left recurrent laryngeal nerve.[78,79] The omohyoideus muscle is a secondary muscle of respiration and contracts during intensive breathing efforts. Therefore, following these procedures, there is no change in laryngeal function or the aperture of the rima glottidis at rest, which minimizes aspiration, but first cervical nerve and omohyoideus muscle activity during intense exercise causes arytenoids abduction.[78,79]

The value of surgical therapy for ILH depends on whether the complaint is exercise intolerance, noise production, or both. Ventriculochordectomy is effective in reducing airway noise and stabilizing the arytenoid cartilage during exercise, but does not improve airway mechanics in horses with ILH as well as other surgical procedures.[64,80,81] Therefore, ventriculocordectomy is the recommended surgical therapy of choice for horses with ILH that produce an abnormal airway noise during exercise, while performing at low intensity.[73,81] Also, ventriculocordectomy or cordectomy is the surgical treatment of choice for horses with vocal fold collapse.

Laryngoplasty or laryngeal prosthesis is the current standard surgical treatment for horses with grade IV laryngeal hemiplegia. Laryngoplasty reduces the high inspiratory upper airway impedance measured in horses with experimentally induced left laryngeal hemiplegia.[64,72,80] The value of adding the ventriculectomy and ventriculocordectomy to further improve the size of the rima glottidis after laryngoplasty is controversial. Ventriculocordectomy or ventriculectomy improves the size of the rima glottidis and, therefore, is routinely performed in addition to laryngoplasty.[82–85] However, ventriculectomy or ventriculocordectomy with laryngoplasty yields no improvement in airway mechanics compared with laryngoplasty alone as evaluated with airway impedance measurement or flow-volume loop analysis in horses with experimentally created ILH.[64] Ventriculocordectomy with laryngoplasty does improve ventilation compared with laryngoplasty alone based upon blood gas measurements.[86] However, the controversial addition of ventriculocordectomy or ventriculectomy to the laryngoplasty procedure as surgical therapy for horses with grade IV ILH may be resolved as follows. First, airway impedance measurements and flow-volume loop analysis suggest that airway function is normal following laryngoplasty. However, clearly the size of the rima glottidis of a horse with grade IV ILH following laryngoplasty is smaller than the rima glottidis of a normal horse. In fact, in the clinical population of horses with grade IV ILH and laryngoplasty, the left arytenoid cartilage is rarely in a maximally abducted position.[70] Indeed, despite the fact that the majority of horses have the arytenoid cartilage abducted to approximately 80% of maximal abduction immediately after surgery, 6 weeks later that degree of abduction decreases to just above the resting position.[70] The rima glottidis is not restored to normal size after surgery yet airway mechanics are comparable to those measured in normal horses, suggesting that upper airway mechanics testing is relatively insensitive to small changes in function that may, indeed, lead to larger changes in performance. This is consistent with the results in the clinical population of horses where successful performance is restored by laryngoplasty and ventriculocordectomy, but at a lower level. In addition, a population of horses with laryngeal hemiplegia treated with laryngoplasty alone later develop dynamic collapse of the vocal folds, which may occur because of the relaxation of the laryngoplasty and paramedian position of the corniculate process of the arytenoid cartilage.

Partial arytenoidectomy is performed in some horses for treatment of ILH but these horses fail to return to their previous level of competition.[87] Furthermore, although airway mechanics measurements are improved following partial arytenoidectomy, impedance values are significantly higher than those of horses treated with laryngoplasty or those of normal horses.[88]

Laryngeal reinnervation returns upper airway mechanics during exercise to normal, but the time required for successful reinnervation is 9 to 12 months.[78] Therefore, this procedure is generally reserved for yearlings or performance horses other than race horses.[78]

The current treatment of choice for horses with grade IV laryngeal hemiplegia is the placement of a laryngeal prosthesis, or laryngoplasty and a ventriculocordectomy.

Prognosis

The clinical results of treatment of laryngeal hemiplegia with collapse of the upper airway (grade III and IV) are highly dependent on the activity of the horse. Horses used for show and jumping have a 90% chance of returning to their same level of function, while the prognosis is worse for race horses, approximately 60–70%.[70,82,85] Age at which the race horse had a laryngoplasty performed may affect prognosis. Two-

year-old horses respond less favorably to surgery than do older horses.[83–85] It is likely that the difference is due to the unknown level of performance in untested 2-year-old race horses, where approximately 30% of the population reaches the racetrack during the fall of their 2nd year.

Complications of the laryngoplasty include (1) continued exercise intolerance and respiratory noise in 30 to 40% of horses during exercise, (2) chronic coughing due to abduction of the left arytenoid cartilage and the resulting inability of the larynx to protect the trachea from aspiration of ingesta in 20 to 40% of horses, and (3) loosening of the prosthetic suture(s) and loss of an initial degree of abduction in approximately 10% of horses.[77,82–85]

Etiology and pathophysiology

Anatomical considerations

The recurrent laryngeal nerve exits the caudal brainstem as part of the vagus nerve (cranial nerve X) and descends along the trachea dorsal to the common carotid artery with a different course between the left and right recurrent laryngeal nerves. The right recurrent laryngeal nerve leaves the vagus nerve at the level of the second rib turning around the costocervical trunk before ascending toward the larynx. The left recurrent laryngeal nerve leaves the vagus nerve as the latter crosses the aortic arch. The left recurrent laryngeal nerve then runs around the concavity of the aortic arch before ascending toward the larynx. Both recurrent laryngeal nerves ascend cranially, ventral to the common carotid artery, to innervate all intrinsic muscles of the larynx except for the cricothyroid muscles, which are innervated by the ipsilateral external branch of the cranial laryngeal nerve.

The nerve cell bodies of the neurons of the recurrent laryngeal component of the recurrent laryngeal nerves were recently mapped in horses.[89] They were found to be in similar locations in the nucleus ambiguus as in small laboratory species.[89] This new information may allow more precise evaluation of the status of the nucleus ambiguus in horses affected with ILH. The microscopic appearance of the peripheral nerve has been well described.[90,91] At the proximal aspect of the recurrent laryngeal nerve, there are large myelinated axons that innervate the intrinsic laryngeal muscles and cervical esophagus. There are also a large number of unmyelinated axons arranged in large fascicles that are either sensory or postganglionic autonomic fibers. Mostly large myelinated axons with a few unmyelinated axons remain at the distal extremity of the nerve.[90,91]

Pathology

Idiopathic laryngeal hemiplegia is a peripheral neuropathy characterized by a distal loss of large myelinated fibers (distal axonopathy) and neurogenic atrophy of the intrinsic laryngeal muscles supplied by the recurrent laryngeal nerve.[90–94] Histologically, sections of the cricoarytenoideus dorsalis muscle exhibit fiber type grouping intermixed with atrophic fibers, suggestive of denervation and reinnervation.[94] Interestingly, there is a preferential atrophy of the adductor muscles in some horses so adductor deficit of the left arytenoid cartilage is observed despite normal abductor function in affected horses.[93] In addition, although the disease affects preferentially the left recurrent laryngeal nerve, there are some mild pathological lesions found in the right recurrent laryngeal nerve and associated right intrinsic laryngeal muscles.

There is not a perfect correlation between nerve and muscle histopathology and clinical disease or the degree of arytenoid dysfunction.[90,91,94] Horses with a clinical laryngeal grade IV (true laryngeal hemiplegia) have marked pathological lesions. Likewise, there is a good clinical correlation between adductor muscle lesions and their loss of adductor function. Many horses have histopathological lesions with no clinical signs of disease.[90,94] Horses with left-sided ILH can have histopathologic evidence of right-sided lesions without right-sided clinical signs. This subclinical disease and its progression are not well understood. The progression from laryngeal grade I to grade IV is variable. Some horses show no progression in their laryngeal grade and stay at laryngeal grade III for years while others progressed over a period of 2 to 4 months from normal to grade IV.[95,96]

Etiology

As indicated by its name, the etiology of ILH is unknown. Anatomically, the course of the left recurrent laryngeal nerve around the aorta, combined with the pathological appearance of the nerve, is suggestive of a compressive lesion, and led to the theory that the aortic pulse against the recurrent laryngeal nerve might be involved in the pathological process. Experimentally, constricting sutures were placed around the recurrent laryngeal nerve and a mixed array of abductor and adductor axons were affected along the course of the nerve, which is quite different that what is seen in the clinical disease.[91,93]

Risk factors for ILH include gender, breed, size, and perhaps genetics. Male horses are over-represented, as are Thoroughbred and draft horses.[97,98] Horses greater than 16 hands have a higher incidence of ILH and the disease is rarely reported in ponies.[97–99] There may also be a genetic basis for ILH.[99]

Additional causes of ILH included perivascular injections with caustic substances, heart base tumors or other thoracic masses, exposure to organophosphates or lead, thiamine deficiency, and guttural pouch infections, and various neurologic diseases such as equine lower motor neuron disease.

Arytenoid chondritis

- Arytenoid chondritis has three clinical presentations that include mucosal ulceration, granulation tissue formation, and cartilage deformity and airway obstruction.
- Clinical signs during exercise mimic those seen in idiopathic laryngeal hemiplegia.

Fig. 27.26 Endoscopic image of the larynx of a horse with 'kissing lesions' on the axial aspect of the mucosa covering the corniculate processes of the arytenoid cartilages (arrow).

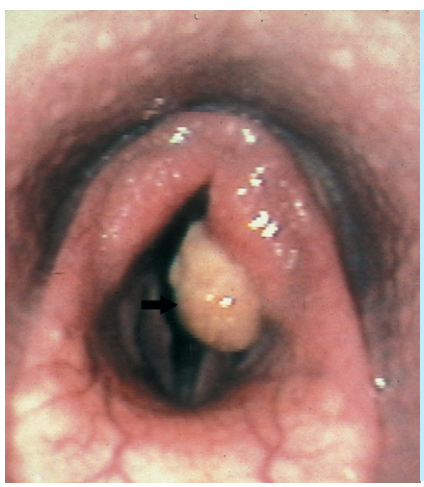

Fig. 27.27 Endoscopic image of the larynx of a horse with arytenoid chondritis. Notice the granulation tissue (arrow) protruding from the left arytenoids.

- Endsocopic examination is diagnostic for arytenoid chondritis.
- Once the arytenoid cartilage is abscessed and deformed, the treatment is surgical arytenoidectomy.

Recognition

History and presenting complaint

Horses affected only with ulcerative lesions of the mucosa on the axial surface of the corniculate processes of the arytenoid cartilages (Fig. 27.26) are generally asymptomatic at rest and during exercise. The lesions are identified during endoscopic examination for reasons unrelated to abnormal airway function. Horses with granulation tissue originating from the arytenoid cartilage and protruding into the lumen of the rima glottidis (Fig. 27.27) or horses with severe arytenoid cartilage abscessation and deformity (Fig. 27.28) have clinical signs of exercise intolerance and upper respiratory noise very similar to horses with laryngeal hemiplegia. If the abscess within the cartilage is large enough, the arytenoid cartilage may be deformed such that it causes severe obstruction of the rima glottidis. Horses with severe airway obstruction due to the deformed, abscessed arytenoid cartilage show signs of respiratory distress such as difficulty breathing or dyspnea and inspiratory wheezing.

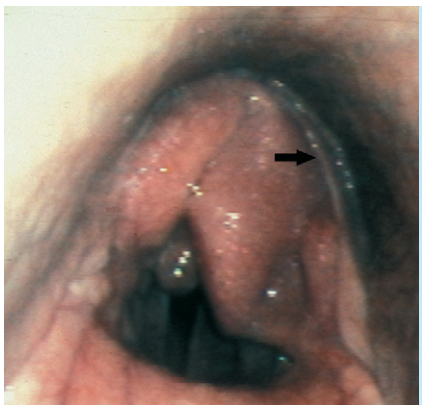

Fig. 27.28 Endoscopic image of the larynx of a horse with severe arytenoid chondritis. Notice the severely deformed left arytenoid cartilage, causing rostral displacement of the palatopharyngeal arch (arrow).

Physical examination

Palpation of the throat and larynx is usually normal. The larynx has a normal contour and asymmetry of the cricoarytenoideus dorsalis muscles is not detected, as in idiopathic laryngeal hemiplegia. Rarely will there be perilaryngeal swelling associated with infection of the arytenoid cartilage. If upper respiratory infection is still present, a horse with ulceration of the mucosa covering the arytenoid cartilage may cough.

Horses that have arytenoid chondritis characterized by granulation tissue formation protruding from the arytenoid cartilage, with or without cartilage deformity, may be exercise intolerant and make an abnormal inspiratory noise during exercise. If the airway obstruction is severe enough to cause airway obstruction at rest, aspiration of feed contents may occur, accompanied by coughing and signs of aspiration pneumonia, though this is rare. Depending upon the severity of respiratory distress, a tracheostomy may be warranted before further diagnostic evaluation is performed.

Special examination

Endoscopic examination of the larynx is frequently diagnostic for arytenoid chondritis. The morphology of the arytenoid cartilages and the integrity of the overlying mucosa should be evaluated, as well as any purulent exudates that may be draining from the cartilage (Fig. 27.29). In addition, it is important to assess the degree of arytenoid movement. If a tracheostomy has been performed, the endoscope can be passed retrograde through the tracheostomy site to further evaluate the morphology of the arytenoid cartilage (Fig. 27.30).

Radiographic examination can also help to identify enlarged or mineralized arytenoid cartilage.

Treatment and prognosis

Therapeutic aims

If mucosal ulceration of the arytenoid cartilage is the only abnormality and the morphology and function of the ary-

tenoids are normal, the goal of treatment is to reduce the local inflammation and prevent bacterial invasion of the arytenoid cartilage. Systemic and topical anti-inflammatory and antimicrobial therapy form the basis of treatment in these cases. Granulation tissue protruding from the arytenoid cartilage is removed sharply or with a laser, and if no abnormality of the arytenoid cartilage or its function is detected, systemic and topical anti-inflammatory and antimicrobial therapy are prescribed.[100] In chronic cases where the arytenoid cartilage is deformed, abscessed, and dysfunctional, the goal of treatment is to restore the diameter of the rima glottidis by surgical removal of the granuloma and the arytenoid cartilage.[101–103]

Therapy

Ulceration of the mucosa covering the arytenoid cartilage is a subclinical finding that is important because the ulcer can serve as an entrance for bacterial invasion into the arytenoid cartilage, potentially leading to abscessation and deformity of the arytenoids.[104] Treatment consists of local therapy with an anti-inflammatory throat spray (glycerin 250 mL, 250 mL DMSO 90% and nitrofurazone 50 mL of a 25 mg/mL solution) applied using a 10-French infant feeding tube placed through the nose to the nasopharynx, 20 cc, twice daily. Systemic antibiotics are prescribed for 3 weeks (trimethoprim sulfa, 15 mg/kg, p.o. q 12 h) and a non-steroidal anti-inflammatory drug (phenylbutazone or flunixin meglumine) for 7–10 days. Endscopic re-evaluation of the larynx should be performed in 3 weeks, with lesions usually healing in 3–6 weeks.

Protruding buds of granulation tissue with normal arytenoid cartilage abduction are treated with surgical resection of the lesion and medical treatment of the resulting mucosal defect as described above. Endoscopic re-evaluation should be performed in 3 weeks and again in 2 to 3 months to determine if the lesion recurs or the process extends into the arytenoid cartilage, resulting in chondritis and cartilage deformity.

In acute cases of unilateral arytenoid chondritis, medical treatment as described above is initiated. The abscessed cartilage is probed to determine if surgical drainage is possible.[100] To accomplish this, the horse is sedated and, via endoscopy, local anesthetic is liberally applied to the laryngeal mucosa. The ventral throat area is clipped and aseptically prepared and local anesthetic is injected subcutaneously 5 to 7 cm on ventral midline. A #15 blade is used to make a stab incision through the skin, muscle, and cricothyroid membrane. A 5 mm trochar is placed through the stab incision and the cricothyroid membrane into the lumen of the larynx. An 18-gauge needle is placed through the mucosal defect into the arytenoid cartilage in the area where the granulation tissue was resected. A curette is used to enlarge the opening, initiating drainage of purulent exudate. This procedure is performed with endoscopic guidance in a standing, sedated or anesthetized horse. Following drainage of the abscess, the lesion may regress completely with return of full cartilage abduction. In bilateral cases, even a return to motion of one of the arytenoid cartilages would significantly increase the prognosis for athletic soundness as unilateral arytenoidectomy is more successful and has less morbidity than bilateral arytenoidectomy.

In chronic cases of arytenoid chondritis or if following drainage of the abscess, the arytenoid cartilage function failed to return, an arytenoidectomy is performed. Two types of arytenoidectomy can be performed: partial and subtotal arytenoidectomy.[101–103] The partial arytenoidectomy includes removal of all portions of the arytenoid cartilage except the muscular process of the arytenoid cartilage. Subtotal arytenoidectomy involves removal of the body of the arytenoid cartilage, leaving the muscular and corniculate processes. Subtotal arytenoidectomy has been shown to yield minimal improvement in airway diameter because the unsupported corniculate process collapses into the rima glot-

tidis during inhalation.[105] However, it preserves best the protective mechanism of the larynx and is associated with less aspiration of feed material. Partial arytenoidectomy provides the best improvement in airway diameter, with a small risk of aspiration of feed material.[106] Therefore, if the goal of therapy is restoration of athletic performance, unilateral partial arytenoidectomy is recommended. Following arytenoidectomy, the horses should be fed and watered from the ground to minimize tracheal contamination.

Prognosis

The prognosis for resolution of mucosal ulcers with medical therapy, without the progression to arytenoid chondritis, is excellent. Horses treated with medical therapy for granulation tissue protruding from the arytenoid have a 30% chance of developing arytenoid chondritis. The prognosis for pasture soundness or light riding following arytenoidectomy is very good.[103] In rare cases, tracheal aspiration of feed material occurs at times, resulting in aspiration pneumonia. Bilateral arytenoidectomy has a less favorable prognosis because the potential for aspiration of feed and laryngeal stenosis is increased.[107]

Experimentally, in horses with laryngeal hemiplegia airway mechanics are improved but do not return to normal following partial arytenoidectomy.[106] There is little clinical data available documenting the prognosis for athletic soundness for horses with arytenoid chondritis treated with arytenoidectomy.[101–103,107] For horses with laryngeal hemiplegia, the prognosis for athletic soundness is very similar whether they are treated with laryngoplasty or partial arytenoidectomy.[103]

Etiology and pathophysiology

Etiology

The arytenoid cartilages are a pair of laryngeal cartilages that articulate with the cricoid cartilage. This articulation is the fulcrum for arytenoid cartilage abduction and adduction. The arytenoid cartilage has two processes: the vocal process where the vocal ligament is attached and the muscular process where the cricoarytenoid dorsalis muscle (the laryngeal abductor muscle) inserts (Fig. 27.31).[1] The comma-shaped corniculate process is attached to the apex of the arytenoid cartilage and forms the dorsal border of the rima glottidis.

Arytenoid chondritis develops following trauma to the mucosa of the arytenoid cartilage and invasion of bacteria into the cartilage. In humans, cattle, and presumably horses trauma occurs following severe coughing episodes where the arytenoid cartilages contact each other during these marked adduction episodes, creating contact ulcers.[104,108] During marked adduction, the point of contact of the arytenoid cartilage is a few millimeters proximal to the vocal process. Therefore, an acute upper respiratory infection (i.e. laryngitis) can be an initiating cause of arytenoid chondritis. Inflamed, swollen laryngeal mucosa may be more susceptible to trauma and the development of contact ulcers. Other causes include iatrogenic damage to the mucosa of the arytenoid cartilage during nasogastric intubation, endoscopy, or by coarse feed material.

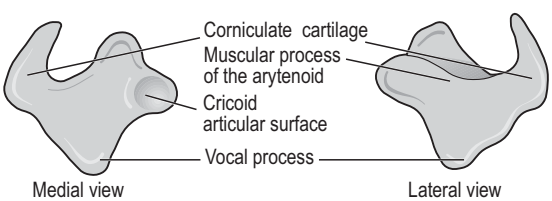

Fig. 27.31
Illustration of the anatomy of the arytenoid cartilage.

Pathophysiology

Arytenoid chondritis has three clinical presentations affecting one or both arytenoid cartilages: mucosal ulceration, granulation tissue projecting in the lumen of the larynx, and arytenoid cartilage abscessation, deformity and dysfunction. Following ulceration of the arytenoid cartilage mucosa, local bacterial invasion of the body of the arytenoid cartilage causes a superficial chondritis resulting in the production of granulation tissues and a fistulous tract. If the infection extends deeper in the body of the cartilage, an abscess may form, and enlargement and deformation of the arytenoid cartilage, and lack of movement result.

The physical presence of the granulation tissue protruding into the rima glottidis causes a static luminal obstruction during both inspiration and expiration. When the cartilage is deformed and immobile, dynamic inspiratory obstruction occurs.

Prevention

Prevention of this syndrome is difficult. Preventing trauma to the arytenoid cartilage by minimizing nasogastric intubation and endoscopic examination is prudent. Treatment of mucosal ulceration and granulation tissue can prevent further bacterial invasion of the cartilage and more severe chondritis from developing.

There has been one report of an association in Thoroughbred horses of equine lymphocyte antigen A9 and chondritis suggesting a possible genetic predisposition to this disease.[109]

Rostral displacement of the palatopharyngeal arch – fourth and sixth branchial arch defect or cricopharyngeal–laryngeal dysplasia

- Rostral displacement of the palatopharyngeal arch results most commonly from laryngeal cartilage malformation.
- Rarely are horses affected at rest but show signs of exercise intolerance and abnormal respiratory noise during exercise.

- Surgical correction is usually unsuccessful due to the cartilage deformity, which most commonly involves the thyroid cartilage.
- Rostral displacement of the palatopharyngeal arch occurs secondarily in horses with arytenoid chondritis, due to deformity of the arytenoid cartilage.

Recognition

History and presenting complaint

Horses affected with rostral displacement of the palatopharyngeal arch are usually asymptomatic at rest and this condition may be diagnosed during routine endoscopic examination of the larynx in yearling horses. Clinical signs are observed during strenuous exercise, frequently when training is instituted. Clinical signs include poor performance and an inspiratory noise the severity of which is related to the severity of the congenital malformation. The character of the inspiratory noise resembles that heard in horses with laryngeal hemiplegia except that it is generally less intense and shorter in duration. In a recent review of 60 cases, 83% of horses made abnormal inspiratory noise, 22% had involuntary aerophagia, 17% had nasal discharge and coughing, and 3% reported tympanic colic.[110]

Physical examination

The most common cause of rostral displacement of the palatopharyngeal arch is congenital malformation of the laryngeal cartilages. The larynx should therefore be palpated in order to detect abnormalities of the laryngeal cartilages. The most common abnormality is deformation of the wing(s) of the thyroid cartilage.[110] The deformity produces a gap between the thyroid and cricoid cartilages that can be easily palpated. Palpation of the muscular processes of the arytenoid cartilages is important because a less prominent or impalpable muscular process suggests arytenoid and/or thyroid cartilage malformation. Paralaryngeal cyst can occur and cause bulging of the lamina of the thyroid cartilage that can be felt unilaterally or bilaterally round the larynx.

Special examination

Endoscopic examination of the larynx is performed to diagnose rostral displacement of the palatopharyngeal arch. The position of the palatopharyngeal arch rostral to the corniculate process of the arytenoid cartilage is pathognomonic for rostral displacement of the palatopharyngeal arch (Fig. 27.32). In addition, the abductor function of the arytenoid cartilages should be carefully evaluated. In a significant proportion of horses affected with rostral displacement of the palatopharyngeal arch, incomplete abduction of one arytenoid cartilage (usually the right) is seen. Endoscopic examination of the airway while the horse is running on a treadmill is performed to assess arytenoid function when abnormal arytenoid cartilage movement is detected during endoscopic examination in the resting horse.

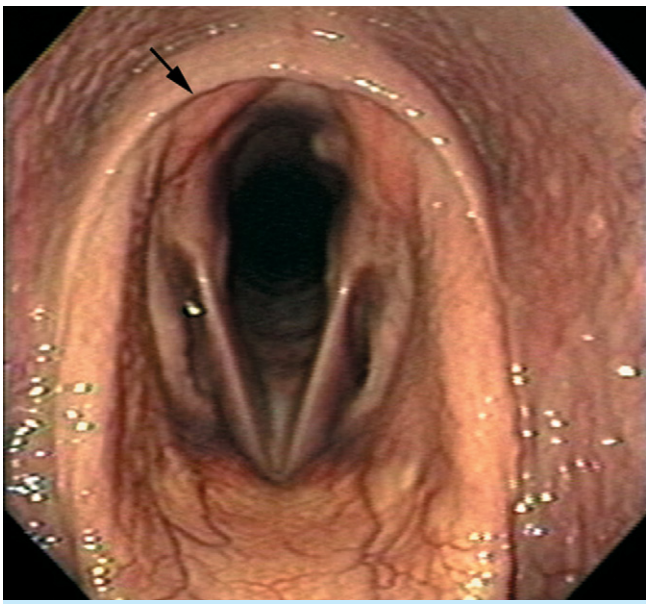

Fig. 27.32
Endoscopic image of the larynx of a horse with rostral displacement of the palatopharyngeal arch. Notice how the palatopharyngeal arch (arrow) protrudes over the corniculate processes of the arytenoid cartilages.

Radiography of the throat is helpful because horses with rostral displacement of the palatopharyngeal arch frequently have an anomaly of the cricopharyngeal sphincter, which is seen radiographically as a continuous column of air between the nasopharynx and the esophagus. The presence of redundant tissue dorsal to the corniculate processes of the arytenoid cartilages is suggestive of rostral displacement of the palatopharyngeal arch. Computer tomography can help identify cartilage malformation and detect paralaryngeal cysts.

Diagnostic confirmation

The diagnosis is made by a combination of laryngeal palpation, radiography and videoendoscopic examination of the upper airway.

Treatment and prognosis

Therapeutic aims

The goal of therapy is to restore airway patency during strenuous exercise. The redundant palatopharyngeal arch can be resected. However, since the cause of the redundant palatopharyngeal arch is laryngeal cartilage deformation, the actual cause of the redundant tissue is not treated. If one of the arytenoid cartilages cannot abduct, procedures used to treat horses with laryngeal hemiplegia will be ineffective in this instance because the cartilages are malformed. If a laryngeal cyst is causing the cartilage malformation, the cyst can be removed.

Therapy

If a laryngeal cyst is present, it should be removed using the lateral laryngeal approach used for laryngoplasty. However, cyst removal does not ensure return of normal abductor function of the arytenoid cartilage. This is because multiple concomitant laryngeal deformations are usually present. Partial arytenoidectomy can be performed in an attempt to maximize the lumen of the airway. Laryngoplasty is generally unsuccessful at abducting the arytenoid cartilage because deformities usually include absence of a normal muscular process. This combined with thyroid cartilage abnormality diminishes any possible movement at the arytenoid cricoid articulation.

Prognosis

The prognosis for athleticism is guarded, but is related to the degree of laryngeal cartilage malformation.

Prevention

Because this congenital malformation is probably heritable, avoiding breeding affected horses will limit occurrence.

Etiology and pathophysiology

Etiology

There is little information on the embryology of horses as it relates to formation of the larynx and nasopharynx. It is, however, well known that the human larynx and its intrinsic musculature, and laryngeal nerves originate from a combination of the fourth and sixth branchial arches.[111,112] Specifically, the cranial laryngeal nerve originates from the fourth branchial arch and the recurrent laryngeal from the sixth branchial arch. The epiglottic cartilage develops separately as it originated from the hypobranchial eminence.

Rostral displacement of the palatopharyngeal arch is a congenital anomaly most commonly seen in Thoroughbreds, which is part of a greater syndrome associated with fourth and sixth branchial arch defects.[110] Abnormalities seen with this congenital disease include absence of cricopharyngeal muscles, deformed thyroid cartilage resulting in an increased space between the thyroid and cricoid cartilage, abnormality of the cricopharyngeus and thyropharyngeus muscles, absence or small muscular process of the arytenoid cartilage, presence of paralaryngeal cyst(s) and associated deformation of laryngeal cartilage.[110,113–116] Vertical displacement of the lamina of the thyroid cartilage over the muscular process of the arytenoid cartilage can occur, and this deformity prevents arytenoid cartilage abduction. The right side of the larynx is most frequently affected but the deformities can occur bilaterally or on the left side.[110]

Rostral displacement of the palatopharyngeal arch can also be seen unilaterally with arytenoid chondritis or following partial arytenoidectomy. This is thought to be due to the physical loss of the corniculate process of the arytenoid cartilage, caudal to which the palatopharyngeal arch membrane normally sits.

Pathophysiology

Most of the clinical signs associated with rostral displacement of the palatopharyngeal arch are respiratory in origin and are due to obstruction of the rima glottidis. More rarely associated abnormality of the cricopharyngeal sphincter leads to dysphagia and aerophagia, which can cause tympanic colic in some horses.

Airway obstruction is caused by collapse of the arytenoid cartilage across the rima glottidis with minimal contribution from the palatopharyngeal arch. This occurs for several reasons including the absence of the muscular process of the arytenoid cartilage, the insertion of the cricoarytenoideus dorsalis muscle, preventing abduction of the arytenoid cartilage. The absence of the cricothyroid articulation leads to caudal displacement of the arytenoid cartilage instead of abduction.[110] Vertical displacement of the thyroid lamina prevents caudolateral displacement of the muscular process of the arytenoid cartilage, a process needed for abduction of the arytenoid cartilage.

When rostral displacement of the palatopharyngeal arch occurs following partial arytenoidectomy, this presentation is unlikely to be of any clinical significance. Decreased performance in horses treated with partial arytenoidectomy may justify endoscopic examination of the larynx with the horse running on the treadmill to determine if dynamic obstruction of the airway due to unilateral collapse of the palatopharyngeal arch membrane occurs.

The digestive dysfunction is rare and caused by regurgitation of esophageal contents back into the nasopharynx due to deficiency in the musculature of the cricopharyngeal sphincter. Regurgitation of feed material back into the nasopharynx and trachea can result in coughing and nasal discharges.[110,116] In addition, aerophagia created by the deficient cricopharyngeal sphincter has been reported to result in tympanic colic.[110]

Guttural pouch mycosis

Recognition

History and presenting complaint

The most common clinical sign of guttural pouch mycosis is severe epistaxis caused by erosion of the internal carotid artery, external carotid artery and/or maxillary artery. Other clinical signs include mucopurulent or hemorrhagic nasal discharge, coughing, dysphagia caused by cranial nerve damage (IX and X), unilateral laryngeal hemiplegia, Horner's syndrome (ptosis, miosis, unilateral facial sweating), parotid pain, tongue paresis, and head shaking.[117–119] Endoscopic examination of the nasopharynx may reveal hemorrhage from one or both nasopharyngeal openings.

Physical examination

Physical examination findings vary depending upon the chronicity of the hemorrhage. If the horse has recently bled severely due to erosion of a major artery within the guttural pouch by a mycotic plaque, the horse will show clinical signs of hypovolemic shock, including sweating, tachycardia, weak peripheral pulses, pale mucous membranes, and cold ears and muzzle. Occasionally, if the mycotic plaque forms over cranial nerves, such as branches of the vagus nerve or the sympathetic trunk, the horse may have clinical evidence of dysphagia and aspiration pneumonia or Horner's syndrome.[117–119] Tongue paresis can occur presumably due to hypoglossal nerve involvement.[120]

Special examination

Endoscopic examination of the nasopharynx and guttural pouches is diagnostic for guttural pouch mycosis.[117,118] Following hemorrhage, a blood clot will protrude from the affected pouch. If the disease is bilateral or the fungus has eroded through the median septum, clots may form at both guttural pouch openings. Inspection of the affected guttural pouch reveals a single fungal plaque or multiple plaques associated with the major arteries of the guttural pouch, including most commonly the internal carotid artery, but also the external carotid artery, and the maxillary artery (Fig. 27.33).[119]

Laboratory examination

Horses may be anemic if guttural pouch hemorrhage is severe or chronic.

Diagnostic confirmation

Differential diagnosis for guttural pouch mycosis includes other conditions that would result in guttural pouch hemorrhage, the most common being avulsion of the longus capitis muscle from the basisphenoid bone, or trauma.[121] Biopsy and culture of the fungal plaque confirms the diagnosis.

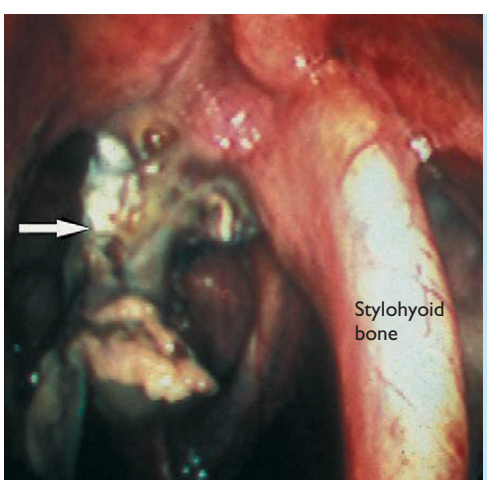

Fig. 27.33 Endoscopic image of the guttural pouch of a horse with guttural pouch mycosis. Notice the gray to black mycotic lesion (arrow).

Treatment and prognosis

Therapeutic aims

The goals of treatment are to prevent life-ending hemorrhage and eradicate the fungal infection from the guttural pouch.

Therapy

Medical treatment of guttural pouch mycosis includes topical application of non-irritating antifungal agents that are effective against *Aspergillus* spp., such as itraconazole and enilconazole.[122] Medical therapy may be initiated if hemorrhage has not occurred and the fungal plaques do not involve any blood vessels. If vascular structures are involved, which is most common, the goal of surgical therapy is to occlude the affected arteries.[117,118] Most simply, the common carotid artery on the affected side can be ligated with the horse standing. This may decrease the hemorrhage, but horses are still at risk for fatal hemorrhage due to collateral circulation through the circle of Willis and the palatine arteries.[118] Alternatively, a combination of internal, external and palatine artery ligation and balloon angioplasty using venous thrombectomy catheters can be performed.[117,118] This technique alleviates the possibility of continued hemorrhage but may result in blindness on the affected side as a result of ischemic optic neuropathy.[123] Affected vessels can also be occluded by use of detachable balloons (Yocan Medical Systems, 4 Spirea Ct, Thornhill, Ontario 13T2W1, Canada) or transarterial coil embolization (Cook Inc., Bloomington, IN). Briefly, the horse is anesthetized and positioned in lateral recumbency with the affected side up. The common carotid artery is carefully isolated and elevated, permitting catheterization with an 18-gauge angiographic needle and an introducer system.[117] Under fluoroscopic guidance, an angiogram is performed by injecting 10 to 20 mL of iohexol:heparinized saline, diluted 1:2, in order to accurately identify the internal, occipital, external, and maxillary arteries, and any aberrant branches of these vessels.[117] Dacron-fiber-covered, stainless steel occluding spring embolization coils are introduced into the internal carotid artery at the level of the basisphenoid bone to prevent retrograde flow from the circle of Willis.[117] Following occlusion of the rostral portion of the internal carotid artery, embolization coils are then placed in the rostral portion of the vessels to prevent normograde blood flow. If the external carotid or maxillary arteries are affected, embolization coil vascular occlusion is performed in the maxillary artery just before the alar foramen, and in the external carotid artery, just after it bifurcates from the linguofacial artery. The common carotid artery is ligated at the site of catheterization.[117]

Prognosis

Approximately 50% of horses that bleed severely die from fatal hemorrhage. If appropriate vascular occlusion is successful, the prognosis for life is excellent. Fungal plaques generally resolve without antifungal medication, 30 to 60 days following vascular occlusion. Dysphagia, unilateral laryngeal hemiplegia, and Horner's syndrome may resolve over 6 to

8 months, or may be permanent. Potential complications related to the surgical procedures include unilateral blindness, cerebral ischemia, and recurrent hemorrhage.[117–119]

Prevention

There is no known method of prevention.

Etiology and pathophysiology

Etiology

The etiology is unknown, but *Aspergillus* spp. is frequently cultured from the diphtheritic plaques.

Pathophysiology

The fungal plaques grow within the guttural pouch, and if they erode through the walls of the internal, external, or maxillary arteries, life-threatening hemorrhage can ensue. Ligation of the common carotid artery or only proximal ligation of affected arteries frequently leads to subsequent hemorrhage due to retrograde flow of blood through the circle of Willis to the erosion in the internal carotid artery, and flow of the blood through the palatine artery to the maxillary and external carotid arteries.[119]

Epidemiology

There is no known geographical predisposition nor age, breed, sex, or occupational predilection for guttural pouch mycosis.

Avulsion of the longus capitis/rectus capitis ventralis muscles

Recognition

History and presenting complaint

Horses with avulsion or rupture of the longus capitis and rectus capitis ventralis muscles usually have a history of trauma, such as falling over or being tied and pulling free.[121] Occasionally, (one case) the trauma may occur as a result of the horse throwing its head and neck overzealously. Affected horses may have bilateral epistaxis, swelling or thickening in the throatlatch area, and may be ataxic or exhibit other signs of neurologic dysfunction.[121]

Physical examination

Horses will often have bilateral epistaxis, may be ataxic or have cranial nerve deficits, and swelling in the area of Vyborg's triangle.[121] Affected horses may have signs of vestibular disease (head tilt, falling, ipsilateral weakness, circling), facial nerve injury (palsy of facial muscles, inability to blink, creased lacrimation and keratitis sicca) and cerebral dysfunction (depressed mentation).

Special examination

Endoscopic examination of the nasopharynx reveals collapse of the dorsal nasopharynx due to the hematoma formation within the dorsal and medial tissues of the guttural pouch and blood or blood clots at the nasopharyngeal openings of the guttural pouches. Within the guttural pouch, hemorrhage and hematoma formation are evident along the medial wall (Fig. 27.34). Lateral radiographic projections of the guttural pouch region show soft tissue density within the guttural pouch compression of the dorsal nasopharynx, and avulsion fracture of the basisphenoid bone (Fig. 27.35).

Laboratory examination

Laboratory examination is normal or there is evidence of hemorrhage.

Diagnostic confirmation

Differential diagnosis for avulsion of the longus capitis and rectus capitis ventralis muscles is guttural pouch mycosis.

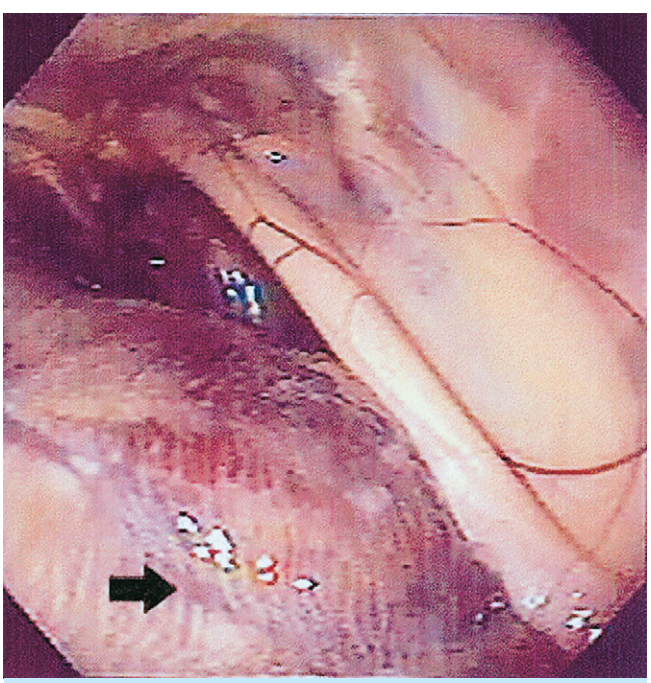

Fig. 27.34
Endoscopic image of the guttural pouch of a horse that avulsed the longus capitis and rectus capitis muscles from the basisphenoid and basioccipitus bones at the base of the skull. Notice the large hematoma (arrow) within the medial compartment of the guttural pouch.

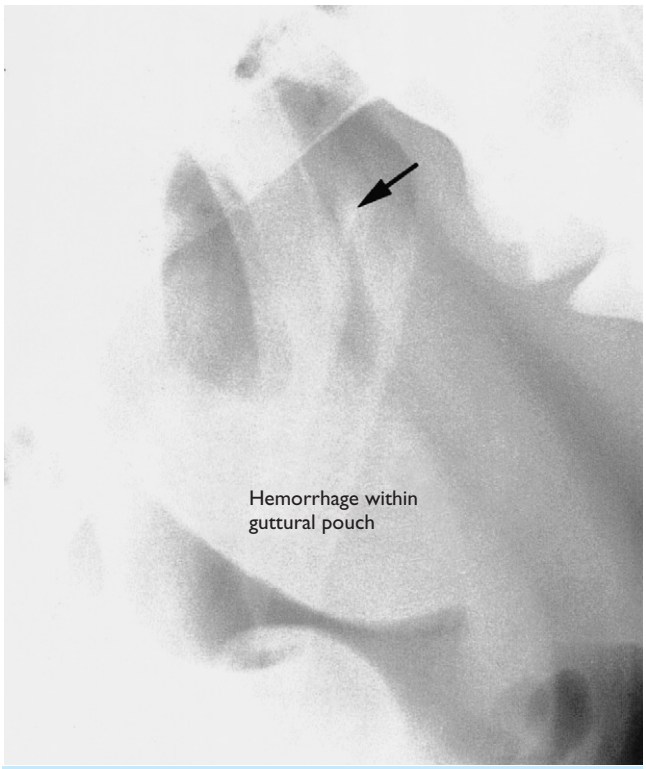

Fig. 27.35
Lateral radiograph of the guttural pouch region of a horse that avulsed the longus capitis and rectus capitis muscles from the basisphenoid and basioccipitus bones at the base of the skull. Notice the bone fragment (arrow) and the hemorrhage within the guttural pouch.

The history of trauma and the appearance of the hematoma within the medial wall of the guttural pouch are diagnostic for this condition.

Treatment and prognosis

Therapeutic aims

The goal of therapy is to provide supportive care if the horse has neurologic signs and confine the horse to minimize the risk of further hemorrhage.

Therapy

Two to three months of stall rest and broad-spectrum antimicrobial therapy are warranted due to the hematoma formation within the guttural pouch.[121] Judicious use of non-steroidal anti-inflammatory therapy for analgesia is recommended. If neurologic signs are severe and the horse is unable to rise, subdural hemorrhage involving the brainstem and cerebral cortex may be suspected and euthanasia is warranted.

Prognosis

The prognosis for return to function is good unless neurologic deficits are severe.[121]

Prevention

There is no known method of prevention.

Etiology and pathophysiology

Etiology

Avulsion of the rectus capitis muscles usually occurs following trauma.

Pathophysiology

Three muscles that flex the head and neck include the large longus capitis muscle and two small muscles, rectus capitis ventralis, and rectus capitis lateralis. These muscle course ventrally between the guttural pouches from their attachments on the basisphenoid and occipital bone, forming the cranial medial wall of the guttural pouches. Simultaneous contraction of these muscles as the horse falls over backwards would lead to avulsion fracture from the basisphenoid and occipital bones, resulting in hemorrhage from the guttural pouch and hematoma formation.

Epidemiology

Horses most commonly affected are young animals early in their training or breaking program. The disease is less common in older horses because they are less likely to fall over backwards or pull back violently when tied.

Temporohyoid osteoarthropathy

Recognition

History and presenting complaint

Most horses with temporohyoid ostreoarthropathy have clinical signs suggestive of facial nerve (cranial nerve VII), and/or vestibulocochlear nerve (cranial nerve VIII) deficits. Presenting complaints included facial nerve paralysis and lip droop, head tilt, ataxia or falling, difficulty eating, corneal ulceration/keratitis, nasal discharge, and head shaking/tossing.[124]

Physical examination

Physical examination findings include fever, facial and vestibulocochlear nerve deficits, including vestibular signs that may resemble ataxia, pain with manipulation of the jaw or opening the mouth, blepharospasm and corneal ulceration.[124]

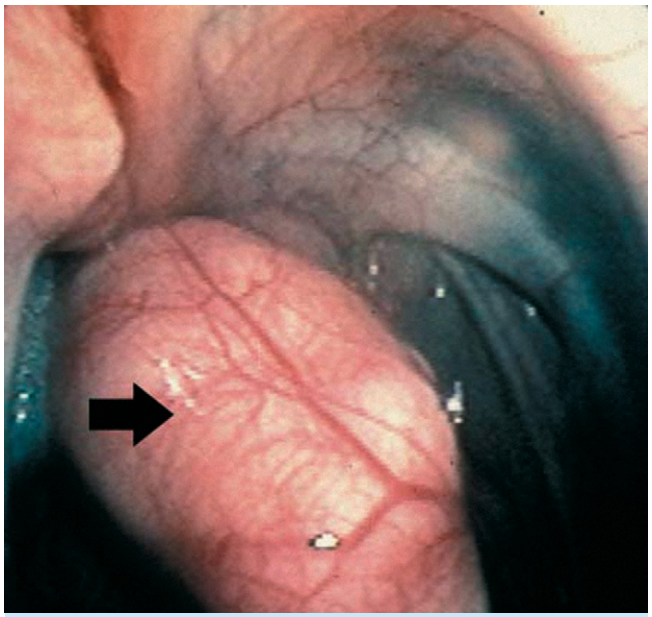

Fig. 27.36
Endoscopic image of the articulation of the stylohoid bone and the petrous portion of the temporal bone in a horse with temporohyoid osteoarthropathy. Notice the enlarged region (arrow) of the proximal aspect of the stylohyoid bone.

Special examination

The diagnosis of temporohyoid osteoarthropathy is made based on physical examination findings and endoscopic examination of the guttural pouches. Skull radiographs and computed tomography are sometimes used to help confirm the diagnosis or more fully describe the lesion at the temporohyoid articulation. Osseous proliferation at the proximal aspect of the stylohyoid bone is seen during endoscopic examination of the guttural pouch on the affected side (Fig. 27.36) Dorsoventral radiographic projections of the skull may show enlargement of the temporohyoid region. Computed tomographic scans may show fusion of the temporohyoid joint and osseous proliferation of the proximal portion of the stylohyoid bone. Occasionally, fracture of the stylohyoid bone can be seen. Schirmer tear test can be performed to assess tear production from the affected eye, especially if signs of facial neuropathy are present.

Laboratory examination

Most frequently, clinical laboratory examination is normal. Leukocytosis, lymphopenia, anemia, and hyperfibrinogenemia may occur.

Diagnostic confirmation

Endoscopic, radiographic, or computed tomographic evidence of temporohyoid fusion or enlargement are diagnostic for temporohyoid osteoarthropathy.

Treatment and prognosis

Therapeutic aims

The goals of therapy include resolution of the vestibular and facial nerve deficits, treatment or prevention of corneal ulceration, and protecting the horse from further trauma resulting from its vestibular disease. Most horses are treated with antibiotics and non-steroidal anti-inflammatory drugs, including trimethoprim sulfa, enrofloxacin, or penicillin and gentamicin for 30 days, and oral phenylbutazone or flunixin meglumine.[124] Surgical treatment or stylohyoidostectomy involves removing a piece of the stylohyoid bone to minimize motion at the temporohyoid articulation.[125] Corneal ulcers are treated with topical medication, and if the eyelid is not functional, a tarsorrhaphy may be performed to protect the cornea until facial neuropathy resolves or improves. Ocular lubricants can be applied to affected eyes several times daily if the cornea is healthy but eyelid function is abnormal.

Prognosis

Following temporohyoid osteoarthropathy, 63% of horses return to athletic activity and most horses return to their intended use. Rehabilitation time may be long, up to 2 years, though many clinical signs will abate within 30 to 60 days.[124]

Prevention

There are no known preventive measures.

Etiology and pathophysiology

Etiology

The etiology is unknown.

Pathophysiology

Temporohyoid osteoarthropathy is probably the result of primary osteoarthritis of the temporohyoid joint.[126] Alternatively, it may be the sequela to otitis media/interna that develops secondary to hematogenous spread of bacteria, ascending infection from the respiratory tract, otitis externa, or extension of guttural pouch empyema.[124,127] The infection and inflammatory reaction of the tympanic bulla, temporohyoid joint, and stylohyoid bone resolves, leaving bony proliferation of the proximal stylohyoid bone and fusion of the temporohyoid joint. Vestibular disease and facial nerve paralysis occur when osseous proliferation impinges on cranial nerves VII (facial) and VIII (vestibulocochlear) or if the petrous temporal bone fractures. The condition is usually unilateral but can be bilateral.

Epidemiology

Temporohyoid osteoarthropathy affects horses of all ages and sex and does not have a geographic predilection.

Tracheal obstructive disease

Primary obstructive tracheal disease in horses is rare, and includes tracheal collapse, fungal granulomas, chondritis, trauma, and foreign bodies. The equine trachea has an oval shape and measures approximately 5 by 7 cm, dorsoventrally to transversely, respectively. It is composed of 48 to 60 incomplete hyaline cartilage rings interspersed by fibroelastic annular ligaments. The dorsal area is made up of fibrous tissue and the trachealis muscle, which is attached to the concave surface of each cartilage ring. The trachealis muscle allows for changes in diameter of the trachea during inhalation and exhalation, while the fibroelastic annular ligaments permit unimpeded flexion and extension of the head and neck, important in running horses.

Recognition

History and presenting complaint

Horses with primary tracheal obstructive disease are exercise intolerant, make an abnormal respiratory noise during exercise or sometimes at rest, which is characterized as a honking sound, and have bilateral nasal discharge that may be mucopurulent or hemorrhagic.

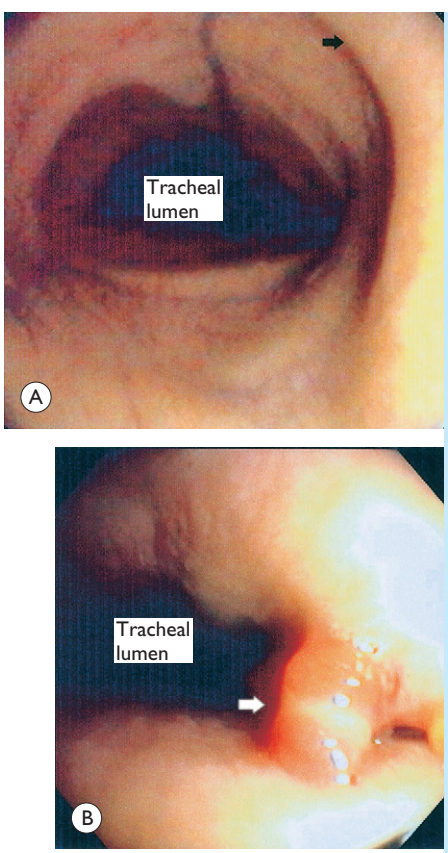

Fig. 27.37 (A) Endoscopic image of the lumen of the trachea of a horse with tracheal collapse. Notice the collapsed tracheal rings (arrow). (B) Endoscopic image of the lumen of the trachea of a horse that had tracheal trauma. Notice the granulation tissue (arrow) protruding into the collapsed lumen of the trachea.

Physical examination

Physical examination is usually normal. If tracheal trauma has occurred, palpation of the ventral cervical region may reveal a concavity in the area of previous trauma, swelling, or scar tissue. Thickened or abnormal tracheal rings may be palpable in the proximal to middle region of the cervical area if the rings have been traumatized or are chondritic. If the trachea is perforated, subcutaneous emphysema is noted along the neck, withers, and shoulders.

Special examination

Endoscopy, radiography, and ultrasonography can be useful to assess tracheal abnormalities. If the tracheal lesion is caused by a static mass, such as a fungal granuloma, chondritic cartilage, or persistently deformed trachea, endoscopic examination of the trachea at rest will be useful in assessing the tracheal lumen (Fig. 27.37A, B). If dynamic tracheal collapse occurs during exercise, endoscopic examination of the trachea during treadmill exercise is required to diagnose the dynamic collapse.[128] Lateral radiographs of the trachea are useful in assessing extraluminal masses that may cause intraluminal obstruction, as well as the position and extent of the tracheal lesion, if it is cranial to the thoracic inlet. Ultrasonography is also used to evaluate soft tissue densities external to the trachea that may impinge on the tracheal lumen such as abscesses, hematomas, or neoplastic lesions.

Laboratory examination

Complete blood count and serum chemistry values are usually normal.

Diagnostic confirmation

The diagnosis is confirmed based on endoscopic examination of the trachea at rest or during treadmill exercise and biopsy, histopathology, or culture of the mass. Endoscopic examination of the trachea at rest confirms intraluminal obstruction, which can occur as a result of trauma. Intraluminal masses, such as fungal granulomas, are biopsied and submitted for culture and cytology.[129] Granulomatous tracheitis caused by *Conidiobolus coronatus* can also be confirmed by agar gel immunodiffusion assay performed at the Centers for Disease Control and Prevention, Atlanta, GA.[129] Lesions of the tracheal rings, such as chondritis, are diagnosed based upon endoscopic examination, history of tracheal trauma or injection, and possibly localization of an abscess within the body of the tracheal cartilage. Dynamic tracheal collapse is diagnosed by endoscopic examination of the trachea during treadmill exercise if clinical signs are not apparent at rest and endoscopic examination of the upper airway and trachea is normal at rest.[128]

Treatment and prognosis

Therapeutic aims

The goal of treatment is to ameliorate the tracheal obstruction.

Therapy

Discrete intraluminal tracheal masses can be excised by use of transendoscopic contact Nd:YAG laser or sharply through a tracheotomy incision if the mass is within an accessible area of the trachea. Treatment of tracheal trauma includes systemic antimicrobial and non-steroidal anti-inflammatory therapy, if the tracheal lumen has been penetrated. Individual tracheal rings that have been traumatically damaged or are chondritic and cause airway obstruction can be resected.[130] Treatment of tracheal collapse is dependent upon the length and accessibility of the trachea involved. Some forms of tracheal collapse can be treated by stenting individual tracheal rings, tracheal prosthesis, or resection and anastomosis of the affected area.[130] Granulomatous tracheitis caused by *Conidiobolus coronatus* was successfully treated by intravenous sodium iodide 20%, 44 mg/kg, once daily for 7 days followed by 1.3 mg/kg organic iodide 4.57%, twice daily for 1 year.[129]

Prognosis

Prognosis for removal of discrete intraluminal masses within the trachea and return to function is excellent.[130] Horses with tracheal collapse have a good prognosis for life, but a guarded prognosis for athletic activity.

Prevention

There is no known method of prevention of tracheal obstruction.

Etiology and pathophysiology

Etiology

Chondritis of tracheal cartilages can occur following intratracheal injections or transtracheal aspiration, if a tracheal ring is perforated during the injection, trauma, or idiopathically.

Pathophysiology

The pathophysiology of tracheal obstruction is based upon the type of obstruction.

Epidemiology

Tracheal obstruction is rare in athletic horses.

CHAPTER 28

Lower airway function: responses to exercise and training

Dorothy M. Ainsworth

Physiologic responses to exercise

Overview

During high intensity exercise, the metabolic demands of the horse – oxygen consumption and carbon dioxide production – increase more than 30-fold relative to resting conditions. As a consequence, the ventilatory output must increase in order to meet gas exchange requirements and to aid in heat dissipation. Despite the recruitment of respiratory muscles that produce large inspiratory and expiratory pressures, complemented by the generation of locomotory-associated intrathoracic and intra-abdominal pressures, the ventilatory response of the horse during high intensity exercise is inadequate. This finding, along with the lack of training-induced improvements in respiratory system output, has led many physiologists to conclude that the respiratory system of the horse is the major limiting factor to athletic performance.

Structure and function of the lower respiratory tract

The intrathoracic trachea bifurcates into the right and left mainstem bronchi at the level of the fifth or sixth intercostal space and enters the hilum of each lung. At its division from the trachea, the right bronchus assumes a straighter, more horizontal position relative to the left bronchus. Each bronchus subsequently divides into lobar, segmental, and subsegmental bronchi with the eventual formation of bronchioles. In the distal part of the bronchial tree, the terminal bronchioles lead into poorly developed respiratory bronchioles or open directly into alveolar ducts.[1] The tracheobronchial lining consists of tall columnar, pseudostratified epithelium interspersed with serous and goblet cells.[2] This is supplanted by short ciliated cells and non-ciliated Clara cells of the bronchioles, and then by type I and type II pneumocytes at the level of the alveoli.[3] Type I pneumocytes, with thin cytoplasmic extensions 0.2 to 0.5 μm thick, cover the majority of the alveolar surface.[3] The cuboidal type II cells, with their characteristic lamellar cytoplasmic inclusions that form surfactant, are also considered to be 'stem cells', replacing the type I cells in lung injury. Also scattered throughout the lower respiratory tract are lymphocytes, macrophages, mast cells and occasional eosinophils, cell types that are critical for the development of pulmonary immune responses.[4]

The pulmonary structures are subserved by two vascular beds. The major source of blood is via the pulmonary circulation, a low-pressure, low-resistance system (during resting conditions), which participates in gas and heat exchange at the alveolar level and provides nutrients to the alveolar constituents. The distribution of the pulmonary arterial flow to the various lung regions in the resting horse does not appear simply to reflect the effects of gravitational forces or the effects of pressure gradients between the pulmonary arteries, veins and alveoli as originally proposed.[5] Using microspheres to examine the distribution of pulmonary blood in resting Thoroughbreds, Hlastala and colleagues (1996) found that blood flow to the cranial most portions of the lungs was uniformly low (in three of the four horses) and that blood flow increased linearly with the vertical height of the lung (opposite to gravity).[6] Hlastala also found a great deal of heterogeneity of blood flow within a single isogravitational plane, suggesting that pulmonary blood flow is not simply related to pressure gradients between pulmonary arteries, veins and the alveoli. Otherwise, at a given vertical height, the distribution of blood flow would have been homogeneous. The investigators suggested that the reduction of pulmonary blood flow to the ventral lung regions might reflect the greater

length and resistance of the vessels bringing blood to these areas.

With just mild exercise (trotting), there is a redistribution of blood flow to the dorsal lung region but no improvement in the heterogeneity of blood flow at a given isogravitational plane.[7] The increased flow to the dorsal lung regions may simply reflect regional differences in vascular reactivity,[8] regional differences in structure (volume density of capillaries), and/or changes in pulmonary vascular pressures.[7]

The bronchial circulation, a high-pressure circulatory bed, is the second source of blood flow to the lungs. At its origin from the aorta, it is a single vessel that subsequently divides into a right and left bronchial artery at the hilar region of the lung. The artery courses along the bronchi and provides nutrients to the lymphatic, vascular and airway components and supplies arterial blood to the pleural surface.[1] In ponies exercising at 6 m/s (7% incline) for nearly 30 min, the bronchial blood flow was found to increase 16-fold relative to resting levels.[9] The increase in blood flow, attributed to a decrease in vascular resistance, was highly correlated with the exercise-induced increases in the pulmonary artery temperature.

The pulmonary structures are innervated by parasympathetic, sympathetic, and non-adrenergic non-cholinergic (NANC) pathways.[10] The relative contributions of these pathways to the airway tone in healthy resting and exercising horses have been examined. Neither muscarinic blockade of the parasympathetic system (the vasoconstrictor system) nor β_2-adrenergic activation of the sympathetic system (the vasodilator system) alters resting airway diameter.

The major function of the lung is gas exchange – uptake of oxygen and elimination of carbon dioxide. During resting conditions, the horse, utilizing a breathing frequency of 12–15 breaths per minute and a tidal volume of nearly 6 liters, produces a total minute ventilation of approximately 72–80 liters per minute.[11] During this same period, the horse consumes approximately 2.1 L/min of oxygen (3000 L/day) and produces approximately 1.7 L/min of carbon dioxide (2400 L/day). Thus the lung provides an important means by which normal arterial oxygen and carbon dioxide tensions and arterial pH are maintained. As discussed below, impairment of this pulmonary function becomes evident in horses exercising at intensities exceeding 60–65% of maximum oxygen consumption.[12]

Additional functions of the lung include metabolism of bioactive amines (pulmonary circulation), production of surfactant and the maintenance of pulmonary defense mechanisms. The lower respiratory tract also aids in thermoregulation through evaporative heat losses. It has been estimated that approximately 25% of the heat load generated during low intensity exercise is dissipated through the respiratory tract.[13]

Pulmonary function testing

In resting horses, respiratory mechanics (tidal and minute volume, breathing frequency, dynamic lung compliance and total pulmonary resistance) have been routinely measured using flow meters and esophageal balloon catheters (Table 28.1) or using the technique of forced oscillation.[18] Measurement of lung volumes other than tidal and minute volume requires the use of the inert gas dilution technique (end-expiratory lung volume, EELV) and the construction of quasistatic pressure–volume curves obtained in anesthetized or heavily sedated horses (total lung capacity (TLC), residual volume (RV)).[19,20] Estimates of TLC range from 45 to 55 liters while those of RV range from 9 to 10 liters (Fig. 28.1). The variability in the lung volume measurements may be due, in part, to positional and anesthetic effects.[19,21] End-expiratory lung volume measurements in awake horses using helium dilution or nitrogen washout techniques yield values ranging from 20 liters to 35 liters.[15,17,22] Note that in horses the term EELV rather than functional residual capacity (FRC) is used to describe the volume of gas remaining in the respiratory system at the end of expiration. As expiration in humans is a passive process, FRC represents the volume resulting from the outward recoil of the chest wall and inward recoil of the lungs. Thus horses, in contrast to humans, breathe below rather than from the FRC of the respiratory system.[23] Vital capacity of the horse, the amount of air that could be inhaled

Table 28.1 Range of ventilatory parameters in horses during eupneic breathing

V_T (L)	4.9	5	4.1	5.7
fb (per min)	15.5	14.5	14.7	9.6
$\dot{V}_E$ (L/min)	75	68	60	55

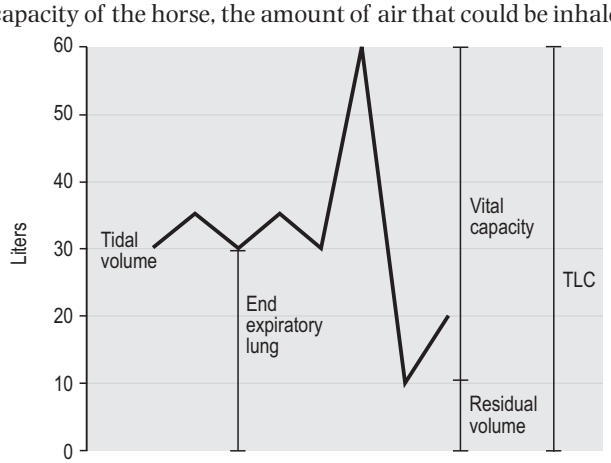

Fig. 28.1
Equine lung volumes. The total lung capacity (TLC) of the horse is approximately 60 liters. During eupneic breathing, the horse uses a tidal volume of 5 liters that may increase to 18 liters during strenuous exercise. End-expiratory lung volume during eupneic breathing is 30 liters but has not been measured during exercise.

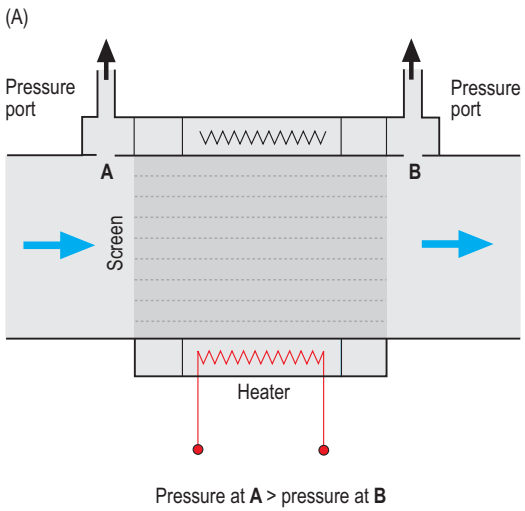

Fig. 28.2
Flow meter. Diagram (A) and photograph (B) of a pneumotach attached to a breathing mask. This device is used to measure airflow in resting and exercising horses. The pressure difference across a heated screen is detected during breathing and transduced to a flow signal. Pneumotachs may become coated with airway secretions. (Reproduced with permission from Marlin and Roberts.[27])

Fig. 28.3
Ultrasonic flow meter. Photograph of a horse wearing a breathing mask with two ultrasonic flow meters centered over each nostril. This may offer less resistance to breathing than the pneumotach, but may suffer from baseline drift. (Reproduced with permission from Marlin and Roberts.[27])

following a forced expiration, ranges from 35 to 45 liters (Fig. 28.1).

Accurately measuring exercise-associated ventilatory parameters such as V_T, fb, C_{dyn}, R_L in the horse has proven to be challenging for several reasons. Breathing masks increase the respiratory tract dead space and cause rebreathing of carbon dioxide.[24] The breathing mask may also alter the horse's respiratory pattern such that locomotory:respiratory coupling during high intensity exercise does not occur.[25,26] Flow meters that are attached to the breathing mask – either pneumotachs (Fig. 28.2A, B) or ultrasonic flow devices (Fig. 28.3) – also may be problematic.[27] Pneumotachs offer a resistance to breathing and when they become coated with airway secretions, overestimate actual airflow.[24] Open flow systems,[28] traditionally used to measure metabolic rates during exercise (Fig. 28.4), have been intermittently converted to closed ventilatory systems, using pneumotach-like devices. The respiratory parameters of 5–10 breaths are obtained before gas exchange impairment occurs (rebreathing CO_2) or before respiratory secretions accumulate on the pneumotachograph.[24] Ultrasonic flow detectors have also been used in place of pneumotachs. These devices may exhibit baseline drift due to moisture buildup and, because they are sensitive to gas densities, are unable to be used in studies examining the effects of various gases (heliox) on respiratory mechanics.[27]

Because of technical difficulties, exercise-associated changes in lung volumes (TLC, EELV) have not been measured in the horse, confounding the interpretation of flow:volume loops. (See 'Mechanical factors limiting ventilation', below.) It is not known if TLC remains unchanged in the horse as it does in the human as the determinants of TLC – respiratory muscle strength, lung and chest wall

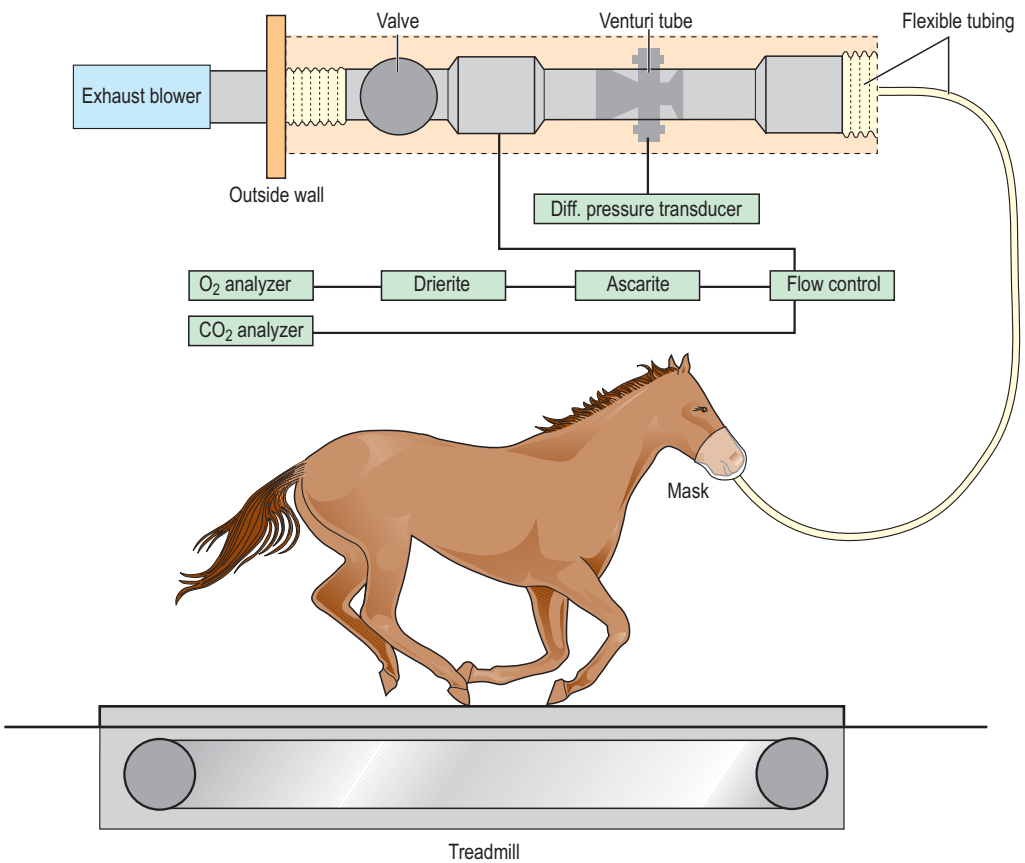

Fig. 28.4
Diagram of an open flow system used to measure expired carbon dioxide and consumed oxygen during exercise. (Reproduced with permission from Seeherman and Morris.[28])

recoil – have not been measured in exercising horses.[29] In humans, FRC decreases with exercise but when high workloads are imposed, EELV may then increase towards or above normal due to expiratory flow limitations.[30] Although EELV has not been measured in the horse, exercise-induced increases in the end-expiratory costal diaphragmatic length (i.e. lengthening of the diaphragm prior to initiation of inspiration) detected by sonomicrometry techniques, suggest that EELV decreases.[31] The actual volume change in EELV is unknown.

Response of the respiratory system to exercise

Metabolic demand

The exceedingly high metabolic demands of strenuous exercise in the horse must be met by corresponding increases in the output of the respiratory and cardiovascular systems. The magnitude of exercise-induced changes in mean oxygen consumption ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$) and in heart rate (HR), as a function of running speed are depicted in Fig. 28.5. Note that $\dot{V}O_2$ and $\dot{V}CO_2$ increase linearly up to speeds of 10 m/s and thereafter change little, as evidenced by the plateau.[32] Exercise speeds required to produce 115% $\dot{V}O_{2\,max}$ would thus be extrapolated by extending the linear portion of the exercise speed–VO_2 relationship. The average maximum oxygen consumption in horses performing incremental exercise tests has been reported to be 138 mL/kg/min in Standardbreds[33] and 142 mL/kg/min in Thoroughbreds.[34] Values as high as 190 mL/kg/min for individual horses have been recorded. Relative to the resting value of 4–5 mL/kg/min,

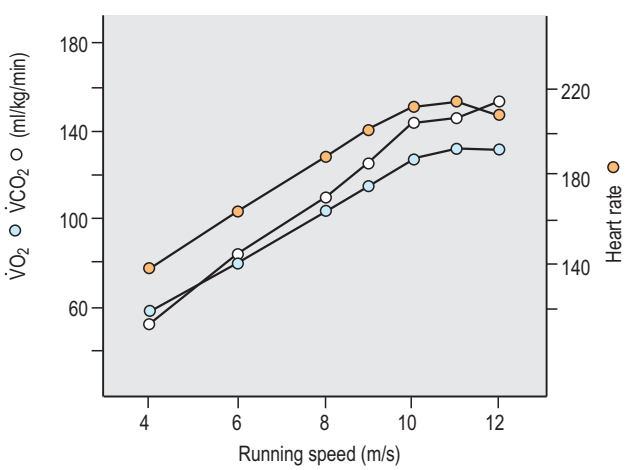

Fig. 28.5
Metabolic demands of exercise. The mean exercise-associated increases in carbon dioxide production ($\dot{V}CO_2$), oxygen consumption ($\dot{V}O_2$) and heart rate (HR) in Thoroughbred horses performing an incremental exercise test. (Reproduced with permission from Rose et al.[32])

Table 28.2 Blood gas data from Thoroughbreds performing an incremental exercise test on a treadmill

	Rest	6 m/s	8 m/s	14 m/s, 3.5° incline	Recovery 5 min walk
pHa (mmHg)	7.42	7.44	7.41	7.21	7.13
$Paco_2$ (mmHg)	43.9	36.5	39.6	50.0	23.8
Pao_2 (mmHg)	101.2	104.2	100.9	73.5	96.9
Cao_2 (mL/dL)	20.6	26.4	27.1	26.5	27.5
Sao_2 (%)	99.0	99.0	98.2	89.3	96.9
Pvo_2 (mmHg)	40.3	27.7	23.1	14.0	49.6
Cvo_2 (mL/dL)	16.4	14.3	9.4	2.3	17.4

pHa, arterial pH; $Paco_2$, arterial carbon dioxide tensions; Pao_2: arterial oxygen tensions; Cao_2, arterial oxygen content; Sao_2, arterial oxygen saturation; Pvo_2, mixed venous oxygen tensions; Cvo_2, mixed venous oxygen content. Reproduced with permission, from Manohar et al.[37]

this represents a 30-fold increase in oxygen consumption during strenuous exercise!

Exercise-associated increases in $\dot{V}o_2$ are mediated by increases in both oxygen delivery and tissue extraction. Delivery of oxygen is enhanced not only by increases in cardiac output, but also by increases in hemoglobin (red cell numbers) that result from splenic contraction. The spleen, which stores approximately one-third to one-half of the horse's total red blood cells, is the source of the 1.7-fold increase in hemoglobin at the onset of exercise.[35] Indeed, splenectomy[36] reduces maximum oxygen consumption by approximately 31%. As each gram of hemoglobin is capable of binding 1.3 mL of oxygen, the total arterial oxygen content (Cao_2), the sum of dissolved and bound oxygen, increases from a resting value of approximately 21 mL/dL to a value of 27 mL/dL in strenuously exercising horses (Table 28.2).[37]

Extraction of oxygen at the tissue level is enhanced by a right shift of the oxyhemoglobin dissociation curve (Fig. 28.6), responding to increases in carbon dioxide tensions, hydrogen ion concentrations or elevations in tissue temperatures. The net result is that the amount of dissolved oxygen (Po_2) is increased as oxygen is 'unloaded' from the hemoglobin. This improves the oxygen gradient between the tissue capillary and the cell mitochondria, enhancing diffusion into the cell. In the horse, the primary mediator of the Bohr effect, the rightward shift of the oxyhemoglobin dissociation curve, appears to be the metabolic acidosis of exercise.[38]

The magnitude of tissue oxygen extraction during exercise, the difference between the arterial (Cao_2) and venous oxygen content (Cvo_2), can be appreciated from the data presented in Table 28.2. At rest, the horse utilizes approximately 4 mL/dL of oxygen as opposed to the nearly 25 mL/dL consumed when the horse gallops at 14.5 m/s on a grade. Understandably, venous oxygen tensions are reduced from 40 torr at rest to 12 torr during maximal exercise. Although, as anticipated, ventilation increases during exercise, the response is insufficient to prevent the development of arterial hypoxemia (Pao_2 < 85 mmHg) and hypercapnia ($Paco_2$ > 45 mmHg). (See 'Gas exchange during exercise', below.)

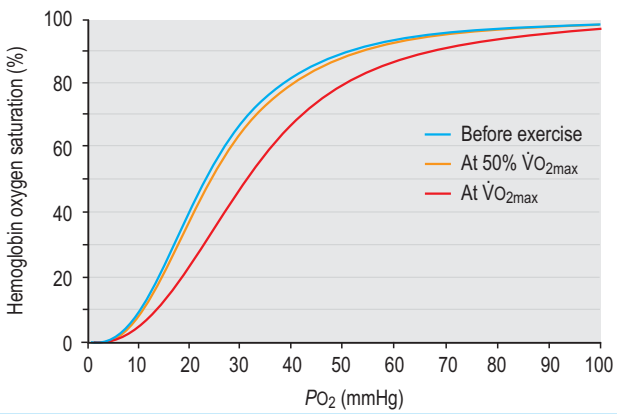

Fig. 28.6
Oxyhemoglobin dissociation curve. With exercise, there is an increase in tissue temperature, carbon dioxide production, hydrogen ion concentration which facilitates unloading of oxygen (right shift of oxyhemoglobin dissociation curve) at the tissue capillary. (Reproduced with permission from Fenger et al.[38])

Ventilatory output

During exercise, the magnitude of the increase in ventilatory output will be a function of the intensity and of the duration of exercise. Representative changes in ventilatory parameters are shown in Table 28.3 for Thoroughbreds[11] and in Table 28.4 for Standardbreds[39] performing an incremental exercise test.

As shown in Table 28.3, tidal volume (V_T) and minute ventilation ($\dot{V}_E$) increase linearly with treadmill speed and correlate with increases in inspiratory muscle activity.[40] Breathing frequency (fb) increases linearly with speed from rest to 8 m/s but, at faster speeds, only slight increases in breathing frequency occur. In Thoroughbreds, breathing frequency is entrained or linked to stride frequency during the canter and gallop, a phenomenon termed locomotory:respiratory coupling (LRC).[41] Breathing frequency may or may not be coupled to stride frequency during trotting and is usually not linked to stride frequency during walking.[42] Interestingly,

despite the development of LRC, stride length and V_T are not tightly coupled during the canter or gallop. This enables V_T to be increased independently in response to metabolic need or demand.[43] That is, in horses galloping at a constant speed on a treadmill, increases in the treadmill incline (and in $\dot{V}O_2$) induce increases in minute ventilation and in V_T without altering stride length.

In contrast to the exercising Thoroughbred, the trotting Standardbred utilizes a slightly different breathing pattern.[39] At submaximal exercise, trotters entrain breathing frequency with stride frequency 1:1 but this ratio changes to 1:1.5, 1:2 or 1:3 at maximum exercise.[44] This increases inspiratory and expiratory times and generates a greater tidal volume. At comparable metabolic workloads ($\dot{V}O_2$ of Thoroughbreds = 140 mL/kg/min, $\dot{V}O_2$ of Standardbreds = 133 mL/kg/min), trotters exhibit a slower breathing frequency and a slightly greater V_T than Thoroughbreds (Tables 28.3, 28.4). At comparable speeds (10 m/s, 0 degrees incline), the ventilatory output of the Standardbreds exceeds that of the Thoroughbred horses but the greater response is commensurate with the increased metabolic workload (166 mL/kg/min versus 114 mL/kg/min).

Exercise-associated alterations in alveolar ventilation ($\dot{V}_A$) have also been measured in horses. In a study of Thoroughbreds performing an incremental exercise test, Butler and colleagues reported a 20-fold increase in $\dot{V}_A$ from the resting value (38 L/min) when horses galloped 12 m/s for 2 minutes.[43] The physiologic dead space to tidal volume ratio (V_D/V_T) initially increased from the resting value of 0.41 when horses trotted, but then returned to the resting value as exercise intensity increased. Although V_T, $\dot{V}_A$ and V_D increase proportionately with exercise, the increase in alveolar ventilation, relative to the increase in $\dot{V}CO_2$, is insufficient to prevent hypercapnia from developing (Tables 28.2, 28.3, 28.4). (See 'Gas exchange during exercise', below.)

During exercise, total pulmonary resistance (R_L) and the work of breathing increase exponentially with ventilatory

Table 28.4 Ventilatory parameters of Standardbred horses during an incremental exercise test

output (Table 28.3). The exercise-associated increase in R_L is attributed to the generation of turbulent flow in the upper respiratory tract during inspiration and the narrowing of intrapulmonary airways during expiration.[11,45,46] Understandably, pretreatment of healthy exercising horses with bronchodilators – clenbuterol, albuterol, or ipratropium – fails to reduce total pulmonary resistance or the work of breathing.[46,47] Note also in Table 28.3 that the work of breathing increases 15-fold from the resting value when the horse gallops at 12 m/s. Minimizing the work of breathing during high intensity exercise has been suggested as a contributing cause to gas exchange failure in the athletic horse.[48]

Control of breathing during rest and during exercise

Rhythmic breathing during eupnea has been attributed to the workings of a central pattern generator that, through its effects on the intermediary bulbospinal neurons of the medulla, ultimately activates inspiratory and expiratory motoneuron pools of the spinal cord. In the resting horse both inspiration and expiration are active processes reflecting the electromechanical activation of the diaphragm (inspiratory muscle) and of the transverse abdominal and external oblique muscles (expiratory muscles).[22,23] The role of the rib cage muscles in generating the breath has not been well studied in the horse.

During eupneic breathing, the initial generation of inspiratory flow precedes electrical activation of the diaphragm and is attributed to outward recoil of the chest wall and relaxation of abdominal expiratory muscles (Fig. 28.7). With diaphragmatic activation, inspiratory airflow again increases, causing the biphasic flow pattern. During expiration, relaxation of the diaphragm contributes to the initial generation of expiratory flow. Once expiratory muscles are activated, there is a further increase in expiratory flow.

When horses are exercised, linear increases in the diaphragmatic electromyogram (EMG) are associated with linear increases in the transdiaphragmatic pressure (Fig. 28.8).[40] Abdominal muscles are also recruited during the exercise hyperpnea. In ponies walking on the treadmill, there is a temporal correlation between the development of peak transverse abdominal EMGs and peak positive esophageal pressure, suggesting an expiratory function for this muscle.[49] In contrast, the EMGs of the rectus abdominis and abdominal oblique muscles in horses during mild to high intensity exercise exhibit a locomotory-associated modulation.[50]

The generation of a breath during eupnea or during the exercise hyperpnea is shaped by inputs from: (i) central and peripheral chemoreceptors; (ii) mechanoreceptors of the intra- and extrathoracic airways and lung parenchyma; (iii) phrenic afferents; (iv) locomotory-associated stimuli; and (v) higher central nervous system (CNS) centers.

Chemoreceptors Chemoreceptors are sensors that detect changes in CO_2, O_2 and pH and have been classified, based upon anatomical location, as either central or peripheral. At a given pH, the ventilatory response of the central chemoreceptors, presumed to be located in the medulla, is greater during a respiratory acidosis than during a metabolic acidosis. The augmented response is attributed to the more soluble CO_2 that easily permeates the blood–brain barrier, activating the central chemoreceptors. In awake chronically instrumented horses, activation of central chemoreceptors by hypercapnic challenge augments both inspiratory and expiratory muscle activation

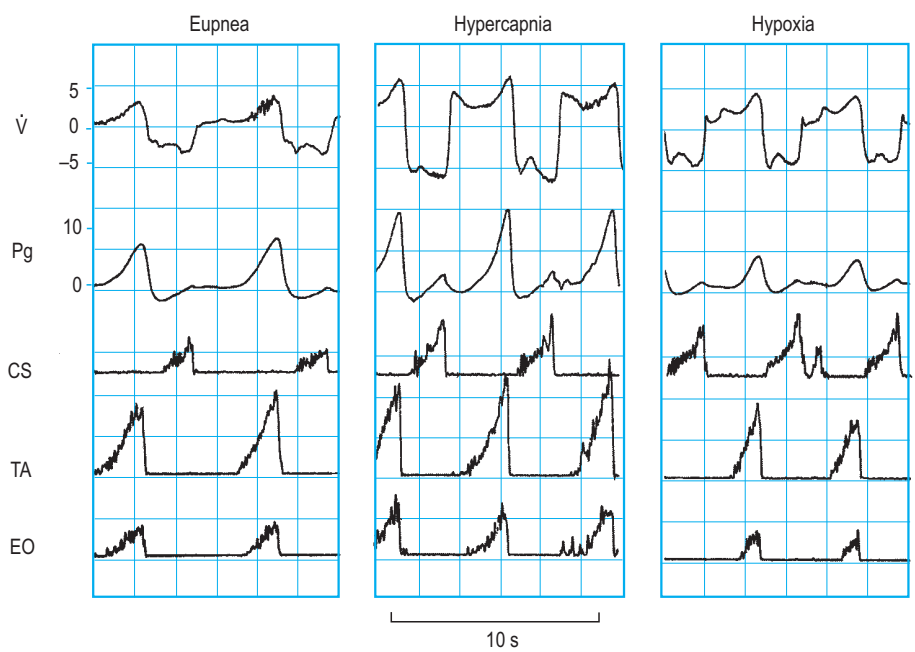

Fig. 28.7
Relationship between respiratory flow ($\dot{V}$), gastric pressure changes (Pg) and respiratory muscle (costal diaphragm (CS), transverse abdominal (TA) and external abdominal oblique (EO)) EMGs during eupneic, hypercapnic and hypoxic breathing. At rest, initial inspiratory flow precedes activation of the diaphragm and is attributed to relaxation of expiratory muscles (decrease in Pg). Similarly, the initial generation of expiratory flow precedes abdominal expiratory muscle activation and is attributed to relaxation of inspiratory muscles. With hypercapnic challenge, inspiratory and expiratory muscles are recruited to increase tidal volume and minute ventilation. Hypoxia causes an increase in inspiratory muscles but less of an increase in abdominal expiratory muscles. (Reproduced with permission from Ainsworth et al.[22])

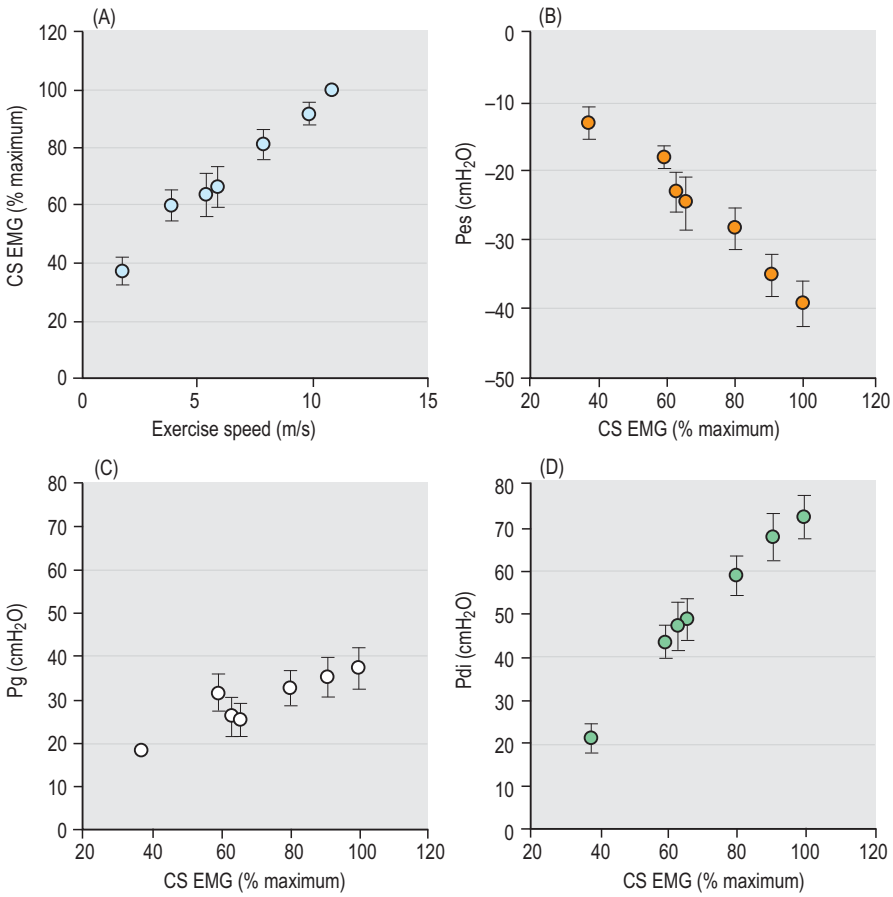

Fig. 28.8
Relationship between diaphragmatic activation and mechanical output during incremental exercise in horses. In panel A, the linear increase in the diaphragm (CS) EMG that occurs as horses exercise at faster treadmill speeds is demonstrated. The increase in electrical activity of this inspiratory muscle is associated with a progressive decrease in peak esophageal pressure (panel B), a progressive increase in peak inspiratory gastric pressure as the diaphragm descends into the abdominal cavity during inspiration (panel C) and a linear increase in the mechanical output of the diaphragm, the transdiaphragmatic pressure (Pdi) during exercise. (Reproduced with permission from Ainsworth et al.[50])

(Fig. 28.7), leading predominantly to a V_T response with little change in breathing frequency.[22]

Peripheral chemoreceptors are located at the bifurcation of the carotid arteries and predominantly detect changes in oxygen tensions. Activation of peripheral chemoreceptors via hypoxic challenge increases the magnitude and frequency of inspiratory muscle activation with little change in abdominal expiratory muscle activity (Fig. 28.7).[22]

Although arterial hypoxia and hypercapnia develop during exercise,[12,51] it does not appear to be the result of impaired chemoreception. When horses breathe a hyperoxic mixture (inspired fraction (F_IO_2) = 0.3) while galloping at 14 m/s, there is a reduction in $\dot{V}_A$ relative to normoxic trials – an expected response. When the F_IO_2 is reduced from 0.21 to 0.16 in those horses galloping at 14 m/s (causing a corresponding decrease in Pao_2 from 56 to 38 torr), tidal volume and minute ventilation increase 20%, confirming that an intact hypoxic drive exists.[48] Interestingly, when exercising horses (14 m/s) breathe a hypercapnic gas mixture (F_ICO_2 = 0.06) causing $Paco_2$ to increase from 50 to 80 torr, ventilation fails to increase in the majority of horses studied.[52] The occasional horse will uncouple breathing with limb movement to increase tidal volume.

The question of why the horse does not increase ventilation in response to the decrease in Pao_2 (65% $\dot{V}O_{2\,max}$) – when mechanical flow limitations do not exist – is unknown. Some investigators have suggested that this breathing strategy simply reflects that of a 'smart' ventilatory controller that 'chooses' to minimize the mechanical cost of breathing rather than to optimize blood gas tension and acid–base balance.[48]

The question of why the horse develops hypercapnia at near maximal exercise is discussed below in the section on 'Mechanical factors limiting ventilation'.

Mechanoreceptors Breathing pattern is also influenced by mechanoreceptive input from receptors within the airways of the respiratory system, within the costovertebral articulations and within the rib cage and abdominal musculature (spindles, Golgi tendon organs). Within the lung, three types of pulmonary mechanoreceptors have been identified: the slowly adapting receptors (SARs), the rapidly adapting receptors (RARs) and the non-myelinated C fibers.[53] Vagally mediated inputs from the SARs, responding to increases in lung inflation, feed back onto the central respiratory controller to terminate inspiration and to activate expiratory muscles. The RARs are mechanoreceptors with a primary function of mediating augmented breaths or sighs. Changes in lung compliance during eupneic breathing are thought to be sensed by RARs which then initiate sighs. Pulmonary and bronchial C fibers, vagally mediated non-myelinated fibers, are activated by substances produced, released and catabolized in the lungs (bronchial C fibers) or by mechanical alterations in the lung parenchyma that occur with congestion and edema (pulmonary C fibers). Their contribution to the

control of breathing in the horse has not been investigated but in other species, activation results in a tachypneic pattern.[53]

In resting ponies, elimination of mechanoreceptor input, either by vagal cooling or by local anesthesia, prolongs inspiratory time, decreases breathing frequency and R_L, increases V_T but has no effect on arterial blood gas tension, minute ventilation and dynamic compliance.[54] In ponies performing mild treadmill exercise (walking, trotting), removal of vagally mediated afferent inputs via hilar denervation produces similar effects. There is an increase in V_T, a decrease in breathing frequency and a preservation of minute ventilation and arterial blood gases.[55] Thus, during low intensity exercise, mechanoreceptor inputs are not critical for the exercise hyperpnea to develop. However, the effects of vagal deafferentation on the pattern of breathing (locomotory:respiratory coupling) or on gas exchange in horses performing high intensity exercise remains to be determined.

Phrenic afferents The diaphragm and the non-respiratory muscles are innervated by small afferents (types III and IV) that respond to mechanical and chemical stimuli.[56] Although the majority of studies examining the effects of phrenic afferents on the control of breathing have been obtained in studies of anesthetized cats and dogs, the data confirm muscle afferents to be powerful stimuli to ventilation. In lightly anesthetized dogs, electrical stimulation of phrenic afferents causes a 500% increase in ventilation – a response equivalent to that induced with breathing 10% CO_2![57] Nevertheless, it does not appear that diaphragmatic afferents are the primary drive for the exercise hyperpnea as diaphragmatic deafferentation does not affect ventilation or arterial carbon dioxide tensions in ponies that are mildly exercised.[58,59]

Locomotory-associated stimuli Thoroughbred horses routinely entrain or couple breathing frequency with limb movement.[41,42] The mechanism of this coupling has not been established but it has been postulated to involve spinal afferents. Evidence for this comes from a study in ponies with partial spinal cord ablation. The net effect of the intervention is to attenuate the exercise-induced increases in breathing frequency, suggesting that feedback from limb movement modifies the exercise hyperpnea.[60]

In addition to neural inputs that would affect the pattern of breathing during exercise, locomotory-associated forces have also been suggested to significantly contribute to the exercise hyperpnea. A number of benefits could possibly derive from integration of locomotion and respiration since locomotion might affect the mechanical characteristics of the respiratory system by stiffening the chest wall, by reducing respiratory system compliance and by increasing the work of breathing.

Three exercise-associated forces postulated to generate airflow in horses during locomotion include: (i) the to and fro movements of the liver and intestines (visceral piston) effecting diaphragmatic movement; (ii) the concussive forces resulting from limb impact that are transmitted to the thoracic cavity to produce pressure and volume changes; and (iii) the compressive forces developing within the abdominal cavity during lumbosacral flexion and extension that ultimately produce pressure and volume changes within the thoracic cavity. Although this biomechanical model of ventilation fits well with the observed locomotory movements and respiratory airflow patterns in galloping horses, little conclusive evidence exists to support their relative contributions to the exercise hyperpnea. Young and colleagues have estimated that the visceral displacements are 230 degrees out of phase with ventilation.[61] They suggested that lumbosacral flexion and extension exerted a more significant biomechanical effect on ventilation. Frevert and colleagues also studied the breathing pattern of galloping horses that occasionally departed from the 1:1 LRC ratio.[62] By ensemble averaging the horse's respiratory flow signals using limb frequency as a trigger, they were able to calculate the contribution of limb concussive forces to ventilation. They found that stride-related volume excursions averaged 10–20% of the tidal volume. Finally, EMG recordings of respiratory muscles obtained in chronically instrumented exercising horses have clearly demonstrated that increases in phasic electrical activity of the diaphgram correlate with increases in transdiaphragmatic pressure generation independent of LRC (Fig. 28.8).[40]

CNS inputs Behavioral and thermal inputs from higher CNS centers influence the pattern of breathing during eupnea and may also exert modifying influences on ventilation during prolonged exercise in the horse.[13,63] For example, when Thoroughbreds exercise at 40% $\dot{V}O_{2\,max}$ for 60 minutes, arterial carbon dioxide tensions decrease 10 torr further from 'steady-state' levels occurring 10 minutes into exercise. During this time, the pulmonary artery temperatures increase 2.6°C and the work of breathing nearly doubles, suggesting to the investigators that the stimulus for the ventilatory increase is a thermoregulatory one.[63]

Other CNS inputs, specifically those radiating from locomotory-associated areas in the CNS, have also been suggested to exert a major role in the development of the exercise hyperpnea. This idea, called the central command concept, was first proposed by Johansson and later refined in 1913 by Krogh and Lindhard.[64] Increases in ventilation during exercise are hypothesized to arise secondary to neural impulses emanating from suprapontine structures which 'command' muscles to exercise. These impulses radiate to respiratory and cardiovascular centers and thus stimulate neuronal activity, driving ventilation and respiratory muscles concurrently. The hypothesis was based primarily on the rapidity of the ventilatory and circulatory responses, which could not be accounted for by humoral mechanisms.[65] Support for the central command theory comes from studies of decorticate cats that walk on a treadmill spontaneously or during electrical or chemical stimulation of the hypothalamic locomotor regions.[66,67] In these studies: (i) the respiratory and cardiovascular responses preceded spontaneous locomotion – suggesting that the 'hyperpnea' was not dependent upon afferent feedback – and (ii) the ventilatory response was proportional to the locomotory response. While appealing, the data have two major limitations. The decorticate cat might not duplicate physiological exercise and the metabolic rate was only minimally increased during the locomotion.[65]

Gas exchange during exercise

When Thoroughbreds or Standardbreds exercise at intensities exceeding 65% of the maximum oxygen consumption ($\dot{V}O_{2\,max}$), arterial hypoxemia occurs and the alveolar–arterial oxygen difference widens.[12,44] As exercise intensity exceeds 85% of $\dot{V}O_{2\,max}$, arterial hypercapnia ensues.[12,44,51,68] This is evident in the data presented in Tables 28.2, 28.3, and 28.4. Gas exchange failure occurs in horses performing treadmill incremental tests, treadmill sprint tests[69] as well as in horses exercising on a racetrack.[12,68,70]

In contrast to the horse, strenuously exercised ponies do not develop hypoxemia and hypercapnia, but rather develop an 'appropriate' ventilatory response characterized by normoxemia and hypocapnia[71] (Table 28.5). The ventilatory equivalent – the volume of expired (or inspired) gas per volume of oxygen consumed – is 1.6-fold greater for the pony as compared to a Thoroughbred! Why the horse fails to develop an appropriate ventilatory response at submaximal exercise (i.e. hypoxemia) is unknown and does not appear to be due to a failure of chemoreception. The inadequate ventilatory response may simply reflect a breathing strategy that minimizes the exponential increase in work of breathing during exercise.[48]

The mechanisms causing the arterial hypoxemia have been extensively investigated in exercising horses using a variety of approaches such as increasing the F_IO_2 or replacing inspired nitrogen with helium.[72,73] It was not until the multiple inert gas elimination technique was adapted for use in the exercising horse that the mechanisms causing the reduced Pao_2 and the widened alveolar–arterial oxygen difference (A–aDo_2) could be partitioned out.[44,74] In this technique, the airway elimination of inert gases that are dissolved in saline and infused into the venous blood is measured. The rate of elimination is dependent upon the ventilation: perfusion ratio and upon the solubility of that inert gas in the blood.[75]

Hypoventilation Although the increase in arterial (and alveolar) carbon dioxide tensions would contribute to the development of hypoxemia during exercise by reducing alveolar oxygen tensions, hypoventilation is not the major cause of hypoxemia.[51] In fact, it only accounts for a 6–7 torr reduction in arterial oxygen tensions at the highest exercise levels. The possible causes of the hypercapnia are discussed in the section on 'Mechanical factors limiting flow', below.

Shunts and ventilation:perfusion inequalities Relative to the resting condition, exercise does not cause an increase in intrapulmonary shunts. Thus, these do not contribute to the development of arterial hypoxemia.[44,45] There is, however, a small but significant increase in the degree of ventilation:perfusion mismatch that develops with exercise. In Standardbred trotters working at 96% of maximum $\dot{V}O_2$, ventilation:perfusion mismatch accounts for 36–41% of the observed arterial hypoxemia.[44,76] In Thoroughbreds galloping at 80% of $\dot{V}O_{2\,max}$, approximately 25% of the arterial hypoxemia is attributed to ventilation:perfusion inequalities.[74,77] The cause of the ventilation:perfusion mismatch is unknown but has been hypothesized to be due to the development of low-grade interstitial edema, pulmonary hemorrhage, regional differences in pulmonary blood flow, reduced gas mixing in the large airways or airway obstruction.[44] Overtrained horses that exhibit red cell hypervolemia also have a worsening of exercise-associated ventilation:perfusion inequalities.[76] Typically such horses develop pulmonary arterial pressures during exercise that are significantly greater than normovolemic cohorts and have an increased incidence of exercise-induced pulmonary hemorrhage.[76]

Diffusion limitation The major cause of the exercise-induced hypoxemia in the horse is a diffusion limitation.[12,44,72,74] During exercise, the combination of rapid pulmonary blood flows coupled with a much reduced venous oxygen content have been hypothesized to cause insufficient time to achieve complete equilibration of gas exchange across the capillary–alveolar interface. Interestingly, the mean capillary transit time has been estimated using the relationship Vc/Qt, where Vc is the total capillary blood volume (calculated from morphometric data)[78] and Qt is the cardiac output. Estimates of capillary transit time range from 386 to 404 milliseconds in the horse[72,76] and exceed transit times of 0.29 seconds for the dog or 0.35 seconds for the pony.[79] However, in contrast to the horse, the dog and pony do not exhibit diffusion limitation despite markedly shortened capillary transit times. Some investigators have suggested that the horse may exhibit a greater degree of heterogeneity in the transit time or in the diffusion:perfusion that is not accounted for by simply calculating the mean capillary transit time.[74]

Table 28.5 Comparison of ventilatory responses of ponies and horses at comparable metabolic work rates after 2 min of exercise

Exercise intensity	Group	Pao_2 (mmHg)	$PaCO_2$ (mmHg)	pHa	HCO_3 (mmol/L)	$\dot{V}_E/\dot{V}O_2$
60% $\dot{V}O_{2\,max}$	Thoroughbreds	81	40	7.47	29	27.6
60% $\dot{V}O_{2\,max}$	Ponies	89	32	7.44	22	43.7
115% $\dot{V}O_{2\,max}$	Thoroughbreds	68	50	7.26	21	26.3
115% $\dot{V}O_{2\,max}$	Ponies	95	35	7.30	17	41.9

PaO_2, arterial oxygen tensions; $PaCO_2$, arterial carbon dioxide tensions; pHa, arterial pH; HCO_3, bicarbonate; $\dot{V}_E/\dot{V}O_2$, ventilatory equivalent.

Mechanical factors limiting ventilation

The cause of the hypoventilation (hypercapnia) during high intensity exercise is unknown but has been postulated to be due to: (i) an increase in dead space ventilation secondary to the high breathing frequency; (ii) a mechanical flow limitation that results from the very short inspiratory and expiratory times; and/or (iii) locomotory:respiratory coupling.

If metabolic workload is held constant and the horse's breathing frequency is manipulated by changing the treadmill incline and speed, there is no effect on arterial carbon dioxide tensions.[80] This suggests that dead space ventilation is not the cause of hypercapnia. The data of Butler and colleagues also demonstrated that the ratio of dead space to tidal volume does not increase with strenuous exercise.[43]

Interestingly, when fb is manipulated by altering treadmill speed and incline while preserving metabolic demand, peak expiratory flow rates change very little (85–95 L/s). This suggests the development of an expiratory flow limitation. As large expiratory pulmonary pressures are generated during exercise, dynamic compression of the non-cartilaginous airways is hypothesized to limit expiratory flow.[80] This hypothesis is supported by data obtained from horses performing strenuous exercise while breathing heliox – a gas mixture consisting of 15% oxygen and 85% helium.[81] By replacing nitrogen with helium, there is a decrease in the gas density of the respired mixtures and a reduction in the turbulent flow. Thus, horses galloping at 8 m/s on a 7% incline while breathing the heliox mixture demonstrate a significant increase in $\dot{V}O_2$, $\dot{V}CO_2$, V_T, $\dot{V}_E$, and fb relative to the normoxic trials. Furthermore, despite an increase in metabolic workload which occurred with the heliox trials, horses were still able to increase alveolar ventilation sufficiently to reduce the severity of the arterial hypercapnia by 4 torr!

Definitive proof of an expiratory flow limitation in exercising horses requires the measurement of flow volume loops relative to changes in end-expiratory lung volume.[41] In human athletes, expiratory flow limitations (Fig. 28.9) occur but may also be reduced or minimized during exercise if EELV is increased.[30,82] However, as the athlete breathes from a higher EELV, the work of breathing is also increased. Although flow:volume loops have been measured in exercising horses (Fig. 28.10), it is not known whether limitation truly occurs and whether the horse can 'adjust' EELV to minimize the limitations to flow.

The question of whether LRC causes hypercapnia during high intensity exercise was addressed in a novel study by Evans and colleagues.[83] They measured arterial blood gases, fb and fs in Standardbred horses that were studied at comparable metabolic workloads either pacing (LRC ratio ≠ 1) or galloping (LRC ratio = 1). At 100% $\dot{V}O_{2\ max}$, the $PaCO_2$ of the galloping horses with strict entrainment was no different from that of the pacing horses that did not entrain breathing with ventilation. This suggested that in Standardbred horses, LRC does not impede alveolar ventilation.[83]

In summary, expiratory flow limitation may be a plausible explanation for the development of hypercapnia during near maximal exercise. However, one cannot discount the possibility that the pattern of breathings elected by the horse during strenuous exercise is also one chosen to minimize the work of breathing, one designed to prevent the development of diaphragmatic fatigue and one that prevents 'steal' of blood flow from the locomotory muscles.

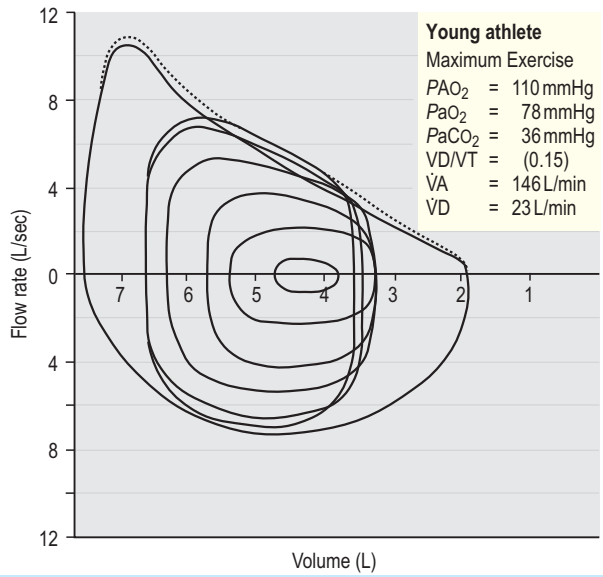

Fig. 28.9
Flow:volume loop from a human athlete performing incremental exercise. Inspiratory flow is below and expiratory flow is shown above the lung volume axis. The dashed line indicates the maximum expiratory flow obtainable in that individual. Eupneic breathing is indicated by the small loop centered near 4.25l. With the onset of exercise, end-expiratory lung volume decreases, but as expiratory flow limitations are reached, end expiratory lung volume increases (loop moves to the left). (Reproduced with permission from Johnson et al.[82])

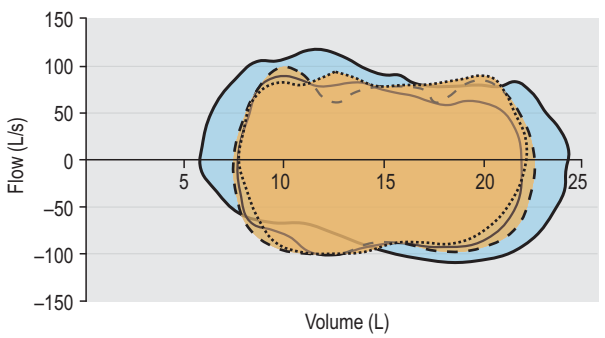

Fig. 28.10
Flow:volume loop from a Thoroughbred horse performing exercise at 115% $\dot{V}O_{2\ max}$. Loops were not placed relative to EELV. The four different loops were obtained while the horse exercised at 0% incline (thin solid line); 5% incline (thick dashed line); 10% incline (thin dashed line) and 20% incline (thick solid line). (Reproduced with permission from Bayly et al.[80])

Physiologic responses to training

Responses and mechanisms

As training is associated with increases in aerobic power, it is logical to assume that the respiratory system would undergo training-induced adaptations to increase its ventilatory output. Evans and Rose (1988) examined the effects of a 7-week submaximal training program on respiratory responses of Thoroughbred horses.[84] Although maximal oxygen consumption increased by approximately 23% (attributed to increases in cardiac output and stroke volume), minute ventilation remained unchanged. Evans and Rose also found a 6 torr reduction in Pao_2 tensions following training in horses exercising at 100% $\dot{V}o_{2\ max}$, but this difference was not statistically significant.[84] Art and Lekeux (1993) also examined the effects of a five-step training program on cardiopulmonary and respiratory parameters in Thoroughbred horses.[85] Each step of the program lasted 3 weeks and consisted of a treadmill acclimatization period, a light exercise period (20 min of turnout), an aerobic training period (walk, trot, canter 3 days/week), an interval training period and a detraining period. A standardized exercise test was performed after each step of the program. Although peak $\dot{V}o_2$ increased from approximately 117 mL/kg/min to 145 mL/kg/min at the end of the training program, training-induced changes in V_T, fb, and $\dot{V}_E$ were not found. The investigators did not measure concomitant changes in arterial blood gases. Christley and colleagues (1997) examined the effects of a 16-week training program on blood gases in Thoroughbreds.[86] The program consisted of an 8-week endurance phase followed by an 8-week sprint phase. They found that training significantly increased $\dot{V}o_{2\ max}$ by 19%, decreased Pao_2 by 5 torr and increased $Paco_2$ by 4 torr. The lack of a significant increase in alveolar ventilation as metabolic workload increased led to the deterioration in blood gas values. Roberts et al[87] measured both ventilatory and blood gas parameters in Thoroughbred horses that underwent a 16-week training session that closely mimicked the one used for race horses in Great Britain. They also found a worsening of the arterial hypoxemia and hypercapnia after training (Table 28.6),[87] confirming the findings of previous investigators. Training does not lead to an improvement in the ventilatory parameters, and because maximum oxygen consumption and carbon dioxide production increase, there is a worsening of the blood gases relative to the pre-training values.

In contrast to the studies that have been conducted in Thoroughbreds, there are few data evaluating the effects of training on ventilatory parameters in Standardbreds.

In summary, although training-induced modifications of the cardiac and musculoskeletal systems occur in the horse, there is a lack of pulmonary adaptations to training. This, combined with the high metabolic demands placed upon the horse during high intensity exercise, leads one to conclude that the respiratory system is a major limitation to the athletic performance of the equine athlete.

Table 28.6 Effects of a 16-week training program on ventilatory parameters in Thoroughbred horses galloping at 12 m/s

	Pre-training	Post-training
V_T (L)	14.6	15
fb (per min)	125	125
$\dot{V}_E$ (L/min)	1550	1800
Peak $\dot{V}_I$ (L/s)	79	80
Peak $\dot{V}_E$(L/s)	60	60
pHa	7.25	7.30
$Paco_2$ (mmHg)	53.6	56.5
Pao_2 (mmHg)	81	65

V_T, tidal volume; fb, breathing frequency; $\dot{V}_E$, expired minute ventilation; $\dot{V}_I$, peak inspiratory flow; $\dot{V}_E$, peak expiratory flow; pHa, arterial pH; $Paco_2$, arterial carbon dioxide tension; Pao_2, arterial oxygen tension. Reproduced with permission from Roberts et al.[87]

CHAPTER 29

Non-infectious diseases of the lower respiratory tract

Laurent L. Couëtil and Kenneth W. Hinchcliff

Inflammatory airway disease (IAD, small airway disease, small airway inflammatory disease, lower airway disease, bronchiolitis)

- IAD is associated with exercise intolerance, cough, and increased respiratory secretions.
- Young athletic horses are commonly affected and up to 65% of race horses have IAD.
- Bronchoalveolar lavage fluid cytology and exercise testing are valuable diagnostic tools for IAD.
- Horses with IAD exhibit various degrees of airflow obstruction and airway hyperresponsiveness.
- Etiology of IAD appears to be multifactorial with environmental dusts playing an important role.
- Therapy is aimed at decreasing environmental dusts and controlling airway inflammation.
- Aerosol therapy with corticosteroids and bronchodilators is effective.

Recognition of the disease

History and presenting complaint

A mild form of lower airway inflammatory disease commonly encountered in young athletic horses has been recognized recently as a separate entity from recurrent airway obstruction (RAO) and termed 'inflammatory airway disease' (IAD).[1–3] In the majority of cases, RAO and IAD may be differentiated on clinical grounds (Table 29.1). However, some have argued that, over time, horses with IAD may progress to RAO.[4] The incidence of IAD in race horses may vary between 11% and 65% depending on the diagnostic criteria used (endoscopy, cytology) and the conditions of examination (i.e. before versus after exercise).[5–7] Horses with IAD usually have a history of decreased performance, mild exercise intolerance, cough, and increased respiratory secretions.[1,8] Foals and older horses may also suffer from IAD.[9,10] In these cases, the diagnosis is often reached by excluding infectious and other non-infectious causes of lower airway inflammation. The possibility of IAD should be considered in horses with signs of respiratory disease including tracheobronchial mucopurulent exudate that do not respond, or relapse, after antimicrobial therapy and further diagnostic tests should be pursued (e.g. bronchoalveolar lavage).

Duration of IAD is 7 weeks on average with a range from 4 to 22 weeks, which is longer than most infectious respiratory diseases.[8,11] In a study involving 170 Thoroughbred horses in training over a 2-year period, it was estimated that during 8 of the 24 months, horses had some degree of IAD.[8] IAD appears to be more common in young athletic horses with the incidence decreasing with increasing age.[6,12] IAD is particularly common in Thoroughbred and Standardbred race horses, but has been also reported in a variety of other breeds such as Quarter Horse, Warmblood, Appaloosa, and American Saddlebred.[7,8,10,13,14] In fact, horses of any breed may be affected but race horses are over-represented because

Table 29.1 Comparison between recurrent airway obstruction (RAO) and inflammatory airway disease (IAD) in horses

		RAO	IAD
Signalment	Age	> 6 years	> 1 year
	Activity level	+/++	++/+++
Clinical signs	Duration	Months to years Recurrent	1–6 months Not recurrent
	Cough	Chronic intermittent	38% of cases
	Exudate in airways	Mucopurulent (++/+++)	Mucoid to mucopurulent (+/++)
	Lung sounds	Breath sounds (++/+++), wheezes, crackles	Normal
	Increased respiratory efforts	++/+++	0/+
	Exercise intolerance	++/+++	+/++
Etiology		Allergy to molds	Multifactorial
Pathophysiology	Lower airway obstruction	++/+++	0/+

	Airway hyper-responsiveness	+/+++	+/+++
Histopathology	Bronchiolitis	++/+++	+/++

Low/mild: +; medium/moderate: ++; high/severe: +++.

of several factors. First, the major limiting factor to performance in a race horse is pulmonary gas exchanges.[15] Therefore even a mild degree of respiratory disease may have a profound negative impact on performance whereas the same problem in a dressage horse would be considered clinically insignificant. Second, most race horses are kept in an environment that is particularly challenging for the respiratory tract. They are often confined in stables with suboptimal ventilation 24 hours/day (except for the training session), exposed to high levels of respirable irritants (e.g. dust and endotoxins from straw and hay), and mingle with a large population of horses originating from various locations.[16,17] Third, race-horse training and racing schedule and frequent traveling are often stressful, impairing the body's immune response and commonly resulting in lower airway disease.

The most common complaints reported by owners of athletic horses with IAD, other than race horses, are chronic cough, exercise intolerance, and prolonged recovery after exercise. These horses may be involved in a variety of activities such as barrel racing, three-day event, dressage, or simply trail riding. Owners often report a history of infectious respiratory disease in the months preceding the diagnosis of IAD with several horses in the barn being affected. The typical history is that all horses recovered except for the one with IAD, which continued to cough intermittently while in the stall and/or being ridden.

Physical examination

The most common clinical signs associated with IAD are increased respiratory secretions, cough, and decreased performance.[1,7,18] Estimation of the quantity of mucus present in the trachea by endoscopy reveals that horses free of respiratory disease have either no mucus or a few isolated flecks and horses with IAD have a pool of mucus at the thoracic inlet or a continuous stream of variable width (Fig. 29.1).[5,6] In addition, the severity of IAD is related to the amount of mucopus and the

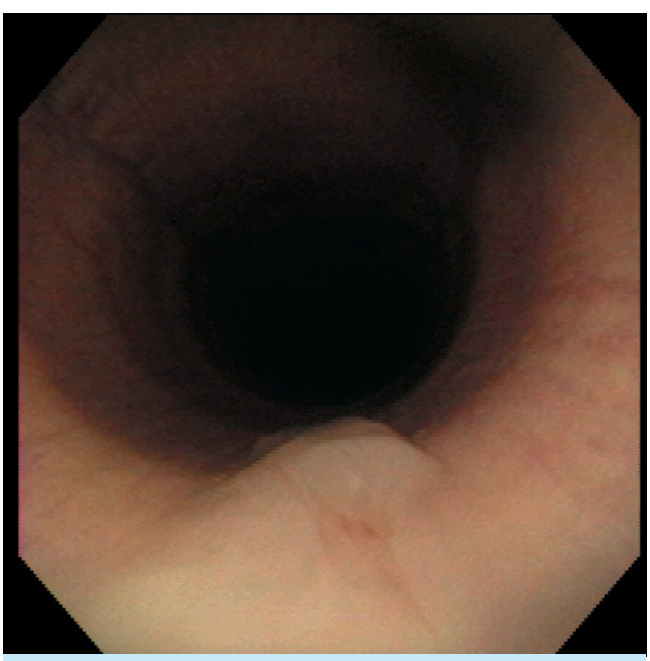

Fig. 29.1
Increased mucopurulent secretions visualized by endoscopy of the trachea in a horse with inflammatory airway disease.

percentage of neutrophils in tracheal wash or in bronchoalveolar lavage (BAL) fluid.[6,10] The incidence of tracheal exudate has been found to increase after strenuous exercise by some investigators[5] but not by others.[19] In healthy horses, the amount of tracheal mucus is not affected by age.[20]

Cough is present in only 38% of horses with IAD. However, 85% of coughing horses have IAD.[8,21] Daily observation of horses in training showed that coughing is not noted 62% of the time during which they have IAD.[8] Epidemiologic studies of Thoroughbred race horses in training found a strong association between coughing, the amount of mucus present in the upper airways, and pharyngeal lymphoid hyperplasia.[12,21] Also, a strong association exists between coughing, isolation of bacteria, and the degree of inflammation in tracheal wash fluid.[6,21] Nevertheless, bacteriologic examination of tracheal wash samples reveals that 35–58% of horses with IAD do not have significant amounts of bacteria in their tracheal wash fluid.

Other clinical signs of respiratory disease such as nasal discharge and fever do not appear to be associated with the disease.[8] Nevertheless, an increased amount of seromucoid nasal discharge post-exercise is commonly observed in horses with IAD. Thoracic auscultation is usually normal; however, some horses may exhibit increased breath sounds or wheezes. Horses with severe IAD may have a slightly increased respiratory rate and abdominal contraction on expiration. For the most part, IAD is subclinical and may go undetected unless coughing is present or tracheal exudate is detected by endoscopy.[10]

Effects of IAD on performance The negative impact of IAD on performance is suggested by several studies. A field study of Standardbred race horses (n = 965) revealed that mucopurulent exudate is visible by post-race endoscopy of the trachea in 39% of horses finishing in the last two positions compared with only 10% of horses finishing first or second.[7] In other words, horses finishing in the last two positions were 5.8 times more likely to have mucopurulent exudate during post-race endoscopy of the trachea than horses finishing first or second ($P < 0.0001$). Another study found that Thoroughbred race horses exhibiting marked decrease in performance had a significantly higher percentage of neutrophils in BAL fluid.[18] Subsequent return to previous level of performance was reported in 41% of horses with IAD after implementation of environmental changes aimed at decreasing the amount of airborne dust in the horses' stall.[18] However, no controlled studies have yet demonstrated a cause and effect relationship between IAD and decreased performance. Other signs associated with exercise intolerance are delayed recovery of normal respiratory rate after exercise and abnormally increased respiratory efforts compared with the level of work. These latter signs are more likely to be recognized in athletic horses other than race horses because most of their activities do not require exercising at or above maximal aerobic capacity.

The effect of IAD on performance is dependent on the level of exercise and the severity of the disease. Pulmonary gas exchange is the limiting factor to performance in fit horses as illustrated by the marked exercise-induced arterial hypoxemia and hypercapnia developed by healthy race horses exercising strenuously.[22,23] During a race, horses exercise at or above maximum aerobic capacity ($\dot{V}O_{2max}$). In this situation, a relatively mild degree of IAD may significantly impair gas exchange and result in decreased performance. IAD is not likely to cause exercise intolerance in a trail riding horse exercising at less than 50% of $\dot{V}O_{2max}$ until the disease causes marked airflow obstruction or frequent coughing. Therefore, the clinician needs to select diagnostic tools and interpret test results based on the horse's fitness level and type of activity.

Mechanisms responsible for decreased performance in horses with IAD are mainly speculative at this point in time. A study of Standardbred race horses performing submaximal exercise tests on a treadmill found that horses with IAD exhibited increased pulmonary artery pressure and red cell volume (RCV/kg bodyweight (BW)) in comparison to healthy controls.[24] These findings suggested a compensatory response to exercise-induced hypoxemia[25,26] even though significant differences in Pa_{O_2} between IAD and control horses were not found. The elevated pulmonary artery pressure was thought to result from increased vascular resistance. Elevation in RCV/kg BW or packed cell volume has been shown to correlate with increase in pulmonary blood pressure and vascular resistance.[27,28] Also, horses with more severe airway disease such as heaves have significantly elevated pulmonary artery pressure.[29,30] Another investigation evaluating gas exchanges and lung biopsy parameters in Standardbred race horses showed that horses with IAD had lower tidal volume and minute ventilation at a speed corresponding to a heart rate of 200 beats/min ($\dot{V}_{E\text{-}200}$/kg BW), and increased RCV/kg BW.[31] In addition, the severity of lung biopsy score was negatively correlated with $\dot{V}_{E\text{-}200}$/kg BW, suggesting that bronchial epithelial hyperplasia of the small airways was probably causing airflow obstruction. Indeed, small airway obstruction may be detected in horses with IAD using sensitive methods such as forced expiration or forced oscillatory mechanics (Fig. 29.2).[10,32,33] One study showed that race horses with IAD exhibited more pronounced exercise-induced hypoxemia than did healthy controls during a standardized run to fatigue treadmill test (Fig. 29.3).[34] Both groups of horses had comparable Pa_{CO_2}, suggesting that impaired gas exchange was likely to be a result of ventilation–perfusion mismatching and not hypoventilation. Exercise-induced hypoxemia is a physiologic phenomenon in horses[22] and the degree of arterial hypoxemia is more pronounced as the level of training increases.[35] Therefore, assessment of the significance of exercise-induced hypoxemia is dependent on control data matched for horses' age and fitness level.

Poor performance may result from a variety of causes such as lameness, exertional rhabdomyolysis, and cardiac and neurologic diseases. More importantly, it is common to diagnose several problems in the same horse.[36] In a retrospective study of 275 horses evaluated because of a complaint of poor performance Morris and Seeherman reported that 84% of cases were diagnosed with a combination of problems involving one or more body system.[36] These findings underscore the importance of performing a comprehensive evaluation of poorly performing horses.

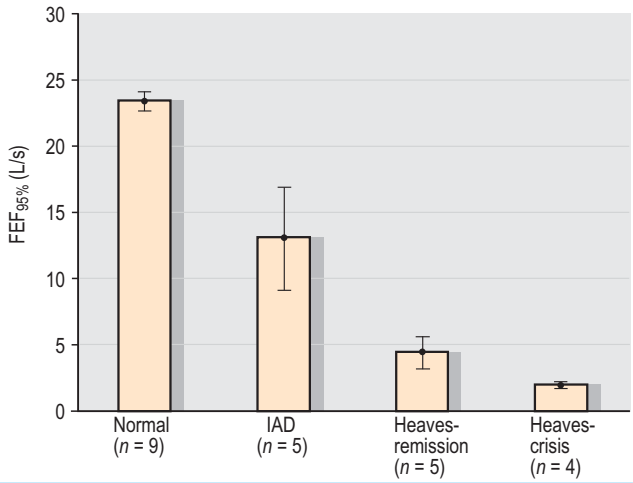

Fig. 29.2

Special examination

Endoscopic examination of the respiratory tract is a simple and valuable diagnostic tool for IAD. Horses with normal respiratory tract have at most a few flecks of mucus visible in the trachea by endoscopy.[20,37] Increased mucopurulent exudate in the tracheobronchial tree is detected in the majority of horses with IAD (Fig. 29.1). Also, endoscopic examination and BAL procedure tend to induce more coughing in horses with IAD.[18] However, increased tracheal exudate is present in the majority of pulmonary diseases other than IAD.[37]

Cytologic examination of respiratory secretions is important when trying to confirm a diagnosis of pulmonary disease. Tracheal secretions may be collected by direct aspiration or wash of tracheal lumen via transcutaneous catheterization or through an endoscope.[38–41] Several studies have shown an association between IAD and neutrophilia in tracheal secretions.[21,42] However, cytologic examination of tracheal mucus in horses free of respiratory disease is highly variable, as illustrated by the fact that neutrophils may range from 3 to 83% of cells.[43,44] In addition, tracheal wash cytology has been found to correlate poorly with pulmonary histopathology.[43,45] Tracheal wash cytology is a useful tool for investigation of IAD in horse populations for research purposes but may not be as valuable for the diagnosis of IAD in individual animals. In contrast, variability in BAL fluid cytology is limited, with most studies reporting neutrophils < 5% of cells (Table 29.2).[46,47] Furthermore, BAL cytology reportedly correlates well with histopathology of the lungs[48] and does not correlate with tracheal wash cytology.[44]

A BAL may be easily performed in field conditions using either a flexible endoscope (≥ 2 m long) or an equine BAL catheter at least 2.5 m long and 10 mm diameter with an inflatable cuff at the end (Bivona, Gary, IN; Cook, Bloomington, IN; Jorgensen Laboratories, Loveland, CO). The technique has been described in detail previously.[49,50] The horse has to be sedated with xylazine hydrochloride (0.4–0.8 mg/kg, i.v.) or detomidine hydrochloride (0.01–0.02 mg/kg, i.v.) and restrained with a nose twitch. The flexible endoscope or BAL tube is then passed through the nasal passages and advanced until wedged into the distal airways. Coughing may be prevented by spraying airways with a 0.2–0.5% lidocaine (lignocaine) solution (5–10 mL at a time) as the instrument is advanced into the respiratory tract, particularly focusing on the glottis and carina. Horses with IAD may cough excessively during the procedure and routine premedication with inhaled albuterol sulfate (1–2 μg/kg) 5–10 minutes prior to the BAL is beneficial. A 100–300 mL bolus of warm sterile saline solution is infused under pressure followed by immediate but gentle aspiration of the fluid using 60 mL syringes or a suction pump. It is important always to use the same technique during a BAL because the volume of fluid used as well as the number of boluses administered have a significant effect on cell count and differential (see Table 29.2). Fluid samples should be processed within 1 to 2 hours or stored on ice or at 4°C if sample shipping to the laboratory is to be delayed. Normal BAL fluid should appear slightly turbid with a layer of white foam on the surface (surfactant). Between 50 and 90% of the volume infused is expected to be retrieved.

Lung function can be measured in a variety of ways including assessment of gas exchanges, determination of lung volumes (spirometry), and evaluation of the movement of air in and out the respiratory tract (lung mechanics). Evaluation of gas exchange was discussed above in the section on effects of IAD on performance. Spirometry is useful in severe obstructive diseases such as RAO but not in milder diseases like IAD. Lung mechanics allows quantification of the degree of airflow obstruction present in horses' airways. Airflow obstruction is the basic mechanism responsible, at least in part, for some of the manifestations of IAD such as exercise intolerance and cough. The advantage of lung mechanics is quantification of airflow obstruction,

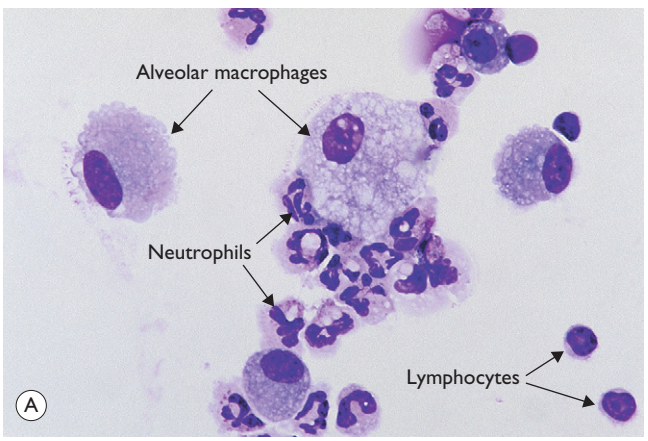
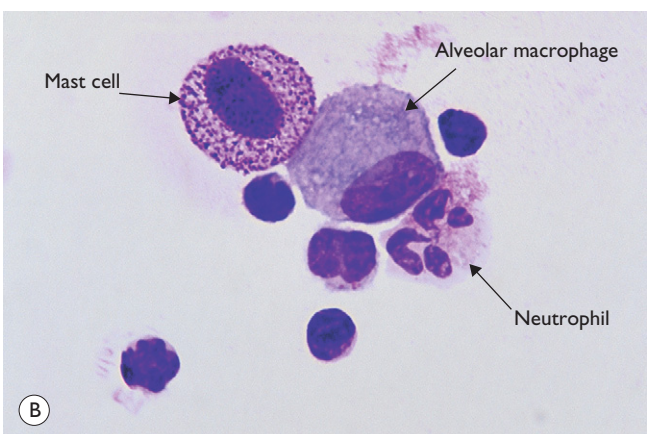
which is often subclinical in horses with IAD, enabling the clinician to determine the severity of the disease process and providing objective means of assessing response to therapy. The disadvantage is that sophisticated equipment and a sound understanding of respiratory physiology are required. Therefore, tests of lung mechanics are currently used mainly in the research arena and in some referral clinics.

There are four main methods used in the horse to evaluate lung mechanics. First, measurement of pleural pressure changes in relation to airflow at the nose during normal (tidal) breathing or 'conventional lung mechanics'. Second, measurement of airflow during forceful exhalation or 'forced expiration'. Third, evaluation of the pressure–flow relationship while an oscillating source of flow is applied to the respiratory system during tidal breathing ('forced oscillometry'). Fourth, measurement of thoracic and abdominal volume changes by inductance plethysmography in relation to airflow at the nose during tidal breathing ('flowmetrics'). Conventional lung mechanics was the first test of lung mechanics adapted to the horse[51] and is still commonly used in research.[52–54] However, this test has not been used extensively in clinical settings because it does not permit detection of airway obstruction until it is severe and clinical signs are then evident.[10,55] Forced expiration (FE) was initially performed in the horse by Gillespie and Leith in anesthetized animals.[56] More recently, the technique was adapted to conscious but sedated horses.[57] In people, FE requires the patient to inhale maximally to total lung capacity (TLC) and immediately exhale as hard and completely as possible to residual volume while expiratory flow, volume, and time are recorded. Expiratory flow is not limited during the first 20% of the FE when lung volume is close to TLC and is only dependent on the level of effort. During the rest of the maneuver expiratory flow reaches a maximum. Increasing effort will not increase expiratory flow further; therefore, this later part of the flow–volume curve is called 'effort independent' and reflects the degree of small airway patency. Similar findings have been reported in horses where forced expiratory flow during late FE (i.e. $FEF_{95\%}$) has been shown to be a sensitive parameter for the detection of mild airway obstruction such as in IAD (Fig. 29.2).[10] Forced oscillometry has the advantage of being non-invasive and has been used both in research and clinical cases. Horses with IAD often show frequency dependence of resistance with higher values obtained at the lower frequencies (1–3 Hz) suggestive of heterogeneous airway obstruction.[32]

Finally, flowmetrics has the greatest potential for use in the field because it is easily portable and also non-invasive.[58]

Another means of detecting airway obstruction is by testing airway reactivity in response to an inhaled irritant such as histamine. Exaggerated airway narrowing in response to an irritant is called airway hyper-responsiveness. Airway reactivity may be quantified using the four tests of lung mechanics described above.[33,57–59] Airway hyper-responsiveness is a prominent feature of IAD in horses with increased BAL fluid eosinophil and mast cell counts.[33,60] The sensitivity of forced oscillometry and flowmetrics is enhanced when used to detect airway hyper-responsiveness. This increased bronchoconstriction in response to inhaled irritants plays an important role in the pathogenesis of the cough and presumably exercise intolerance.





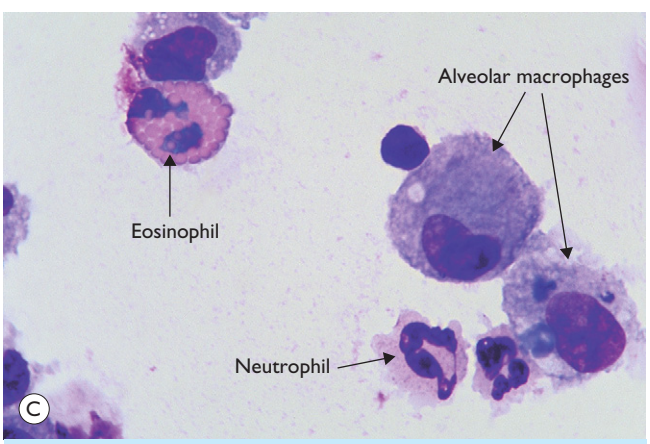


Fig. 29.4
Bronchoalveolar lavage fluid cytology in horses with IAD characterized by increased percentage of neutrophils (A), mast cells (B), and eosinophils (C). ×100.

Laboratory examination

Hemogram and serum biochemistry of horses with IAD are usually within normal limits.

Cytologic specimens of BAL fluid are prepared by centrifugation and processed with Wright's stain. Differential cell counts should be determined by examination of at least 200 cells per slide and preferably 500. Cytologic analysis of BAL fluid allows recognition of three types of inflammatory profiles in IAD (Table 29.2).[50] The most commonly encountered profile is characterized by an increased total nucleated cell count with mild neutrophilia (5–20% cells), lymphocytosis, and monocytosis (Fig. 29.4A).[1,10,18] Two other cytologic profiles characterized by increased percentages of mast cells (> 2%, Fig. 29.4B) and eosinophils (> 1%, Fig. 29.4C) are also observed in some horses with IAD.[2,60] In contrast, BAL of horses with RAO shows moderate to severe neutrophilia (> 20% cells), lymphopenia, and decreased alveolar macrophages.[10,61,62] Cytology of BAL fluid collected from horses with RAO in clinical remission may be normal if sufficient time away from offending allergens has been allowed. Some RAO cases may be clinically normal but still exhibit some degree of pulmonary neutrophilia and, therefore, may be difficult to differentiate from IAD. A practical way to discriminate RAO from IAD is by performing a hay challenge and monitoring clinical signs of respiratory disease, which should develop within a few hours to a few days in RAO affected horses.[53,63] Horses with IAD exposed to moldy hay may exhibit a worsening of coughing and pulmonary neutrophilia. However, they do not develop increased respiratory efforts or nostril flaring like RAO affected horses do.

Necropsy examination

Histopathologic examination of the lungs may be conducted ante-mortem using transcutaneous lung biopsy needles or post-mortem. Horses with IAD present similar histopathologic findings to horses with RAO but with less severe and chronic changes.[48] Typical morphologic findings include peribronchiolitis, bronchiolitis, bronchiolar epithelial hyperplasia, goblet cell metaplasia, luminal mucus, and in some cases alveolitis.[24,31] Severity of histopathologic changes assessed by a scoring system appears to be negatively correlated to various indices of respiratory and cardiovascular function in horses with IAD.[31] Consequently, as pulmonary lesions become more severe, horses become more exercise intolerant.

Diagnostic confirmation

In horses presenting with clinical signs including cough, increased respiratory secretions, and poor performance

detailed history, physical examination, and diagnostic tests should help eliminate differential diagnoses. Horses with IAD are not febrile; therefore, presence of a fever suggests infectious respiratory diseases such as viral diseases, bronchopneumonia, pleuropneumonia, and pulmonary abscess. Hematology findings may be helpful. However, they are often non-specific. Leukocytosis with neutrophilia is commonly found with bacterial respiratory infections and during the acute phase of a bacterial infection, increased numbers of immature neutrophils ('left shift') may be observed. Neutrophilia may also accompany non-infectious inflammatory diseases (e.g. toxins), neoplasia, mycotic, and parasitic infections. Hematologic changes during the early phase of a viral respiratory infection (e.g. influenza) are often characterized by normocytic, normochromic anemia, lymphopenia or lymphocytosis, and sometimes neutropenia.[64,65] Neutrophilia may follow within a week of initial clinical signs, particularly in cases of secondary bacterial infection. Monocytosis

Table 29.3 Therapeutic aerosols used for the treatment of inflammatory airway disease (IAD) and recurrent airway obstruction (RAO)

Drug	Trade name (Laboratory)	Dose delivered per actuation	Number of doses per canister	Device	Dose	Duration of action
Bronchodilators						
Albuterol	Torpex (Boehringer and 3M)	120 μg	200	3M ED	1–2 μg/kg[a]	1 hour
	Combivent (Boehringer)	120 μg (+ 21 μg ipratropium)	200	AeroMask	2–3 μg/kg	1 hour
	Proventil (Schering)	120 μg	200

may develop during the recovery phase of a viral infection.

Coughing is often chronic intermittent (> 3 weeks) in horses with IAD. Main differential diagnoses are mild cases of RAO and summer pasture-associated obstructive pulmonary disease (SPAOPD), and parasitic pneumonitis. Horses with RAO and SPAOPD typically display severe exercise intolerance and increased respiratory efforts during periods of disease exacerbation. However, these signs may be subtle during periods of disease remission. In those cases, pulmonary function testing or more simply, moldy hay challenge will help reaching a definitive diagnosis. Neutrophilia is commonly observed in BAL fluid from horses with RAO, SPAOPD, and IAD.[1,61,66] The neutrophilia is usually more pronounced with RAO and SPAOPD than with IAD. However, there is significant overlap between diseases.[10] Eosinophilic inflammation may be associated with IAD,[67] parasitic pneumonitis (*Parascaris equorum*, *Dictyocaulus arnfieldi*), hypersensitivity pneumonitis, fungal pneumonia, and cutaneous habronemiasis.[2,68,69] Clinical signs of parasitic pneumonitis are non-specific. Fecal flotation (Baermann technique) is often not diagnostic of *P. equorum* infection because migration through the lungs occurs during the prepatent period.[70] *D. arnfieldi* follows a complete cycle in donkeys, mules, and asses. However, the infection is usually not patent in horses. Therefore, the Baermann fecal flotation is not useful either. *P. equorum* pneumonitis is more commonly detected in foals less than 6 month of age. *D. arnfieldi* usually occurs in horses in contact with infected donkeys and rarely by ingesting larvae excreted by infected horses.[71] A presumptive diagnosis may be reached when respiratory secretions reveal eosinophilic inflammation with sometime evidence of parasite eggs or larvae, exposure to donkeys exists, and anthelmintic therapy results in clinical improvement.[70] Increased metachromatic cells (mast cells, basophils) have been described in horses with IAD but this has not been associated with other types of respiratory disease.[2,4]

Treatment

Therapeutic aims

Treatment of IAD should combine environmental changes and medical therapy. The goals of medical therapy are to control airway inflammation and relieve airflow obstruction using mainly corticosteroids and bronchodilators. Most of the drugs and dosages recommended are based on studies performed on horses with RAO. However, good clinical response of IAD has been observed using those guidelines (Table 29.3). Both systemic and aerosolized drugs are effective, but the potential for adverse effects and prolonged elimination times is greater with systemic administration. The advantages of aerosol therapy are ease of administration, high efficacy, and safety. The disadvantages are cost and environmental effects of certain types of propellants (i.e. CFCs). Non-steroidal anti-inflammatory and antihistamine drugs are ineffective for the treatment of IAD.

Therapy

Environmental changes Inhaled dust particles play an important role in the pathophysiology of IAD and treatment of IAD should always include recommendation to decrease environmental irritants to airways. Several measures may help reduce exposure of the horse's airways to respirable particles and are discussed in detail in the section on RAO, below.

Systemic medical therapy Systemic corticosteroids are effective for the treatment of non-infectious respiratory inflammation. Nevertheless a good understanding of the relationship between potency, duration of action, and adrenal suppression is needed in order to minimize potential undesirable side effects. The same corticosteroids used for RAO may be used to treat IAD (see RAO section for complete discussion).

Oral administration of low-dose (50–150 U every 24 hours) interferon alpha (IFNα) for 5 days has been shown to reduce neutrophil, macrophage, lymphocyte, and total nucleated cell counts in the BAL fluid of race horses with IAD followed over 2 weeks.[72] A parallel reduction in BAL fluid immunoglobulins and inflammatory mediators concentrations was demonstrated, which suggested plasma exudation as a result of airway inflammation.[73] Higher doses of IFNα (450 U) appeared to be less effective. Endoscopic scores based on respiratory exudate, cough, and pharyngeal lymphoid hyperplasia were significantly reduced after 1 week of therapy but were not different from placebo at 2 weeks. Mast cell and eosinophil counts did not change after IFNα therapy. Until the pathophysiology of IAD is established, pulmonary anti-inflammatory effects of IFNα may be attributed to antiviral activity or immunomodulatory properties.[73]

Non-specific immunostimulants such as *Propionobacterium acnes* are recommended as an adjunct treatment for a variety of chronic respiratory diseases and as prophylactic agents for stress-associated (e.g. long-distance transport, weaning) respiratory diseases.[74,75] However, the efficacy of such therapy has not been demonstrated conclusively for IAD.

Aerosol therapy This topic is discussed in detail in the RAO section. Drugs used in the treatment of IAD are listed in Table 29.3.

Corticosteroids No clinical trials have been reported concerning the use of inhaled corticosteroids for IAD. However, the same drugs used to treat RAO are beneficial for IAD and as a general rule the low end of the range recommended for RAO is appropriate for IAD cases. Beclomethasone dipropionate (2–4 μg/kg, every 12 hours) and fluticasone propionate (1–3 μg/kg, every 12 hours) are recommended to treat IAD using commercially available metered dose inhaler (MDI) delivery devices (AeroMask, Equine Haler). Improved clinical signs, decreased airway hyper-responsiveness, and reduced pulmonary inflammation are detectable within 2 weeks of therapy.

Bronchodilators Bronchodilators are indicated to relax airway smooth muscle and relieve airflow obstruction. Two main classes of inhaled bronchodilators have been used in the horse: β_2-agonists (e.g. albuterol) and anticholinergics. Bronchodilators should not be used as only therapy for IAD because they do not suppress airway inflammation and do not reduce airway hyper-responsiveness.[76] In addition, prolonged use of β_2-agonists without corticosteroids induces receptor downregulation, which renders the drug less effective. In horses with significant airway obstruction, bron-

chodilators should be administered prior to corticosteroids in order to optimize lung deposition.

As for corticosteroids, the choice of inhaled bronchodilator and dosages recommended to treat IAD are the same as for RAO.

Cromones Sodium cromoglycate (cromolyn) has been shown to improve clinical signs and to decrease bronchial hyper-responsiveness when administered to horses with IAD characterized by a high mast cell count in BAL fluid (Table 29.3).[2] However, it is ineffective for the treatment of IAD with other inflammatory profiles.

Prognosis

Horses with IAD have a good prognosis for return to previous level of performance. In some cases the disease may recur but in the majority of cases implementation of environmental changes combined with medical therapy results in long-lasting resolution of the clinical signs.

Etiology and pathophysiology

Putative causes of IAD include bacteria, viruses, and inhaled environmental pollutants with a modulatory role played by factors such as the horse's immune response and genetic make-up.

The likelihood of isolating bacteria from tracheal wash samples collected from race horses in training is strongly associated with the cytologic degree of inflammation.[6,8,21] Isolation of more than 10^3 colony-forming units of pathogenic *Streptococcus* spp. is also strongly associated with coughing.[21] Bacterial species most frequently isolated are *Streptococcus* spp., *Pasteurella/Actinobacillus* spp., and *Bordetella* spp. *Mycoplasma* have not been reported in horses with IAD. Reportedly, race horses diagnosed with lower airway infection based on BAL cytology respond to antibiotic therapy in 31% of the cases.[18] The marked increase in the risk of coughing in horses with high numbers of bacteria in tracheal secretions, the common isolation of bacteria with potential to cause pulmonary disease, and the association between IAD and detection of intracellular bacteria in tracheal secretions argue for a causative role of bacteria in the pathogenesis of IAD (see page 683).

However, several factors suggest that bacteria may in fact be present in the trachea because of contamination during sampling or transient colonization of the proximal airways. First, no bacteria are cultured in 27–54% of horses with IAD.[6,77] Second, the trachea is not a sterile environment and potentially pathogenic bacteria may be isolated by tracheal wash in 8–25% of healthy horses with isolation of non-pathogenic organisms in as many as 75% of those horses.[78,79] Third, the presence of bacteria in the airways may result from decreased mucociliary clearance and not from primary infection. Fourth, successful treatment of IAD with oral IFNα or inhaled glucocorticoids suggests that infectious agents are not causative agents but rather opportunistic invaders of the tracheobronchial tree.[4,50,72]

Contrary to common belief, respiratory viruses do not appear to play an important role in IAD. Several reports have shown no evidence of viral infections in horses with IAD based on serology or virus isolation aimed at detecting equine herpes, influenza, adenovirus, and rhinoviruses.[5,8,21] These findings are consistent with the fact that no relationship has been found between presence of fever and IAD.[8]

The role of exposure to dust in the pathogenesis of IAD is suggested by several studies. Healthy yearlings fed hay demonstrate a significant increase in BAL fluid neutrophil count and percentage, and a higher airway inflammation score when housed in a stable than when kept on pasture.[80] Natural exposure of healthy horses to moldy hay or controlled exposure to organic molds and endotoxins to levels encountered during natural exposure results in BAL fluid neutrophilia[62,82,83] and airway hyper-responsiveness.[81] Also, horses in training kept on straw bedding experience episodes of IAD that last longer than in horses bedded on paper.[8] These findings are consistent with data showing that conventional horse management consisting of indoor housing with straw bedding and feeding of hay results in much larger dust exposure levels than housing of horses on wood shavings and pelleted feed or keeping them on pasture.[16,84] Some horses with IAD demonstrate increased eosinophil or metachromatic cell counts in BAL fluid, suggesting hypersensitivity response of the lower airways to inhaled allergens.[1,2,4,60]

Atmospheric oxidants such as ozone have the potential to cause lower airway inflammation in horses, but levels encountered during natural exposure are unlikely to induce IAD in otherwise healthy animals.[85] Nevertheless, horses exercising strenuously while exposed to ozone levels comparable to atmospheric concentrations develop histologic evidence of airway damage and horses with IAD have elevated indices of oxidant injury[86] in BAL fluid, suggesting that oxidant injury may play a role in the pathophysiology if IAD.[85,87]

Several additional factors commonly encountered in athletic horses may contribute to the pathogenesis of IAD. Transportation of horses over long distances may induce airway inflammation and colonization of the tracheobronchial tree by bacteria.[88,89] Strenuous exercise results in colonization of the lower airways by large numbers of bacteria (10- to 100-fold compared with pre-exercise levels).[90] Both heaves in horses and asthma in people have a significant heritable component.[91,92] Therefore, airway response to environmental challenges is probably modulated by certain genes, and study of linkage between respiratory diseases such as heaves and IAD and certain immunomodulator genes will help identify animals at risk and in designing better ways of treating and preventing respiratory diseases.

Epidemiology

Several epidemiologic studies concerning IAD have been conducted on Standardbred and Thoroughbred race horses. However, only anecdotal reports are available for other breeds. The incidence of IAD is 22% in Standardbreds based on endoscopic evidence of mucopurulent exudate in the tracheobronchial tree within 30–90 minutes after a race.[7] In Thoroughbreds in training, the incidence is 50% on average

using similar endoscopic criteria as in Standardbreds. However, the incidence ranged from 13% in horses examined at rest to 65% in horses evaluated after strenuous exercise.[5] A few isolated specks of exudate were observed in 58% of the horses examined and a continuous stream was present in 42%. Similar results have been reported when the definition of IAD is based on an inflammation scoring system including detection of exudate during tracheal endoscopy and proportion of neutrophils and nucleated cell count in tracheal wash fluid. Only 38% of horses with IAD have a cough. However, horses that cough are four times more likely to have IAD.[8] Monthly fluctuation in the incidence of IAD based on inflammation score in Thoroughbreds in training may vary between 0 and 45%.[8] Age appears to be a significant factor, with 2-year old horses being two to seven times more likely to be affected by IAD than older horses.[8,12,42]

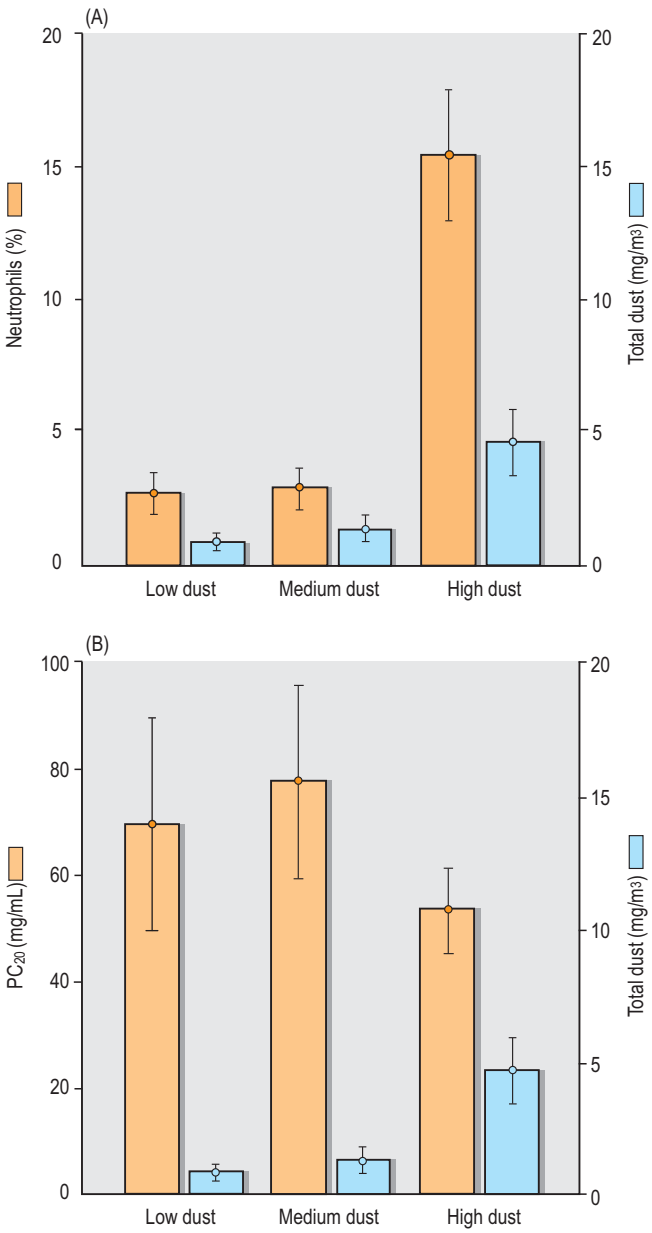

Fig. 29.5
Effect of dust exposure on (A) bronchoalveolar lavage fluid cytology and (B) airway responsiveness to histamine challenge. Low dust: horse in stall fed pellets and bedded on wood shavings; Medium dust: horse in stall fed pellets and bedded on straw; High dust: horse in stall fed moldy hay and bedded on straw. Total dust was measured in the breathing zone of the horse. PC_{20}: provocative concentration of histamine required to decrease $FEV_{1.5}$ by 20%.

Prevention

The risk of IAD is significantly lower in older horses, suggesting that development of an appropriate immune response may protect horses from IAD.[12,42] Even though viral diseases do not appear to play a major role in IAD, proper vaccination against respiratory pathogens prior to introduction of young horses into the stable is recommended.

Air quality, in particular low dust level, is an important part of preventive measures (see discussion of environmental changes in the RAO section, below). Horses kept in well-ventilated stalls and bedded on shredded paper are four times less likely to develop IAD than horses housed in closed stalls and bedded on straw.[8] Also, a study showed that young healthy horses fed hay while being maintained on pasture for a 3-month period did not exhibit signs of respiratory disease. However, they developed pulmonary neutrophilic inflammation within a month of being housed inside a barn on the same diet and bedded on straw.[80] Another study found that adult horses free of respiratory disease initially and exposed to incremental amounts of dust for 2 weeks at a time showed an increased percentage of neutrophils in BAL fluid and an increase in airway responsiveness to histamine challenge (Fig. 29.5).[81] These studies suggest that exposure of horses to dust levels commonly encountered in standard housing systems is sufficient to cause airway inflammation and pulmonary dysfunction in otherwise healthy horses.

Recurrent airway obstruction (RAO, SPAOPD, heaves, chronic obstructive pulmonary disease (COPD), broken wind)

- RAO is associated with exercise intolerance, increased tracheobronchial exudate, mild to severely increased respiratory efforts, and occasionally cough.
- Mature and older horses housed in stables for extended periods and fed hay are commonly affected.
- Horses suffering from summer pasture-associated obstructive pulmonary disease (SPAOPD) are clinically indistinguishable from RAO except that they develop clinical signs while at pasture during the summer.

- Bronchoalveolar lavage fluid cytology and response to bronchodilators are valuable diagnostic tools for RAO.
- Horses with RAO exhibit severe airflow obstruction and airway hyper-responsiveness.
- RAO appears to be hypersensitivity to inhaled organic molds with additional role played by inhaled endotoxins.
- Therapy is aimed at decreasing exposure to environmental allergens, decreasing airway inflammation with glucocorticoids, and relieving airway obstruction with bronchodilators.

Recognition of the disease

History and presenting complaint

Recurrent airway obstruction (RAO) or heaves is an allergic disease characterized by cough, accumulations of mucopurulent secretions in the tracheobronchial tree, abnormal breath sounds, increased respiratory efforts, and exercise intolerance.[93] Coughing and nasal discharge are frequently reported in horses with RAO (84% and 54% respectively). However, they are non-specific signs of respiratory disease.[11] Similarly, presence of tracheal exudate is common (96%) yet it is also found in a variety of pulmonary diseases. Exercise intolerance is usually marked but highly dependent on the level of exertion required of the horse as well as disease severity. Frequent bouts of coughing may be the main perceived cause of exercise intolerance. Horses with RAO exhibiting mild respiratory signs at rest may only show abnormally increased respiratory efforts for a given exercise intensity or prolonged recovery post-exercise. Because of a lack of objective data on 'normal' cardiopulmonary variables during exercise and recovery period in healthy horses, most of the assessment concerning exercise intolerance is based on the owner's or trainer's perception.

Clinical signs of RAO usually resolve within a few days after placing the horse on pasture or improving the environment by reducing organic dusts and increasing ventilation in the stall. Conversely, susceptible horses housed indoors and exposed to moldy hay develop clinical signs within a few hours to a few days.[53,59] Summer pasture-associated obstructive pulmonary disease (SPAOPD) is clinically indistinguishable from RAO except that historical findings reveal disease flare-ups while horses are kept at pasture during summer months and clinical improvement during winter or after horses are housed indoor.[66,94] Horses with RAO and SPAOPD tend to be mature (> 7 years) to old animals and there is no apparent breed or sex predilection.[11,94] Duration of the disease varies from months to years with periods of disease exacerbation (crisis) alternating with periods of clinical remission of variable duration. Hence, clinical signs are recurrent but the disease is permanent.[3]

Effects of RAO on performance RAO is widely accepted as a cause of exercise intolerance. However, few studies have attempted to understand the mechanisms responsible for this impaired performance. Horses with severe clinical signs are markedly hypoxemic and sometimes hypercapnic at rest, but values are not different from healthy controls during periods of disease remission.[53,95,96] Pronounced ventilation–perfusion mismatching appears to be responsible for these gas exchange abnormalities.[29,97,98] During submaximal exercise, horses with RAO in crisis become significantly more hypoxemic and hypercapnic and these abnormalities are associated with decreased expired minute ventilation and increased work of breathing.[99] Interestingly, alveolar ventilation and oxygen consumption may be maintained because of compensatory mechanisms such as decreased dead space ventilation, increased cardiac output and hemoglobin concentration. However, these compensatory mechanisms are likely to increase oxygen consumption by respiratory and cardiac muscles and to reduce the amount of oxygen available for exercising muscles, the net result being exercise intolerance as demonstrated by Art et al.[99] This phenomenon has been demonstrated in humans where respiratory muscles consume 10–15% of maximum oxygen consumption in trained athletes and up to 50% in chronic obstructive pulmonary disease (COPD) patients.[100] Decreasing the workload on respiratory muscles by mechanical ventilation during exercise has been shown to improve oxygen supply to locomotor muscles.[101] Consequently, locomotor muscle fatigue may in fact limit exercise capacity in humans with COPD exercising beyond the anaerobic threshold. On the other hand, COPD patients exercising below the anaerobic threshold may be more limited by ventilation. Whether these findings apply to exercising horses with RAO remains to be proven.

Physical examination

Horses with RAO may present with a wide spectrum of clinical signs depending on disease severity. Horses with mild RAO may exhibit little to no clinical signs of respiratory disease

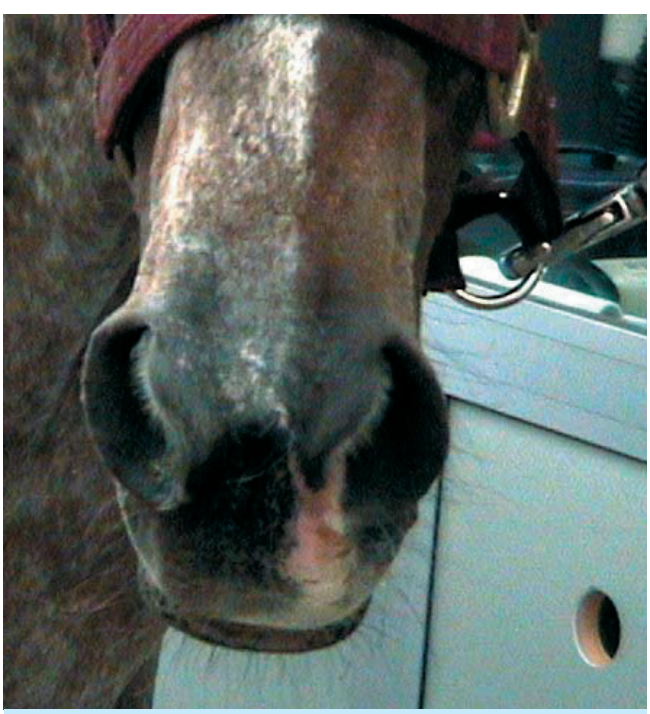

Fig. 29.6
Horse with RAO exhibiting increased respiratory efforts (nostril flaring).

except for exercise intolerance and may be difficult to differentiate from horses with IAD (Table 29.1). On the other end of the spectrum, horses with severe RAO show markedly increased respiratory efforts manifested by nostril flaring, head and neck extension, pronounced abdominal muscle contraction during expiration (heaving), and exaggerated rib excursion during inspiration (Fig. 29.6). Over time, horses develop hypertrophy of the external abdominal oblique muscles resulting in the characteristic 'heave line'. Respiratory rate is quite variable but is usually elevated. These clinical signs result from small airway obstruction secondary to airway inflammation, bronchospasm, mucus plugging of airways, and thickening of the airway wall.

Bilateral mucoid to mucopurulent nasal discharge may be present. A deep cough may be heard intermittently or in bouts of paroxysmal coughing. Thoracic auscultation may reveal increased breath sounds bilaterally, an extended area of auscultation, and abnormal breath sounds (i.e. crackles, wheezes). Horses' thick chest wall renders auscultation an insensitive indicator of pulmonary disease with abnormal findings obtained in less than 50% of horses with RAO.[11]

Special examination

Horses with normal respiratory tract have either no or just a few flecks of mucus visible upon endoscopy of the airways.[20,37] The presence of variable amounts of respiratory secretions in the tracheobronchial tree is found in the majority of RAO horses. However, it is also common in horses with IAD and infectious pulmonary diseases.[5,7,37] Horses with severe pulmonary disease, including heaves, often exhibit marked airway erythema and bronchial edema illustrated by blunting of the carina and 'bumpiness' of the airway surface (Fig. 29.7). Nevertheless, many horses with severe heaves and large amounts of tracheal exudate do not have visible signs of tracheobronchial inflammation.[37]

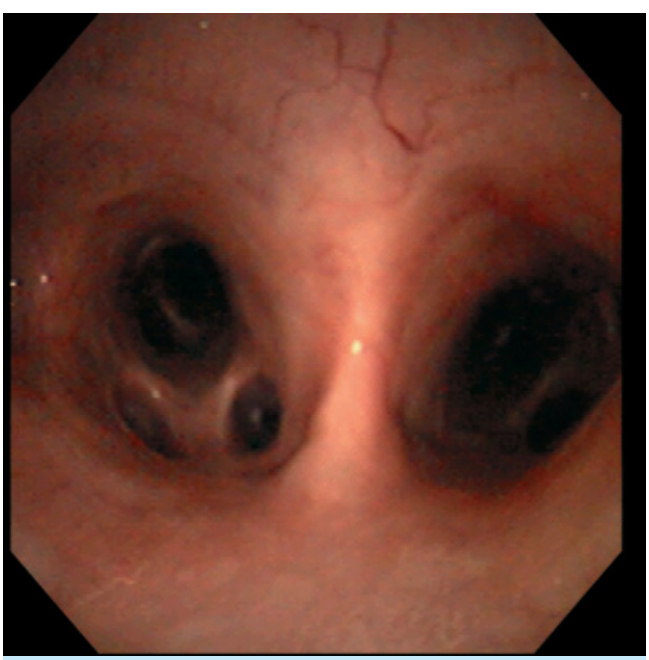

Fig. 29.7
Endoscopic view of the carina in a horse with RAO and marked bronchial edema.

Collection of respiratory secretions using tracheal wash (TW) or BAL techniques is important for diagnostic purposes and monitoring response to therapy. Description of the techniques and indications have been discussed in the IAD special examination section of this chapter. Sedation of the horse prior to BAL collection is mandatory and sometimes needed as well for TW. Administration of α_2-agonist sedatives (e.g. xylazine, detomidine) to horses with RAO results in significant decrease in respiratory rate, minute ventilation, and variable effects on pulmonary resistance (R_L) and dynamic lung compliance (C_{dyn}).[102–104] Pao_2 in affected horses is either maintained or only mildly decreased after administration of sedatives. Similar effects of sedatives on lung function are reported in healthy horses. Therefore, administration of sedatives to horses with RAO prior to diagnostic procedures is considered safe. The volume of fluid retrieved during the BAL procedure may be decreased in RAO horses due to small airway collapse as fluid is aspirated back. However, as long as the volume of fluid infused is sufficient (250–500 mL) there is no significant difference in absolute or differential cell counts between aliquots retrieved sequentially.[105] Therefore, interpretation of BAL fluid cytology in horses with RAO has diagnostic value even if the procedure only yielded a small amount of fluid.

Thoracic radiographs may be useful to rule out pulmonary diseases other than RAO. However, interpretation of radiographs is considered insensitive because radiographic findings correlate poorly with histopathology of the lungs and interpretation of images is highly variable between examiners.[106] Also, no radiographic findings are specific for a particular inflammatory lung disease, which renders chest radiography of limited value for the diagnosis of RAO.

Pulmonary function tests allow quantification of lung dysfunction using various techniques (see discussion in 'IAD/special examination'). During episodes of disease exacerbation, bronchoconstriction, edema of airway wall, and accumulation of secretions in the airways result in airflow obstruction and stiffening of the lungs. These structural changes translate into functional changes such as increased maximal changes in transpulmonary pressure (ΔP_{plmax}) R_L and decreased C_{dyn} (Table 29.4).[6,18] Values return within the normal range when horses are in disease remission. However, measurement of lung mechanics during tidal breathing is not sensitive and test results usually become abnormal when horses display obvious clinical signs of heaves. These tests are still useful in clinical practice to evaluate reversibility of airway obstruction after administration of a bronchodilator or to assess response to therapy because clinical signs alone are poor predictors of lung function, i.e. a significant degree of airway obstruction may still be present after the course of therapy even though clinical signs have resolved.[107] Another test of lung function called forced expiration has the advantage of being more sensitive than standard lung mechanics, allowing detection of airway obstruction in RAO horses in the absence of clinical signs (i.e. disease remission; Fig. 29.2).[108] Unfortunately, this test is technically

demanding and currently restricted for laboratory use. Lung function may be assessed using forced oscillatory mechanics (FOM), which requires only placement of a face mask on the horse. Horses with RAO in crisis exhibit frequency dependence of resistance. However, horses with mild clinical signs or in disease remission usually have values within normal limits.[32,109] Another non-invasive method that is well suited for field-testing combines the use of respiratory inductance plethysmography and pneumotachography during normal breathing at rest.[58] Airflow measured at the nostril opening by a pneumotachograph is compared with the flow signal derived from bands placed around chest and abdomen. Several indices derived from this lung function test correlate with conventional lung mechanics (ΔP_{plmax}, R_L) and allow quantification of airway obstruction in horses with RAO as well as response to bronchodilators or histamine challenge.[58]

A unique feature of horses with airway obstruction (RAO, SPAOPD, IAD) is their increased airway narrowing in response to challenge with irritants such as histamine or methacholine (hyper-responsiveness). Response to challenge (bronchoprovocation) may be assessed using different types of lung function test such as standard lung mechanics,[59,110–113] forced oscillatory mechanics,[114] respiratory inductance plethysmography,[33,58] and forced expiration.[57] In general, the greater the airway obstruction, the more pronounced the bronchoconstriction for a given concentration of irritant. Bronchoprovocation may prove to be a useful method for the detection of mild to moderate RAO in horses that do not display overt clinical signs.

Lung volume measurements, in particular functional residual capacity (FRC), are increased in horses with RAO compared with healthy controls.[115,116] However, as disease severity increases, the amount of air trapped behind obstructed airways rises and may lead to decreased FRC when measured by gas dilution techniques (helium or nitrogen),[117] when in fact FRC measured by plethysmography would show an increased volume.[118] The maximum volume of air that can be exhaled after a deep inspiration (FVC) is not smaller in horses with RAO, but the time needed to exhale FVC is significantly longer.[10] As a result, horses with airway obstruction have decreased forced expiratory volume in a given time (e.g. FEV_1 for volume exhaled in 1 second) and decreased forced expiratory flow during end expiration (Fig. 29.2). These findings suggest that expiratory flow limitation would be likely to occur during strenuous exercise when horses complete 1.5–2 respiratory cycles per second and contribute to the exercise intolerance manifested by RAO horses.

In addition to alteration in lung mechanics, RAO horses exhibit abnormal gas exchanges at rest during periods of disease exacerbation leading to hypoxemia and sometimes hypercapnia.[117,119] These blood gas abnormalities are mainly the result of ventilation–perfusion mismatch and increased dead-space ventilation.[29] Horses with mild clinical signs usually have normal blood gases. During exercise, the degree of exercise-induced hypoxemia and hypercapnia is markedly worse in RAO horses in crisis compared with those in remission.[99] Deterioration in gas exchanges appears to be mainly due to further deterioration in the ventilation–perfusion relationship.

Few studies have examined the relationship between lung histopathology, clinical signs, and lung function in horses with chronic airway disease. Significant correlation between percutaneous lung biopsy scores and clinical signs ($r = 0.58$) has been reported in RAO horses[120] and between mucus score in lung biopsies and clinical signs ($r = 0.78$) in horses with SPAOPD.[121] Also, clinical signs are correlated with indices of lung function such as ΔP_{plmax} in both RAO and SPAOPD.[10,121] Another investigation evaluating gas exchanges and lung biopsy parameters in Standardbred race horses with IAD showed that the severity of lung biopsy score was negatively correlated with lower minute ventilation at a speed corresponding to a heart rate of 200 beats/min, suggesting that bronchial epithelial hyperplasia of the small airways was probably causing airflow obstruction.[31] However, a similar relationship was not found in horses with RAO.

Laboratory examination

Hemogram and serum biochemistry are usually within the normal range,[61] although some horses with acute severe RAO may exhibit a mild hyperfibrinogenemia.

Cytologic examination of TW or BAL fluid is often useful to reach a final diagnosis. TW fluid obtained from horses with RAO and SPAOPD usually reveals a marked increased in neutrophil percentages (> 50%; range, 7–96%).[37,39,45,79] Neutrophils are non-degenerate and even if bacteria are isolated in some cases, they do not play a role in the pathogenesis of the disease. Increased amounts of mucus containing casts of inspissated mucus originating from the bronchioles (Curschmann's spirals) are often present in long-standing cases.[38] Several reports also found a wide range of neutrophil ratios in TW collected from clinically healthy horses (0–88%).[37,44] Therefore, the usefulness of TW cytology for diagnosis of RAO and SPAOPD is limited. BAL fluid is preferred in diffuse pulmonary disease such as RAO and SPAOPD because BAL fluid cytology is more representative of lung histopathology.[43,44] BAL fluid cytology in healthy control horses reveals that lymphocytes and alveolar macrophages predominate and neutrophils represent < 10% of the total nucleated cell count (Table 29.5).[47,62,121] A marked absolute and relative neutrophilia (> 20%) is usually observed in BAL fluid from horses with RAO and SPAOPD (Table 29.5).[61,62,121] In affected horses the range of neutrophil percentages is wide (10–98%) but no significant differences exist between BAL fluid cytology collected from different regions of the lung.[47]

Necropsy examination

The classic histopathologic lesion in horses with RAO is bronchiolitis characterized by peribronchiolar lymphoplasmacytic, neutrophilic, and sometimes eosinophilic cell infiltration, bronchiolar goblet cell metaplasia, epithelial hyperplasia, and accumulation of mucopurulent exudate in the bronchioles' lumen.[120,122,123] Similar changes are also frequently detected in the large airways.[124] Other lesions reported in severely affected horses are peribronchiolar fibrosis and epithelial metaplasia. Horses with SPAOPD display histopathologic changes that are indistinguishable from RAO.[121] Emphysema is rarely present in RAO horses and both centrilobular and panlobular forms have been reported.[125–127] Lungs of affected horses tend to remain overinflated at post-mortem examination because of air trapping secondary to airway obstruction and not emphysema. In general, there is a good correlation between the degree and extent of histopathologic changes and clinical severity.[122–124]

However, lesions are usually extensive but multifocal in nature, making interpretation based on small size samples (e.g. percutaneous lung biopsy) hazardous.[123]

Ultrastructural changes are characterized by loss of ciliated cells in the larger airways and replacement by a hyperplastic epithelium.[124] Examination of terminal airways and alveoli shows degenerative changes affecting non-ciliated bronchiolar epithelial cells (Clara cells) suggesting that Clara cells may be the target for antigens and inflammatory mediators during the disease process.[123]

Diagnostic confirmation

Horses presenting an abnormal increase in respiratory efforts should be examined to rule out upper and lower airway causes (Fig. 29.8). Upper airway obstruction may be associated with loud abnormal respiratory sounds (stridor). Lower airway diseases are often associated with abnormal breath sounds upon thoracic auscultation. Typically, upper airway obstruction results in increased inspiratory efforts whereas intrathoracic airway obstruction is associated with increased expiratory efforts. Fixed obstructions result in sounds, respiratory efforts, and respiratory times that are comparable during inspiration and expiration. Variable (dynamic) obstructions are characterized by a marked difference between inspiratory and expiratory sounds. Endoscopic examination should be performed rapidly in order to localize the disease process.

A decrease in lung sounds in the ventral thorax is usually indicative of pleural effusion or diaphragmatic hernia. Decreased lung sounds dorsally associated with increased resonance upon percussion of the thorax are consistent with pneumothorax. Diagnosis may be confirmed by ultrasonography of the thoracic cavity. The presence of abnormal lung sounds (crackles, wheezes) in horses with fever and respiratory distress suggests infectious pulmonary disease (e.g. bronchopneumonia, pulmonary abscess, interstitial pneumonia, necrotizing pneumonia).[128,129] A horse with labored breathing, normal rectal temperature, and abnormal lung sounds should be treated with a fast-acting bronchodilator (e.g. aerosolized albuterol, intravenous atropine) to assess the role of bronchoconstriction. Marked improvement in clinical signs strongly suggests reversible obstructive pulmonary disease such as RAO and SPAOPD. Marginal or no improvement may be associated with restrictive pulmonary diseases (e.g. pleural effusion, pulmonary edema, interstitial pneumonia, pulmonary fibrosis, silicosis, mediastinal mass), or non-respiratory diseases (e.g. cardiac failure). Thoracic radiography and cardiac ultrasonography are indicated to characterize the disease process and evaluate the severity of the lesion.

Horses in respiratory distress with no abnormal respiratory sounds should be further evaluated. Horses with

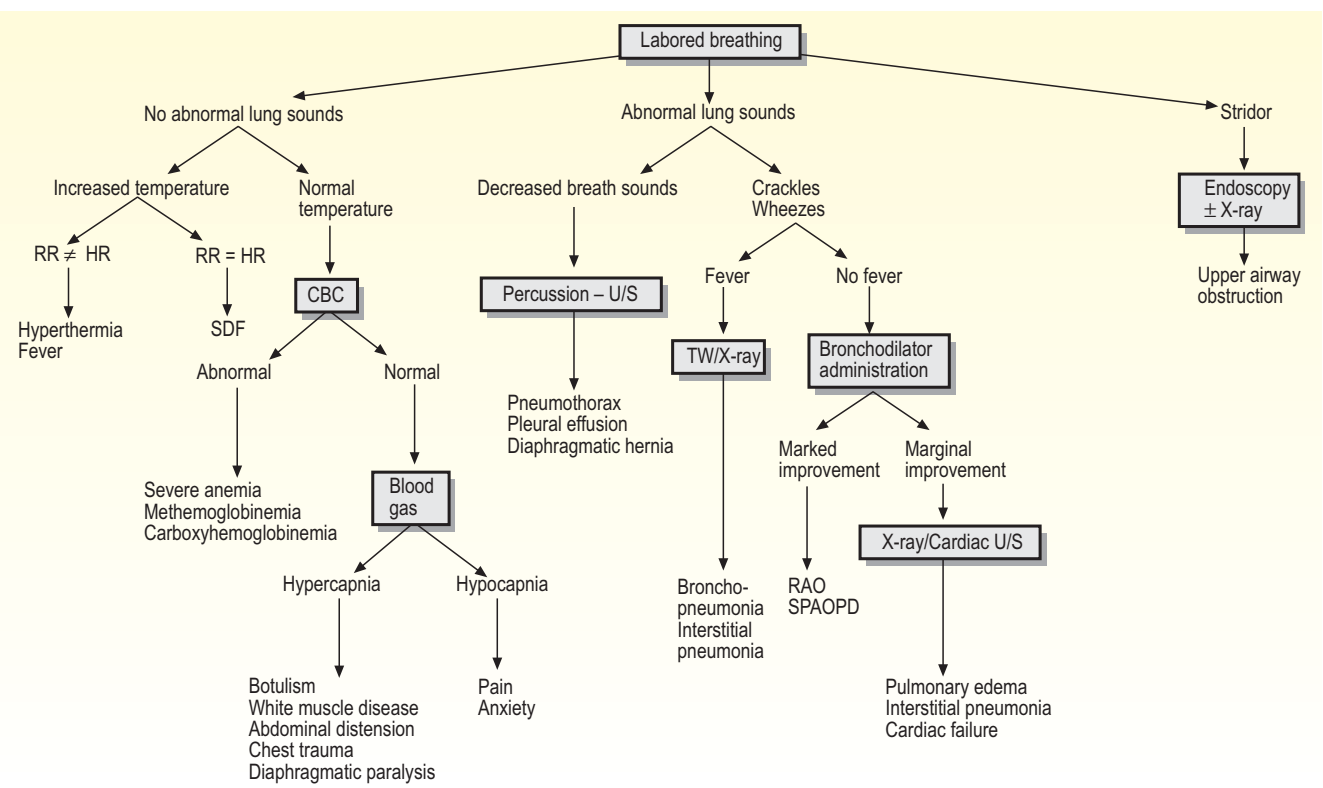

Fig. 29.8
Diagnostic approach in horses with labored breathing. synchronous diaphragmatic flutter present with pronounced abdominal contractions that might be mistaken for increased respiratory effort. However, in this case spasmodic contractions of the flank are synchronous with the first heart sound and are independent of the normal respiratory cycle.[130] A markedly elevated rectal temperature may be associated with conditions causing hyperthermia (e.g. exercise, hot environment) or fever and contribute to respiratory distress. Collection of blood for packed cell volume measurement and hematology is valuable to detect anemia and diseases resulting in decreased oxygen-carrying capacity of the blood (methemoglobinemia, carboxyhemoglobinemia). Only severe anemia resulting in packed cell volume < 8–10% may cause labored breathing at rest. Anemia does not lower arterial oxygen tension but does cause hypoxemia (a decrease in oxygen content in blood) and a decrease in the delivery of oxygen to tissues (i.e. tissue hypoxia). Therefore, anemic horses have a normal Pa_{O_2} and hyperventilation results from acidification of cerebrospinal fluid secondary to increased anaerobic metabolism. An arterial blood gas sample is indicated in horses with normal hematologic findings. Hypercapnia may be associated with conditions impairing respiratory muscle function (e.g. botulism, nutritional muscular dystrophy, diaphragmatic paralysis) or chest wall movement (e.g. abdominal distension, chest trauma). Hypocapnia indicates hyperventilation and may be in response to painful conditions (e.g. colic) or to anxiety.

Treatment and prognosis

Therapeutic aims

The goals of therapy are to control airway inflammation and relieve airflow obstruction. Treatment of RAO and SPAOPD should place emphasis on environmental changes.[53] Medical therapy is useful to control clinical signs in severely affected animals and when improvement in environmental management is limited. The main classes of drugs recommended for RAO and SPAOPD are corticosteroids to treat airway inflammation and bronchodilators to relax airway smooth muscle. Improvement of mucociliary clearance may also help reduce airway obstruction.

The type of activities the horse is performing as well as the initial complaint from the owner should be taken into consideration before therapy is recommended. For example, a RAO-affected horse used for showjumping that started exhibiting decreased performance and coughing while being maintained in a low-dust environment should benefit from medical therapy. However, a brood mare exhibiting an acute RAO crisis 2 weeks after being housed in the barn for the winter may only need simple environmental control measures (e.g. changing bedding and feed) to be implemented in order to resolve clinical signs even though lung function and BAL fluid cytology may take weeks to improve.

Therapy

Environmental changes Several measures help reduce exposure of the horse's airways to respirable particles and are discussed in detail below (RAO prevention). Placing RAO horses in crisis into a low-dust environment (e.g. wood shavings bedding and pelleted diet) results in significant improvement in lung function within 3 days, even if environmental changes only take place in the affected horse's stall.[131] Horses become free of clinical signs within 1 to 2 weeks in optimal indoor housing or outside on pasture.[59,132] Some horses may only improve partially after being placed on pasture, especially chronic long-standing cases. Medical therapy will help most of those cases to become free of clinical disease (remission), at which point medication can be discontinued. Subsequently, horses may remain free of clinical disease for extended periods if they are kept in a low-dust environment. Because of the nature of the disease, susceptible horses may suffer another bout of the disease when exposed to allergens.

Horses suffering from SPAOPD are affected during the summer while at pasture, presumably from inhaling plant allergens such as pollen and thermophilic molds.[66] In those cases, removal from pasture and confinement to a low-dust indoor environment is recommended. However, medical therapy is often needed to provide clinical resolution.[66,133] The management of affected horses may be complicated by the fact that some animals suffer from both RAO and SPAOPD.[133]

Systemic medical therapy Most horses are easy to treat by the oral or injectable route and the cost of systemic therapy is usually less than that of aerosol therapy because of the need to purchase a delivery device (i.e. face mask) for aerosol administration. However, systemic therapy with corticosteroids or bronchodilators may result in adverse effects because of the dosages required for clinical efficacy.

Corticosteroids Corticosteroids are potent inflammation inhibitors with known efficacy for the treatment of heaves. Triamcinolone acetonide is a potent long-acting corticosteroid that may improve lung function for 2 to 4 weeks after administration of a single dose (0.09 mg/kg, i.m.) to RAO horses maintained on straw bedding and fed hay.[134] Neutrophil percentage in BAL fluid may also be significantly decreased within 2 weeks of treatment. Depending on the dose of triamcinolone used, endogenous cortisol production may be suppressed for 2 to 4 weeks but adrenal gland response to ACTH administration is maintained.[134]

Dexamethasone (0.1 mg/kg, i.v., every 24 hours) induces a marked improvement in clinical signs and lung function of RAO horses by the third day of treatment.[54] These beneficial effects may persist for at least a week after treatment is discontinued. A reduction in BAL fluid neutrophilia is evident within 3 days of therapy and after 1 week, proliferation of pro-inflammatory lymphocytes is prevented.[135] Dexamethasone results in marked adrenal suppression of endogenous cortisol production starting 2 hours after administration and persisting approximately 3 days after treatment ends. However, adrenal gland response to exogenous ACTH is maintained.[136,137] Treatment of RAO horses with dexamethasone 21-isonicotinate (0.04 mg/kg, i.m., every 72 hours) reduces airway obstruction 3 days after treatment initiation with a maximum effect obtained after 7 days.[138] Oral forms of dexamethasone are commonly used in the field for the treatment of

RAO but pharmacokinetic or efficacy data are currently not available.

Oral prednisone has for a long time been advocated for the treatment of RAO. However, several reports have now documented its poor efficacy.[131,138,139] In a crossover study, RAO horses in crisis were placed in a low-dust environment for 14 days while half of them received prednisone tablets (2.2 mg/kg, by mouth, every 24 hours) and the other half were left untreated. Pulmonary function improved significantly between day 3 and day 14 in both groups. However, no significant effect of prednisone treatment was detected.[131] The only beneficial effect of prednisone treatment was a significant decrease in the number of the BAL fluid neutrophils. The reason for this lack of efficacy is related to the pharmacokinetic characteristics of the drug.[140] Prednisone is poorly absorbed after oral administration of tablets or liquid forms and the active metabolite prednisolone is detected in the serum in small quantities in very few horses (1/5 with tablet form, 0/5 with liquid form). Conversely, both liquid and tablet forms of prednisolone are well absorbed in the horse with a bioavailability > 50%.[140] Significant adrenal suppression may be detected after treatment with prednisone tablets, but it is short-lived and less pronounced than with prednisolone tablets.

Deleterious side effects associated with corticosteroid therapy may develop depending on drug potency, dose used, and treatment duration. Long-acting and potent corticosteroids (e.g. triamcinolone, dexamethasone) are more likely to cause adverse effects such as immune suppression, iatrogenic Cushing's disease, adrenal cortex suppression and possibly laminitis.[137,141,142] For these reasons, triamcinolone acetonide administration should not be repeated at less than 3-month interval.[143] Responsiveness of adrenal glands to ACTH persists during dexamethasone therapy using doses up to 30 mg per day for 31 days. Therefore, adrenal atrophy is unlikely to develop if therapy lasts less than a month.[144] Discontinuation of dexamethasone after an extended treatment period should be done carefully to avoid acute adrenocortical insufficiency. Dexamethasone doses as low as 0.01 mg/kg result in adrenal suppression for up to 24 hours as compared with < 24 hours for prednisolone.[144] Therefore, discontinuation of prolonged dexamethasone therapy should be performed by slowly and gradually decreasing the dose until the least suppressive amount (0.01 mg/kg) is given every third day for a minimum of 2 weeks. Alternatively, dexamethasone therapy may be replaced by an equipotent dose of prednisolone (1 mg dexamethasone ≈ 7.5 mg prednisolone) that will be tapered down to alternate day treatment. Before treatment is discontinued, an ACTH stimulation test should be performed to assess the adrenocortical reserve necessary for the horse to cope with stress.

Bronchodilators Bronchodilators are indicated to relax airway smooth muscle and relieve airflow obstruction, but they should not be used alone because they have no anti-inflammatory properties and do not reduce airway hyperresponsiveness.[76] In addition, prolonged use of a certain type of bronchodilator (e.g. β_2-agonists) as sole medication induces airway receptor downregulation and renders the drug less effective. This phenomenon is prevented by combined use of β_2-agonists with corticosteroids. Bronchodilator administration is also beneficial in horses that exhibit mild clinical signs, particularly those involved in athletic activities, because significant bronchospasm may be present.

The three classes of drugs available as systemic bronchodilators are anticholinergics, β_2-agonists, and methylxanthines. Atropine (0.01–0.02 mg/kg, i.v.) is an anticholinergic drug that has been used systemically in horses with heaves and shown to provide rapid and marked improvement in lung function (mean reduction in ΔP_{plmax} of 68–83%) and clinical signs.[96,145,146] Effects occur within 10 minutes of administration, peak around 30 minutes and last a maximum of 1–2 hours. Potentially serious side effects such as ileus and abdominal pain usually develop when higher dosages are used (22–88 mg)[147] but are rare with low dose atropine (≤ 0.02 mg/kg) unless administration is repeated. Atropine may be used as a single dose for the rapid relief of severe airway obstruction and for diagnostic and prognostic purposes. However, fast-acting aerosolized bronchodilators (e.g. albuterol) are safer and at least as effective alternatives.

Clenbuterol hydrochloride syrup (Ventipulmin) was approved by the Food and Drug Administration (FDA) in 1998 for the treatment of heaves in horses in the USA. Injectable and oral formulations have been available in other countries for many years. In an open field trial involving 239 horses with heaves 75% improved clinically after administration of oral clenbuterol (0.8–3.2 μg/kg, every 12 hours for 10–30 days) and 25% did not respond to treatment.[148] The percentage of horses responding to treatment increased as the dose of clenbuterol was augmented (24% at 0.8 μg/kg to 75% at 3.2 μg/kg). A controlled clinical trial failed to demonstrate any benefit of the drug (0.4 mg/horse, by mouth, every 12 hours, $n = 7$) after 10 days of treatment.[139] Clenbuterol may also help airway mucociliary clearance by increasing ciliary beat frequency.[149] Mild side effects such as sweating, muscle tremors, and excitement occur in less than 9% of horses treated with oral clenbuterol.[148] More concerning side effects are cardiovascular remodeling detected by echocardiography immediately post-exercise in healthy horses treated with medium doses of clenbuterol (2.4 μg/kg, by mouth every 12 hours) for 8 weeks.[150] At the end of the 8-week treatment period, horses receiving clenbuterol had elevated left ventricular mass, calculated stroke volume, aortic root diameter (+ 24–30%), and larger left ventricular diameter at end systole and diastole (+ 24–40%) compared with non-treated control horses, suggesting a deleterious effect of clenbuterol on cardiac function.

Administration of the β-adrenergic drug isoproterenol (0.1–0.2 mg/kg, i.v.) to heavey horses results in clinical and lung function improvement within 15 minutes. However, results are variable between animals and heart rate more than doubles because of stimulation of cardiac β_1-receptors.[145] Terbutaline, a β_2-receptor agonist, has been used orally, intravenously and by nebulization in horses.[146] Efficacy of the oral route for the treatment of heaves is unlikely because bioavailability is less than 1%.[151]

Both intravenous (0.01 mg/kg) and aerosol (0.02 mg/kg) routes of administration may improve lung function of heavey horses for up to 6 hours but marked adverse reactions such as central nervous system (CNS) stimulation, sweating, and trembling are likely to occur with the i.v. route.[146,151]

Methylxanthine and derivatives may be beneficial in horses with heaves. However, plasma levels necessary for bronchodilation vary widely between horses and the range between effective and toxic concentration is narrow.[152,153] Aminophylline (5–12 mg/kg i.v.) and theophylline (5–10 mg/kg, by mouth) administered every 12 hours improve lung function and clinical signs in up to 50% of affected horses.[145,154] Common side effects are hyperesthesia, hyperexcitability, and muscle tremors. Pentoxifylline (36 mg/kg, by mouth, every 12 hours for 14 days) administered to RAO-affected horses results in significant improvement in lung function and is not associated with adverse effects.[155]

Enhancement of mucociliary clearance Horses with RAO and SPAOPD accumulate large amounts of mucopurulent secretions with higher viscoelasticity in their airways, therefore contributing to airflow obstruction.[156] Mucociliary clearance may be enhanced by stimulation of the ciliary apparatus or by decreasing mucus viscoelasticity, but the latter appears to be the most important factor.[157] Different types of drugs may enhance clearance of respiratory secretions including mucolytics (e.g. acetylcysteine, dembrexine hydrochloride) and drugs capable of improving mucociliary transport (e.g. β_2-agonists). However, none have been shown to be beneficial for the treatment of heaves.

Other treatments Furosemide (frusemide, 1 mg/kg i.v. or aerosol) also results in significant improvement in the lung mechanics of RAO horses but not in arterial blood gases.[158] Antihistamine drugs are commonly used to treat RAO horses in the field, but they appear to have limited usefulness and no controlled study has proved their efficacy.

A technique of overhydration consisting in the intravenous administration of 30–40 L of isotonic saline solution over a 3- to 4-hour period may benefit heavey horses.[159,160] But the method is not without risks (e.g. pulmonary edema, electrolyte abnormalities, death) and thus far, no controlled study has demonstrated its efficacy for the treatment of heaves.

Aerosol therapy Administration of therapeutic substances via inhalation has the advantage of delivering high concentrations of the drug directly into the lungs while minimizing the amount absorbed systemically and therefore, reducing the risk of adverse effects. In addition, systemic side effects and drug residue are decreased. Clinical response to aerosol medications is a function of the dose deposited in the airways, which is dependent on the delivery device, the particle size characteristics of the inhaled aerosol, the pattern of breathing, and airway disease.[161]

Deposition of therapeutic aerosols within the respiratory tract occurs mainly by inertial impaction and gravitational sedimentation.[162] Inertial impaction is largely responsible for particle deposition in nasal passages, nasopharynx, and central airways. Impaction of aerosolized particles on airway walls can occur if their size is sufficiently large (≥ 1 μm) or the air stream rapidly changing direction (e.g. high flow rate, branching airways, turbulent flow). Smaller particles (≥ 0.5 μm) that are able to reach peripheral airways and alveoli may deposit on airway surfaces by gravitational sedimentation when the air stream is sufficiently slow. Aerosols with mass median aerodynamic diameter (MMAD) > 5 μm are mainly deposited in the upper airways while the majority of particles < 1 μm are exhaled.[162] The deposition of particles in small conducting airways and alveoli is maximal when aerosol MMAD is between 1 and 5 μm.

The most important factor for aerosol deposition is the speed of inhalation.[162] As inspiratory flow rate or breathing frequency increases more particles are deposited in the upper airways. Penetration of aerosol into peripheral airways is improved when inhaled volume increases. Obviously, manipulation of these factors in the horse is limited.

Airway narrowing increases aerosol deposition in central airways and results in poor deposition in peripheral airways.[161] In horses with severe airway obstruction (i.e. RAO), aerosol deposition after administration of inhaled albuterol (360 μg) results in rapid (5 minutes) improvement in peripheral airway deposition.[163] Improved lung deposition of therapeutic aerosols is also likely to occur after administration of a bronchodilator in horses with IAD exhibiting significant airflow obstruction or bronchial hyper-responsiveness.

Therapeutic aerosols may be produced by nebulizing a solution, administrating aerosols prepackaged in metered dose inhalers (MDIs), and inhaling the drug using dry powder inhalers (DPIs). Several types of devices are used to improve delivery of aerosol to the horse's lung such as facemask, nosepiece, and extension tubing (spacer or holding chamber). The fraction of drug deposited into the lungs varies between 0.3 and 7.4% for nebulizers and 6.1 and 23.3% for MDI delivery devices (6.1% AeroMask, 8.2% Equine Haler, 23.3% 3M Equine device).[164–167] Spacers and holding chambers are designed to alter the size distribution of particles originating from the MDI or nebulizer, resulting in a reduction in upper airway deposition and an increase in the mass of drug contained in respirable particles.[161] A valve is usually present between the spacer and the horse's nostril; therefore, precise synchronization between MDI actuation and onset of inhalation is not required.

Corticosteroids Five different inhaled corticosteroids are available in the USA: beclomethasone dipropionate, budesonide, flunisolide, fluticasone proprionate, and triamcinolone acetonide (Table 29.3). A common test of potency for inhaled corticosteroids (McKenzie skin blanching) allows relative ranking of the compounds from least to most potent: flunisolide = triamcinolone acetonide < beclomethasone dipropionate = budesonide < fluticasone propionate.[168] At the time of this writing, only clinical trials with beclomethasone and fluticasone have been reported in the horse.

Clinical trials in horses with heaves indicate that beclomethasone dipropionate at dosages ranging from 500–1500 μg twice a day (3M Equine device) to 3750 μg twice a day (AeroMask) results in significant clinical and lung function improvement as well as reduction in pulmonary inflammation.[169,170] Therapeutic effects are measurable within 24 hours of administration. Administration of a low

dose of beclomethasone dipropionate (500 μg twice a day) to horses with heaves results in similar efficacy as high dose (> 1500 μg twice a day) but with less adrenal suppression.[169]

Fluticasone propionate has been used successfully for the treatment of heaves in horses using 2000 μg twice daily (AeroMask).[171] Treatment of horses with inhaled fluticasone (AeroMask) using 3000 μg twice a day results in adrenal suppression. However, no adrenal suppression is detectable with 2000 μg twice a day.[171,172]

Bronchodilators Two main classes of inhaled bronchodilators have been used in the horse: β_2-agonists and anticholinergics (Table 29.3). Bronchodilators should not be used as only therapy for RAO because they do not suppress airway inflammation and do not reduce airway hyperresponsiveness.[76] In addition, prolonged use of β_2-agonists without corticosteroids induces receptor downregulation, which renders the drug less effective. In horses with significant airway obstruction, bronchodilators should be administered prior to corticosteroids in order to optimize lung deposition.

β_2-agonists induce airway smooth muscle relaxation regardless of bronchoconstriction mechanism and also inhibit mast cell degranulation.[76] Albuterol, pirbuterol, and fenoterol are short-acting bronchodilators (1 hour) with rapid onset of action (5 minutes).[173–175] Some horses may benefit from the effects of albuterol for up to 7 hours.[176] Salmeterol and formoterol are long-acting β_2-agonists (6–8 hours) suitable for twice daily dosing but with slow onset of action (15 minutes).[177]

Ipratropium bromide is an anticholinergic drug chemically derived from atropine but devoid of side effects when administered by inhalation. Nebulization of 2 μg/kg causes bronchodilation for approximately 6 hours with a maximum effect obtained 1 hour after administration.[178] The effects of anticholinergic drugs on airway smooth muscle are additive to β_2-agonists.[76]

Prognosis

A follow-up survey involving 51 RAO-affected horses revealed that the median survival time following diagnosis was 8 years and that 87% of horses would be expected to survive 3 years after being diagnosed with RAO.[179] Seventy-nine percent of respondents reported recurring episodes of heaves and 21% believed that the condition had resolved. And while 21% of diagnosed horses were retired, 74% were still used in various athletic activities. These findings are considered good considering that > 77% of horses were still fed hay and housed indoors for at least part of the day.[179] Some investigators found that horses diagnosed with more severe disease were less likely to survive 2–4 years, but other investigators did not.[120,179]

Etiology and pathophysiology

Etiology

RAO is associated with exposure to high levels of organic molds particularly abundant in moldy hay and poorly ventilated stables.[180] Susceptible horses are allergic to inhaled spores and exposure to an environment rich in molds triggers clinicals signs within a few hours to a few days.[53,59] Clinical signs usually resolve within a few days of horses being removed from the dusty environment. Numerous studies have documented that traditional horse management exposes them to high dust levels originating mainly from bedding and feed.[16,17,84,181–186] In addition, horses are exposed to higher levels of dust around the nose (breathing zone) in the stable because of their feeding behavior.[84] As water content of hay at baling increases mold growth rises to reach a maximum for hay baled at 35–50% moisture.[187] Approximately 70 species of fungi and actinomycetes have been identified and among them thermophilic molds such as *Aspergillus fumigatus*, *Faenia rectivirgula* and *Thermoactinomyces vulgaris* are commonly present.[187] These spores have a small diameter (MMAD < 5 μm), allowing them to be inhaled in peripheral airways (respirable particles) where they may trigger an inflammatory reaction.[188] Furthermore, BAL fluid neutrophilia increases in a dose-dependent fashion as the quantity of inhaled dust rises.[189]

Several studies suggest that RAO and SPAOPD are caused by a mold allergy. Analysis of BAL fluid and sera collected from RAO-affected horses reveals significantly higher levels of IgE and IgA against mold allergens than in control horses consistent with a type I hypersensitivity reaction.[190,191] Unexpectedly, tracheal wash fluid collected from SPAOPD-affected horses contains a lower concentration of IgE than that from controls.[192] Immunohistochemical studies of lung tissues have shown high levels of IgA and IgG(Fc) in the airways of RAO-affected horses and the number of immunoglobulin staining cells increases with disease severity.[193,194] Quantification of serum precipitating antibodies against common environmental allergens and evaluation of response to intradermal challenge with these allergens are of little value for diagnosis and treatment of heaves because there is considerable overlap between control and affected horses.[195–197] Comparison of cytokine profiles in BAL fluid of horses exposed to dust challenge revealed an increased mRNA expression for interleukin-4 (IL-4) and IL-5 and a decreased expression for IFNγ in horses with heaves consistent with a Th2-type response.[198] Th2-type lymphocyte responses regulate allergic reactions by stimulating IgE production and promoting recruitment and activation of mast cells and eosinophils as in human asthma. These findings provide further support for an allergic basis of RAO.

Endotoxins are present in large quantities in the horses' environment and may potentiate the inflammatory response to inhaled molds.[16] Inhalation challenge using hay dust fractions suggests that endotoxin and other substances (e.g. β-glucans) are more important than particles for neutrophil recruitment to the lungs of RAO-affected horses.[199] Research in humans and other species indicates that timing and dose of inhaled endotoxins also play a modulatory role in the induction of airway inflammation as early exposure during childhood may prevent later development of asthma in people and exposure later in life worsen it.[200]

A study involving German Warmblood and Lipizzaner horses found RAO prevalence among offspring to be low

when neither parent is affected by the disease, but when one or both of the parents are affected the offspring are 3.2 and 4.6 times more likely to suffer from RAO, respectively ($P < 0.05$).[91] These findings strongly suggest that, as in human asthma, genetic susceptibility may be an important and heritable factor contributing to the development of heaves.

Pathophysiology

RAO susceptible horses develop signs of airway obstruction when exposed to a dusty environment rich in molds (e.g. hay, straw) and these signs are reversible if horses are placed in a low-dust environment (e.g. pasture).[53,59] Clinical signs associated with airway obstruction such as cough, increased respiratory efforts, and mucopurulent secretions are the result of airway inflammation. In addition, pulmonary inflammation is associated with airway hyper-responsiveness to both specific (e.g. molds, other allergens) and non-specific stimuli (e.g. histamine, endotoxin). Hence, RAO in horses is similar to asthma in people except that the equine disease is characterized by neutrophilic inflammation and asthma is associated with eosinophilic inflammation, although airway neutrophilia is a common feature of acute severe asthma and with grain-dust induced asthma in people.[201,202]

The cascade of events leading to pulmonary dysfunction starts shortly after susceptible horses are exposed to allergens. Circulating neutrophils are recruited to the lungs within 4 hours of an allergen challenge and are detectable in BAL fluid in 5 hours.[83,203] In addition, BAL fluid from horses with heaves contains increased numbers of cells expressing mRNA for IL-4 and IL-5 and decreased numbers of cells expressing mRNA for IFNγ consistent with a predominant Th2-type lymphocyte response as in human asthma.[198] Numerous inflammatory mediators are increased in respiratory secretions or blood of RAO horses after allergen challenge. However, the complex relationships between effector cells, inflammatory mediators, and clinical signs are still unclear. Histamine concentration in BAL fluid is elevated in RAO horses 5 hours after allergen challenge, but administration of antihistamines is usually poorly effective.[204] Various metabolites of arachidonic acid degradation such as prostaglandin E_2, thromboxane B_2, and 15-hydroxyeicosatetraenoic acid are increased in BAL fluid or plasma of affected horses. However, cyclo-oxygenase blockade does not improve clinical signs of the disease.[205–207] Recruitment of neutrophils to the airways may be explained by increased levels of chemotactic substances such as IL-8, macrophage inflammatory protein-2, leukotriene B_4 and platelet-activating factor present in BAL fluid of RAO horses in crisis.[208–210] In turn, primed neutrophils that migrate to the lungs may release reactive oxygen species leading to oxidative stress and proteases (e.g. MMP-9, MMP-8, MMP-13) responsible for further tissue damage.[211–213]

In asthma, airway inflammation is associated with overexpression of numerous proteins involved in immunologic and inflammatory processes. Increased gene expression is a prerequisite for protein overexpression, which in turn is a consequence of increased activation of transcription factors such as NF-κB, AP-1, cAMP, and others.[214] NF-κB is overexpressed in bronchial cells of RAO horses in crisis and the level of NF-κB activity is strongly correlated with the degree of lung dysfunction.[215] RAO horses in crisis improve rapidly after being removed from the allergenic environment. However, resolution of airway inflammation, in particular neutrophilia, usually lags behind resolution of lung dysfunction by weeks to months.[61,62] Persistence of airway granulocytes is correlated with sustained NF-κB activity which is markedly decreased after granulocyte cell death.[215] Furthermore, activated granulocytes release high levels of IL-1β and TNFα leading to NF-κB activation which in turn results in IL-1β and TNFα expression.[216] The prolonged survival of granulocytes in RAO affected horses may result from expression of anti-apoptotic proteins that may protect these cells or delay apoptosis.

Epidemiology

RAO is an occupational disease of horses housed indoors and fed hay. It is more commonly diagnosed in parts of the world where summers are frequently humid (e.g. northern Europe, northeast USA) than in areas with a warm and dry climate (e.g. Australia).[217] Presumably, wet summers lead to higher quantities of moldy hay being harvested, although this assumption has not been proven yet. Conversely, SPAOPD is commonly diagnosed in horses living in hot and humid climates (e.g. southern USA) where they spend most of the time on pasture and the highest prevalence of the disease is observed during the summer months.[94] Nevertheless, the condition is also diagnosed in areas where RAO is traditionally believed to be more prevalent and some horses may suffer from both conditions.[133]

Prevalence of RAO has been reported as high as 55% of horses in Switzerland based on endoscopy and tracheal wash cytology.[218] Considering the case definition used by the authors, the prevalence was probably overestimated because horses with IAD would have been diagnosed as RAO. In a North American survey conducted on 166 horses selected at random at a slaughterhouse, RAO was diagnosed histopathologically in 19 horses (incidence of 12%).[43]

RAO and SPAOPD tend to be diagnosed in horses > 7 years of age and there is no apparent breed or sex predilection.[11,94] However, in a case-controlled study of horses diagnosed with RAO at 19 North American Veterinary Teaching Hospitals ($n = 2888$) we found that Thoroughbred horses were significantly more likely to be diagnosed with the disease than were other breeds (odds ratio, 2.4; $P < 0.001$; Couëtil, in press).

Prevention

Inhaled dust particles play a central role in the pathophysiology of RAO and management of the disease should always include recommendations to decrease environmental exposure. Particle deposition in the respiratory tract is related to their mean aerodynamic diameter (MMAD), which depends on particle size, shape, and density. Large particles

(MMAD > 5 μm) will be mainly deposited in the nasal passages. Smaller ones (MMAD < 5 μm) are called respirable particles because they tend to be deposited in the lower airways where they can exert their pro-inflammatory effects. Among respirable dust particles, mold spores from hay and straw including *Aspergillus fumigatus*, *Faenia rectivirgula* (previously called *Micropolyspora faeni*) and *Thermoactinomyces vulgaris* have been directly implicated.[84,188] Two main approaches help reduce exposure of the horse's airways to respirable particles. The first appraoch is to use feedstuff and bedding that generate low dust levels. For example, changing bedding material from straw to cardboard can cut respirable dust levels in half and reduce mold concentration to negligible levels.[181] The second approach is to increase removal of airborne particles by improving ventilation in the building.[182]

The ideal environment for horses with RAO is pasture because exposure to dust is significantly less than in stalls, regardless of feed and bedding quality.[16,183] If for practical reasons the horse cannot be kept on pasture at all times, ventilation in the barn and stall, the type of bedding, feedstuff, and general management should be scrutinized in order to minimize allergen exposure. However, owners need to realize that for RAO horses kept on pasture, exposure to organic dust for even a few hours, such as when bringing horses indoors to be fed or during periods of inclement weather, may be sufficient to recruit inflammatory cells to the lungs resulting in airway hyper-responsiveness and clinical signs.[83,110]

Horses with SPAOPD are generally affected between June and September when they spend more than half of each day on pasture.[94] Consequently, the recommended environment for these horses during the summer is low-dust indoor housing.[66,133]

Simple changes such as switching bedding from straw to wood shavings and feeding pellets or silage instead of hay can decrease respirable dust at least five-fold.[16,84] The relative amounts of respirable particles in different types of feed and bedding materials, from the least dusty to the dustiest, are concentrate with molasses > whole grain – silage (×2) > cardboard bedding (×2.7) > alfalfa pellets (×4.5) > rolled grain – good straw (×6) > wood shavings (×15) > good hay (×30).[181,184] Concentrate with molasses was given a reference value of 1 and numbers in parentheses represent the numbers of fold increase in respirable particles for the different types of feed and bedding. If hay has to be part of the horse's diet, the amount of dust generated can be reduced by feeding it after soaking it or preferably keeping it immersed in a tub of water. An obvious potential problem with this approach is the generation of more mold in the stall if previously wet hay gets mixed with the bedding. Tub water has to be changed every day. RAO horses maintained in clinical remission at pasture and then housed long-term in a very low-dust environment (i.e. cardboard bedding, grass silage, grain with molasses) do not show detectable changes in BAL fluid cytology or pulmonary function.[181] But housing susceptible horses in an environment usually considered low-dust, such as wood shavings bedding and fed grass silage, may result in bronchial hyper-responsiveness despite horses maintaining normal tidal breathing lung mechanics.[185,186] Environmental control targeting only the affected horse's stall and not the rest of the stable may be sufficient to improve clinical signs of RAO horses but not to normalize lung function and pulmonary inflammation.[131]

The activity in the barn also affects dust exposure with peak levels during the day especially at the time of feeding and cleaning of the stalls, when dust levels can increase more than 10-fold.[183] Therefore, dust-generating tasks such as cleaning stalls and sweeping floors should be performed when RAO-susceptible horses are outside the barn. Grooming also generates airborne dust particles and should be done outside or using a vacuum cleaner system.

Exercise-induced pulmonary hemorrhage (EIPH)

- Exercise-induced pulmonary hemorrhage is a common disorder of race horses, among which it occurs worldwide.
- EIPH may, rarely, manifest as epistaxis after exercise and may be a cause of poor performance. It rarely causes death.
- Diagnosis is based on demonstration of blood in the airways either by tracheobronchoscopy after exercise or by examination of tracheal aspirate or bronchoalveolar lavage fluid.
- Furosemide (frusemide) is commonly used to treat EIPH, although its efficacy under field conditions has not been demonstrated.
- EIPH is caused by rupture of pulmonary capillaries with subsequent development of pulmonary inflammation, fibrosis and angiogenesis contributing to continued hemorrhage during exercise.

Recognition of disease

History and presenting complaint

Poor athletic performance and epistaxis are the most common presenting complaints for horses with exercise-induced pulmonary hemorrhage (EIPH). While poor performance may be attributable to any of a large number of causes, epistaxis associated with exercise is almost always secondary to EIPH.

Epistaxis due to EIPH occurs during or shortly after exercise and is usually first noticed at the end of a race, particularly when the horse is returned to the paddock or winner's circle and is allowed to lower its head. It is usually bilateral and resolves within hours of the end of the race. Epistaxis may occur on more than one occasion, especially when horses are raced or exercised at high speed soon after an initial episode.

Failure of race horses to perform to the expected standard (poor performance) is often, accurately or not, attributed to EIPH. Many horses with poor performance have cytologic

evidence of EIPH on microscopic examination of tracheobronchial aspirates or BAL fluid or have blood evident on endoscopic examination of the tracheobronchial tree performed 30 to 90 minutes after strenuous exercise or racing.[219,220] However, it is important to recognize that EIPH is very common in race horses and it should be considered the cause of poor performance only after other causes have been eliminated. Severe EIPH undoubtedly results in poor performance and, on rare occasions, death of Thoroughbred race horses.[221] However, the effect of less severe EIPH on race performance of Thoroughbred or Standardbred horses has not been conclusively determined. A relationship between finishing position and incidence of EIPH, diagnosed by bronchoscopic examination, was not detected for 191 Thoroughbred race horses that finished in first, second, or third place.[222] Furthermore, there was no relationship between the proportion of horses with EIPH and placing (first, second, or third versus other) in another 98 horses.[222] Similarly, there was no relationship between finishing position and proportion of horses with EIPH in 191 Thoroughbreds examined after racing.[223] There was no relationship between severity of EIPH, assessed on tracheobronchoscopic examination, and race performance in 258 Thoroughbreds or 296 Standardbred race horses.[224] Together, these studies do not demonstrate a clear relationship between the presence of EIPH, or its severity, and race performance.

In contrast to the studies discussed above, among 452 Thoroughbred horses examined after racing in Hong Kong, those finishing in the first three positions had less severe EIPH than did horses finishing in lower positions.[225] Of horses finishing in the first three places, 43.9% had evidence of EIPH on tracheobronchoscopic examination after racing whereas 55.9% of horses finishing in fourth to fourteenth place had evidence of EIPH.

Results of studies in Standardbred race horses indicate either a lack of effect of EIPH on performance or an association between EIPH and superior performance. There was not a relationship between presence of EIPH and finishing position in 29 Standardbred race horses with intermittent EIPH examined on at least two occasions,[226] nor in 92 Standardbred race horses examined on one occasion.[227] However, of 965 Standardbred race horses examined after racing, those finishing first or second were 1.4 times more likely (95% CI 0.9–2.2) to have evidence of EIPH on tracheobronchoscopic examination than were horses that finished in seventh or eighth position.[228]

Physical examination

Apart from epistaxis in a small proportion of affected horses, there are few abnormalities detectable on routine physical examination of horses with EIPH. Rectal temperature and heart and breathing rates may be elevated as a consequence of exercise in horses examined soon after exercise, but values of these variables in horses with EIPH at rest are not noticeably different to horses with no evidence of EIPH.[229] Affected horses may swallow more frequently during recovery from exercise than do unaffected horses, probably as a result of blood in the larynx and pharynx.[230] Coughing is common in horses recovering from strenuous exercise and horses with EIPH are reported to have a hacking cough, although this observation may not be very specific.[222] After recovery from exercise, horses with EIPH are no more likely to cough than are unaffected horses.[231] Other clinical signs related to respiratory abnormalities are uncommon in horses with EIPH. Respiratory distress is rare in horses with EIPH and when present indicates severe hemorrhage or other serious lung disease such as pneumonia, pneumothorax or rupture of a pulmonary abscess. Lung sounds are abnormal in a small number of EIPH-affected horses and when present are characterized by increased intensity of normal breath sounds during rebreathing examination.[229] Tracheal rales may be present in horses with EIPH but are also heard in unaffected horses.[230]

Epistaxis associated with exercise is almost always attributable to pulmonary hemorrhage. The severity of epistaxis ranges from flecks or a small amount of blood at one nostril present after the horse lowers its head at the end of exercise to profuse hemorrhage from both nostrils occurring during exercise (Fig. 29.9). Epistaxis occurs in a small proportion of race horses.[222,223,230,232–236] The prevalence of epistaxis in race horses varies between 0.1 and 9.0%, with the frequency depending on the breed, age and sex of horses selected for study, the type of racing, and the timing and frequency of observation of horses after racing. Epistaxis occurs in 0.13% of Thoroughbred race horses in Japan,[232] 5.9% of Thoroughbreds in Hong Kong,[225] 0.8% of Thoroughbreds in California,[222] 9.0% of Thoroughbreds in Pennsylvania,[223] and 3.5% of Quarter Horses.[234] Epistaxis is more common in older horses, with horses 5 years of age or older being 6.4 times as likely as 2-year-olds to have epistaxis.[223,225,230,232,235] Female Thoroughbreds are 1.4 times as likely as stallions to have epistaxis.[232] Epistaxis is more common after races < 1600 m than in longer races.[232] However, horses in steeplechase races, which are typically

Fig. 29.9
Horse with epistaxis secondary to EIPH. Note blood splattered on the horse's chest.

longer than 2000 m, are at greater risk of epistaxis than are horses in flat races.[230,232,235,237]

Horses that have experienced one episode of epistaxis are more likely to have a second episode. For this reason most racing jurisdictions do not permit horses with epistaxis to race for a period of weeks to months after the initial instance, with more prolonged enforced rest after a subsequent episode of epistaxis and retirement from racing after a third bout. The recurrence rate after one episode of epistaxis in Thoroughbred horses is approximately 13.5% despite affected horses not being permitted to race for one month after the initial episode of epistaxis.[232] This high rate of recurrence suggests that the inciting pulmonary lesions have not healed.

Diagnostic tests

There are a variety of techniques available for determining the presence and severity of EIPH including direct visualization of the airways through a flexible endoscope or examination of bronchial lavage fluid or tracheal aspirates for evidence of hemorrhage. The utility of these diagnostic tests varies and choice of examination technique depends on the time between the horse racing and the examination and the desired sensitivity of the test. For instance, tracheobronchoscopic examination is most appropriate if a horse is examined within 1–2 hours of exercise whereas examination of airway washings is most appropriate if the examination is days to a week after strenuous exercise. Radiography, pulmonary scintigraphic examination and lung function tests are useful in eliminating other respiratory diseases as a cause of poor performance, but are minimally useful in confirming a diagnosis of EIPH or in determining the severity of hemorrhage.

Tracheobronchoscopy Observation of blood in the trachea or large bronchi of horses 30–120 minutes after racing or strenuous exercise provides a definitive diagnosis of EIPH. The amount of blood in the large airways varies from a few small specks on the airway walls to a stream of blood occupying the ventral one-third of the trachea (Fig. 29.10). Blood may also be present in the larynx and nasopharynx. If there is a strong suspicion of EIPH and blood is not present on a single examination conducted soon after exercise, the examination should be repeated in 60–90 minutes. Some horses with EIPH do not have blood present in the rostral airways immediately after exercise, but do so when examined 1–2 hours later. Blood is detectable by tracheobronchoscopic examination for 1–3 days in most horses, with some horses having blood detectable for up to 7 days.

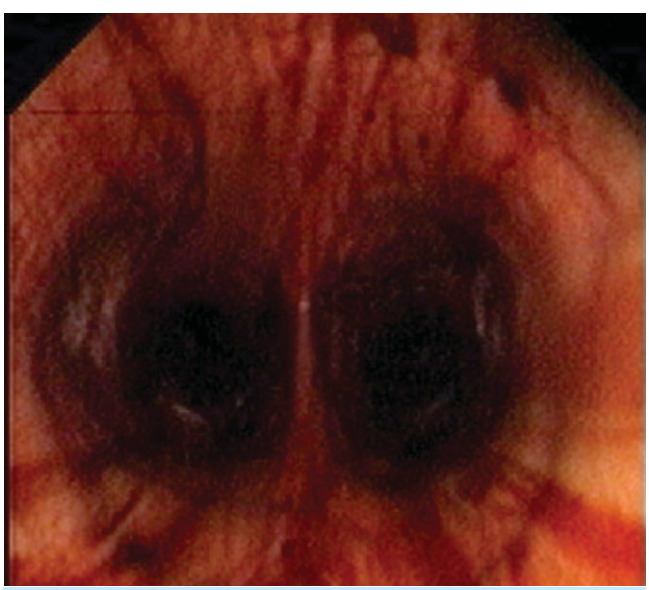

Fig. 29.10
Tracheobronchoscopic image of the carina of a horse with severe EIPH.

Tracheobronchoscopic examination is performed using a 1–1.5 m flexible endoscope. Endoscopes of 1 m length allow visualization of the rostral trachea to the level of the thoracic inlet, but do not permit direct examination of the caudal trachea and large bronchi. Use of an endoscope of at least 1.5 m length is recommended to allow direct examination of all the large airways. The examination is performed with the horse restrained while the endoscope is passed through the ventral meatus into the nasopharynx. Most horses will tolerate passage of an endoscope into the caudal trachea with minimal restraint such as application of a nose twitch. Some horses may require administration of sedatives or tranquilizers. Administration of tranquilizers will alter pharyngeal and laryngeal function and may impair assessment of abnormalities of the upper airway. The nasopharynx and larynx are then examined for the presence of blood or other abnormalities and the endoscope is passed through the larynx into the cranial trachea. The trachea is examined as the endoscope is passed caudally so that the carina and cranial aspects of the left and right bronchi are visualized.

Bronchoscopic examination can be used to estimate the severity of EIPH through use of a grading system.[222,225,226,238] A commonly used grading system has a scale of four levels from 0 (no hemorrhage visible) to 3 (streak of blood > 5 mm wide) and its repeatability on consecutive examinations in Thoroughbred horses has been demonstrated. Of 56 horses examined at least twice, 21 (38%) had identical scores on each examination, 26 (41%) had scores that differed by one grade and nine had scores that differed by two grades.[238] It is assumed that a higher score represents more severe hemorrhage, but while the repeatability of this scoring system has been established, the relationship between the amount of blood in the large airways and the actual amount of hemorrhage has not been established.

Examination of airway secretions or lavage fluid The presence of red cells or macrophages containing either effete red cells or the breakdown products of hemoglobin (hemosiderophages) in tracheal or BAL fluid provides evidence of EIPH (Fig. 29.11). Detection of red cells or hemosiderophages in tracheal aspirates or bronchoalveolar lavage fluid is believed to be both sensitive and specific in the diagnosis of EIPH.[220,239] Examination of airway fluids indicates the presence of EIPH in a greater proportion of horses than does tracheobronchoscopic examination after strenuous exercise or racing. The greater sensitivity of examination of airway fluid

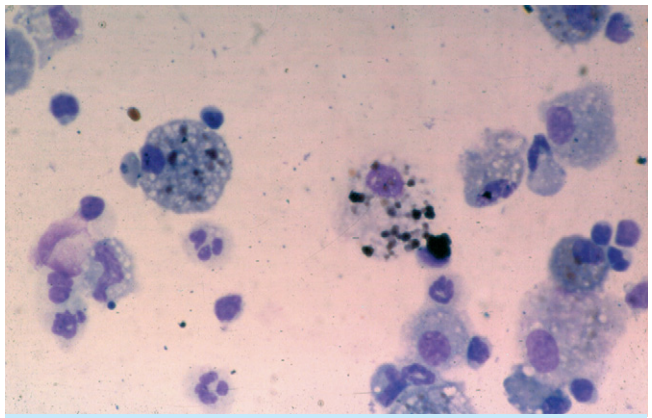

Fig. 29.11
Hemosiderophages in bronchoalveolar lavage fluid of a Standardbred race horse.

is probably attributable to the ability of this examination to detect the presence of small amounts of blood or its residual products and the longevity of these products in the airways. While endoscopic examination may detect blood in occasional horses up to 7 days after an episode of EIPH, cellular evidence of pulmonary hemorrhage persists for weeks after a single episode.[220,239–242] Red blood cells and macrophages containing red cells are present in bronchoalveolar lavage fluid or tracheal aspirates for at least one week after strenuous exercise or instillation of autologous blood into airways and hemosiderophages are present for at least 21 days and possibly longer.[220,239–242]

Recent studies have reported on the use of red cell numbers in BAL fluid as a quantitative indicator of EIPH.[241,243–246] However, this indicator of EIPH severity has not been validated nor demonstrated to be more reliable or repeatable than tracheobronchoscopic examination and visual scoring. Furthermore, considerable concern exists over the suitability of red cell counts in BAL fluid for assessment of severity of EIPH given that an unknown area, although presumably small, of the lung is examined by lavage and there is a risk that this area of lung may not be representative of the lung as a whole, similar to the situation of examination of bronchoalveolar lavage fluid of horses with pneumonia.[247]

Tracheal aspirates may be obtained any time after exercise by either aspiration during tracheobronchoscopic examination or aspiration through a percutaneous intratracheal needle and catheter. Aspirates obtained through an endoscope may not be sterile, depending on the collection technique. BAL fluid can be obtained either through an endoscope wedged in the distal airway or through a cuffed tube inserted blindly into a distal airway. Collection of fluid through an endoscope has the advantage of permitting examination of the distal airways and selection of the area of lung to be lavaged. However, it does require the use of an endoscope that is longer (2 m) than those readily available in most equine practices. A commercial BAL catheter does not require use of an endoscope and can be readily used in field situations.

For both endoscopic and lavage tube collection of BAL fluid the horse is restrained and sedated (xylazine 0.5–1.0 mg/kg i.v., detomidine 20–40 μg/kg i.v.). Some clinicians administer butorphanol (0.02–0.5 mg/kg i.v.) or local anesthetic (lidocaine (lignocaine), 20 ml of a 2% solution diluted with saline to a total volume of 100 ml and administered into the trachea) to suppress coughing. Application of a nose twitch may be necessary in some horses. The endoscope or lavage tube is passed into the trachea and then advanced caudally until it wedges in the distal airway. The cuff of the lavage tube is then inflated and a quantity of fluid (150–300 ml) of isotonic fluid (phosphate buffered 0.9% sodium chloride or similar) rapidly injected. After allowing the horse several breaths, the fluid is aspirated with the first 20 ml being discarded. Blind passage of the lavage tube usually results in its lodging in the dorsocaudal lung region.[248]

Radiography Thoracic radiography is of limited use in detecting horses with EIPH. Radiographs may demonstrate the presence of densities in the caudodorsal lung fields of some horses (Fig. 29.12),[249] but many affected horses have minimal to undetectable radiographic abnormalities. Examination of thoracic radiographs of horses with EIPH may be useful in ruling out the presence of another disease process, such as a pulmonary abscess, contributing to the horse's pulmonary hemorrhage or poor athletic performance.

Pulmonary scintigraphy Scintigraphic examination of lungs has the potential to detect horses with EIPH but to date technical limitations have precluded its routine use for this purpose.[250,251]

Exercise testing During incremental exercise on a treadmill, horses with EIPH have more severe exercise-induced arterial hypoxemia, hypercapnia and higher blood lactate concentrations than do control horses.[252] These changes indicate abnormalities in gas exchange in horses with EIPH but are not sufficiently large to be useful clinically. Blood gas tensions in horses with EIPH are within the normal ranges.

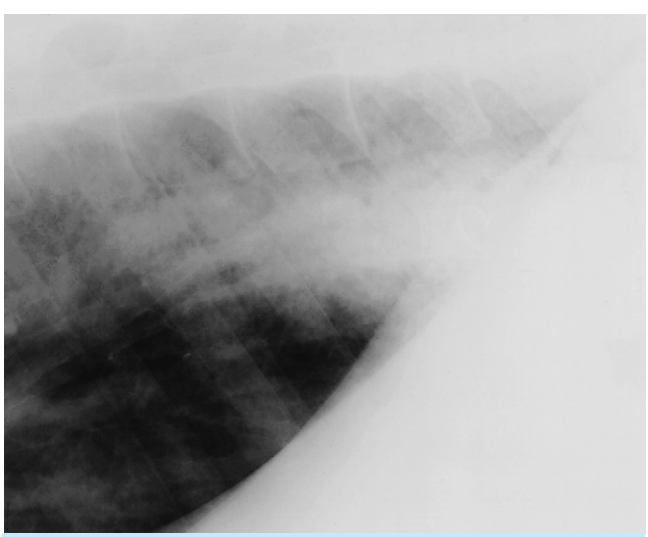

Fig. 29.12
Thoracic radiograph of a 5-year-old Thoroughbred race horse. Radiographic signs of EIPH are evident as the wedge-shaped density in the dorsocaudal lung fields.

Necropsy examination

Exercise-induced pulmonary hemorrhage is a rare cause of death of race horses. Necropsy examination of affected horses is usually incidental to examination for another cause of death. Pertinent abnormalities in horses with EIPH are restricted to the respiratory tract. Grossly, horses examined within hours of strenuous exercise, such as horses necropsied because of catastrophic musculoskeletal injuries incurred during racing, may have severe petechiation in the caudodorsal lung fields (Fig. 29.13). Horses with chronic disease have blue/gray or blue/brown discoloration of the visceral pleural surfaces of the caudodorsal lung fields that is often sharply demarcated, especially on the diaphragmatic surface (Fig. 29.14).[253] The discoloration affects both lungs equally with 30 to 50% of the lung fields being discolored in severe cases.[253] Affected areas do not collapse to the same extent as unaffected areas and, in the deflated lung, have a spleen-like consistency.[253] On the cut surface, the discolored areas of lung are predominantly contiguous with the dorsal pleural surface and extend ventrally into the lung parenchyma. Areas of affected lung may be separated by normal lung. There is proliferation of bronchial vessels, predominantly arteries and arterioles, in affected areas.[254] Histologically, affected areas exhibit bronchiolitis, hemosiderophages in the alveolar lumen and interstitial spaces, and fibrosis of interlobular septa, pleura and around vessels and bronchioles.[255]

Table 29.6 Causes of epistaxis or hemorrhage into airways of horses

Hemorrhage into trachea or bronchi:
Exercise-induced pulmonary hemorrhage
Pulmonary abscess
Trauma
Pneumonia
Pulmonary foreign body
Hemangiosarcoma
Pulmonary neoplasia
Epistaxis:
All of the above
Guttural pouch mycosis
Ethmoidal hematoma
Thrombocytopenia
Trauma
Neoplasia

Table 29.7 Pharmacotherapeutic and management interventions used to prevent exercise-induced pulmonary hemorrhage in horses

Putative mechanism and contributing factor	Intervention	Evidence of efficacy
High pulmonary capillary pressure		
High cardiac output	Furosemide (frusemide)	Increasing evidence of efficacy of furosemide in control of EIPH
	Dehydration	
	Other diuretics	
Insufficient pulmonary vasodilation	Antihypertensive agents:	No studies to investigate efficacy or effect on PAP
	Guanabenz	
	Clonidine	
	Enalapril	No effect on PAP during intense exercise
	Nitric oxide donors/analogs:	NG reduces PAP of standing horses. No evidence of effect on
	Nitroglycerin (NG)	PAP during exercise. NO blockade by L-NAME does not affect
	Nitroprusside	PAP during intense exercise
	L-arginine	
	Phosphodiesterase inhibitors:	No known effects on PAP or EIPH
	Sildenafil (Viagra)	
	Aminophylline	
Increased blood viscosity (reduced red cell deformability, echinocytosis)	Pentoxifylline	No effect on PAP during intense exercise. Effect on EIPH not reported
Low alveolar pressure – increased upper airway resistance		
Upper airway abnormalities (increased inspiratory resistance)	Surgical correction of obstruction	No demonstrated efficacy on EIPH
Resistance at nares	Nasal dilator strips (Flair)	Decreases red cell count in bronchoalveolar lavage fluid collected after intense exercise
Low alveolar pressure – intrathoracic obstruction		
Bronchoconstriction	Bronchodilatory drugs:	No demonstrated efficacy on EIPH. Clenbuterol does not affect PAP during exercise
	Clenbuterol	
	Albuterol	
	Ipratropium	
	Pyrroglycolate	
Lower airway inflammation	Anti-inflammatory drugs:	
	Corticosteroids	No demonstrated efficacy of corticosteroids in preventing EIPH
	Cromolyn sodium	Cromolyn sodium has demonstrated lack of efficacy
	Low allergenic stall bedding (paper)	No efficacy in reducing EIPH
Interstitial inflammation and bronchial angiogenesis		
Progressive lung injury	Rest	No demonstrated efficacy in reducing EIPH
	Corticosteroids	No demonstrated efficacy in reducing EIPH
Coagulopathy or platelet dysfunction		
Excessive fibrinolysis	Aminocaproic acid	Inhibits fibrinolysis. No demonstrated efficacy in preventing EIPH
	Estrogens	Rationale unclear. No demonstrated efficacy in preventing EIPH
Increased platelet aggregation	Aspirin	Inhibits platelet aggregation. No demonstrated effect in preventing EIPH
Capillary fragility	Hesperidin-citrus bioflavinoids	No effect on EIPH in 45 horses

PAP, pulmonary artery pressure; EIPH, exercise-induced pulmonary hemorrhage, NO, nitric oxide.

Diagnostic confirmation

Presence of EIPH is most immediately confirmed by tracheobronchoscopic examination of the horse after strenuous exercise. Detection of red blood cells or hemosiderophages in tracheal aspirates or BAL fluid is also indicative of EIPH. The finding of hemorrhage in the airways of a horse soon after exercise allows a strong presumptive diagnosis of EIPH. Other causes of hemorrhage into airways are listed in Table 29.6.

Treatment and prognosis

Therapeutic aims

The aims of treatment are to reduce the severity of hemorrhage and minimize the adverse sequelae to hemorrhage. Sequelae to hemorrhage include airway and interstitial inflammation and fibrosis.

Treatment

Therapy for EIPH is controversial in that a wide variety of treatments is used but there is no conclusive evidence of efficacy for any of them in horses under field, i.e. racing, conditions (Table 29.7). Therapy of EIPH is usually a combination of attempts to reduce the severity of subsequent hemorrhage and efforts to minimize the effect of recent hemorrhage.

Treatment of EIPH is problematic for a number of reasons. First, the pathogenesis of EIPH has not been determined although the available evidence supports a role for stress failure of pulmonary capillaries (see below). Second, there is a lack of information using large numbers of horses under field conditions that demonstrates an effect of any medication or management practice (with the exception of bedding) on EIPH. There are numerous studies of small numbers of horses (< ~40) under experimental conditions but these studies often lacked the statistical power to detect treatment effects and, furthermore, the relevance of studies conducted on a treadmill to horses racing competitively is questionable. Treatments for EIPH are usually intended to address a specific aspect of the pathogenesis of the disease and will be discussed in that context.

Prevention of stress failure of the pulmonary capillaries Stress failure of pulmonary capillaries, and subsequent subsequent hemorrhage, is believed to occur as a result of the high transmural pressures in pulmonary capillaries that develop in the lungs of horses during strenuous exercise. There is therefore interest in reducing the pressure difference across the pulmonary capillary membrane in an effort to reduce EIPH. Theoretically, this can be achieved by reducing the pressure within the capillary or increasing (making less negative) the pressure within the intrathoracic airways and alveolus.

Reducing pulmonary capillary pressure Furosemide (frusemide) administration as prophylaxis of EIPH is permitted in a number of racing jurisdictions worldwide (Fig. 29.15).[256] Within the USA and Canada, almost all Thoroughbred, Standardbred and Quarter Horse racing jurisdictions permit administration of furosemide before racing. Approximately 85% of all Thoroughbred race horses in the USA and Canada receive furosemide at some stage of their career and, on average, 75% of horses in a race receive furosemide.[257] Although accurate numbers are not available, it appears that a smaller proportion of Standardbred and Quarter Horse race horses receive furosemide before racing. Furosemide is administered to 22–32% of Standardbred race horses and 19% of racing Quarter Horses in two racing jurisdictions.[258–260]

The efficacy of furosemide in treatment of EIPH is uncertain. While field studies of large numbers of horses do not demonstrate an effect of furosemide on the prevalence of EIPH,[224,261] studies of Thoroughbred horses running on a treadmill provide evidence that furosemide reduces the severity of EIPH.[245,246] Under field conditions, based on tracheobronchoscopic evaluation of the severity of bleeding, furosemide has been reported to reduce or have no influence on the severity of bleeding.[224,238] This apparent inconsistency may be attributable to measurement of red blood cell counts in BAL fluid of horses that have run on a treadmill not being

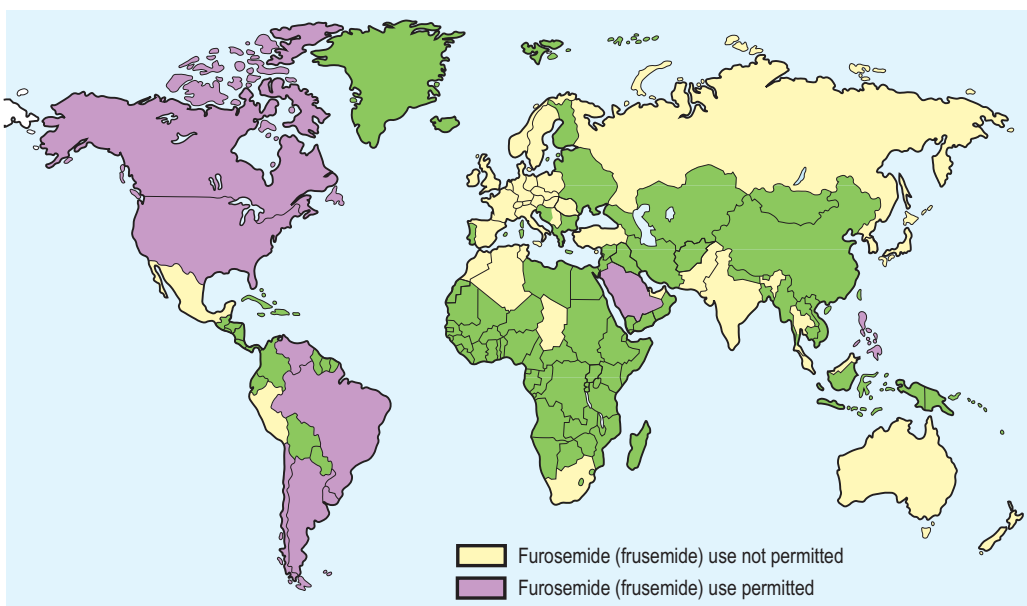

Fig. 29.15
Map depicting racing jurisdictions (purple) that permit administration of furosemide (frusemide) on the day of racing. Source: www.horseracingintfed.com.

representative of effects of furosemide under field conditions. The weight of evidence from field studies does not support a role for furosemide in preventing or reducing the severity of EIPH.

The mechanism by which furosemide may reduce the severity of EIPH is unknown although it is speculated that furosemide, by attenuating the exercise-induced increase in pulmonary artery and pulmonary capillary pressure of horses, reduces the frequency or severity of pulmonary capillary rupture.[262–264]

Furosemide is associated with superior performance in both Thoroughbred and Standardbred race horses.[257,258] Thoroughbred horses treated with furosemide were 1.4 times as likely to win the race, earned more money and had a standardized 6 furlong race time 0.56 to 1.09 seconds less than untreated horses.[257] Similarly, furosemide reduced one mile race times of Standardbred pacers by 0.31 to 0.74 seconds.[258]

Antihypertensive agents used in control of systemic (not pulmonary artery) hypertension in humans have been used in an effort to prevent EIPH in horses. Drugs including guanabenz and clonidine have been administered to horses to prevent EIPH, but the efficacy of these drugs in preventing EIPH or reducing pulmonary capillary pressure of exercising horses has not been demonstrated. Enalapril is effective in inhibiting angiotensin-converting enzyme (ACE) activity in horses, but does not affect pulmonary artery pressure of exercising horses.[265] Similarly, the efficacy of enalapril in preventing EIPH has not been demonstrated.

Nitric oxide is a potent vasodilator in many vascular beds. Administration of nitroglycerin (a nitric oxide donor) reduces pulmonary artery pressure of standing horses, but does not affect pulmonary artery pressure of horses during intense exercise.[266] L-Arginine is a nitric oxide donor with no demonstrated efficacy in reducing pulmonary capillary pressure or EIPH in horses. The effect of L-NAME, an inhibitor of nitric oxide synthetase, on pulmonary artery pressure during maximal exercise is controversial with either no effect or a decrease in pulmonary artery pressure reported.[267,268] Interestingly, L-NAME administration caused an increase in severity of EIPH.[267] Sildenafil, a phosphodiesterase inhibitor that accentuates the effect of nitric oxide and is used in the treatment of erectile dysfunction in men, has been administered to horses in an apparent attempt to reduce EIPH. However, its efficacy in preventing EIPH or reducing pulmonary capillary pressure has not been demonstrated.

An increase in pulmonary capillary pressure secondary to altered rheostatic properties of blood during exercise has been suggested as a possible contributing factor for EIPH.[269] Furosemide increases blood viscosity whereas pentoxifylline increases red blood cell deformability and may attenuate the increase in blood viscosity that occurs during exercise.[270–272] However, pentoxifylline does not affect pulmonary capillary pressure of exercising horses and did not affect the prevalence of EIPH in a small experimental study.[273]

Increasing alveolar inspiratory pressure Airway obstruction, either intrathoracic or extrathoracic, increases airway resistance and results in a more negative intrathoracic (pleural) pressure during inspiration to maintain tidal volume and alveolar ventilation. Causes of extrathoracic airway obstruction include laryngeal hemiplegia and other abnormalities of the upper airway (see Chapter 27), whereas intrathoracic obstruction is usually a result of bronchoconstriction and inflammatory airway disease. Horses with partial extrathoracic inspiratory obstruction or bronchoconstriction and airway inflammation associated with recurrent airway obstructive disease (heaves) have pleural (and hence alveolar) pressures that are lower (more negative) than those in unaffected horses or in horses after effective treatment.

Partial inspiratory obstruction, such as produced by laryngeal hemiplegia, exacerbates the exercise-induced decrease in intrapleural pressures with a consequent increase

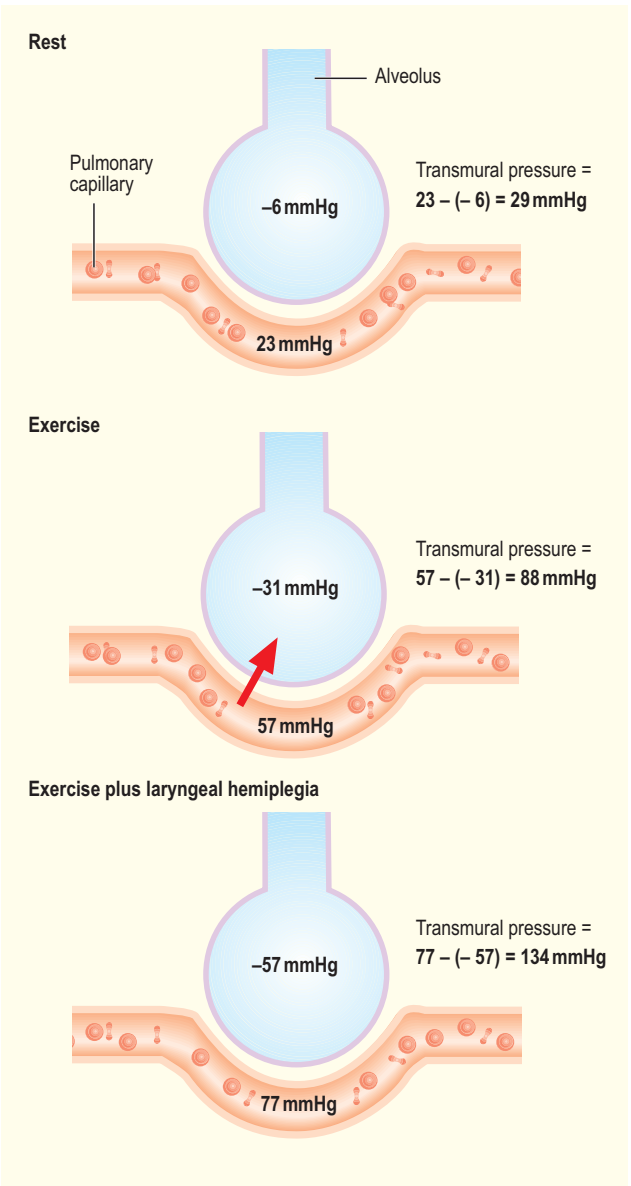

Fig. 29.16
Schematic representation of determinants of transmural pressure in a horse at rest, during intense exercise, and during intense exercise with left laryngeal hemiplegia. Data from Ducharme et al.[276]

in transmural capillary pressures (Fig. 29.16).[274–276] These changes may exacerbate the severity of EIPH although an association between upper airway obstructive disease and EIPH has not been demonstrated. Surgical correction of airway obstruction is expected to resolve the more negative intrapleural pressure but its effect on EIPH is unknown.

Recently, the role of the nares in contributing to upper airway resistance, and hence lowering inspiratory intrapleural pressure during intense exercise has attracted the attention of some investigators (Fig. 29.17). Application of nasal dilator bands (Flair strips) reduces nasal resistance by dilating the nasal valve,[277] and reduces red cell count of BAL fluid collected from horses after intense exercise on a treadmill.[244,245] However, the effect of this intervention in horses racing competitively has not been demonstrated.

The role of small airway inflammation and bronchoconstriction in the pathogenesis of EIPH is unclear. However, horses with EIPH are often treated with drugs intended to decrease lower airway inflammation and relieve bronchoconstriction. Beta-adrenergic bronchodilatory drugs such as clenbuterol and albuterol are effective in inducing bronchodilation in horses with bronchoconstriction, but their efficacy in preventing EIPH is either unknown or, in very small studies, is not evident. Clenbuterol does not alter the hemodynamic responses of horses to exertion nor attenuate exercise-induced arterial hypoxemia in normal horses.[278,279] Ipratropium, a parasympatholytic drug administered by inhalation, showed promise in a very small study (two horses) of preventing EIPH.[280] Corticosteroids, including dexamethasone, fluticasone and beclomethasone, administered by inhalation, parenterally or enterally reduce airway inflammation and obstruction, but have no demonstrated efficacy in preventing EIPH. Cromolyn sodium (sodium cromoglicate) has no efficacy in preventing EIPH.[281]

Water vapor treatment (inhalation of water saturated air) has been proposed as a treatment for EIPH because of its putative effect on small airway disease. However, water vapor treatment has no effect on EIPH.[282]

Fig. 29.17 Horse wearing a nasal dilator (Flair) strip. Photograph courtesy of Dr S. Holcombe.

The use of bedding of low allergenic potential (shredded paper) to prevent EIPH has no apparent effect on the prevalence of EIPH.[283] While it is suggested that the severity of EIPH may be reduced by preventing or minimizing small airway disease, studies to demonstrate such an effect have not been reported. However, optimizing the air quality in barns and stables and preventing infectious respiratory disease appear sensible precautions.

Interstitial inflammation and bronchial angiogenesis

Hemorrhage into interstitial tissues induces inflammation with subsequent development of fibrosis and bronchial artery angiogenesis.[240,254,284] The role of these changes in perpetuating EIPH in horses is unclear, but is likely to be of some importance. Treatments to reduce inflammation and promote healing with minimal fibrosis have been proposed. Rest is an obvious recommendation and many racing jurisdictions have rules regarding enforced rest for horses with epistaxis. While the recommendation for rest is intuitive, there is no information that rest reduces the severity or incidence of EIPH in horses with prior evidence of this disorder.

Similarly, corticosteroids are often administered, either by inhalation, enterally or parenterally, in an attempt to reduce pulmonary inflammation and minimize fibrosis. Again, the efficacy of this intervention in preventing or minimizing severity of EIPH has not been documented.

Excessive bleeding

Coagulopathy and fibrinolysis Exercise induces substantial changes in blood coagulation and fibrinolysis.[285] However there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.[286,287] Regardless, aminocaproic acid, a potent inhibitor of fibrin degradation, has been administered to horses to prevent EIPH. The efficacy of aminocaproic acid in preventing EIPH has not been demonstrated. Similarly, estrogens are given to horses with the expectation of improving hemostasis although the effect of estrogens on coagulation in any species is unclear. There is no evidence that estrogens prevent EIPH in horses.

Vitamin K is administered to horses with EIPH presumably with the expectation that it will decrease coagulation times. However, as EIPH is not associated with prolonged bleeding times, it is unlikely that this intervention will affect the prevalence or severity of EIPH.

Platelet function Aspirin inhibits platelet aggregation in horses and increases bleeding time.[288] Seemingly paradoxically, aspirin is sometimes administered to horses with EIPH because of concerns that increased platelet aggregation contributes to EIPH.[289] There is no evidence that aspirin either exacerbates or prevents EIPH.

Capillary integrity Capillary fragility increases the risk of hemorrhage in many species. Various bioflavinoids have been suggested to increase capillary integrity and prevent bleeding. However, hesperidin and citrus bioflavinoids have no efficacy in prevention of EIPH in horses.[290] Similarly, vitamin C is administered to horses with EIPH without scientific evidence of any beneficial effect.

Overview of treatment Selection of therapy for horses with EIPH is problematic. Given that most horses have some degree of pulmonary hemorrhage during most bouts of intense exercise, the decision must be made not only as to the type of treatment and its timing but also which horses to treat. Moreover, the apparent progressive nature of the disease with continued work highlights the importance of early and effective prophylaxis and emphasizes the need for studies of factors, such as air quality and respiratory infections, in inciting the disorder.

The currently favored treatment for EIPH is administration of furosemide (frusemide) before intense exercise. Its use is permitted in race horses in a number of countries. Increasingly persuasive laboratory evidence of an effect of furosemide to reduce red cell count in BAL fluid collected from horses soon after intense exercise supports the contention that furosemide is effective in reducing the severity of EIPH in race horses. However, it should be borne in mind that neither the relationship between severity of EIPH and red cell count in BAL fluid nor the efficacy of furosemide in reducing severity of EIPH in race horses in the field has been demonstrated. In fact, there is strong evidence that furosemide does not reduce the prevalence of EIPH and other evidence that it does not reduce the severity of EIPH under field conditions. The association between furosemide administration and superior performance in Standardbred and Thoroughbred race horses should be borne in mind when recommending use of this drug.

Rest is an obvious recommendation for horses with EIPH, but the hemorrhage is likely to recur when the horse is next strenuously exercised. The duration of rest and the optimal exercise program to return horses to racing after EIPH is unknown, although some jurisdictions require exercise no more intense than trotting for 2 months. Firm recommendations cannot be made on duration of rest because of a lack of objective information.

Although a role for lower airway disease (either infectious or allergic) in the genesis of EIPH has not been demonstrated, control of infectious diseases and minimization of non-infectious lower airway inflammation appears prudent.

Prognosis

The prognosis for racing for horses with clinically significant EIPH is guarded because of the progressive nature of the disease. Horses that have experienced severe EIPH on one occasion are likely to do so again regardless of treatment. However, the risk of horses experiencing a repeated bout of severe hemorrhage and the effect of EIPH on career longevity are unknown.

Pathophysiology and etiology

The likely proximate cause of EIPH is rupture of alveolar capillary membranes with subsequent extravasation of blood into interstitial and alveolar spaces (Fig. 29.18).[291] The source of blood in such instances is the pulmonary circulation. Bleeding from bronchial circulation during exercise has been suggested based on histologic evidence of bronchial angiogenesis in horses that have experienced previous episodes of EIPH.[292] Whether there is a contribution of the bronchial circulation to EIPH has not been determined. Regardless of the contribution of bronchial circulation to blood in the airways, the likely initial lesion is in capillaries associated with the pulmonary circulation. Hemorrhage into the interstitial space and alveoli, with subsequent rostral movement of blood in the airways, results in blood in the trachea and bronchi and, infrequently, epistaxis.

Fig. 29.18

The 'a' is the alveolar airspace and the arrow mark the site of disruption of the pulmonary capillary epithelium. Reproduced with permission from West et al.[291]

Rupture of alveolar capillaries occurs secondary to an exercise-induced increase in transmural pressure (pressure difference between the inside of the capillary and the alveolar lumen) (Fig. 29.16). If the transmural stress exceeds the tensile strength of the capillary wall, the capillary ruptures.[293] The proximate cause of alveolar capillary rupture is the high transmural pressure generated by positive intracapillary pressures (largely attributable to capillary blood pressure) and the lower intra-alveolar pressure (generated by the negative pleural pressures associated with inspiration). During exercise, the absolute magnitudes of both pulmonary capillary pressure and alveolar pressure increase, with a consequent increase in transmural pressure.[276,293] (Fig. 29.16) Strenuous exercise is associated with marked increases in pulmonary artery pressure in horses.[243,263,294] Values for mean pulmonary arterial pressure at rest of 20–25 mmHg increase to greater than 90 mmHg during intense exercise because of the large cardiac output achieved by exercising horses. Although pulmonary capillary pressure cannot be measured directly, it can be estimated from pulmonary artery wedge pressures. Different techniques for estimating pulmonary capillary pressure produce varying values, but invariably exercise induces a marked increase in pulmonary

capillary pressure.[276,295,296] Combined with the increase in pulmonary capillary pressure is a marked decrease (more negative) in pleural, and therefore alveolar, pressures during exercise. Pleural pressures of normal horses during inspiration decrease from approximately –0.7 kPa (–5.3 mmHg) at rest to as low as –8.5 kPa (–64 mmHg) during strenuous exercise.[297] Together, the increases in pulmonary capillary pressure and decreases (more negative) in intrapleural (alveolar) pressure contribute to a marked increase in stress in the alveolar wall. Although the alveolar wall and pulmonary capillary of horses are stronger than those of other species, rupture may occur because the wall stress in the alveolus exceeds the mechanical strength of the capillary.[298]

Other theories of the pathogenesis of EIPH include (Table 29.8): small airway disease, upper airway obstruction, hemostatic abnormalities, changes in blood viscosity and erythrocyte shape, intrathoracic shear forces associated with gait, and bronchial artery angiogenesis.[292,299] It is likely that the pathogenesis of EIPH involves several processes, including pulmonary hypertension, lower alveolar pressure and changes in lung structure, that summate to induce stress failure of pulmonary capillaries.

Obstruction of either the upper or lower airways has been proposed as a cause of EIPH.[300] Inspiratory airway obstruction results in more negative intrapleural, and therefore alveolar, pressures. This effect is exacerbated by exercise with the result that alveolar transmural pressure is greater in horses with airway obstruction (Fig. 29.16).[274,276] The higher transmural pressure in such horses may increase the severity of EIPH, although this has not been demonstrated. Moreover, while inspiratory airway obstruction may predispose to EIPH, the prevalence of this condition is much less than that of EIPH, indicating that it is not the sole factor inducing EIPH in most horses.

Horses with moderate to severe EIPH have histologic evidence of inflammation of the small airways,[255,301] and there is a clear association between presence of EIPH and inflammatory changes in bronchoalveolar or tracheal aspirate fluid.[239,302] However, because instillation of autologous blood into the airways induces a marked inflammatory response in normal horses,[240] it is unclear if inflammation alone induces or predisposes to EIPH or if the inflammation is a result of EIPH. Theoretically, small airway inflammation and bronchoconstriction have the potential to produce intrathoracic airway obstruction and, therefore, a more negative alveolar pressure. Given that small airway disease is common in horses, there is the potential for an important effect of factors such as viral infections, air pollution and allergic airway disease to contribute to the initiation or propagation of EIPH.

Exercise is accompanied by marked changes in blood flow characteristics attributable to an increase in hematocrit and decrease in red cell deformability.[269,303] These changes cause an increase in microvascular shear stress and thus could, conceivably, contribute to capillary rupture.[303] However, there is at present no direct evidence that indicates that this is an important feature of EIPH.

The characteristic location of lesions of EIPH in the caudodorsal lung fields has led to the proposal that hemorrhage is a result of tissue damage occurring when waves of stress, generated by forelimb foot strike, are focused and amplified into by the narrowing cross-sectional area of the caudal lung lobes.[299] According to the theory, the locomotory impact of the forelimbs results in transmission of forces through the scapula to the body wall, from where they pass into the lungs and caudally and dorsally. As the wave of pressure passes into the narrower caudodorsal regions of the lungs it generates progressively greater shearing forces which disrupt tissue and cause EIPH.[299] However, studies of intrapleural pressures have not demonstrated the presence of a systemic pressure wave passing through the lung and do not provide support for this hypothesis.[304]

Horses with EIPH have been suspected of having defects in either hemostasis or fibrinolysis. However, while exercise induces substantial changes in blood coagulation and fibrinolysis,[285] these is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.[286,287]

Overview Regardless of the cause, rupture of pulmonary capillaries and subsequent hemorrhage into airways and interstitium causes inflammation of both airways and interstitium with subsequent development of fibrosis and alteration of tissue compliance (Fig. 29.19). Heterogeneity of compliance within the lungs, and particularly at the junction of normal and diseased tissue, results in development of abnormal shear stress with subsequent tissue damage. These changes are exacerbated by inflammation and obstruction of small airways with resulting uneven inflation of the lungs.[305] The structural abnormalities, combined with pulmonary hypertension and the large intrathoracic forces associated with respiration during strenuous exercise, cause repetitive damage at the boundary of normal and diseased tissue with further hemorrhage and inflammation. The process, once started, is lifelong and continues for as long as the horse continues to perform strenuous exercise.[292]

Table 29.8 Potential factors inducing or contributing to the severity of exercise-induced pulmonary hemorrhage

Pulmonary capillary hypertension
Rheologic properties of blood
Negative intrapleural (alveolar) pressures
Extrathoracic airway obstruction (e.g. laryngeal hemiplegia)
Intrathoracic airway obstruction (e.g. bronchoconstriction)
Small airway inflammatory disease
viral or bacterial infections
allergy
air pollution (dust, ozone)
Coagulopathy
abnormal platelet function
capillary fragility
Bronchial neovascularization
Pulmonary fibrosis and altered compliance
Locomotory forces
foot strike
abdominal piston

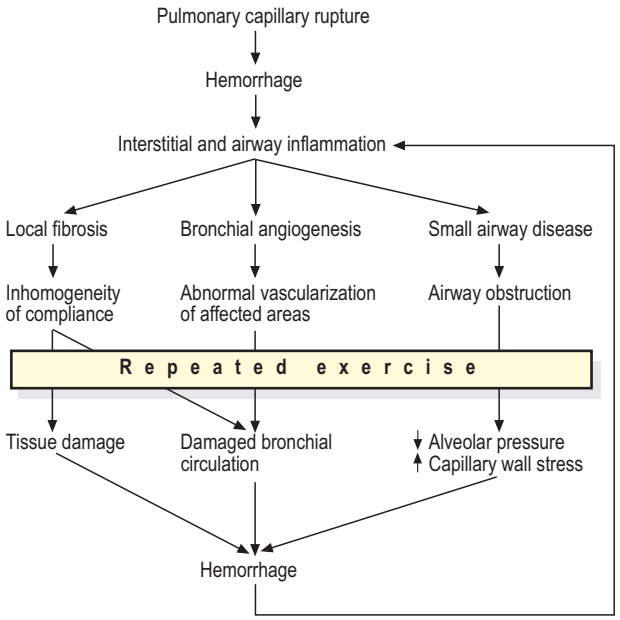

Fig. 29.19
Proposed pathogenesis of EIPH.

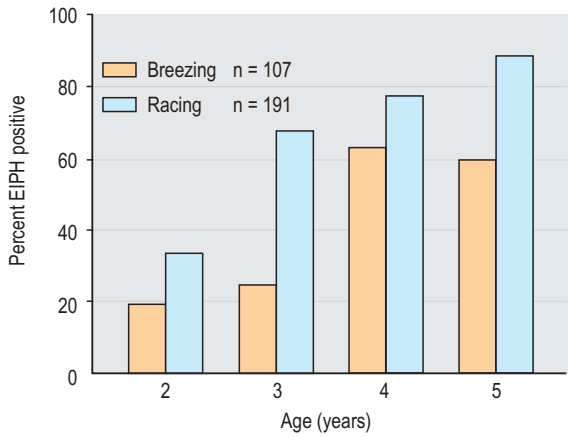

Fig. 29.20
Relationship between prevalence of EIPH and age and speed (racing or breezing) in Thoroughbred horses. Reproduced with permission from Raphel and Soma.[223]

Epidemiology

Exercise-induced pulmonary hemorrhage is a disorder of horses that run at high speed, such as Thoroughbred or Standardbred race horses. The disease is almost unknown in endurance horses or draft breeds. As a general rule, the more intense the exercise or higher the speed attained, the greater the proportion of horses with EIPH.

The prevalence of EIPH varies with the method used to detect it and the frequency with which horses are examined. Almost all Thoroughbred race horses in active training have hemosiderophages in BAL fluid, indicating that all have some degree of EIPH.[220] The prevalence of EIPH decreases when diagnosis is based on endoscopic examination of horses after exercise or racing.

Exercise-induced pulmonary hemorrhage is very common in Thoroughbred race horses with estimates of prevalence, based on a single endoscopic examination of the trachea and bronchi, of 43–75%.[223,225,306] The prevalence increases with the frequency of examination with over 80% of horses having evidence of EIPH on at least one occasion after examination after each of three consecutive races.[261] The prevalence of EIPH in Standardbred race horses is assumed to be lower, with 26–34% of horses reported to have blood in the trachea after racing.[227,307] However, these studies were based on a single examination and one[307] only reported as positive those horses with blood covering more than one-half of the tracheobronchial tree. When examined after each of three races, 87% of Standardbred race horses have evidence of EIPH on at least one occasion,[226] suggesting that EIPH is as common in Standardbred race horses as it is in Thoroughbred race horses.

Exercise-induced pulmonary hemorrhage occurs in approximately 62% of racing Quarter Horses, and has been observed in Quarter Horses used for barrel racing.[234] The disorder occurs in racing Appaloosa horses.[233] Approximately 11% of polo ponies are affected with EIPH.[308]

Age is an important risk factor for EIPH with the prevalence of the disorder being higher in older horses (Fig. 29.20).[223,225,306] There is no consistent effect of sex on prevalence of EIPH.[223,225,227,306]

Among Thoroughbred race horses the prevalence of EIPH increases with increasing speed.[223,301] The prevalence of EIPH is greater in Thoroughbreds after racing than after breezing (galloping) (Fig. 29.20) and lesions of EIPH are not detected in young Thoroughbred race horses that have not trained at speeds above 7 meters per second.[223,301]

Prevention

Aspects of prevention of EIPH are discussed under 'Treatment and prognosis'. At present, there are no recognized and accepted approaches for prevention of EIPH in young horses. Development of strategies for prevention will depend on an understanding of the inciting causes of EIPH.

Interstitial pneumonia

- Interstitial pneumonia is a rare disease of horses that can be caused by infections, toxins, or immune-mediated mechanisms, but most cases remain undiagnosed.
- Acute cases often present for acute respiratory distress whereas chronic cases have a history of progressive weight loss and increasing respiratory difficulty.
- History, clinical examination, lung function testing, and thoracic radiographs help reach a presumptive diagnosis

of interstitial pneumonia, but histology of a lung biopsy is required to confirm diagnosis.
- Treatment is usually unrewarding and prognosis is poor.

Recognition of the disease

History and presenting complaint

Interstitial pneumonia is an uncommon cause of pulmonary disease in horses, with both acute and chronic presentations having been described. Affected animals may vary in age from foals as young as 1 month to horses over 20 years and present with acute or chronic onset of tachypnea, weight loss, exercise intolerance, increased respiratory efforts, fever and cough.[309–312] Clinical presentation may vary from horses developing acute respiratory distress in less than 24 hours to horses exhibiting progressive weight loss and exercise intolerance over a period of months. Animals usually fail to improve in response to antimicrobial and anti-inflammatory therapy.

Physical examination

Horses presenting acute forms of the disease usually exhibit respiratory distress characterized by nostril flaring, tachypnea, increased respiratory efforts, and cyanotic mucous membranes.[310,313] Fever, tachycardia, and abnormal breath sounds (e.g. wheezes, crackles) upon thoracic auscultation are frequently found during physical examination. Other horses display decreased breath sound intensity over the entire lung field despite obvious breathing difficulty.[311] Chronic cases often exhibit progressive weight loss and increasing breathing difficulties. Horses may be asymptomatic in the early stages of chronic interstitial pneumonia (e.g. silicosis).[314]

Special examination

Thoracic radiographs often reveal a severe, diffuse interstitial pattern occasionally forming a miliary to nodular pattern (Fig. 29.21).[310,314] Areas of alveolar opacities with air bronchogram may be seen in addition to bronchointerstitial patterns. Repeating radiographs may be useful to follow disease progression. However, it is a poor predictor of lung function and radiographic findings may be normal in a horse with significant exercise intolerance. Ultrasonography of the chest may reveal an irregular lung surface with small hyperechoic areas.[311]

Transcutaneous lung biopsy often provides a definitive diagnosis. However, complications such as pulmonary hemorrhage, pneumothorax, and rarely death can occur.[315,316] Histologic findings in acute severe cases reveal diffuse, necrotizing bronchiolitis and alveolitis, hyaline membrane formation, interstitial edema and fibrosis, and type II pneumocyte hyperplasia.[310,311,317] Lesions secondary to silicosis are characterized by areas of fibrosis with multiple granulomatous lesions containing macrophages with intracytoplasmic, eosinophilic, birefringent crystalline material.[314]

Lung function testing is useful to characterize the type and severity of pulmonary disease. Interstitial pneumonia results in decreased lung elasticity and as a result greater distending pressure is required from inspiratory muscles in order to achieve any volume change (restrictive lung disease). These changes may be detected by measurement of lung mechanics during tidal breathing. Typical changes are decreased dynamic lung compliance (C_{dyn}), increased changes in transpulmonary pressure (ΔP_{plmax}), and normal pulmonary resistance (R_L; Fig. 29.22). In contrast, horses with obstructive lung disease such as RAO exhibit increased ΔP_{plmax} mainly because of increased R_L. Decreased lung elasticity also limits the maximum volume of air that the horse can inhale (vital capacity) but does not affect the ability to exhale rapidly. As a result forced vital capacity (FVC) is reduced but the ratio forced expiratory volume in 1.5 second ($FEV_{1.5}$):FVC is normal or high (Fig. 29.23). Horses with RAO in crisis have a mildly reduced FVC and a markedly decreased $FEV_{1.5}$:FVC ratio.

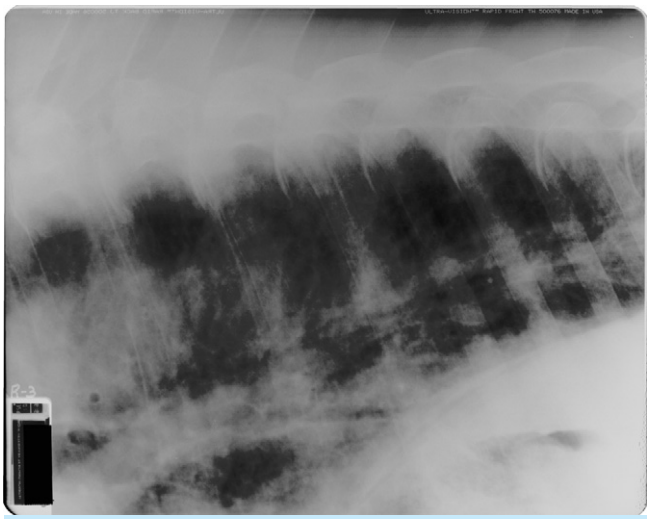

Fig. 29.21
Thoracic radiograph of 14-year-old Thoroughbred horse diagnosed with interstitial pneumonia. Radiographic findings indicate a marked, diffuse broncho-interstitial pattern in the dorsocaudal lung fields.

Laboratory examination

Hematologic findings include leukocytosis, neutrophilia, and hyperfibrinogenemia.[310,312] Occasionally, thrombocytopenia and abnormal clotting times may be detected in severely affected animals with bleeding diathesis (e.g. epistaxis, petechia, ecchymosis).[310] Common abnormalities detected on arterial blood gas analyses include hypoxemia and hyper- or hypocapnia.[312,318]

Various bacteria (e.g. *Streptococcus zooepidemicus*, *Rhodococcus equi*, *Escherichia coli*) may be isolated from respiratory secretions collected by TW or BAL in foals. However, bacteria, viruses, or fungi are usually not cultured from adult horses.[310,312] Cytological analyses often show inflammatory changes characterized by increased number of non-degenerative neutrophils and no visible pathogens. Accumulation of intracellular crystalline materials in pulmonary alveolar macrophages is commonly detected in horses with silicosis.[314]

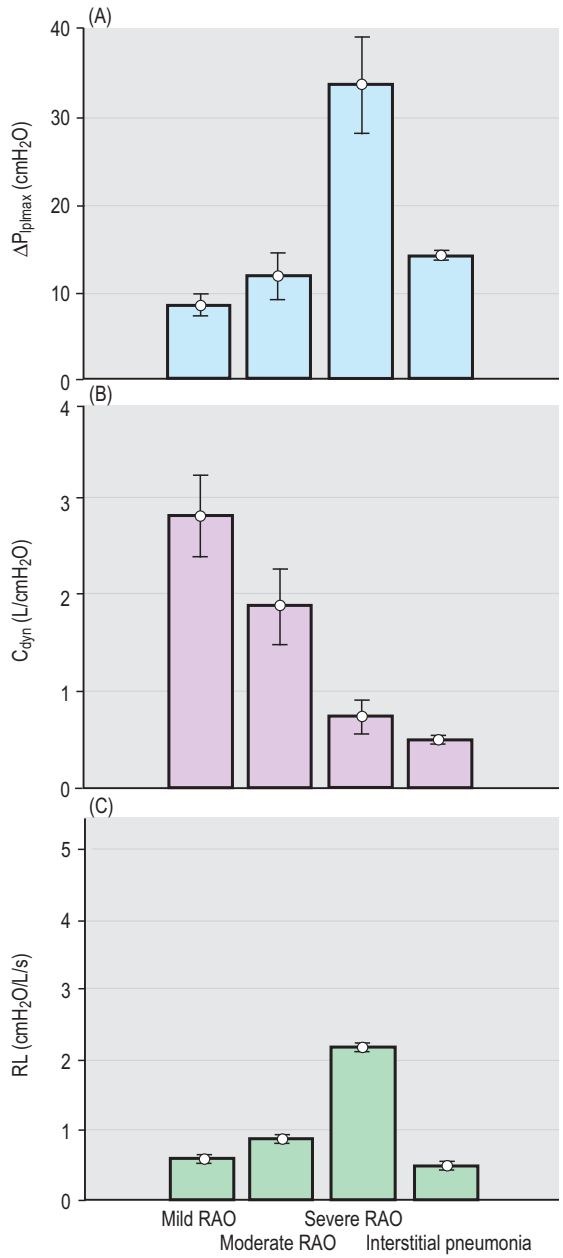

Fig. 29.22
Lung mechanics during tidal breathing in horses with RAO and one horse with interstitial pneumonia. (A) Maximum transpulmonary, pressure changes. (B) Dynamic compliance. (C) Pulmonary resistance.

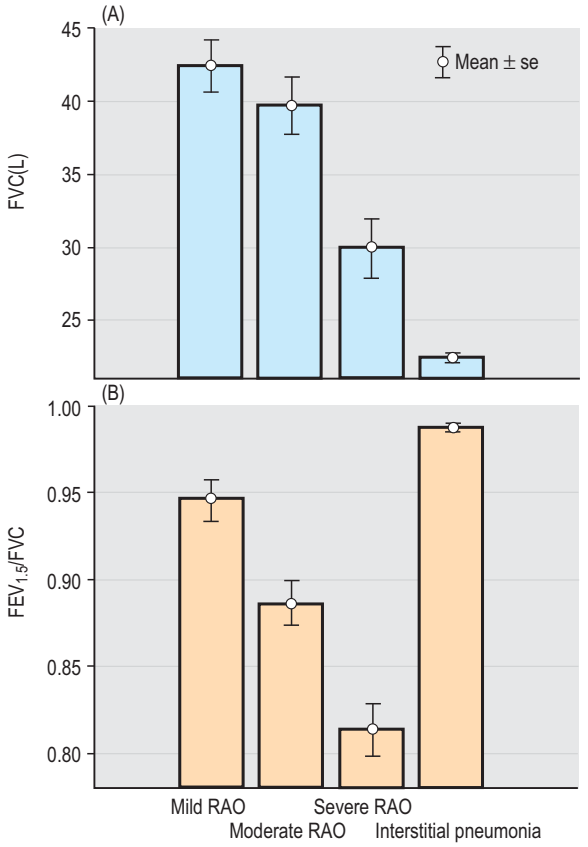

Fig. 29.23
Forced expiration parameters in horses with RAO and in one horse with interstitial pneumonia. (A) Forced vital capacity. (B) Forced expiratory volume in 1.5 s ($FEV_{1.5}$)/forced vital capacity (FVC).

Necropsy examination

Gross pathologic findings include diffusely enlarged and abnormally heavy lungs that fail to collapse upon opening of the thorax, variable amounts of pink foamy liquid in airways, a mottled, lobulated appearance of the lungs, and in some cases, interstitial emphysema.[317,318] Main histologic findings in chronic cases are interstitial fibrosis. Acute lesions include severe, diffuse bronchiolitis, alveolar septal necrosis with neutrophilic infiltration, interstitial edema, hyaline membrane formation, and type II pneumocyte hyperplasia. Cases of silicosis are characterized by diffuse granulomatous pneumonia with areas of pulmonary fibrosis and granulomatous tracheobronchial lymphadenitis.[314,319] Granulomas are composed mainly of macrophages containing refractile particles (≤ 1 μm).

Diagnostic confirmation

The diagnostic approach concerning horses with respiratory distress has been discussed in detail in the RAO section (see 'Diagnostic confirmation'; Fig. 29.8). The main test consists in the administration of a fast-acting bronchodilator (e.g. aerosolized albuterol) to rule out reversible obstructive pulmonary diseases such as RAO and SPAOPD. Thoracic radiography and transcutaneous biopsy are often necessary to confirm a diagnosis of interstitial pneumonia.

Treatment and prognosis

Therapeutic aims

The main goals are to improve tissue oxygenation, decrease pulmonary inflammation, treat underlying infections and

potential complications, and avoid additional stressors.[313] The latter includes strict stall rest in a well-ventilated, cool and dust-free environment.

Therapy

Treatment of tissue hypoxia includes oxygen supplementation through nasal or transtracheal insufflation and bronchodilator administration. In order to improve arterial blood oxygen tension minimum oxygen flow rates of 5 L/min in foals and 12 L/min in adults may be required and should be adjusted based on clinical response or preferably repeated arterial blood gas analysis. Long-acting inhaled bronchodilators are indicated to help decrease the work of breathing (see discussion in the RAO 'Therapy' section). Non-steroidal anti-inflammatory drugs (e.g. flunixin meglumine) may be beneficial. However, corticosteroids appear to be more effective at decreasing pulmonary inflammation and preventing fibrosis, and their use is associated with positive outcome.[311,318] Both inhaled (Table 29.3) and systemic corticosteroids may be administered using similar dosages as for RAO horses in crisis. Antimicrobial therapy is recommended to treat primary or opportunistic infections. Broad-spectrum treatment should be initiated while waiting for tracheal wash cytology and culture results, and should last at least 3 to 6 weeks.[313] Intravenous fluid therapy should be used with caution because cases of severe interstitial pneumonia often exhibit pulmonary hypertension and additional fluids may lead to or aggravate pulmonary edema. Furosemide (frusemide) therapy may be useful in such cases.[320]

Prognosis

Horses with interstitial pneumonia have a poor prognosis. However, some cases have been successfully treated and able to return to athletic activities. One study describes survival of 9 out of 23 cases of interstitial pneumonia in foals.[310] Based on review of the literature, survival rate in adult horses appears to be less favorable.

Prevention

Avoidance of exposure to environmental or toxic causes of interstitial pneumonia (e.g. silicosis, hypersensitivity pneumonitis, smoke inhalation, pneumotoxins) is recommended. However, because the majority of cases of interstitial pneumonia are of unknown etiology, preventive measures are limited to general respiratory hygiene (e.g. low-dust environment, good ventilation) and prophylaxis against respiratory pathogens.

Etiology and pathophysiology

Etiology

A potential cause is found in only a minority of interstitial pneumonia cases. Infectious agents associated with interstitial pneumonia include viruses (e.g. *Morbillivirus*), bacteria (*Streptococcus zooepidemicus*, *Rhodococcus equi*, *Escherichia coli*), parasites (*Parascaris equorum*, *Dictyocaulus arnfieldi*), protozoa (*Pneumocystis carinii*), and fungi (*Aspergillus* spp., *Cryptococcus* spp., *Histoplasma* spp.).[69,317,318,321] Pneumotoxins may be released after ingestion of certain plants such as *Perilla frutescens* and *Eupatorium adenophorum*.[322,323] Alternatively, inhalation of chemicals (e.g. smoke, silicon dioxide crystals) or organic antigens (fungi, endotoxins) may directly injure the lungs and result in intersitial pneumonia.[314,324,325]

Pathophysiology

Interstitial pneumonia may result from direct injury of the alveolar epithelium (pneumocytes I and II), from inhaled toxins or from hematogenous injury to pulmonary capillaries or alveolar basement membrane.[326] Acute lung injury begins with an exudative phase resulting from disruption of the alveolar–capillary barrier. Exudate may form hyaline membranes that become partially attached to alveolar and airway walls. Inflammatory cells, in particular neutrophils, accumulate in the alveolar walls and may cause further tissue damage by the release of proteases and reactive oxygen species.[213,327] A proliferative phase characterized by type II pneumocyte hyperplasia follows the exudative phase within a few days, resulting in thickened alveolar walls. If the horse survives the initial pulmonary insult, the lesions may progress towards alveolar fibrosis characteristic of the chronic phase of interstitial pneumonia.

Epidemiology

Most of the reported cases are sporadic in occurrence. However, multiple cases may occur when horses are exposed to common environmental toxins such as pasture rich in pneumotoxic plants or regions with a high level of crystalline silicates. Cases of interstitial pneumonia have been described in young foals to old horses of various breeds and sex.

CHAPTER 30

Viral respiratory disease in athletic horses

Paul Morley

Importance of viral respiratory infections in athletic horses

Viral respiratory infections are one of the most common health problems in horses throughout the world. These infections are self-limiting and associated disease is not life-threatening, except in extreme cases. However, athletic horses generally have an increased risk of becoming infected and disease associated with these infections has greater consequences for athletes because of their intended use.

How big is the problem?

Infectious respiratory disease (IRD) is one of the most common reasons that athletic horses are removed from scheduled training and performances.[1–3] Interestingly, it has been suggested that IRD is a more frequent cause of performance disability among human athletes than all other diseases combined.[4–7] Even mild respiratory disease can affect equine athletes such that they are not able to attain peak performance. Most clinical occurrences of acute IRD in horses are primarily if not solely attributable to viral respiratory infections.[8] While bacteria and mycoplasma can be primary pathogens, bacteria may be more important in exacerbating clinical disease after a primary viral insult. Major exceptions would be disease caused by *Streptococcus equi* subsp. *equi* and *Rhodococcus equi*, although the latter is only a significant problem in foals.

The importance of respiratory disease among athletic horses is generally well recognized in the equine industries. In 1997 the United States Department of Agriculture (USDA) performed a survey to identify concerns that were of highest priority to the horse industry in the USA.[9] This needs assessment survey showed that problems in horses related to the respiratory system were the third most important health problem reported by all survey respondents (n = 2599), respiratory disease was the top health concern for respondents who used horses primarily for racing, and a majority of respondents considered respiratory disease agents, collectively (e.g. influenza virus, herpesvirus, etc.), to be their highest concern among infectious diseases.[9] A survey of 1200 equine practitioners in the USA found that veterinarians considered viral respiratory disease second only to colic in importance among medical problems of horses.[10] In addition to affecting the success of individual athletic performances, outbreaks of acute infectious respiratory disease can significantly disrupt entire athletic competitions. For example, dramatic outbreaks have been seen when novel strains of influenza virus are introduced into naïve populations (Fig. 30.1). The worldwide importance of viral IRD is further substantiated by the classification of equine influenza, equine rhinopneumonitis (herpesvirus), and equine arteritis as List B diseases for equids by the Office Internationale des Epizooties (OIE) because they are considered to significantly affect international trade of animals and animal products.

Why do equine athletes have an increased risk of viral infections?

First, equine athletes are typically young and often do not have the fully developed immunity to infectious agents that is acquired through repeated exposure to agents that commonly affect horses. Second, athletic horses are often congregated in large groups at training and performance facilities which increases the probability of introduction and exposure

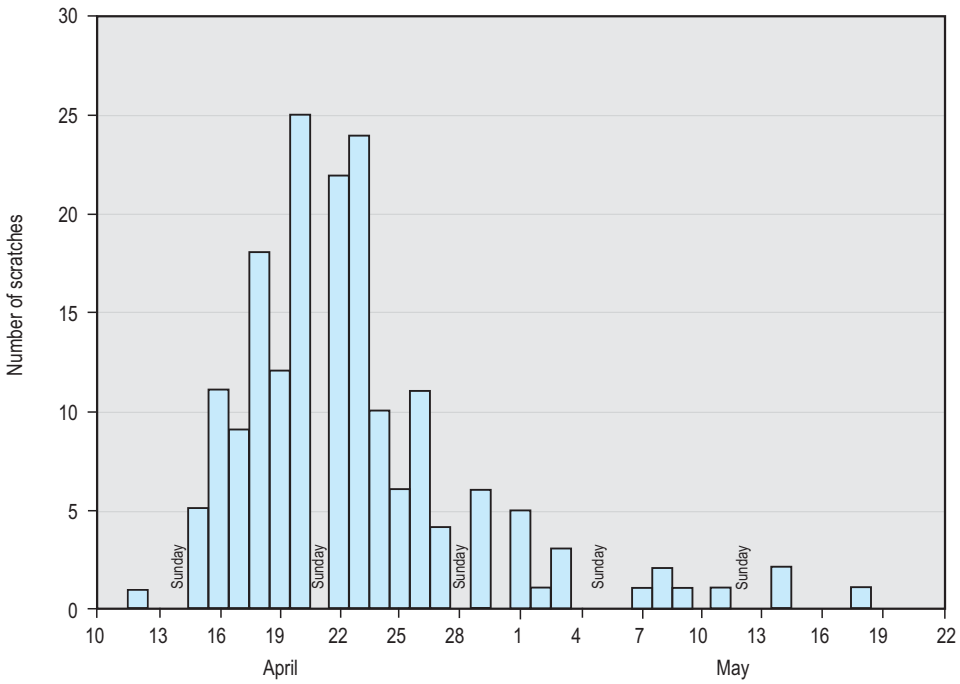

Fig. 30.1
Withdrawals from races (scratches) among 600 horses stabled at a racetrack during an influenza epidemic in April 1963. Similar epidemics were observed throughout North America following introduction of Influenza A/equine/Miami/63 (H3N8). Note the lower rate of scratches observed after the epidemic during May. Adapted from Scholtens et al[70] by permission of Oxford University Press.

to novel contagious pathogens. Third, intensive management of equine athletes at training facilities increases the probability of exposure through management practices such as the shared use of tack and other equipment, as well as through increased exposure via respiratory aerosols and contaminated surfaces. Fourth, environmental conditions encountered by equine athletes may impair non-specific clearance mechanisms through respiratory exposure to noxious chemicals (e.g. ammonia), dust, fungi, and molds. Drying and irritation of mucous membranes caused by airflow across their surfaces have been proposed as factors affecting non-specific immunity in human athletes,[11] and may also impact on the health of equine athletes. In addition, race horses are known to inhale significant quantities of small dirt particles when racing on dirt surfaces. These respiratory irritants may exacerbate non-infectious respiratory problems such as recurrent airway obstruction (heaves), which in turn are strongly believed to be a predisposing factor in viral respiratory infections in humans.[12,13] This is supported by the observation that the amount of airborne particulate matter in stabling environments significantly affected airway inflammation during an outbreak of equine herpesvirus type 1 (EHV1) infection.[14,15] Infected horses stabled in barns with adequate ventilation and lower air particulate counts had less lower airway inflammation when compared with infected horses stabled in less suitable environments.

The frequency of IRD among equine and human athletes may also be related to important effects that exercise has been shown to have on immune function. Physical stresses related to athletic activity have been repeatedly shown to be associated with transient changes of in vitro and in vivo measures of systemic and local immune function, including changes in catecholamine and cortisol release, neuropeptide hormone release, cytokine release and activity, secretion of mucosal antibody, and the functional activity of blood and pulmonary leukocytes.[16–23] These documented changes provide a basis for the 'open window' model proposed to describe cumulative effects of exercise on the immune system in humans.[16,24,25] According to this theoretical model, moderate exercise stimulates immune function during the event and for a short time after. In contrast, heavy exertion is related to an initial stimulation followed by a longer-lasting (i.e. hours) depression in cell-mediated immune function. It is proposed that during this 'open window' of immune depression athletes have an increased risk of becoming infected with a variety of pathogens. Since elite athletes often train intensively on a daily basis, the cumulative time that they are at increased risk of infection may be significant.[16,25,26] In an effort to summarize the relationship between exercise and infectious disease, it has been proposed that the apparent relationship between intensity of exercise and its predisposing effect on the risk of upper respiratory tract infections in humans fits a J-shaped curve.[16,25] This model suggests that the risk of IRD in athletes is attenuated by moderate physical activity, but is exacerbated by chronic, intensive athletic activity. While similar research in horses is not as comprehensive, the limited work that is available suggests that similar effects can be found in horses.[27–37]

This relationship between exercise and immune function is obviously not simple, and is probably modulated by several other factors such as likelihood of exposure to novel pathogens, lack of adequate rest, mental stress, transport, inappropriate nutrition or weight loss, and concurrent infectious or non-infectious disease. This is probably one of the reasons that studies directly evaluating the relationship between exercise and the occurrence of infectious disease in humans have met with equivocal results, even though the effects on various markers of immune function have been

repeatedly and convincingly demonstrated.[38] Unfortunately, almost no information is available directly examining the effects of athletic activity on the risk of IRD occurrences in horses.

How common is infectious respiratory disease in horses?

While IRD is very common among all horses there are few comprehensive estimates of the frequency of disease. There are two recent published estimates of IRD incidence in equine athletes that were obtained through prospective monitoring of race-horse populations.[2,39] A study performed at a single Canadian racetrack where investigators monitored disease occurrence during two race seasons estimated that the incidence of undifferentiated IRD was about 49 IRD cases per 1000 horse-months.[39] A prospective study of a cohort of Thoroughbred horses in Australia estimated the incidence of reported coughing and nasal discharge (infectious or non-infectious) to be approximately 1.8 cases per 1000 horse-months.[2] It is not clear if the difference in observers explains some of the difference between these estimates (reported by research investigators versus owner reported), or if the intensive nature of horse stabling at North American racetracks compared with more extensive management of race horses elsewhere is partially responsible for differences between these two estimates. The absence of influenza virus as a disease agent in Australia could also have affected these estimates. The largest population-based study estimating the frequency of undifferentiated IRD occurrence among horses was conducted by the USDA as part of the National Animal Health Monitoring System (NAHMS) Equine '98 study.[40] While the population for this study of owner-reported disease specifically excluded horses stabled at racetracks, it did include race horses that were stabled at other facilities. However, it should be noted that these data include respiratory disease occurrences from horses of all ages, including those < 1 year old. An estimated 1.5% (SE = 0.2) of horses per quarter developed IRD during this study, and the rate of reported IRD among race horses housed off-track was nearly three times greater than the average for all horses (4.3% of horses per quarter, SE = 1.9). The occurrence of IRD was reported to vary by season, and disease incidence was greatest in the spring (March through May, 2.6% of horses, SE = 0.6), and least common during the winter (December through February, 0.8% of horses, SE = 0.2). In a smaller, but similar longitudinal study, data regarding the occurrence of disease was collected from randomly selected horse operations in Michigan, and the estimated incidence of undifferentiated respiratory disease was 33 cases per 1000 horse-years.[41]

Recognizing infectious respiratory disease

Clinical signs

Horses with IRD generally develop similar clinical signs regardless of which primary or secondary agents are causing clinical disease.[8] Disease is most frequently typified by the occurrence of mucopurulent nasal discharge and sometimes coughing. In a 3-year study of respiratory disease at a Canadian racetrack, regardless of etiology, 80–95% of

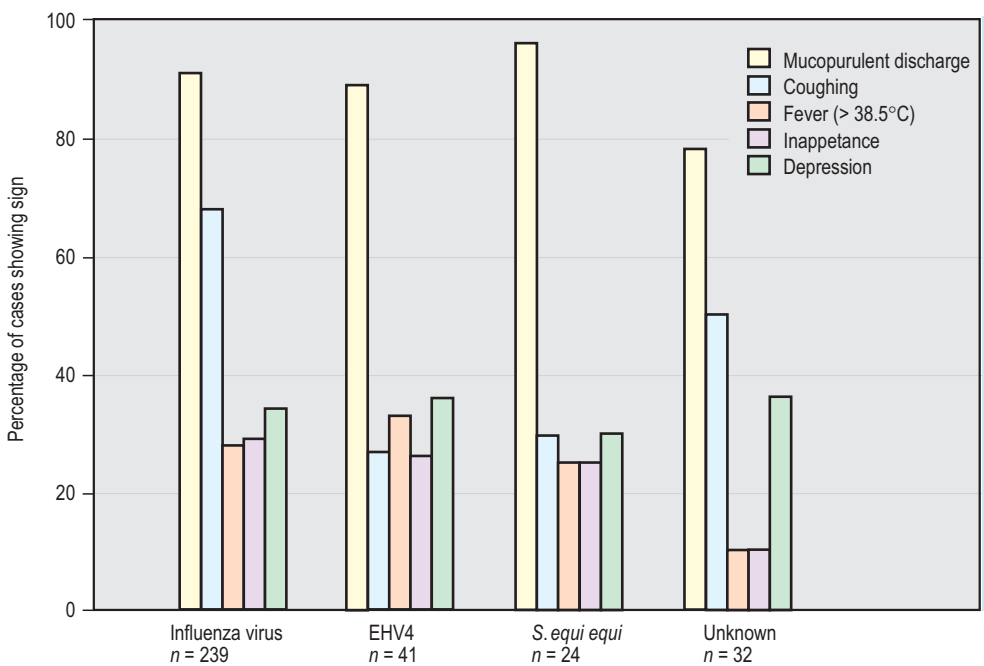

Fig. 30.2
Clinical signs, by etiology, in race horses diagnosed with IRD during a 3-year study in Canada.

affected horses developed mucopurulent nasal discharge, while the occurrence of coughing was less common and more variable (30–75% coughed depending upon the etiology; Fig. 30.2).[8] Increased serous nasal discharge may be noted prior to becoming more mucoid. Paroxysmal coughing in a majority of affected animals is suggestive of influenza virus infection, but this is not always predominant during influenza outbreaks, especially if clinical disease is mild. Fever (rectal temperature > 38.5°C or 101.5°F) is less commonly noted in affected animals (10–30%).[8] Abscessation and dramatic enlargement of submandibular lymph nodes can sometimes allow differentiation of animals infected with *Streptococcus equi* subsp. *equi*, but not all infected animals develop this pathognomonic sign.[8] Many horses infected with viral respiratory agents remain asymptomatic, especially if they are older and are more immune. Others only show vague signs such as lethargy, decreased appetite, and suboptimal performance. Evaluation of horses with mild signs and suboptimal performance may reveal evidence of lower respiratory tract infections (visible airway inflammation, inflammatory cytology, recovery of bacterial agents such as *Streptococcus zooepidemicus* subsp. *zooepidemicus*). It is not clear if viral agents play a major role in less acute lower respiratory disease. However, seroconversion to equine herpesvirus was found to be associated with occurrences of less severe lower airway inflammatory disease, in addition to the isolation of *S. equi* subsp. *zooepidemicus* and *S. pneumoniae*.[42]

While most acute viral respiratory infections have been thought to primarily or solely affect the upper respiratory tract, recent investigations suggest that the lower respiratory tract can also be significantly affected during acute viral respiratory infections.[43] Ultrasound examinations showed that horses either experimentally and naturally infected with influenza virus can develop substantial areas of pulmonary consolidation and peripheral (pleural and subpleural) irregularities.[43] However, it is not clear if these lesions are principally caused by viral damage, or if this is a result of viral–bacterial co-infection. The bacterial flora of the upper respiratory tract change dramatically after viral infections, and this is principally characterized by proliferation of beta-hemolytic streptococci (Fig. 30.3; PS Morley, KW Hinchcliff, RD Slemons, DK Gross, unpublished data).[44] However, it is not clear whether this change is simply a result of viral mucosal damage and solely coincidental with clinical disease, or whether this change contributes significantly to clinical disease in horses with IRD. Pneumonia is a well-recognized sequela to severe viral respiratory infections in humans, and has also been reported after introduction of novel influenza viruses to naïve equine populations.[28,45–48] However, this is an infrequently recognized complication of most viral respiratory infections in horses. Interestingly, the significant pulmonary consolidation that was seen after severe experimental influenza virus infections resolved uneventfully without any treatment, even in horses that continued to exercise following challenge.[43] There are few published results from objective investigations of clinical parameters in horses with viral IRD. Horses infected with influenza virus have been shown to have increased resting respiratory rates and heart rates that coincided with the occurrence of fever.[43] Pulmonary auscultation of horses experimentally and naturally infected with influenza virus showed that they often develop abnormal lung sounds, which was most frequently characterized as wheezing (DK Gross, PS Morley, KW Hinchcliff, RD Slemons, unpublished data).[43,49]

Other systemic disease signs are sometimes reported in association with viral respiratory infections. These signs are perhaps most commonly recognized in association with EHV1 infection; abortion and neurologic disease are well recognized in association with EHV1 infections. While essentially all EHV1 infections are thought to originate in the respiratory tract, signs of respiratory disease are not always evident before abortion or the onset of neurologic disease. Although equine arteritis virus is considered an infrequent cause of respiratory disease, it has also been associated with edema of the head, legs, prepuce and abdomen, and abortion. Other systemic signs including myocarditis, rhabdomyolysis, and purpura have been reported as possible sequelae of

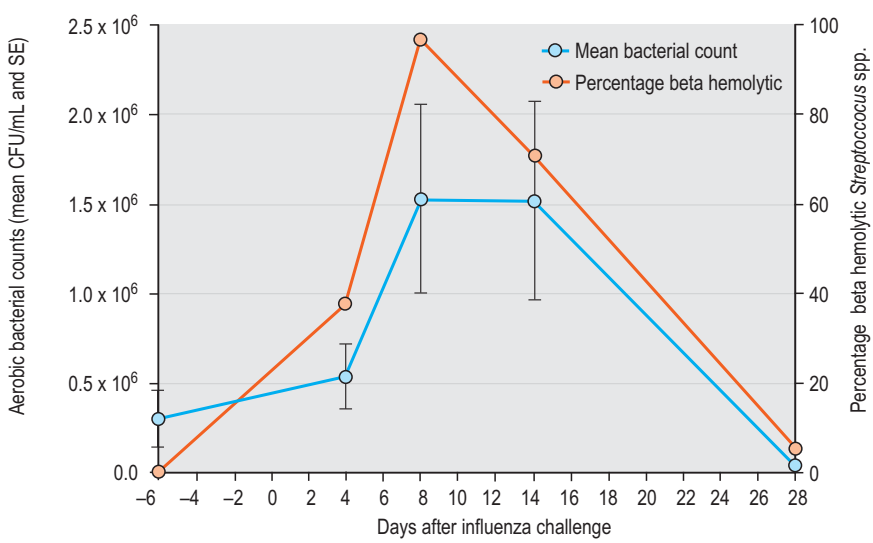

Fig. 30.3
Bacteria recovered from aerobic culture of transtracheal wash fluid following influenza challenge in naïve horses.

influenza virus infections. While it is sometimes assumed that influenza virus is a direct cause of myocarditis in horses, there is no published documentation of influenza virus infections affecting the cardiac tissues in horses. This is consistent with the fact that influenza virus is strongly epitheliotropic and that viremia is not a recognized feature of influenza virus infections.[50] Although myocarditis has been recognized in humans in association with viral infections, this condition is more likely to be identified in association with Parvo B19, enteroviruses, adenoviruses, or cytomegalovirus, and is very rarely found in association with influenza virus infections.[51] It seems likely that myocardial damage or purpura found in association with IRD would result from disseminated streptococcal infection in horses rather than viral respiratory infections.

Laboratory diagnosis

Viral IRD is often diagnosed solely upon clinical evaluation and history. However, clinical signs associated with one virus cannot be used to reliably distinguish IRD caused by other pathogens. This is important because establishing an etiologic diagnosis can be very important for targeting disease prevention efforts early in some disease outbreaks. Viral agents have been clearly shown to vary in their clinical importance as well as in their infectious and contagious nature. However, efforts to control IRD in horses can be hampered because it can be difficult to quickly establish an etiologic diagnosis for IRD.

Serology

Viral infection is most often confirmed in horses using serology, which may be the most sensitive method available. However, even when isolation and epidemiologic data point to a single etiology for outbreaks of respiratory disease, serologic investigations found that only 72% of horses with disease thought to be caused by influenza virus infection seroconverted to this virus during epidemics, and only 36% of horses with disease thought to be caused by EHV4 seroconverted to herpesvirus.[8,39] By far the most commonly recognized viral agents associated with respiratory disease in horses are influenza and EHV4. However, diagnostic laboratories do not routinely test for other types of viral infections. In addition, regardless of the etiology, most serologic tests require evaluation of multiple blood samples; the first must be obtained soon after infection and then at least 2 or more weeks later. It may not be logistically possible to obtain samples at these times or it may not be practically relevant or important to veterinarians or owners.

Virus isolation

Virus isolation is a very specific method for diagnosis of viral infection, but culture techniques need a week or more for completion and require specialized laboratory equipment and skills. Early identification and sampling of affected horses is critical for virus isolation as horses shed viruses for only a short period after infection. Isolation techniques have also been found to be quite insensitive as a diagnostic test during several field investigations.[8,39,52] Because it can take weeks to obtain results, data from serology or virus isolation is often not very useful for enacting measures to control respiratory disease. As such, it would be useful to have simple tests available for rapid diagnoses of virus infections at the onset of epidemics so that control measures could be instituted.

Rapid diagnostic tests

In recent years rapid detection assays have been developed in research laboratories for identification of several viral agents (e.g. antigen capture ELISA, PCR), but most of these tests are not widely available for use in disease prevention efforts. Rapid antigen detection kits for influenza virus are, however, commercially available throughout the world. While it would be useful to have rapid tests available for other equine respiratory pathogens, influenza virus probably causes a majority of IRD cases among athletic horse populations (where it is present in the world; Fig. 30.4), and it is one of the most contagious pathogens, which increases the importance of early intervention efforts. Most of these rapid influenza detection assays are based upon using monoclonal or polyclonal antibodies to detect highly conserved viral antigens. Most commercial assays can be completed in about 15–30 minutes and several have been shown to be useful for detection of influenza virus in horses.[53–56] Because they have been standardized and are sold in kits, they are more useful for a broad variety of diagnostic applications than are isolation techniques. Although these tests are rapid and extremely useful, they have limitations. Optimal timing of sampling is important for antigen detection assays just as it is for virus isolation. Evaluation of nasal secretions collected from horses naturally infected with influenza virus suggests that only about one-third of clinically affected horses would be positive using the Directigen assay (Becton Dickinson Microbiology Systems, Cockeysville, Maryland), which has been the most

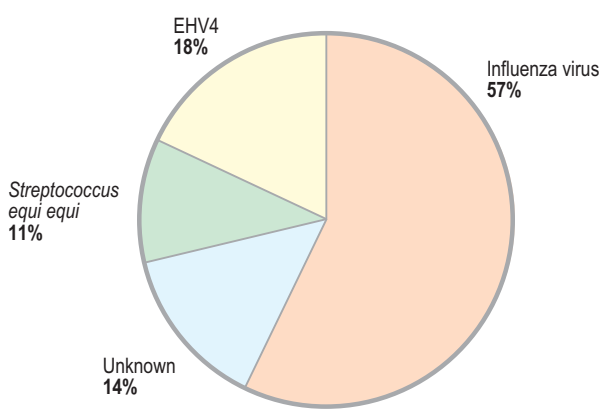

Fig. 30.4
Etiology of IRD identified in a 2-year longitudinal study at a Thoroughbred racetrack in Canada (n = 277).

widely used assay in horses.[53] Other rapid influenza tests may be more sensitive, but they may also be less specific, which can be very important when these tests are used as part of stringent disease control programs.[55,56] It is important to note that more sensitive influenza detection assays have been shown to detect viral antigen in horses recently vaccinated with modified-live intranasal products, as well as from non-vaccinated horses that were in contact with vaccinated horses.[56] This may be particularly important to consider if both vaccination and rapid detection assays are being used in disease prevention efforts during outbreaks.

Despite intensive investigative efforts, veterinarians frequently diagnose clinical IRD respiratory disease without identifying a primary etiologic agent. Potential pathogens were not identified from about 25% of IRD outbreaks investigated in England over a 6-year period.[57] Investigators in Kentucky were unable to determine the etiology of 34% (14/41) of IRD outbreaks investigated over a 5-year period.[58] Among 168 respiratory disease occurrences investigated during 1979, pathogens were identified for 44%.[59] Investigators in Canada were not able to identify an etiology for 14% (32/277) of IRD cases identified during a 2-year longitudinal study of respiratory disease among race horses (Fig. 30.4).[60] The lack of etiologic diagnosis for some IRD cases observed in these investigations is at least partially attributable to concentrating diagnostic efforts on identifying infection with agents that most frequently cause disease. It is likely that more comprehensive diagnostic efforts would identify agents in affected animals that tend to cause either less dramatic outbreaks or sporadic rather than epidemic disease (e.g. equine herpesvirus type 2 or equine rhinitis virus).

Ancillary diagnostic procedures

Although rarely utilized in most horses with viral IRD, information obtained from radiography, ultrasonography, and endoscopy may be useful for evaluating the extent and nature of guttural pouch and lower respiratory tract involvement. However, there is little published literature regarding findings of these ancillary diagnostics when applied in horses infected with various viral respiratory agents. Horses have been shown to develop marked consolidation after experimental infection with influenza virus which resolved without treatment or complication.[43] Similar findings have also been observed by these investigators in naturally infected horses. Endoscopic examination of these experimentally infected horses showed mild erythema and inflammation of the pharynx and airways, with increased amounts of mucoid respiratory secretions. Transtracheal wash fluid collected from horses infected with influenza virus was found to have increased cellularity and marked neutrophilia when compared with pre-infection values.[43] These changes were most severe for a week after infection, but changes could be detected for much longer. Intracellular bacteria were noted in about 25% of horses for up to 14 days after infection. Hemotology may also provide useful information about the general condition of horses, and horses infected with influenza virus were shown to have mild changes in white blood cell (WBC) counts and fibrinogen. However, these changes were not marked or useful in characterizing the severity of pulmonary disease.[43] Serum creatinine kinase values were not markedly affected by influenza infections. While these changes may have been useful in characterizing the general health status of horses, they were non-specific and generally did not help in establishing specific etiology.

Treatment and prognosis for viral respiratory disease in horses

Almost all viral respiratory infections are self-limiting and the primary therapeutic aim is to provide supportive care. Care should be taken to ensure that affected horses have access to clean water and adequate quantities of palatable feed as infected horses have been shown to lose weight and body condition.[43] Providing stabling in areas with minimal dust and ammonia exposure tends to lessen airway irritation and decrease the likelihood of secondary bronchitis and pharyngitis which can limit athletic performance.

Rest

It is often recommended that athletic horses with typical IRD be rested for an extended period after illness, sometimes for several weeks. This is intended to reduce the risk of serious complication such as pneumonia, pleuritis, and exercise-limiting reactive airway disease. However, there are no published reports documenting the efficacy of this practice. One investigation specifically investigated whether moderate exercise exacerbated clinical disease in horses experimentally infected with influenza virus.[43] This study found that all of the horses developed pneumonia following infection and that there was an exacerbated loss of body condition and mild differences in resting heart and respiratory rates among exercised horses. However, all of the horses fully recovered without treatment according to parameters investigated, regardless of whether they were rested. It should be noted, however, that this study evaluated a small number of horses and did not specifically evaluate performance parameters that might be important for equine athletes.

Antibacterial and antiviral agents

Horses with uncomplicated viral respiratory infections will probably recover without drug therapy; use of anti-inflammatory drugs and other non-specific treatments may reduce fever and make affected animals more comfortable, but it is not clear whether they alter the course of disease. Severely affected horses may benefit from antimicrobial therapy as the bacterial flora of the respiratory tract changes dramatically during viral infections (Fig. 30.3; PS Morley,

KW Hinchcliff, RD Slemons, DK Gross, unpublished data).[8] Bacteria can be recovered from the lower airways of horses that exhibit signs of primary viral IRD,[42,61,62] but it should be noted that there are no published studies evaluating the ability of antimicrobial (antibacterial) drugs to alter the course of IRD in horses with primary viral infections. Even horses with documented pulmonary consolidation and pneumonia secondary to experimental influenza infections were shown to recover uneventfully without the use of antimicrobial drugs.[43] Most horses affected by viral IRD show marked clinical improvement within a week of the onset of disease. Ongoing respiratory disease may reflect complications related to more severe pulmonary involvement, and these horses should be evaluated using ancillary diagnostics including pulmonary ultrasound and cytology and culture of transtracheal wash fluids.

Specific antiviral therapies for equine influenza virus and equine herpesvirus have been evaluated in equine and mouse models. However, none are licensed for this use in horses. In addition, considering the self-limiting nature of viral IRD, cost alone would preclude their use in most horses, regardless of safety or efficacy. In addition, use of antiviral drugs in humans is known to select for resistant strains. Amantadine and rimantadine have been used in humans infected with influenza virus, and both have demonstrated in vitro activity against equine influenza virus.[49,63] Oral administration of rimantadine has been evaluated in a small number of horses and administration of 30 mg/kg, by mouth, every 12 h for 4 days was associated with amelioration of clinical signs.[49] However, given the self-limiting nature of untreated influenza virus infections in horses this therapy is of questionable value. Absorption of amantadine administered orally is inconsistent and effective plasma concentrations cannot be reliably attained.[63] In addition, while intravenous administration yielded more reproducible plasma concentrations, horses have a relatively small therapeutic margin and treatment can result in seizures.[63] Use of this drug is therefore not recommended. There are a variety of reports regarding evaluation of antiviral compounds against equine herpesvirus in in vitro and mouse models, but only one published report of use in horses.[64] Respiratory disease associated with equine herpesviruses is generally mild and self-limiting, but use of these drugs in horses with other clinical disease syndromes (e.g. neurologic disease) or valuable pregnant mares may be warranted. However, caution is required as there are no reports documenting the efficacy and safety of these drugs in naturally infected horses.

Prevention of viral respiratory disease in horses

The basic features of infectious disease control programs for horse populations are similar, regardless of the type of disease or the agent that is being targeted. Specific practices employed need to be tailored to the population of horses, the facilities involved, and the diseases of greatest concern.[65,66] Consider the following basic requirements and features for effective disease prevention programs:

- Understand the mode of transmission and important biological aspects for infectious diseases of interest.
- Identify management or host factors that facilitate transmission (considering the previous item in this outline).
- Categorize animals according to risk of having or acquiring the disease of interest or infecting others. Prioritize prevention and control efforts according to those risk categories.
  - Appropriate categorization may be accomplished based upon known risk factors or history (e.g. age, history of travel, vaccination status, etc.).
  - This categorization may be facilitated by use of diagnostic procedures when appropriate (e.g. serology to help in characterizing immunity to an agent).
  - Grouping horses according to these risk categories will facilitate management and decrease the risk of transmission to animals in other risk categories. However, it is possible to manage individual horses appropriately according to their disease risk category assuming that adequate rigor is employed.
  - Prepare contingency plans for changes in disease risk when IRD is detected in the population, e.g. the need to move horses to facilitate management, or to restrict movement and access to control disease transmission.
- Monitor for evidence of disease in the population. As the adage goes, 'you cannot manage what is not measured.' Viral respiratory agents can be extremely contagious, and large portions of susceptible populations can be affected when they are introduced. Early intervention can decrease the impact of these outbreaks, but this requires active monitoring of the population and swift action when disease is detected. Employment of rapid diagnostic tests to assist in identifying viral etiologic agents is useful in providing timely, measured responses that are appropriate for the degree of contagiousness of the different agents and the significance of associated disease.
- Employ prophylactic measures that have a reasonable expectation of efficacy and are appropriate for the degree of risk aversion and the budget of the facility (e.g. vaccination, hygiene practices such as hand washing, barrier nursing precautions, foot baths, etc.).
  - Ordering available prophylactic measures based upon cost and degree of efficacy will assist in determining which should be applied first, and which should only be considered if the degree of risk aversion is high.
  - These practices vary depending upon the risk category of the animals.
  - Decisions to employ prophylactic measures often must be made far in advance of identifying IRD if they are to be of maximal benefit. For example, appropriate immunological priming is critical for vaccination to be of maximal benefit. This often requires a series of vaccinations given over several weeks.

  - Avoid wasting time, money, and effort employing prophylactic measures that do not have reasonable expectation of efficacy. More treatments are not necessarily better! Try to only use vaccines that have been adequately evaluated for efficacy. Employing non-efficacious treatments also creates a false sense of security for owners and managers, as well as increasing the likelihood that they will be dissatisfied with previous veterinary advice.
- Do not forget or underestimate the importance of optimizing the overall health and wellbeing of horses when designing disease prevention programs. Minimize stress when possible. Optimize nutrition, and provide clean, fresh water ad libitum. Maximize cleanliness, hygiene, air quality, and comfort in stabling environments. Avoid treatments and management practices that unnecessarily increase the risk of infection.

Preventing transmission

The most important aspect of preventing IRD is to minimize the likelihood of adequate direct or indirect contact that allows exposure to agents that is adequate to establish infection. As testament to this statement, it is possible to identify large, isolated horse populations in the USA and Canada that are naïve to influenza virus despite the fact that this agent is frequently recognized and considered endemic in those countries. These populations have minimal protective immunity and are highly susceptible to disease, which is a major reason that they are frequently used for experimental research on IRD.[43,67,68] These populations remain disease free because of their closed nature and the minimal likelihood of exposure to influenza virus. Given the ubiquitous nature of some IRD agents (e.g. EHV1 and EHV4), it is harder to prevent all exposure, but frequent high-risk contact increases the risk of introducing highly contagious and highly pathogenic strains. Studies of IRD in race horses have shown that horses with higher concentrations of serum antibody to influenza virus have decreased risk of disease during EHV4 epidemics, and horses with higher EVH4 concentrations have lower risk of disease during influenza epidemics.[8] This suggests that horses with increased risk of exposure to one respiratory virus are likely to have an increased risk of exposure to all respiratory viruses. This emphasizes the importance of non-specific control measures such as stringent biosecurity measures.

Indirect transmission

Direct contact among horses is obviously important for transmission of infectious respiratory agents, but the importance of indirect contact must not be overlooked. Viral IRD agents vary in their contagiousness via respiratory aerosols, and this mode of transmission seems most important in propagation of influenza epidemics. In addition, indirect transmission via contaminated surfaces and fomites can play a critical role in introduction of respiratory agents.[69–71] In many instances outbreaks in susceptible populations occur as a result of indirect transmission, and epidemics can certainly be exacerbated by this route. During a longitudinal study of respiratory disease it was noted that grooms would often wipe the face and body of affected horses with a rag, and then repeat the same procedure on unaffected horses using the same grooming tool.[39] Tattooing of young horses using the same instrument was thought to be associated with spread of infection in another outbreak.[39] Contaminated trailers, tack, waterers, and even clothing of handlers have also been implicated in introduction of respiratory agents.

Barrier nursing precautions and personal hygiene

An important concept related to care of patients with contagious diseases is the use of barrier nursing precautions. Barrier nursing precautions (e.g. gloves and water impervious gowns) can be used whenever working with high-risk patients to prevent strike-through and to minimize the potential for cross-contamination between patients. Barrier gowns are assigned for use with specific animals so that clothing most likely to be contaminated essentially stays with the patient. Disposable gloves, and separate coveralls or inexpensive disposable plastic barrier gowns (PolyWear gowns, #GEB-4250; PolyConversions Inc., Rantoul, IL 61866) could be assigned for use with specific animals. Rubber boots and disinfectant footbaths can also be used to reduce the risk of footwear serving to traffic infectious agents between stalls. In addition, limiting the number of people contacting high-risk patients and assigning specific people to care for animals in different risk categories will also reduce the risk of transmission.

Personal hygiene and cleanliness is indisputably an important cornerstone of infection control. All personnel contacting animals should be required to wear clean, appropriate attire at all times. Contaminated hands are perhaps the most frequent route of indirect nosocomial transmission in all species.[72] Frequent hand washing should be required particularly before and after handling affected animals. Alcohol-based hand sanitizing gels are available for use when it is not possible to wash hands. These hand sanitizing gels have been shown to be equal in efficacy to full surgical scrub when properly applied, but gros contamination must be removed by hand washing. I often illustrate the common-sense importance of hand hygiene as a disease control measure with students by asking them to look closely at their hands and to consider whether they would appreciate a physician with similar cleanliness performing an examination or an invasive procedure on them.

Cleaning and disinfection

Effective cleaning and disinfection are critical for breaking transmission cycles for viral agents in horse populations. Stalls should be cleaned and thoroughly disinfected between all horses, especially when they have been used to house high-risk animals. Particular attention should be paid to

disinfecting feeders, waterers, and surfaces frequently contacted by hands. Cleaning tools should not be used for animals in different risk categories unless they have been appropriately cleaned and disinfected. Bedding and feces should be removed from stalls between horses to facilitate more thorough cleaning. Dumpsters, wheelbarrows, and cleaning tools should be visibly marked for easy identification, and different sets should be assigned for use with a specific risk group. Several reviews are available regarding disinfection recommendations for livestock facilities.[73–75] Applying copious amounts of disinfectant to dirty surfaces is not effective for decontamination. Disinfectants are quickly inactivated in the presence of even small amounts of dirt and organic debris and can only be truly relied upon when applied to clean surfaces. Physical disruption is generally required to adequately remove gross contamination and surface films to ensure adequate disinfection. High pressure washing can be an efficient method for cleaning large areas but it is also possible to further disseminate surface contaminants as they may be aerosolized in the cleaning process. Some disinfectants such as phenolics are more effective in the presence of organic material, but they are also more likely to cause irritation with skin contact in horses or personnel. Bleach, chlorhexidine, and quaternary ammonium-based products are less irritating, but are easily inactivated. Recently, aerosolizing of a peroxygen compound (cold fogging) has been described as a means of inactivating airborne viruses as opposed to relying upon surface disinfection.[76] Cold fogging can also be used for dispersal of disinfectants in large buildings. However, this should only be performed with appropriate personal protection equipment for personnel and also should only be used with products that are less irritating and toxic for humans and animals.

Housing and facility design

Design of animal facilities is a critical consideration for optimal performance of disease prevention programs. Stalls and buildings should be constructed to minimize the potential for direct and indirect contact between horses. In addition, it is extremely useful to have areas that can be separated to quarantine newly introduced animals, as well as provide separation between horses in different risk categories. Care should be given to ensure that animals can receive adequate care in these different areas, preferably without trafficking animals or equipment through the environment of horses in different risk categories. At a minimum consideration should be given to separating high-risk animals from other animals with an empty stall. Cleanable surfaces should be maintained throughout practice environments wherever possible. Concrete floors are preferable to dirt, particularly for housing animals shedding contagious pathogens, as it is impossible to disinfect the latter completely. Rubber stall mats are usually quite porous, and it is very difficult to maintain effective seals at edges. This has been shown to be important in outbreaks documented in several veterinary teaching hospitals. Sealing or painting exposed wood and other porous surfaces greatly improves cleanability. However, it is important to consider quality of products and maintenance of painted surfaces when selecting sealants, as chipped and peeling paint provide a niche for bacterial contamination that is difficult to clean. Attention must also be paid to controlling wildlife (e.g. mice and birds) and insect vectors, although these are usually not considered important as a means of transmitting viral respiratory disease among horses.

Management of disease control efforts

Perhaps one of the greatest obstacles to implementing a comprehensive infection control program for all horses at large facilities is obtaining cooperation from all of the owners, managers, and veterinarians. In many training or performance facilities, athletic horses are congregated in large groups with different people responsible for care of each different group. Generally, producers only want to pay for care of their own animals and thus procedures and costs for a comprehensive control program would need to be agreed upon and shared. Even if most owners and managers wish to employ such a program, like a chain with a single weak link, it only takes one hold-out employing less optimal biosecurity practices to allow introduction of a highly contagious agent, thus placing all horses at the facility at risk. In these situations it is useful to develop a cooperative agreement among all users of a facility, and empower a single individual to direct or oversee disease control efforts. This person could also oversee surveillance efforts so that there is uniform rigor in detection and management of sick horses. This would also facilitate prompt intervention which may help decrease the severity of outbreaks when they occur. This proactive approach has been very useful for control of infectious diseases of all types among horses hospitalized at Colorado State University.

Vaccination

Vaccines can play an important role in decreasing susceptibility to infectious agents, but their use should not supersede other control efforts. The efficacy of specific influenza vaccines has been well demonstrated,[27,67,77,78] but other vaccines have limited efficacy[79,80] or published information from properly designed efficacy studies is not available. Data regarding protection provided by herpesvirus vaccines are even more equivocal.[8,80–82] Equine arteritis virus is the only other respiratory virus for which there are commercial vaccines, but their use can be restricted because of importation restrictions on seropositive stallions. Development of efficacious vaccines for respiratory viruses is complicated by the apparent short duration of immunity that follows even natural exposure, and the genetic variability and rapid genetic mutation in some viruses. While most manufacturers recommend annual boosters on vaccine labels, many equine experts recommend vaccination at much shorter intervals (e.g. every 3 months or less).[47] A vaccine that must be boosted every 3 months or more frequently is obviously performing suboptimally; managers and veterinarians should view this as strong evidence of the imperfect protection provided by some

commercial vaccines. One of the challenges that manufacturers of equine vaccines have faced is the strong aversion among owners and managers for any overtly detectable local or systemic response to vaccination. The primary concern should be whether vaccines can be used safely to evoke a protective immune response, i.e., the risk of acceptable local or systemic reaction is worth the benefit of protective immunity. Unfortunately, many managers would prefer to pay for and employ ineffective vaccines at frequent intervals rather than have any observable response to vaccination. Veterinarians have been known to be fired when vaccinations have resulted in local swelling at injection sites. This would seem to be an extremely short-sighted and inadvisable approach to selection of vaccines. Consider that vaccines are commonly used for children when they are known to cause local (swelling, pain, induration) as well as systemic responses (fever, malaise, inappetence) as long as use provides the benefit of protective immunity.

Etiology of viral respiratory disease in horses

The most important viral agents associated with respiratory disease in athletic horses are influenza virus, EHV4, EHV1, and equine arteritis virus (EAV). Influenza virus and EHV4 are the viral agents most commonly identified in association with respiratory disease (Fig. 30.4). Herpesvirus type 1 is important because of its ubiquitous nature as well as the significance of non-respiratory clinical disease that is less commonly seen in association with infection (neurologic disease and abortion). Disease associated with EAV is much less common than infection, and this agent is more important because of associated reproductive losses. Other viral agents have been isolated from horses with IRD including equine adenovirus, equine rhinitis virus, and others. While infection with these agents may be associated with the occurrence of clinical disease, particularly sporadic cases, there is very little controlled evidence documenting the significance of these agents in relation to other more common agents.

Influenza virus

Characteristics

Influenza virus is a pleomorphic orthomyxovirus with a segmented double-stranded RNA genome. The segmented RNA genome predisposes this virus to genetic reassortment and mutation, which promotes rapid viral evolution. There are three types of influenza virus (types A, B, and C) that are differentiated by their highly conserved internal proteins (matrix protein and nucleoprotein); horses are only infected by some type A influenza viruses. The more variable surface glycoproteins, hemaglutinin and neuraminidase, contain the major antigenic determinants and are used to characterize subtypes of influenza virus (e.g. H3N8). RNA viruses are more prone to genetic variation, which probably influences important variability identified in antigenically dominant surface epitopes. Three distinct subtypes of influenza virus have been isolated from horses since 1956. These are represented by the following prototype strains: influenza A/equine/Prague/56 (H7N7), which is sometimes referred to as A1 equine influenza, influenza A/equine/Miami/63 (H3N8), which is sometimes referred to as A2 equine influenza, and influenza A/equine/Jilin/89 (H3N8). Only strains that evolved from the Miami/63 isolate are currently circulating in horse populations, but this virus has evolved into two genetically and antigenically distinguishable strains:[83–85] a so-called 'Eurasian' lineage, and an 'American' lineage. The 'American' lineage viruses can be further differentiated into three evolutionary strains.[84] Contrary to geospecific strain names, 'American' lineage viruses are commonly isolated from horses in Europe and Asia, and a 'Eurasian' lineage virus was isolated from horses in Canada in 1991.[84] Tracking antigenic variation among strains of influenza virus is important because natural exposure and vaccination tend to promote strain-specific immunity. For example, while serum antibody concentrations tend to correlate well with immunity, antibody concentrations have been shown to be more strongly correlated with protection when animals were challenged with influenza virus from a homologous lineage than when they were challenged with virus from a heterologous lineage.[86]

Although some investigators have hypothesized that strains of H7N7 influenza may still circulate and that it is important to continue inclusion in vaccines, this strain of virus appears to no longer circulate as the last two reported isolations of this virus subtype occurred in Malaysia in 1977[87] and in India in 1987.[88] In 1989 a novel strain of H3N8 influenza virus emerged in horses in China and was thought to have been directly transmitted from birds,[28,89] but this strain also appears not to have been sustained in equine populations.[90]

Distribution

Equine influenza virus affects horses throughout the world, with only a few exceptions. Some member countries report to the OIE that they are free from disease,[48] but the rigor of scientific evidence to support this status varies considerably. Rigorous investigations in countries such as Australia and New Zealand have never found evidence of infection in resident horses, and there are some countries such as Singapore and Japan that have previously had infected horses but have apparently eliminated the virus through rigorous control efforts.[48]

Transmission and pathogenesis

Influenza virus is spread via aerosols, as well as by direct and indirect contact with infected horses and contaminated surfaces. As an enveloped virus, influenza virus is not particularly hardy in the environment, but epidemics have been known to result from contact with people and fomites that

have been moved from one operation to another. The incubation period is 24 to 48 hours, and clinical disease is highly variable. Virus can only be recovered from horses for about 10 days after infection at most, but viral antigen has been recovered from respiratory secretions only for as long as 21 days post-infection.[91] Influenza virus infects epithelial cells throughout the respiratory tract. Cell death and damage to mucociliary apparatus results in airway irritation and accumulation of cellular debris and respiratory secretions. Disease may be enhanced by proliferation of respiratory bacteria and secondary bacterial infections of respiratory tissues (Fig. 30.3). Disease is self-limiting in most cases.

Epidemiology and risk factors

Influenza virus is capable of being spread throughout large geographic areas and even continents when novel viruses are introduced to naïve horse populations.[70,71,88,89,92] For example, a study of sanctioned Thoroughbred and Standardbred race meetings in the USA after introduction of a novel virus in 1963 found that the outbreaks had been detected in 78% of respondent racetracks (49/63), and the virus spread throughout the USA and Canada during a 6-month period (Fig. 30.5).[70] This spread of disease highlights the importance of disease control in athletic horses which tend to be the most mobile sector of equine populations in most countries. Introduction of horses that travel from one horse population to another has been repeatedly shown to be the major inciting incident for influenza epidemics. As horses do not become persistently infected with influenza virus, animals with acute infections are critical for the introduction of virus into susceptible populations. Unfortunately horses can be infected and shed influenza virus while remaining asymptomatic, or at least only mildly affected. Considering this, some disease control programs have employed the use of rapid antigen detection tests as a screening tool for newly introduced horses.[93] Assuming that the prevalence of infection among these horses would generally be very low, the negative predictive value for this test would be quite high, and regulatory officials could be quite certain that test-negative animals were truly uninfected. However, the positive predictive value would be unavoidably very low, and positive tests would frequently be false-positive in these testing conditions.[56] However, this testing is fairly innocuous and very rapid, and the consequences of introducing influenza virus can be very significant. Some inaccuracy in testing is unavoidable and as such, this low positive predictive value may be acceptable if the managers are highly risk averse.

Just as frequent contact between populations increases the risk of introduction, frequent direct and indirect contact among horses within a population increases the risk of infection during influenza outbreaks. Care must be taken to reduce inadvertent contact, and to consider all horses in a population as being significant in the control of disease. Longitudinal studies in Canada showed exercise ponies had much greater risk of disease during influenza epidemics, which was probably attributable to their frequent contact with other horses.[94] In addition, there was less concern about their health than there was for race horses, which ironically increased the risk for all horses in the population.

Factors related to specific immunity against influenza virus are also very important in determining a horse's risk of disease. Several studies have repeatedly shown that serum antibody concentrations strongly correlate with the risk of disease, and even small increases can be associated with a dramatic decrease in disease risk. For example, horses with high antibody concentrations were shown during a series of influenza epidemics to have 2–6 times lower odds of disease

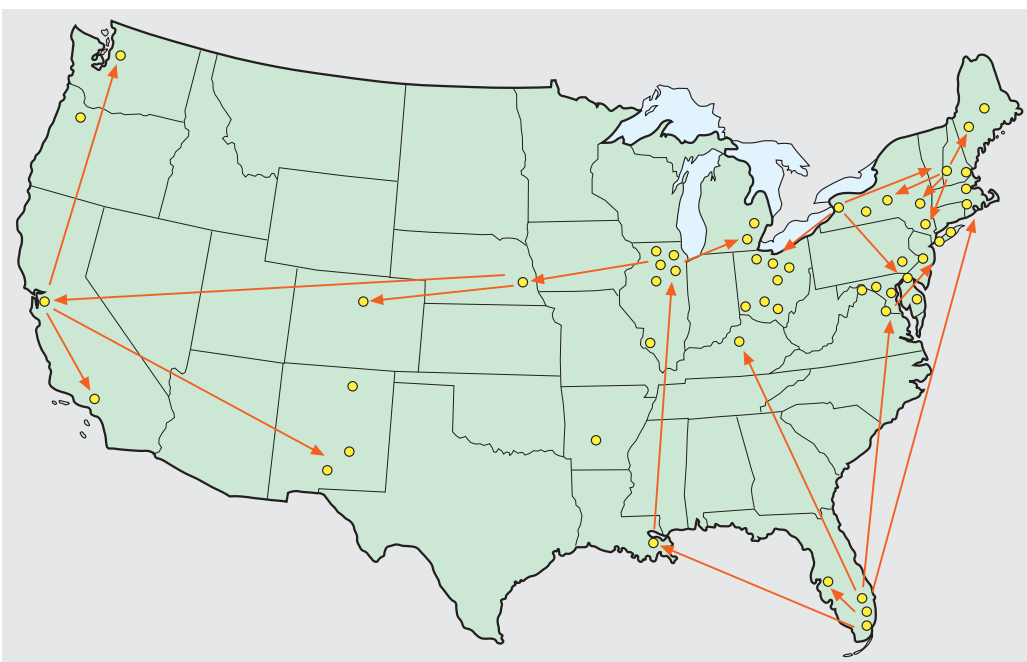

Fig. 30.5
Spread of Influenza A/equine/Miami/63 (H3N8) at racetracks in the 6-month period following introduction in 1963. Dots indicate racetracks with influenza outbreaks, arrows represent movement of horses thought to be associated with transmission. Reproduced from Scholtens et al[70] by permission of Oxford University Press.

compared with those with low antibody concentrations, and about 10–40 times lower odds of disease compared with those that were seronegative.[94] In a recent nation-wide cross-sectional study conducted by the USDA, only about one-third of all horses tested had high antibody concentrations to influenza virus; about one-third were seronegative and one-third had low antibody concentrations. Age is also associated with the risk of influenza infection, which probably is a surrogate marker of the probability of previous exposure to disease agents. This is supported by studies documenting a relationship between age and increasing antibody concentrations.[40] This age-associated disease risk is particularly important for athletic horses given the predominance of young horses in these populations.

The strength and repeatability of the association between age and measures of previous exposure demonstrate their importance as predictors of disease risk. As such, these factors can be used as important factors in categorizing horses for future disease risk, and help in targeting control measures on horses in the highest risk categories. Serum antibody concentrations could be measured as horses enter populations and more rigorous biosecurity precautions could be employed with those horses having low antibody concentrations. This information could also be used to specifically target vaccination protocols. Information collected from longitudinal studies in Canada suggested that 25% of the IRD associated with influenza virus would have been prevented during epidemics if all horses had high serum antibody concentrations prior to exposure.[94] While efficacious killed virus vaccines administered intramuscularly invoke protection by stimulating humoral immunity, it is important to note that a new modified-live intranasal vaccine has been shown to be efficacious without stimulating increases in serum antibody concentrations.[67] If vaccines are to be used in prevention efforts, it is critical to use only products with reasonable expectation of efficacy.[67,77,78] as several equine influenza vaccines that are available commercially have been shown to perform suboptimally.[79,80]

Equine herpesvirus

Characteristics

Herpesviruses are subdivided into three subfamilies based upon genetic structure: alpha, beta, and gamma. There are five herpesviruses known to infect horses, four of which have been shown to infect tissues of the respiratory tract.[95] EHV4 is an alphaherpesvirus that is thought to be a frequent cause of respiratory disease in horses. EHV1 is also an alphaherpesvirus, and while infections typically originate in the respiratory tract, it is more commonly associated with other severe systemic illness (neurologic disease and abortion) and less commonly with respiratory disease. EHV2 and EHV5 are slow-growing gammaherpesviruses that have been recovered from numerous tissues of healthy and clinically diseased horses. Their role and importance in the occurrence of clinical IRD have not been fully elucidated. All of these viruses are known to cause latent infections, that is, infection results in the viral genome being retained in host cells for long periods without transcription or translation. In practical terms, this essentially means that horses are infected for life, and that viral infections can recrudesce repeatedly throughout an animal's life. This recrudescence can result in clinical disease or be inapparent. Recent investigations suggest that essentially all foals are infected with EHV1, EHV2, EHV4, and EHV5 at very young ages.[96,97] Viruses that are homologous to EHV1, EHV2, and EHV3 have been isolated from donkeys and have been designated asinine herpesviruses (AHV3, AHV2, and AHV1, respectively). Herpesviruses are enveloped and are relatively sensitive to a variety of disinfectants and environmental conditions.

EHV4 and EHV1 were once considered the same virus (EHV1) and older descriptions of associated disease can therefore confuse readers who are not aware of the timing of this differentiation. Classically described herpesvirus rhinopneumonitis is now believed to be most commonly associated with EHV4 infections. There is extensive genetic and structural homology between these viruses especially for antigenically dominant surface glycoproteins.[95] This gives rise to apparent cross-reactivity in immunity, especially in horses that have been exposed to both viruses on multiple occasions. As such, serology is often performed against one virus or the other, and the results are assumed to reflect antibody that will react with both viruses. This cross-reactivity is also of interest relative to vaccination.

EHV2 and EHV5 were also considered the same virus until recently. The association between infections with these viruses and the occurrence of clinical IRD is less well established. EVH2 and EHV5 have been recovered from horses with non-specific signs of IRD, but they are also commonly recovered from unaffected horses. In more objective studies, virus was more likely to be recovered from foals and horses with clinical respiratory disease than from asymptomatic animals.[98–100] As methods designed to emphasize recovery of EHV2 and EHV5 have not been included in recent large-scale epidemiologic studies, it seems likely that they cause some disease currently classified as having an unknown etiology (Fig. 30.4). EHV2 and EHV5 genetically resemble Epstein–Barr virus of humans, which is also a gammaherpesvirus.[60] There appears to be significant variability among EHV5 isolates,[101] which may affect the likelihood that horses can be reinfected, as well as the ability to diagnose and investigate EHV5 using serology or polymerase chain reaction (PCR). These viruses appear to be as ubiquitous as EHV1 and EHV4, and limited studies suggest that foals are infected early in life.[97]

Distribution

EHV1 and EHV4 have been studied extensively and all available data suggest that the viruses are ubiquitous in all horse populations throughout the world. Information about the distribution of disease as recorded on the OIE website suggests that IRD associated with herpesvirus is not present among horses in some countries. However, despite the importance of these viruses and the OIE List B status of

equine rhinopneumonitis, this is undoubtedly an example of regulatory under-reporting and lack of investigative rigor. Although not extensively studied, EHV2 and EHV5 infections have been identified in horses is North America, Europe, Australia, and New Zealand, suggesting that these viruses have worldwide distribution.

Transmission and pathogenesis

It is believed that all EHV1 and EHV4 infections originate in the respiratory tract, and result in the virus genome being inserted as an episome in host cell nuclei. New infections and recrudescence both result in lymphocyte associated viremia, which allows virus to spread to tissues at distant sites. Viremia is more commonly detected with EHV1. EHV1 and EHV4 are believed to become latent in lymph nodes associated with the respiratory tract, and although not considered neurotropic, viral genome has also been identified in trigeminal ganglia. Strains vary in their tendency to cause disease, and specific strains of EHV1 are more likely to cause neurologic disease or abortion. Abortion is thought to result from both placental and neonatal infections. Unlike neurologic disease associated with herpesvirus in cattle, humans and pigs, herpesvirus myeloencephalitis in horses is not believed to be commonly associated with direct infection of neurologic tissues.[95] Diffuse vasculitis is a prominent feature of EHV1 infections, which may be the inciting factor of neurologic diseases it has also been proposed to be caused by deposition of virus–antibody complexes that create an inflammatory response in neurologic tissues.[95] Little is known about transmission and pathogenesis associated with EHV2 and EHV5. Viral infections can be detected in essentially all foals,[97] and virus has been isolated from peripheral blood leukocytes, suggesting that viremia and latency are similar to those of EHV1 and EHV4.

Epidemiology and risk factors

Repeated EHV1 and EHV4 infections are common among horses of all ages, which is also probably true for EHV2 and EHV5. Respiratory disease associated with EHV4 has also been documented to occur repeatedly in young horses. Compared with influenza virus, EHV4 is a much more common cause of IRD in horses < 1 year, and a less common cause of large IRD outbreaks among horses > 2 years old. Younger race horses have been shown to have an increased risk of IRD during outbreaks associated with EHV4. The frequency of disease associated with EHV2 and EHV5 has not been well described, but these agents may also be associated with sporadic disease or small outbreaks. Recrudescence is always a potential source of virus given the ubiquitous nature of equine herpesviruses, and this may be a common cause of sporadic IRD. However, epidemiologic data also suggests that novel disease-causing strains of EHV1 and EHV4 can be introduced into populations resulting in outbreaks of respiratory disease, neurologic disease, or abortion, suggesting that horizontal transmission is an important source of EHV1 and EHV4 during epidemics. These viruses can be transmitted by aerosols, but epidemiologic data regarding patterns of disease during outbreaks suggests that direct transmission, and indirect transmission via fomites and contaminated surfaces are more important methods of transmitting virus during outbreaks. Horses that frequently come into contact with other horses have been shown to have increased risk of IRD associated with EHV4.[8]

Because of the cell-associated nature of herpesvirus infections, it has been suggested that cell-mediated immunity is far more important than humoral immunity in protecting horses from disease. As such, the use of killed-virus vaccines and the relationship between serum antibody and protective immunity has been questioned. Cell-mediated immunity is undoubtedly important for protecting horses. However, field investigations have shown that higher serum antibody titers are associated with decreased IRD risk in association with EHV4 infections.[8,52] It is not clear if humoral immunity was protective or whether it was simply a marker of horses with stronger cell-mediated immunity against these agents. It was also shown that horses with high influenza virus antibody titers had lower risk of disease during an EHV4 outbreak, supporting the idea that antibody titers may to some degree be simple markers of previous exposure, and not entirely direct indicators of immunity.

Equine arteritis virus

Characteristics

Equine arteritis virus (EAV) is the prototype virus of the recently established genus *Arterivirus*. It is an enveloped RNA virus and is therefore relatively sensitive to drying and common disinfectants. While some variability has been demonstrated in the viral genome, there is only one recognized serotype. EAV has a limited host range and is only known to infect equids. Infections are far more common than is the occurrence of respiratory disease and EAV is primarily a concern because of associated reproductive disease. EAV is particularly problematic to the equine industries because of its ability to establish a carrier state in intact stallions. These carrier animals are important for introducing and maintaining the virus in equine populations, as well as because of their impact on trade of horses and semen. Infection is apparently more common among some breeds, especially Standardbred horses, but this is probably attributable to a higher number of carrier stallions rather than a true difference in susceptibility.

Distribution

EAV is thought to have a worldwide distribution, even though outbreaks are reported only occasionally. However, despite having OIE List B status, many countries report that they have never recognized this agent or disease.[48] Again, this is probably attributable to under-reporting and lack of investigative rigor. There has been an apparent decrease in the number of reported outbreaks, which may be attributable to increased availability of diagnostic testing as well as

increased awareness throughout the world regarding disease impact and effective disease control measures. Recent broad-based investigation of EAV infection in the USA found that about 2% of unvaccinated horses were seropositive, and another investigation based on selective sampling in the UK found that 2% or less of unvaccinated horses were seropositive.[102,103]

Transmission and pathogenesis

EAV is shed via the respiratory tract by acutely infected horses, in the semen of carrier stallions, as well as in amniotic fluid, placenta, and fetuses of aborted mares. Less important sources of virus include blood, feces, and urine of acutely infected animals. Infections in carrier stallions are inapparent even though virus is shed in their semen for their entire life, or until they are castrated. EAV infections do not apparently affect fertility of stallions. Asymptomatic infections are common, and stallions may become long-term carriers of the virus even without showing signs of disease. The incubation period in clinically affected animals is about 3 to 7 days. Clinical disease can be indistinguishable from that caused by other IRD agents, but affected horses may also develop swelling and edema that is most commonly noted in the legs, scrotum, sheath, or udder, as well as abortion in pregnant mares. Modified live and killed virus vaccines are commercially available. Control recommendations for EAV from the American Horse Council include the use of modified live vaccines,[104] and the killed virus vaccine is used in Great Britain and Ireland.[105] It should be noted that vaccination decreases the risk of disease, but does not prevent infection.[105]

Epidemiology and risk factors

Perhaps the most dominant factor affecting spread and maintenance of EAV in populations is the presence of persistently infected stallions that shed virus in semen. Further, while outbreaks of clinical disease are sometimes reported, most infections result in very mild or no clinical signs. This allows opportunity for further spread of virus without the presence of identifiable disease that might trigger enactment of more rigorous control strategies. Seroprevalence has been repeatedly shown to vary among breeds, and is highest among Standardbred horses, which may be attributable to the number of persistently infected stallions. In a broad-based cross-sectional study performed by the USDA, the seroprevalence among adult non-vaccinated Standardbreds was about 24%, compared with 4.5% among Thoroughbreds, 3.6% among Warmbloods, and about 1% among other horses.[102] Horses from operations used primarily for breeding or for boarding and training were more likely to be seropositive than horses from other operations.[102] Various countries have enacted control strategies centered on identifying persistently infected stallions, reducing the likelihood of exposure to acutely infected horses, and use of vaccines to decrease the risk of disease and decrease the risk of stallions becoming persistently infected.

Other respiratory viruses

Several other viruses have been recovered from the respiratory tract of horses showing signs of IRD, as well as from clinically normal horses. The role that these viruses play in the occurrence of respiratory disease in horses is not clear. While it is interesting that these viruses can be recovered from horses with clinical IRD, these data would be more convincing if evidence of infection was found more commonly in disease cases compared with non-cases in the same populations. A brief description of two of these agents follows.

Equine rhinitis virus

Horses are commonly infected with equine rhinitis-A virus and equine rhinitis-B virus (formerly classified as equine rhinovirus types 1 and 2, respectively). Seroprevalence has been shown to approach 100% in young and adult horses. Limited experimental challenge studies indicate that this agent can cause IRD under some conditions. Horses commonly shed virus in nasal secretions and in urine. Studies evaluating the distribution of this agent have not been performed in many countries, but infections have been documented in North America, Australia, New Zealand, UK, and Europe, suggesting a worldwide distribution.

Equine adenovirus

Equine adenovirus type 1 has been isolated from horses throughout the world, and seroprevalence can approach 100% in mature horses. In most horses infection is not believed to cause clinical disease, or it is very mild. However, adenovirus infections cause significant disease in Arabian foals with primary, severe combined immunodeficiency disease (PSCID). A limited study of experimental challenge in two immunocompetent foals showed that infection can result in pathologic changes under certain conditions.

CHAPTER 31

Bacterial infections of the respiratory tract of athletic horses

J. Richard Newton, James L. N. Wood and Kenneth W. Hinchcliff

Streptococcus equi infection ('strangles')

- Highly contagious disease of horses characterized by outbreaks of disease.
- Disease is spread by fomites and direct transmission. Inapparent carriers are important in perpetuating the disease.
- Clinical signs include fever, depression, cranial lymphadenopathy and purulent nasal discharge.
- Metastatic infection causes abscesses in thoracic and abdominal lymph nodes and in other organs.
- Treatment includes drainage of accessible abscesses, supportive care and, in some cases, administration of antibiotics.
- Prevention centers on detection of carriers and exclusion of infected horses. Vaccination is of limited efficacy in preventing the disease.

Recognition of disease

History and presenting complaint

Streptococcus equi infection is the most frequently reported infectious disease of horses worldwide, with affected horses usually having either direct or indirect contact with other infected horses or known outbreaks.[1,2] However, the sudden onset of disease may not be readily attributable to contact with horses with obvious clinical signs of strangles and in these cases transmission from an outwardly healthy carrier is usually the source of infection.[3]

Although the disease occurs commonly in non-athletic horses it occurs at least sporadically among groups of high-value equine athletes. At least in the early stages of outbreaks of strangles, pathognomonic clinical signs of lymphadenopathy may not be present and unless specific diagnostic tests are conducted, non-specific signs of respiratory disease (including nasal discharge, coughing and pyrexia) may inadvertently be attributed to infection by organisms other than *S. equi*.[4,5]

Physical examination

An early clinical sign of strangles is marked pyrexia (39.4–41.1°C/103–106°F) associated with depression and loss of appetite.[1,2] Affected horses invariably develop an initial serous nasal discharge that becomes purulent and profuse within 2 days and some cases have a soft, moist cough and/or purulent ocular discharge.

Strangles is classically characterized by a lymphadenitis associated with rapid metastasis of *S. equi* infection from buccal and nasopharyngeal mucosal surfaces to the draining

Fig. 31.1

lymph nodes of the head and neck. This spread probably occurs within hours of infection. Within several days the submandibular (Fig. 31.1) and parotid lymph nodes (Fig. 31.2) become palpably firm, swollen and painful and with abscessation of these and the retropharyngeal lymph nodes (RPLNs). The pharynx becomes obstructed, causing difficulty in breathing (hence the name 'strangles'; Fig. 31.3). One to two weeks after signs initially appear, the abscessated lymph nodes usually develop sinuses and rupture their purulent contents through either the skin (Figs 31.1, 31.2) or into the guttural pouches (Figs 31.4, 31.5).[5] At this stage of the disease horses often show a sudden and marked clinical improvement. Rupture of the RPLNs results in guttural pouch empyema that may then drain into the pharynx through the pharyngeal pouch opening (Figs 31.6, 31.7), the most dependent part of the pouch when the horse has its head lowered to the ground.[3,5–7] This purulent discharge is either swallowed or flows down the nose to appear as a profuse nasal discharge. Lymph nodes of the head may

abscessate sequentially so that in most cases the entire clinical course of disease lasts several weeks, although not all infected animals in outbreaks necessarily show typical signs.

A strongly presumptive diagnosis of strangles may be made on clinical grounds in horses that demonstrate lymph node abscessation, although in some outbreaks lymphadenitis may only occur in later cases or remain clinically inapparent.[4,5] However, in these apparently atypical strangles outbreaks, earlier abscessation of RPLNs in some horses may be confirmed by the detection of guttural pouch empyema on endoscopic examination.

Morbidity rates of 100% are not uncommon in some susceptible populations and mortality rates of 8–10% have been reported amongst cases,[8,9] although rates are usually much lower in well-managed animals. As well as the usual clinical signs of strangles, serious complications occur in as many as 20% of cases.

Metastatic ('bastard') strangles Metastatic strangles is the systemic spread of infection by *S. equi*, with abscessation of parts of the body other than the lymph nodes of the head. A wide range of structures may be affected, including the lungs, liver, spleen, kidneys, brain, spinal cord, joints, endocardium, and the cervical, pulmonary, prescapular, mediastinal and mesenteric lymph nodes. Abscesses also occur paravertebrally, and cutaneously, on the limbs (Fig. 31.8) and in the perianal, periorbital and facial regions.

A diagnosis of metastatic strangles should initially be suspected with the presentation of overt and unusual clinical signs in any animal that is known to be either currently suffering, or has recently recovered from or has had contact with horses with strangles. Signs of metastatic strangles may be indicative of the anatomical site(s) of infection but are often fairly non-specific and include increased respiratory effort, periodic pyrexia, depression, inappetence, intermittent colic and chronic weight loss.

Fig. 31.8 Discharging abscess on the hind quarters of a horse with metastatic strangles (picture courtesy of H. Townsend).

Fig. 31.9 Facial edema and nasal discharge in a horse with strangles-associated purpura hemorrhagica (picture courtesy of P. Dixon).

Fig. 31.10 Hemorrhage and edema on the mucosal surface of the upper lip in a horse with purpura hemorrhagica (picture courtesy of H. Townsend).

Purpura hemorrhagica Purpura hemorrhagica is a strangles-related immune-mediated condition that usually occurs suddenly in older horses. Purpura is characterized by vasculitis resulting in subcutaneous edema especially involving the head (Fig. 31.9) and limbs and petechial hemorrhages on the surfaces of the mucosae (Fig. 31.10), musculature and viscera. Immune complexes, containing the surface M-protein antigen of *S. equi*, have been shown to be involved in the pathogenesis of purpura.[10,11] The vasculitis may be widely disseminated through the body affecting many organs, including the gastrointestinal tract, kidneys, lungs, muscles and heart, and the resulting peripheral edema may be so severe as to cause circulatory collapse and death. Diagnosis of purpura hemorrhagica is generally made on the basis of typical clinical signs, which usually appear between 2 and 4 weeks after an apparent resolution of strangles or following administration of a strangles vaccine.

Special examination

Confirming a diagnosis of guttural pouch empyema with or without chondroids following strangles is achieved by direct visual assessment of both pouches using endoscopy (Figs 31.6, 31.11) or radiography (Fig. 31.7). Cytologic assessment and culture and polymerase chain reaction (PCR) of *S. equi* in lavage samples collected via a sterile disposable catheter passed through the biopsy channel of the endoscope should accompany visual examination as infection and inflammation may be present in the absence of obvious and visible pathology.[6,12]

The diagnosis of guttural pouch empyema with chondroids may also be made by radiography of the head (Fig. 31.12)[6,12] and *S. equi* may be cultured from lavages collected by direct percutaneous sampling of the pouch.[13,14]

Metastatic strangles Further diagnostic procedures may aid the confirmation of the presence and site of *S. equi* abscessation in metastatic strangles. Appropriate techniques include hematologic examination (usually showing leukocytosis with left shift and mature neutrophilia), clinical biochemistry (raised serum globulin and fibrinogen levels) and peritoneal and/or pleural fluid evaluation (raised white blood cell count, protein and fibrinogen levels, presence of intra- and extracellular cocci on a stained smear even though bacteriological culture is frequently negative). Examination per rectum (with or without transrectal or transabdominal ultrasound examination) may reveal an abnormal abdominal mass that is generally resented on palpation. Abdominal abscesses may be diagnosed by exploratory laparotomy or laparoscopy. Sometimes the diagnosis can only be made at necropsy in animals found dead or after elective euthanasia for intractable idiopathic disease. Isolation of *S. equi* from abscesses provides a definitive diagnosis of metastatic strangles.

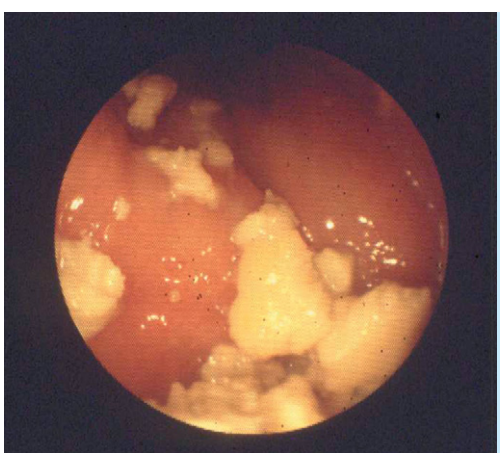

Fig. 31.11 Endoscopic appearance of a guttural pouch with chondroids forming following strangles.

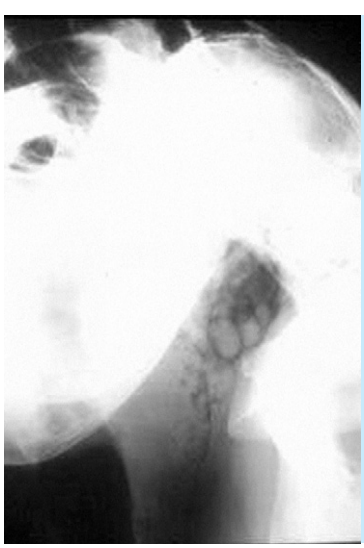

Fig. 31.12 Radiographic appearance of chondroids in the guttural pouch of a horse following strangles.

Laboratory examination

Sample submission To maximize effective containment and control of strangles outbreaks, a definitive diagnosis should be made as early as possible, especially in horses that do not have classical signs of lymphadenitis. This may be achieved by bacterial culture of *S. equi* from appropriate samples such as aspirated pus from lymph nodes (Fig. 31.13)

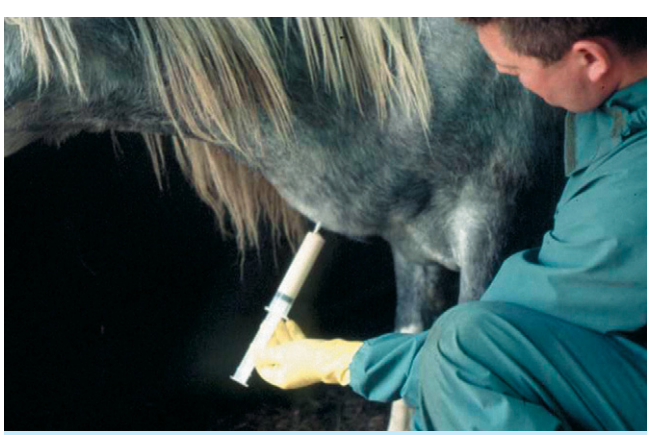

Fig. 31.13 Aspiration of pus from an infected lymph node in a case of metastatic strangles.

and swabs or washings from discharging abscesses and the nasopharynx. Samples should preferably be submitted from a large and representative sample of suspected cases, rather than a single sample from a single case. In addition, care should be taken with the interpretation of negative laboratory results, especially from horses demonstrating signs that are typical of strangles. Draining abscesses frequently become rapidly colonized by other bacteria that overgrow and mask the presence of *S. equi*. Therefore, a negative result on a single short nasal swab from one horse, for example, should not necessarily be taken as assurance that *S. equi* is not involved in an outbreak of respiratory disease in a group of horses. This is because mucosal colonization by *S. equi* may be short-lived and as with draining abscesses the background flora is complex and the presence of *S. equi* may be hidden. Consequently, it is wise always to follow the general rule of thumb that 'if it looks like strangles, then it probably is strangles'.

Bacterial culture Conventional bacterial culture and differential identification from other hemolytic bacterial species, particularly the closely related *S. zooepidemicus*, by sugar fermentation and Lancefield group typing remain the cornerstone of definitive diagnosis of *S. equi* infection. *Streptococcus equi* is conventionally identified by the inability of subcultures of its hemolytic colonies to ferment ribose, sorbitol, trehalose and lactose when inoculated into serum sugar broths and by possession of the Lancefield group C antigen in a latex agglutination test.

In chondroids formed after strangles, *S. equi* can be cultured and demonstrated histologically on the surface and lining fissures within their structure (Figs 31.14, 31.15).

Polymerase chain reaction (PCR) PCR assays are now available for diagnosis of *S. equi* infection on nasopharyngeal swabs or nasal wash samples.[15,16] PCR is used in conjunction with culture to improve the sensitivity of detection of *S. equi*, especially in outwardly healthy but potentially infectious horses that pose a risk of transmission if in close contact with susceptible animals.[4] PCRs have been developed for detection of the DNA of the hypervariable region of the M-protein gene[16] and 16S–23S RNA gene intergenic spacer,[15] which in combination are able to differentiate *S. equi* from the vast majority of subtypes of the ubiquitous but closely related *S. zooepidemicus* species.

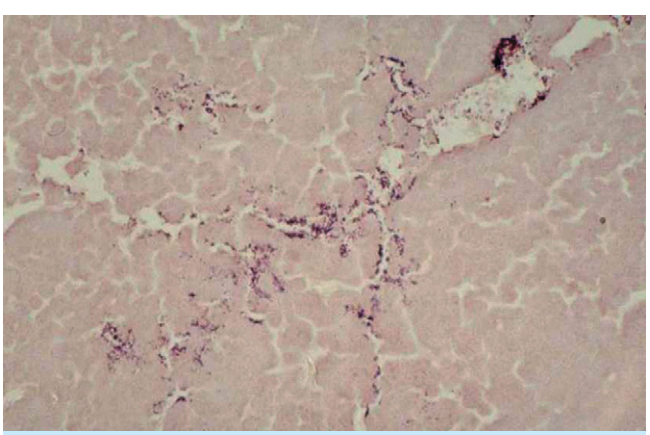

Fig. 31.14
Dark Gram-positive staining *S. equi* lining fissures within a chondroid removed from the guttural pouch of a horse following strangles.

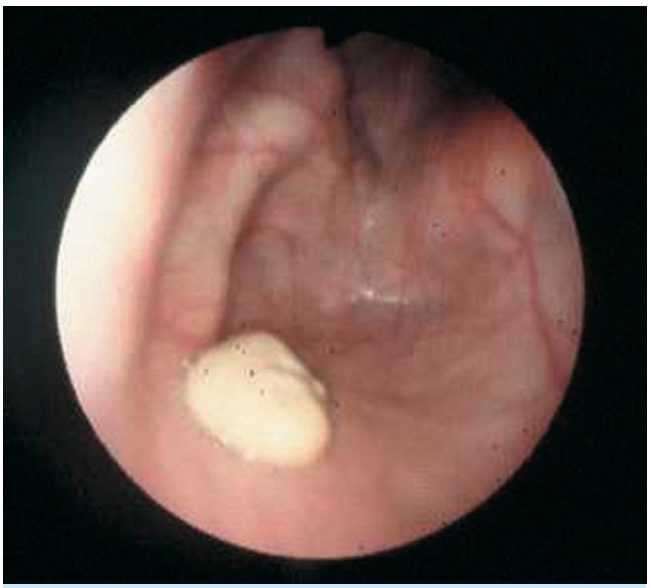

Fig. 31.15
A single chondroid within a guttural pouch.

During recent intensive outbreak investigations in the UK using repeated swabbing of the nasopharynx and endoscopy of guttural pouches, variants of *S. equi* have been isolated from a significantly higher proportion of carriers (24%) compared with clinical cases of strangles (< 1%, Fisher's exact P = 0.0002).[17] The variants lacked DNA that coded for up to 20% of the surface expressed M-protein and were shown to express truncated forms of this protein compared with non-variant *S. equi*.[17] As variants were much more prevalent in outwardly healthy horses than those with signs of strangles, they possibly represented a less virulent but immunizing subtype of *S. equi*, which may have been contributing to herd immunity by acting as a natural, live vaccine. Experimental infection in naïve Welsh mountain ponies has, however, shown that variant *S. equi* expressing a truncated M-protein are as pathogenic as subtypes with the full M-protein, producing typical clinical signs of strangles including lymph node abscessation, 'bastard' strangles (Fig. 31.13) and guttural pouch empyema. This demonstrates that at the present time all carriers should be regarded as potential sources of new strangles outbreaks.

Necropsy examination

Diagnosis of metastatic strangles can often only be made at necropsy in animals found dead or after elective euthanasia for retractable idiopathic disease, with the culture of *S. equi* from abscesses providing a definitive diagnosis of 'bastard' strangles.

Necropsy findings have confirmed that the guttural pouch is frequently the only site of carriage of *S. equi* in otherwise outwardly healthy horses that continue to harbor the organism long after initial infection.

Diagnostic confirmation

The presence of *S. equi*, identified by culture or PCR in appropriate swab, lavage or aspirate samples from horses with evidence of respiratory disease, including guttural pouch empyema or abscessation, confirms a diagnosis of strangles. However, some caution is required with results that are positive by PCR only, as this finding may reflect the persistence of killed bacteria, as was demonstrated in two horses following treatment for guttural pouch empyema and/or chondroids.[18] However, despite the disadvantage that PCR might produce such 'false positives', in the context of presumptively detecting *S. equi* carriers, PCR has the advantage of detecting DNA in the nasopharynx that might have originated from living bacteria in the guttural pouches. Large unguarded nasopharyngeal swabs[6] greatly facilitate the sampling of any material draining from the guttural pouches into the nasopharynx. Given the risk for 'false positives', however, PCR can only be regarded as a presumptive test for *S. equi* carriers until infection has been demonstrated in the guttural pouches by culture.

Treatment and prognosis

Therapeutic aims

The only treatment usually needed for the majority of cases of strangles is provision of a dry and warm environment, palatable and easily swallowed food and good quality nursing care. Maturation and discharge of abscesses should be encouraged by use of poultices and lancing. This should be followed by frequent flushing with 3–5% dilute povidone-iodine solution until discharge of pus ceases. Lancing of abscesses and emergency surgical tracheostomy may be needed when there is acute respiratory obstruction. Non-steroidal anti-inflammatory drugs (NSAIDs) may be administered as appropriate to reduce the pyrexia, pain and inflammation associated with *S. equi* infection and consequently improve the demeanor of affected horses and maintain their appetite (Table 31.1).

The use of antimicrobial therapy in strangles remains extremely controversial. Although *S. equi* is susceptible in vitro to many of the antimicrobials that are commonly used in horses, their effectiveness in vivo may be poor. This is especially true where there has been migration of infection to the lymph nodes or where there is accumulation of pus such as in guttural pouch empyema or 'bastard' strangles. Furthermore, there are frequently problems with recurrence of lymphadenitis and subsequent abscessation some time after the antimicrobial treatment ends. Although it is commonly cited that use of antimicrobials induces metastatic strangles, there is little scientific evidence to support this and this severe complication is known to occur in outbreaks where no such treatment has been used. In addition, use of antimicrobials may instill a false sense of security in owners

Table 31.1 Details of treatments commonly used for strangles and its complications

Drug name	Drug type	Indication	Dose rate	Route of administration	Duration of treatment
Procaine penicillin G	Antibiotic	Treat *S. equi* infection	10,000–20,000 IU/kg q 12–24 h	Intramuscular	5–7 days but longer for metastatic strangles
Ceftiofur	Antibiotic	Treat *S. equi* infection	2 mg/kg q 12–24 h	Intramuscular or intravenous	Up to 10 days
Trimethoprim potentiated sulfonamide	Antibiotic	Treat *S. equi* infection	15–30 mg/kg q 12 h	Oral	Up to 28 days
Phenylbutazone	NSAID	Reduce pyrexia, pain and inflammation	4.4 mg/kg q 24 h	Oral	As required
Flunixin	NSAID	Reduce pyrexia, pain and inflammation	1.1 mg/kg q 12–24 h	Intravenous	Up to 5 days
Meclofenamic acid	NSAID	Analgesia with metastatic strangles	2.2 mg/kg q 24 h	Oral	As required
Dexamethasone	Steroid	Reduce vasculitis with purpura hemorrhagica	Up to 0.20 mg/kg q 24 h	Intramuscular, intravenous or oral	As required

q, Every; NSAID, non-steroidal anti-inflammatory drug.

and veterinary surgeons that animals are no longer infectious and so strict hygiene measures are no longer necessary. Consequently, the use of antimicrobial therapy in strangles outbreaks should be very carefully considered. If antimicrobials are used (Table 31.1) it is strongly recommended there should be continued close clinical monitoring of animals for several weeks after the end of antibiotic administration, during which time the highest standards of hygiene should also be maintained. Further screening of animals during this period by bacterial culture of nasopharyngeal swab or lavage samples is strongly recommended, although false positive PCR results are possible during this time.[18]

Metastatic strangles Treatment of metastatic strangles is possible when abscesses are accessible so that they can be drained and flushed with dilute povidone-iodine. A prolonged course of large dose parenteral procaine benzylpenicillin (Table 31.1) should be initiated and administered daily for several weeks. Alternatively, oral antimicrobial treatment, such as trimethoprim potentiated sulfonamide, can be used for longer periods of treatment.

Other appropriate symptomatic treatment, such as analgesics (Table 31.1), may be administered where indicated. The diagnostic techniques described earlier may be useful in monitoring for remission of abscessation during and following treatment.

Purpura hemorrhagica Treatment of purpura hemorrhagica is aimed (i) at removing antigenic stimulation by *S. equi*, (ii) at reducing the exaggerated immune response, (iii) at reducing vasculitis and (iv) at providing supportive therapy. It has been proposed that this may be achieved by use of procaine benzylpenicillin to treat the *S. equi* infection and intravenous administration of corticosteroids such as dexamethasone (Table 31.1) to suppress the immune response and reduce vessel wall inflammation. However, penicillin treatment is controversial as it can lead to bacterial cell lysis that could increase amounts of circulating M-protein, which may potentially increase immune complex formation and consequently worsen clinical signs. Supportive care, such as leg wraps, light walking exercise, hydrotherapy, diuretics and intravenous fluid administration, should be used as necessary.

Guttural pouch empyema Appropriate approaches to treatment of guttural pouch empyema in individually affected horses depend on the volume and consistency of the material within the pouch(es).[5,12,18–20]

Repeated flushing of pus-filled pouches via rigid bovine uterine catheters or indwelling Foley catheters using saline or dilute povidone-iodine solution, followed by lowering of the head to allow drainage or use of a suction pump attached to the endoscope, have been shown to help the elimination of empyema.[12,18] Administration of both topical and systemic sodium benzylpenicillin improves the success rate of treatment.

Topical instillation of 20% (w/v) acetylcysteine solution has also been used to aid the treatment of empyema.[19] Acetylcysteine, by disrupting disulfide bonds in mucoprotein molecules, has a denaturing/solubilizing activity, thereby decreasing the viscosity of mucus and helping natural drainage from the pouch. Erythema of the guttural pouch mucous membranes has been observed though following use of acetylcysteine.[18]

In more long-standing cases there is inspissation of the purulent material, which produces a thickened empyema and leads to chondroid formation that does not readily drain into the pharynx. These cases are less straightforward to treat by topical therapy as they are usually refractory to large volume irrigation and early attempts at removal by endoscopically guided instruments have been technically difficult and time-consuming. Conventional treatment of such cases has been by the surgical technique of hyovertebrotomy and ventral drainage through Viborg's triangle. This technique, however, carries all the inherent risks of general anesthesia and surgical dissection around the major blood vessels and nerves of this region of the head and neck, as well as the possibility of *S. equi* contamination of the hospital environment and subsequent risk of transmission to susceptible horses. More recently, use of improved sedation techniques and endoscopic instruments, including use of memory-helical polyp retrieval baskets passed through the biopsy channel of the endoscope, now more easily facilitates non-surgical removal of chondroids, even if they are found in very large numbers and in conjunction with empyema. This is usually sufficient for successful treatment of even the most severe guttural pouch pathology when combined with topical and systemic antimicrobial therapy.

Therapy

Table 31.1 summarizes types of therapy with their indications, dose rates, routes of administration and duration of treatment for treatments commonly used with strangles and its complications.

Prognosis

The prognosis for most cases of uncomplicated strangles is good although airway obstruction following enlargement of abscessated lymph nodes of the head and neck may be fatal unless emergency tracheostomy is performed. 'Bastard' strangles may carry a poor prognosis, especially if abscesses are large and not readily accessible for continued external drainage. Purpura hemorrhagica may be rapidly fatal despite appropriate treatment.

Etiology and pathophysiology

Etiology

Strangles is caused by a primary infection with *Streptococcus equi*, a Gram-positive, Lancefield group C, beta-hemolytic bacterium.

Molecular characterization of *S. equi* and the closely related *S. zooepidemicus* has shown that isolates of *S. equi* are antigenically more similar and are actually derived from the antigenically more diverse *S. zooepidemicus* species. Various molecular typing techniques such as random amplified

polymorphic DNA analysis (RAPD), multilocus enzyme electrophoresis (MEE) and pulsed-field gel electrophoresis (PFGE) have been applied to different *S. equi* isolates from around the world and show that not all isolates are antigenically identical. However, to date no correlation between antigenically distinct types and clinical severity of outbreaks has been shown using these techniques.

Pathophysiology

The incubation period for strangles varies between 3 and 14 days depending on infectious dose and the host's immune status. There appears to be a very rapid (within hours of colonization) transfer of *S. equi* infection from the site of initial infection usually on the buccal or nasopharyngeal mucosal surfaces to the draining lymph nodes of the head and neck. *S. equi* is able initially to resist phagocytosis by polymorphic leukocytes but this is then followed by a massive recruitment of white blood cells with consequent abscess formation with associated fibrosis and walling off of infection. Eventually abscesses discharge through the weakest point, which is usually the skin in the case of the submandibular and parotid lymph nodes but dorsally through to the lumen of the guttural pouch for retropharyngeal lymph nodes. Horses usually make a rapid and uneventful recovery following natural drainage of abscessated lymph nodes. Metastatic strangles is believed to follow blood- or lymph-borne metastasis of *S. equi* infection to sites distal to infected lymph nodes. The signs of purpura hemorrhagica are mediated through immune complexes formed between the M-protein antigen of *S. equi* and immunoglobulins of the host's exaggerated immune response.[10,11]

Epidemiology

Active and recovering strangles cases are an extremely important and easily recognizable source of new *S. equi* infections for susceptible horses through their purulent discharges from lymph nodes, nose and eyes. Transmission of *S. equi* infection occurs when there is either direct or indirect transfer of these purulent discharges between affected and susceptible horses. Direct transmission refers to horse-to-horse contact, which occurs through normal equine social behavior involving head-to-head and nose-to-nose contact.

Indirect transmission occurs with the sharing of contaminated housing, water sources, feed or feeding utensils, twitches, tack, and other less obvious fomites such as the clothing and equipment of handlers and veterinary surgeons and, anecdotally, even via other animal species.

The organism is also able to remain viable and infectious in the environment for extended periods if maintained in moist discharges, particularly when not exposed to chemical disinfectants and/or sunlight.[21]

It is increasingly recognized that transmission originating from outwardly healthy animals may be of greater importance than from purulent discharges from sick horses because the source of infection is not obvious and appears suddenly and without warning.

Horses that are incubating the disease are outwardly healthy and potentially infectious but do themselves go on to develop signs of strangles. It is assumed that normal nasal secretions are the source of infection in these animals. The other important outwardly healthy but potentially infectious horses are those convalescent cases that continue to harbor the organism after full clinical recovery. A moderate proportion of horses continue to harbor *S. equi* for several weeks after clinical signs have disappeared, although in the majority the organism is no longer detectable 4 to 6 weeks after total recovery. It is therefore appropriate to consider all recovered horses as potentially infectious for at least 6 weeks after their purulent discharges have dried up.

In a proportion of outwardly healthy, potentially infectious horses, carriage and at least periodic shedding of *S. equi* occurs for prolonged periods after apparent full and uncomplicated recovery. These horses are commonly referred to as long-term, asymptomatic *S. equi* carriers and there is strong anecdotal evidence that they can be a source of new disease in a large proportion of outbreaks, even in well-managed groups of horses.[4,12] If strangles control measures are to be fully effective there must be recognition of the importance of carrier animals and appropriate detection and management of these animals.[4,5,18]

It appears probable that short-lived empyema of the guttural pouches is the most common outcome of uncomplicated drainage of RPLN abscessation. However, in up to 10% of horses in strangles outbreaks[4] there is apparent failure of this clearance mechanism resulting in chronic empyema of the pouch. The failure of drainage of the guttural pouch may be related to the extended periods for which some housed horses are kept with their heads elevated. In some horses, guttural pouch empyema with *S. equi* infection may persist asymptomatically for many months or even years.[6] In these long-standing cases pus in the pouches inspissates and then eventually forms into discrete, ovoid, smooth concretions known as chondroids. Chondroids may occur singly (Fig. 31.15) or as multiples (Fig. 31.16), sometimes in very large numbers, and have been shown to harbor viable *S. equi* within their core (Fig. 31.14).

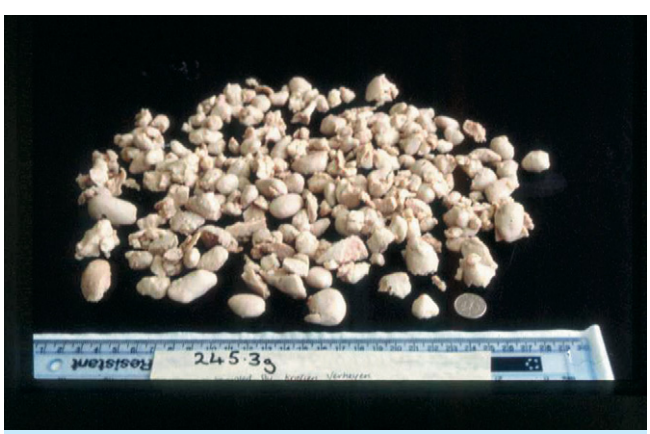

Fig. 31.16
Multiple chondroids removed non-surgically from the guttural pouch of a horse after strangles.

By the identification, segregation and treatment of these potentially infectious horses, prolonged outbreaks have been successfully controlled and further outbreaks undoubtedly prevented.[4,5,12] A systematic program of repeated nasopharyngeal swabbing or nasal washing (i.e. at least three samples taken at weekly intervals) of horses following the cessation of clinical signs or during quarantine of incoming horses, using conventional culture in conjunction with PCR, has successfully identified carrier horses.[4]

Control of outbreaks

Investigation of strangles outbreaks by veterinary surgeons should begin with a detailed history to evaluate the full extent of the potential disease problem. The review should aim to identify affected groups of horses and allow the geography of the premises and the management practices on them to be assessed for further risks and future opportunities for disease control. A practical disease control strategy should then be agreed and implemented. The general aims and measures for such a strategy are outlined in Table 31.2. However, this outline strategy will need to be adapted to the individual circumstances of each specific premises and outbreak.

In summary, all movements of horses on and off the affected premises should be stopped immediately with implementation of parallel segregation and hygiene measures. Strangles cases and their contacts should be kept in clearly marked 'dirty' (i.e. *S. equi* positive) areas of isolation. The overall aim of the control strategy, following bacteriological screening, is to move horses from the 'dirty' to 'clean' areas where non-affected and non-infectious horses are kept. Considerable care should be taken to maintain the highest standards of hygiene throughout the premises and for the duration of the investigation. Screening of all convalescing cases and their healthy contacts should be conducted using nasopharyngeal swabs or lavages, with special care taken to maintain good hygiene to avoid inadvertent transmission between horses during sampling. Repeated weekly swabs or lavages should be taken over several weeks and tested for *S. equi* by conventional culture and PCR, but because PCR can detect dead as well as living bacteria, positive PCR results should only be regarded as provisional, subject to further investigation. Most asymptomatic, long-term carriage of

Table 31.2 Aims and measures used to control transmission of *S. equi* on affected premises

	Aim	Measure
1.	To prevent the spread of *S. equi* infection to horses on other premises and to new arrivals on the affected premises	Stop all movement of horses on and off the affected premises immediately and until further notice
2.	To establish whether horses are infectious in the absence of clinical signs of strangles (i.e. asymptomatic carriers)	At least three nasopharyngeal swabs or lavages are taken at approximately weekly intervals from all recovered cases and their contacts and tested for *S. equi* by culture *and* PCR
3.	To determine if horses are likely to be free from infection with *S. equi* (i.e. non-infectious for strangles)	At least three consecutive nasopharyngeal swabs or lavages are negative for *S. equi* by culture and PCR
4.	To determine if horses are likely to be harboring *S. equi* (i.e. infectious for strangles)	*S. equi* is cultured or detected by PCR on any of the screening swabs. (Horses with only positive PCR results are considered provisionally positive subject to further tests)
5.	To prevent direct transmission of *S. equi* infection by isolation of infectious horses from those screened negative for *S. equi*	Infectious horses are maintained in so-called 'dirty' (i.e. *S. equi* positive) isolation areas that are physically cordoned from the other 'clean' areas of the premises where non-infectious horses are kept. Clustering of cases in groups should allow parts of the premises to be easily allocated as 'dirty' and 'clean' areas
6.	To prevent indirect cross-infection by *S. equi* from horses in the 'dirty' area to those in the 'clean' area of the premises	Potentially infectious horses in the 'dirty' area are preferably looked after by dedicated staff or are dealt with *after* non-infectious horses in the 'clean' area. Strict hygiene measures are introduced including provision of dedicated clothing and equipment for each area, disinfection facilities for personnel and thorough stable cleaning and disinfection methods
7.	To monitor horses in the 'dirty' areas for persistence of *S. equi* infection and to establish sites of carriage of infection	Nasopharyngeal swabbing or lavages are continued with endoscopic examination of the upper respiratory tract including guttural pouches in those horses in which *S. equi* was detected after clinical signs had disappeared. Horses that satisfy the non-infectious criteria of measure 3 above or have at least the third swab of the series negative by PCR (to allow for possible persistence of PCR-positive but dead bacteria) are returned to the 'clean' area
8.	To eliminate inflammation and *S. equi* infection from the guttural pouches and other sites	Removal of lesions through a combination of flushing and aspiration of saline and removal of chondroids using endoscopically guided instruments. Topical and systemic administration of penicillin antimicrobial treatment to eliminate *S. equi* infection (see 'Treatment and prognosis')

S. equi occurs in the guttural pouches of recovered horses. Therefore endoscopy of the upper respiratory tract, especially the guttural pouches, should be performed in all outwardly healthy horses in which *S. equi* is detected, either by culture or by PCR. Guttural pouch lavages should also be tested for *S. equi* using culture and PCR. Other sites such as the nasal sinuses or trachea should also be considered in horses that continue to harbor *S. equi* in the absence of pathology or *S. equi* infection of the guttural pouches.[3]

Prevention

Although more preferable than controlling outbreaks, prevention of strangles is extremely difficult to achieve, particularly in the absence of specific measures aimed at reducing the risk of inadvertent introduction of *S. equi* infection through asymptomatic carriers. Prevention is especially problematic where there is frequent movement and mixing of horses and where strangles outbreaks elsewhere have not been appropriately investigated and controlled or are known about. Wherever possible animals being introduced to a new population of horses should be maintained in strict isolation (quarantine) where they are screened for *S. equi* by repeated nasopharyngeal swabs or lavages. This should be performed in accordance with the protocol outlined for controlling outbreaks (i.e. three samples taken at weekly intervals), with samples tested for *S. equi* by culture and PCR and animals testing positive by either test being retained in isolation for further investigation and treatment. High standards of hygiene should also always be maintained to avoid indirect transmission between quarantined and resident horses.

Vaccination

Although strangles occurs in most countries around the world, relatively few nations currently use vaccination as a means of control or prevention and in those areas where it is used, strangles remains an endemic and extremely significant equine infectious disease. Despite there being some limited scientific evidence to show that strangles vaccines are effective in reducing the severity of disease, the protective immunity that they convey is generally poor and very short-lived. Importantly, as well as their limited effectiveness, many problems have been encountered with both local and systemic reactions to strangles vaccines. Although the original heat-inactivated whole culture vaccines (so-called bacterins) have higher rates of reaction compared with the later protein-rich extract products, both have been associated with an unacceptably high level of adverse effects. Recently a live, intranasal vaccine based on an apparently avirulent and naturally occurring strain of *S. equi* has been used in North America. Whilst this type of vaccine, if it remains truly avirulent, might have superior immunizing ability and minimal side effects compared with the intramuscularly administered inactivated or protein-based vaccines, there have also been problems reported with adverse reactions to this live mutant vaccine strain of *S. equi*. Reactions similar to those signs seen in the natural disease have been reported, albeit at a lower rate than encountered with disease. Such signs include nasal discharge, abscessation of lymph nodes and other sites, allergic reactions, systemic responses and purpura-like signs. These reactions and the occurrence of *S. equi* abscesses at the site of intramuscular injection given immediately after intranasal administration of this vaccine demonstrate the potential of this product to produce strangles-like signs in horses.

In keeping with other streptococcal pathogens, the virulence of *S. equi* is most probably determined by a complex series of multiple, genetically coded determinants. This is demonstrated by the lack of efficacy of M-protein vaccines and by the ability of a live, intranasal vaccine strain, the naturally occurring M-protein gene deletion mutants and heat-inactivated bacterin vaccines to all produce abscesses. Therefore, in order to produce a truly effective strangles vaccine with maximal efficacy and minimal side effects, it will be necessary to have knowledge and understanding of the mechanisms of the vast majority, if not all, of these determinants. To this end, the entire DNA genome of *S. equi* has recently been sequenced.

Detailed analysis of the *S. equi* genome should provide novel understanding of the mechanisms by which *S. equi* causes strangles in horses and how it manages to evade host immune responses. Further research based on the genome sequence should lead to the development of more effective and safer strangles vaccines for horses.

The role of bacteria, including *Streptococcus zooepidemicus*, in inflammatory airway disease

- Inflammatory airway disease is common in athletic horses.
- Some, but not all, cases are associated with bacterial infection, in particular *Streptococcus zooepidemicus* and *Actinobacillus*/*Pasteurella* spp.
- The role of environmental factors, such as stabling, is debated.

Recognition of disease

Clinical recognition of inflammatory airway disease (IAD) associated with bacteria follows standard patterns for the diagnosis of IAD, with the simple addition that quantitative bacteriology is needed to assess the presence of bacteria (and their clinical significance). Recognition is thus not discussed at length here, but rather, readers are referred to Chapter 29 in this book.

Etiology and pathophysiology

Etiology

There are few published studies that consider the role of either viruses or bacteria in the etiology of IAD. Most studies that do consider their role in IAD are based on disease in young race horses, although there are some that consider lower respiratory tract disease in foals.

Multidisciplinary epidemiological studies of IAD have provided strong evidence for a multifactorial etiology of IAD.[22] It is not argued here that bacteria are the only cause of IAD, merely that they are likely to be responsible for a significant proportion of the syndrome as a whole.

IAD associated with bacteria has been most extensively studied in Thoroughbred race horses in the UK; there are also several published studies of the relationship between bacteria and respiratory disease in young Thoroughbred race horses in Australia. The evidence for a role of bacteria in IAD in these young animals is reviewed below. Disease of the older horse is not considered here, not because bacteria cannot play a role in such animals, but rather because there are no published studies that objectively consider any such role.

When reviewing the evidence, the mean duration of cases of acute IAD in young race horses – around 2 months – needs to be considered.[22,23] In this respect, conclusions derived from cases seen at secondary and tertiary referral institutes are likely to be quite different in nature from those that come from population-based epidemiological investigations.

It is important that associations between disease and the presence of infections are analyzed quantitatively when considering evidence of possible causation. This is expensive and time-consuming in large-scale epidemiological studies, but nonetheless important. Evidence for epidemiological associations being causal requires careful and inclusive evaluation of all possible evidence.[24] Difficulties with experimental animal models means that *direct* evidence for causation will only be available when the impact of effective vaccination programs is studied in comparative and controlled studies. Such studies will not be possible until efficacious vaccines against the major bacterial agents implicated have been developed. In the field, it is often not possible to isolate implicated bacterial infections in pure culture from cases of disease; mixed infections are the norm, as indeed they are in cases of pneumonia in both horses and farm animals. However, this section is restricted to IAD; the presence of bacteria reported from cases of pneumonia is not considered here.

Direct evidence In young race horses, *Streptococcus pneumoniae* capsule type 3 has been recognized for some time as an important respiratory pathogen[25] – and its first reported isolation from horses dates back more than 30 years ago.[26] This is a major respiratory pathogen in humans, although the capsule type 3 isolated from horses appears genetically distinct from human strains, being deficient in pneumolysin and streptolysin, these being major pathogenic determinants.[27] Not only was the infection associated with the presence of IAD,[25] which the authors referred to as lower respiratory tract disease using a case definition that would classify it as IAD, but they were also able to reproduce signs of IAD experimentally by instilling the organism into the trachea of resting ponies.[28]

This preliminary epidemiological and experimental evidence for *S. pneumoniae* has been further supported by additional strong evidence from large-scale epidemiological studies of respiratory disease in young race horses in both Britain and Australia. In Britain, there was a close association between the organism and IAD in 2-year-old horses[29] and the infection was associated with coughing in young race horses in Australia;[30] although IAD itself was not studied, 85% of the cases of coughing in this study were suffering from IAD. This infection is relatively uncommon in cases of respiratory disease in young race horses (6%:[23]; 12%:[30]) in contrast to *Streptococcus zooepidemicus* and the *Actinobacillus/Pasteurella* group of bacteria.

Several of these studies of IAD or coughing in young race horses have reported a close association between the presence of *S. zooepidemicus*, particularly in large numbers, and IAD[22,29,31] as well as with coughing or other non-specific signs of respiratory disease.[30,32] However, there are few if any published reports of attempts to reproduce disease experimentally in equids with either organism, although septicemia can be induced with intravenous challenge[33] and disease can be reproduced in both mice and llamas with *S. zooepidemicus*.[34]

Along with *S. pneumoniae* and *S. zooepidemicus*, *Actinobacillus/Pasteurella* spp. have been found to be associated with IAD, coughing and non-specific signs of respiratory disease in young race horses in Britain and Australia.[22,23,29–32,35,36] In every published study, *S. zooepidemicus* was the bacterium associated with IAD most commonly isolated from the trachea.[22,23,29–32,36,37] As *S. zooepidemicus* was also the bacterium usually isolated in the largest numbers, it would be reasonable to conclude that this bacterial species probably plays the largest role of all conventional bacteria in the disease syndrome.

Indirect evidence All studies of IAD in young horses have found that the likelihood of disease, the prevalence and/or the incidence of IAD decrease as animals get older (Fig. 31.17)[22,23,29–32,36,37] or have spent longer in the stable environment.[30,32,36,37]

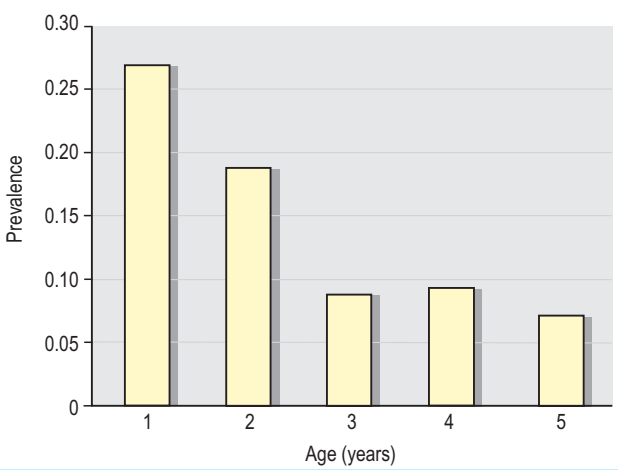

Fig. 31.17
Variation in prevalence of IAD in young race horses with age.

It is clear that a poor environment can exacerbate or prolong IAD[22] but our observations that IAD is frequently observed in weanling pony foals kept at grass[37] argue strongly against the stable environment being the only cause.

Desensitization to stable environmental contaminants could be hypothesized as a reason for a decrease in the frequency of disease in older animals, but this is most unlikely given that sensitization to them is implicated in the causal pathway of RAO in the older animal.

It is most likely that the decreases in the rates of IAD in older animals that correlate with the length of time in the stable environment and/or increasing age are due to the development of immunity to the infections that are responsible for a large part of the disease. The multidisciplinary investigations of IAD that have been undertaken have generally reported that these infections are usually bacterial rather than viral.[29]

Are the associations reported from epidemiological studies causal? Particular care needs to be taken when considering evidence of causation from epidemiological studies. Most of the studies referred to above used multivariable statistical methods, which reduces the likelihood of confounding, at least by measured variables. Furthermore, use of the nine Bradford Hill criteria[24] to assess whether the epidemiological associations between these bacteria and IAD are likely to be causal does suggest that bacteria do cause lower respiratory tract disease in horses.

Several studies have confirmed a reasonable strength of association (measured as relative risk) and a significant biological gradient for these bacteria and IAD, with increasing numbers of bacteria having a greater strength of association with disease.[22,25,29,36,38,39] Examination of tracheal wash data from young Thoroughbred race horses using a zero to nine ordinal scoring of airway inflammation demonstrates a significant biological gradient for increasing mean $\log_{10}$ colony-forming units (CFU) per milliliter of *S. zooepidemicus* and *Actinobacillus/Pasteurella* and increasing inflammation score (Fig. 31.18). There was no such gradient for *Staphylococcus*.

The associations with IAD are also specific for the three bacterial species of *S. zooepidemicus*, *Actinobacillus/Pasteurella* and *Streptococcus pneumoniae* and are consistent between different studies.[22,25,29,36,38,39] Bacterial infections as causes of IAD in young horses are biologically plausible, are coherent as the results do not conflict with current knowledge and are analogous with similar and identical bacteria being the cause of respiratory disease in other species. Furthermore, *S. equi*, a subtype of *S. zooepidemicus*,[15] causes 'strangles' in horses and is generally accepted as a primary bacterial equine pathogen. There is experimental evidence that intratracheal inoculation of *S. pneumoniae* causes IAD and pneumonia in young pony foals, with the organism being recovered from the trachea and pneumonic lesions.[28] A temporal relationship between bacterial infection and IAD is difficult to confirm due to the possibility of an earlier predisposing viral infection. However, results of a longitudinal study of IAD failed to show that the association between bacteria and IAD is dependent on prior infection with any of the known equine viruses[29] – and infection with the most common virus, equine herpesvirus 1/4, which was also the only virus statistically associated with IAD, was only detected in 7.5% of cases, despite the use of sensitive serological techniques.

Epidemiology

The results from investigations of endemic IAD in training yards,[22,23,39] as well as from outbreak investigations[35,40] have been reported. The substantial variation between years and between training yards in the prevalence of IAD (Fig. 31.19) gives the syndrome, at least in the UK, the appearance of occurring in outbreaks,[23] suggesting an infectious etiology.

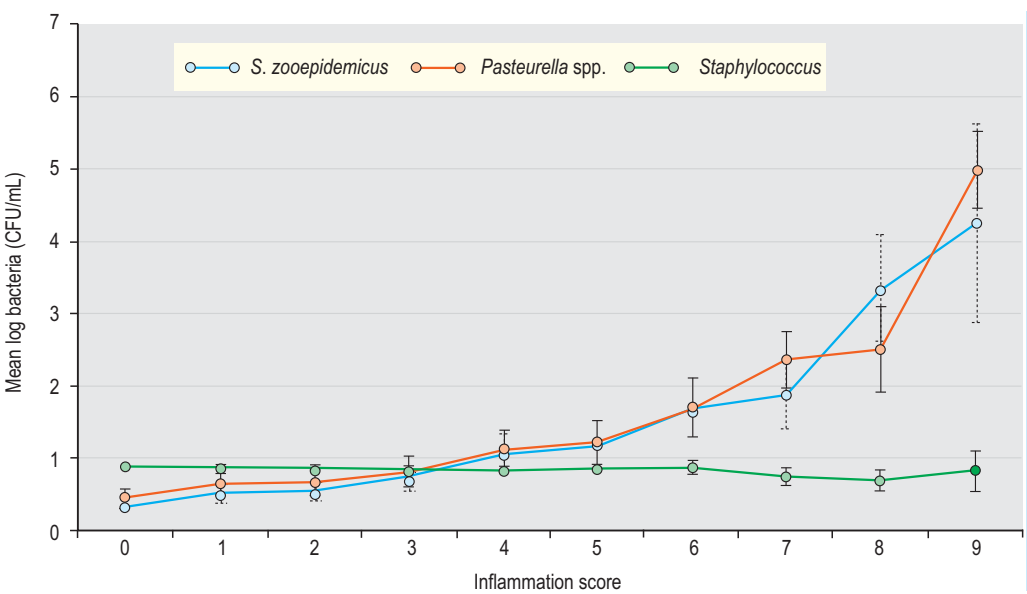

Fig. 31.18 Variation in mean $\log_{10}$ CFU/mL of three bacterial species with inflammation score in young race horses.

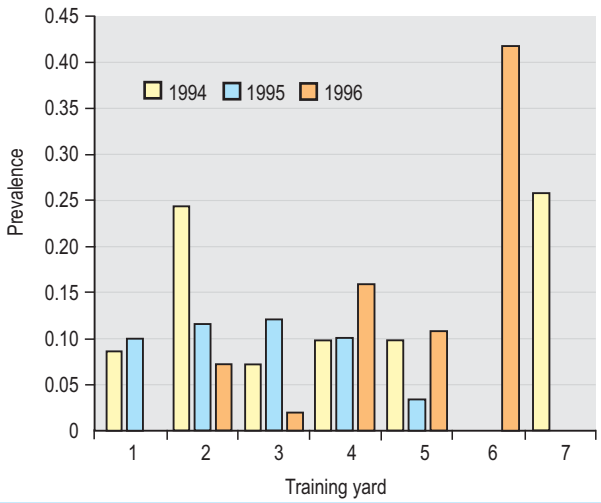

Fig. 31.19
Variation in prevalence of IAD in young race horses with year and trainer.

The disease in Britain is generally much more common in the winter and early spring, declining in prevalence through the year until the annual recruitment of young susceptible yearling animals into training yards in the autumn (Fig. 31.20). This is again consistent with the acquisition of immunity in individual animals and the progressive development of herd immunity in relatively stable groups through the year.

We have studied the molecular epidemiology of *S. zooepidemicus* in both horses in training and young ponies at grass;[37] workers from Kentucky have also reported results from similar investigations based on bacterial genotype and phenotype.[16,41] The molecular results have shown that, within a background of apparently constant *S. zooepidemicus* challenge, different strains of the bacterium are spreading or declining through different groups of animals.[37] All of the studies undertaken thus far have been too small to reliably detect small differences in pathogenicity between different strains; no large differences have yet been reported. The results, along with those from detailed evaluation of *Pasteurella* spp. subtypes,[42] indicate that great care needs to be taken when interpreting results from studies that have not used detailed molecular tools that identify differences between otherwise identical strains of these bacteria. Much more dynamic spread of different, non-cross-reactive strains is likely to be occurring between and amongst groups of horses than is apparent when using traditional microbiological methods.

Much work is necessary to clarify the role of bacteria in IAD, particularly in the older horse, but there is increasing acceptance that, at least in the acute disease in the young equine athlete, bacterial infections play an important role in the etiology.

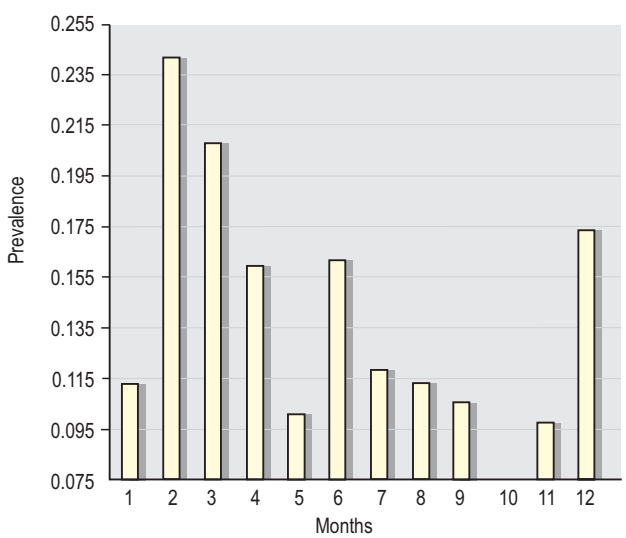

Fig. 31.20
Variation in prevalence of IAD in young race horses with month of the year.

Equine pleuropneumonia (pleuritis, pleurisy)

- Combination of pneumonia and accumulation of inflammatory exudate in pleural space is referred to as pleuropneumonia.
- Risk factors for development of the disease include transportation, viral respiratory disease, general anesthesia, esophageal obstruction, and penetrating chest wound.
- Clinical signs include combinations of fever, depression, anorexia, exercise intolerance, nasal discharge, mucopurulent nasal discharge and cough.
- Identification of pneumonia and inflammatory, septic pleural fluid confirms the diagnosis.
- Tracheal aspirate fluid and pleural fluid should be cultured and the results used to direct treatment.
- Treatment involves prolonged administration of antimicrobials and drainage of pleural fluid.
- Prognosis for life is good with aggressive treatment. Prognosis for return to racing is fair.

Recognition of disease

History and presenting complaint

Horses with pleuropneumonia frequently have a history of transportation over long distances (> 800 km), recent viral respiratory disease or contact with horses with evidence of infectious respiratory disease, recent general anesthesia, choke (esophageal obstruction), rupture of the esophagus or penetrating chest wound.[43,44] While spontaneous disease does occur, most cases in athletic horses are associated with one of these risk factors. The presence of pleural effusion in a horse lacking one of these risk factors should raise the index of suspicion of unusual underlying disease, such as neoplasia or congestive heart failure.

Physical examination

Acute pleuropneumonia is characterized by the sudden onset of combinations of fever, depression, inappetence, cough, exercise intolerance, respiratory distress, shallow respirations, respiratory distress and nasal discharge. Horses with chronic disease have exercise intolerance, weight loss, mild depression, intermittent fever, cough and mucopurulent nasal discharge.

Acutely affected horses are usually pyrexic, tachycardic and tachypneic. Pyrexia, while an expected finding, is not always detected, especially in horses administered non-steroidal anti-inflammatory drugs. Inappetence and depression are common clinical signs. Spontaneous coughing is unusual although manipulation of the trachea or pharynx will usually induce a soft cough. The horse may be reluctant to move or may exhibit signs of chest pain, including reluctance to move, pawing and anxious expression, that may be mistaken for colic, laminitis or rhabdomyolysis. Affected horses often stand with the elbows abducted and walk with a stiff, stilted gait taking small steps. Thoracic excursions during breathing are shallow. Nasal discharge ranges from serosanguineous to mucopurulent and occurs from both nostrils. The breath may be malodorous.

Horses with chronic pleuropneumonia have intermittent fever, mild tachycardia and tachypnea. Inappetence and weight loss are usual. Exercise intolerance is marked and exercise may be associated with coughing, subsequent fever and mucopurulent nasal discharge. Nasal discharge ranges from serosanguineous to mucopurulent, is usually present in both nares and is exacerbated when the horse lowers its head. The breath may be malodorous, although this is a more common finding in horses with subacute to chronic disease. Ventral edema occurs in approximately 50% of horses with pleuropneumonia.[44]

Auscultation Auscultation of the thorax reveals attenuation of normal breath sounds in the ventral thorax in horses with significant accumulation of pleural fluid. However, the attenuation of normal breath sounds may be mild and difficult to detect, especially in large or fat horses or in horses in which there is only slight accumulation of pleural fluid. Auscultation of the thorax with the horse's respiratory rate and tidal volume increased by having it breathe with a large airtight bag over its nostrils may reveal crackles and wheezes in the dorsal lung fields and attenuation of the breath sounds ventrally. However, this procedure is unnecessary and not recommended if there is clear evidence of pulmonary disease or pleural effusion is detected on routine auscultation or other examination. There is often fluid in the trachea detectable as a tracheal rattle.

Percussion Use of percussion to detect accumulation of pleural fluid requires knowledge of the boundaries of the lung fields in a normal horse. The boundaries of the lung fields are the 17th intercostal space at the level of the tuber coxae, 16th space at the level of the tuber ischii, 13th space at the level of the midthorax, 11th space at the level of the shoulder and 6th space at the olecranon (Fig. 31.21). Percussion of the chest wall in horses with excessive pleural fluid or pulmonary consolidation will reveal a clear line of demarcation below which the normal resonant sounds are muffled. This line of demarcation represents the dorsal limit of the pleural fluid. Both lung fields should be examined to identify localized areas of consolidation. Careful percussion of the thorax is a cheap and effective means of identifying the presence and extent of pleural fluid accumulation.

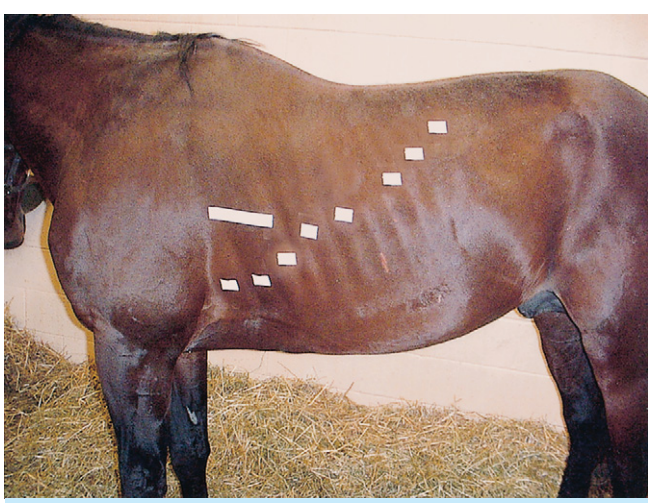

Fig. 31.21
Lung fields as detected by percussion. Short white marks indicate normal lung fields. Long white mark indicates level of fluid accumulation in a horse with pleuropneumonia.

Special examination

Ultrasonography Ultrasonographic examination of horses suspected of having pleural effusion provides definitive identification of presence of fluid. Thorough

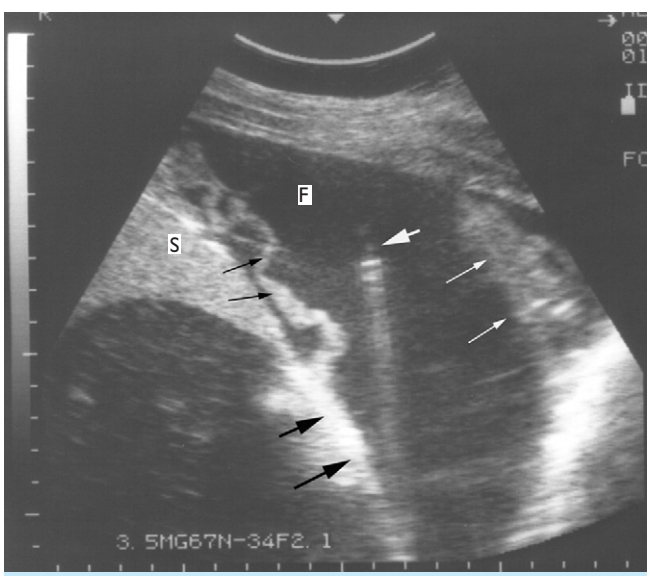

Fig. 31.22
Ultrasonogram of the left hemithorax of a horse with acute pleuropneumonia demonstrating accumulation of fluid (F) within the pleural space, an atelectic lung lobe (small white arrows) and free gas within the pleural fluid (large white arrow). The spleen (S), diaphragm (large black arrows) and pericardial-diaphragmatic ligament (small black arrows) are evident. Dorsal is to the right of the photograph.

ultrasonographic examination of both hemithoraces invariably reveals the presence of excessive pleural fluid in horses in which it is present (Fig. 31.22). It is a very sensitive technique with which to detect accumulation of pleural fluid, determine the character of the fluid, identify localized areas of fluid accumulation or pulmonary consolidation, identify sites for thoracocentesis and to monitor response to treatment.[45,46] Pleural fluid initially accumulates ventrally in acute cases, but may become localized dorsally in chronic cases with septation of the pleural space and trapping of fluid. Ultrasonographic examination is much more sensitive in detecting the presence of pleural effusion than is thoracic radiography.[45]

The examination is best performed using a 3.5 to 5.0 sector scanner. Linear probes, such as those used for routine reproductive examination, are adequate to identify fluid but do not allow good examination of all areas of the chest accessible with sector scanners. The entire thorax should be examined in a systematic fashion. The presence of and characteristics of fluid within the pleural space, presence and location of pulmonary consolidation or abscessation and potential sites for diagnostic and therapeutic thoracocentesis should be identified. For horses with long-standing disease, the area cranial to the heart should be examined for the presence of cranial thoracic masses (abscesses). This examination requires that the horse's ipsilateral forelimb be placed well forward, usually with the aid of an assistant, to allow adequate visualization of the cranial thorax.

The ultrasonographic characteristics of the pleural fluid should be noted. Pleural fluid may contain small gas echoes, an indication of infection with anaerobic bacteria and a poor prognosis,[46] strands of fibrin, or echogenic material consistent with cellular debris (Fig. 31.22). Sterile pleural effusion, such as may be present during the earliest stages of the disease, is clear and homogeneous without fibrin strands. With increasing chronicity the amount of fibrin increases, the parietal and visceral pleura become thickened, and the pleural fluid becomes echogenic consistent with the presence of cellular debris. Regions of consolidated or atelectic lung adjacent to the visceral pleura may be evident on ultrasonographic examination (Fig. 31.22), but lung consolidation deeper in the lung cannot be visualized on ultrasonographic examination.

Radiography Radiographic examination of horses with excessive pleural fluid reveals ventral opacity which obscures the ventral diaphragmatic and cardiac silhouettes (Fig. 31.23). It is not possible on radiographic examination to differentiate accumulation of pleural fluid from consolidation of the ventral lung lobes.[45] Radiographic examination may be useful in demonstrating lesions, such as pulmonary abscesses or consolidation, that are not confluent with the visceral pleura and therefore not able to be detected by ultrasonographic examination (Fig. 31.24). The dorsal lung regions, visible above the line of fluid and consolidation, often have a severe interstitial opacity and evidence of bronchopneumonia. Pneumothorax may be present in horses in which thoracocentesis has been performed or chest tubes have been placed, or that have developed bronchopleural fistulae.

Thoracocentesis and tracheal aspiration Pleural fluid should be collected by thoracocentesis of both hemithoraces and submitted for cytologic and bacteriologic examination.

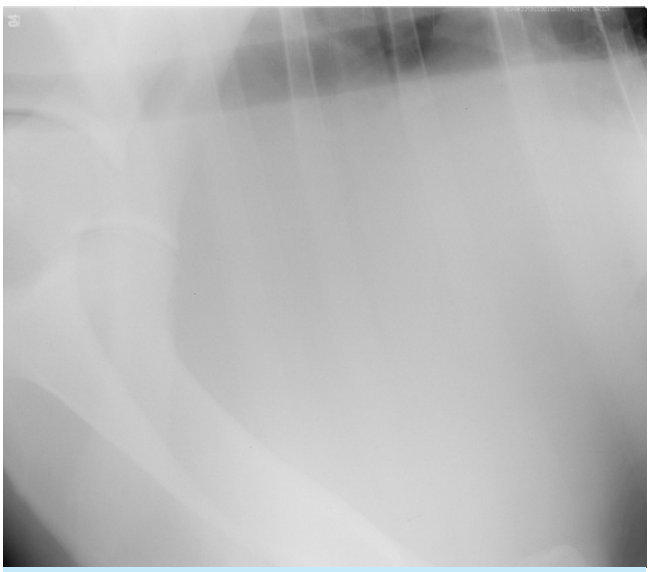

Fig. 31.23
Lateral thoracic radiograph of a horse with acute pleuropneumonia. Accumulation of fluid in the pleural space obscures the cardiac and ventral diaphragmatic silhouette.

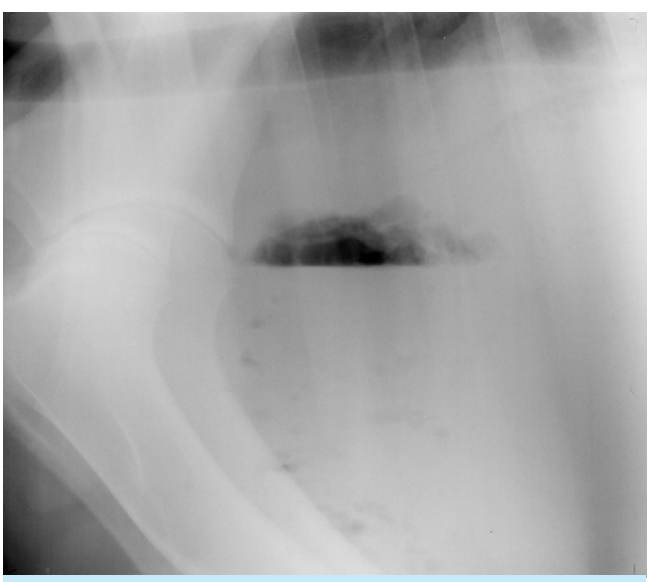

Fig. 31.24
Lateral thoracic radiograph of a horse with pleuropneumonia. Abscessation within the cranial thorax is evident.

Collection of pleural fluid is essential in confirming the diagnosis, allowing culture of the causative bacteria, and providing a baseline cell count and protein concentration by which to judge the success of treatment.

A tracheal aspirate should be collected and submitted for bacteriologic and cytologic examination. Both tracheal aspirates and pleural fluid should be examined in any horse with pleuropneumonia as bacteria may be recovered from one, but not the other, sample.[47] Examination of bronchoalveolar lavage fluid is not useful in diagnosing pleuropneumonia in horses.[48]

Laboratory examination

Hematology and serum biochemistry Acute pleuropneumonia is characterized by leukocytosis with a mature neutrophilia, mild to moderate anemia, hyperfibrinogenemia, and hypoalbuminemia.[49] There are similar findings in horses with chronic disease and hyperglobulinemia is also usually present. Severely affected horses with acute disease often have hemoconcentration and azotemia.

Pleural fluid and tracheal aspirates

Pleural fluid in acute cases is usually cloudy and red to yellow. It has an increased leukocyte number ($> 10.0 \times 10^9$ cells/L) composed principally of degenerative neutrophils, and an abnormally high protein concentration (> 2.5 g/dL, 25 g/L), and may contain intracellular and extracellular bacteria.[50] A Gram stain of the fluid should be examined. The pleural fluid should be cultured for aerobic and anaerobic bacteria. A putrid odor suggests infection by anaerobic bacteria. Sterile pleural fluid has pH, Po_2 and Pco_2 and lactate, glucose and bicarbonate concentration similar to that of venous blood.[51] Infected pleural fluid is acidic, hypercarbic and has an increased concentration of lactate and decreased concentrations of bicarbonate and glucose compared with venous blood.[51]

Tracheal aspirates have a leukocytosis comprised of degenerate neutrophils with intra- and extracellular bacteria. Cultures of tracheal aspirates more frequently yield growth than do cultures of pleural fluid (90% versus 66%).[47]

Isolation of bacteria from tracheal aspirates or pleural fluid may be affected by prior antimicrobial treatment. The chances of culturing bacteria from tracheal aspirate or pleural fluid samples may be increased by collection of samples after withholding antimicrobials from the horse for 24 hours. While briefly withholding antimicrobials may not be contraindicated in horses with chronic disease, it is not recommended for horses with acute disease.

Necropsy examination

The pneumonia involves all areas of the lungs but is most severe in the cranial and ventral regions. The pleura are thickened and have adherent fibrin tags and there is excessive pleural fluid. The pleural fluid contains strands of fibrin and is usually cloudy and serosanguineous to yellow. Histologically, there is a purulent, fibrinonecrotic pneumonia and pleuritis.

Diagnostic confirmation

The presence of excessive pleural fluid containing bacteria and degenerate neutrophils in combination with clinical signs of respiratory disease provides confirmation of the disease.

Diseases that cause respiratory distress and pleural effusion in horses are listed in Table 31.3.

Table 31.3 Diseases causing pleural effusion in horses

Pleuropneumonia
Intrathoracic neoplasia including extension of gastric squamous cell carcinoma
Penetrating chest wounds
Esophageal perforation
Diaphragmatic hernia
Congestive heart failure
Hemangiosarcoma (causing hemothorax)
Pulmonary hydatidosis
Pulmonary infarction
African horse sickness

Treatment and prognosis

Therapeutic aims

The therapeutic aims are prompt institution of broad-spectrum antimicrobial therapy, removal of infected pleural fluid and cellular debris including necrotic lung, relief of pain, correction of fluid and electrolyte abnormalities, relief of respiratory distress, prevention and treatment of complications including laminitis (for discussion of complications, see 'Prognosis').

Therapy

Antimicrobial therapy The prompt institution of systemic, broad-spectrum antimicrobial therapy is the single most important component of treatment of horses with pleuropneumonia (Table 31.4). Antimicrobial therapy is almost always started before the results of bacterial culture of pleural fluid or tracheal aspirate are available and antimicrobial sensitivity of isolated bacteria determined. Use of antibiotics or combinations of antibiotics with a broad spectrum of antimicrobial activity is important because of the polymicrobial nature of most infections. The wide range of Gram-positive and Gram-negative bacteria associated with the disease (see 'Etiology') makes prediction of the susceptibility of the causative organisms difficult. Furthermore, superinfection with bacteria, especially Enterobacteriaceae and obligate anaerobes, commonly occurs in horses with disease initially caused by a single bacterial species. Administration of drugs that are effective in the treatment of penicillin-resistant obligate anaerobes is also important.

Antimicrobial therapy should be broad spectrum to include coverage of the likely bacteria involved in the disease. It should therefore provide coverage against *Streptococcus* spp., *Actinobacillus*/*Pasteurella* spp., Enterobacteriaceae and anaerobes including *Bacteroides* spp. A combination of penicillin G, an aminoglycoside and metronidazole provides broad-spectrum coverage and is a frequently used empirical therapy until the results of bacterial culture are known. Results of bacterial culture and subsequent antimicrobial susceptibility testing may aid selection of further antimicrobials. However, superinfection with Gram-negative and anaerobic bacteria is common and there is a sound rationale for continued use of a combination of antimicrobials providing broad-spectrum coverage throughout treatment of the disease.

Antimicrobial therapy will be prolonged in most cases, usually being required for at least one month and often several months. As the disease resolves it may be possible to

Table 31.4 Antimicrobial agents and recommended doses for treatment of pleuropneumonia in horses

Drug	Dose, route and interval	Comments
Procaine penicillin G	22 000–44 000 IU/kg, i.m. q 12 h	Effective against *Streptococcus* spp. and most anaerobes with the exception of *Bacteroides fragilis*. Achieves low plasma concentrations but has prolonged duration of action. Cheap. Synergistic with aminoglycosides. Should not be used as sole treatment
Sodium or potassium penicillin G	22 000–44 000 IU/kg, i.v. q 6 h	Effective against Gram-positive organisms (except penicillinase producing bacteria such as *Staphylococcus* spp.) and most anaerobes. Achieves high plasma concentrations. Synergistic with aminoglycosides. Expensive
Ampicillin sodium	11–22 mg/kg, i.v. or i.m., q 6 h	Wider spectrum than penicillin G. Achieves high plasma concentrations. Synergistic with aminoglycosides
Ceftiofur sodium	2.2 mg/kg, i.m. or i.v. q 12 h	Wide spectrum of action against Gram-positive and -negative organisms and most anaerobes. Can be used as sole treatment, though not recommended. Clinical results sometimes disappointing
Chloramphenicol	50 mg/kg, p.o. q 6 h	Good spectrum of action including anaerobic bacteria. Poor oral bioavailability and disappointing clinical efficacy. Use prohibited in some countries. Potential human health hazard
Gentamicin sulfate	7 mg/kg, i.v. or i.m. q 24 h	Active against *Staphylococcus* spp. and many Gram-negative organisms. Inactive against anaerobes. Poor activity against *Streptococcus* spp. Synergistic with penicillin
Amikacin sulfate	21 mg/kg, i.v. or i.m. q 24 h	Wider spectrum of Gram-negative activity than gentamicin. Expensive
Trimethoprim-sulfonamides	15–30 mg/kg, p.o. q 12 h	Theoretical wide spectrum of action. Disappointing clinical efficacy
Rifampin	5–10 mg/kg, p.o. q 12 h	Penetrates abscesses well. Active against Gram-positive bacteria and some Gram-negative. Must be used in conjunction with another antibiotic (not an aminoglycoside)
Ticarcillin-clavulanic acid	50 mg/kg, i.v. q 6 h	Broader spectrum of Gram-negative activity than penicillin G. Expensive
Metronidazole	15–25 mg/kg, p.o. q 6–8 h	Active against anaerobes only. Used in conjunction with other antimicrobials (especially penicillin and aminoglycosides). Neurotoxicity rare

i.v., intravenous; p.o., orally; i.m., intramuscular; q, every.

change from parenteral antibiotics to orally administered antibiotics such as a combination of trimethoprim and a sulfonamide, although the clinical response to this combination is sometimes disappointing.

Cessation of antimicrobial therapy should be based on lack of fever, nasal discharge, respiratory distress or cough, lack of evidence of intrathoracic abscesses on ultrasonographic and radiographic examination of the thorax, and resolution of neutrophilia and hyperfibrinogenemia. There should be no appreciable pleural fluid on ultrasonographic examination.

Drainage of pleural fluid Chronic, effective drainage of the pleural cavity and intrathoracic abscesses is critical for successful treatment of horses with pleuropneumonia.[52] Horses with sterile pleural fluid may require only a single drainage of pleural fluid. More severely affected horses may require intermittent drainage on each of several days, and most cases will require insertion of a tube into the pleural space to provide continuous drainage for several days to several weeks. Horses with chronic disease may benefit from a thoracotomy that provides continuous drainage and the ability to lavage the chest. Ultrasonographic examination of the chest is very useful in identifying the presence of pleural fluid, the optimal sites for drainage, and the efficacy of drainage.

Intermittent drainage can be achieved by inserting a bovine teat cannula or similar blunt cannula into the pleural

space. This should be done aseptically and under local anesthesia. If ultrasonographic examination is not available, the cannula should be placed in the 6–8th intercostal space on the right side or the 7–9th on the left side just above the level of the olecranon. Pleural fluid that does not contain large fibrin clots (which clog the cannula) can be drained and the cannula removed. However, the process is slow if large quantities of fluid must be removed. Intermittent drainage is indicated when the quantities of pleural fluid are small (< 5 L), relatively cell free, or localized. This situation is most likely to occur in horses with acute disease.

Insertion of large bore trocars (20–30-French, 6–10 mm outside diameter) facilitates rapid fluid removal, allows drainage of viscid fluid and provides continuous drainage (Fig. 31.25). The chest tube should be inserted in an aseptic fashion under local anesthesia at sites indicated by ultrasonographic examination or as described above. A one-way valve should be attached to the external end of the tube to prevent aspiration of air and development of a pneumothorax. A balloon or condom with the end removed is an effective one-way valve. The presence of an intact, functional one-way valve is critical in preventing development of a pneumothorax. The chest tube is secured to the chest wall with a purse-string suture. The tube may be retained for several days to a week, but should be monitored frequently (every few hours) and cleared of fibrin clots as needed.

Complications of drainage of pleural fluid include: collapse of the animal if the fluid is removed too rapidly; pneumothorax; sudden death due to cardiac puncture or laceration of a coronary vessel; and perforation of abdominal viscera. Collapse can be prevented by administering fluids intravenously during pleural fluid drainage and by removing the fluid gradually (over a period of 30 minutes). Some horses develop a cellulitis around the chest tube that requires the tube be removed.

Thoracotomy or resection of a rib may be required in chronic cases to provide drainage of intrathoracic abscesses or chronic pleural effusion that is refractory to treatment with antimicrobials (Fig. 31.26).[52] Thoracotomy is an effective intervention in many horses with advanced pleuropneumonia and should not be considered an emergency or heroic procedure. Dangers of thoracotomy include the development of bilateral pneumothorax with subsequent death, persistent drainage of pleural fluid through a chronic fistula, and diminished athletic performance. Horses in which a thoracotomy, and especially that involving resection of a rib, has been performed are unlikely to return to active racing or similar strenuous athletic endeavors.

Pleural lavage Infusion and subsequent removal of 5–10 L of warm saline or balanced polyionic electrolyte solution into the affected pleural space may be beneficial in the treatment of cases with viscid fluid or fluid containing large

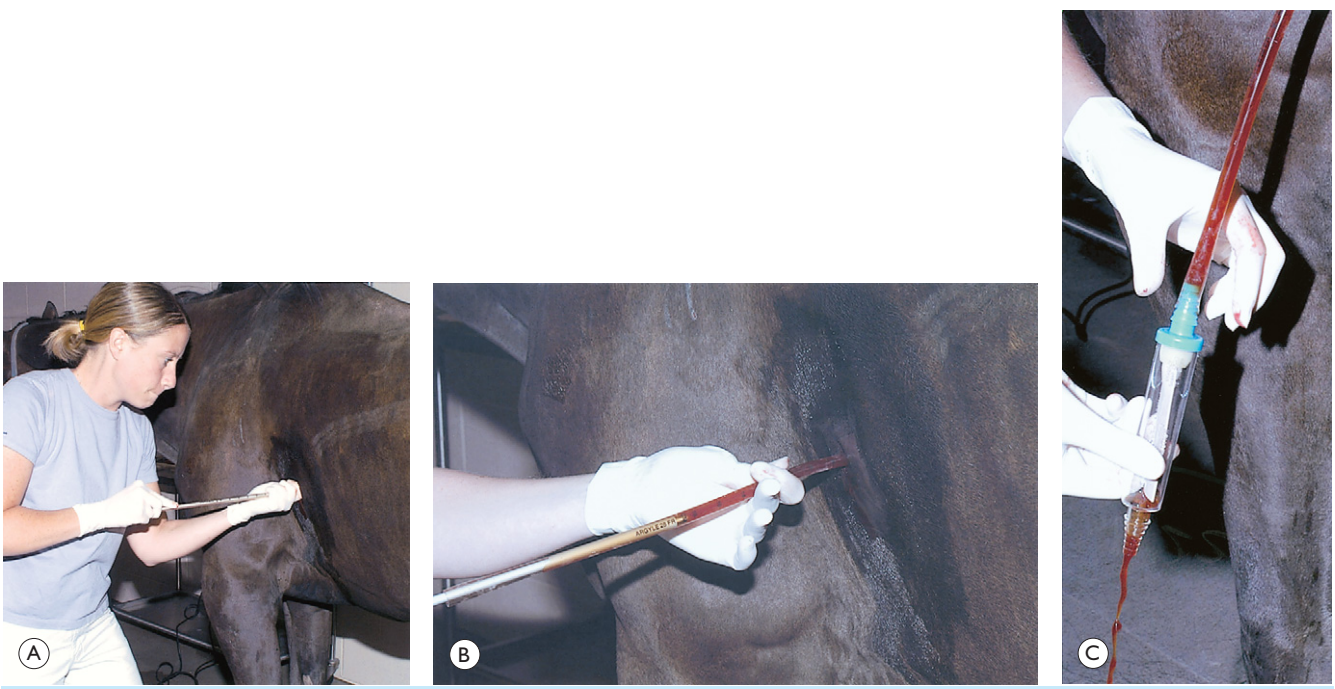

Fig. 31.25
(A) Insertion of a chest tube into a horse with pleuropneumonia. Considerable force is necessary to advance the thick trocar into the horse's chest. The hand of the operator against the chest is used to control the rate at which the trocar is advanced. Once the trocar has penetrated the parietal pleura, evident as a reduction in force needed to advance the trocar, the chest tube is advanced over the trocar into the pleural space. (B) Pleural fluid begins to drain as the trocar is removed from the chest tube. If fluid is not immediately apparent, the chest tube should be repositioned. (C) Attachment of a Heimlich valve or similar one-way valve will permit free drainage of fluid from the pleural space while preventing aspiration of air.

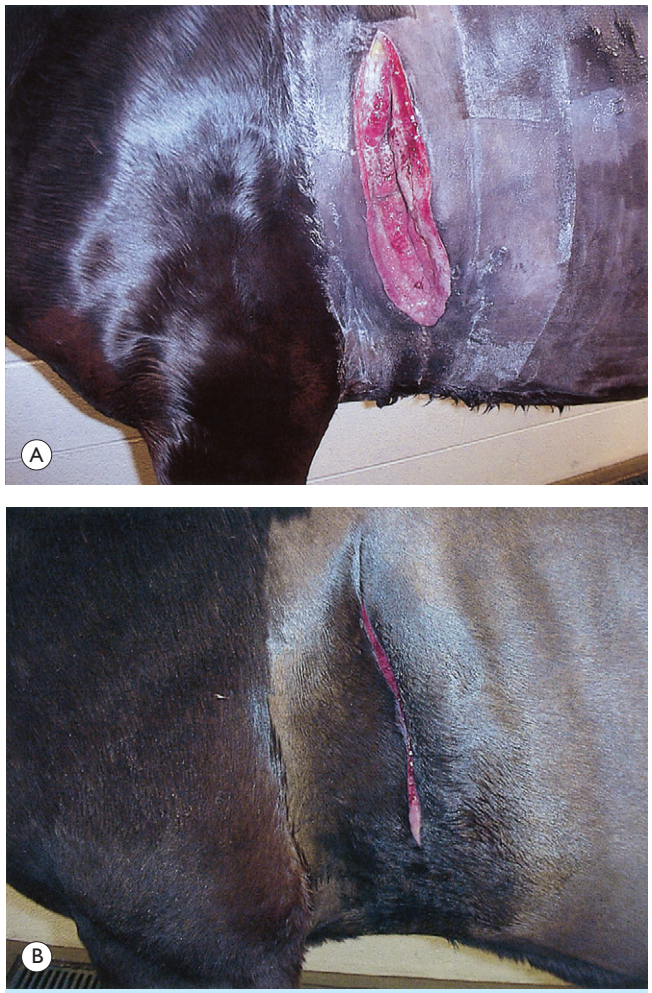

Fig. 31.26
(A) Thoracotomy in a horse with extensive pleural disease. Most thoracotomy incisions will be smaller, but large incisions are sometimes required if there is extensive loculation of fluid. (B) Healed thoracotomy of horse pictured in (A).

amounts of fibrin and cell debris. The fluid can be infused through the chest tube that is used to drain the pleural space. Care should be taken not to introduce bacteria with the infusion.

Supportive therapy Acutely or severely ill horses may be dehydrated, azotemic and have acid–base disturbances. These horses should be treated with appropriate fluids administered intravenously.

Pleuropneumonia is a painful disease and every attempt should be made to relieve the horse's chest pain. Non-steroidal anti-inflammatory drugs including flunixin meglumine (1 mg/kg, by mouth, i.m. or i.v., every 8 hours) or phenylbutazone (2.2 mg/kg, by mouth or i.v., every 12 hours) often provide effective analgesia and presumably reduce inflammation in the pleural space.

Horses should be provided with good nursing care including a comfortable stall, free access to palatable water, and a good diet. Affected horses will often not eat adequately and should be tempted with fresh and nutritious fodder.

Attention should be paid to the horse's feet to detect early signs of laminitis and allow appropriate measures to be taken.

Prognosis

The clinical course of the acute form of the disease may be less than 10 days if effective therapy is instituted before the pleural effusion becomes infected or there is substantial deposition of fibrin in the pleural space. The prognosis for a return to previous function is good in horses that respond to treatment. However, in most cases, even if appropriate therapy is instituted, the disease becomes chronic. The prognosis for life for horses able to be treated aggressively is very good (60–95%) and the prognosis for return to previous function if the horse survives is reasonable (60%).[44,53] The prognosis for return to previous function for horses that developed chronic disease and complications is poor (31%).[53]

Complications

Complications of pleuropneumonia include development of jugular thrombophlebitis (25% of cases), pulmonary, mediastinal or pleural abscesses (10–20% of cases), cranial thoracic mass (5–10% of cases), bronchopleural fistula (5%), pericarditis (2%), and laminitis (1–14%).[44,49,54] Intrathoracic abscesses are evident as chronic disease, weight loss, cough, and fever, and are readily detected by a combination of ultrasonographic and radiographic examination. Cranial thoracic masses are evident as an elevation in heart rate, prominent jugular pulse, spontaneous jugular thrombosis and forelimb pointing. The signs are referable to a mass in the cranial thorax displacing the heart caudally and to the left and impairing venous return to the heart in the cranial vena cava.[54] Ultrasonographic and radiographic examination reveals the presence of the mass. Bronchopleural fistulae develop when a section of pulmonary parenchyma sloughs leaving an open bronchiole that communicates with the pleural space.[55] The bronchopleural fistula can be diagnosed

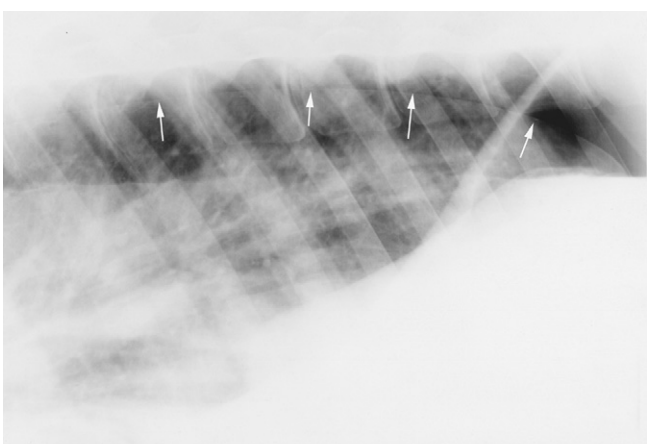

Fig. 31.27
Pneumothorax in a horse with pleuropneumonia. Partially collapsed lung is evident in the dorsal thorax (arrows).

by infusion of fluorescein dye into the pleural space and detecting its presence at the nares, or by pleuroscopic examination.[49] Mild pneumothorax develops in horses with chest tubes that permit aspiration of air into the chest, bronchopulmonary fistulae or thoracotomy (Fig. 31.27).

Etiology

Pleuropneumonia of horses is almost always associated with bacterial infection of the lungs, pleura and pleural fluid. The most common bacterial isolates from tracheal aspirates or pleural fluid of horses with pleuropneumonia are aerobes or facultative anaerobes including: *Streptococcus zooepidemicus*, *Pasteurella* spp., *Actinobacillus* spp., Enterobacteriaceae (particularly *E. coli*, *Klebsiella* spp. and *Enterobacter* spp.), *Pseudomonas* spp., *Staphylococcus* spp. and *Bordetella* spp.[44,47,56] *S. zooepidemicus* is isolated from over 60%, *Pasteurella*/*Actinobacillus* spp. from approximately one-third, and Enterobacteriaceae spp. from approximately 40% of cases.[44,47,56]

Obligate anaerobes isolated include *Bacteroides* spp. (including *B. fragilis*), *Clostridium* spp., *Eubacterium* and *Fusobacterium* spp.[44,47,56] *Bacteroides* spp. are isolated from approximately 20%, *Clostridium* spp. from 10%, and *Eubacterium* spp. from 6% of horses with pleuropneumonia.[47] *Mycoplasma felis* is an unusual cause of pleuritis in horses.[57]

Equine pleuropneumonia is associated with polymicrobial infections of the lungs and pleura in 50–80% of cases, although disease caused by infections of a single bacterial species occurs.[47,56] Infections by single bacterial species are usually by *S. zooepidemicus*, *Pasteurella*/*Actinobacillus* spp., or Enterobacteriaceae whereas almost all infections by anaerobes are polymicrobial.[47] Infection by obligate anaerobic bacteria is associated with disease of greater than 5–7 days' duration.[58]

Pleuritis is also caused by penetrating chest wounds, perforated esophagus, thoracic neoplasia and pulmonary hydatidosis.[44,59–61] Other diseases, such as congestive heart failure, may cause pleural effusion without inflammation.

Pathogenesis

Bacterial pleuropneumonia develops following bacterial colonization of the lungs with subsequent extension of infection to the visceral pleura and pleural space. Organisms initially colonizing the pulmonary parenchyma and pleural space are those normally present in the upper airway, oral cavity and pharynx, with subsequent infection by Enterobacteriaceae and obligate anaerobic bacteria.[58] Bacterial colonization and infection of the lower airway is attributable to either massive challenge or a reduction in the efficacy of normal pulmonary defense mechanisms or a combination of these factors.[58] Factors that increase bacterial contamination of the lower respiratory tract include prolonged head elevation, such as may occur during transportation, impaired pulmonary defense mechanisms secondary to viral respiratory tract disease, aspiration of feed material in dysphagic horses, and aspiration of dirt and grass during high intensity exercise.[58,62–64] Transportation may also impair the activity of pulmonary defense mechanisms allowing otherwise innocuous bacterial contamination to cause disease.[62]

Bacterial multiplication in pulmonary parenchyma is associated with the influx of inflammatory cells, principally neutrophils, tissue destruction and accumulation of cell debris in alveoli and airways. Infection spreads both through tissue and via airways. Extension of inflammation, and later infection, to the visceral pleura and subsequently pleural space causes accumulation of excess fluid within the pleural space. Pleural fluid accumulates because of a combination of excessive production of fluid by damaged pleural capillaries (exudation) and impaired reabsorption of pleural fluid by thoracic lymphatics.

Accumulation of parapneumonic pleural effusions has been arbitrarily divided into three stages: (1) exudative, (2) fibrinopurulent, and (3) organizational.[65] The exudative stage is characterized by the accumulation of sterile, protein-rich fluid in the pleural space as a result of increased pleural capillary permeability. Bacterial invasion and proliferation, further accumulation of fluid, and deposition of fibrin in pleural fluid and on pleural surfaces occurs if the disease does not resolve rapidly and is referred to as the fibrinopurulent stage. The organizational stage is associated with continued fibrin deposition, restriction of lung expansion and persistence of bacteria. The pleural fluid contains much cellular debris and bronchopleural fistulae may develop.

Epidemiology

Pleuropneumonia occurs worldwide in horses of all ages and both sexes, although most cases occur in horses > 1 and < 5 years of age.[47] Estimates of the incidence or prevalence of the disease are not available. The case fatality rate varies between 5 and 65%, with the higher rate reported in earlier studies.[53,66]

Risk factors

The risk of a horse developing pleuropneumonia is increased by 4 if the horse is a Thoroughbred race horse, 14 if the horse was transported more than 500 miles in the previous week, 10 if the horse has a recent (< 2 week) history of viral respiratory tract disease or exposure to a horse with such disease, and 4 if the horse has raced within the previous 48 hours.[43] Other suggested risk factors include general anesthesia, surgery, disorders of the upper airway, exercise-induced pulmonary hemorrhage, esophageal obstruction and dysphagia.

Prevention

Prevention of pleuropneumonia involves reduction of risk factors associated with the disease. The main risk factors are other infectious respiratory disease and transportation. Every effort should be made to prevent and treat respiratory disease in athletic horses, including institution of effective

vaccination programs. Horses with infectious respiratory disease should not be vigorously exercised until signs of disease have resolved.

Transportation of athletic horses is common and essential for their participation in competitive events. It cannot, therefore, be eliminated. Every effort should be made to minimize the adverse effects of transportation on airway health. Recommendations for transport of horses first made in 1917 are still relevant.[67,68] Updated, these recommendations include the following:

- Not transporting a horse unless it is healthy. Horses with fever should not be transported.
- Knowledgeable staff familiar with the horse should accompany the horse.
- Suitable periods of rest and acclimation should be provided before recently transported or raced horses are transported.
- The time during which horses are confined for transportation should be kept to a minimum. Horses should be loaded last and unloaded first in flights with mixed cargo.
- The route taken should be the most direct and briefest available.
- Horses should be permitted adequate time to rest at scheduled breaks. If possible, on long journeys horses should be unloaded and allowed exercise (walking) and access to hay and water.
- Horses should have frequent, preferably continuous, access to feed and water during transportation.
- Horses should not be exercised after arrival until they are free of fever, cough or nasal discharge.
- Horses should not be restrained during transportation such that they are unable or unwilling to lower their head.
- Air quality should be optimal in the vehicle used to transport the horse.

CHAPTER 32

Heart and vessels: function during exercise and response to training

David C. Poole and Howard H. Erickson

The horse is often considered one of, if not the, premier athletic mammalian species. However, depending upon the criterion used there are other distinct (and sometimes surprising) contenders for that title. For example, as seen in Fig. 32.1, compared with the Thoroughbred race horse (65 km/h, 40 miles/h), the cheetah can achieve speeds in excess of 70 miles/h (120 km/h) and several species of antelope as well as the blackbuck, gnu and ostrich are all faster than the horse (fastest human ~27 miles/h, 43 km/h). The fastest horses ever clocked are Quarter Horses which may reach speeds of 50–55 miles/h (90 km/h).[1] Because body length determines the distance that individual muscles shorten, it might be more appropriate to judge athletic ability in terms of speed relative to body length.[2] From this perspective, the Merriam kangaroo rat is superlative, achieving 110

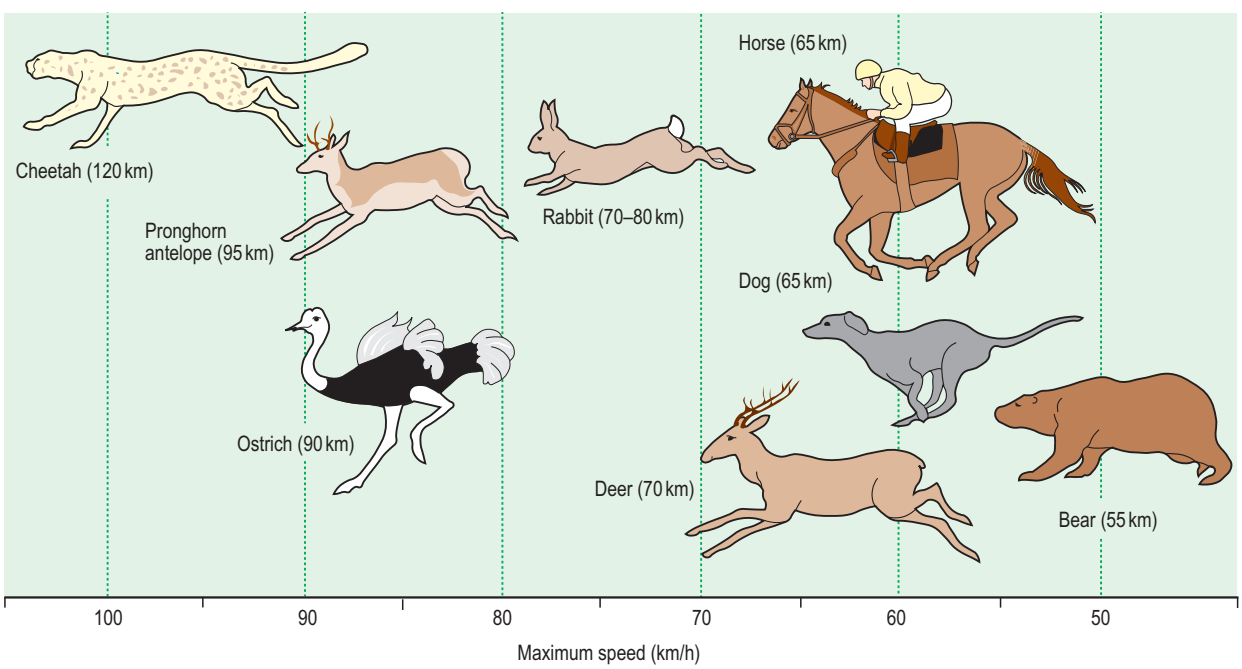

Fig. 32.1
Approximate maximum speeds for a variety of terrestrial mammalian species and the ostrich. Please note that the Quarter Horse has been clocked close to 90 km/hr (55 miles/h)[1] whereas maximal speeds for the Thoroughbred as seen in this figure with rider are somewhat lower. For converting to other commonly used units: 10 km/h = 6.2 miles/h or 2.8 m/s.

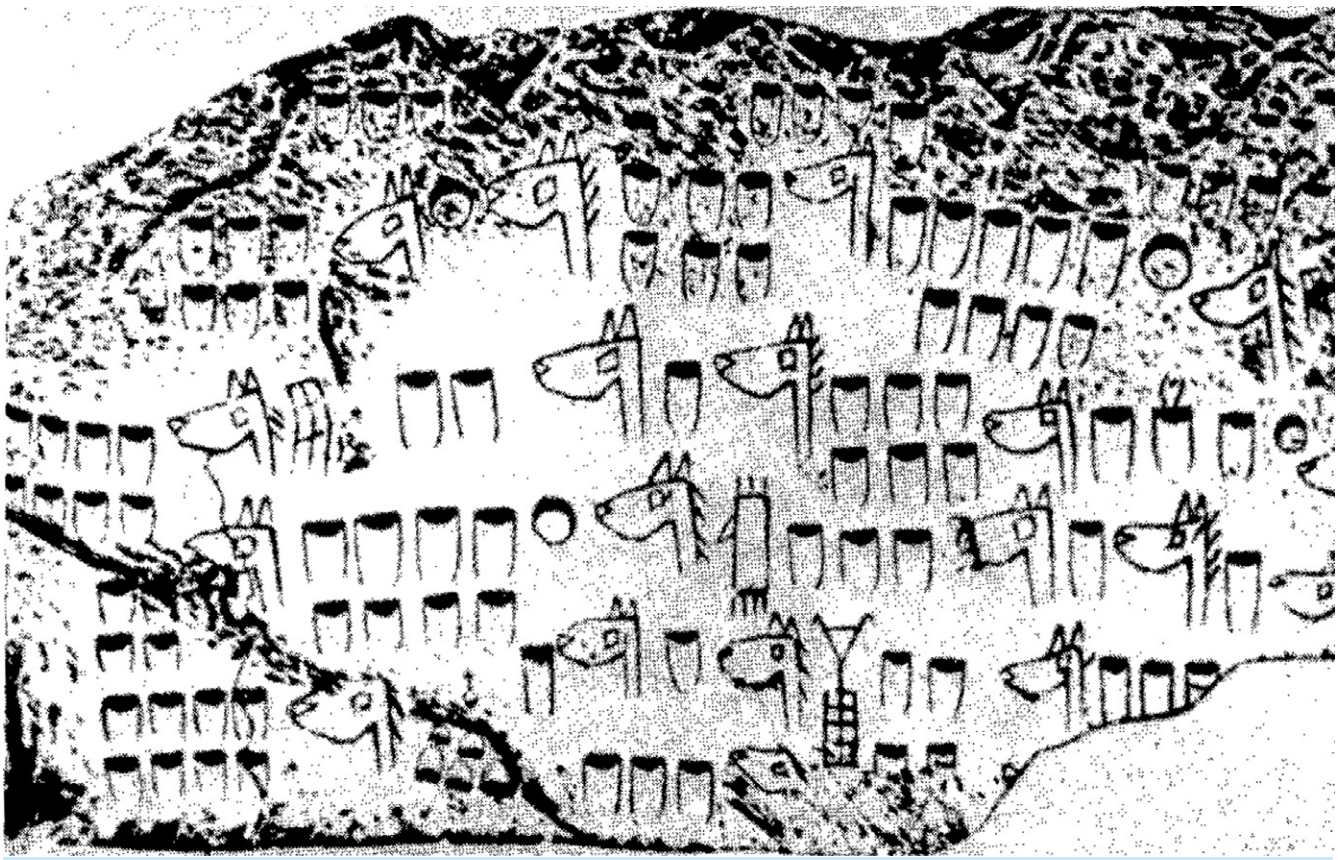

Fig. 32.2
Chaldean pedigree chart (circa 4000 BC) demonstrating that selective breeding of horses was practiced at least 6000 years ago. (Reproduced with kind permission from Lyons and Petrucelli[6] and the World Health Organization, Geneva.)

body lengths per second which is three times faster than the cheetah (32 length/s) and an order of magnitude faster than the horse (~10 length/s).

Within humans, the aerobic capacity or maximal oxygen uptake ($\dot{V}O_{2max}$) is considered an excellent (though by no means the sole) indicator of performance for running events over 1 minute in duration. Across the spectrum of terrestrial mammalian species, aerobic capacity increases over five orders of magnitude as a function of body size from approximately 0.001 L/min in the 2-g Etruscan shrew (world's smallest mammal) to in excess of 80 L/min in the elite Thoroughbred race horse. Whereas it is possible that a large rapidly walking elephant may have a higher total $\dot{V}O_2$, this remains to be demonstrated. When aerobic capacity is expressed relative to body mass, the diminutive Etruscan shrew (~ 400 mL O_2/kg/min)[2,3] reigns supreme as this measure of performance decreases systematically with increasing body mass. Amongst the larger animals, the pronghorn antelope (~ 300 mL O_2/kg/min)[4] and the horse (> 200 mL O_2/kg/min)[2,5] are outstanding and each can consume more O_2 in toto and per unit body mass than any other mammal of their respective sizes.

This chapter addresses the structural and functional capacities of the cardiovascular system that permit the horse to achieve such prodigious O_2 flows and athletic performances. As we shall see, a large, high-capacity heart is requisite. Whereas animals such as the shrew and pronghorn antelope have evolved in accordance with the laws of nature, the horse has been subjected to several thousand years of selective breeding (Fig. 32.2)[6] based upon athletic performance. As detailed below, this practice has produced a disproportionate increase in the horse's heart size and pumping capacity (cardiac output, $\dot{Q}$) compared to lung capacity; the consequence of this is a structural and functional failure of the respiratory system during maximal exercise.

The purpose of this chapter is to present those features of the equine heart and cardiovascular system that facilitate this animal's extraordinary performance. Those mechanisms underlying respiratory system failure will be discussed as they relate intimately to the cardiovascular system. Particular attention will be afforded to the plasticity of the equine cardiovascular system to exercise training and although such changes are important, compared with the magnitude of inherited interanimal variations, they are relatively modest. Throughout this chapter and contingent upon available data, reference will be made to several other species including the human, dog, ox, and camel as a basis for comparison (Fig. 32.3).[7]

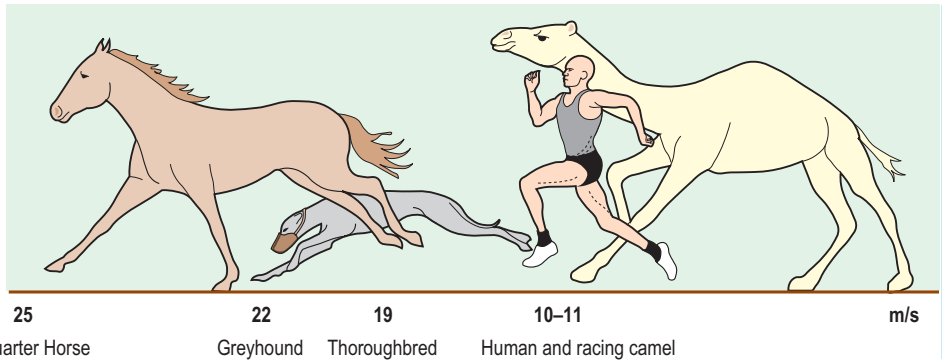

Fig. 32.3
Relative maximum speed in m/s of the four main athletic species. For converting to other commonly used units: 10 m/s = 36 km/h or 22 miles/h. (Revised from Derman & Noakes.[7])

Role of the heart and cardiovascular system in setting aerobic capacity $\dot{V}O_{2max}$

The energetic capability of skeletal muscle is so high that it far surpasses the capacity of the respiratory and cardiovascular systems to deliver O_2. In Thoroughbreds skeletal muscle comprises over 50% of body mass[8] and aerobic capacity ($\dot{V}O_{2max}$) (at least of Standardbreds) increases as a function of fat-free mass.[9] Moreover, under many conditions $\dot{V}O_{2max}$ is considered to be O_2-supply limited because the mitochondrial oxidative enzyme capacity for utilizing O_2 exceeds that of the cardiorespiratory systems to deliver O_2. In support of this notion, there is strong evidence that increasing muscle O_2 delivery during intense exercise will elevate $\dot{V}O_{2max}$. Specifically:

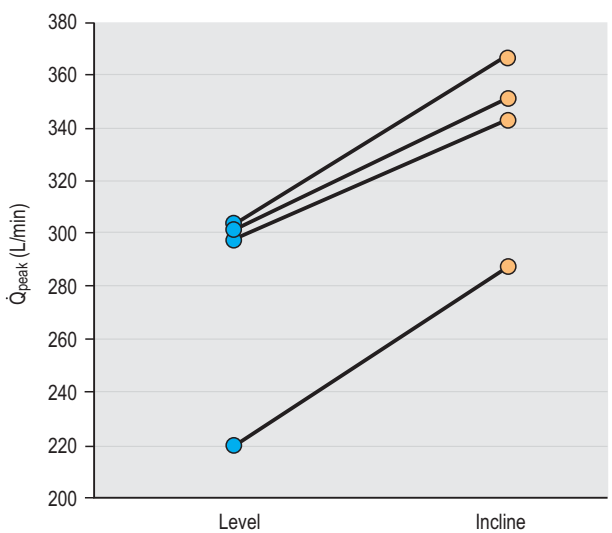

Fig. 32.4
Running on an incline (6°) significantly increases cardiac output at maximal exercise ($\dot{Q}_{peak}$) and also elevates $\dot{V}O_{2max}$. (Redrawn from McDonough et al.[12])

1. Breathing high O_2 mixtures elevates arterial O_2 content and $\dot{V}O_{2max}$ in horses[10] and humans.[11]
2. With respect to equine $\dot{V}O_{2max}$, there is recent evidence that horses run to maximal speeds on an incline (6°) exhibit higher cardiac output ($\dot{Q}$) (Fig. 32.4) and $\dot{V}O_{2max}$ values than on the flat. This increased $\dot{Q}$ and $\dot{V}O_{2max}$ results from an elevated stroke volume[12] and may relate to greater hindlimb muscle recruitment, greater swings in intrapleural pressures (higher tidal volume) aiding heart function, and/or increased hydrostatic pressures improving muscle blood flow.
3. Pericardectomy elevates stroke volume, cardiac output and $\dot{V}O_{2max}$ in dogs[13] and pigs.[14]
4. Restricting the exercising muscle mass in humans to 2–3 kg (knee extensors) rather than the 15–20 kg recruited during running or cycling elevates mass specific $\dot{V}O_2$.[15,16]
5. Blood doping (reinfusion of autologous red cells) elevates $\dot{V}O_{2max}$ in humans.[17]

Several steps in the pathway of O_2 from the atmosphere to its site of utilization within muscle mitochondria may limit the achievable $\dot{V}O_{2max}$.[18,19] These include O_2 diffusion across the blood–gas barrier in the lungs, conductive transport of O_2 in the blood (cardiac output, $\dot{Q}$, and O_2 concentration, Cao_2) and diffusion of O_2 from the skeletal muscle capillary into the myocyte. The coordinated function of respiratory, cardiovascular and muscular systems provides for rapid changes in O_2 flux from lungs to mitochondria (Fig. 32.5) and in most species, including the horse, human, and dog, the strongest determinant of $\dot{V}O_{2max}$ is the capacity of the cardiovascular system to transport O_2 (i.e. $\dot{Q}o_2$, Fig. 32.6). However, during maximal exercise in the horse other steps in the O_2 pathway also become limiting in large part because of the disproportionality between the cardiovascular and respiratory systems. For example, O_2 loading in the lung is impaired and arterial hypoxemia becomes manifested (see 'Cardiovascular physiology and responses to exercise' below). In addition, the ability to offload O_2 in the muscle capillary is limited by the finite O_2 diffusing capacity of skeletal muscle which is determined by the capillary bed and blood flow within those capillaries. Fig. 32.7 integrates the conductive and diffusive elements of O_2 transport to demonstrate how the horse achieves its very high $\dot{V}O_{2max}$.

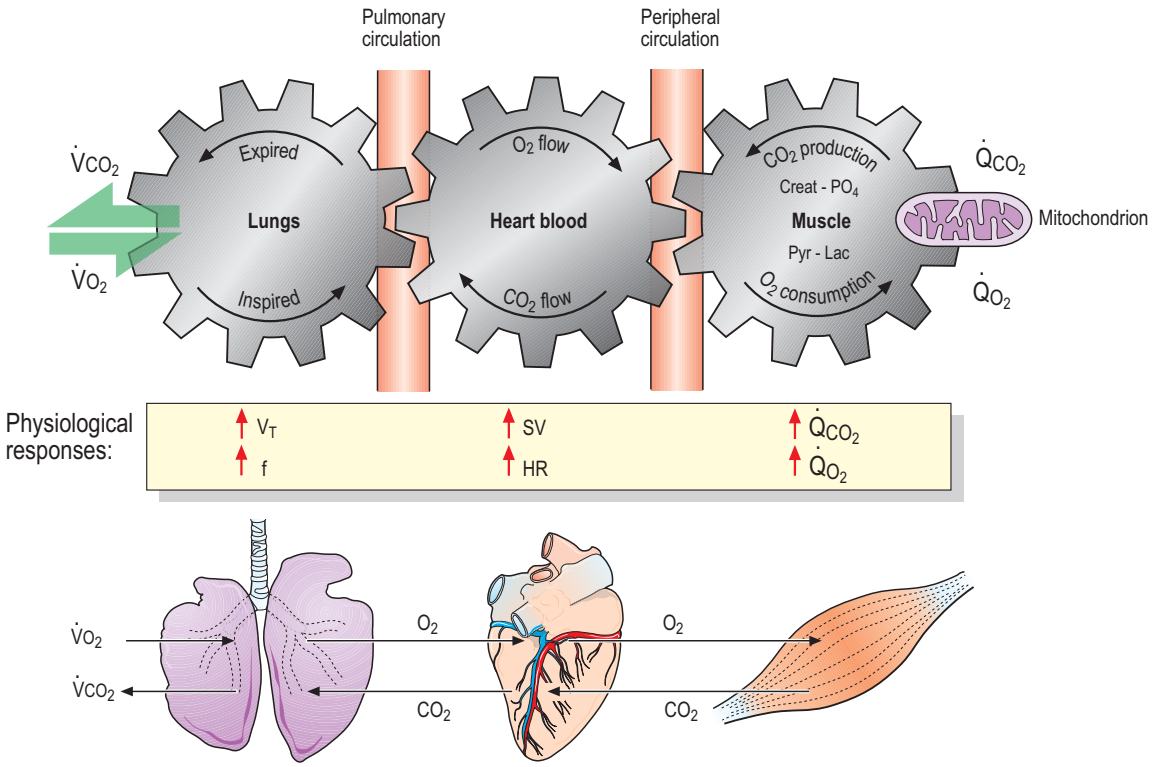

Fig. 32.5
Illustration of the pathway for oxygen (O_2) from the atmosphere to its site of utilization within muscle mitochondria. The cogs demonstrate that the respiratory (lungs), cardiovascular (heart and blood vessels), and muscle systems must increase O_2 flux in a tightly coordinated fashion to effectively deliver adequate O_2 to facilitate muscular performance. $\dot{Q}O_2$, mitochondrial O_2 delivery; $\dot{V}O_2$, oxygen uptake; $\dot{V}CO_2$, CO_2 output, SV, stroke volume; HR, heart rate; V_T, tidal volume; *f*, breathing frequency; CO_2, carbon dioxide; Creat, creatine; Pyr, pyruvate; Lac, lactate; $\dot{Q}CO_2$, mitrochondrial carbon dioxide production. (Upper panel redrawn from Wasserman et al 1994.[20])

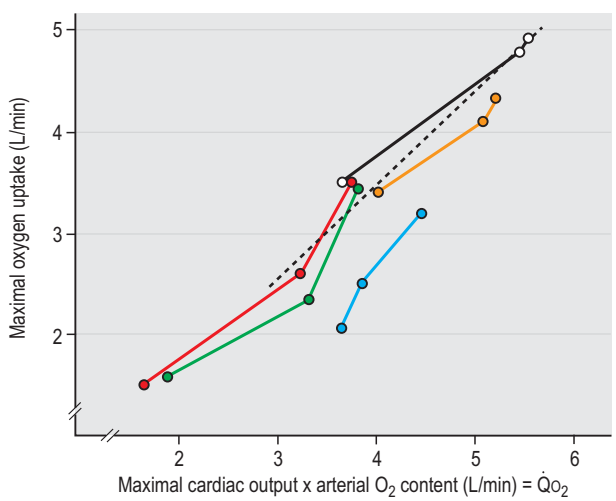

Fig. 32.6
Relationship between increased O_2 delivery ($\dot{Q}O_2$) and maximal oxygen uptake ($\dot{V}O_2$) after bedrest and exercise training in five humans (Redrawn from Saltin et al.[21])

Conductive O_2 transport (lungs to muscle) Given that high rates of O_2 delivery ($\dot{Q}O_2$) are of paramount importance for achieving this high $\dot{V}O_{2max}$, it is instructive to break down the components of $\dot{Q}O_2$:

O_2 delivery = cardiac output × arterial O_2 content

$$\dot{Q}O_2 = \dot{Q} \times CaO_2$$

$$\dot{Q} = HR \times SV$$

Therefore,

$$CaO_2 = ([Hb] \times 1.34 \times \%Sat) + \sim 0.3 \text{ mL/100 mL dissolved } O_2$$

$$\dot{Q}O_2 = HR \times SV \times [Hb] \times 1.34 \times \%Sat$$

$\dot{Q}O_2$ = Heart rate × stroke volume × hemoglobin concentration × O_2 binding capacity of Hb × % of O_2 binding sites filled

In the horse during maximal exercise, SV is determined principally by heart size and HR may approach 240 beats/min which is unusually high for such a large animal. Circulating hemoglobin concentration ([Hb]) increases nearly twofold above rest as red blood cells are released from the large muscular spleen in response to increased sympathetic activity. Table 32.1 demonstrates that the size of the heart and spleen is relatively larger in the horse than in either the ox or man. Relative heart size in the athletic dog approaches that found in the horse, but the horse is unusual in that the spleen is so large. Note that in the horse, the proportion of skeletal muscle is very high (close to 50%) and the lungs are relatively small (particularly with respect to heart size, see 'Cardiovascular physiology and responses to exercise' below). A comparison between actual heart size and $\dot{V}O_{2max}$ in the athletic horse and human is shown in Fig. 32.8.

Diffusive O_2 transport within muscle $\dot{V}O_{2max}$ is the product of $\dot{Q}_{max}$ and the extraction of O_2 primarily by the muscles as described by the Fick equation:

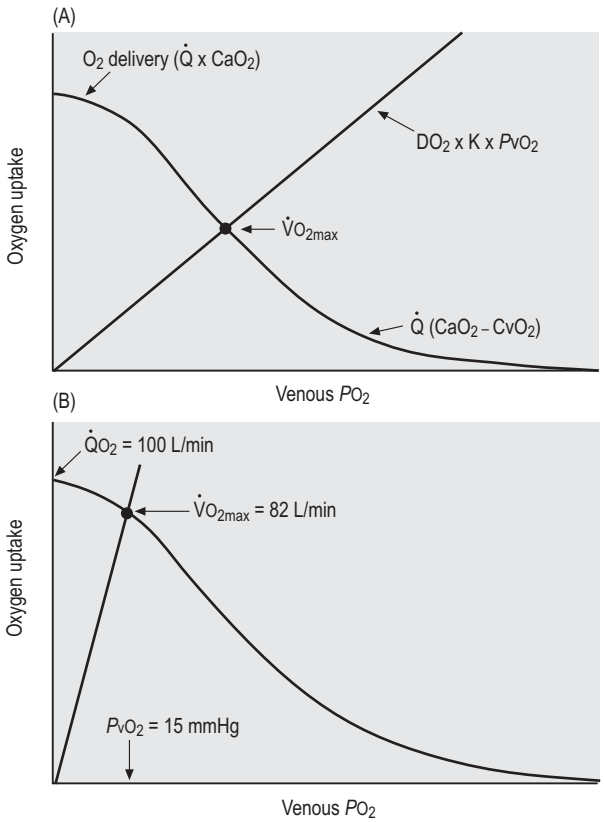

Fig. 32.7
Determination of maximal O_2 uptake ($\dot{V}O_{2max}$) by conductive ($\dot{Q}O_2$) and diffusive movement of O_2 by the cardiovascular and muscle microcirculatory systems ("Wagner" diagram[18]). The curved line denotes mass balance according to the Fick principle and the straight line from the origin represents Fick's law of diffusion. DO_2 is effective diffusing capacity and K is a constant that relates venous PO_2 to mean capillary PO_2. PvO_2, CaO_2, and CvO_2 are the partial pressure of venous O_2 and the concentrations of O_2 in arterial and venous blood, respectively. $\dot{V}O_{2max}$ occurs at the intersection of the two relationships. (A) is a general schematic whereas (B) presents actual values for a very fit Thoroughbred at maximal exercise. Understanding the conductive and diffusive determinants of $\dot{V}O_{2max}$ is essential for interpreting the structural and functional mechanisms that increase $\dot{V}O_{2max}$ with exercise training (see p. 720). See text for additional details.
((A) redrawn from Wagner et al.[18])

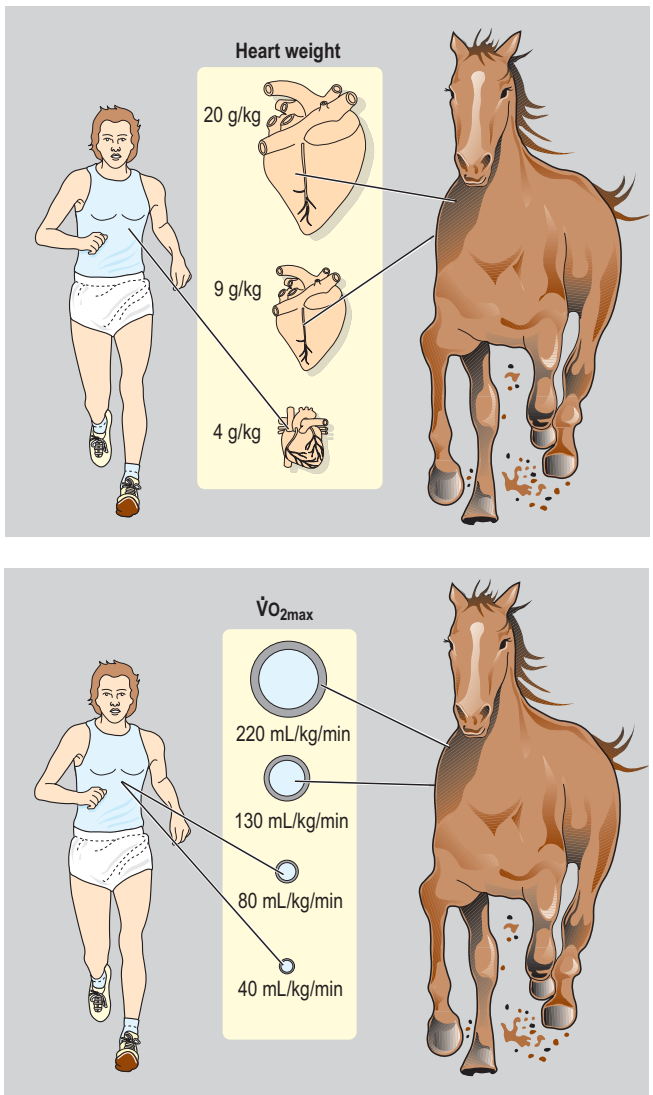

Fig. 32.8
Comparison of heart size (per kg body weight) and $\dot{V}O_{2max}$ ranges within healthy human and equine populations. Note that exercise training increases heart size and weight and also $\dot{V}O_{2max}$ (see Table 32.7 for references).

Table 32.1 Relative comparison of the weight of organs key to the loading and transport of O_2 as a % of body weight. (Data from Webb & Weaver[22])

	Horse	Dog	Ox	Man
Spleen	0.2–1.1	0.3	0.2	0.3
Heart	0.7–1.1	0.8	0.4	0.5
Lungs	0.9–1.5	0.9	0.7	1.4

$$\dot{V}O_{2max} = \dot{Q}_{max} \times (CaO_2 - CvO_2)$$

where CaO_2 and CvO_2 denote arterial and mixed venous O_2 contents. Figure 32.7 demonstrates that the effective muscle diffusing capacity (estimated by the slope of the line projecting from the origin) determines the level to which CvO_2 will fall at maximal exercise (i.e. extraction) and also the $\dot{V}O_{2max}$. The section 'Cardiovascular physiology and responses to exercise' details the determinants of muscle diffusing capacity.

This chapter deals primarily with horses in their athletic prime and considers their maximal capacities irrespective of age per se. In this respect, horses increase their cardiovascular (Fig. 32.9) and muscle oxidative enzyme (Table 32.2) capacities substantially during their first 3 years. Thus, 3- to 4-year-old horses have larger hearts,[23,25] and a lower HR[23] (larger stroke volume) at a given running speed, as well as a reduced blood lactate response to submaximal running

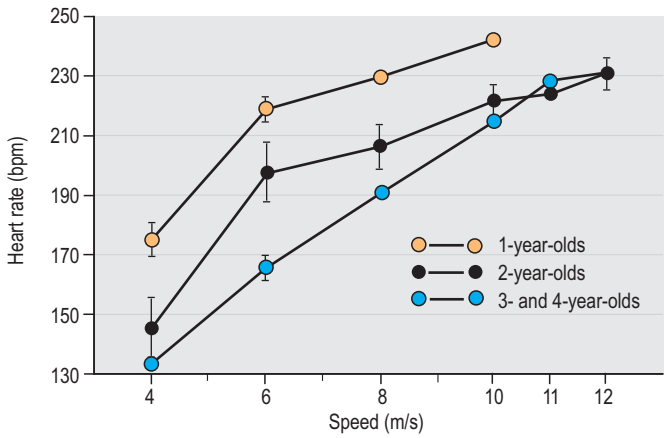

Fig. 32.9.
Reduction in heart rate response to running as a function of age which reflects increased heart size and stroke volume at 2–4 years of age in comparison with 1 year olds. (Redrawn from Rose et al.[23])

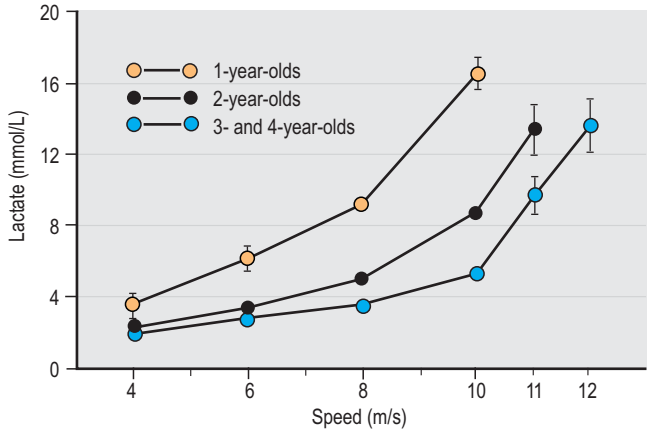

Fig. 32.10
Decreased blood lactate response to submaximal running speeds as horses age from 1 to 3 and 4 years. (Redrawn from Rose et al.[23])

speeds (Fig. 32.10).[23] The mechanistic bases for these last two alterations as they relate to increased heart size and vascular adaptations which improve muscle O_2 delivery and exchange are encompassed within the training section of this chapter ('Exercise training').

Anatomy of the cardiovascular system

Heart size

The size of the heart is a key determinant of maximum stroke volume, cardiac output, and hence aerobic capacity and exercise performance (Figs 32.11–13). This relationship has been documented in humans by examination of the electrocardiogram (ECG), ultrasound, radiographs, and post-mortem examination of heart size. For example, Paavo Nurmi, multiple Olympic champion distance runner reportedly had a heart mass nearly three times larger than predicted for his body size. At post-mortem, the heart of the seven-time Boston Marathon winner Clarence DeMar, who died of a nonmyocardial cancer, was substantially larger than normal and his coronary arteries were threefold larger than found in his nonathletic counterparts.[27]

In horses, heart mass approximates 0.9–1% of body mass, which is greater than that for other nonathletic species (Fig. 32.14) and may be as much as 1.1% of body mass in trained horses.[22] Amongst different horse breeds, racing horses have proportionally larger hearts (Fig. 32.14) and Table 32.3 lists some famous horses and their heart weights. The heaviest horse heart actually weighed was that of Sham at 18 lb (8.2 kg), who was consistently runner-up to Secretariat. Secretariat was a Triple Crown winner and holds the track record at Belmont Park (2 min 24.4 s for 1.5 miles on turf).

Table 32.2 Citrate synthase (CS), 3-hydroxy-Acyl CoA dehydrogenase (HAD), and lactate dehydrogenase (LDH) activities in the middle gluteal muscle of Thoroughbreds and Standardbreds of different ages. (Reproduced with kind permission from Snow & Valberg[24])

		Enzyme activities (mmol/kg/min)							
		Thoroughbreds				Standardbreds			
Age	Sex	No.	CS	HAD	LDH	No.	CS	HAD	LDH
1	M	20	31	20	1793	10	29	29	1936
1	S	21	32	18	1714	15	30	23	1927

4–6	S	24	67	38	1397	15	68	34	1460
Age			XXX	XXX	XX		XXX	NS	XXX
Sex			NS	NS	NS		NS	NS	NS

Note: Significance over the four age groups: XX, $P < 0.01$; XXX, $P < 0.001$; M, mare (filly); S, stallion (colt).

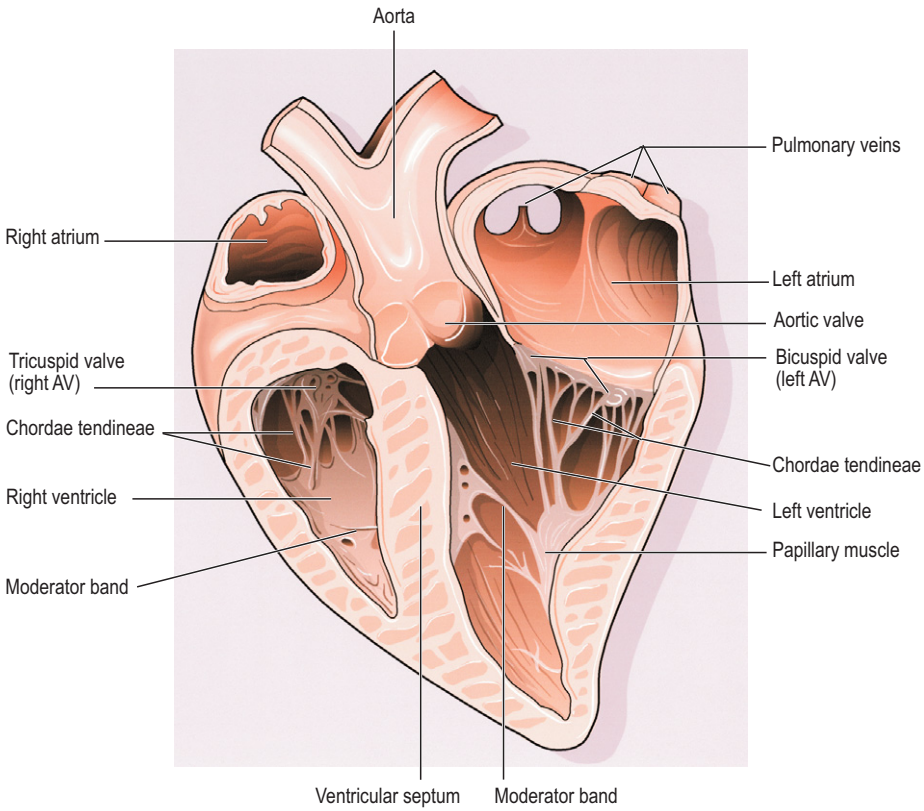

Fig. 32.11
Cross-section of the equine heart showing principal anatomic structures. AV, atrioventricular valve (see Fig. 32.12).

Tragically, Secretariat's heart was never weighed. However, the same pathologist, Dr Thomas Swerczek, who weighed Sham's heart estimated that Secretariat's heart weighed 22 lb (10 kg) and he considered it to be in perfect condition.[27] If that weight is correct, Fig. 32.13A predicts that Secretariat may have achieved a cardiac output in excess of 500 L/min and Fig. 32.13B a $\dot{V}o_{2max}$ over 120 L/min! To place heart size in visual perspective, Fig. 32.15 compares Key to the Mint's 15.8 lb (7.2 kg) heart to that of an unexceptional stallion.

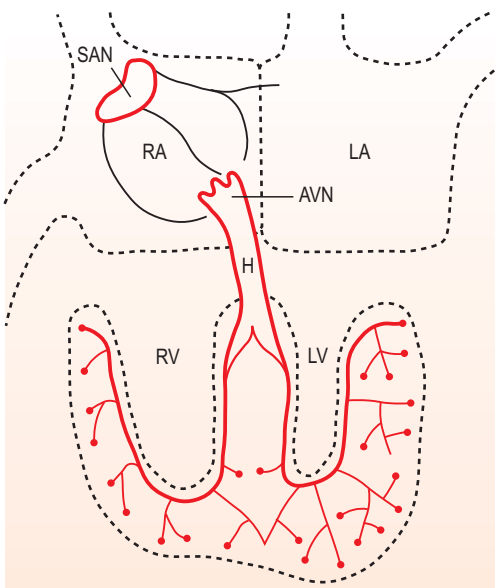

Fig. 32.12
Conduction system of the equine heart which is composed of specialized cardiac muscle fibers rather than nerves. Note the extensive arborization of the Purkinje fibres across the ventricular walls that is characteristic of the horse heart and which results in effective depolarization from multiple points. SAN, sinoatrial node; RA, right atrium; LA, left atrium; AVN, atrioventricular node; H, bundle of His; RV, right ventricle; LV, left ventricle. (Courtesy of R. Hamlin).

Given the crucial importance of heart size in setting athletic potential, there has been great interest in establishing a convenient and accurate noninvasive method of estimating this variable in horses. The mean/average duration of the QRS complex (in ECG leads I, II, and III, Fig. 32.16) has been shown to correlate with heart mass at autopsy and also racing performance.[28] Thus, larger hearts have a wider QRS complex and the so-called 'heart score' measured in milliseconds has been related to heart mass and subsequently predicted stroke volume and cardiac output as shown in Tables 32.4 and 32.5. It should be noted, however, that other studies have not been able to confirm the relationship between heart score and heart mass.[29–33] Based upon the inheritance of heart scores in race horses,[34] there is currently great interest in identifying the gene, located on the X-chromosome, that codes for heart mass.[27]

An important feature of the equine heart that may contribute to exercise-induced pulmonary hypertension concerns the disparity in size of the right and left atrioventricular (AV) valves. Specifically, at Kansas State University Professors M. Roger Fedde and Howard H. Erickson (unpublished findings) have determined that the cross-sectional area of the left AV valve is only 63% that of the right AV valve (i.e. 38.1

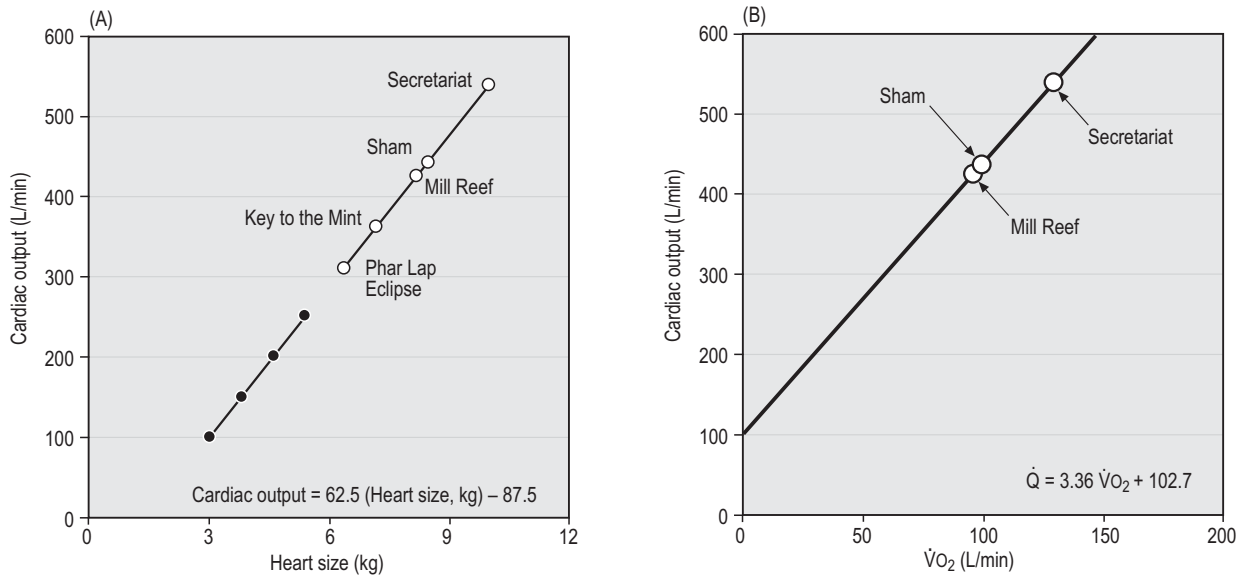

Fig. 32.13
Relationship between heart size and cardiac output ($\dot{Q}$) (A) and $\dot{V}O_2$ and cardiac output at maximum exercise (B). (A) The solid symbols are determined from the data of Evans & Rose (1988),[26] the hollow symbols are determined from that relationship and the measured or estimated (Secretariat) heart weights published for each named horse.[27] (B) An arterial–venous O_2 difference of 22.8 mL/100 mL of blood is assumed to estimate $\dot{V}O_{2max}$ values for Secretariat and Sham. The echocardiographic data of Young et al[5] are consistent with this relationship. Note Secretariat's extraordinary cardiac output (~ 540 L/min) and $\dot{V}O_{2max}$ (over 120 L/min which would be 240 mL O_2/kg/min at 500 kg bodyweight).

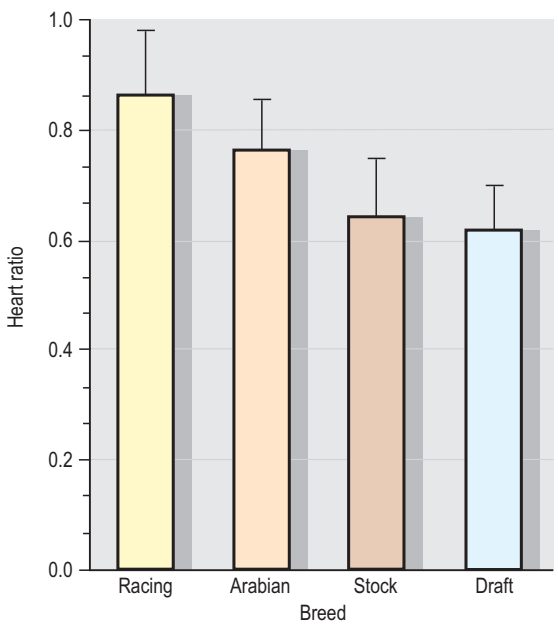

Fig. 32.14
Heart ratio (heart weight as a percentage of bodyweight) with standard deviations for racing, Arabian, stock and draft horses. Note that after training, heart ratio may reach 1.1% or higher.[22] (Revised from Kline and Foreman.[28])

vs. 60.8 cm^2). As the smaller cross-sectional area will substantially elevate resistance to blood flow, this is expected to raise left atrial, pulmonary venous, pulmonary capillary, and, ultimately, pulmonary arterial pressures.

Spleen

As shown above, O_2 delivery depends not only upon cardiac output ($\dot{Q}$) but also upon arterial O_2 content (Ca_{O_2}), and the

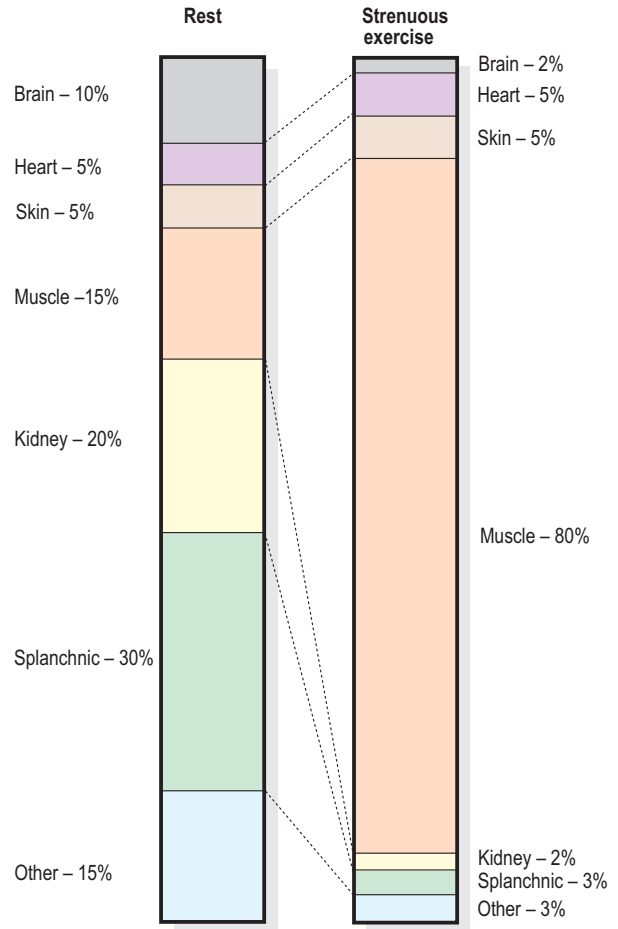

Fig. 32.18
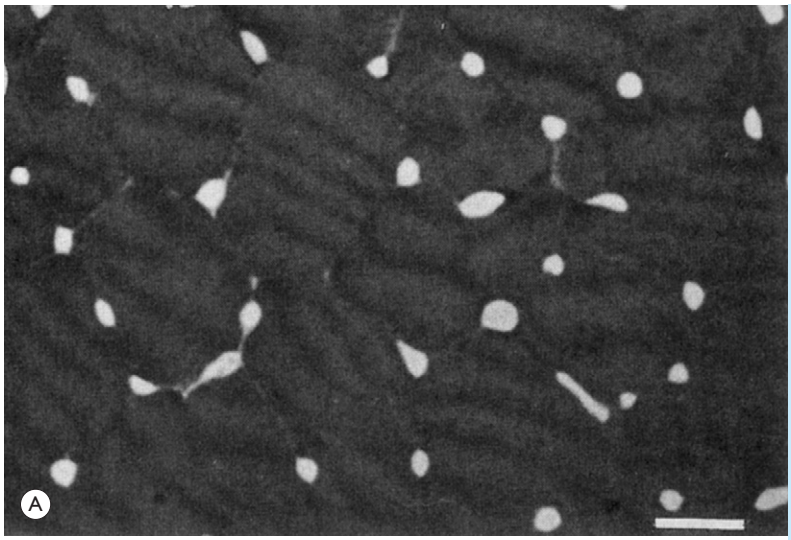
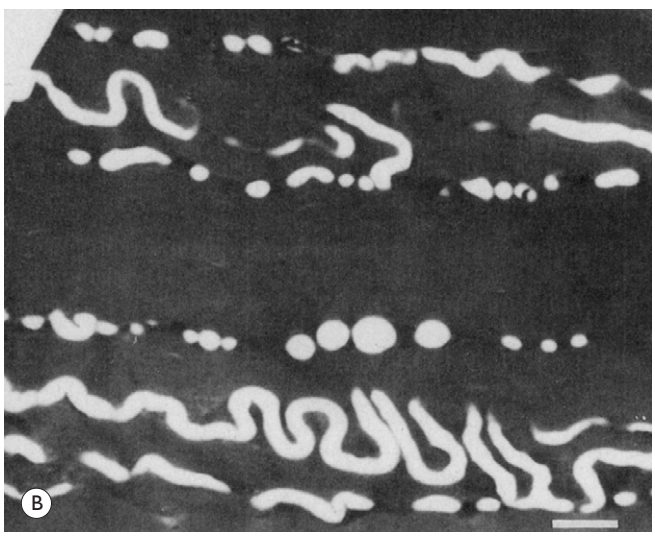
Distribution of cardiac output ($\dot{Q}$) at rest and during maximal exercise. In the highly trained, very fit Thoroughbred, it is possible that skeletal muscle blood flow may reach as much as 90% of cardiac output. (Values from Erickson.[41])

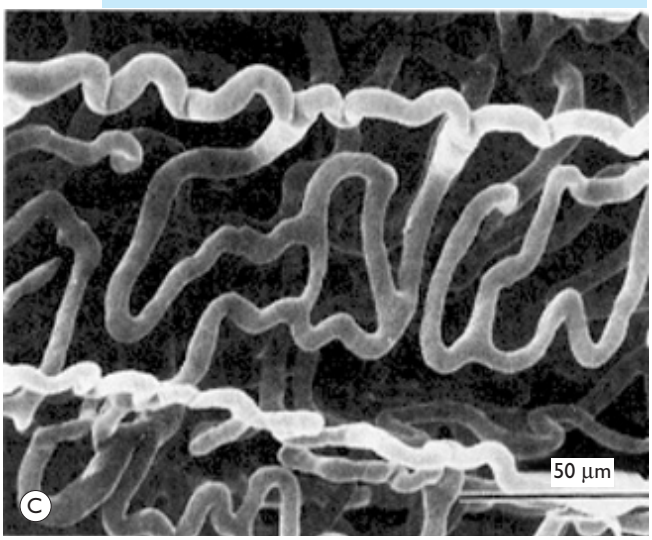
more of red cells into the circulation, thereby doubling the number of circulating red blood cells.[35–38] In keeping with the importance of $\dot{Q}o_2$ in determining racing performance, splenectomy reduces $\dot{V}o_{2max}$ by over 30% in the Thoroughbred.[37] Splenic reserve is correlated with spleen weight and total blood volume but not body mass per se.[32,35,38] Racing horses have a significantly greater splenic mass than non-racing breeds, i.e. Arabian, stock, draft[28] (Fig. 32.17).

Systemic circulation and microcirculation

In the Thoroughbred, total blood volume approximates 10% of body mass[39,40] and of this approximately 50 L of blood, 75% resides in the systemic circulation of which 60% is in the highly distensible venous system and only 15% in the arteries. Depending upon the activity undertaken (e.g. digestion, thermal stress, exercise) the cardiovascular system must redistribute $\dot{Q}$ amongst the appropriate organs. Physical exercise produces the most profound physiological stress to the horse and as shown in Fig. 32.18, the percentage of $\dot{Q}$ that perfuses the splanchnic region and kidneys is reduced from ~ 50% at rest to only 5% at maximal exercise. By contrast, exercising skeletal muscle may receive 80–90% of $\dot{Q}$ compared with only 10–20% at rest. Such flexible and precise control over blood flow distribution demands a network of powerful muscular arterioles that provide the principal resistance to flow in the systemic circulation and which can dilate or constrict rapidly in response to the vasoactive effects of muscle metabolites, prostacyclins, and nitric oxide (dilation) or sympathetic stimulation, angiotensin and endothelin (constriction). From rest to maximal exercise, skeletal muscle blood flow may increase over 60–70-fold. Although the perfusion pressure does increase substantially, elevated muscle vascular conductance (dilation) constitutes the primary mechanism by which the increased muscle blood flow ($\dot{Q}$m) is achieved and this response is detailed in the section 'Cardiovascular physiology and responses to exercise' below. Following a systematic series of bifurcations through several orders of progressively narrower arterioles, the vascular tree ramifies into a series of capillaries which form the principal site for blood–tissue exchange (Fig. 32.19). The capillary wall is devoid of smooth muscle and presents a barrier typically less than 1 μm thick between the capillary blood and the myocyte sarcolemma. The density, volume, and surface area of the skeletal muscle capillary bed is correlated closely with oxidative capacity and thus muscle fiber type.[44,45] In equine muscle (transverse section across fibers), there may be between 400 and 800 capillaries per square millimeter with







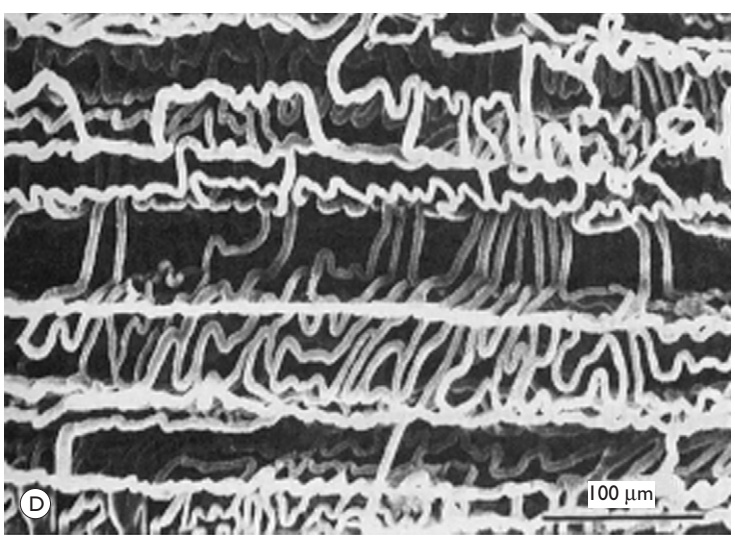


Fig. 32.19
The capillary bed of skeletal muscle possesses a complex three-dimensional geometry with extensive branching and capillaries that become extremely tortuous at short muscle sarcomere lengths forming a convoluted network around the fibers. (A, B) Light micrographs of pony vastus medialis muscle perfusion-fixed at 1.90 μm sarcomere length and cut transverse (A) and longitudinal (B) to the fiber longitudinal axis. Capillaries have been flushed clear of red cells and appear white surrounding the perimeter of the individual muscle fibers (A). A, B scale bar = 25 μm. a mean diameter of 4–6 μm[42,46] and these contain over 80% of the intramuscular blood volume. As we shall see in the Section 'Cardiovascular physiology and responses to exercise' below, the capillary volume is crucial for setting red blood cell transit time in the capillary and facilitating O_2 offloading during exercise (or loading in the pulmonary capillary).

Pulmonary circulation and microcirculation

At rest, the pulmonary circulation holds about 20% of total blood volume (mostly in larger compliant vessels rather than the capillaries) which decreases at exercise onset. Because the pulmonary circulation has to accept the whole output of the right ventricle, it is a low-pressure, high-conductance system with arteries and arterioles that are far less muscular than seen for the systemic circulation. Approximately half of the pulmonary vascular resistance is precapillary and the capillaries themselves constitute an important site of resistance particularly at high lung volumes and when alveolar pressure is positive during breathhold or forced exhalation.

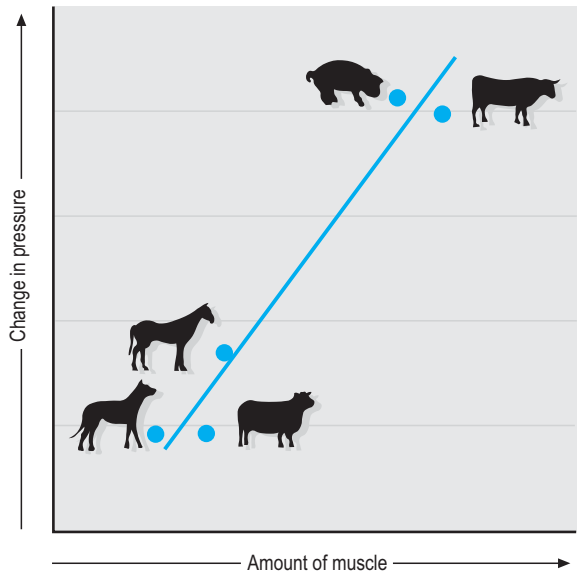

Fig. 32.20
Species variation in the muscle thickness in the walls of small pulmonary arteries and the change in pulmonary arterial pressure evidenced during hypoxic exposure. Note that the horse has far less muscle (and thus change in pulmonary arterial pressure) than the cow and the pig when exposed to hypoxia. (Redrawn from Robinson.[47])

The pulmonary vasomotor tone can be influenced by a variety of neural and humoral factors. Specifically, pulmonary arteries have both sympathetic and parasympathetic innervation and respond to serotonin, epinephrine, norepinephrine, isoproterenol, acetylcholine, angiotensin II, leukotrienes, prostacyclins, histamine, thromboxane, bradykinin, and arachidonic acid. However, as seen in Fig. 32.20, the horse has relatively little pulmonary vascular smooth muscle compared with cattle and pigs.[47] Thus, the horse exhibits only a weak vasoconstrictive response which is most evident in the low susceptibility of the horse to pulmonary hypoxic vasoconstriction but which causes a profound pulmonary hypertension in cattle and pigs at altitude. During exercise, the elevated pulmonary arterial pressures induce recruitment and distension of the vascular bed which reduces vascular resistance, elevates vascular conductance, and increases pulmonary capillary volume (Fig. 32.21). Despite this elevated conductance, pulmonary vascular pressures do become extraordinarily high during maximal exercise (see 'Cardiovascular physiology and responses to exercise' below).

The pulmonary capillaries form a dense plexus around each alveolus and, unlike their systemic counterparts, are not embedded within a supporting tissue matrix and thus are subject to collapse at positive alveolar pressures particularly when perfusion pressure is low. In the horse, these vessels are about 6–7 μm in diameter[49] (which is narrower than found in dog or rabbit lungs) and have a total wall thickness

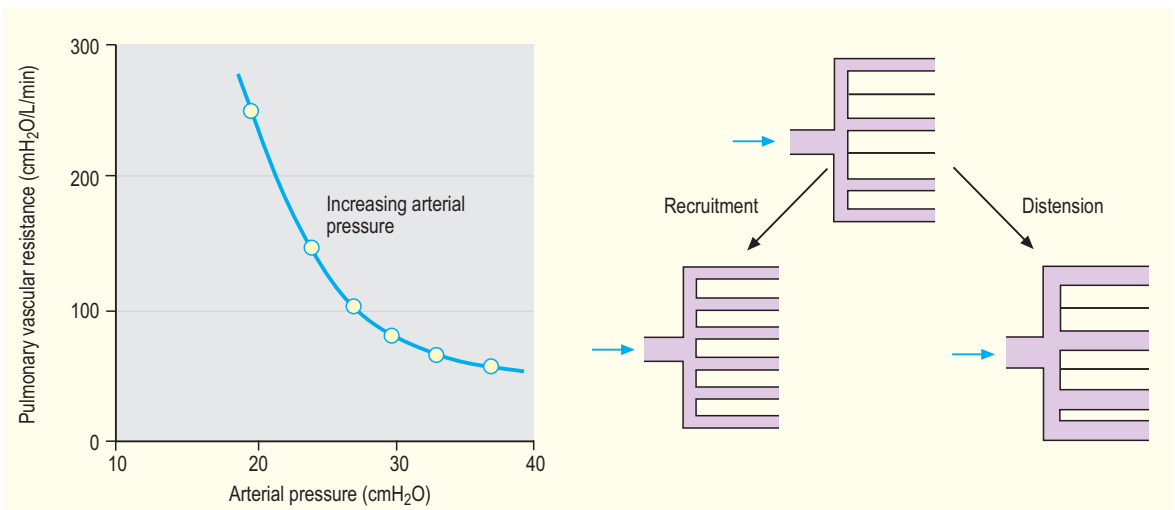

Fig. 32.21
Elevated pulmonary arterial pressure reduces pulmonary vascular resistance because it forces a recruitment of previously non-perfused vessels and distends those vessels recruited. (Revised from West.[48])

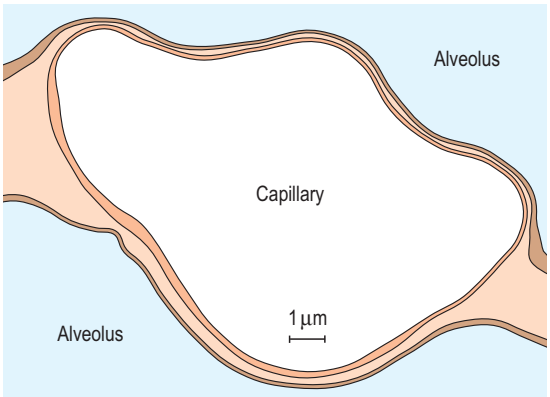

Fig. 32.22

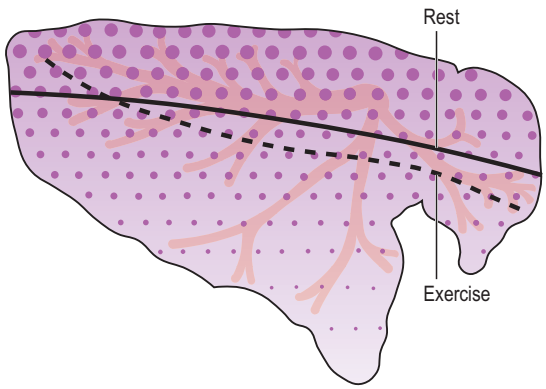

Fig. 32.23
Distribution of pulmonary blood flow in the lung at rest. The shading indicates relative blood flow (the darker the area, the greater the blood flow) and the solid and broken lines indicate relative dorsal–caudal blood flow at rest and during exercise, respectively. Note that pulmonary blood flow is not regulated by gravity, as once thought. (Data from Hlastala and colleagues;[51] redrawn from Robinson.[47])

(capillary endothelium, basement membrane, alveolar epithelium) which averages only 0.9 µm (Fig. 32.22). Consequently, even at relatively low transmural pressures (positive luminal plus negative alveolar) these vessels bulge into the alveolar space and may rupture during exercise (exercise-induced pulmonary hemorrhage). Pulmonary capillary blood volume constitutes only a very small fraction of that present in the pulmonary circulation, which confers the advantage of maximizing blood-gas spatial contact but has the consequence of limiting red blood cell transit time in the capillary. Pulmonary capillary blood volume in the horse is 60–80% greater than that of a steer of the same mass.[50]

In healthy animals, active vasomotor control is thought to play a relatively minor role (compared with the effects of hydrostatic pressure gradients, lung volume, and alveolar pressure) in setting the distribution of blood flow within the pulmonary circulation. However, recent investigations have demonstrated that there is a gravity-independent distribution of $\dot{Q}$ toward the dorsal aspect of the lung (Fig. 32.23).[51] This effect may be explained by a regionally dependent arteriolar reponsiveness. For example, arterioles in the upper lung regions exhibit a pronounced vasodilation to methacholine (an endothelium-dependent vasodilator) whereas those at the bottom do not.[52]

Cardiovascular physiology and responses to exercise

Cardiac output

Cardiac output ($\dot{Q}$) is defined as the volume of blood ejected from the right or left ventricle and is usually expressed per minute. As illustrated in Table 32.6, cardiac output is the most important means of increasing muscle O_2 delivery during exercise and is the principal determinant of $\dot{V}O_{2max}$,

Table 32.6 Cardiovascular responses to maximal exercise in a 500-kg horse. (Data from Erickson[41])

Variable	Rest	Exercise	Exercise/rest ratio
Heart rate (beats/min)	30	210–250	7–8
Cardiac output			
L/min	30	240–>450	8–13
SV (mL)	1000	1700	1.7
Systolic/diastolic arterial blood pressure (mmHg)	130/80	230/110	1.6
Pulse pressure (mmHg)	50	120+	3–4
Pulmonary artery pressure (mmHg)	20–30	90–140	3–4
Hemoglobin concentration (g/dL)	13	17–24	1.3–1.6
O_2 consumption (mL/min/kg)	2–4	160–220	40–110
L/min	1.5–20	80–110	40–75
$a - v\ O_2$ difference (mL/100mL)	5	20–25	4–5

which can vary from 90 to 220 mL/kg/min.[5,53] Very fit Thoroughbreds have had $\dot{Q}$ values measured in excess of 350 L/min and as mentioned above, based upon estimated heart size, it is likely that superlative athletes have achieved $\dot{Q}$ values between 400 and 540 L/min (Figs 32.13A, B, 32.14). During submaximal exercise, $\dot{Q}$ (and body O_2 delivery, $\dot{Q}O_2$) increase linearly with running speed and also $\dot{V}O_2$.[54–56] Increased $\dot{Q}$ in combination with the splenic-induced polycythemia may elevate $\dot{Q}O_2$ over 20-fold in a very fit Thoroughbred race horse from rest to maximal exercise. Increases in $\dot{Q}$ are driven most powerfully by heart rate with a smaller contribution from elevated stroke volume (Table 32.6).

Heart rate

At exercise onset, heart rate increases rapidly from approximately 30 beats/min at rest to approximately 110 beats/min via parasympathetic withdrawal, with the consequence that at low running speeds heart rate may elicit an early overshoot (Fig. 32.24).[26,57,58] At faster speeds, further heart rate elevations are achieved less rapidly and are driven by the sympathetic nervous system and circulating catecholamines. Maximum heart rate varies between 204 and 241 beats/min and a reduction with age has been described recently in horses.[59] In human populations a decrease of 1 beat/min/yr has been well established.[60,61] Maximum heart rate is not considered to be an important measure of fitness and as seen in the section 'Exercise training' below, does not change with training. The speed or velocity a horse can achieve or sustain at a submaximal heart rate of 140, 170 or 200 beats/min (i.e. V_{140}, V_{170}, and V_{200}) provides information about stroke volume and cardiovascular capacity and pertains directly to fitness and racing potential.[53] Both heart rate[26,57] and $\dot{V}O_2$[62] increase faster after a warm-up, although as cardiac output does not appear to limit $\dot{V}O_2$ kinetics at exercise onset,[63,64] the

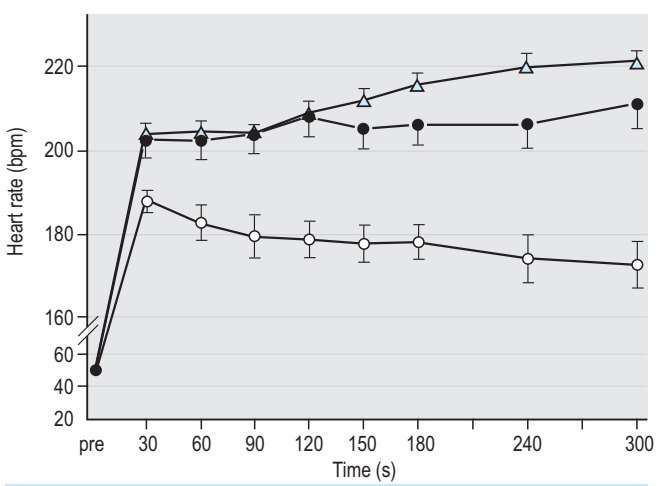

Fig. 32.24
Heart rate response following the onset of exercise at 50% (hollow circles), 75% (solid circles), and 100% (triangles) $\dot{V}O_{2max}$ in Standardbred race horses. Note the pronounced early overshoot at 50% $\dot{V}O_{2max}$. (Redrawn from Evans & Rose.[57])

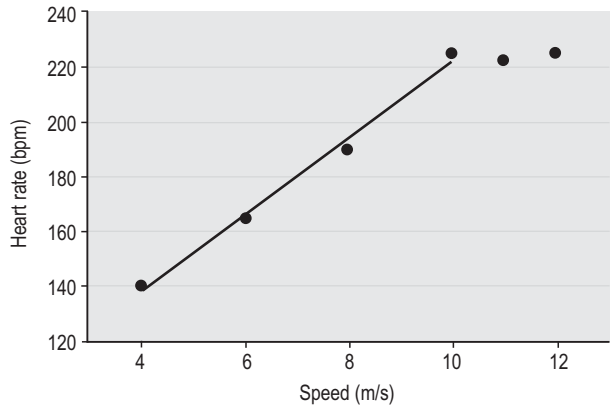

Fig. 32.25
Relationship between running speed and heart rate from 4 m/s to maximal speed (12 m/s) in a race-fit Thoroughbred race horse. (Redrawn from Evans.[53])

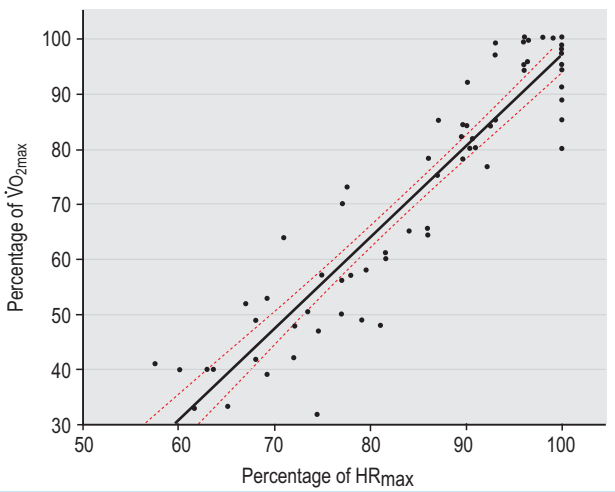

Fig. 32.26
Relationship between %maximum heart rate and $\%\dot{V}O_{2max}$ in horses of varying fitness levels. (Redrawn from Evans & Rose.[67])

two are probably not linked mechanistically. There is a linear relationship between heart rate and running speed and between $\%HR_{max}$ and $\%\dot{V}O_{2max}$ (Figs 32.25, 32.26).[53,65–67] However, at a constant running speed in the heavy intensity domain, heart rate may continue to rise and this is accompanied by rising ventilation, $\dot{V}O_2$, and $\dot{Q}$.[68] This 'slow component' of the cardiorespiratory response is driven by elevated metabolic requirements within the exercising muscles,[69] a progressive fall in blood volume, and also thermoregulatory responses to the rising body temperature.

Stroke volume

Stroke volume refers to the volume of blood ejected per beat from the left or right ventricle and increases from approximately 1000 mL (2–2.5 mL/kg) at rest up to 1700 mL (3–4 mL/kg) or higher at maximal exercise (Table 32.6).[12,53,54,56,66] If a maximum heart rate of 225 beats/min is assumed for Secretariat, his stroke volume would have been well in excess of 2000 mL/beat. Typically, stroke volume

increases sharply at exercise onset up to around 40% $\dot{V}O_{2max}$ consequent to increased blood volume, venous return, and filling pressures according to the Frank–Starling mechanism.[26,70] What is particularly remarkable is that ventricular filling (and thus stroke volume) does not appear to be compromised at maximal exercise despite heart rates of 4 beats/s.

Arterial O_2 content (CaO_2) and O_2 delivery ($\dot{Q} \times CaO_2 = \dot{Q}O_2$)

As described in the first section, arterial O_2 content, CaO_2, is determined principally by blood hemoglobin concentration (which sets the O_2 carrying capacity) and the % saturation of those hemoglobin binding sites with O_2. At rest, arterial hemoglobin concentration is 12–14 g/100 mL, whereas at maximal exercise the spleen has expelled sufficient red blood cells to increase this up to 21–24 g/100 mL. This corresponds to a packed cell volume increase from 35% at rest to 70% at maximal exercise. Thus, at maximal exercise if hemoglobin was 100% saturated with O_2, each 100 mL of blood would hold between 27 and 31 mL O_2. However, as discussed below arterial O_2 saturation falls from around 95% at rest to below 85% at maximal exercise,[10] and this will decrease CaO_2 to 23–26 mL/100 mL. Even considering this effect, with a $\dot{Q}$ of 400 L/min, the Thoroughbred can deliver a prodigious 100 L O_2/min to the body during maximal exercise.

Determinants of O_2 loading

Pulmonary circulation

The rapid increase in pulmonary blood flow at exercise onset in concert with the polycythemic hyperviscosity[37,71–73] elevates pulmonary vascular pressures (Fig. 32.27) and forces recruitment of non-flowing vessels and distension of flowing vessels (Fig. 32.21). This behavior elevates pulmonary vascular conductance several fold but does not prevent mean pulmonary arterial pressure from exceeding 120 mmHg in fit horses;[63,74–78] the consequences of this hypertension include exercise-induced pulmonary hemorrhage (EIPH) and are detailed below. Splenectomy (reduced blood viscosity),[37,73] diuretic therapy (furosemide),[78–82] and nitric oxide (vasodilator)[77] are all effective modalities for reducing maximal pulmonary arterial pressures during exercise. However, splenectomy reduces $\dot{Q}O_2$ and thus negatively impacts both $\dot{V}O_{2max}$ and performance.[37] As mentioned in the section, 'Anatomy of the cardiovascular system', in contrast to conventional wisdom, it has now been established that gravity is not the sole or even the primary regulator of the regional distribution of blood flow within the equine lung. Elegant fluorescent microsphere studies by Bernard, Hlastala, Erickson and colleagues have determined that pulmonary $\dot{Q}$ is preferentially distributed towards the dorsal aspect of the lung at rest and during exercise (Fig. 32.23)[51,83] likely due to a regional variation in sensitivity to endothelium-induced vasodilation.[52]

Exercise-induced arterial hypoxemia

As demonstrated in Fig. 32.28, blood leaving the horse's lung during maximal exercise is profoundly hypoxemic.[10,84] Several mechanisms impair O_2 loading in the pulmonary capillary. These are described below in order of importance.

Alveolar–capillary O_2 diffusion limitation (~ 70% of alveolar-to-capillary O_2 pressure gradient) During maximal exercise the horse develops a significant alveolar-to-capillary O_2 pressure (P) gradient.[84] Unlike in other species such as man, in whom alveolar hyperventilation drives arterial PCO_2 below resting and in which alveolar PO_2 becomes elevated during intense exercise, in the horse alveolar PO_2 may fall and consequently the increased alveolar-to-capillary O_2 pressure gradient results from the reduced arterial PO_2. The primary reason for the elevated alveolar-to-capillary O_2 pressure gradient and arterial hypoxemia relates to the prodigious values of $\dot{Q}$ achieved. The average transit time for a red blood cell (RBC) within the pulmonary capillary is determined by the ratio between pulmonary capillary blood volume and $\dot{Q}$. In the horse at rest, pulmonary capillary volume is some 1.8-fold that of an equivalently sized steer[50] and RBCs probably spend 0.75–1 s within the capillary, which is thought to be three to four times longer than necessary for equilibration with the alveolar O_2 (Fig. 32.28). However, as we have seen during maximal exercise, $\dot{Q}$ may increase from rest by up to 13-fold and although capillary volume does increase it can only do so by a small fraction of this. Consequently, red cell capillary transit time will decrease. Morphometric estimation of mean exercising red cell transit time places it at 0.3–0.5 s.[50,85] This is probably a gross overestimate of that present in very fit race horses that can achieve $\dot{Q}$ values around 400 L/min and it is pertinent that even if this were the mean transit time there would exist a substantial population of red cells with considerably shorter transit times. Because of the sigmoid shape of the O_2 dissociation curve, it is not possible for those cells with longer transit times to compensate for those that do not equilibrate with the alveolar gas. The consequence of this mixing of hypoxemic with normoxemic blood in the pulmonary veins will be arterial hypoxemia. In addition, the rightward shift of the O_2 dissociation curve consequent to elevated blood temperatures, arterial hypercapnia, and acidosis will reduce the hemoglobin–O_2 affinity and further exacerbate alveolar– capillary disequilibrium.

Alveolar hypoventilation As mentioned above, at maximal exercise the horse's arterial PCO_2 may exceed 65 mmHg.[10,72,74,86] As calculated from the alveolar gas equation, this will cause alveolar PO_2 to fall from approximately 100 mmHg at rest to approximately 90 mmHg at maximal exercise (Fig. 32.28).

Mild ventilation-to-perfusion ($\dot{V}/\dot{Q}$) mismatch During exercise, the horse develops a small but significant degree of $\dot{V}/\dot{Q}$ mismatch. However, this is not thought to contribute in a quantitatively important fashion to the exercise-induced arterial hypoxemia.[84,87] The percentage of $\dot{Q}$ that does not come into contact with alveolar gas (i.e. shunt) is trivially small (≤ 1%).

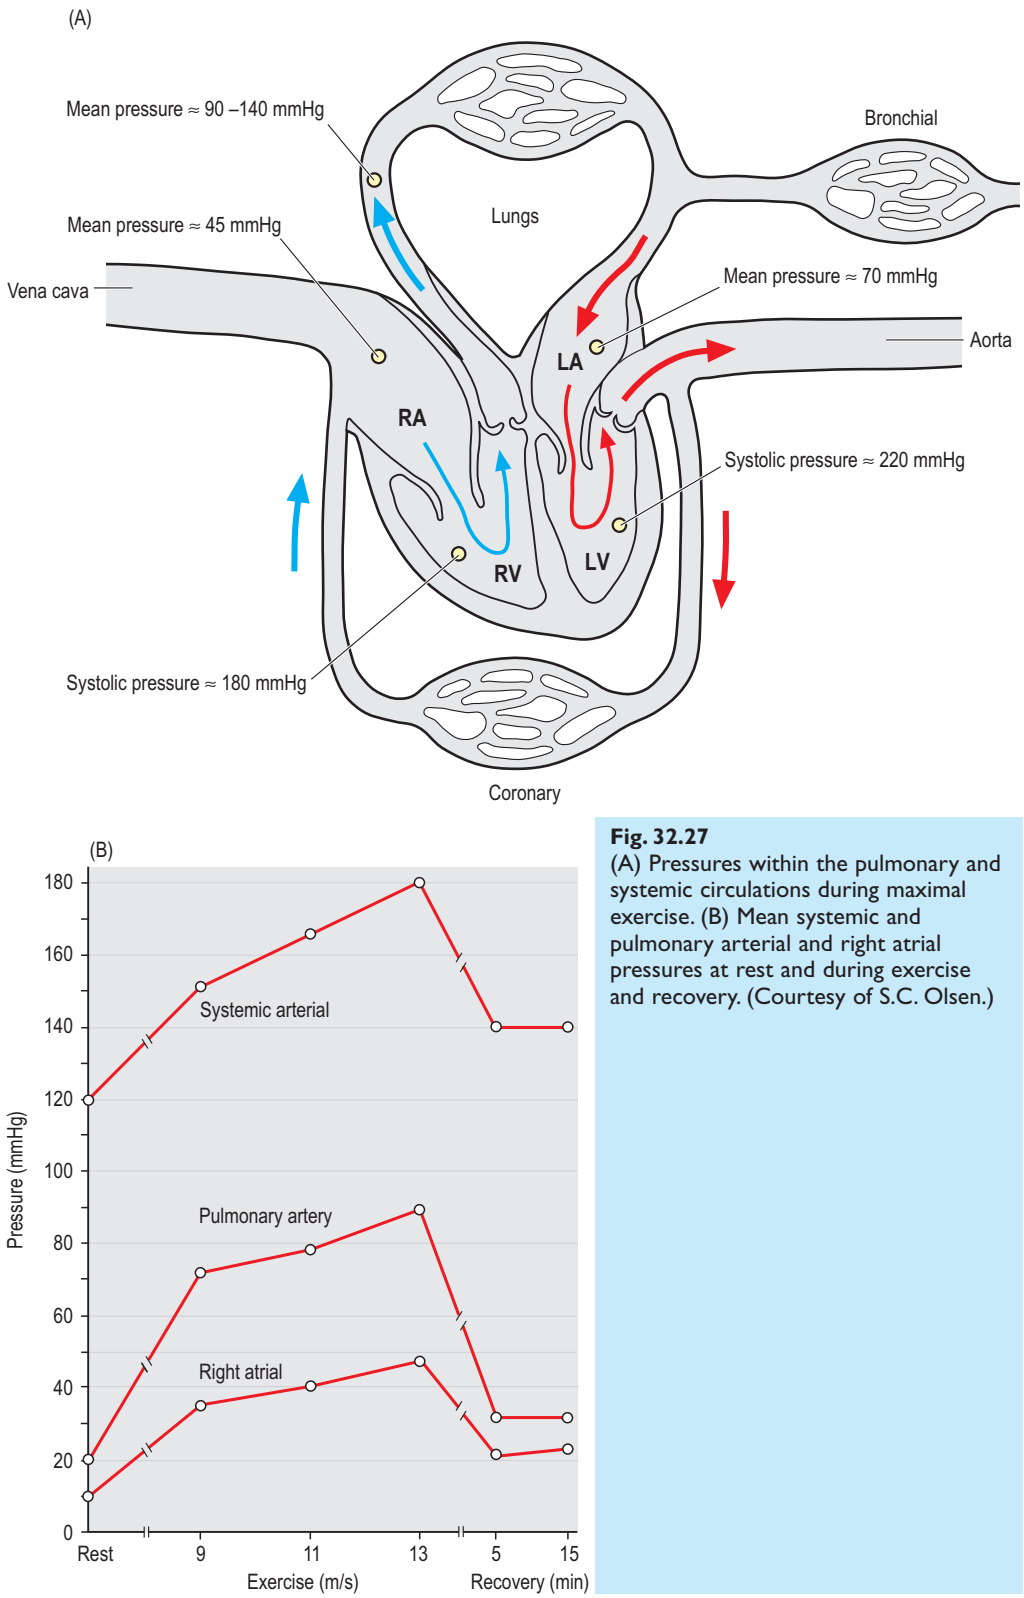

Fig. 32.27
(A) Pressures within the pulmonary and systemic circulations during maximal exercise. (B) Mean systemic and pulmonary arterial and right atrial pressures at rest and during exercise and recovery. (Courtesy of S.C. Olsen.)

Exercise-induced pulmonary hemorrhage

Exercise-induced pulmonary hemorrhage (EIPH) is characterized by rupture of the blood–gas barrier and the presence of blood in the alveolar space and airways. In extreme cases, frank epistaxis may occur. EIPH is prevalent in Thoroughbreds, Standardbreds, and also Quarter Horses during sprint racing, where repeated endoscopic examination indicates an incidence approaching 95%.[88–93] Microspheres (10–15 μm)

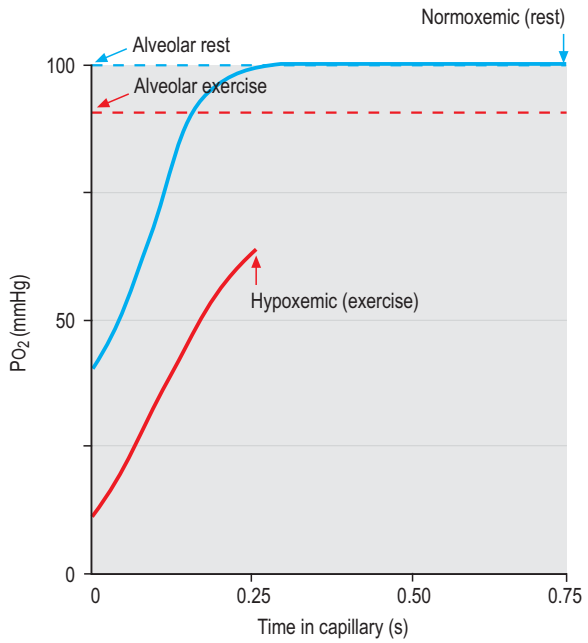

Fig. 32.28
Partial pressure of O_2 (P_{O_2}) in the red blood cell as a function of pulmonary capillary transit time at rest and during exercise. Note the reduction in alveolar P_{O_2} during exercise (alveolar hypoventilation) and the profound decrease in red cell P_{O_2} as it enters and leaves the capillary during maximal exercise.

injected into the jugular vein have identified the pulmonary rather than the bronchial (systemic) vasculature as the site of EIPH[75] and elegant electron microscopy studies have captured red cells actually erupting from breaks in the fragile blood–gas barrier (Fig. 32.29).[94,95]

EIPH must ultimately arise from high positive intraluminal pressures coupled with very negative alveolar pressures which summate across the blood–gas barrier causing failure (Fig. 32.29).[74,96,97] However, the etiology of EIPH is complex and numerous mechanisms have been implicated.[93] These include:

1. alveolar pressure fluctuations which may be exacerbated by upper airway obstruction (inspiratory nasal collapse;[98] laryngeal hemiplegia[99])
2. pulmonary hypertension consequent to high $\dot{Q}$ values (> 120 mmHg mean pulmonary artery pressure[74,75,80,97]), exercise-induced hyperviscosity,[71,100] and possibly arteriolar vasoconstriction[72,76,77]
3. redistribution of blood within the lung[83]
4. mechanical stresses of respiration and locomotion.[101]

Additional factors that may contribute to elevated pulmonary arterial pressures include flow limitation induced by the relatively small cross-sectional area of the atrioventricular (AV) valves,[93] possible regurgitation through the AV valves consequent to high ventricular pressures, and also a left ventricular relaxation rate that may be too slow to allow rapid filling at lower left atrial pressures.[93,102,103] With regard to valvular regurgitation, Young & Wood[104] performed cardiac auscultation on 111 Thoroughbreds aged 2–5 and reported that the incidence of mitral and tricuspid regurgitation was 7% and 13%, respectively. After training, this increased significantly to 22% (mitral) and 26% (tricuspid).

Following the observation that pulmonary artery pressures and capillary transmural pressures reach extraordinarily high levels in the exercising horse and that there are threshold pulmonary arterial and capillary pressures above which the integrity of the blood–gas barrier is disrupted,[97,105] EIPH research and therapeutic interventions have focused on reducing these pressures.[93] Diuretic treatment with furosemide which lowers pulmonary vascular pressures has the greatest proven efficacy in this regard.[78,80,106,107] Nasal passage support with the Flair nasal strip also reduces EIPH, presumably by reducing alveolar pressure swings and the transmural pressure gradient.[78,98,107,108] Other treatment strategies involving Chinese herbal remedies and IgG are currently being evaluated.[106] Experiments using furosemide,[78] nitric oxide inhalation,[77] and inhibition of nitric oxide synthase[72,76] have demonstrated that interventions which lower peak pulmonary artery pressure may not necessarily induce a corresponding reduction in EIPH.[93] Thus, regulation of the distribution of pulmonary $\dot{Q}$ and vascular conductance may be crucial for limiting EIPH and continues to be an active and important avenue of research.

Systemic circulation

Cardiovascular control must subserve two crucial and sometimes conflicting demands. Namely, muscle $\dot{Q}$ must achieve a level commensurate with O_2 and substrate requirements (up to 100-fold resting) whilst maintaining systemic mean arterial pressure (MAP) within acceptable limits. Excessive vasodilation lowers MAP and compromises blood flow to critical organs such as the brain. By contrast, excessive MAP impairs vascular integrity, elevates vascular fluid exudation, and causes tissue damage.

MAP is the product of $\dot{Q}$ and total peripheral resistance (TPR). TPR is determined principally by the aggregate cross-sectional area of all recruited arterioles and also blood viscosity. Figure 32.30 details many of the factors controlling vascular smooth muscle and thus vascular conductance within skeletal muscle. Even at maximal exercise, there is a profound sympathetic vasoconstrictor tone within skeletal muscle[110] and blood pressure regulation depends upon the interaction of central nervous system reflexes emanating from the brain (central command) and those within the working muscle.[111–115] MAP rises from 110 to 138 mmHg at rest to as high as 200 mmHg during maximal exercise (Table 32.6, Fig. 32.27).[53,55,72,76,116,117] In addition to MAP, systolic left ventricular and right atrial pressures increase substantially[53,56,66,75] and myocardial contractility (peak derivative of left ventricular pressure, LV$dp/dt$) rises progressively with running speed.[53]

From rest to exercise, skeletal muscle arterial and arteriolar vasodilation allows TPR to fall precipitously which facilitates enormous $\dot{Q}$ values with a relatively modest rise in

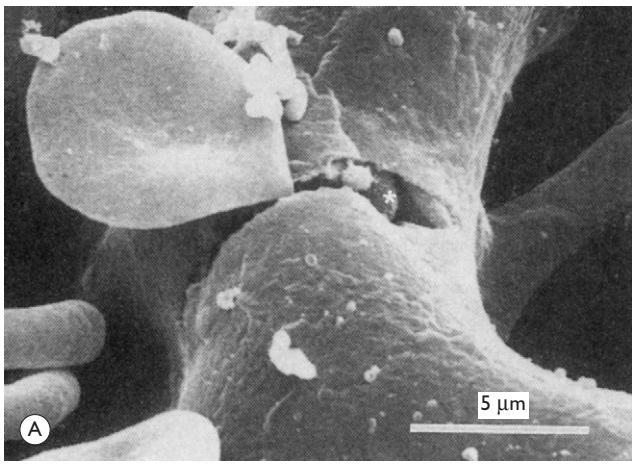

Fig. 32.29
Rupture of the pulmonary capillaries. (A) Red blood cell emerging from a split in the blood–gas barrier into the alveolar space. MAP. Specifically, if $\dot{Q}$ increases from 30 (rest) to 450 (maximal exercise) L/min for a corresponding increase in MAP from 120 to 180 mmHg, TPR must fall by 90% (i.e., 4 to 0.4 mmHg/L/min). The control of skeletal muscle vasomotor tone involves a complex array of mechanical (muscle pump, shear stress, myogenic), humoral (vasoactive metabolites, catecholamines) and neural (sympathetic, anterograde and retrograde conducted vasodilation) mechanisms (Fig. 32.30). Recent findings from Kindig and colleagues[72,76,77] indicate a major role for NO in increasing systemic and vascular conductances during intense running (Fig. 32.31). There have been several excellent recent reviews on the regulation of muscle vascular conductance[113–115,118] and it is apparent that the precise mechanisms which mediate the rapid increase of muscle $\dot{Q}$ and $\dot{Q}o_2$ at exercise onset remain to be resolved.[119] The matching between $\dot{Q}o_2$ and $\dot{V}o_2$ during exercise is so precise that it has inspired the suggestion that the system behaves as though there is an O_2 sensor located within the muscle or its vascular bed.[115] However, if present such a sensor remains elusive.

During exercise, muscle $\dot{Q}$ is distributed heterogeneously between and within muscles depending on their recruitment,

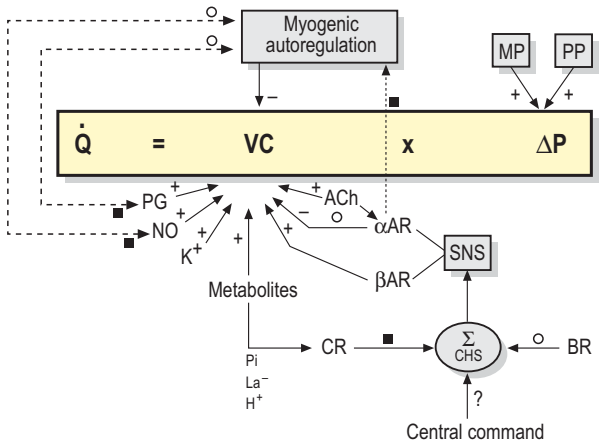

Fig. 32.30
Muscle blood flow (Qm) is regulated by the interaction of multiple mechanical (top row) and nonmechanical (bottom row) factors which act directly on vascular smooth muscle to either reduce (–) or increase (+) limb vascular conductance (VC). Qm will also increase if the pressure gradient (Δ*P*) across the capillary bed is enhanced by the muscle pump (MP) following muscle contraction or elevated perfusion pressure (PP). In addition, VC may be changed by the action of the sympathetic nervous system (SNS) after integration of opposing reflex inputs arising from the baroreflex (BR) and chemoreflex (CR) and also from higher centers within the brain. There are also other factors that may potentiate (solid squares) or constrain (hollow circles) the effect of other regulatory agents (dotted lines). The net blood flow response to exercise is the result of all of these factors. PG, prostaglandins; NO, nitric oxide; K^+, potassium ion; Pi, inorganic phosphate; La^-, lactate ion; βAR, beta-adrenergic receptor; αAR, alpha-adrenergic receptor; ACh, acetyl choline. (Redrawn from Shoemaker & Hughson.[109])

oxidative capacity, fiber type, and $\dot{V}O_2$ demands.[114] Thus, in the exercising horse, $\dot{Q}$ in heavily recruited, highly oxidative red muscles in the limbs and respiratory system may achieve peak values of 1–3 L/min/kg.[46,120–122] Specifically, Armstrong and colleagues[46] measured vastus intermedius $\dot{Q}$ at 1.5 L/min/kg in Standardbred horses running at $\dot{V}O_{2max}$ (134 mL/kg/min; $\dot{Q}$ 288 L/min). Within the thigh muscles sampled, the vastus intermedius had the highest citrate synthase activity (mitochondrial volume density, 9%) and myoglobin concentration and exhibited the greatest $\dot{Q}$. Indeed, across the several muscles/muscle portions sampled there was a strong correlation ($r = 0.947$) between citrate synthase activity and $\dot{Q}$ at $\dot{V}O_{2max}$.

The respiratory muscles, and in particular the diaphragm, are extremely oxidative and during near maximal exercise diaphragm $\dot{Q}$ may exceed 2.5 L/min/kg.[120,121] Vasodilation and inspiratory resistance studies have revealed that, even at $\dot{V}O_{2max}$, the diaphragm retains a considerable vasodilator reserve. Specifically, prodigious diaphragm $\dot{Q}$ values close to 4 L/kg/min are feasible.[120–123] It is quite possible that exceptional athletes or individuals with laryngeal hemiplegia exhibit substantially higher diaphragm blood flows than their less fit but healthy counterparts and that the respiratory muscles 'steal' $\dot{Q}$ from the exercising limb muscles,[124] thereby compromising running performance.

The heart, in keeping with its great energetic demands, rich vascularity, and mitochondrial content,[125] sustains an extraordinarily high blood flow during exercise. Specifically, in Standardbreds run at $\dot{V}O_{2max}$, left and right ventricular and septal blood flows increase from their pre-exercise value (0.4–0.6 L/kg/min) up to 2.6–2.9 L/kg/min[46,126] Atrial blood flows are somewhat lower at rest (0.3 L/kg/min) and at $\dot{V}O_{2max}$ (1.3–1.4 L/kg/min). One remarkable feature of the equine heart is that there is little or no gradation of blood flow across the myocardial wall. This is surprising given the high compressive forces to which the subendocardial vessels are subjected as systolic pressures greatly exceed 200 mmHg. There is also evidence that the myocardium retains a substantial vasodilator reserve during maximal exertion, at least in ponies.[127]

Muscle blood flow ($\dot{Q}m$) and O_2 delivery ($\dot{Q}O_2m$) across the rest–exercise transition

The close matching between $\dot{Q}O_2m$ and $\dot{V}O_2$ (Fig. 32.5) presents a strong case for $\dot{Q}O_2m$ being controlled ultimately by muscle metabolism.[16,113,115,128–131] However, $\dot{Q}O_2m$ increases within the first one or two contractions at exercise onset and this timecourse is generally accepted to be far faster than that of $\dot{V}O_2$[132] and is thus too rapid to be explained by metabolic feedback[131] and arteriolar vasodilation mediated by common vasodilators.[133] Consequently, it is thought that the muscle pump, which substantially reduces venular pressure, is key to increasing the pressure differential across the muscle vascular bed and augmenting flow almost instantaneously (Fig. 32.32).[132,134,135] It is also possible that conducted vasodilation, initiated within the capillaries adjacent to active muscle fibers, causes vasodilation upstream within the arteriolar bed.[118,136] Kindig and colleagues[63,64] have demonstrated recently that inhibition of nitric oxide formation using L-NAME actually speeds the rate of $\dot{V}O_2$ increase at exercise onset in Thoroughbreds (Fig. 32.33). Thus, despite any L-NAME induced $\dot{Q}O_2$ reduction,[72,137] relief of nitric oxide-mediated mitochondrial inhibition[138] allows a more rapid $\dot{V}O_2$ increase. This provides the most compelling evidence to date that muscle O_2 delivery does not limit the energetic ($\dot{V}O_2$) response to exercise.

Determinants of O_2 exchange within skeletal muscle: the microcirculation

In skeletal muscle, O_2 diffuses down its pressure gradient from the capillary towards the mitochondria at a rate ($\dot{V}O_2$) that is determined by the O_2 pressure (PO_2) difference between capillary and mitochondria and the tissue diffusing capacity for O_2 (D) according to Fick's law ($\dot{V}O_2 = D[PO_2cap - PO_2 mito]$). The enduring dogma that there is a large PO_2 gradient from the myocyte sarcolemma to the most distant

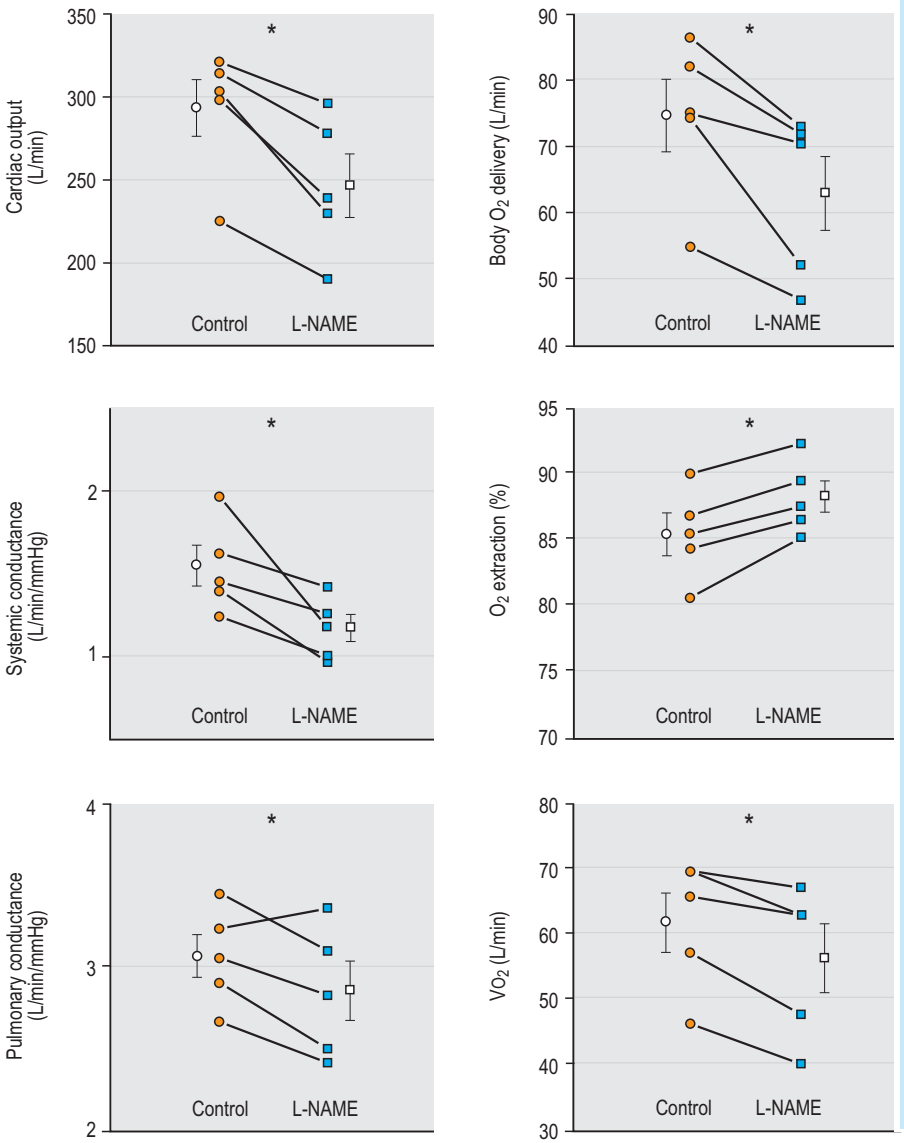

Fig. 32.31
Effect of inhibition of nitric oxide production by L-NAME (nitric oxide synthase inhibitor, N^G-L-nitro-arginine methyl ester) on cardiovascular responses, O_2 delivery ($\dot{Q}O_2$), O_2 extraction and O_2 uptake ($\dot{V}O_2$) at maximum exercise. Solid symbols denote individual horses, hollow symbols are mean ± standard error. The L-NAME condition significantly (* $P < 0.05$) reduced all variables in addition to the maximum speed attained. (Reproduced with kind permission from Kindig et al.[72])

mitochondrion is at odds with the more recent observation that intramyocyte Po_2 during exercise is low (1–3 mmHg) and without appreciable transverse or longitudinal variation (Fig. 32.34).[139] This is important because it means that the greatest fall in Po_2 occurs in very close proximity (1–2 μm) to the RBC even in the presence of potentially long diffusion distances (> 40 μm) to the mitochondrion. Intramyocyte O_2 transport is thought to be facilitated by myoglobin particularly within fibers in which oxidative enzyme activity is high. The mitochondrial system comprises a catenated network that may enhance O_2 and high-energy phosphate transport.[140,141]

From the above, the inescapable conclusion is that the size (surface area) and geometry (luminal diameter, tortuosity, branching) of the muscle capillary network combined with the flux and distribution of RBCs within that network are of paramount importance for gas exchange. Within skeletal muscle, capillary surface area is regulated as a function of fiber mitochondrial volume,[44] which itself is indicative of maximal O_2 demand (Fig. 32.35). Within the major limb muscles there are 700–800 km of capillary length per kg which supplies 40–50 mL of mitochondria.[42,46] The capillaries form a dense, interconnecting network of vessels that average 4–6 μm in diameter (RBCs are 5.5 μm in diameter) that becomes extremely tortuous at short muscle sarcomere lengths.[42] By contrast, at long sarcomere lengths (>2.8 μm), the capillaries become straight and highly aligned with the muscle fibers. As the capillaries stretch, their luminal diameter is reduced and this increases their resistance to RBC passage.[142,143]

Observation of capillary RBC flux and distribution during muscle contractions presents a formidable challenge to scientists. It is only very recently that events within muscle capillaries have been observed across the rest–contractions transition. At rest in rat spinotrapezius muscle, approximately 80% of capillaries support RBC flow[143] at a velocity of

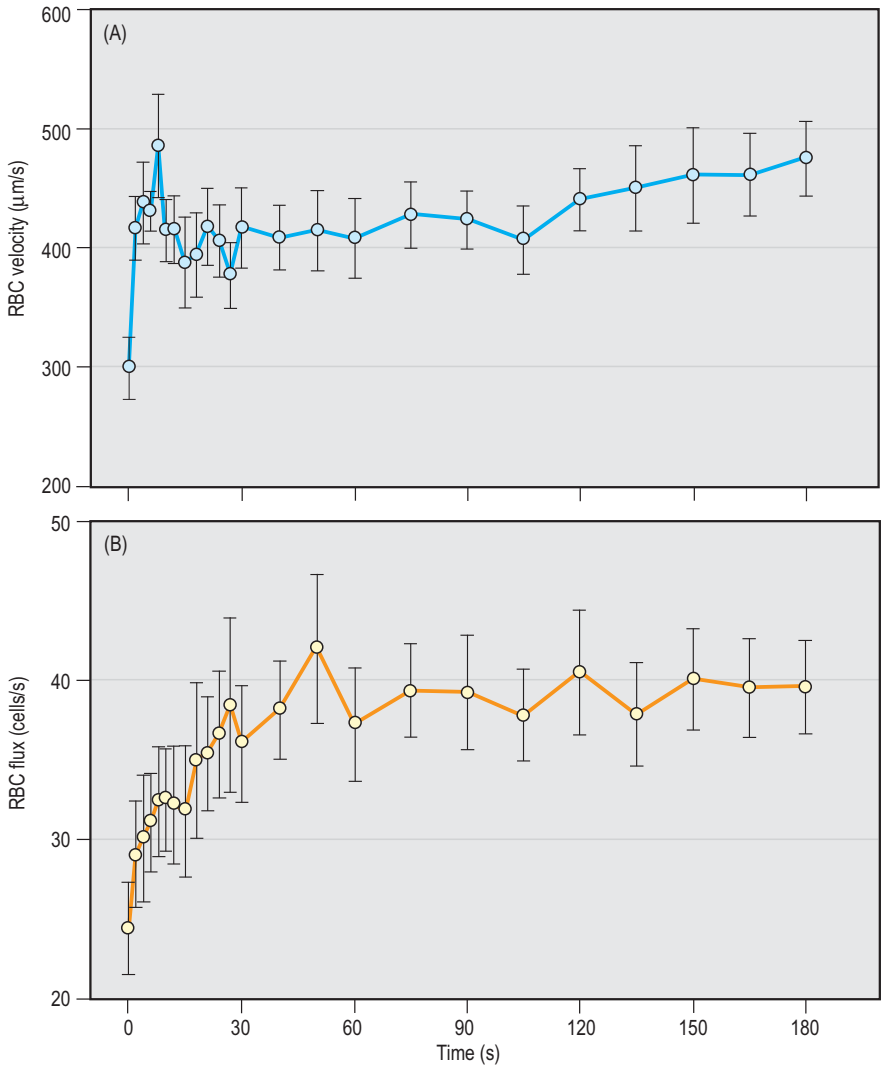

Fig. 32.32
Within the capillary bed of skeletal muscle, red blood cell (RBC) velocity (A) and flux (B) increase within the first few contractions at the start of exercise. (Reproduced with kind permission from Kindig et al.[134])

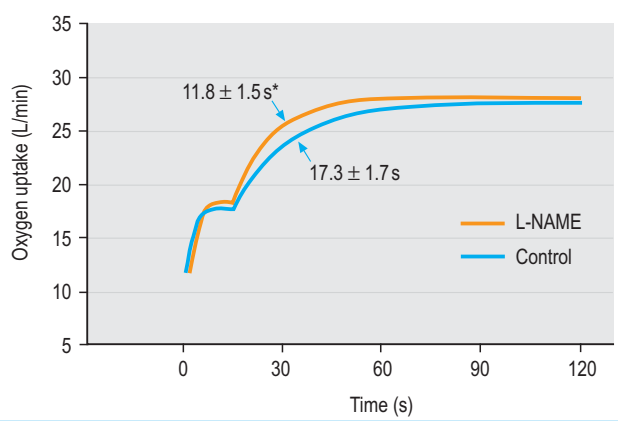

Fig. 32.33
Inhibition of nitric oxide production by L-NAME (nitric oxide synthase inhibitor, N^G-L-nitro-arginine methyl ester) significantly speeds the O_2 uptake ($\dot{V}O_2$) response at the onset of moderate speed running (7 m/s). (Reproduced with kind permission from Kindig et al.[64])

approximately 250 μm/s and a capillary tube hematocrit that averages only 25–50% of systemic values.[141] The instantaneous muscle O_2 diffusing capacity is thought to be determined by the number of RBCs in the capillary lying adjacent to the muscle fiber.[144] Consequently, the total length of capillaries adjacent to a muscle fiber in combination with their hematocrit (i.e. number of RBCs per unit length of capillary) will set the potential for O_2 flux. As muscle contracts and blood flow increases, capillary RBC velocity and flux are elevated rapidly (Fig. 32.32) and hematocrit increases towards systemic values.[134] If we extrapolate what is known from microscopic observations in contracting rodent muscle to the exercising horse using equine capillary morphometric[42] and blood flow[46] data, from rest to maximal exercise capillary hematocrit is predicted to increase from approximately 10% up to approximately 60% and mean RBC capillary transit time decreases to about 1–2 s (which is substantially longer than seen in the pulmonary capillaries). This presents a remarkable scenario. Specifically, during maximal exercise, if the systemic polycythemia is expressed at the microcirculatory level (as suggested from rodent studies), the sixfold increase in

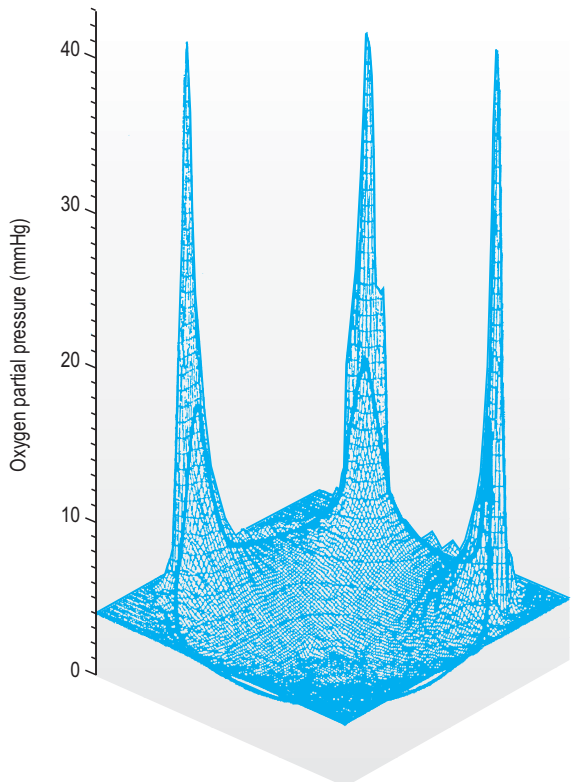

Fig. 32.34
Three-dimensional reconstruction of the O_2 partial pressure (P_{O_2}) profile within the muscle capillary and the contracting myocyte. Sarcolemma is indicated by thick line. Notice that the principal drop in P_{O_2} occurs in close proximity (within 1 μm) to the capillary spikes and that the intramyocyte P_{O_2} profile is remarkably flat without appreciable P_{O_2} gradients. This suggests that, at least in red muscle fibers containing myoglobin, even relatively large intracellular O_2 diffusion distances to the mitochondria are of little consequence. (Redrawn from Honig et al.[139])

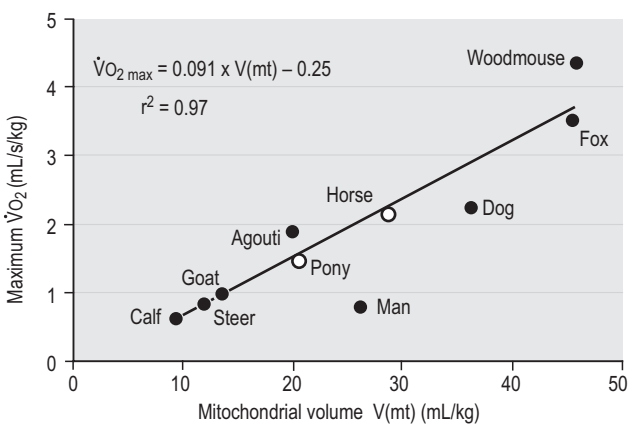

Fig. 32.35
There is a close relationship between whole body mitochondrial content and $\dot{V}O_{2max}$ across a wide range of mammalian species. This supports the notion that $\dot{V}O_{2max}$ increases in proportion to the structural capacity for muscle to utilize O_2. V(mt), mitochondrial volume. (Redrawn from Wagner et al.[18])

capillary hematocrit will facilitate rapid blood to muscle O_2 exchange. Moreover, as capillary RBC transit time is not thought to become limiting for O_2 offloading until values less than 0.3–0.5 s are reached, the mean transit time of 1–2 s in horse muscle is so long that there likely exists only a small proportion of capillaries where O_2 offloading is limited. These considerations help explain how the horse achieves such excellent O_2 extractions (up to 85–90%) at very high cardiac outputs.

Exercise training

Regular physical exercise or exercise training produces a coordinated pattern of structural and functional adaptations within the cardiovascular and muscular systems. The first three main sections of this chapter dealt with the anatomy and physiology of these systems and their responses to acute exercise (i.e. a single bout). This section details the remarkable plasticity of the cardiovascular and muscular systems in response to training and focuses primarily on those adaptations which elevate $\dot{V}O_{2max}$ and running performance. There exists a substantial literature on this topic in other species such as the human, dog, and rat,[45,113,131,145] and this section will avoid an exhaustive overview. Rather it will focus on understanding the mechanistic basis for the elevated training-induced $\dot{V}O_{2max}$ that occurs in both young and old horses.[59]

Historically, $\dot{Q}$ and $\dot{Q}O_2$ have been considered the principal, if not the sole, determinants of $\dot{V}O_{2max}$ and its increase with training. However, the insightful modeling and novel experiments of Professor Peter D. Wagner at the University of California at San Diego[18] and others[146–149] have established

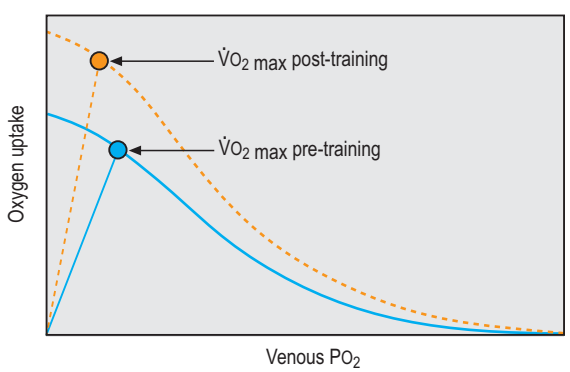

Fig. 32.36
The Wagner diagram demonstrates that exercise training increases $\dot{V}O_{2max}$ by elevating both conductive (curved line, due to increased stroke volume) and diffusive (straight line, due principally to increased muscle capillarity) O_2 transport. Note that even a modest reduction in venous P_{O_2} (5–10%)[150] after training requires a substantial increase (~ 30%) in muscle O_2 diffusing capacity. Moreover, if training solely increased convective O_2 delivery and there was no augmentation of muscle diffusing capacity, venous P_{O_2} would rise after training. This has not been observed. For additional information see legend to Fig. 32.7 and Table 32.7.

Table 32.7 Principal cardiovascular effects of exercise training in the horse at maximal exercise

Variable	% Increase	Reference(s)
$\dot{V}O_{2max}$	10–25	67,150,158–161
Mean arterial pressure (at max)	NC	
Total peripheral resistance	Decreased	
Conductive oxygen transport, max		
Heart weight	10+	22,25
Cardiac output, max	Increased	
Stroke volume, max	10+	56
Myocardial hypertrophy		
LV mass	33	25,152
LV internal diameter	7	152
Plasma volume	19–30	150,155,162
Central venous pressure	?	
Pericardial hypertrophy	Yes?	
Systemic [hemoglobin]/hematocrit	NC or decreased	150
Arterial O_2 content	NC or decreased	
Red cell mass	15	150
Heart rate, max	NC	59,158,163
Muscle diffusing capacity		
Arterial–venous O_2 extraction, max	5	150
Capillarity		
Capillary density	13–36	161,164,165
Capillary–fiber ratio	70	161,166
Myoglobin	?	
Oxidative enzymes	Up to 100	159,164,165,167–169,170
Mitochondrial volume	75–200	161,171
Capillary hematocrit	Increased?	
Capillary RBC transit time	?	
Velocity — submaximal heart rates/blood lactate concentrations		
V200	NC or increased	172
V140	Increased	173
V_{La4}	Up to 31	165,174
La_9	(–51)	174
Run time to fatigue (90–100% $\dot{V}O_{2max}$)		
Time	140	161

NC, no change; ?, unknown.
$\dot{V}O_{2max}$, maximal oxygen uptake; V200, V140, running velocity at a heart rate of 200 and 140 beats/min; respectively; V_{La4}, running velocity that induces a lactic acidosis of 4 mmol/L; La_9, blood lactate concentration at a running velocity of 9 m/s.

that $\dot{V}O_{2max}$ and training-induced increases thereof are the result of a coordinated sequence of adaptations that increases the capacity for conductive and diffusive movement of O_2 from the atmosphere to its site of utilization within muscle mitochondria. The 'Wagner' diagram combines these conductive and diffusive elements (as seen in Fig. 32.7), and it is instructive to use this diagram to understand how training increases $\dot{V}O_{2max}$ (Fig. 32.36). The relationship seen in Fig. 32.36 presents the increased $\dot{V}O_{2max}$ as an elevated cardiovascular O_2 delivery ($\dot{Q}O_2$) concomitant with an elevated fractional O_2 extraction (increased $Ca-CvO_2$) that reduces muscle effluent and mixed-venous PO_2. Typically, training-induced increases in fractional O_2 extraction and reduction of venous PO_2 are relatively modest, and this observation has led to the erroneous belief that adaptations to training within muscle that increase O_2 diffusing capacity (e.g. increased muscle capillarity) are of no, or at least, lesser importance than those cardiovascular changes that elevate $\dot{Q}O_2$. Nothing could be further from the truth. Notice from Fig. 32.36 that simply increasing $\dot{Q}O_2$ at the same diffusing capacity (i.e. slope of line from the origin to $\dot{V}O_{2max}$) will *decrease* O_2 extraction and *elevate* venous PO_2. That this response is not seen after training is the result of adaptations within the capillary bed (Table 32.7) that substantially increase muscle O_2 diffusing capacity.[44,131,151] Table 32.7 lists the primary adaptations to training that produce the response evident in Fig. 32.36.

Training usually increases $\dot{V}O_{2max}$ between 10 and 25% and as in other species[45,113,131,145] the % improvement is dependent upon initial fitness with fitter individuals having less room for improvement. In addition to an increased muscle O_2 diffusing capacity, the higher post-training $\dot{V}O_{2max}$ is driven by an elevated $\dot{Q}$ (and $\dot{Q}O_2$) consequent to increased SV. Maximal heart rate does not change. At maximal exercise,

the elevated $\dot{Q}$ occurs without any increase in MAP and so the elevated $\dot{Q}$ must be countered by a precisely matched fall in total peripheral resistance.[113]

Mechanistic bases for training-induced SV increase

After training, ventricular mass and volume is increased.[25,152] Training elevates blood/plasma volume and subsequently end-diastolic volume and this stretches the myocardial fibers and increases both the force and velocity of contraction. This adaptation occurs in the absence of any substantial changes in myocardial contractility per se[113,153,154] and as MAP is unchanged by training, it cannot be caused by modulation of cardiac afterload. Training expands plasma volume[150,155] and this may elevate ventricular preload by increasing central venous pressure. However, experiments in humans have not demonstrated that expanding plasma volume consistently increases central venous pressure and SV.[113] What is certain is that removal of the pericardium does increase SV and maximal $\dot{Q}$ in the absence of altered preload.[13,14] Indeed, removing the pericardial constraint to myocardial expansion produces an increased maximal $\dot{Q}$ similar to that found after weeks or months of training. There is evidence that volume overload chronically stretches the pericardial sac[156] and decreases its stiffness[157] such that after training a much smaller rise in cardiac filling pressure is needed to increase SV[113] and a greater SV can be achieved. To date, there is no available evidence that pericardectomies have been performed as an ergogenic aid in racing horses. It is pertinent that training-induced increases in heart size may promote valvular (mitral and tricuspid) insufficiencies and regurgitation which will act to limit the improvement in cardiac output.[104]

Mechanistic bases for increased muscle vascular conductance and O_2 diffusing capacity (and increased Ca_{O_2}–Cv_{O_2}) after training

Arterial O_2 content (Ca_{O_2}) is not elevated by training (although small increases in arterial P_{O_2} during submaximal exercise may be found),[173] hence any increased Ca_{O_2}–Cv_{O_2} must result from a decreased Cv_{O_2}. This decreased Cv_{O_2} does not arise from a greater vasoconstriction in other organs or inactive muscle vascular beds but rather from a preferential redistribution of the training-induced $\dot{Q}$ increase towards the active muscles[113,114,175] and a greater total and fractional extraction of O_2 within those muscles.

Exercise training induces a rapid and profound growth of arterioles and capillaries within skeletal muscle[45,176–179] and increases the sensitivity of cardiac[180] and skeletal muscle[181,182] arterioles to vasoactive mediators such as prostaglandins, catecholamines, and nitric oxide. Moreover, training increases the availability of nitric oxide in the myocardium by upregulating endothelial nitric oxide synthase, which is the enzyme responsible for much of the nitric oxide production within the arterial tree.[183] It is quite possible that this latter adaptation occurs also in skeletal muscle. Exercise training increases $\dot{Q}$ capacity in muscles composed of both slow- and fast-twitch fibers provided they are recruited during exercise.[184] The distribution of $\dot{Q}$ within and between muscles is altered after training which may be important for improving the matching of O_2 delivery ($\dot{Q}_{O_2}$) to O_2 utilization ($\dot{V}_{O_2}$).[114,141] After training, capillary length and surface area per fiber volume as well as capillary surface to fiber surface contact is increased in proportion to the elevated muscle oxidative enzyme capacity.[44,45,131,177] Such capillary proliferation increases the capillary surface area available for O_2 exchange and by increasing capillary volume may prevent or at least constrain any reduction in capillary RBC transit time that would otherwise result from the elevated muscle $\dot{Q}$. It is pertinent that the effect of training on capillary RBC transit time will depend on the precise proportionality between increased $\dot{Q}$ and elevated capillary volume. Moreover, the effect of training on capillary hematocrit (a key determinant of blood-muscle O_2 movement) is not at present known. What is certain is that muscle O_2 diffusing capacity increases dramatically with training to facilitate a substantially increased total O_2 extraction (Fig. 32.36).

Conclusions

Both the cardiovascular and muscular systems evidence great plasticity. During maximal exercise after training, improved cardiac function elevates total $\dot{Q}$ and muscle $\dot{Q}$ (and $\dot{Q}_{O_2}$) Synchronized muscle vascular and intramyocyte oxidative enzyme proliferation permits trained muscle to accept this increased $\dot{Q}$, elevate O_2 exchange, and facilitate a greater O_2 utilization at maximal exercise (increased $\dot{V}_{O_{2max}}$). At submaximal running speeds, exercise training speeds $\dot{V}_{O_2}$ kinetics,[131] tightens metabolic control which reduces glycolysis and glycogen utilization,[45,145] and elevates stroke volume thereby lowering heart rate. This in turn may actually reduce the $\dot{V}_{O_2}$ cost of running at submaximal speeds.[131] The training response may be augmented by hypoxia and is modulated by running speed, frequency, and duration.

CHAPTER 33

Diseases of the heart and vessels

Lesley Young

Cardiac murmurs and arrhythmias are detected commonly in performance horses, creating problems for veterinarians who must then determine their significance.[1–4] This chapter will address the diseases and abnormalities affecting the heart and vessels of the athletic horse:

- abnormalities of cardiac rhythm
- cardiac murmurs
- diseases of the myocardium and pericardium
- diseases of the vessels.

When performance horses are presented with a cardiac arrhythmia, or murmur, an accurate history and a thorough physical examination are often all that is required to determine the relevance of the abnormality. As determination of the significance of cardiac abnormalities detected by auscultation forms the largest part of performance horse cardiology, this chapter will first address the general approach to equine cardiology cases, including the technique of cardiac auscultation. During discussion of specific cardiovascular abnormalities, emphasis will be placed on diagnosis, the physical signs used to assess severity and prognosis, and the most useful ancillary aids for determining the significance of cardiovascular dysfunction in performance horses.

General approach to equine cardiology

Overall approach

The horse is equipped with enormous cardiac reserve (see Chapter 32) and as a result, evaluation of the equine cardiovascular system at rest provides limited information. Only when increased demand is placed on the heart during exercise will the effect of more subtle cardiac or vascular lesions become obvious. It is clearly important not to lose sight of the plethora of other reasons that cause horses to fail to perform to owners' expectations.[5] As has been emphasized elsewhere in this book, the probability of heart disease is low on the list of causes of poor performance, compared to orthopedic or respiratory disease. Clearly field, or treadmill, exercise tests provide the optimal environment to assess cardiac function in equine athletes, but it is often impractical or inappropriate to evaluate the heart at the limits of its reserve. As a result, the clinician must rely on clinical history to provide a subjective assessment of exercise tolerance and physical examination to assess the hemodynamic effect of any lesions present. In many cases, electrocardiography and echocardiography provide additional information useful in forming a diagnosis and prognosis.

Clinical history

The importance of obtaining a thorough case history cannot be overemphasized in considering the significance of cardiac murmurs or dysrhythmias in horses. It will usually be obvious if a horse is in overt heart failure, but this is not a frequent diagnosis in performance horses. It is much more common to discover a cardiac murmur or dysrhythmia in an apparently normal horse during a pre-purchase examination, when the horse is presented with a history of poor performance, or when a horse is examined because of illness.

As a result, the clinician must rely on clinical history to provide a subjective assessment of exercise tolerance and physical examination to assess the hemodynamic effect of any lesions present.

Cardiac auscultation

Despite advances in technology, cardiac auscultation remains the most important technique for the diagnosis of cardiac disease in horses. It is important to develop a systematic, logical approach to cardiac auscultation for it to yield maximum information. The recent suggestion that equine clinicians find interpretation of auscultation findings difficult only serves to emphasize the importance of developing the necessary skills to perform this very important technique with confidence.[6]

Findings from cardiac auscultation are always used in combination with performance history, patient details, and the remainder of the clinical examination to evaluate the significance of any suspected cardiovascular abnormalities.

Technique

Rules

- Always auscultate both sides of the chest.
- Always palpate for an apex beat on both sides of the chest (Fig. 33.1).
- Always maintain a standard systematic approach for listening to the whole cardiac cycle at each valve area.

Location of valve areas Classically landmarks for localization of cardiac valve areas have been described with reference to rib spaces and anatomic landmarks.[7] The mental effort of remembering the landmarks, coupled with marked breed variation in thoracic conformation, makes this approach difficult to put into practice. It also encourages the clinician to remove the stethoscope from the patient's chest, to examine each valve individually, potentially leaving wide areas of the cardiac auscultation area unexamined. An alternative approach is suggested.

Left hemithorax Palpation of the left apex beat (Fig. 33.1) provides an easy landmark for the mitral valve auscultation area. The apex beat should be palpated with the flat of the left hand. The stethoscope is then placed exactly over the apex beat. The point of maximal intensity (PMI) of sounds associated with the mitral valve is usually in this area. In this region the first heart sound, S_1, caused by various vibrations at the onset of ventricular systole, should be loud. The third sound, S_3, associated with the end of rapid early ventricular filling, may also be audible. It is important to appreciate that the normal diastolic sounds S_3 and S_4 are not always clearly audible in every horse. Once in position at the apex beat, the examiner should concentrate specifically on both diastole and systole for a number of complete heart cycles. The stethoscope is then moved slowly and deliberately in radiating directions around the mitral valve area while maintaining contact with the chest wall, until S_1 is no longer clearly audible.

The remaining valve areas on the left are then accessed by gradually moving the stethoscope in a cranial direction from the mitral valve area. Once more, the stethoscope remains in contact with the chest wall at all times. As the stethoscope is advanced slightly dorsal and cranial, the relative loudness of S_1 and S_2 is reversed, and S_2 is accentuated relative to S_1. As this occurs, the stethoscope is positioned at the point of maximal intensity of the semilunar valves. The first, more caudal and dorsal, valve encountered is the aortic valve. Once in the outflow valve area, the clinician performs the same radial scan of the area as for the mitral valve. S_2 will be loudest over the pulmonary valve, which is situated more cranial and slightly ventral to the area in which S_2 first becomes accentuated. Occasionally an audible splitting of S_2 may be heard in the area of the pulmonic valve. Usually the sound is split due to earlier closure of the aortic valve compared to the pulmonic valve, but the situation can also be reversed in horses.[8] The fourth heart sound, S_4, composed of vibrations arising from active atrial contraction is usually heard best in the area cranial and dorsal to the apex beat.

Right hemithorax It should also become standard to palpate for an apex beat on the right hemithorax. The vibrations are often palpable in narrow-chested athletic horses. If

Fig. 33.2
Auscultation of the right hemithorax is best achieved when the right forelimb is pulled forward.

an apex beat is detected, it represents an excellent starting point for thoracic auscultation. The auscultation area is more cranial on the right, and forward placement of the forelimb is necessary in many horses (Fig. 33.2). The only valve sounds reliably heard in this area are associated with the tricuspid valve. A similar radiating survey, with the stethoscope in contact with the chest wall, should be performed around the point of maximal intensity of the heart sounds on this side. Many clinicians find auscultation of the right side unrewarding, because the heart sounds are usually quieter on the right and there is more variation between horses. When difficulties arise, it is usually because the stethoscope is not positioned sufficiently cranial.

Abnormalities of cardiac rhythm

General principles

- Arrhythmias occur commonly in athletic horses[9] and the majority, with the notable exception of atrial fibrillation (AF), usually do not affect performance.
- In horses, use of limb leads for recording ECG traces is not advised. Wires and crocodile clips attached to the limbs are poorly tolerated and subject to a large amount of movement artifact. In addition the pattern of depolarization of the equine ventricle precludes using multiple leads for assessment of cardiac size and mean electrical axis.[10–12]
- The base apex-lead system, or modifications to it, are used exclusively for rhythm diagnosis in equine medicine (Fig 33.3). This lead system produces large complexes, which are easy to identify.[13]
- Diagnosis of arrhythmias has been greatly enhanced by improvements in technology that allow ECG recordings to be taken readily in resting and exercising horses (Fig 33.4). The newer technology, based on palm-top computers and hand-held battery-operated devices, is becoming increasingly affordable for equine veterinarians (Fig 33.5). Increased availability and practicability of this equipment means that disorders of cardiac rhythm are diagnosed more frequently in horses at rest and during exercise and their significance must then be determined.

Cardiac disease is a rare primary cause of poor performance in the equine athlete, but on the rare occasion that performance is affected by cardiac disease, arrhythmia is the commonest underlying cause.[5] Paradoxically, alterations in cardiac rhythm are common in athletic horses because of their normal high parasympathetic drive,[14] so the equine clinician is faced with a wide variety of normal rhythms in resting horses. Bradyarrhythmias (slow rhythms) are normal findings in athletic horses, as are sinus and atrioventricular block.[9,15] Despite this, on rare occasions, all of these normal rhythms can also result from cardiac disease, when the arrhythmia causes serious decrements to performance and presents significant risks to the rider and horse.[16] Conversely, obvious arrhythmia such as atrial fibrillation, may have no obvious effect on the performance of horses engaged in activities that are not aerobically challenging (dressage or show jumping). By contrast, if all of the cardiac reserve must be used, the effect of the same arrhythmia on performance is devastating (racing, three-day eventing).[17–19] Finally, cardiac rhythm disturbances often occur as a result of disease in other body systems or metabolic disturbances.[20,21] In such cases, the arrhythmia rarely indicates primary heart disease.

The main hemodynamic effect of abnormalities of cardiac rhythm is to change cardiac output. These alterations can result from effects on heart rate or stroke volume. In some

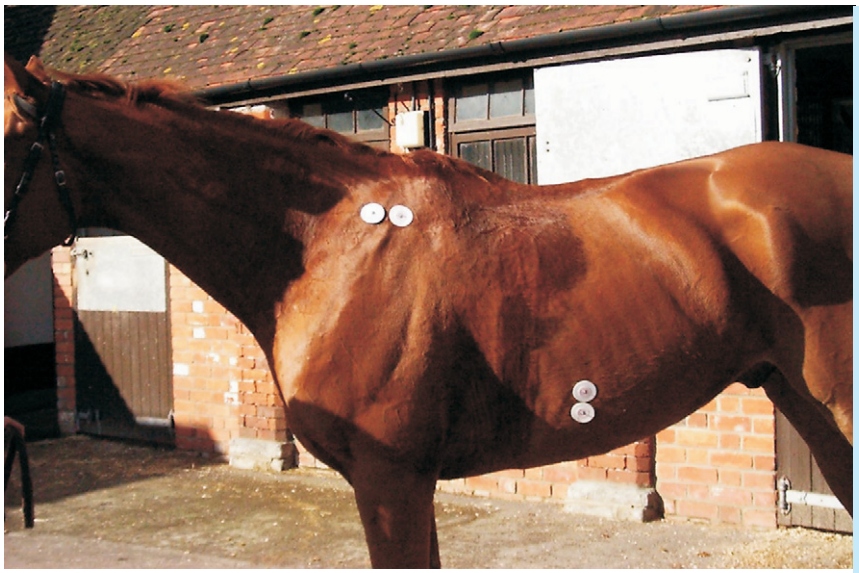

Fig. 33.3
Placement of four silver/silver chloride adhesive electrodes suitable for recording an ECG during ridden exercise. High-quality adhesive electrodes must always be used for exercising recordings and a spare electrode is always applied before exercise commences, in case one should become dislodged during fast work. This lead configuration is a modified base-apex system. The recording system used in this case was bipolar (positive and negative leads only) and did not require an earth. For recorders with an earth lead, a similar configuration can be used, with the extra earth electrode placed on the shoulder, or behind the withers near the negative lead.

To record a true base-apex lead the positive or left arm electrode is positioned at the left cardiac apex, and the right arm negative electrode is placed two-thirds of the way down the jugular groove on the right. The third (earth) electrode is placed in a remote position away from the heart. The ECG is recorded from lead 1 on a standard three-lead ECG machine. This configuration will give maximum deflections for both atrial and ventricular waveforms, but is completely unsuitable for prolonged monitoring, or exercising recordings. The vertical modification shown will still produce large QRS deflections, but the atrial deflection (P wave) will be slightly lower in amplitude than that of a true base-apex configuration.

cases, especially when the abnormal rhythm is fast, arrhythmia begets further arrhythmia as myocardial oxygen demand increases and coronary perfusion declines in the face of reduced diastolic blood pressure. It remains an important general rule that treatment of arrhythmia is only indicated when the abnormal rhythm has, or is likely to have, a significant effect on cardiac function, or when treatment is likely to resolve the arrhythmogenic mechanism (e.g. correction of acid–base and electrolyte imbalances).

Fig. 33.4
Placement of four silver/silver chloride adhesive electrodes suitable for recording an ECG during ridden exercise. Once in place as depicted in Fig. 33.3, the electrodes remain visible to the rider and/or examiner. As a result they can be reattached easily should they become dislodged, and are unlikely to be affected by the saddle or girth slipping backwards during fast exercise. The recording device is just visible attached to an elastic surcingle behind the rider's leg where it usually causes minimum disruption and discomfort. For harness racing the electrodes are positioned similarly, away from any moving harness straps. Radiotelelemetric recording systems can be used to obtain exercising traces. These units use a local transmitter carried by the horse that continuously transmits the signal to a local recorder. They are expensive and require that the recorder remain within at least 250 m of the exercising horse. This can create practical problems for many equine athletes, unless a horse regularly exercises with a scurry or there is good vehicular access to the exercise grounds.

Fig. 33.5
Portable devices have been developed that are competitively priced and able to record up to 60 minutes of ECG from exercising horses; these devices have promise for equine sports medicine. (Courtesy of Wheeler Monitoring (email: jcwheeler@iee.org).)

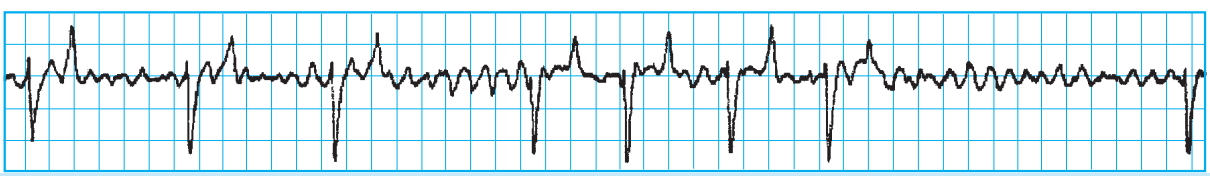

Fig. 33.6
Electrocardiogram (base-apex configuration) of a horse with atrial fibrillation. The typical characteristics include an irregularly irregular rhythm, coarse baseline perturbations called flutter (F) waves, and QRS complexes of normal width and morphology. Atrial fibrillation

- A re-entrant rhythm disorder characterized by an irregularly irregular rhythm (Fig. 33.6).
- The abnormal rhythm may occasionally self-correct within hours to days of becoming established.
- Atrial fibrillation (AF) is the commonest cardiovascular cause of poor performance in racehorses.
- AF can be associated with severe cardiac disease, or occur in the absence of detectable cardiac lesions.
- Treatment depends on whether underlying cardiac disease is present and the effect of the abnormal rhythm on performance.
- The prognosis for successful treatment and return to previous athletic function in the absence of cardiac disease is fair to good.

Recognition

History

AF may occur in horses with no other evidence of cardiac disease, or it may be precipitated by atrial dilation secondary to underlying heart disease, most commonly longstanding mitral regurgitation[17] (Fig. 33.7). When AF occurs in isolation, it is often larger breed horses that are affected. Affected animals usually present with a history of poor performance at maximal exertion (during finishing or sprinting in racehorses, galloping or hill work in event horses and hunters). Although horses affected with AF can compensate for suboptimal cardiac filling by increasing heart rate at all levels of exercise to maintain forward cardiac output, they attain maximum heart rate at lower exercise intensity and therefore fatigue sooner.[22,23] Despite attaining peak heart rates exceeding 280 beats/min, affected horses fail to wholly compensate for their reduced diastolic function. In some horses, AF is associated with epistaxis.[18,24]

If AF develops suddenly, during fast work, there is an acute decrease in cardiac output, and affected horses may pull up suddenly, sometimes with ataxia and distress. Immediate thoracic auscultation reveals a rapid chaotic rhythm. Obvious performance decrements are not invariably the case, however, as affected horses may appear to work normally at submaximal intensity. The rhythm, once initiated can be sustained, but short-lived paroxysmal AF also occurs during exercise (Fig. 33.8).[25] Paroxysmal AF resolves in the minutes, hours, or days following exercise and may be difficult to

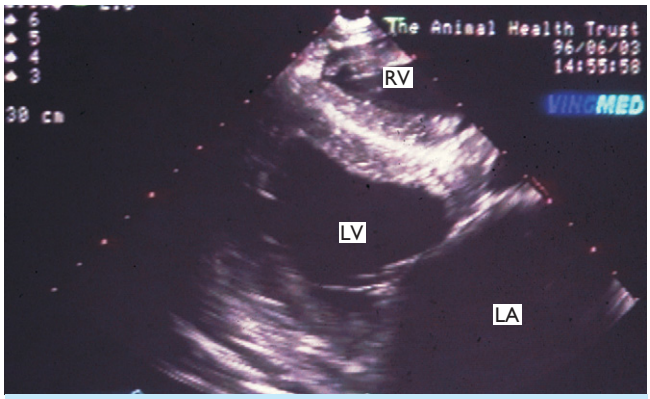

Fig. 33.7
Two-dimensional echocardiograph from a 3-year-old colt in training with a season-long history of poor performance, believed by the trainer to be due to chronic foot lameness. When the colt developed a cough, veterinary examination revealed a fast irregular heart rhythm and a grade 5/6 murmur suggestive of mitral valve regurgitation. The image is taken from the right hemithorax and shows massive left atrial enlargement from longstanding severe mitral regurgitation. Although the colt had no physical signs of heart failure, treatment was not attempted and the horse was euthanased. LA, left atrium; LV, left ventricle; RV, right ventricle.

detect. As a result, AF is a possible cause for fading during racing or competition when horses are subsequently presented in normal sinus rhythm.[26]

Physical examination

Auscultation findings in cases of AF will depend on the underlying cause. The irregularly irregular rhythm will be common to all cases of sustained AF, but in horses with AF secondary to atrial dilation from cardiac disease, there will be an elevated heart rate, characteristic cardiac murmurs, and physical signs of heart failure. Careful auscultation of these cases will reveal the underlying cause such as mitral regurgitation or ventricular septal defect. Horses with AF but no significant underlying heart disease usually have a normal resting heart rate. Vagal tone at the atrioventricular node will cause waxing and waning of the cardiac rhythm that can appear deceptively similar to second degree atrioventricular block.[27] This feature can be confusing, but the two rhythms can always be differentiated with patient auscultation because an unexpected early beat will be always be detected (Fig. 33.9A).

Other findings include a complete absence of the fourth heart sound (associated with atrial contraction), often with increased intensity of the third sound. The first and largest of the three jugular pulsations will also be absent. Other clinical signs will be evident if the abnormal rhythm is associated with heart failure.

Special examination

Electrocardiography will reveal an irregularly irregular rhythm with a complete absence of P waves. Cardiac rate will depend on the presence or absence of associated cardiac disease. Fibrillation or F waves may or may not be visible (Figs 33.6, 33.9B). Echocardiography can be a useful adjunctive aid to determine the presence or absence of cardiac lesions and assess chamber size, when physical examination and clinical history cannot rule out significant cardiac disease (Figs 33.7, 33.10B).

Laboratory tests

AF can be associated with alterations in electrolyte status. Plasma or serum concentrations of cardiac troponin I, isoenzymes of lactate dehydrogenase, and other biochemical markers of myocardial injury and inflammation are rarely elevated in cases of AF, unless the condition is associated with toxic damage to the heart, or end-stage valve disease.

Fig. 33.8 Base apex ECG taken from a 7-year-old Thoroughbred mare, 20 minutes after dramatically fading during fast work. Heart rate is still elevated (average rate 140 beats/min) and the rhythm is irregularly irregular. The QRS complex width and morphology is normal and P waves are not visible. There are positive baseline undulations between the seventh and eighth and ninth and tenth beat that may be mistaken for P waves (downward pointing red arrows). Closer inspection reveals them to be too close to the QRS complex that follows and more characteristic F waves are visible in the long diastolic interval before the final QRS complex. This trace illustrates the high heart rate maintained by horses affected with paroxysmal atrial fibrillation. The horse spontaneously converted to normal sinus rhythm within 5 hours of the bout occurring.

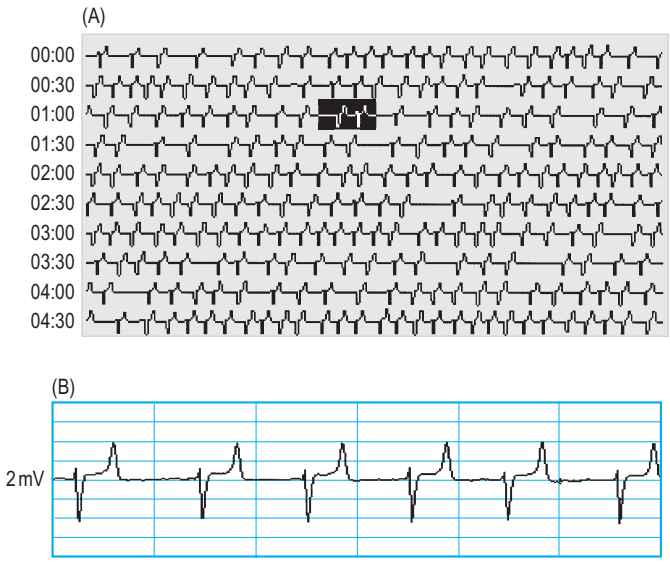

Fig. 33.9 (A) Summary of a continuous 5-minute ECG recording from a 5-year-old Thoroughbred race horse. The summary clearly demonstrates the irregular irregularity of atrial fibrillation that would become obvious with prolonged monitoring by auscultation. Notice that during periods of rapid conduction the rhythm can seem almost regular and that during periods of slow conduction it might be mistaken for sinus arrhythmia and second degree AV block. As a result, the rhythm is not infrequently missed when a cursory examination by auscultation is performed. (B) This expanded ECG trace of the horse in A shows fine atrial fibrillation. Even after increasing the sensitivity of the ECG recorder obvious coarse F waves were not visible. Only the absence of P waves and the fairly subtle irregularity of R–R intervals reveal the underlying rhythm disturbance. The horse converted to normal sinus rhythm after oral administration of a total of 24 g of quinidine sulfate.

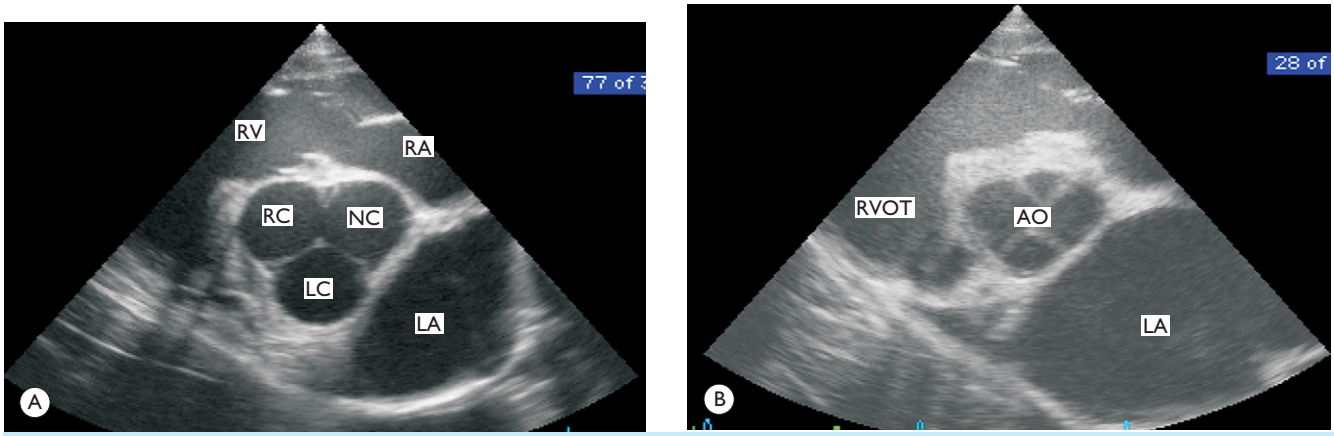

Fig. 33.10
(A) Two-dimensional echocardiograph from an 8-year-old Thoroughbred race horse with atrial fibrillation associated with a sudden decrease in race performance. The image is derived from the right hemithorax with the transducer positioned to obtain a short-axis view of the atrium and aorta. Comparison of the relative width of the left atrium with respect to the aortic root provides useful reference for determination of left atrial enlargement, regardless of horse size. Normal horses have a left atrial to aortic root ratio of less than 1.2:1. Although there was a grade 2/6 murmur of mitral regurgitation, the left atrial:aortic width ratio was within normal limits. The horse converted to normal sinus rhythm after administration of 45 g of quinidine sulfate p.o. LC, left coronary cusp of aortic valve; NC, non-coronary; RC, right coronary cusp; LA, left atrium; RV, right ventricle; RA, right atrium. (B) Two-year-old Thoroughbred flat racing filly with atrial fibrillation that presented with lethargy and poor exercise tolerance. The image is derived from the right hemithorax with the transducer positioned to obtain a short-axis view of the atrium and aorta. Visual inspection of the same image as in Fig. 33.10A shows the greatly increased left atrial:aortic width ratio (2.9:1). The difference is accentuated as low output cardiac failure has reduced left ventricular stroke volume and blood pressure and concurrently aortic diameter has also reduced. The filly was treated using digoxin to control cardiac rate, diuretics to reduce congestion, an angiotensin converting enzyme inhibitor (enalapril) to reduce cardiac afterload, and a calcium-sensitizing agent and phosphodiesterase inhibitor (pimobendan) to enhance myocardial contractility and further reduce afterload. Quinidine treatment is not appropriate when atrial fibrillation occurs secondary to left atrial enlargement. AO, aorta; RVOT, right ventricular outflow tract; LA, left atrium.

Treatment

Therapeutic aims

The therapeutic aims vary depending on the circumstances and cause of AF. When AF affects athletic performance and there is no evidence of underlying heart disease, therapy aims to convert AF to normal sinus rhythm and to prevent its recurrence. However, if AF is not associated with performance decrements, treatment may not be required, provided underlying heart disease can be ruled out. When AF coexists with heart failure, the abnormal rhythm should not be

specifically treated. Treatment goals in this instance include control of ventricular response rate, reduction of volume overload by diuretics, and cardiac afterload reduction by vasodilation.[28,29]

Therapy

Before drug therapy is contemplated, any underlying fluid, electrolyte or acid–base abnormalities should be corrected. When horses become dehydrated, or develop abnormalities of acid–base and electrolyte abnormalities, as might occur during three-day events or endurance competitions, restoration of fluid and electrolyte balance alone may be sufficient for normal sinus rhythm to restore itself.

Quinidine sulfate, a Class 1A antiarrhythmic, is traditionally administered to affected horses via a stomach tube to convert AF to normal sinus rhythm.[30,31] Intravenous administration of quinidine gluconate has been described,[32] but this preparation, though more convenient, is less effective when the arrhythmia is longstanding.[31,33] The intravenous preparation of quinidine gluconate is not available in the UK and production of quinidine sulfate has recently been discontinued. As a result quinidine must now be imported and as difficulty in obtaining quinidine sulfate increases in Europe, there has been a drive to investigate alternative treatments of equine AF. The Class 1C antiarrhythmic, flecainide, is more efficacious than quinidine in returning human patients to sinus rhythm after sustained[34] and paroxysmal AF,[35] and its use has been investigated in horses.[36] Flecainide was effective in returning horses to normal sinus rhythm after AF was induced by rapid atrial pacing,[37] but there are currently no data available on the efficacy of flecainide in naturally occurring disease. Class 3 agents, amioderone, sotalol, dofetilide, and ibutilide, also lengthen action potential duration and are being increasingly used alone and in combination for acute and chronic treatment of paroxysmal[35] and sustained AF in humans.[38] These agents have not been fully investigated in horses and their cost is likely to be prohibitive. Direct current cardioversion is also used in human medicine to convert AF to normal sinus rhythm and a similar technique has been used successfully to treat refractory atrial flutter in a horse.[39]

Treatment of atrial fibrillation with quinidine sulfate

Horses should not be treated for the first 72–96 hours following the development of AF, as some will spontaneously revert to normal sinus rhythm. Treatment should be contemplated only if there is no evidence of cardiac failure and if there is compromise of athletic ability.

Regime Traditionally the administration of a test dose of quinidine sulfate (10 mg/kg p.o.) was given to check for idiosyncratic reactions before commencing treatment. However this is not necessary and treatment is begun with 20 mg/kg quinidine sulfate administered via nasogastric tube (10 g per 500 kg horse). This dosage is repeated every 2 hours until sinus rhythm is restored, signs of toxicity develop, or a maximum total dose of 60–80 g (120 mg/kg) is achieved.

Signs of toxicity include urticaria, diarrhea, anorexia, weakness, ataxia, and tachycardia.[18,31] Nasal edema with stertorous breathing, and depression are commonly observed after only a few doses. Horses receiving quinidine should not be moved, as quinidine causes hypotension through α-receptor blockade.[40] A relationship has been demonstrated between high plasma quinidine concentrations ataxia and respiratory tract stridor, but not between plasma quinidine concentrations and tachycardia, diarrhea, or colic.[31] These authors also noted that conversion to normal sinus rhythm was less likely when signs of quinidine intoxication were present.[31] Laminitis has also been reported after quinidine treatment, but this side effect appears to be rare. Sudden death can also occur, usually without premonitory signs. In common with all Class 1A antiarrhythmic drugs, quinidine also has pro-arrhythmic properties.[41] By lengthening the myocardial cell refractory period through an effect on the repolarizing potassium channels, quinidine increases the risk of severe ventricular rhythm disturbances.[40] Because the drug increases atrioventricular (AV) nodal conduction, it has the potential to produce rapid supraventricular, as well as ventricular, tachycardia.[40] ECG recordings should be made before each treatment, and the QRS and QT interval measured. A 25% increase in the width of the QRS interval is associated with quinidine intoxication.[31]

Heart rate and rhythm must be monitored throughout treatment. The most common arrhythmia is supraventricular tachycardia (SVT) and it can be treated by the intravenous administration of 0.002 mg/kg digoxin.[31] However, digoxin has a slow onset of action and a long half-life and although the drug decreases AV nodal conduction and reduces heart rate, it also tends to stabilize AF by increasing the number of wavelets circulating in the atria and decreasing their wavelength.[42] This electrophysiological property makes digoxin of questionable benefit in the conversion of AF and it may be best withheld unless the supraventricular rhythm is life threatening. Usually, provided no further quinidine is given, tachycardia gradually subsides as plasma quinidine concentrations fall.

Horses that fail to revert to sinus rhythm after administration of 120 mg/kg quinidine, or that develop unacceptable side effects during cumulative dosing, sometimes respond to a second series of 20 mg/kg treatments after 24 hours without drug administration. Indeed some horses convert to normal sinus rhythm up to 24 hours after the final dose of quinidine has been administered without any additional drug administration or treatment. Recognition that horses are less likely to convert to normal sinus rhythm during quinidine intoxication,[31] probably explains this phenomenon, as the plasma concentration of the drug will return to the therapeutic range with time. The potential severity of quinidine's side effects has led to modifications of the traditional cumulative 2-hourly regime and an alternative regime has been suggested.[31] If a horse fails to respond to the initial 2-hourly treatments, when signs of toxicity develop, or when the maximum dose of quinidine has been reached, quinidine administration is continued at 6-hourly

intervals. These workers also recommend that digoxin (0.01 mg/kg) be given orally every 12 hours until sinus rhythm is restored. It has been suggested that this treatment regime reduces side effects, and decreases the total dosage of quinidine needed for successful conversion. It is worthy of note, however, that there is a possibility that the horse might convert to normal sinus rhythm once quinidine treatment has been discontinued without additional treatment, making the actual benefit of this regime difficult to assess. As a result, a pragmatic approach to patients failing to respond on day 1 of treatment is to wait for 24 hours without further drug administration and then commence 6-hourly quinidine administration, only if the 2-hourly regime fails for a second time. This modified regime avoids the practical difficulties of treatments during night hours. The use of digoxin in cases with pre-existing myocardial dysfunction has also been suggested, or after initial treatment fails,[31] but as discussed previously, concurrent use of digoxin also carries the risk that the abnormal rhythm may be stabilized, rather than abolished.

Aftercare Following successful conversion to normal sinus rhythm and return to a normal resting heart rate, it has been suggested that the horse should be checked for the presence of atrial premature systoles using 24-hour Holter monitoring.[43] The presence of frequent premature atrial systoles and atrial arrhythmias is suggested to indicate an increased risk of recurrence of AF. These authors suggest specific antiarrhythmic therapy (quinidine or digoxin) or anti-inflammatory therapy (see later) and prolonged rest (3–4 months) for such cases to reduce the likelihood of recurrence.[40] Unfortunately, there is no data available to assess critically the benefit of these various strategies for horses following successful conversion to normal sinus rhythm. As a result, in commercial practice when there are considerable financial pressures for horses to perform, coupled with a short competitive season, only after a patient reverts repeatedly to AF would such measures be contemplated.

A more pragmatic approach, even when AF may have been longstanding, is to rest the horse completely for 5–7 days, to allow the residual affects of quinidine to subside. The horse is then gradually returned to fast training over 3–4 weeks. Owners/trainers are advised to monitor cardiac rhythm regularly by palpation of the apex beat (Fig. 33.1), especially after fast work, throughout this period. While longer periods of rest may be optimal to allow the atria the best chance to remodel both mechanically and electrophysiologically, the cost–benefit of prolonged rest is currently unknown and commercial pressures usually preclude this.

Prognosis

Horses with longstanding AF (> 4 months) are less likely to convert to normal sinus rhythm and are more likely to revert to fibrillation after treatment than horses with more recent onset of the arrhythmia.[17,31] The success rate for conversion from AF to normal sinus rhythm using quinidine varies between 82 and 87%.[18,31] As a result, failure to achieve normal sinus rhythm occurs not uncommonly and owners should always be forewarned that success is not inevitable. When treatment of AF is successful, horses should return to their previous exercise tolerance. However, if the dysrhythmia is not affecting performance, in most cases, treatment should not be attempted. In some horses, recurrence of paroxysmal or sustained AF is a problem, although some owners and trainers become aware of the trigger factors and learn to manage them accordingly. In other cases when frequent recurrence or poor tolerance of treatment occurs, an alternative career can often be found for the horse. In such cases, and before treatment is attempted, it is important to establish that the rhythm is present in isolation and has not occurred secondary to atrial enlargement and heart failure (Figs 33.7, 33.10B). It is also advisable to monitor the heart rate and rhythm regularly at the intensity of exercise at which the horse is expected to perform. When AF exists with signs of heart failure, prognosis for return to athletic activity is hopeless.

Etiology and pathophysiology

AF is a re-entrant rhythm disturbance. The mechanism that was widely held to underlie the arrhythmia was that of multiple wavelets, a model that hypothesized that large numbers of wavelets moved randomly through the atria.[44] This theory has recently been superseded by evidence from complex electrophysiologic mapping studies that have suggested the wavefronts actually originate from the uninterrupted periodic activity of a small number of discrete re-entrant sites in the left atrium (rotors) possibly in the region of the pulmonary veins.[45] It seems likely that the rhythm is maintained because of differences in electrophysiologic characteristics between anatomic sites in the atria and between the left and right atria themselves. Regardless of the mechanism, the rhythm is maintained by a large atrial mass and inherent differences in the length of the refractory periods of atrial cells. The cells with long refractory periods produce physiologic blocks, and the large mass of tissue allows cells to repolarize before the initial wavefront has died out. As a result, waves of excitation continuously circle around the atria. Both atrial flutter and true AF occur in the horse. The difference probably reflects the number of wavelets in circulation. (Figs 33.6, 33.9B).

The risk of re-entry becoming established is increased with changes in autonomic tone.[46] Both parasympathetic and sympathetic stimulation increase the inhomogeneity of refractoriness within the atria, by changing the refractory period of the myocytes.[47] Most commonly in horses these changes occur during fast exercise or recovery, but they can also be invoked by use of vagotonic drugs such the α-adrenoreceptor agonists (xylazine, romifidine, and deto-

midine) and the opiates (butorphanol). Paroxysmal and sustained AF can also follow sedation, anesthesia,[48] and occasionally occurs after disease in other body systems.[49,50]

AF results in a decreased stroke volume due to the loss of the atrial contribution to filling. The atria contribute up to 15–20% to ventricular filling, but in most horses at rest the loss of the atrial contraction has little effect on cardiac output.[49] However during exercise when the heart rate is high and the time available for ventricular filling is reduced, the atrial contribution to filling becomes important. Therefore horses with AF have reduced performance only during maximal exertion, unless there is some other underlying cardiac disease that has precipitated the dysrhythmia. When present, AF always affects performance in racehorses.

Longstanding AF results in extensive electromechanical remodeling of the atrial muscle cells, including changes in the expression of membrane-bound ion channels.[45] This effect probably explains why sinus rhythm is difficult to recapture and subsequently maintain in some of these horses. In the series of cases examined by Else & Holmes,[51] 36/45 affected horses had gross lesions affecting the atria, including dilation, thinning, and fibrosis. The left atrium was more commonly affected than the right. Eighty percent of affected horses had lesions affecting the cardiac valves, most commonly the mitral valve, confirming clinical evidence that left atrial enlargement and mitral valve disease are important in the pathogenesis of sustained AF in horses.

Epidemiology

This arrhythmia is the commonest cardiovascular cause of poor performance in horses. Based on this author's epidemiologic studies on UK training yards, the approximate incidence of the sustained form of the arrhythmia is 1% in National Hunt Thoroughbreds. When large numbers of horses from a mixed population were examined, the prevalence of AF varied between 2.5 and 2.4%[51] and increased with age, an observation that probably explains the difference between the two groups of horses. Else & Holmes also observed that draught and heavy horses were overrepresented in their affected horses. The prevalence of the sustained form of AF is lower in smaller Thoroughbreds, but it appears to have a similar prevalence in Standardbred horses.[17] It is likely that paroxysmal AF occurs more commonly than is recognized in horses of all types, since unless performance is obviously affected, the rhythm goes unnoticed,[25] a situation that is similar in people.[52] Standardbreds, young horses, and males predominated in a group of 67 horses studied by Reef and colleagues (1988), but it is likely that these data reflect the bias of sex, breed and age in athletic horses, rather than relate to prevalence of AF in the horse population per se.[17] In the same study the majority of horses affected with AF had no clinical evidence of other cardiac disease (56.7%),

Supraventricular premature systoles

- Supraventricular premature beats arise from tissue above the level of the atrioventricular node. They usually originate in the atria and occur not infrequently in athletic horses.
- Their significance and underlying etiology is not well understood, although increased excitability of atrial tissue is associated with atrial stretch in severe cardiac disease (Figs 33.7, 33.10B).
- They can also be associated with primary myocardial damage (myocarditis), systemic disease, and electrolyte and acid–base derangement.
- Electrocardiographic examination is required for a definitive diagnosis.
- Electrocardiographic monitoring during appropriate exercise will be required to assess the effects of changes in autonomic tone and to determine the effect, if any, of the arrhythmia on performance.

Recognition

History

Supraventricular premature beats are usually detected incidentally during cardiac auscultation or palpation of arterial pulses in otherwise normal horses. They may be detected in association with myocardial inflammation or, more commonly, severe cardiac disease that has resulted in atrial dilation e.g. atrioventricular valve disease, large ventricular septal defect, or dilated cardiomyopathy. Supraventricular arrhythmia may also accompany systemic disease or any condition that modifies autonomic tone and alters electrolyte and acid–base status.

Physical examination

Isolated cardiac contractions are noted to follow too early in an otherwise normal rhythm during cardiac auscultation or pulse palpation. During supraventricular tachycardia, a fast regular rhythm will be noted by auscultation.

Special examination

A definitive diagnosis and the origin of all ectopic complexes must be determined by electrocardiography (Figs 33.11, 33.12A). When the complexes are atrial in origin, one or more premature complexes with normal QRS morphology will break the regular cardiac rhythm. The morphology of the preceding P wave may be different to the sinus beats (Fig. 33.12A), but the QRS complex will follow after the normal P–R interval. Occasionally the premature P wave will be buried in the preceding T wave and may be difficult to locate (Fig. 33.11).

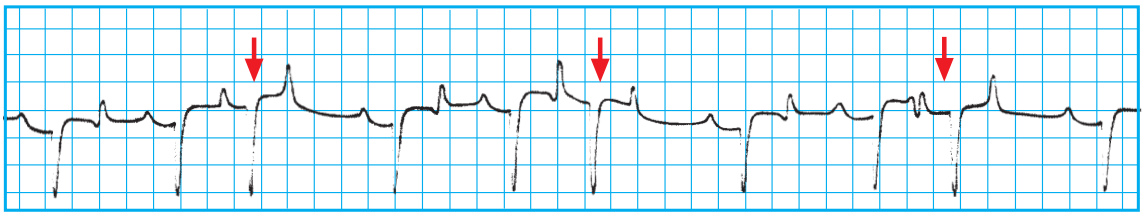

Fig. 33.11
Atrial premature beats in a 4-year-old National Hunt horse. The cardiac rhythm is broken by premature QRS waves indicated by red arrows. The premature complexes have a normal morphology and width. Their origin is not immediately obvious, as discrete associated ectopic P′ waves are difficult to discern because of their close proximity to the preceding T wave. Only in the third complex is a P′ wave obvious as it interrupts the preceding T wave. Note the normal P′–R interval that precedes the ectopic beat. Closer inspection of the T wave of the first two ectopic beats reveals them to be subtly different from the sinus T waves, suggesting that they also contain a P′ wave.

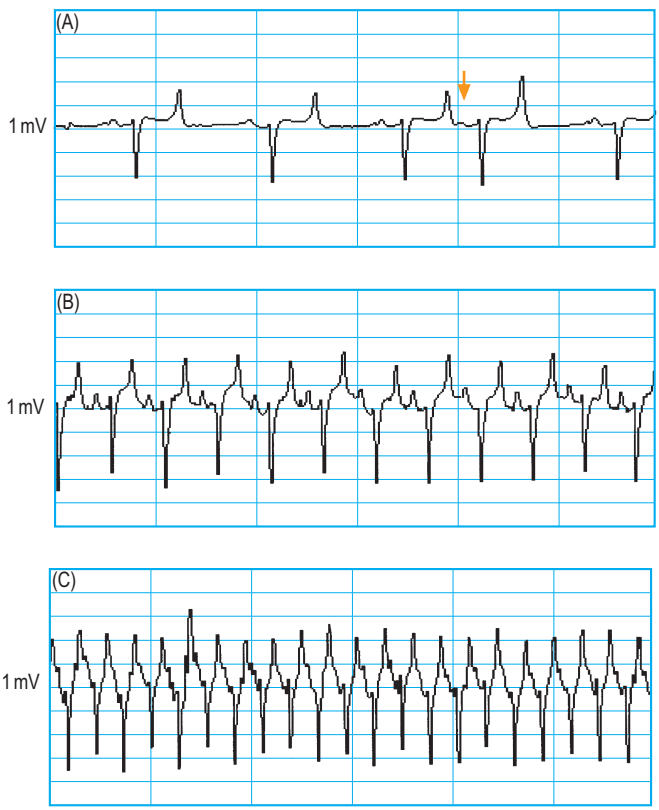

Fig. 33.12
(A) Atrial ectopy in an 8-year-old National Hunt gelding first diagnosed with the condition as a 2-year-old colt. Note the single atrial ectopic beat (arrow) followed by a normal P′–P interval. The ectopic P′ wave has a slightly different shape; unlike the sinus beats it is not bifid. (B) Same horse as in A. On exercise the ectopic focus was overridden, as shown in this trace from the horse taken during trotting (heart rate = 110). The R–R interval is constant and P waves are still visible, distinct from the preceding T waves. (C) Same horse as in A and B. At very fast heart rates (heart rate = 232) the P wave becomes increasingly difficult to discern, as it is now buried in the preceding T wave, but the R–R interval is absolutely regular. There is thus no evidence that the atrial arrhythmia present should be affecting performance in this individual. The condition was never treated and the horse was a successful flat and jumps racehorse, until lameness terminated his career at 8 years old.

In horses with isolated atrial premature beats without underlying disease, an ECG during appropriate ridden exercise will be required to assess the effect of exertion upon the arrhythmia and to evaluate its effect on athletic performance (Fig. 33.12).

Other tests In all cases of persistent supraventricular ectopic activity in horses, thorough evaluation of electrolyte status and assessment of other body systems should precede expensive specialized cardiac examinations.

Laboratory analysis of blood samples for concentrations of cardiac troponin I and isoenzymes of lactate dehydrogenase may also be useful to assess active myocardial necrosis and inflammation.

Echocardiography is also used to rule out cardiac chamber enlargement and abnormal wall motion suggestive of previous myocardial damage. In the majority of cases the results of all these examinations are unremarkable, or equivocal.

Treatment

Therapeutic aim

It is a general rule that arrhythmia should always be considered in the context of the patient's concurrent disease. Treatment of an atrial rhythm disturbance is only warranted when there is obvious decrement to cardiac function as a result of the abnormal rhythm, or if the rhythm is likely to degenerate into a more sinister life-threatening arrhythmia, a situation that is unlikely for most atrial arrhythmias.

As isolated atrial premature beats are not infrequently encountered in performance horses, they present a dilemma to the veterinarian. Usually specific antiarrhythmic treatment is not indicated, as the premature beats are too infrequent to significantly affect cardiac output at rest. Clearly in these animals it is important to establish what happens to heart rhythm during exercise. In many cases when sinus rate exceeds the firing rate of the single ectopic focus, there is overdrive suppression of the ectopic focus and cardiac rhythm is normal (Fig. 33.12).

Therapy

Atrial arrhythmias due to confirmed or suspected non-infectious myocardial disease may respond to treatment with

anti-inflammatory agents (dexamethasone 0.02–0.2 mg/kg) and rest. However the efficacy of treatment is not proven and a period of rest alone (2–3 months) can also result in resolution of the arrhythmia. We have also used oral prednisolone therapy in some cases. This treatment's efficacy is not proven either, but seems to be well tolerated. Our usual regime for a 500 kg horse is 400 mg prednisolone, orally, once daily for 4–7 days, 200 mg prednisolone daily for 4–7 days, and then 100 mg prednisolone daily for 4–7 days.

Prognosis

The prognosis for horses with atrial prematurity in the absence of cardiac disease is good. In these horses, the arrhythmia is rarely associated with poor performance and although there is a theoretical increased risk of AF developing in affected horses, this complication seems to occur rarely. Usually these horses remain in full work and competition, the arrhythmia may resolve, or be evident at each subsequent examination. When the arrhythmia is associated with laboratory or echocardiographic evidence of myocarditis, the prognosis is more guarded, although a percentage of affected animals will return to athletic performance following rest, steroid therapy, or the combination. When supraventricular arrhythmia is associated with severe cardiac disease, the prognosis is poor.

Etiology and pathophysiology

Specific information regarding the etiology of supraventricular ectopic beats in horses is lacking, but based on data from other species, the condition is associated with cardiac disease resulting in atrial dilation, stretch, and hypoxia. In the absence of specific cardiac pathology, electrolyte abnormalities alter atrial myocyte automaticity and, coupled with alterations in autonomic balance, promote ectopic activity and arrhythmias in other species. In horses, it has been suggested that the ectopic foci come from areas of local ischemia in the atria that provide the physiologic substrate for increased automaticity as the myocytes become hypoxic and die. Indeed areas of diffuse and focal fibrosis are common in the equine myocardium at post-mortem examination.[53–55] The precise etiology of the lesions is unknown, but the hypothesis that they are important in the pathogenesis of atrial arrhythmia is supported by a case report by Button and colleagues.[56] These authors identified areas of myocytolysis and replacement with fibrous tissue in the atrial myocardium of a Quarter Horse with multiple atrial arrhythmias.

Ventricular premature systoles

- Ventricular premature beats arise from tissue at or below the level of the atrioventricular junction (Figs 33.13, 33.14).
- Five or more consecutive ventricular premature beats constitute ventricular tachycardia, a rapid and potentially life-threatening rhythm that can lead to ventricular fibrillation and death.
- The significance and underlying etiology of ventricular premature beats in horses is not well understood, although in common with other species, increased excitability of equine ventricular myocardium is associated with ventricular dilation and myocardial hypoxia, inflammation, or necrosis.
- In horses ventricular premature beats are most often associated with disease of other body systems, electrolyte and acid–base derangement.[20]
- Ventricular premature beats occur commonly in the early cardiac slowing period after fast exercise in athletic horses when their presence rarely indicates cardiac pathology (Fig. 33.15).
- Because of the possibility of life-threatening ventricular tachycardia developing during exercise, horses with ventricular premature beats at rest should be retired from ridden work until thorough systemic and cardiovascular examinations can be performed.

Recognition

History

Ventricular premature beats are usually detected incidentally during cardiac auscultation or palpation of arterial pulses in otherwise normal horses. They may be detected in association with severe cardiac disease that has resulted in ventricular dilation (e.g. aortic valve disease or dilated cardiomyopathy), myocardial inflammation (e.g. myocarditis), or during disruption of the normal intracardiac conduction system (e.g. intra-interventricular septal rupture of an aortic root aneurysm).[57] Ventricular arrhythmia may also accompany systemic disease[21] or extreme exertion,[58] and any other conditions that modify autonomic tone, induce hypoxia, and alter electrolyte and acid–base status.[20]

Isolated and multiple ventricular ectopic beats are commonly detected in horses during the immediate early slowing period after maximal exercise. They rarely seem to be associated with primary cardiac disease and probably should not be overinterpreted when they appear only at this time. If they occur during work, the situation is quite different and an underlying cause should be sought and treated if possible. In the meantime the horse must be retired from ridden work because the risk of ventricular fibrillation is a significant danger to both horse and rider.

In general when considering ventricular ectopic beats in horses 'judge them according to the company they keep'.

Physical examination

Ventricular premature beats are usually detected incidentally during cardiac auscultation or palpation of arterial pulses, when they can be difficult to distinguish from

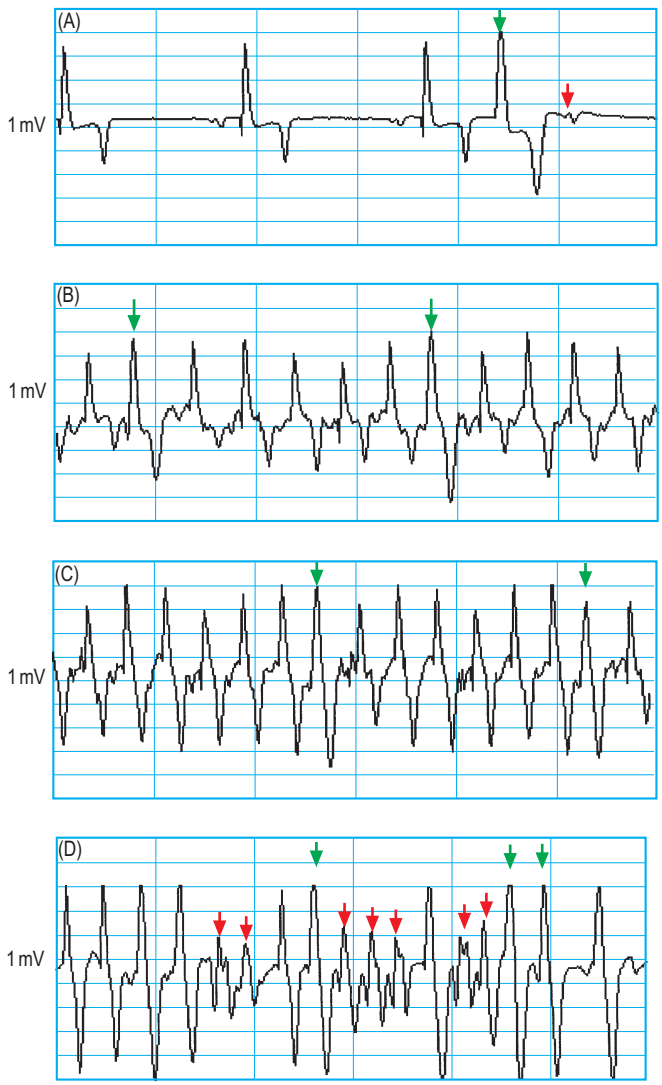

Fig. 33.13
(A) Inverted base apex ECG obtained from a 9-year-old Thoroughbred race horse with an arrhythmia at rest. A wide bizarre complex occurs after the third sinus beat. The bizarre shape of the premature QRS complex (green arrow) suggests ventricular origin and this is confirmed by the presence of the dissociated sinus P wave (red arrow) that follows at the normal sinus rate. Atrioventricular (AV) dissociation is another hallmark of ventricular prematurity. The sinus P wave follows as normal, but is not conducted to the ventricles, as they remain refractory due to the premature beat. In cases like this it is important to determine the effect of exercise on the ectopic focus and cardiac rhythm. In this case treadmill exercise was used. (B) Inverted base apex ECG from the same horse during trot. Note the increased sinus rate (heart rate = 120). Beats 2 and 8 are premature (green arrows) and have a slightly different conformation and are slightly wider suggesting a ventricular origin. There is still AV dissociation, but as sinus rate has increased the inverted P wave is just visible at the start of the inverted QRS complex of the premature beat. (C) As in A and B, the ventricular prematurity continues (green arrows, beats 8 and 15) during hack canter at 10 m/s.
(D) Inverted base-apex ECG from the horse in A–C 30 seconds after exercise to fatigue. Although ectopic beats are common in the early recovery period after exercise in athletic horses, (see Fig. 32.15), this horse suffered multiple sustained runs of ventricular prematurity. Beats 5, 6, 9, 10, 11, 13, and 14 are ventricular fusion beats (red arrows). These complexes occur when an ectopic ventricular beat is superimposed on a normal sinus beat. Beats 8, 12, 15, and 16 are premature ventricular beats (green arrows). This horse was rested for 3 months and repeat exercise testing showed the ectopic focus to have resolved. He returned to full competition.

supraventricular premature beats. Depending on their proximity to the previous conducted beat, they may be associated with a palpable pulse deficit. Isolated cardiac contractions are noted to follow too early in an otherwise normal rhythm and are usually followed by an obvious pause that might help to distinguish them from atrial premature contractions. During ventricular tachycardia, a fast regular rhythm will be noted by auscultation.

Special examination

A definitive diagnosis and the origin of the ectopic complexes can be determined by electrocardiography. When the complexes are ventricular in origin, one or more premature complexes with normal or abnormal QRS morphology will break the regular cardiac rhythm. Although QRS morphology may vary, these complexes are always dissociated from normal sinus activity. The sinus node continues to fire at its normal rate, since the atria are electrically isolated from the ventricles and the site of ectopic activity (Fig. 33.13A, 33.14). If the premature beat originates in the ventricular myocardium it will have a wide and bizarre configuration, since it will not be conducted using the normal His–Purkinje system (Fig. 33.13A). By contrast, if it arises from the atrioventricular junctional tissue, or from high up in the His–Purkinje system, the QRS complex may be similar in configuration to the normal sinus beats (Fig. 33.14). In this case, the premature impulse is still conducted through the ventricle using normal conduction pathways and therefore is neither altered in shape, nor abnormally prolonged.

Other tests In all cases of persistent ventricular ectopic activity in horses, thorough evaluation of electrolyte status and assessment of other body systems should precede expensive specialized cardiac examinations.

Laboratory determination of plasma or serum concentrations of cardiac troponin I and the isoenzymes of lactate dehydrogenase may be useful to assess active myocardial necrosis and inflammation.

Echocardiography is also used to rule out cardiac chamber enlargement and abnormal wall motion suggestive of previous myocardial damage. The results of all these examinations may be unremarkable or equivocal.

Fig. 33.14
Junctional ventricular ectopic beats in a horse presented with poor performance. The normal sinus rhythm is broken by a premature QRS complex with similar morphology to the normal sinus beats. The premature beat (green arrow) is followed immediately by a P wave (red arrow). As the ventricle is still refractory, the P wave does not result in a QRS complex, but normal sinus rhythm is not interrupted. This AV dissociation is a hallmark of ventricular prematurity. Although the premature complex is not noticeably wider than the sinus beats, it is still ventricular in origin. Its configuration suggests that it originates from the AV junctional, or His–Purkinje system, and has been conducted using the normal conduction pathways. Note that the T wave preceding the ectopic beat is exactly the same as the other sinus T waves, so that an ectopic P′ wave could not have been hidden within it (compare with Fig. 33.11). (ECG courtesy of Mr Charlie Smith MRCVS, Greenwood Ellis & Ptners, Newmarket, UK.)

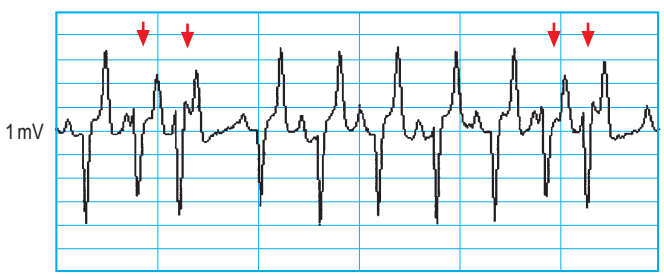

Fig. 33.15
The difficulty of interpretation of postexercise ventricular ectopy is illustrated by the trace recorded from a Thoroughbred race horse during recovery from work at home. The horse worked only at three-quarters pace. This rhythm shows ventricular ectopic beats occurring in pairs or couplets (red arrows). Couplets occur after the first and the eighth beats and were frequent for 2 minutes after exercise. In this case the abnormal complexes are not unduly wider than the normal sinus beats, indicating a junctional origin. This finding is not uncommon in horses. A definite diagnosis of a ventricular origin is possible however, because there is clear evidence of AV dissociation. Note that the first abnormal complex appears too close to its preceding P wave, that in turn has followed the P wave of the normal beat after an appropriate time. The third normal sinus P wave in each case is buried in the ST segment between the coupled ectopic beats. This recording was taken from an 8-year-old National Hunt horse rated in the top 10% of National Hunt racehorses in the UK. The trace was recorded 2 weeks after the horse had won a £13 000 race and 1 week before finishing second in a £17 000 race. The ECG was taken during normal work at home on a 'slow' day. There was no history of poor performance. The horse lost his place in the second race after jumping badly. There was no evidence of cardiorespiratory, systemic disease nor poor athletic performance in this individual.

Treatment

Therapeutic aim

The therapeutic aims are to treat the underlying disease process, restore normal electrolyte and acid–base status, return the heart to normal sinus rhythm if the ventricular rhythm disturbance is life threatening, and abolish abnormal ventricular automaticity.

Therapy

It is a general rule that arrhythmia should always be considered in the context of the patient's concurrent disease. Premature systoles are usually associated with hypoxia, myocardial disease, electrolyte and metabolic disturbances, elevated sympathetic tone, fever, and toxemia. Therefore the first therapeutic aim is to treat any of the predisposing disorders rather than the arrhythmia per se.

Treatment of a ventricular rhythm disturbance with antiarrhythmic agents is only warranted when there is obvious decrement to cardiac function as a result of the abnormal rhythm, or if the rhythm is likely to degenerate into a more sinister life-threatening arrhythmia (ventricular fibrillation). This scenario is most likely to occur during general anesthesia, the postoperative period, or during generalized sickness. The Class 1B, fast sodium channel blocker lidocaine is generally accepted to be the drug of choice for the treatment and management of ventricular arrhythmia in this context.[59]

Specific antiarrhythmic treatment for ventricular ectopic beats in performance horses is usually not indicated, as they are too infrequent to significantly affect cardiac output at rest. However ventricular ectopic beats may be the only abnormal finding in horses presented for poor or loss of performance when their significance is much more perplexing. In most cases the ectopic beats do not occur with sufficient frequency during exercise to significantly compromise cardiac output (Fig. 33.13), yet despite extensive investigations, no other cause of poor performance can be established. It seems possible that increased ventricular automaticity reflects myocardial cellular damage or is a marker of subtle damage to other elements of the oxygen transfer chain that in themselves are responsible for reduced aerobic capacity and performance limitation. The precise nature of the insult, or its etiology, is unknown and further studies of affected horses are clearly required. However, clinical experience and anecdotal evidence suggest that a clinical syndrome of poor performance associated with ventricular ectopy and reduced heart rate recovery following fast exercise exists in Thoroughbred race horses in the UK. Usually biochemical markers of myocardial damage (isoenzymes of lactate dehydrogenase or cardiac troponin I) are not significantly elevated at the time horses are presented. There is usually no specific indication to treat the arrhythmia, so treatment is usually empiric including rest with, or without, steroid therapy section (see 'Therapy' in 'Supraventricular premature systoles').

Prognosis

The prognosis for ventricular prematurity and ventricular arrhythmia is dependent upon the severity of the underlying disease. When the arrhythmia is associated with laboratory or echocardiographic evidence of myocarditis, the prognosis is guarded/poor, although a percentage of affected animals will return to their previous athletic performance following rest and/or steroid therapy.

Ventricular ectopic beats that occur only in recovery from fast exercise are usually of no significance (Fig. 33.15).

Etiology and pathophysiology

Specific information regarding the etiology of ventricular ectopic beats in horses is lacking, but based on data from other species, increased automaticity of ventricular myocytes is associated with cardiac disease resulting in ventricular dilation, stretch, and hypoxia. In the absence of primary cardiac pathology, electrolyte abnormalities, hypoxia, toxins and alterations in acid–base status can provide the physiologic substrates for increased myocyte and pacemaker irritability and invoke re-entry.[60]

It has been suggested that isolated ventricular ectopic beats emanate from ischemic foci that provide the physiologic substrates for increased ventricular automaticity during myocyte death. There is circumstantial evidence to support this hypothesis, as areas of focal fibrosis are common in the equine myocardium at post-mortem examination.[53–55] The precise etiology of these lesions is unknown, although small coronary artery occlusion by arterial atherosclerosis has been proposed as a possible underlying cause.[55,61] Canley & McCullogh[55] demonstrated a significant association between the occurrence of proximal aortic *Strongylus vulgaris* lesions and the presence of focal ischemic lesions in the myocardium. They hypothesized that this association was not the result of direct larval damage to the heart but was caused by microembolization from the parasitic lesions in the proximal aorta that caused myocardial obstructive arteriosclerosis. The role of myocardial cell death and ischemia in the etiology of ventricular rhythm disturbances in horses is supported by case reports by Traub-Dargatz and colleagues in 1994 and Machida and colleagues (in 1992). These workers identified areas of myocytolyis and replacement fibrosis in the ventricular myocardium of horses after fatal ventricular dysrhythmias.[62,63]

Fig. 33.16
(A) Sustained base apex ECG recording at rest in a 2-year-old colt presented for poor performance. Atrial fibrillation was suspected during cardiac auscultation. The summary trace shows that the arrhythmia is caused by apparent variations in sinus firing rate (sinus arrhythmia) and sinus block when there is complete absence of sinus activity for at least one R–R interval. (B) Expansion of the ECG trace confirms the presence of atrial activity P waves preceding each QRS complex. (C) Same horse as in B. Excitement or exercise rapidly restored the rhythm to normal. Heart rate and rhythm during fast exercise were also normal. Treadmill exercise testing revealed the colt to have dynamic airflow obstruction caused by dorsal displacement of the soft palate.

Bradydysrhythmias

- These include sinus bradycardia and arrest (Fig. 33.16), second (Fig. 33.17) and third degree atrioventricular (AV) block (Fig. 33.18).
- All these rhythms, except third degree atrioventricular block, are also normal findings in athletic horses, reflecting high resting parasympathetic tone.
- When pathologic, they are characterized by an inappropriately low heart rate and blunted chronotropic responses to exercise, or sympathomimetic agents (atropine).
- Third degree AV block is rarely diagnosed in athletic horses, but when present it always affects performance and carries a guarded prognosis.

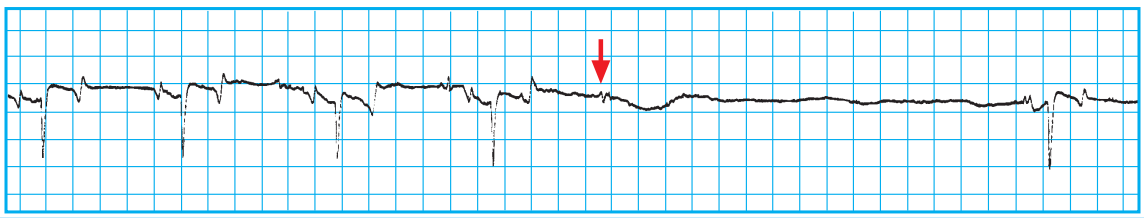

Fig. 33.17
Sinus arrest and second degree block in a 14-year-old endurance horse. One nonconducted P wave (red arrow) is visible during the long pause and is followed by complete sinus arrest. There is a total absence of ventricular escape activity. The clinical history that follows is fairly typical. The pony initially presented with traumatic uveitis. Two weeks later she was found with a severely swollen carpus and damage to buckets in the loose box. One week later the pony was observed to collapse by her owner. Holter for 24 hours monitoring showed maximum pauses of 10 seconds, but as is frustratingly common in these cases, no collapse occurred during the monitoring period. The pony responded to oral clenbuterol therapy and after a period of 6 months rest, returned to ridden work. The response to treatment in older animals may be less impressive, possibly because the underlying pathology is advanced disease of the conduction tissues.

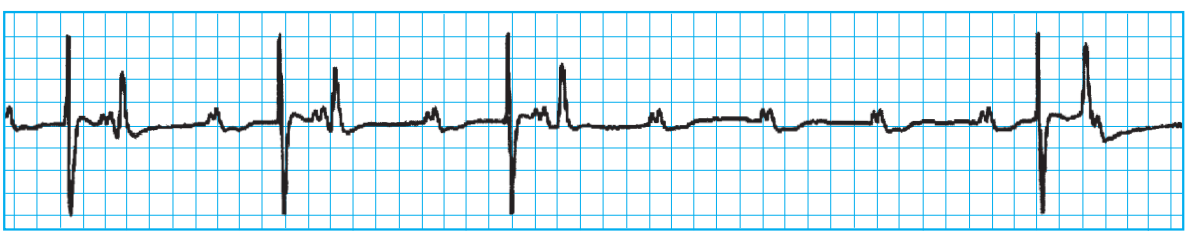

Fig. 33.18
Third degree atrioventricular block in a 12-year-old Thoroughbred. There is complete AV dissociation or third degree AV block. Bifid P waves occur at a rapid rate and can be visualized within the ST segment of the QRS complexes. In this case the QRS complexes are not regular, but their rate is slow. They are junctional ventricular escape complexes. The mare had a variety of atrial arrhythmias over a 24-hour period including third degree AV block. She presented acutely after multiple episodes of collapse in a single day. The referring veterinary surgeon administered antibiotics and corticosteroids. Without further treatment the mare reverted to normal sinus rhythm within 72 hours. ECG courtesy of Miss Constance Fintl MRCVS (Dick Vet, Edinburgh).

Recognition

History

The usual presenting signs for horses with significant bradydysrrhythmias include syncope, ataxia, exercise intolerance, and collapse.

Significant cardiac disease can usually be ruled out in a horse with a very low resting heart rate or marked arrhythmia at rest, if excitement or exercise restore rate and rhythm to normal.

It is common for a marked arrhythmia to be noticed within a minute of cardiac slowing after fast exercise in athletic horses. This arrhythmia is a normal manifestation of increasing parasympathetic influence and usually occurs when heart rate falls to 130–150 beats/min. When electrocardiographic examination is performed, the arrhythmia is usually a marked sinus arrhythmia and is thus described as 'transient post-exercise sinus arrhythmia' (Fig. 33.19). The arrhythmia is usually short-lived, but can cause alarm for an inexperienced examiner. Postexercise sinus arrhythmia is another normal arrhythmia, found commonly in athletic horses, that does not indicate cardiac pathology.

Physical examination

In horses affected with significant bradydysrhythmia, auscultation usually reveals an inappropriately slow resting heart rate that may be regular. Resting heart rate may be less than 20 beats/min.

Occasionally horses present with evidence of unexplained trauma when collapse occurs at night, or is not observed.

During severe second degree AV block, one or more isolated fourth (atrial) heart sounds, S_4, will be audible during the long diastolic pauses. In sinus block, S_4 will be absent and the diastolic pauses silent. In third degree AV block, S_4 may be audible in a regular fast rhythm underlying the predominant slow ventricular rhythm. In third degree AV block pronounced waves, 'cannon a waves', that travel rapidly all the way up the jugular vein are also obvious.

Fig. 33.19
Electrocardiographic recording taken from a Thoroughbred race horse, 20 seconds after completion of exercise to fatigue. The trace illustrates transient postexercise sinus arrhythmia. There is some baseline interference as the horse is walking and blowing heavily, but positive P waves are visible before each QRS complex. The rhythm is noticeably irregular representing sinus arrhythmia. This is a common finding in athletic horses following exercise.

Increased atrial pressure causes the augmented waves as the right atrium contracts against the closed tricuspid valve.

Special tests

Electrocardiography will provide a definitive diagnosis (Figs 33.16–33.19). Ideally 24-hour ambulatory ECG monitoring (Holter) should be employed for a definitive diagnosis in cases of collapse. Affected cases often have blunted chronotropic responses to both exercise and parasympatholytic agents, but these tests are frequently difficult to interpret.

Treatment

Therapeutic aims

To restore normal sinus rhythm, normal heart rate at rest, and to normalize heart rate response to exercise.

Therapy

Pathologic sinus bradycardia is found most commonly in elderly performance horses. Occasionally horses affected with profound second degree AV block and sinus bradycardia respond favorably to daily oral administration of β_2-adrenoreceptor agonist drugs, e.g. clenbuterol.

Third degree AV block is very rare in horses, and is rarely amenable to medical treatment when it occurs in older animals. In most species third degree AV block is permanent and transvenous pacing is required for permanent relief of clinical signs. Dual chamber pacing has been described in horses.[64,65] The technique has also been used successfully to treat third degree AV block in a horse that subsequently returned to competition.[16]

In contrast to other species, in younger and middle-aged horses, third degree AV block can be transient and normal sinus activity can resume after variable periods of time elapse. It seems likely that in these cases, a reversible inflammatory process causes transient complete block at the AV junction. Based on this unproven hypothesis, the use of corticosteroid drugs is sometimes recommended for these individuals.[33]

Prognosis

In all cases of symptomatic bradyarrhythmia, the prognosis is guarded to poor. In younger horses with acute onset of clinical signs the condition is sometimes reversible and affected animals can return to previous levels of activity. Transvenous pacing carries a fair prognosis for return to athletic performance, but as in all species, the technique can be associated with complications.[66]

Etiology and pathophysiology

In the resting horse most bradydysrhythmias are of no clinical significance, as within limits cardiac output can be maintained by an increase in stroke volume. The trained horse has an increased resting stroke volume and therefore the resting heart rate is usually low. During exercise, however, there is an increased requirement for muscle perfusion, systemic vascular resistance falls and cardiac output must therefore increase in order to maintain arterial blood pressure. As increasing heart rate is the major cause of the increased cardiac output, if low heart rate is maintained during exercise, cardiac output will be inadequate and performance will be limited.

Although second degree AV block is the commonest manifestation of high vagal tone in horses, other bizarre sinus arrhythmias, including sinus block, can occasionally be encountered in normal individuals (Fig. 33.16). Normal heart rate responses to exercise and excitement rule out significant pathology in these individuals.

Pathologic sinus, second and third degree AV block indicates total or partial block in conduction in the sinus, atria, or AV node. This clearly results from cardiac lesions, thought to be associated with transient or permanent inflammation or degeneration and fibrosis of the intracardiac conduction system.

Epidemiology

Profound sinus bradycardia, pathologic second degree and third degree AV block occur only rarely in athletic horses, being much more common in aged animals. Sporadically the condition can be seen in younger horses and is usually associated with inflammation of the conduction system and/ or myocardium.

Cardiac murmurs

General principles

This section will cover the basic approach to heart murmurs in athletic horses, their diagnosis, prognosis, and assessment of their significance.

A number of murmurs occur in normal horses that are not associated with underlying cardiac disease. These murmurs have been variously called, **functional**, **physiologic**, **innocent** or **flow** murmurs. These murmurs are common in athletic horses of all breeds (Table 33.1).

Murmurs associated with mitral and tricuspid valve regurgitation are also commonly detected in performance horses (Table 33.1, 33.2), yet any influence on their athletic performance remains controversial. Although there is no doubt that severe regurgitation and resultant cardiac failure cause obvious performance decrements,[67,68] the effect of mild and moderate regurgitant murmurs is less certain.[1]

Recent data[3] have shown that AV valve regurgitation increases after 6 months race training in Thoroughbreds (Table 33.3). It seems likely that the eccentric cardiac hypertrophy and increased blood volume that accompany athletic training[69] result in secondary stretch of the valve annulus and increased regurgitation.

Endocarditis is a rare condition causing valvular regurgitation and cardiac murmurs. Blood-borne bacteria colonize the valves (usually mitral and aortic) and the resulting inflammation and deformation leads to chronic regurgitation. *Pasteurella*, *Actinobacillus* and *Streptococcus* species are most likely to be causative in horses,[70] although other agents have also been reported.[71–73] Prognosis is poor, even if the horse survives the early acute phase and bacterial cure is achieved; there may be sufficient damage to the cardiac valves to preclude return to previous performance, or cause death from heart failure.[74]

Table 33.1 Prevalence of cardiac murmurs by auscultation in 2-year-old Thoroughbreds in training

Murmur	% of population affected		
	Young & Wood[3]	Kriz et al.[1]	Patteson & Cripps[2]
Mitral regurgitation	21	3.8	1.2
Tricuspid regurgitation	25.5	27.4	4.7
Aortic regurgitation	2	0.5	0
Diastolic flow	65	33	44
Systolic ejection	34	57.4	55
No murmurs	11	18.9	24.7

Note: Patteson & Cripps defined mitral and tricuspid valve regurgitation as pansystolic murmurs only. As it is now generally accepted that murmurs of mitral and tricuspid valve prolapse may not extend throughout systole, this may explain the difference in prevalences of atrioventricular valve regurgitation. Patteson & Cripps also noted a much higher prevalence of systolic murmurs on the left and right hemithorax, suggesting that some early systolic murmurs of mitral and tricuspid valve prolapse were classified as systolic ejection murmurs

Table 33.2 Prevalence of cardiac murmurs by auscultation and color flow Doppler echocardiography in older race-fit National Hunt steeplechase horses

Regurgitaton	% Prevalence by auscultation		% Prevalence by Doppler
	Patteson & Cripps[2]	Young & Wood[4]	Young & Wood[4]
Mitral	5.6	22	58
Tricuspid	16.4	47	88
Aortic	2.2	4	62

Physiological murmurs

Systolic ejection murmurs

Systolic ejection murmurs are commonly heard over the pulmonary and aortic valves in normal horses. Usually the

Table 33.3 Prevalence of murmurs and regurgitation by color flow Doppler echocardiography at the aortic mitral and tricuspid valves in fifty 2-year-old Thoroughbreds before and after 6 months' race training.[3]

Regurgitation	% Prevalence before training		% Prevalence after training	
	Auscultation	Doppler	Auscultation	Doppler
Mitral	7.3	25	21	35
Tricuspid	12.7	57	25.5	66
Aortic	0	18	2	44

murmur is early–mid systolic, crescendo–decrescendo in character and variable in intensity. Usually these murmurs are heard best over the left hemithorax, cranial over the heart base when S_2 becomes accentuated. Submaximal exercise often increases the intensity of these murmurs. In some horses, it can be difficult to separate a functional ejection murmur from a murmur of mitral regurgitation, but an ejection murmur, unlike the murmur of mitral regurgitation, should end before S_2. Ejection murmurs will disappear at maximal heart rates, but the amount of exercise needed to achieve this varies according to the fitness of the horse. Ejection murmurs are equally prevalent in other conditions that provoke high sympathetic tone, e.g. colic, anemia, sepsis, pain, or fever. A major feature of all physiologic murmurs is their variability with changes in heart rate and or excitement.

Functional diastolic murmurs: diastolic filling murmurs

Most physiologic filling murmurs occur either in early diastole (before S_3) or are presystolic (after S_4 but before S_1). The **presystolic** murmurs are associated with vibrations in the atria, and are usually low pitched and rumbling. The murmur can be heard on either side of the chest. The **early diastolic murmurs**, closely following S_2 are soft and blowing and are believed to be associated with rapid ventricular filling. They usually end at S_3 and are heard from the left and right hemithorax. An early diastolic musical murmur is not infrequently heard in conditioned horses. This murmur is very variable, and is usually heard best from the mitral or tricuspid valve area. The murmur follows S_2 by a short interval and ends abruptly at S_3. It is commonly known as a '2-year-old squeak,' although it is present in athletic horses of all ages. Diastolic murmurs are also very variable depending on heart rate and excitement.

Murmurs associated with cardiac dysfunction

Tricuspid regurgitation

Recognition

History

These murmurs are usually detected incidentally during cardiac auscultation. Tricuspid regurgitation is unlikely to be a primary cause of poor performance or heart failure.

A murmur of tricuspid regurgitation is often detected in horses presenting with heart failure due to mitral valve insufficiency. Severe pulmonary hypertension results in secondary dilation of the right ventricle and tricuspid annulus and causes tricuspid valve regurgitation.

Physical examination

The murmur of tricuspid regurgitation (TR) is a systolic murmur heard over the right side of the thorax. It is usually soft and band shaped and extends throughout systole and may incorporate S_1 and S_2. Occasionally tricuspid regurgitation is crescendo in character and may not occupy all of systole, in this case it is usually described as 'tricuspid valve prolapse.'

Special examination

Color flow Doppler echocardiography (Fig. 33.20) will confirm the presence of tricuspid regurgitation. The use of pulsed or continuous wave Doppler techniques allows an estimate of pulmonary artery pressure to be obtained from the modified Bernoulli equation.[75] Two-dimensional and M-mode echocardiography allow cardiac chamber size to be visually assessed. The nonsymmetric shape of the right ventricle and atrium mean that it is very difficult to obtain repeatable and meaningful measurements of chamber size[76] and it is probably advisable to visually appraise the two chambers relative to the left ventricle. The tricuspid valve of affected horses invariably appears morphologically normal, but may prolapse into the right atrium during systole (Fig. 33.21).

Treatment

There is no specific treatment available.

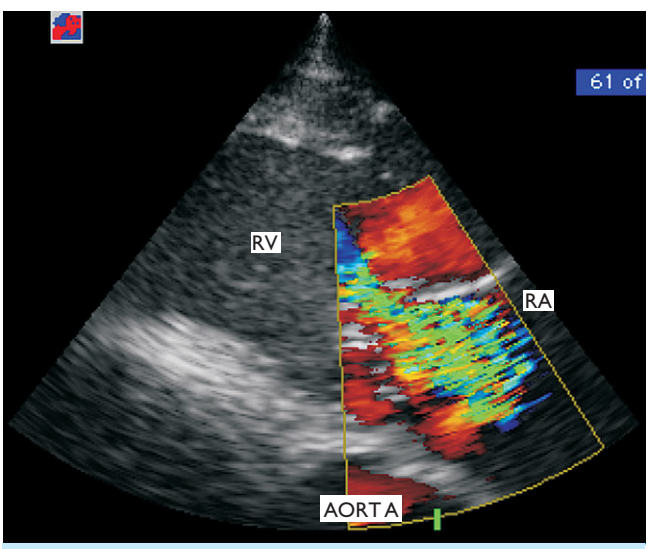

Fig. 33.20
Color flow Doppler study of tricuspid valve regurgitation in an 8-year-old race horse. A grade 4/6 systolic murmur on the right hemithorax was detected incidentally at a veterinary examination. The horse was a successful handicap steeplechaser with no history of poor race performance. A green jet of blood can be seen entering the right atrium through the closed tricuspid valve. RA, right atrium; RV, right ventricle.

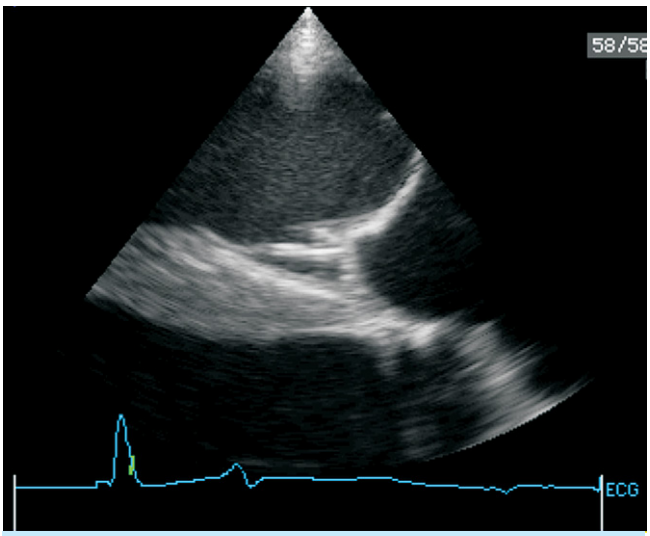

Fig. 33.21
Two-dimensional image of the tricuspid valve of the horse shown in Fig. 33.20. Abnormal systolic valve motion was visible in real time. The anterior valve leaflet buckled backwards into the right atrium during systole. However, there is no structural valve abnormality. Abnormal systolic movement is the most frequently encountered echocardiographic feature of tricuspid valve dysfunction in performance horses. Unfortunately due to their geometry, right atrial and ventricular echocardiographic measurements are not very repeatable in horses, making assessment of volume overload of the right heart very difficult. It is rare to see convincing evidence of right heart enlargement due to primary tricuspid valve dysfunction in performance horses.

Prognosis

Echocardiographic follow-up of an increasing number of horses affected with tricuspid valve regurgitation indicates that the valve dysfunction rarely progresses to cause clinical signs of heart disease. The condition does not seem to predispose to rupture of chordae tendinae, nor readily result in congestive heart failure. Equally it is unlikely that low or moderate grade tricuspid regurgitation as an isolated finding will cause performance-related problems in the vast majority of horses.

While tricuspid regurgitation is likely not normal, it is certainly very common, and in horses without evidence of valve lesions the condition does not render the horse unfit to ride and carries an excellent prognosis. Although theoretically right atrial enlargement as a result of severe tricuspid regurgitation should increase the risk of development of AF, in the author's experience primary tricuspid valve disease is a rare underlying cause of AF and congestive heart failure. It is important to note that AF is common in large athletic horses, a group in which the prevalence of audible tricuspid regurgitation is high (Table 33.2). This obvious association does not necessarily mean that the two conditions are necessarily related, indeed it seems unlikely from clinical experience, but a causative influence of tricuspid regurgitation on AF cannot be ruled out based on currently available data.

Etiology and pathophysiology

Tricuspid valve regurgitation is the commonest valve insufficiency in athletic horses.[1–4] Tricuspid regurgitation is also increased after athletic training,[3] suggesting that training-induced eccentric hypertrophy is important in the pathogenesis of the condition. These data are supported by that of Pollak and colleagues,[77] who found that tricuspid regurgitation was more common in elite female athletes than in sedentary women. Else & Holmes[53,54] found evidence of fibrous thickening and distortion of tricuspid valve leaflets and similar changes in the chordae tendinae. These authors also noted a smaller prevalence of hemorrhagic lesions on the right ventricular first order chordae and suggested that they might be precursors to chordae rupture, although their precise etiology was not established. Interestingly, the prevalence of tricuspid valve lesions in the large post-mortem survey of Else & Holmes was much lower than the prevalence of murmurs of tricuspid valve regurgitation and regurgitation detected by Doppler techniques in athletic horses.[1–4] These data support the growing suspicion that in many athletic horses, tricuspid regurgitation is physiologic, rather than caused directly by valve disease.

Secondary dilation of the tricuspid valve annulus resulting in tricuspid regurgitation also occurs during severe pulmonary hypertension.[51] Increased pressure in the pulmonary circulation increases afterload on the right heart and stimulates eccentric and concentric right ventricular hypertrophy. Deformation of the tricuspid valve apparatus then results in tricuspid valve regurgitation. Pulmonary hypertension is associated most commonly with left-sided cardiac failure and more rarely with pulmonary thromboembolic and hypoxic pulmonary diseases.

Epidemiology

Our recent work[4] shows that isolated TR is the most commonly encountered murmur in National Hunt type horses, occurring in almost 50% of mature horses at full race fitness (Table 33.2). The prevalence is less in flat racing Thoroughbreds based on our data[3] and that of others.[1,2] Young & Wood noted a relationship between body weight and the presence of tricuspid regurgitation in flat racing Thoroughbreds.[3]

Mitral regurgitation (Figs 33.22, 33.23)

Recognition

History

The condition is usually detected incidentally during cardiac auscultation.

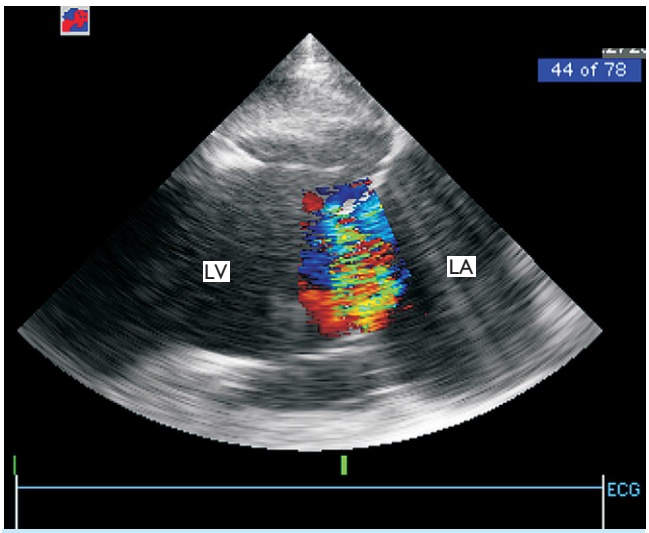

Fig. 33.22
Color flow Doppler image showing moderate to severe mitral valve regurgitation in a 6-year-old Thoroughbred race horse. The horse had a grade 5/6 murmur over the apex beat area of the left hemithorax. A grade 3/6 murmur of tricuspid regurgitation was also audible at the right hemithorax. The murmurs were detected incidentally during epidemiologic studies on the horse's training yard. Despite the moderate to severe regurgitation present over 2 years of the study, the horse had won races and been moderately successful as a handicap steeplechaser. He had however never really lived up to the owner and trainer's initial expectations and had the reputation of being 'ungenuine'. In the UK, it is not uncommon for this description to be applied to racing Thoroughbreds, later found to be affected with moderate to severe AV valve regurgitation. LA, left atrium; LV, left ventricle.

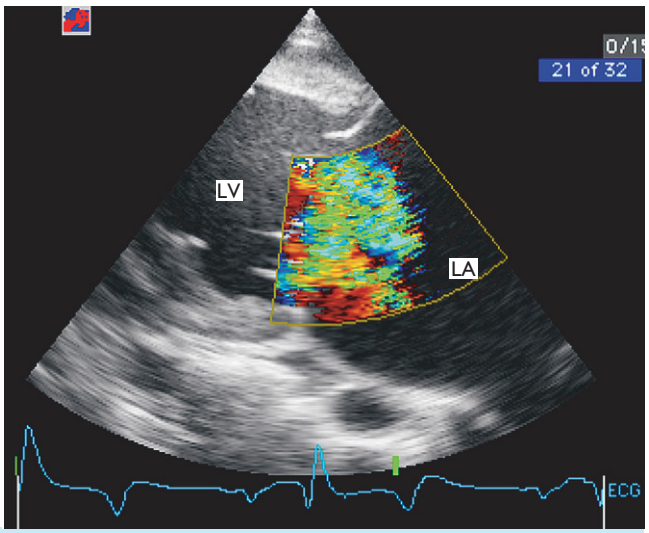

Fig. 33.23
Color flow Doppler study showing severe mitral regurgitation in a 2-year-old filly in training. There is a large green/blue regurgitant jet entering a grossly dilated left atrium. The filly presented with recurrent pyrexia due to repeated bouts of respiratory infection. A grade 5/6 left-sided cardiac murmur and elevated heart rate (58 beats/min) were noted on auscultation. Despite being in cardiac failure, poor performance was not noted by the trainer, as the filly had only just begun canter work. As in this case, coughing usually arises due to secondary bacterial infection, rather than primarily from the interstitial and alveolar edema present concurrently. LA, left atrium; LV, left ventricle.

The murmur of mitral regurgitation is often detected in horses that present in heart failure, as severe mitral valve insufficiency is the commonest cause of the heart failure syndrome in horses.[78]

Physical examination

The murmur of mitral regurgitation is loudest on the left hemithorax, in the area of the apex beat. It can radiate forwards towards the heart base, which may cause confusion, if there is a coexistent functional ejection murmur. In common with tricuspid regurgitation, the murmur is usually band shaped and pansystolic. It should not vary with exercise. If mitral regurgitation is severe, resulting in the retrograde flow of large quantities of blood into the left atrium, S_3 may be more pronounced.

Occasionally mitral regurgitation is crescendo in character and may be musical or vibrant. In this case the murmur may not occupy all of systole. The presence and intensity of the murmur may also be variable. When the murmur has these characteristics it is usually classified as 'mitral valve prolapse.'

Rupture of a mitral chord (Fig. 33.23) or severe longstanding mitral regurgitation usually results in acute left-sided heart failure and a plethora of associated signs:

- pulmonary edema and increased respiratory rate (Fig. 33.24)
- increased heart rate
- rapid acute onset cardiac cachexia (Fig. 33.25)
- poor peripheral pulses (Fig. 33.26) and cold extremities
- the murmur associated with such catastrophic valve dysfunction might be expected to be very loud, but this is not invariably the case; the murmur is usually associated with a precordial thrill, and will invariably radiate over very large areas of the chest wall
- severe left atrial enlargement (Figs 33.7, 33.10B), which not uncommonly results in the development of AF (Fig. 33.6).

Although heart failure almost always results from primary mitral valve dysfunction, horses not infrequently present with biventricular failure, the signs of which include:

- peripheral edema (Figs 33.27, 33.28)
- jugular engorgement
- development of a loud right-sided murmur of tricuspid regurgitation (Fig. 33.20).

Special examination

Color flow Doppler echocardiography will confirm the presence of mitral regurgitation (Figs 33.22, 33.23, 33.29). The

Fig. 33.24
Thoracic radiograph from a horse with acute rupture of a major mitral chordae tendinae. There is an alveolar and interstitial pattern most marked in the cardiophrenic angle in this lateral radiograph. Coughing is not a feature usually noted with pulmonary edema in horses, unless there is secondary bacterial infection, which occurs not infrequently. Alveolar and interstitial edema occurs as a consequence of marked elevations in left atrial pressure, from left-sided heart failure. Thoracic auscultation is frequently disappointing in these patients even though pulmonary edema is known to be present. The increased respiratory rate that always accompanies severe alveolar edema is the most reliable method for detecting pulmonary congestion in horses. Occasionally white (occasionally blood-tinged) frothy edema fluid may appear at the nostrils.

use of pulsed or continuous wave Doppler techniques allows an estimate of transmitral pressure gradient to be obtained and thence assessment of left ventricular systolic function. Two-dimensional and M-mode echocardiography are used to evaluate cardiac chamber size and left ventricular wall motion. In severe mitral regurgitation, there is dilation and septal hypermotility as the volume overloaded left ventricle ejects into the low pressure left atrium. The left atrium will be dilated as evidenced by an increase in the ratio of the aortic diameter to that of the left atrium (Fig. 33.10). There may be evidence of pulmonary hypertension and dilation of the main and right pulmonary artery, best assessed by comparison with the diameter of the aorta.

In mild disease, cardiac dimensions will remain within normal range and often the valve appears morphologically normal. Valve thickening or noticeably abnormal valve motion may be observed in more severe cases. Occasionally a flail valve leaflet may be visible after mitral chordae rupture has occurred.

In horses with mild–moderate mitral regurgitation and without evidence of heart failure, ECG examination during appropriate exercise is recommended to assess heart rate response to exercise. This is especially important when the cardiac murmur is implicated in poor performance or is detected at a pre-purchase examination.

When there is overt heart failure, thoracic radiography is useful to confirm the presence of the alveolar-interstitial infiltrate characteristic of pulmonary edema.

Treatment

There is no specific treatment for valve regurgitation and in horses with compensated valve dysfunction, no treatment is indicated. When signs of heart failure become evident (Fig. 33.10B) therapy focuses upon control of heart rate (digoxin), reduction of volume overload (diuretics), and reduction of cardiac afterload (angiotensin converting enzyme inhibitors). Once signs of heart failure are present, the horse must be immediately retired from ridden exercise. Aggressive treatment is expensive and palliative only, it will not return the horse to its previous athletic performance. In

Fig. 33.25
Yearling Thoroughbred colt with severe mitral valve regurgitation and atrial fibrillation. Cardiac cachexia or loss of lean body mass is an inevitable consequence of heart failure and occurs in the absence of obvious inappatence. It is often dramatic in onset, occurring within a very short time of cardiac decompensation. It is usually most obvious in the highly muscled areas, e.g. the hindquarters in mature conditioned horses or, as in this case, in the neck and shoulders of young stock.

Fig. 33.26
Palpation of a peripheral pulse provides a 'window' to the heart's function as a pump. It may also provide a clue to the severity of valve lesions that are picked up on auscultation. The facial artery provides a convenient site for examination. If a patient is in heart failure, heart rate will be elevated above the normal expected value for the animal's type and fitness. These patients usually sustain their heart rates between 55 and 80 beats/min dependent on type and severity of disease. Pulse quality reflects the difference between the systolic and diastolic blood pressure. The difference between the two, rather than the magnitude of either, is detected when the pulse is palpated. To obtain an estimate of mean arterial pressure, the amount of digital pressure needed to occlude the pulse can be assessed. Pulse quality can also reflect the severity or type of underlying cardiac disease. A characteristically bounding pulse (i.e. a wide difference between systolic and diastolic pressure) can be indicative of marked aortic insufficiency in older horses, or extracardiac left to right shunts in foals. (Courtesy of Dr LE Young and Dr KJ Blissitt, Royal (Dick) School of Veterinary Studies, Edinburgh.)

Fig. 33.27
Dependent edema in a 9-year-old hunt horse, 2 weeks after rupture of a mitral chordae tendinae. A plaque of pitting edema is visible in the most dependent area of the ventral abdomen. Occasionally the sheath and brisket are also involved. Although the underlying cause of heart failure in this case was left sided, as is typical, after a variable time, increased pulmonary vascular pressures cause secondary failure of the right ventricle, resulting in systemic congestion. (Courtesy of Dr LE Young and Dr KJ Blissitt, Royal (Dick) School of Veterinary Studies, Edinburgh.)

view of the hopeless prognosis, many owners request immediate euthanasia for their horses and as a result treatment is rarely performed.

Prognosis

Mitral valve disease of sufficient severity to cause cardiac failure will have a devastating effect on athletic performance and a very poor prognosis for life. The prognosis for isolated compensated mitral regurgitation remains much less certain. This is because overall the condition is less common than tricuspid valve regurgitation, and although there has been some long-term follow-up of horses with mild to moderately loud mitral valve murmurs, mitral valve disease remains the commonest cause of congestive heart failure in horses. Despite this, the general consensus amongst cardiologists is that, like tricuspid valve dysfunction, provided valve lesions do not accompany the regurgitation, prognosis is usually good.

Fig. 33.28
Edema of the lower limbs occurs commonly in horses, but is rarely associated with cardiac disease. This 6-year-old riding pony has end-stage heart failure from a large ventricular septal defect. He has edema of his brisket and the antebrachium, but minimal swelling of his lower limbs. (Courtesy of Dr LE Young and Dr KJ Blissitt, Royal (Dick) School of Veterinary Studies, Edinburgh.)

Most investigators agree that isolated low-grade mitral valve regurgitation (Fig. 33.29) should not significantly affect athletic performance in horses engaged in less strenuous disciplines. There is strong suspicion that AV valve dysfunction might reduce maximum aerobic capacity and prevent an individual from realizing their genetically conferred maximal athletic potential, but for most horses, even moderate decreases are unlikely to be noticed by the owner or rider.

Of all murmurs detected, isolated mitral valve regurgitation is most problematic when detected during pre-purchase examinations. Because of the current paucity of follow-up information, there is no definitive solution and ultimately the prospective rider/owner/trainer must make up his or her own mind regarding the suitability of the horse. Most investigators are confident that a horse with low-grade mitral valve regurgitation and a normal resting heart rate is safe to ride, and that its performance is unlikely to be noticeably affected by a small amount of valve dysfunction. Auscultation is useful to monitor the progression of regurgitation over long periods, but in a one-off physical examination, the veterinary surgeon knows nothing about the appearance of the valves, the extent of left atrial or ventricular enlargement, or the previous or subsequent rate of development of the valve dysfunction. Invariably when a moderately loud murmur is detected at a pre-purchase or insurance examination, it is usually advisable to refer the horse for specialist echocardiographic and ECG examinations. In the majority of performance horses, it is unlikely that the murmur has arisen as a result of serious progressive valve lesions, but this can never be guaranteed in the absence of more detailed examinations. In some cases, commercial pressures may dictate that the veterinarian informs the prospective client of the existence of the murmur and is then forced to make an educated guess about its likely impact. In these cases, when heart rate and work history are normal and the murmur is equal to or less than grade 3/6 in intensity, it is unlikely that the murmur will be associated with reduced performance, or be rapidly progressive. Referral to a specialist center for cardiac ultrasound examination is the best approach whenever any doubt exists regarding the origin or significance of a murmur detected during pre-purchase or insurance examination. It is important to note that murmurs of mitral valve regurgitation are rare in yearling Thoroughbreds, though the prevalence of murmurs increases in older horses (Table 33.2). As a result, young animals destined for racing with a confirmed mitral valve murmur should be viewed with great suspicion.

The variable systolic murmurs of mitral valve prolapse are generally considered to carry a good prognosis. In other species, notably dogs and humans, mitral valve prolapse is a precursor of progressive mucinous valvular degeneration

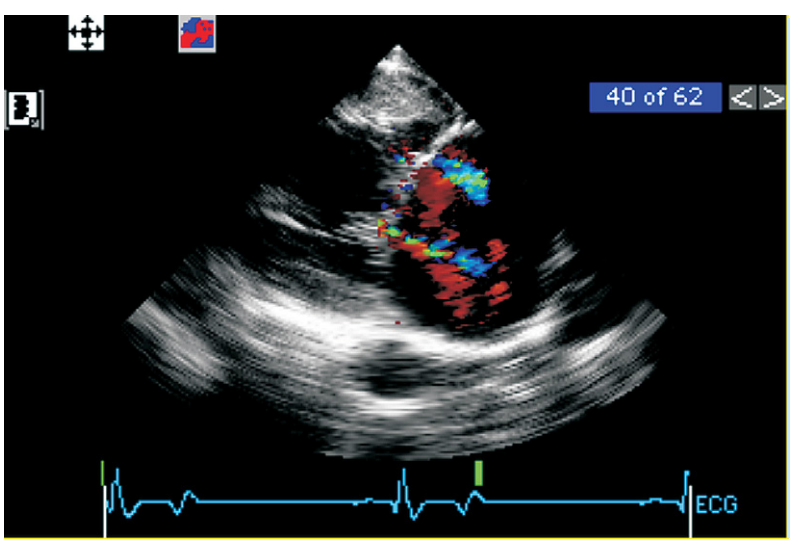

Fig. 33.29
Color flow Doppler echocardiograph obtained from the left hemithorax of a 9-year-old Thoroughbred race horse. The image shows two discrete regurgitant jets entering the left atrium through the closed mitral valve in systole. The horse had a grade 2–3/6 murmur of mitral valve regurgitation. It is not uncommon to visualize more than one regurgitant jet in horses with mitral valve dysfunction. In this case, the jets were small, traveled at high velocity, and occupied only a small area of the left atrium. Left atrial and ventricular size was normal.

and severe mitral valve regurgitation. Similar data is not available for horses, but current opinion suggests that isolated mitral prolapse rarely progresses to cause significant cardiac disease during the career of most performance horses.

Etiology and pathophysiology

During mitral insufficiency, blood is ejected retrograde into the left atrium. For the most part the regurgitant fraction is small and the condition remains well compensated. Only when the regurgitant fraction is large, or increases through progressive valve dysfunction, will forward cardiac output be compromised and volume and pressure overload of the left atrium begin. As a progressively greater proportion of the left ventricular output is ejected into the low-pressure left atrium, progressive dilation of both chambers occurs and stretching of the fibrous annulus further exacerbates mitral valve incompetence. Reduction in arterial blood pressure as forward cardiac output decreases causes activation of neurohumeral reflexes that further accelerate the vicious cycle of the heart failure syndrome; a syndrome that is always terminal. Congestive signs develop when horses with severe mitral valve disease survive low-output left-sided failure for even a short period of time. Increased left atrial pressure causes pulmonary venous congestion and increased afterload to the right ventricle. There is subsequent pressure overload of the right ventricle and dilation of the tricuspid valve annulus so that progressive tricuspid regurgitation develops. Meanwhile low output failure of the left ventricle and pulmonary edema compromise coronary perfusion and oxygenation and worsen the mechanical function of both ventricles.

The recently observed variability of mild mitral valve murmurs with changes in sympathetic tone and exercise can be explained because the mitral valve is an apparatus composed of leaflets, chordae, and papillary muscles, and not simply an inert fibrous structure. Changes in the loading conditions of the heart and papillary muscles and alterations in myocardial function with changing neurohumoral drive probably change leaflet coaptation, thus preventing, reducing or increasing the regurgitation present at the valve.

The mitral valve was the valve most likely to be affected by gross post-mortem changes in the post mortem study of Else & Holmes.[53,54] Microscopic changes included variable fibrosis and infiltration of the superficial valve layers (atrialis and spongiosa) with histiocytes, lymphocytes, and fibrobalsts.[53,54] Occasionally the deeper (fibrosa and ventricularis) layers of the valve were involved and their involvement usually resulted in deformation of the valve cusps. The precise etiology of valvular damage was not established, but the absence of polymorphonucleated cells, except in two animals, led these authors to speculate that an infectious cause was unlikely in the majority of cases. Their speculation is supported by clinical evidence suggesting that bacterial endocarditis occurs only rarely in horses.[70] Rupture of a first order mitral chordae has been repeatedly reported in association with severe mitral regurgitation and heart failure in horses,[79–81] but the precise etiology of the damage to the chordae is yet to be fully explored or explained.

Epidemiology

Recent data show that the prevalence of mitral valve regurgitation in racing Thoroughbreds varies between 3.8 and 21% (Tables 33.1, 33.2). As there is convincing evidence that athletic training increases the prevalence of AV valve regurgitation (mitral and tricuspid) in Thoroughbreds, this relationship might in part explain the difference in prevalence of AV valve regurgitation found by different investigators (Table 33.3). The effect of age on prevalence of AV valve regurgitation has yet to be established, although from our own ongoing epidemiologic studies the prevalence of AV valve murmurs assessed by color flow Doppler and auscultation is much lower in Thoroughbred yearlings than in all other groups. The prevalence of gross mitral valve lesions also increased with age in a large post-mortem study.[53,54]

Ventricular septal defect (Fig. 33.30)

- The ventricular septal defect is the most commonly occurring congenital heart defect in horses. Experience suggests that although the defect can be found in all breeds, it seems especially common in Arabians, Standardbreds and small pony breeds (Welsh Section A and Shetland ponies).
- The condition is not restricted to foals. Because of the huge cardiac reserve of the horse, large lesions are often detected before athletic training commences at insurance or pre-purchase examinations. Indeed this is probably the most frequently encountered clinical scenario.
- The defect can also be associated with other more complex congenital abnormalities (Fig. 33.31), but these cases are rare amongst athletic horses.
- Ventricular septal defects can cause secondary aortic valve insufficiency.

Recognition

History

Loud cardiac murmurs are usually detected during a pre-purchase or insurance examination of a horse without clinical signs. However, when the ventricular septal defect is large, the horse/pony might present in biventricular heart failure or with signs of poor performance. These scenarios are unusual. Occasionally affected horses present with unexpectedly early-onset diastolic murmur of aortic valve insufficiency (see below).

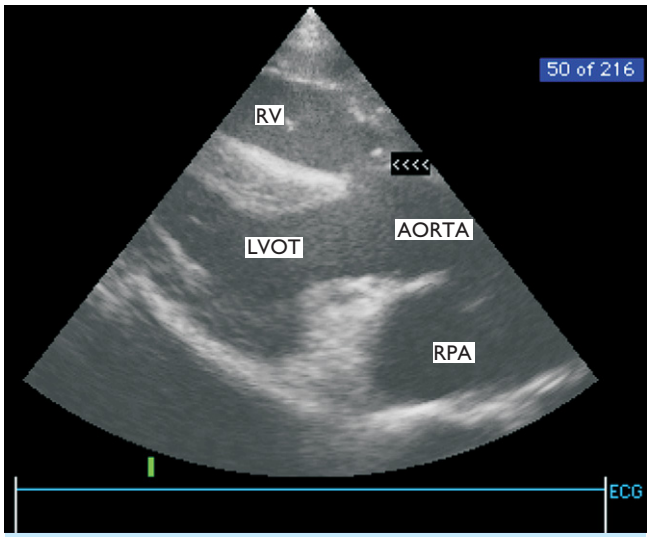

Fig. 33.30
Two-dimensional echocardiograph from the right hemithorax of a yearling Thoroughbred with a grade 5/6 pansystolic murmur with point of maximal intensity on the right side. There is a moderately large ventricular septal defect (labeled <<<<) at the top of the interventricular septum. This image has been optimized to visualize the septal defect so that the right pulmonary artery (RPA) is transected obliquely, rather than in true short axis. Failure to attain standard images of intra- and extracardiac structures can lead to errors in measurements of chamber and vessel size and great caution must be applied when interpreting nonstandard views. Despite this, the RPA does appear to be dilated when compared to the aorta, seen here in oblique long axis. This observation was repeatable in other 2D images that were optimized for the vessels. This observation suggests that there is significant pulmonary overperfusion, a finding supported by an increased right ventricular stroke volume as estimated by pulsed Doppler echocardiography. Although the filly is currently compensating for the defect, the defect size and the resultant large left to right shunt fraction suggests that she has no future as a racehorse. Smaller restrictive defects, despite being associated with a loud murmur, are sometimes compatible with an athletic career, especially in less strenuous disciplines. RV, right ventricle; LVOT, left ventricular outflow tract; RPA, right pulmonary artery.

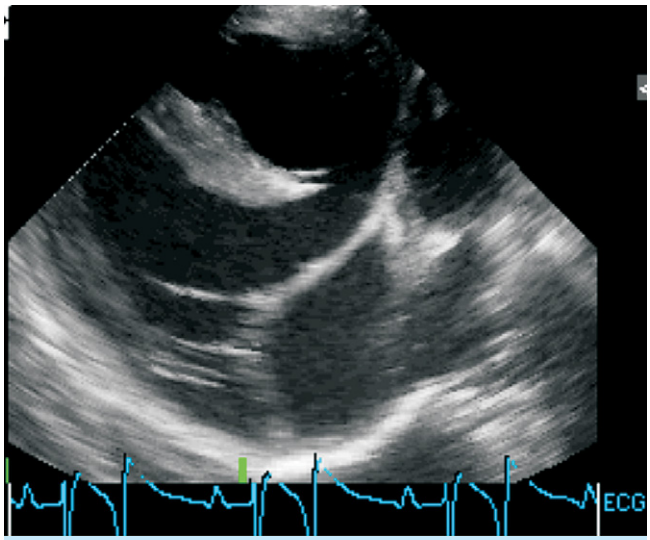

Fig. 33.31
Large ventricular septal defect in an 18-month-old Thoroughbred colt, examined after failing a veterinary examination for insurance because of a loud heart murmur. The large septal defect was found in association with other complex congenital abnormalities including dextroposition of the aorta, right ventricular hypertrophy, and subvalvular pulmonic stenosis,. These abnormalities are collectively known as tetralogy of Fallot. Despite such severe congenital abnormalities, the colt had no history suggestive of cardiac disease.

Presenting signs. The murmur of ventricular septal defect is loudest cranial on the right side of the chest. It is usually band shaped and is often associated with a precordial thrill. This murmur is caused by blood shunting across the defect, from the left ventricle to the right. Most ventricular septal defects occur in the membranous septum, close to the aortic valve (Fig. 33.30). The resultant high-velocity jet of blood then impinges on the right ventricular free wall and swirls ventrally towards the pulmonary artery (Fig. 33.32). The vibrations caused by this flow pattern result in the characteristic cranial and ventral radiation of the right-sided murmur. The murmur may be audible as far ventral as the sternum.

Though much less common, defects can also occur in the muscular part of the interventricular septum (Fig. 33.33) or in the area of the pulmonary outflow. The former still result in a right-sided cardiac murmur, but the pattern of radiation of the murmur differs. By contrast, defects that open into the pulmonary outflow tract result in a murmur whose point of maximal intensity is cranial and ventral on the left hemithorax at the level of the pulmonary valve.

Another discrete murmur is often also heard in association with large septal defects in horses. It is best heard over the heart base on the left hemithorax. Contrary to popular opinion this is not referred from the right side. This is an ejection murmur, with PMI over the pulmonary valve area. It is known as a murmur of **relative pulmonary stenosis**. It arises as a result of augmented flow of blood through a normal pulmonary valve.

A further secondary finding, associated with a large defect and shunt fraction, is an increased intensity of S_3 that results from augmented filling of the left ventricle in diastole. When the defect is large, the resultant left atrial and ventricular enlargement eventually result in left heart failure and the plethora of associated clinical signs.

Special tests

Two-dimensional and M-mode echocardiography are necessary to evaluate the size of the defect. The loudness of the primary murmur may not be helpful in this condition, since loud murmurs are often associated with restrictive

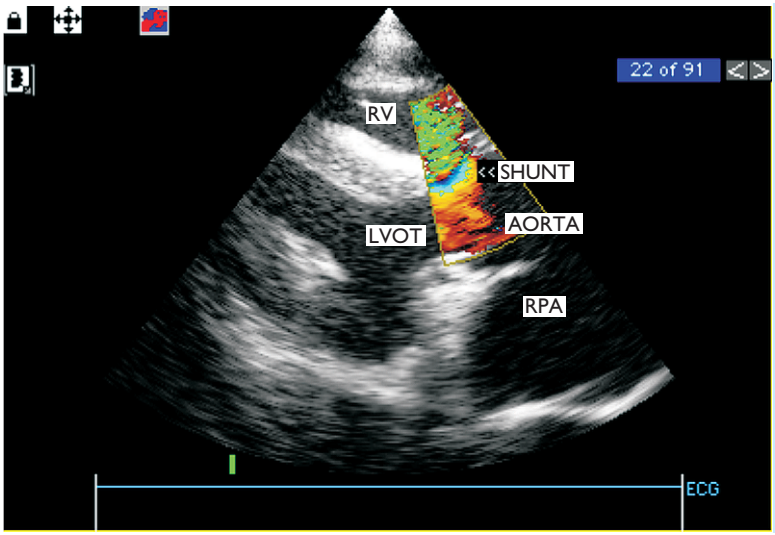

Fig. 33.32
Color flow Doppler study obtained from the filly in Fig. 33.30. The color flow study demonstrates left to right flow of blood through the defect during systole. The shunted blood travels through the defect and swirls ventrally and cranially towards the pulmonary valve, giving rise to the characteristic ventral and cranial radiation of the murmurs associated with membranous septal defects. LVOT, left ventricular outflow tract; RPA, right pulmonary artery; RV, right ventricle.

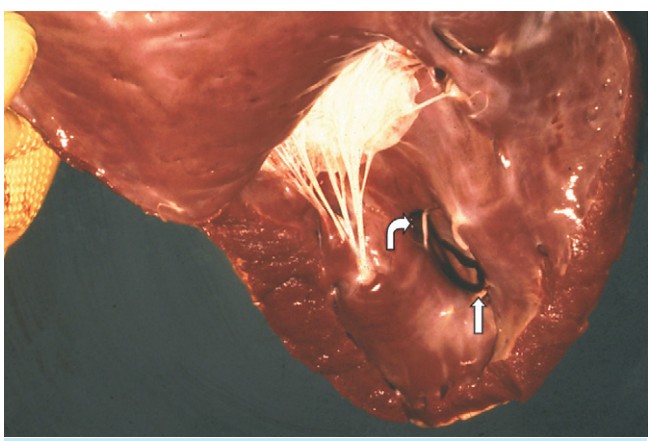

Fig. 33.33
Post-mortem specimen showing a large muscular ventricular septal defect in a 2-year-old Arabian filly. A widely radiating grade 5/6 murmur was detected from the right hemithorax at a pre-purchase examination. There was no medical history consistent with cardiac disease and the filly appeared to have normal exercise tolerance relative to her peer group. As her prognosis for useful athletic performance was hopeless and a congenital cardiac defect rendered her unsuitable for breeding, her owners elected her for euthanasia. (Courtesy of Dr LE Young and Dr KJ Blissitt, Royal (Dick) School of Veterinary Studies, Edinburgh.)

(nonsignificant) defects. It has been suggested that defects less than 2.5 cm in diameter in an adult horse are compatible with normal athletic performance and are unlikely to result in heart failure.[82] Since ponies are often affected, a more universally applicable method is to use Doppler echocardiography to measure peak flow across the defect, or to compare stroke volume from the right and left ventricle. Reef and colleagues[82] suggested that velocity across the defect that exceeded 4 m/s was likely to be associated with a restrictive defect. When using these methods, it is crucial to ensure that the continuous wave ultrasound beam or pulsed Doppler sample volume are aligned parallel to the shunt or ventricular outflow. If adequate alignment is not achieved, blood flow velocity will be significantly underestimated and the defect's significance overestimated. Left atrial size and pulmonary artery dilation can also be assessed using two-dimensional (2D) methods, and these measurements are also helpful in determining a prognosis for life and performance.

While auscultation findings and clinical signs are helpful in assessing size of a defect and its clinical impact, only 2D and Doppler echocardiography are ultimately able to provide information about the severity of volume overload and a quantitative assessment of defect size.

Treatment

No surgical or medical treatment for ventricular septal defects is currently available for horses. Only if heart failure develops is treatment warranted and should include drugs to control heart rate (digoxin), diuretics to reduce volume overload, and angiotensin converting enzyme inhibitors for reduction of cardiac afterload.

Prognosis

The prognosis for small restrictive defects found incidentally in performance horses is generally good. Certainly absence of a separate murmur of relative pulmonary stenosis and loud S_3 sounds indicate that the volume of abnormal blood flow through the defect is small and that the defect is likely to be restrictive. Such defects rarely progress to cause clinical problems. Progression of disease, even with moderately large defects, can be slow, affected horses often compensating well into adulthood. As with all cases of heart disease, echocardiographic examination of an affected horse allows the size of lesion and its hemodynamic impact to be determined. Whether an animal is suit-

able for athletic duties will depend upon the size of the defect and the degree of volume overload, and the type of work to be performed.

When detected at pre-purchase examination all septal defects undoubtedly constitute unsoundness, but the horse may still be able to perform a useful job in all but the most athletic of disciplines, especially when the defects are small and restrictive. Although small membranous defects may have minimal impact on blood flow, their position can cause disruption and instability of the aortic valve leaflets that results in rapidly progressive aortic valve regurgitation and secondary left ventricular volume overload (see below).

Etiology and pathophysiology

The condition occurs as a result of anomalous development of any of the components of the interventricular septum, most commonly the dorsal membranous portion that forms part of the fibrous skeleton of the heart. Although the precise genetics and mechanisms of inheritance of the condition in horses are unknown, affected animals should not be used for breeding.

Restrictive defects that result in a small shunt are usually well tolerated and have minimal hemodynamic impact. When defects are large, left-sided heart failure develops due to volume overload of the left atrium. The right ventricle tends to be relatively spared, as the pulmonary valve is open when the bulk of the volume is shunted across the defect and it passes directly into the pulmonary artery. Pulmonary overcirculation occurs and marked dilation of the pulmonary artery can result in pulmonary artery rupture. As a result horses with evidence of pulmonary overcirculation should be retired from ridden work.

Epidemiology

In the series of 27 cases described by Reef,[82] Standardbreds and Arabians were overrepresented compared to the hospital population and Thoroughbreds were underrepresented. European experience suggests that Welsh section A and Shetland ponies also have a high prevalence of the condition.

Aortic insufficiency

Recognition

History

Diastolic cardiac murmur is usually detected incidentally. Occasionally horses may have a history of ataxia during exercise or die suddenly, usually during exercise. Aortic regurgitation may be found in association with congestive heart failure, AF, and mitral valve regurgitation.

Presenting signs Aortic insufficiency occurs commonly in older horses. The murmur is diastolic, usually decrescendo, and has a PMI at the aortic valve, although it will often radiate widely towards the apex. Because the aorta is a midline structure, as the disease progresses, the murmur often becomes audible over the right hemithorax. It is thus the only murmur that can be routinely auscultated from both sides of the thorax. The murmur often has a musical quality and may appear to 'buzz' or 'whoo'. The musical quality is believed to arise as the regurgitant jet hits the anterior leaflet of the mitral valve (Fig. 33.34), or is due to resonance and vibration of the aortic root.

When severe, the condition can result in noticeably bounding arterial pulses (Fig. 33.26). This occurs because there is a rapid run off of aortic pressure in diastole, as blood leaks backwards into the low-pressure chamber of the relaxed left ventricle.

When the regurgitant fraction is large, there is volume overload of the left ventricle (Fig. 33.35). There is also dilation of the mitral valve annulus and, in consequence, secondary mitral regurgitation may occur. Thus when a systolic murmur of MR is heard in conjunction with the diastolic murmur of aortic insufficiency, prognosis is much more guarded.

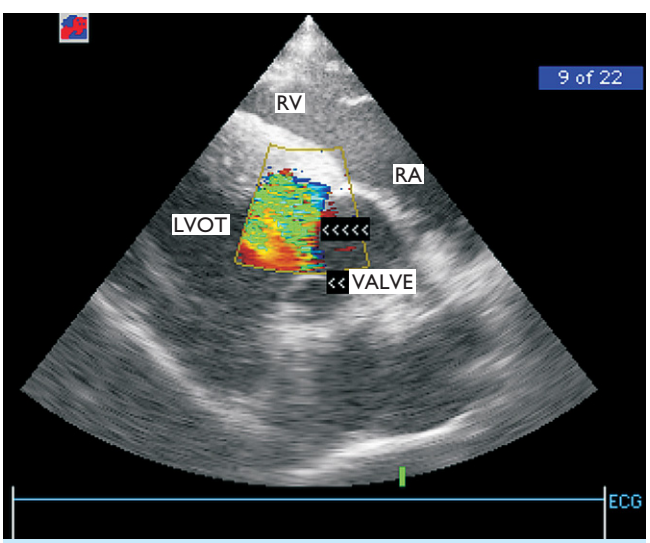

Fig. 33.34
Color flow Doppler study of aortic valve regurgitation in a 16-year-old Grand Prix dressage horse. The image shows a green jet of blood traveling from the center of the aortic valve towards the interventricular septum. The two-dimensional image showed valve leaflet thickening typical of nodular degeneration in the older horse. There was no evidence of exercise-induced arrhythmias and left ventricular dimensions were still within normal limits. The horse is subject to regular echocardiographic and electrocardiographic examinations as aortic valve degeneration is progressive. Currently he is able to remain in full competition, as there is no significant left ventricular dilation. LVOT, left ventricular outflow tract; RA, right atrium; RV, right ventricle.

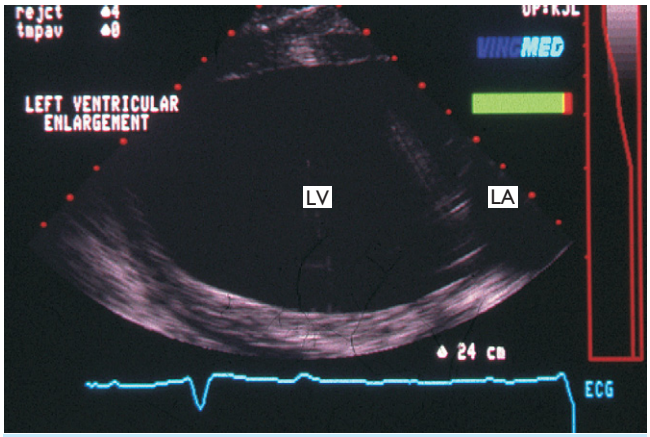

Fig. 33.35
Two-dimensional echocardiograph from the right hemithorax from an 11-year-old riding horse with a grade 5/6 murmur of aortic regurgitation. Note the rounded bloated appearance of the dilated left ventricle. Dilation results in increased afterload to the left ventricle and increases both myocardial work and oxygen demand. Coronary perfusion is simultaneously reduced as diastolic aortic pressure falls. Stretch and hypoxia increase the likelihood of ventricular arrhythmia and there is increasing risk of exercise-induced arrhythmias and sudden death. Severe volume overload also causes dilation of the mitral valve annulus resulting in secondary development of mitral regurgitation that can ultimately result in left-sided heart failure. LA, left atrium; LV, left ventricle. (Courtesy of Dr KJ Blissitt, Royal (Dick) School of Veterinary Studies, Edinburgh.)

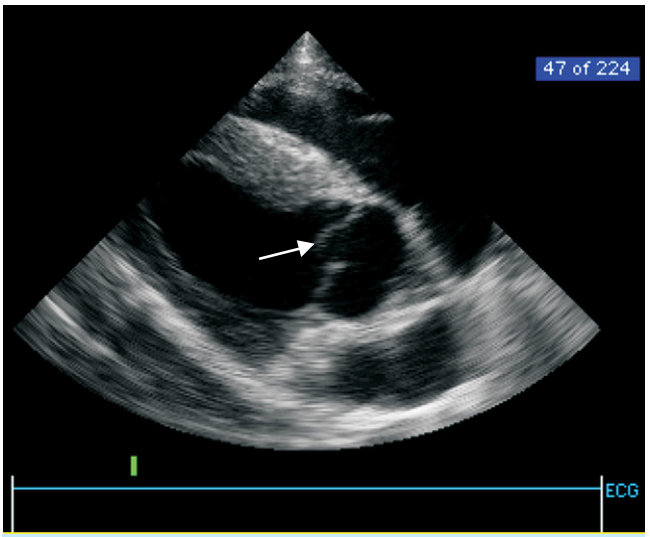

Fig. 33.36
Two-dimensional echocardiograph from a 9-year-old National Hunt race horse with a grade 3/6 murmur of aortic regurgitation. The image has been optimized to show the aortic valve (center). The non-coronary leaflet (arrow) has prolapsed into the left ventricular outflow tract. There is a bright echogenic nodule at the coaptation point of the valve, the usual site of nodular degeneration in older horses.

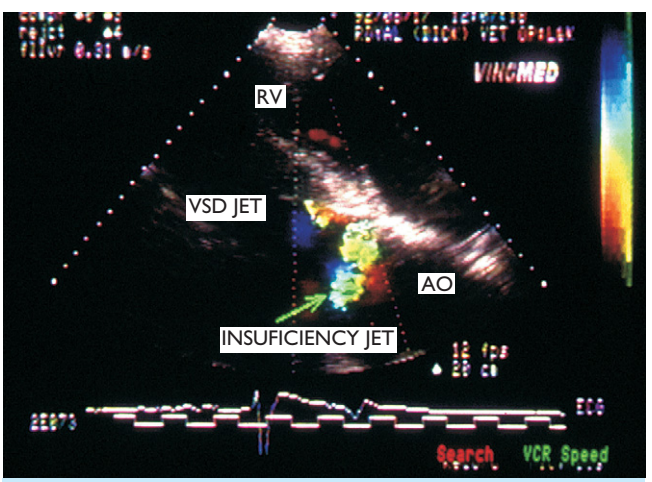

Fig. 33.37
Color flow Doppler study of the aorta and left ventricular outflow tract from the right hemithorax of a 7-year-old novice event horse during late diastole. The horse failed a pre-purchase examination after a grade 3/6 diastolic murmur was detected from the left heart base. The image shows two discrete regurgitant jets (labeled), one from the aortic valve and one from a small ventricular septal defect which closes when the ventricle shortens in systole. AO, aorta; RV, right ventricle; VSD, ventricular septal defect.

Special examination

Color flow Doppler echocardiography will confirm the presence of aortic regurgitation (Fig. 33.34). Pulsed or continuous wave Doppler techniques allow estimates of right and left ventricular stroke volume and regurgitant fraction to be made. Two-dimensional and M-mode echocardiography are used to evaluate cardiac chamber size and left ventricular wall motion. In severe aortic regurgitation, there is left ventricular dilation (Fig. 33.35) and secondary mitral regurgitation.

Careful examination of the aortic valve using 2D and color flow Doppler techniques may demonstrate the underlying cause of the valve dysfunction. Typical findings include valve leaflet prolapse (Fig. 33.36) and nodular degeneration, thickening of the valve leaflets, or evidence of a small ventricular septal defect (Fig. 33.37). There is often diastolic fluttering of the anterior mitral valve leaflet visualized by 2D or M-mode echocardiography.[83] In severe volume overload and secondary mitral regurgitation, premature closure of the mitral valve and septal hyperkinesis may also be a feature.[84]

In horses with mild–moderate aortic valve regurgitation and without evidence of heart failure, electrocardiographic examination during appropriate exercise is mandatory to ensure that there is an absence of exercise-induced ventricular arrhythmias.

Treatment

There is no specific treatment for aortic valve regurgitation available and in horses with compensated valve dysfunction,

none is indicated. When signs of left ventricular volume overload become evident (Fig. 33.35), or signs of heart failure are present, the horse must be immediately retired from ridden exercise. Palliative therapy focuses upon control of heart rate (digoxin), reduction of volume overload (diuretics), and reduction of cardiac afterload (angiotensin converting enzyme inhibitors). On the rare occasion that valve dysfunction is caused by endocarditis, targeted antibiotic therapy will be required.

Prognosis

Most commonly the condition arises due to normal progressive aging changes of the valve leaflets and when the murmur is detected in older horses the prognosis for life and performance is generally good. In such cases performance problems are rarely reported and the ultimate cause of death or euthanasia in these horses is usually noncardiac. In older horses, the condition usually progresses slowly and they are usually able to continue their normal activities, provided they are monitored regularly by echocardiography and ECG.

Aortic insufficiency also occurs sporadically in younger horses when the only abnormalities on echocardiography include leaflet prolapse, dilation of the aortic root, and premature degenerative changes (thickening or nodular degeneration). In these horses the condition might progress to heart failure during the course of the horse's athletic career. In some cases progression is very slow and the horse's career may not be noticeably compromised, but progression of regurgitation and volume overload is impossible to predict in individuals, so all affected cases must be carefully monitored. As a result when the murmur is encountered during a pre-purchase examination, although each patient must be considered individually, in general the murmur should be viewed with concern.

When a systolic murmur of mitral valve regurgitation is heard in conjunction with the diastolic murmur of aortic insufficiency, or there is hyperkinesis of peripheral pulses, it is likely that there is a large regurgitant fraction and that mitral valve regurgitation is secondary to severe volume overload. As a result prognosis is much more guarded and the horse must be retired from ridden duties.

Etiology and pathophysiology

Usually the condition arises due to nodular degeneration of the valve leaflets, a change that appears to be age related.[53,54] When a loud murmur of aortic insufficiency is detected in a horse under 15 years of age there has been premature progression of aortic valve disease and a complicating reason, other than normal aging processes, is implicated. Vegetative endocarditis, though very rare, can affect both aortic and mitral valves in horses,[70] and prognosis for performance and survival is poor. More commonly premature regurgitation is caused by prolapse of the noncoronary cusp of the aortic valve into a small ventricular septal defect (Fig. 33.37).[82] In many affected horses, the septal defect is not of hemodynamic significance per se, as there is little or no blood flow through it during systole as the heart contracts and shortens. Aortic valve regurgitation has also been implicated in the pathogenesis of aneurysm formation in the proximal aorta.[85]

When the regurgitant fraction is large, there is volume overload of the left ventricle (Fig. 33.35) and dilation of the mitral valve annulus resulting in mitral regurgitation. The severely dilated ventricle also becomes prone to exercise-induced ventricular arrhythmias. This increased susceptibility occurs due to increased cardiac work and myocardial oxygen demand caused by increased cardiac preload and the augmented afterload of cardiac dilation. These factors are coupled with reduced diastolic blood pressure and thence coronary perfusion pressure. The risk of arrhythmia is heightened when myocardial oxygen demand increases and diastole shortens during exercise. As a result, affected horses should be monitored regularly by echocardiography and exercising ECG as long as they remain in ridden work.

Epidemiology

In a population of 1159 horses comprising many retired animals, the presence of a diastolic murmur of aortic insufficiency was found to be significantly associated with age.[86] The murmur is only infrequently detected in race horses,[1–4] but the prevalence is greater in older National Hunt Thoroughbreds than in those engaged in flat racing (Tables 33.1, 33.2).

Complex congenital lesions

A wide variety of complex cardiac abnormalities have been reported in foals.[87–95] They are however uncommon[96] and often result in early signs of heart failure and cyanosis. Complex developmental abnormalities have a higher incidence in Arabian foals, but they can occur in all breeds, occasionally presenting at adulthood or adolescence[97] (Fig. 33.38). Complex congenital lesions are not compatible with athletic performance, but depending upon the amount of intracardiac shunting and venous admixture, can carry a surprisingly good prognosis for short- to medium-term survival.

Diseases of the myocardium

- Diseases of the myocardium are poorly understood in horses.
- They are characterized by loss of performance and arrhythmias at rest and during exercise.
- Measurement of serum or plasma concentration of cardiac troponin I and the isoenzymes of lactate

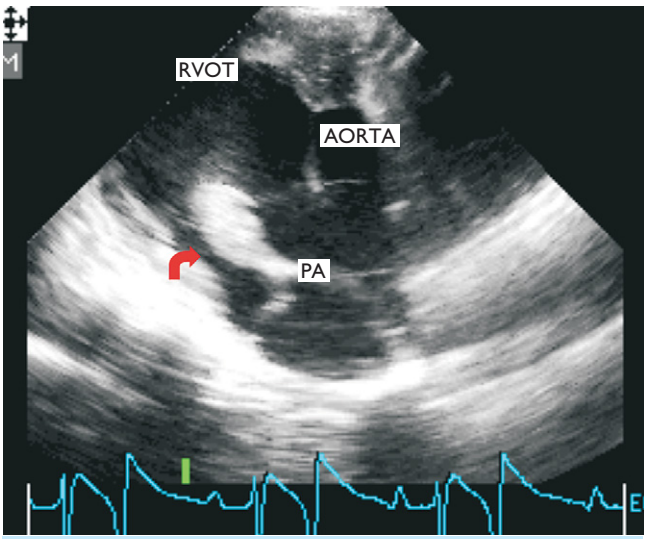

Fig. 33.38
Two-dimensional echocardiograph from the right hemithorax of an 18-month-old Thoroughbred with tetralogy of Fallot. This is a cranial short-axis view of the right ventricular outflow tract (RVOT). The outflow tract connects directly with a dilated aorta and a pulmonary artery (PA). Subvalvular pulmonic stenosis is severe (red arrow).

dehydrogenase will be elevated in severe acute cases of myocardial inflammation and necrosis.

- Dilated cardiomyopathy occurs rarely in athletic horses and has been associated with nutritional deficiencies in young horses and cattle.
- Occasionally toxic damage to myocytes occurs when a cardiotoxin is accidentally introduced into equine feed. The ionophores salinomycin and monensin have caused a number of such outbreaks throughout the world.[98–102]
- Horses that survive ingestion of cardiotoxins usually develop a dilated hypocontractile ventricle that mimics dilated cardiomyopathy.
- True inherited idiopathic cardiomyopathy, as occurs in other species, has not yet been identified in horses.

Recognition

History

Myocarditis has been linked to poor performance syndromes occurring in individuals, or in outbreaks in racing stables. Myocarditis may be the underlying cause of atrial and ventricular arrhythmia in athletic horses. In the acute phases of toxic damage to the myocardium, one or more horses may die suddenly from fatal ventricular arrhythmia.

Physical examination

In many mildly affected cases, the horse is normal on physical examination at rest. A cardiac rhythm disturbance may be present during auscultation, or during palpation of the apex beat or peripheral pulse. If cardiac function is severely compromised, the horse will present with signs of biventricular heart failure (see 'Mitral regurgitation' above).

Special examination

A definitive diagnosis of the origin of the ectopic complexes (atrial or ventricular) will be determined by electrocardiography (see 'Supraventricular premature systoles' and 'Ventricular premature systoles' above). In cases of poor performance an ECG during appropriate exercise is advisable.

In acute cases, measurement of serum cardiac troponin I and the isoenzymes of lactate dehydrogenase can sometimes provide a definitive diagnosis of myocardial inflammation and necrosis, though in most horses these analyses are not conclusive. It is important to appreciate that these laboratory tests are poorly validated in horses and that their sensitivity and specificity in this species have not yet been determined. In addition, they have been developed to assess acute ischemic events in people, when the amount of myocardial damage and necrosis is enormous. With the possible exception of toxic damage to the equine myocardium, in equine practice it is unlikely that such severe acute myocardial damage is likely to occur, so it is not surprising that in our hands these tests are frequently disappointing. In addition, when horses present with suspected myocardial dysfunction, it is quite possible that the acute insult to the heart or any causative agent were present considerably earlier, further reducing the power of serologic and biochemical testing methods. Of the biochemical tests currently available, cardiac troponin I probably has the highest specificity for myocardial injury and appears to be phylogenetically conserved between mammals. New markers of myocardial injury will undoubtedly continue to be developed for assessment of myocardial injury in human medicine. Unfortunately, for the reasons stated above, no matter how specific these tests become, it is unlikely that a biochemical marker will ever be able to definitively diagnose mild myocardial dysfunction in horses.

Echocardiography is also useful to assess the cardiac chambers and systolic function. Abnormal wall motion suggestive of localized myocardial damage may be present, or there may be extensive areas of fibrosis and calcification of the myocardium and endocardium.

The results of all these examinations may be unremarkable or equivocal, especially on horses with vague signs of poor performance or lone arrhythmia.

It has also been suggested that postexercise echocardiography may be a more sensitive method to detect mild ischemic damage to the myocardium in horses.[103,104] M-mode echocardiography is used within 60 seconds of exercise to fatigue in an attempt to mimic the stress echocardiography that is carried out during exercise in people to detect subclinical disease.[105] Unfortunately it is not practical to perform the examination during steady-state exercise in horses and the technique appears to have a very high coefficient of variation in normal horses.[106] Despite this

limitation, the method's advocates claim that the technique has been useful in horses undergoing performance evaluation on the treadmill.[104]

Treatment

Therapeutic aim

Treat underlying disease process and any life-threatening arrhythmia. Remove access to toxin. Improve nutritional status.

Therapy

In all suspected outbreaks, or in individual animals, thorough evaluation of previous medical history, bacteriologic or serologic examination and assessment of nutritional status of affected horses and, any horses in contact with the affected animals, should be undertaken.

In most cases of extensive myocardial damage or necrosis, treatment is ineffectual once clinical signs are apparent. Therapy is therefore aimed at the control of clinical signs and amelioration of cardiac failure with the use of appropriate antiarrhythmic drugs to treat life-threatening rhythm disturbances. Affected horses should always be completely rested to reduce myocardial oxygen demand.

In less severely affected cases with signs of poor performance or lone arrhythmia, rest and steroid therapy have been advocated (see 'Supraventricular premature systoles' above). When biochemical markers of myocardial damage are elevated at diagnosis, their levels can be used to monitor progress.

Prognosis

The prognosis for myocardial disease is dependent upon the severity of the underlying damage to the myocardium. In general the prognosis for return to athletic function is hopeless if there is echocardiographic evidence of reduced systolic function or marked chamber dilation. The prognosis for survival is also poor.

When myocarditis is suspected in horses presenting with poor performance and arrhythmia, and when there are no echocardiographic or biochemical abnormalities, prognosis is fair. A percentage of affected horses will return to their previous athletic performance following rest and/or steroid therapy. In the absence of a definitive test to diagnose myocarditis in horses, unfortunately it is questionable whether true myocardial inflammation was ever present in many of these cases. Myocardial biopsy is an invasive, high-risk procedure, and as a result it seems unlikely that our understanding of this condition will improve in the foreseeable future.

Etiology and pathophysiology

In most species the usual underlying cause of myocardial damage is ischemia resulting from coronary artery occlusion, usually arteriosclerosis. A similar etiology may underlie the condition in horses, as areas of focal fibrosis are common in the equine myocardium at post-mortem examination.[53–55] Cranley & McCullagh[55] also demonstrated a relationship between proximal aortic *Strongylus vulgaris* lesions and the presence of focal ischemic lesions in the myocardium and hypothesized that microembolization from parasitic lesions in the proximal aorta produced obstructive arteriosclerotic lesions in myocardial arterioles. In most horses, the areas of fibrosis are focal and do not penetrate the whole thickness of the ventricular myocardium,[53–55] but it is possible that during cell ischemia and death, before fibrosis occurs, these areas act as foci for arrhythmogenesis. In more severely affected horses, there may be sufficient damage to wide areas of myocardium to provoke extensive remodeling and lasting damage to cardiac function. Unfortunately in most post-mortem studies the fibrotic lesions cannot be correlated to clinical signs before death and in many cases the lesions appear inactive. In addition, improved anthelmintic management of equidae has resulted in a marked reduction in the incidence of thrombo-ischemic lesions associated with large strongyle infestations (Dr Ken Smith, personal communication), although minor intimal tracking consistent with strongyle damage remains a common incidental finding at post-mortem examination.[107] Although the precise etiology was uncertain, a number of authors have found post-mortem evidence of acute myocarditis in horses presenting with severe ventricular arrhythmia and poor performance.[61,63,108]

Ionophores such as monensin,[109,110] and salinomycin[98] and rattlesnake poison[111] cause direct damage to myocytes resulting in cell death, replacement fibrosis, arrhythmia, and loss of systolic function.

In the poor performance syndrome in racing yards, the cardiac signs are often observed some time after an outbreak of infectious respiratory disease, but despite extensive serologic and bacteriologic investigations, in most cases, a causative agent cannot be identified. More research is needed in this area. In humans, viruses are believed to be associated with dilated cardiomyopathy,[112] and during influenza virus epidemics there may be unexpected mortality of humans due to cardiovascular diseases.[113] The precise mechanism of viral damage to the myocardium is not fully understood, but may involve procoagulant effects.[113] It is possible that similar sporadic cases of virus-associated or postviral myocarditis occur in the equine population, but at the moment this is entirely speculative. There is, however, evidence that equine viruses, including equine viral arteritis, equine herpesvirus-1, and African horse sickness virus, replicate in epicardial or myocardial blood vessels in natural and experimental disease,[114–116] and myocarditis has been reported in horses infected with influenza virus.[117,118]

Idiopathic dilated cardiomyopathy in dogs and humans results from various genetic mutations of the proteins involved in cardiac contraction. There is reduced contractile function and ultimately cell death and fibrous remodeling

that result in a dilated poorly contractile ventricle and symptoms of heart failure and arrhythmia. There have been clinical and anecdotal reports of a similar syndrome in horses, based on the post-mortem or echocardiographic diagnosis of a large dilated heart. However it is important to appreciate that myocardial failure and dilation accompanies all types of heart failure in end-stages, so that echocardiographic evidence of dilated poorly contractile ventricle is not diagnostic of dilated cardiomyopathy.

Epidemiology

No epidemiologic information is currently available, as myocarditis is too poorly understood in horses.

Diseases of the pericardium

Recognition

History

Affected horses may present with general signs of malaise or evidence of heart failure including weakness and collapse.[119]

Presenting signs

In horses affected with bacterial pericarditis, there will be associated signs of infection and sepsis. Cardiovascular signs depend upon the volume of pericardial fluid. In cardiac tamponade (large effusion compressing the right atrium), jugular distension, subcutaneous edema, ascites, pleural effusion and abdominal enlargement will be evident. Peripheral pulse quality is poor and heart rate is increased. There may by muffling of the heart sounds with the presence of pericardial friction rubs in some cases.[119,120]

Special tests

Two-dimensional echocardiography will identify fluid in the pericardial space. There may be obvious compression of the right cardiac structures, depending upon the volume of effusate present.

Electrocardiography will reveal sinus tachycardia, but the QRS amplitude will be less than usual. Electrical alternans, as occurs in other species, is rare in horses.[119,120]

Hematology, bacteriology and analysis and culture of pericardial fluid are valuable in determining etiology and treatment in cases of septic pericarditis.

Therapy

Therapeutic aims

To release pressure on the right heart chambers and restore normal cardiac filling and to achieve bacteriological cure in cases of septic pericarditis

Treatment

Aggressive pericardial drainage and lavage have been recommended for effusions associated with cardiac compromise.[119] Additional antibiotic therapy as indicated by culture and sensitivity will also be indicated in bacterial pericarditis. In cases of nonseptic idiopathic pericarditis, corticosteroids are recommended.[119,120] Surgical pericardectomy was also attempted as a treatment for restrictive pericarditis in a horse, but the results were disappointing and the condition recurred.[121]

Prognosis

In a series of 18 cases described by Worth & Reef,[119] all 14 of the horses treated successfully returned to their previous athletic performance. Only one treated horse died in the series of 10 cases of idiopathic pericarditis described by Freestone and colleagues,[120] suggesting that with aggressive treatment prognosis is good. In contrast to other species, there are few reports of effusion returning repeatedly after drainage. If effusion results from sepsis, or trauma, the prognosis is more guarded and will depend upon the nature of the effusion and the response to antimicrobial agents.

Etiology and pathophysiology

In the series of 18 cases described by Worth & Reef,[119] pericarditis was defined as idiopathic in six horses. A bacterial cause was identified in five horses and the remaining horses had nonseptic pericarditis associated with bacterial (five horses) and viral respiratory disease (two horses). Laboratory analysis of pericardial fluid samples from 10 cases of idiopathic pericarditis classified six cases as aseptic serofibrinous, three cases as eosinophilic, and one case as histiocytic.[120]

The hemodynamic effect of pericardial effusion depends upon the volume of effusion and the amount of compression of the thin-walled right atrium. Increased pericardial pressure impedes ventricular filling and increases end-diastolic pressure. Reduced stroke volume of the right heart causes reduction in arterial blood pressure and activates the renin–angiotensin system resulting in massive retention of Na and water. Backward failure of the right ventricle rapidly occurs, resulting in jugular distension and abdominal, pleural and subcutaneous fluid accumulation. Low-output failure simultaneously results in weakness and exercise intolerance.

Epidemiology

Isolated cases of pericarditis occur only rarely in athletic horses and no specific epidemiologic information is available. In spring of 2001 in central Kentucky, outbreaks of pericarditis and uveitis were recognized in grazing yearlings. The outbreaks occurred concurrently with mare reproductive

loss syndrome on breeding establishments. The syndrome was only detected in horses at grass and as a result, athletic animals were not affected.[122] The precise etiology of the syndrome remains uncertain at this time.

Diseases of the vessels

Parasitic arteritis

General

Three general syndromes of large vessel disease are recognized in performance horses. These are: sudden death due to large vessel rupture; acute or recurrent colic due to arteritis and thrombosis of the cranial mesenteric arteries or renal arteries; and a vague history of increasingly poor performance and hind limb lameness with aortoiliacofemoral thrombosis.

Aortic and great vessel rupture

Recognition

History and presenting signs

Horses present with sudden death or sudden-onset pallor, tachycardia, and weakness, usually during exercise. Subacute cases may also present with ventricular arrhythmia, usually ventricular tachycardia.[57] Rapid weak pulses with pulse deficits are usually obvious. Horses are often in extreme distress and exhibit profuse sweating. They are frequently misdiagnosed as colic cases. There is usually a loud continuous cardiac murmur, the position of which varies according to the site of rupture.

Treatment

There is no specific treatment. Antiarrhythmic drugs may be used to control the ventricular rhythm disturbance for symptomatic relief. Response to drug therapy is variable, depending upon the extent of damage to the conduction tissues.

Prognosis

Death usually occurs acutely or very soon after vessel rupture due to ventricular arrhythmia or hypovolemic shock. When rupture is into the right heart, the horse may present subacutely with a sudden onset continuous heart murmur, ventricular arrhythmia, and/or acute distress. The prognosis for subacute cases depends on the site and size of the aortic rupture. Usually, but not invariably, they are also fatal.

Etiology and pathogenesis

Rupture of the aorta, at the level of the sinus of Valsalva, aortic arch, or the main pulmonary artery and its branches, can occur.[123–125] When a large vessel ruptures into the thoracic cavity, death is immediate through rapid hypovolemic shock. Aortic aneurysms are reported most frequently at or around the right coronary sinus up to the brachiocephalic trunk.[85,126–128] It seems likely that an aneurysmal weakness at the site of vessel rupture also underlies sudden death and rupture is most likely during strenuous exercise when arterial and pulmonary vascular pressure increases. These sites are also commonly affected with lesions associated with *Strongylus vulgaris* migration[55] and parasitic damage to arteries has been postulated to underlie great vessel rupture in horses. In subacute cases rupture of the aneurysm usually occurs at the level of the right coronary artery from whence it dissects into the interventricular septum,[57] pulmonary artery,[129] or the right heart.[130] When the aneurysm dissects through the interventricular septum, there is widespread damage of the cardiac conduction system resulting in the characteristic ventricular rhythm disturbances. Occasionally volume overload leads to right heart failure after rupture of the aneurysm into the right ventricle.[130]

Pulmonary artery aneurysm and vessel rupture can be associated with severe pulmonary hypertension in left heart failure.

Epidemiology

Large vessel rupture tends to occur most frequently, but not exclusively, in older performance horses.

Cranial mesenteric parasitic arteritis

History and presenting signs

Cranial mesenteric parasitic arteritis cases present with acute colic symptoms when mesenteric arterial occlusion is complete, or with chronic weight loss, diarrhea and intermittent recurrent colic if occlusion is partial.[131]

Special tests

Peritoneal fluid aspiration and rectal examination will be necessary to establish a diagnosis.

Therapy

Therapeutic aims

Therapy is usually palliative but aims to restore normal nutrition, hydration and electrolyte status, and normal gut function.

Treatment

Larvicidal anthelmintics are recommended. For thromboembolic colic, laparotomy and resection of devitalized bowel

may be required. Fluid therapy and analgesic administration may also be required in cases of acute and chronic colic.

Prognosis

Depends on the severity of the presenting signs in colic cases, but repeated bouts of colic can continue until an acute ischemic episode occurs.

Etiology and pathophysiology

During migration, *Strongylus vulgaris* larvae damage the arterial endothelium. This results in activation of inflammatory mediators, disruption of the normal integrity of the vessel wall, and intimal thickening.[107] The resulting turbulence and expression of inflammatory mediators promotes platelet adhesion, fibrin deposition, and thrombus formation. Lesions are most likely to form at vessel branches, where eddy formation and turbulence naturally occur.

Epidemiology

Parasitic arteritis is most likely to occur in horses with a history of inadequate or inappropriate anthelmintic use.

Aortoiliacofemoral thrombosis

Presenting signs

Clinical signs vary from mild hind limb stiffness that reduces performance to more severe unilateral or bilateral hindlimb lameness induced by strenuous exercise. Fairly commonly, increasingly poor performance is often noted before the onset of more dramatic clinical signs. The affected limb may feel cooler after fast exercise. Affected horses may also become distressed and unpredictable and sweat profusely immediately following very strenuous work. There may be reduced saphenous venous refill time in the affected limb after exercise and the affected limb may feel cooler. In longstanding cases there may be unilateral hind limb muscle atrophy.[132,133]

Special tests

Aortoiliacofemoral thrombosis may be diagnosed by careful rectal palpation revealing vessel occlusion/aneurysm at the bifurcation of the caudal aorta. Two-dimensional ultrasonography is the most practical method to make a definitive diagnosis,[134] although Doppler and nuclear scintigraphic methods[135] have also been used. In athletic horses, the thrombus is usually only partially occlusive at presentation and flow limitation occurs initially at maximal exercise. As the thrombus increases in size, flow limitation occurs with progressively less strenuous activity.

Therapy

Therapeutic aims

To relieve signs of hindlimb ischemia by restoring limb blood flow. Strategies include preventing further thrombus formation, encouraging thrombolysis, providing analgesia, and allowing a collateral circulation to develop.

Treatment

Specific treatments with various anticoagulant agents[136] and surgical removal of thrombus have been described. None have been critically assessed and recovery will always depend upon the development of collateral circulation and prevention of further clot formation. In athletic horses, daily administration of aspirin is often recommended, but its efficacy is unknown.[132] Monthly administration of ivermectin coupled with twice daily administration of phenylbutazone has also been suggested, but the efficacy of this regime is also difficult to assess as improvements in clinical signs may result from the development of collateral circulation alone.[137]

Prognosis

The prognosis for return to previous levels of athletic performance after aortoiliacofemoral thrombosis is poor.

Etiology and pathophysiology

Characteristically organized lesions are found at the aortic quadrification and extend into the distal portions of the femoral and internal iliac arteries. The lesions may be partially or completely occlusive and consist of well-organized and well-vascularized fibrous tissue, occasionally containing hemorrhagic or degenerate areas. Proximal to the organized masses, thrombi are often present.[138] The pathogenesis of the lesions remains unclear. *Strongylus vulgaris* larval damage has been implicated, but actual larvae or inflammatory cells are not usually present in the lesions[138] and the larvae rarely migrate to such caudal arterial locations.[107] In addition, the disease is most frequently reported in athletic animals with a good standard of management. Others have suggested that the condition may be similar to arteriosclerosis obliterans in humans when intimal damage, expression of inflammatory mediators, thrombus formation and fibrosis result in progressive vessel occlusion.[138] It has been proposed that equine iliac arteries may be predisposed to damage because of vessel branching that results in turbulent flow at a location that is already predisposed to damage because of large forces of locomotion and tight fascial attachments to surrounding tissues.[137]

Epidemiology

The condition has been documented in horses of all ages and sexes, but clinical signs are more frequently reported in male

performance horses.[138] It is possible this observation reflects the higher proportion of males engaged in strenuous activity rather than a true sex difference in prevalence of arterial damage. The average age of horses in a series of 15 cases was 5.2 years.[138]

Jugular vein thrombosis

Recognition

History

This condition is often associated with prolonged intravenous catheterization following surgical procedures. Horses with endotoxemia or septicemia are at increased risk.[139] Venous thrombosis and thrombophlebitis also follow repeated jugular venepuncture, particularly when the drugs being administered are irritant, or intravenous technique is poor.

Presenting signs When one vein is affected there may be no obvious clinical signs except localized firmness and cording of the vessel. When both vessels are affected, there will be proximal engorgement of vessels coupled with subcutaneous and local edema. Head and laryngeal swelling can occur in extreme cases. Head swelling is always exacerbated when the head is lowered, e.g. during grazing. When a long length of vein is occluded by thrombus, there may be bacterial colonization resulting in pyrexia, depression, neck stiffness, heat, and pain. Inadvertent perivascular deposition of irritant drugs such as phenylbutazone, guiaphenesin, thiopentone and hypertonic solutions also results in heat, swelling and localized pain. If sufficiently severe, the initial chemical irritation may be followed by a marked inflammatory response, tissue necrosis, and skin sloughing.

Special examination

Two-dimensional ultrasound examination is useful to assess the extent of the thrombus, or check jugular vein patency in cases of severe perivascular inflammation and swelling. An echodense cavitating thrombus is usually present within the jugular vein. The appearance of brightly echogenic areas within the thrombus suggests that gas-forming bacteria are present and that aggressive treatment will be required. Hematologic and biochemical investigation usually demonstrates leucocytosis, neutrophilia, and hyperfibrinoginemia.

Treatment

Therapeutic aims

Therapy is focused upon the need to discourage further thrombus formation and the control and prevention of infection, thus reducing the chances of septic embolization and systemic complications. In mild or unilateral cases treatment may not be required as spontaneous recanalization occurs in many affected horses.

Therapy

Prolonged systemic antibiotic therapy will be required when bacterial infection is present. All intravenous catheters must be removed and further venepuncture cease. Surgical excision and removal of the affected vein may be required when the lesion is extensive and infected.[140–142] Concurrent administration of nonsteroidal anti-inflammatory drugs, hot packing, and massage may also provide analgesia and relief during the acute phase.

When inadvertent perivascular injection of a known irritant has occurred, the drug should be diluted by instilling large volumes (at least 1 L) of isotonic electrolyte solution around the site. Local anesthetic agents (without epinephrine) can be added to the diluent solution to provide analgesia.

Prognosis

In most cases prognosis is good and normal jugular filling returns after recanalization occurs. If there is infection and septic embolization, the prognosis is more guarded. If early aggressive treatment is not performed after perivascular injection of a known irritant, there may be extensive necrosis and sloughing of neck skin that ultimately requires reconstructive surgery. Occasionally there may be damage to the recurrent laryngeal nerves, carotid artery, ventral neck muscles, and the vago-sympathetic trunk.

Etiology and pathogenesis

Localized or diffuse vascular endothelial damage exposes endothelial collagen and promotes platelet and fibrin adhesion and thrombus formation. When the thrombus is occlusive there is increased venous pressure resulting in swelling and edema in dependent areas. When thrombus or thrombophlebitis is complicated by sepsis there will be pyrexia and the possibilty of septic emboli causing disease in other body systems. Horses with a hypercoagulable state, or with endotoxemia and sepsis, are at a higher risk of thrombosis and thrombophlebitis.[139] Although the jugular vein is most commonly affected, thrombosis of other systemic veins has also been reported.[143]

Epidemiology

Jugular thrombosis and thrombophlebitis occur sporadically in performance horse and are usually iatrogenic associated with administration of drugs or intravenous catheterization.

Immune-mediated vasculitis

History

Immune-mediated vasculitis is associated with previous and ongoing infections including *Streptococcus equi* (strangles),

equine viral arteritis, ehrlichiosis, equine infectious anemia, and equine influenza. Occasionally the syndrome occurs after other systemic diseases including neoplasia and colitis.[144] As a result the condition is rare in athletic horses.

Presenting signs, treatment, and prognosis

Immune-mediated vasculitis usually results in cutaneous lesions (crusting, ulceration), edema, erythema, pyrexia, reluctance to move, depression, and inappetance. Treatment depends upon the underlying cause, although corticosteroids are recommended in the absence of active infection. Prognosis depends on the underlying cause, speed of recognition of clinical signs, and patient response to early aggressive treatment.

CHAPTER 34

Metabolic responses to exercise and training

A. Reeta Pösö, Seppo Hyyppä and Raymond J. Geor

Introduction

The superior performance capacity of horses may have its roots in evolution as the means for a horse to escape its predators, and natural selection has led to the survival of the fastest individuals. Several physiologic factors contribute to the horse's athletic prowess. Aerobic capacity, as indicated by maximal oxygen uptake,[1–3] is more than twice that of elite human athletes. This exceptional oxygen uptake is made possible by a high cardiac output and capillary and mitochondrial density in skeletal muscle, and also by the splenic reservoir of 4–12 L of red blood cells released into circulation at the beginning of exercise. Several studies in horses and other species have shown that the augmentation in oxygen-carrying capacity resultant from increased red cell volume markedly increases aerobic capacity.[4–6] The horse is also advantaged by high muscle glycogen stores[7,8] that provide a readily available pool of substrate for ATP synthesis, thereby avoiding limitations to performance associated with inadequate substrate supply. In addition, equine skeletal muscle has higher buffering capacity compared to other species[9] which allows the horse to tolerate high muscle lactate concentrations during exercise.[10–12] Not only is the muscle able to tolerate high concentrations of lactate, but also the behavior of equine red blood cells (RBC) appears to differ from that of other athletic species. In horses, but not in other species studied so far, RBC appear to function as a lactate sink which may contribute to the efflux of lactate from contracting skeletal muscle.[13–16]

Skeletal muscle is well adapted for upregulation of metabolic rate with increasing intensity of exercise. For example, oxygen uptake, which at rest may be as low as 4 mL/kg/min,[6] increases in exercising horses up to 160–200 mL/kg/min.[1–3] In Standardbred horses running at 100% of $\dot{V}O_{2max}$, total muscle blood flow has been estimated at 226 L/min or approximately 78% of total cardiac output.[17] Therefore, the increase in metabolic rate is even greater in contracting skeletal muscle and oxygen consumption may approach 250 mL/per kg muscle per min.[18] This change in oxygen uptake indicates acceleration of aerobic pathways for energy

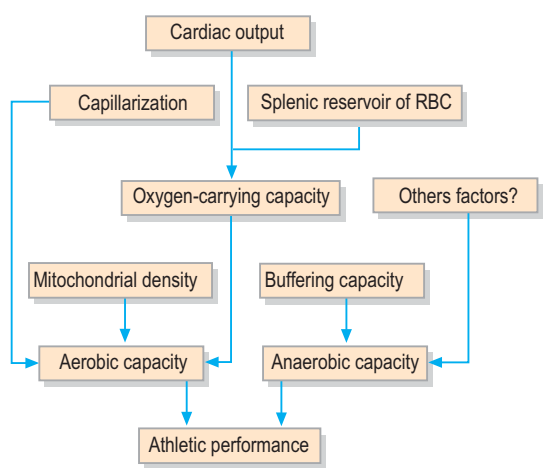

Fig. 34.1
Athletic performance from a metabolic viewpoint is a sum of aerobic and anaerobic capacities. When energy sources are not limiting, aerobic capacity depends both on the availability of oxygen and the ability of muscle tissue to use oxygen for energy. Much less is known about the factors, other than buffering capacity, that influence anaerobic capacity.

transduction, but during high-intensity exercise the rate of anaerobic metabolism also increases. Adenosine triphosphate (ATP) content in muscle remains nearly constant over a large range of changes in muscle activity,[19–22] indicating that ATP demand for muscle contraction is balanced by adenosine diphosphate (ADP) rephosphorylation. During maximal exercise or due to shortage of glycogen and other fuels, the rate of ATP utilization may exceed the rate of production, with resultant activation of the enzyme myokinase and eventually loss of adenine nucleotides. In human skeletal muscle, energy consumption may be up to 3 mmol ATP/kg muscle per s[23] and if it is assumed that similar maximal rates occur in equine muscle during intense exercise, it is evident that ATP resynthesis from the aerobic oxidation of glucose or fatty acids will not meet energy demands during maximal exercise.[24] The remainder must be derived from anaerobic processes, mainly glycolysis of glucose to lactate.

Integration of various body systems

Exercise requires the co-ordinated function of the central nervous, respiratory, cardiovascular, hematologic and musculoskeletal systems. At the onset of exercise, the rapid and pronounced effects on the cardiovascular system and overall metabolic rate are initiated and controlled by neuroendocrine mechanisms with the catecholamines norepinephrine and epinephrine being the primary regulators. These hormones are synthesized and secreted by the adrenal medulla; norepinephrine also by postganglionic sympathetic neurons. In horses, high plasma concentrations of epinephrine during exercise suggest that the adrenal medulla plays a more important role in the sympathoadrenal response than in other species.[25] Heart rate increases from the resting level of 30–40 beats per minute (bpm) up to 200–250 bpm.[26] In addition, cardiac contractility increases and systole is shortened. Together, these changes result in an up to 10-fold increase in cardiac output, which in horses during exercise may be over 300 L/min, a value that is 2–3 higher than in steers of the same size.[27] Catecholamines also cause contraction of the spleen and thus the release of 4–12 L of red blood cells into circulation.[4,28] Due to neural factors, hypoxia and hormones such as atrial natriuretic peptide, arginine vasopressin and hormones of the renin–angiotensin system, vasodilation occurs in muscles, thereby reducing total peripheral resistance.[29] Simultaneous vasoconstriction and reduction in blood flow to other tissues allows blood flow in skeletal muscle to increase by 70–76-fold,[26] while an 80% reduction in renal blood flow has been reported.[18,29–31]

The rate of respiration, which in galloping horses is coupled to stride frequency, also increases. Catecholamines are involved in the stimulation of respiration rate and also contribute to an increase in minute ventilation via relaxation of bronchioles.[32]

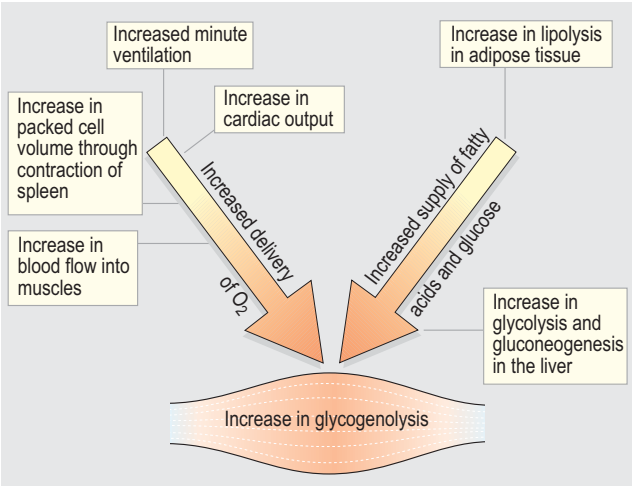

Fig. 34.2
Exercise-induced changes in various body systems. Delivery of oxygen to working muscles is increased due to the effects of catecholamines and other hormones on the lungs, heart, spleen and blood vessels. Simultaneously, catecholamines together with other catabolic hormones increase the supply of energy substrates via circulation and through increased breakdown of muscle glycogen.

Hormonal mechanisms are also important for the mobilization and utilization of energy substrates. The catecholamines together with insulin and cortisol increase the availability of fuels for energy transduction. In muscle, rapid degradation of glycogen is induced through activation of glycogen phosphorylase and inhibition of glycogen synthesis. Similar changes in the liver lead to release of glucose into circulation, which is further augmented through stimulation of gluconeogenesis. In adipose tissue, catecholamines activate hormone-sensitive lipase, which results in an increase in the plasma concentration of free fatty acids. The inhibitory effect of insulin on lipolysis is attenuated as epinephrine decreases the release of insulin from pancreas (Fig. 34.2).

Methods of assessing metabolic responses to exercise

Exercise testing

To allow day-to-day or horse-to-horse comparisons, conditions for exercise testing should be standardized, which usually means the use of a high-speed treadmill. Modern, high-speed treadmills are capable of speeds in excess of 17 m/s. However, for safety reasons exercise tests involving maximal effort are often performed at lower speed with the treadmill set at an incline of up to 6° (10% grade). The advantages of treadmill testing are obvious – the speed and duration of exercise bouts can be controlled and the ambient

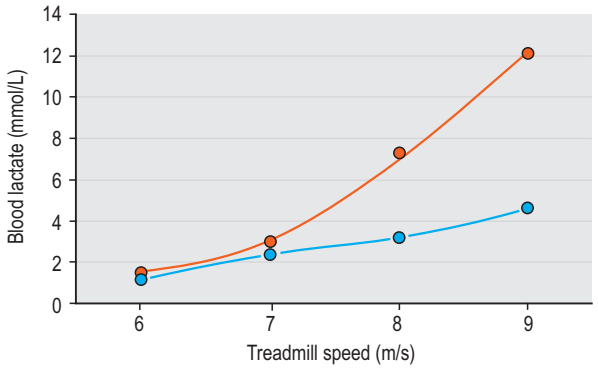

Fig. 34.4
Blood lactate response to submaximal treadmill exercise depends on the aerobic capacity of the horse. In untrained horses (orange circles) 2-minute steps at speeds indicated on the *x*-axis induce a rapid increase in blood lactate concentration, while the higher aerobic capacity of trained horses (blue circles) allows energy transduction without accumulation of lactic acid.

temperature can be kept constant. Furthermore, in countries where the ambient temperature and humidity are usually low, a climate-controlled treadmill laboratory facilitates exercise testing under conditions of high temperature and/or humidity.[33–35] Equally important is that while the horse is moving, blood samples can be taken through a catheter placed in a vein or an artery either with a syringe or constantly with the help of a peristaltic pump and a fraction collector.[36] Heart rate can be monitored with a pulse meter or by calculating it from an electrocardiogram and activity of different muscles can be recorded by electromyography.[37] Furthermore, the horse can be equipped with a mask that allows measurement of respiratory gases. Additional weight may be placed on the horse to simulate the weight of a rider or the horse can actually be mounted by an experienced rider.[38] The treadmill is also a suitable tool to study locomotion, because the horse is not moving forward and thus it is possible to film movements with a high-speed camera (Fig. 34.3).

Several types of treadmill tests have been developed since 1960s when Professor Sune Persson in Sweden designed a submaximal standardized exercise test,[4] modifications of which are nowadays frequently used all over the world. In the original test the horse runs four successive 2-minute intervals with the aim of reaching a heart rate of 200 bpm at the highest speed. Blood samples are taken at the end of each 2-min bout that is long enough to allow the heart rate to level off at each speed. This test and its modifications, which include differences in the incline and the duration of exercise intervals, are very useful, for example, for determination of lactate threshold and other indices of aerobic capacity. A typical result from such an exercise test for two horses, one well trained and the other less trained, is shown in Figure 34.4.

In tests to determine maximum heart rate and oxygen uptake ($\dot{V}O_{2max}$) the intervals are usually shorter, often 1 min, up to a speed when the horse is no longer able to keep up with the treadmill. Treadmill tests are also well suited for endurance-type exercise. The speed may be constant throughout the test or may include faster and slower phases. The duration of the test is either determined in advance or the test is continued until the onset of fatigue. The test may also be designed to simulate a specific type of event, such as the competition exercise test that simulates the endurance test of a three-day event.[39] It is also possible to load the horse with additional weights in a system that simulates draught work.[40] Because some indices of exercise capacity, such as V_{La4} (the running speed that elicits a blood lactate concentration of 4 mmol/l) or V_{200} (the running speed that elicits a heart rate of 200 bpm), may be influenced by apprehension, the horses should be acclimatized to the treadmill, a procedure that usually takes 1–2 exposures.[41]

The main drawback of treadmill exercise testing is the expensive equipment needed. Therefore horses are often tested on a track, where it is possible to simulate any type of competition but more difficult to control the speed and take blood samples when compared to treadmill testing procedures. Also the testing conditions may vary from one testing occasion to another, because ambient temperature, wind, track surface and other extraneous factors in the vicinity of the track may influence the results. Furthermore, the horse has to be stopped every time a blood sample is taken and therefore the speed cannot be increased as smoothly as on a treadmill. The stop, although short, may also influence the concentrations of metabolites in blood. Several studies show, however, that track tests are reproducible and reliable,[42–44] but comparison to treadmill tests is difficult.[45]

Samples and measurements to study the effects of exercise

Blood samples are often used to estimate the effects of exercise, as they are easier to collect and less invasive than muscle

samples. From a metabolic viewpoint, the most interesting samples would be those taken from veins coming directly from exercising muscles, especially if combined with arterial samples. These would allow for calculation of oxygen uptake, the consumption of various fuels and the efflux of catabolic products. However, for practical reasons samples are most often taken from the jugular vein, which represents mixed venous blood. For some metabolites, the concentrations in jugular venous blood are similar to those in arterial blood,[46] while others such as lactate differ.[47] It should, however, be kept in mind that concentration of any substance in blood is a sum of its release into and its disappearance from the blood and the analysis of blood samples gives information only about the very moment the sample is taken, but does not tell anything about the rates of events.

Metabolites, such as non-esterified fatty acids (NEFA), are usually analyzed from blood plasma or serum but for some analysis, especially glucose and lactate, whole blood can also be used. The analysis of lactate is complicated because equine RBC appear to function as a lactate sink and up to 50% of blood lactate may be in RBC.[13,48] Although there is a close correlation between whole-blood and plasma lactate concentrations,[13,49] this is not true on an individual basis because the uptake of lactate into RBC varies interindividually.[15,48] On the basis of lactate transport activity, Standardbred horses can be divided into two populations: one with high and the other with low lactate transport activity in their RBC.[15,50] Lactate transport capacity appears to be inherited with the high capacity being caused by the dominant allele.[50] Because of this interindividual variation in lactate distribution and differences in arterial and venous lactate concentrations,[47] it is extremely important to standardize the sampling and the treatment of samples when, for example, lactate threshold values are measured. To demonstrate the effects of RBC lactate transport activity on the interpretation of blood lactate data, the following example is given. Two horses had the same blood lactate concentration of 18.7–18.8 mmol/L after exercise. One of the horses with high lactate transport activity in its RBC had a plasma lactate concentration of 21.4 mmol/L, while the other with low lactate transport activity in RBC had a plasma lactate concentration of 29.6 mmol/L. Thus, if lactate threshold was calculated on the basis of blood lactate concentrations the two horses would have had the same value, but if the determination was based on plasma values a significant difference would have been recorded.[24]

As stated above, the blood samples are not suitable to measure rates or fluxes. To study these isotope techniques are available. When a small amount of a substrate labeled with a radioactive, e.g. ^{14}C, or a stable, non-radioactive, e.g. ^{13}C, isotope is infused into the circulation, the disappearance of the isotope can subsequently be analyzed from serial blood samples and the rate of substrate utilization can be calculated. Of these alternatives, the use of stable, non-radioactive isotopes is safer but the disadvantages are the high price of stable-isotope labeled substrates as well as the complexity of the analysis techniques, which also requires special apparatus.[51–53] Recent equine studies have employed stable isotope tracer techniques in exercise studies. Geor et al,[54–57] Jose-Cunilleras et al[58] and Pagan et al[59] used a constant-rate infusion of a stable isotopically labeled tracer of glucose in order to quantify rates of glucose production and utilization during sustained exertion. From concurrent calculations of whole-body rates of carbohydrate (CHO) oxidation and the rate of plasma glucose disappearance (glucose R_d), it was also possible to estimate the contribution by plasma glucose and intramuscular CHO (glycogen and lactate) to total CHO use. The latter calculations were based on the assumption that the glucose R_d was equal to actual plasma glucose oxidation rate. This assumption has been validated in human subjects during exercise[60] but not yet verified in horses.

Metabolic changes in muscle are determined by analysis of biopsy samples, which are usually taken from the middle gluteal muscle at the depth of 2, 4 or 6 cm.[61–65] If samples are taken before exercise and immediately after exercise, it is possible to estimate the consumption of glycogen and accumulation of lactate. Muscle samples are also useful to follow the recovery of energy stores and to evaluate training effects, because in addition to the changes in fuels and metabolites, it is also possible to determine the muscle fiber composition, capillarization and mitochondrial density and to measure activity of enzymes.

Muscle samples can be analyzed as a mixed sample containing all fiber types or on a single fiber or fiber-type basis. For practical reasons most biochemical analyses are performed on mixed muscle samples because of the substantially greater amount of work required for isolation of single fibers. A semiquantitative alternative is the use of histochemical analysis, e.g. for the analysis of glycogen in single fibers. The differences in the results between mixed muscle and single fiber analysis may be enormous. Concerning glycogen analysis, a 50–60% decline may be observed in homogenates of mixed muscle obtained after exercise, but examination of individual fibers from the same sample may reveal complete depletion of glycogen in some fibers and minimal change in others.[66–69] The same is true for ATP. The concentrations of ATP in some fibers are extremely low after maximal exercise, while in other fibers from the same sample the levels are close to resting values.[70,71]

Lactate threshold (V_{La4}) and the speed of the horse at a heart rate of 200 bpm (V_{200}) are useful indicators of aerobic capacity and frequently used in the evaluation of fitness and state of training. These indices are easy to measure, can be determined both on a track and a treadmill and do not require any expensive equipment. Metabolically, lactate threshold is said to represent the maximal work intensity at which ATP is produced aerobically, i.e. there exists a steady-state situation in blood lactate concentration, wherein lactate is released (mainly from muscles) into circulation at the same rate as it is used by other tissues. Based on studies in humans, it has been shown that blood lactate concentration starts to increase exponentially around a concentration of 4 mmol/L. Similarly, in horses lactate threshold is expressed as the speed of the treadmill or the speed of the horse on a track when blood lactate concentration is 4 mmol/L.

The speed at a heart rate of 200 bpm (V_{200}) has been suggested to indicate both the cardiovascular and metabolic capacities of a horse.[72] Aerobic capacity, measured as maximum oxygen uptake ($\dot{V}o_{2max}$), correlates with the running speed over 2000 m.[73] $\dot{V}o_{2max}$ is also useful, because thereafter it is possible to express workloads as a percentage of $\dot{V}o_{2max}$.[74] Rose et al[75] used different exercise protocols to determine $\dot{V}o_{2max}$ and found that the test itself did not markedly influence the results and the close correlation between maximum oxygen uptake and maximum heart rate allows estimation of the former on the basis of the latter variable.[76]

Anaerobic capacity is far more difficult to estimate and many of the tests used to evaluate anaerobic power of human athletes are not suitable for horses. So far, the only test that can be applied from human sports medicine is the measurement of maximal accumulated oxygen deficit (MAOD), which is calculated from the difference of calculated O_2 demand and maximum oxygen uptake.[77]

The expired gases, oxygen and carbon dioxide, can additionally be used to calculate the respiratory exchange ratio (R), i.e. the ratio of carbon dioxide produced over oxygen consumed. Using stoichiometric equations for the combustion of CHO and fat, values for R can be used to estimate the relative contribution of these substrates to energy expenditure during exercise. It should be noted, however, that these estimates are invalid at high work intensities wherein a portion of expired CO_2 is derived from the bicarbonate buffer system (the buffering of lactic acid) and values for R may be greater than 1.0.

Sources of metabolic fuel

Fuel for ATP synthesis in skeletal muscle is either stored in the muscle cells or taken up from the circulation. The utilization of fuels is limited by their availability, activity of oxidative enzymes and the availability of oxygen for their complete oxidation and/or the density of mitochondria in the muscle. Major fuels stored in the muscle fibers are glycogen, triglycerides and phosphocreatine and the fuels from circulation are fatty acids and glucose. Because water content of the muscle cells may change during exercise, the concentrations of muscle substrates are often expressed as mmoles (or μmoles) per kg dry muscle.

Equine skeletal muscle has a high capacity to store glycogen; in trained horses, typical values are around 600–650 mmol/kg dry muscle.[66,68,78–80] In human muscle, similar high values are reached only after successful carbohydrate loading procedures. The hydrolyzable carbohydrate content of typical feeds for athletic horses is already high and additional carbohydrate supplementation only slightly increases muscle glycogen content.[81–83] The content of triglycerides in equine skeletal muscle is highly variable.[83,84] The third form of fuel stored is phosphocreatine (PCr), a high-energy phosphate. Although the content of PCr is enough to support ATP production for a few seconds only, it is important both in the beginning and at the end of maximal effort.

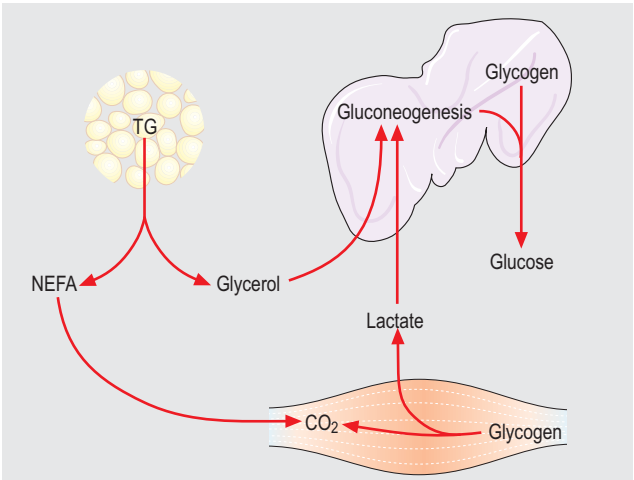

Fig. 34.5 During exercise, energy stores in muscle, liver and adipose tissue are mobilized by the action of catecholamines and other hormones. Fatty acids (NEFA) are released from triglycerides (TG) in adipose tissue and transported by circulation to the working muscles. Muscle glycogen is the body's main store of carbohydrates, but additional glucose from liver glycogen and gluconeogenesis is provided via circulation.

The main energy stores outside the muscle tissue are adipose tissue for lipids and liver for glucose, the latter derived from hepatic glycogenolysis and gluconeogenesis. During exercise, an increase in epinephrine concentration contributes to the mobilization of these energy stores. Glucose is released from liver, through the action of glucose–6-phosphatase, and lipids from adipose tissue enter circulation as non-esterified fatty acids (NEFA). Additional glucose may be produced in the liver from glycerol that is a byproduct of lipolysis as well as lactate and alanine formed in the muscle (Fig. 34.5).

The release of nutrients from the gastrointestinal tract depends on pre-exercise feeding regimens (see below). In general, equine diets are rich in carbohydrates (e.g. hemicellulose) that are not degraded by salivary and pancreatic amylase, but rather are subjected to bacterial fermentation in the cecum and colon. Short-chain (or volatile) fatty acids, mainly acetate, propionate and butyrate, are produced via this process. It has been shown that, at rest, acetate may provide approximately 30% of the energy utilized by the hindlimb,[85] while propionate is used mainly for gluconeogenesis.[86,87] The direct contribution of these substrates to energy use during exercise is not known.

Major metabolic pathways for energy transduction

ATP for muscle contraction may be produced by aerobic and anaerobic pathways. It has to be kept in mind that ATP is not a storage form of energy. Rather, it is the 'metabolic currency'

for cellular processes such as muscle contraction and because cellular stores are small, the rate of ATP synthesis must keep pace with utilization.

Equine skeletal muscle has a high oxidative capacity and, in trained horses, all type I and type IIA fibers are rich in mitochondria and the activities of oxidative enzymes such as citrate synthase (CS) and 3-hydroxyacyl-CoA dehydrogenase (HAD) are high.[88–91] Both carbohydrates and fatty acids can be used as substrates for aerobic energy transduction, the proportion of which varies with the intensity of exercise. During a 400 m Quarter Horse race, about 40% of energy is derived from aerobic metabolism, while aerobic metabolism accounts for 70–80% of the energy used by Thoroughbreds and Standardbreds in races of 1600–2100 m.[92] During endurance events, nearly all energy metabolism is aerobic.[92]

At rest, when the plasma concentration of fatty acids is low, blood glucose may account for about 80% of oxygen consumed by the hindlimb.[85] The capacity of aerobic metabolism is limited by oxygen delivery or the capacity of muscle fibers to use oxygen. The main anaerobic pathway of energy metabolism is glycolysis for which glucose is either derived from blood or from the glycogen stored in muscle. Although the yield of ATP per one mole of glucose degraded is only 2–3 moles, muscle has a high glycolytic capacity. On the basis of glycolytic enzyme activities measured in equine[79,90,93] and human[23] skeletal muscle, the capacity for anaerobic energy transduction is well in excess of the maximal rate of energy consumption. The disadvantage of this mechanism is the excessive production of lactic acid which eventually will lead to fatigue (Fig. 34.6).

Mechanisms of fatigue

Both high- and low-intensity exercise eventually result in fatigue, but the mechanisms are completely different: the accumulation of lactic acid and other metabolic byproducts during intense exercise versus substrate depletion (fuel shortage) during longer duration exercise at low or moderate intensity. After high-intensity exercise, lactic acid concentrations in muscle range from 100 to 200 mmol/kg dry muscle.[10–12,19,22,94] The accompanying increase in proton concentration results in a marked decrease in muscle pH, with values as low as 6.5–6.3 measured in horses following intense, fatiguing exercise.[19,95] The decrease in pH may be the single most important factor in the development of fatigue during intense exercise. Low pH disturbs calcium release and especially calcium uptake by the sarcoplasmic reticulum, and thus the relaxation phase of muscle contraction cycle is slowed. ATP synthesis is also compromised because the key regulatory enzyme of glycolysis, phosphofructokinase, is inhibited by protons. Furthermore, acidification changes the structure of myosin heads such that the efficiency of ATP binding decreases.[96]

The means to prevent intramuscular acidosis include buffers, the most important of which are proteins, the bicarbonate system, phosphate and carnosine.[96,97] Although buffering capacity of equine muscle is higher than in other species, it is still not enough to prevent acidosis.[9,98] The second mechanism for regulation of cell pH is the transport of protons out of the cell.[99,100] Only the acid form, lactic acid, is able to diffuse through cell membranes; both protons and lactate anions require a transporter for transmembrane movement. In skeletal muscle, there are two carriers that may facilitate the efflux of protons: the Na^+/H^+ exchange protein and monocarboxylate transporters.[99,100] During Na^+/H^+ exchange, one Na^+ is transported into the cell and simultaneously one H^+ is carried out from the cell. There are no studies on the activity of Na^+/H^+ exchange in equine muscle, but in human muscle this carrier plays a minor role and monocarboxylate transporters (MCT), which simultaneously transport one proton together with one lactate anion, are responsible for most proton efflux.[99,100] Several isoforms

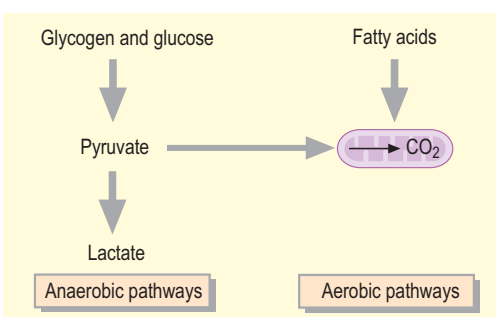

Fig. 34.6 The capacity (indicated by the breadth of the arrows) of glycolytic enzymes to produce energy by anaerobic metabolism is high in comparison to aerobic pathways from glucose and fatty acids. The latter are limited by transport of substrates across cell membranes, the number of mitochondria, the activity of mitochondrial enzymes and the availability of oxygen.

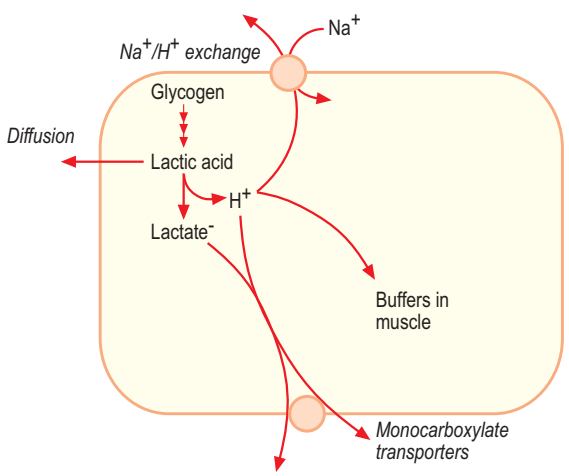

Fig. 34.7
Lactic acid formed via anaerobic glycolysis is almost completely dissociated into a lactate anion and a proton. The means to prevent acidification of the cell include different buffer systems and transport of hydrogen ions out from the muscle cell. Most hydrogen ions are transported by the monocarboxylate transporter (MCT) with Na^+/H^+ exchange playing a minor role.

of MCTs have been characterized, but only two or three are expressed in skeletal muscle. The main isoforms in muscle are MCT1 and MCT4 and, in some species, MCT2 is also expressed.[101–103] MCT1 and MCT4 have also been found in equine skeletal muscle (Koho N, Hyyppä S, Pösö AR, unpublished observation). In human athletes, MCT1, which is the main lactate carrier in oxidative muscles, is upregulated by exercise. On the other hand, the content of MCT4, which is the dominant isoform in glycolytic fibers, increases only with high-intensity training.[105,106] In human subjects, the endurance training-associated decrease in muscle lactate accumulation during exercise is associated with an increase in skeletal muscle MCT content,[107] demonstrating the importance of MCTs for the regulation of intramuscular pH (Fig. 34.7).

During high-intensity exercise acidification may be the main reason for fatigue, but a reduction in energy stores may be another contributing factor. After maximal exercise (e.g. trotting races), some muscle fibers appear to be completely devoid of glycogen and studies of single fibers demonstrate marked ATP depletion.[66,68,70,71] In rats, there is a linear relationship between ATP degradation in skeletal muscle and the development of fatigue during high-intensity exercise[108] and depletion of ATP during maximal tests suggests that a similar relationship may also exist in horses.[11,109]

During endurance exercise, the intensity is usually low to moderate and there is no marked accumulation of lactic acid.[67,79,110,111] Therefore, acidification is not a major cause of fatigue. From a metabolic viewpoint, the major contributing factor to the development of fatigue is a shortage of fuel, especially depletion of glycogen stores,[79,83] as demonstrated by a correlation between the extent of glycogen depletion and the duration of exercise.[112] Low blood glucose concentration also may contribute as it limits the glucose availability to the central nervous system. In addition, central fatigue may be due to increased formation of serotonin in the central nervous system.[113]

During endurance exercise, factors not related to substrate supply may be more important in the development of fatigue. These include the loss of electrolytes in sweat which may disturb the neuronal control of muscle contractions, loss of water in sweat that may hamper oxygen and substrate supply via the circulation, and hyperthermia.

Responses and mechanisms

Responses in metabolite concentrations in plasma

During exercise, the major hormonal change in blood is an increase in the concentrations of norepinephrine and epinephrine that, in addition to their effects on the cardiovascular and respiratory systems, induce metabolic changes in muscle, liver and adipose tissue. The increase in catecholamine concentrations occurs at the onset of exercise and is proportional to exercise intensity. In horses during maximal effort, the responses are several fold greater than in humans.[25,114,115] Other hormonal changes with metabolic implications include a decrease in insulin and increases in cortisol and glucagon.[54,111,116–118]

Due to the above-mentioned hormonal changes, concentrations of metabolic fuels such as NEFA and glucose are increased in circulation. NEFA is released from the adipose tissue together with glycerol. It has been suggested that of these two, glycerol is a more reliable indicator of lipolysis.[119,120] The background to this suggestion lies in the fact that muscle tissue, which accounts for about 40% of the bodyweight, is the main user of NEFA and thus even small changes in the oxidation of fatty acids in the muscle will greatly influence the concentration of NEFA in plasma. On the other hand, the concentration of glycerol is not influenced by changes in muscle metabolism as it is mainly utilized by the liver. This is demonstrated by studies in which NEFA and glycerol concentrations have been measured in tests where the intensity of exercise varies. The results show that NEFA concentration decreases significantly during intense exercise, while glycerol concentration increases steadily.[80,120,121] Especially during low-to-moderate intensity exercise, there is a progressive increase in lipid oxidation with increasing exercise duration.[82,122] Horses differ from other athletic animals in that there is an increase in the circulating triglycerides (TG) during exercise.[121] TG are released from the liver as very low density lipoproteins (VLDL),[121] and may have been synthesized in response to increased delivery of NEFA to the liver. Lipoprotein lipase located on the outer side of the endothelial membranes in muscle capillaries will release fatty acids from circulating VLDL-TG for oxidation in muscles.

Changes in blood glucose concentration depend on the type of exercise. Plasma glucose concentration tends to decrease during prolonged exercise (> 3 hours), but during short, intense exercise both decreases and increases have been recorded,[67,118,120,123,124] depending on exercise intensity and training and feeding status of the horse. The regulation of blood glucose during exercise is complex, but changes in prevailing hormone concentrations are important. The exercise-associated increase in hepatic glucose output is mainly mediated via a decrease in the insulin:glucagon ratio, whereas the rate of uptake and utilization in exercising muscle is restrained by increases in circulating epinephrine.[56]

As discussed earlier, lactate is the end-product of anaerobic metabolism and lactate concentrations in blood increase during high-intensity exercise. Lactate concentrations after different types of competitions and exercise tests are shown in Table 34.1. Usually, the highest lactate concentrations are seen 2–10 minutes after exercise. In equine blood, a significant amount of lactate may be in RBC; uptake is rapid and depends on the activity of MCT on the RBC membrane.[48]

As a result of ATP degradation during high-intensity exercise, breakdown products of purine nucleotides such as ammonia, hypoxanthine, uric acid and allantoin appear in blood.[14,22,109,127,134] In horses, the predominant end-products of purine catabolism are uric acid and allantoin. The time to peak concentration varies individually and peak

Table 34.1 Maximal lactate concentrations after exercise (values are means ± standard error of the mean)

	Distance/time	Blood lactate (mmol/L)	Plasma lactate (mmol/L)	References
Endurance races	80–100 km	1.6 ± 0.1	0.50 ± 0.2	111,116,126
Standardbred races (trotting)	2100 m	21.6 ± 0.9	24.5 ± 0.7	13,91
Standardbred races (pacing)	1760–2160 m		20.9 ± 4.1	130
Thoroughbred races	1100–3800 m	29.6 ± 4.7	33 ± 1.9	47,126–129
Three-day event, cross-country	6200 m		19.1 ± 4.2	126,131
Showjumping			9.0 ± 0.9	132
Polo			9.2 ± 1.2	125
Donkey after exercise			10 ± 1.4	133

concentrations are reached as late as 30 min after exercise.[134,135] Marked accumulation of uric acid, allantoin and ammonia is seen mainly after intense exercise and the breakdown of adenine nucleotides is probably triggered by accumulation of ADP and the decrease in muscle pH.[127,135,136] In horses, the threshold value for accumulation of these breakdown products is a muscle pH of 6.8, which represents a lactate concentration of 80 mmol/kg dry weight in muscle and about 12 mmol/L in blood.[22,134] It has been suggested that the peak concentration of uric acid or ammonia is useful as an indicator of ATP degradation in muscles.[135]

Changes in muscle

In muscle, the most prominent changes are a decrease in glycogen content, accumulation of lactic acid and degradation of ATP and phosphocreatine (PCr). Glycogen, which is stored as macro- and proglycogen molecules, is the target for glycogen phosphorylase that is activated by muscle contraction and epinephrine. From the molecular weight it can be calculated that macroglycogen has about 2100 non-reducing ends from which the release of glucose may begin simultaneously.[137] Proglycogen, on the other hand, has a much smaller molecular weight and the number of non-reducing ends in this type of glycogen is only 64–128 per molecule.[137] In humans, proglycogen appears to be more readily available for degradation and in the early phases of exercise, especially when exercise intensity is low to moderate, glycogen breakdown occurs from proglycogen molecules only.[138,139] In horses during an endurance race, macroglycogen is utilized to a greater extent than proglycogen.[140] Breakdown of macroglycogen is activated only at high-intensity exercise in humans,[138] but in horses during intense exercise both pro- and macroglycogen seem to contribute equally to glycogenolysis.[141] Although the physiological roles and regulation of macro- and proglycogen metabolism are far from clear, subcellular location and the density of branches in the outer tiers of the molecules may be involved.[139]

As mentioned, during fatiguing high-intensity exercise muscle glycogen concentration decreases by up to 50%. Although fatigue during such exercise is often ascribed to accumulation of lactic acid and depletion of PCr and ATP,[69,109] depletion of glycogen in individual fibers may also contribute.[66,69] After endurance rides a more complete depletion of glycogen is seen and, in some horses, muscle biopsy samples may be completely devoid of glycogen.[67,110]

Marked accumulation of lactate in muscle is seen only when the intensity of exercise exceeds the anaerobic threshold. After a near-maximal exercise test, lactate accumulation in muscle correlates with the amount of glycogen utilized.[142] Accumulation depends also on the oxidative capacity of muscle,[94,142] and thus horses that have a high proportion of type IIB fibers with low oxidative capacity have higher lactate concentrations in their muscles after high-intensity exercise.[94] In addition, muscle hemodynamics[100,143] and the activity of monocarboxylate transporters[107] (i.e. the rate of lactate efflux) will influence the extent of lactate accumulation in muscle. Muscle lactate concentrations up to 200 mmol/kg dry weight have been measured in equine muscle.[12,22]

The changes in muscle TG content with exercise are more difficult to estimate because interindividual variation, both in TG content and utilization rate, is high.[83,84,142] In middle gluteal muscle, TGs are stored mainly in type I fibers and type IIB fibers have the lowest content.[79] A decrease in muscle TG content is more evident in association with endurance-type exercise,[79,82,122] but a decrease also may occur after short, near-maximal exercise.[142]

Phosphocreatine (PCr), a high-energy phosphate stored in muscle, is depleted during high-intensity exercise.[21,109,135,144] The synthesis of PCr after exercise is very rapid and thus results are greatly influenced by the time of sampling in relation to end of exercise. ATP concentration starts to decline and ADP begins to accumulate when ATP consumption exceeds the capacity of ADP rephosphorylation. The myokinase reaction (ADP + ADP → ATP + AMP) is activated to keep the concentration of ADP low. To drive this reaction towards formation of ATP, AMP is further deaminated to inosine monophosphate (IMP). The accumulation of IMP closely mirrors the loss of ATP.[127] This reaction cascade eventually leads to loss of adenine nucleotides and fatigue will follow.

Partitioning of energy supply at different workloads

The relative contribution of different substrates (i.e. carbohydrate, fat, protein) to fuel metabolism during exercise is determined by a number of factors, including the intensity and duration of exercise, muscle composition (i.e. fiber types), training status, diet and the type of food consumed before exercise (the effects of habitual diet and pre-exercise feeding on metabolic response are further discussed below). At rest when energy transduction is fully aerobic, muscle may use volatile fatty acids, lipids and carbohydrates. Equine diets are usually low in lipids and plasma NEFA concentration is also low at rest. Thus, during periods of inactivity the utilization of lipids for energy may be limited by their low concentration. The main energy sources are acetate, which is formed by bacterial fermentation in the colon and cecum, and glucose.[85]

Contemporary metabolic studies in horses have utilized stable isotope tracer methodology in combination with indirect calorimetry (O_2 uptake measurements and respiratory exchange ratio) for calculation of substrate oxidation rates during exercise at different intensities.[54–56,59,59] Figure 34.8 depicts the estimated relative contributions of lipid, plasma glucose and muscle glycogen to energy expenditure in horses during exercise at 30% and 60% of $\dot{V}O_{2max}$. During the early phases of moderate-intensity exercise (35–55% $\dot{V}O_{2max}$), use of carbohydrate (plasma glucose, muscle glycogen) predominates[145] but if exercise is continued for longer periods there is increased utilization of fats as indicated by a progressive decrease in the respiratory exchange ratio.[54,82,122] However, the utilization of plasma glucose and muscle glycogen continues, and is reflected by lowered blood glucose concentrations and depletion of muscle glycogen after endurance exercise.[67,79,110,111]

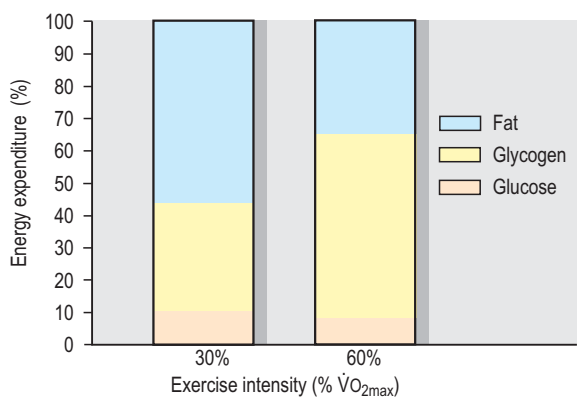

Fig. 34.8
The estimated relative contributions of lipid, plasma glucose and muscle glycogen to energy expenditure in horses during exercise at approximately 30% and 60% of maximum aerobic capacity ($\dot{V}O_{2max}$). When compared to exercise at 30% $\dot{V}O_{2max}$, there is increased reliance on muscle glycogen (and a decreased energy contribution from fat) for energy transduction during exercise at 60% $\dot{V}O_{2max}$. (Adapted from Geor et al.[56])

The main energy source at maximal performance is muscle glycogen. This is directly demonstrated in studies which show diminished anaerobic power in horses that perform high-intensity exercise after glycogen depletion.[146] Lipids are also used during intense exercise as demonstrated by decreases in NEFA concentrations during intense exercise bouts.[80,120,121]

Effects of ambient temperature

Exercise causes a decrease in plasma volume[28] and if exercise is undertaken in high temperature and humidity, high rates of sweat fluid loss will exacerbate the reduction in plasma volume.[35] In extreme conditions, sweating rate may be 10–15 L/h[147] and during the cross-country phase of a three-day event a horse may lose 2–4% of bodyweight, while a 10% loss of bodyweight may be incurred during endurance rides.[147,148] If the horse is unacclimatized, exercise in hot, humid conditions will decrease maximum oxygen uptake and increase lactate production, i.e. the primary change being a decrease in aerobic capacity with increased reliance on anaerobic metabolism.[149]

The opposite, exercise in cold, dry conditions (–25°C), does not change indices of aerobic capacity. However, respiratory rate is lower during exercise in cold when compared to thermoneutral ambient conditions.[150] Resting metabolic rate may increase by 70% from the values at thermoneutrality in cold-stressed horses.[151]

Effects of warm-up

The purpose of a warm-up is to adjust the body to transition from rest to exercise and thereby gain the dual benefits of enhanced performance and reduced risk of injury by a gradual increase in exercise intensity. An active warm-up increases body and muscle temperature by about 1°C as a result of the heat generated during muscular activity. Warm-up improves tissue oxygenation, because epinephrine and norepinephrine released during warm-up increase respiratory rate, tidal volume and heart rate, cause the spleen to contract and release stored RBC into the circulation, and increase blood flow to skeletal muscles. Catecholamines also activate glycogenolysis and lipolysis and thus increase the supply of energy fuels to the muscle, while elevated temperature decreases the activation energy of metabolic reactions. A higher temperature also increases elasticity of muscles, tendons and ligaments, which may reduce the risk of injury and allow for full range of motion in the joints.

Two equine studies have demonstrated that a brief period (5–10 min) of warm-up exercise, completed 5 min before the start of treadmill exercise at 115–120% of $\dot{V}O_{2max}$, results in a significant acceleration in $\dot{V}O_2$ kinetics, i.e. the rate of rise in $\dot{V}O_2$ after exercise onset.[152,153] This change in oxygen uptake kinetics enhances the ability of muscle to work aerobically and reduces lactate accumulation during high-intensity exercise.[152–154] In one study, both a low- and a high-intensity

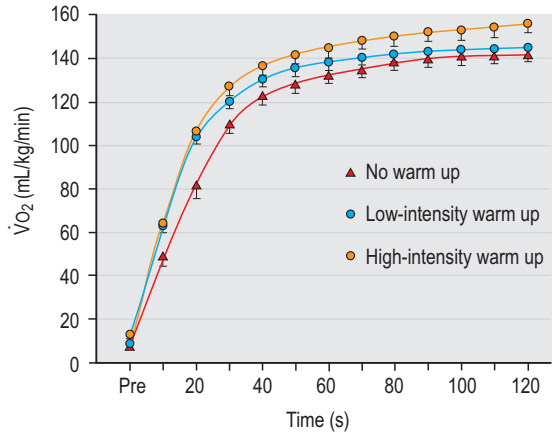

Fig. 34.9
Effects of a low- and high-intensity warm-up on oxygen consumption ($\dot{V}O_2$) in six horses during 2 minutes of intense exercise (~ 115% of maximum aerobic capacity). Note the acceleration in the rate of rise in $\dot{V}O_2$ when exercise was preceded by a warm-up. (Adapted from Geor et al.[153])

warm-up resulted in a significant increase in the run time to fatigue during intense treadmill exercise when compared to exercise undertaken without prior warm-up[154] (Fig. 34.9)

The ideal duration and intensity of warm-up exercise is not known and likely depends on the nature of the subsequent exercise task and the prevailing ambient conditions. On the one hand, if the warm-up period is too brief to allow time for the rise in body temperature the desired effect is not gained, whereas if exercise intensity during warm-up is too high significant lactate accumulation will be present at the onset of performance exercise. The studies by Tyler et al[152] and Geor et al[153] demonstrated that even a low-intensity warm-up (5 min of trotting exercise) is beneficial in terms of an enhancement in aerobic energy metabolism during subsequent galloping exercise. The benefits of warm-up are likely diminished if the rest period between warm-up and performance is extended so that the horse cools down.

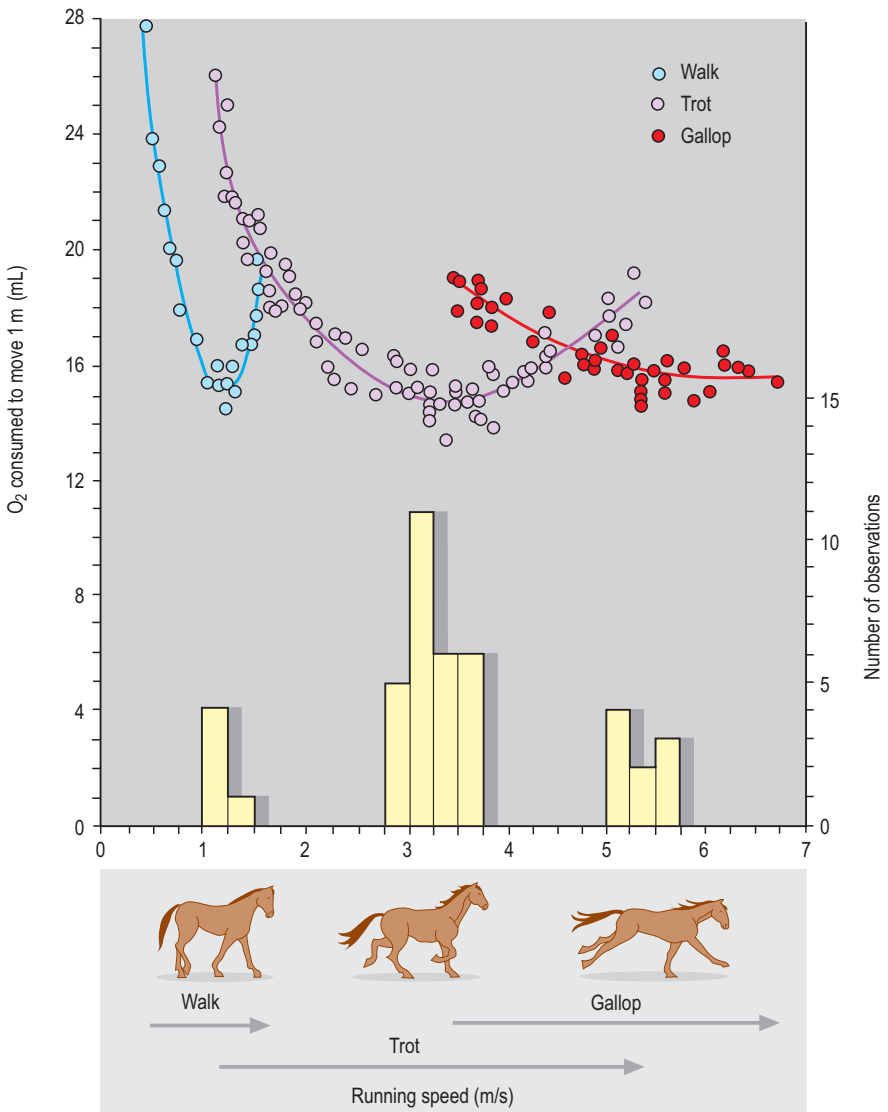

Fig. 34.10 The relationship between net energy cost, expressed as mL O_2 consumed to move 1 m, and speed at the walk, trot and gallop in small horses. Notice that the minimum energy cost is similar for all gaits. If allowed to do so, the horse changes gait at the speed where energy cost of the two adjacent gaits is the same. (Figure originally published by Hoyt & Taylor[155] and reprinted with the permission of Nature Publishing Group.)

Economy of locomotion

Stride length and stride frequency are the main determinants of running speed. Net energy cost, which is expressed as mL O_2 consumed over distance covered, varies minimally over a great variety of speeds because as speed increases horses change gait (walk, trot, canter, gallop) to an energetically more efficient one. Within a given gait, energy cost changes with increasing speed along a U-shaped curve which overlaps with the respective curve for the adjacent gait.[155,156] The change in gait occurs at the crossover point where net energy cost is the same for the two gaits, e.g. walk and trot or trot and gallop. This relationship has been described in detail by Hoyt & Taylor (see Fig. 34.12).[155] When allowed to choose gaits, the horse has a tendency to voluntarily utilize a relatively narrow set of speeds around the nadir of the energy cost curve. Possible explanations for this behavior include minimizing musculoskeletal stresses and maximizing metabolic economy.[157] Locomotion pattern also depends on other factors, the most important of these being muscle composition.[158,159] These factors may have performance implications, especially in Standardbred events (trotting or pacing) where the horse is forced to maintain a certain gait for an extended period of time and at speeds that are not energetically optimal for the gait in question (Fig. 34.10).

Differences between breeds

Thoroughbreds have higher maximum oxygen uptake than other breeds (Table 34.2) and thus their aerobic capacity is also higher than in other breeds. Another basis for differences in metabolic responses is muscle fiber composition. In faster breeds, such as Thoroughbreds, the percentage of type I fibers in locomotor muscles is lower than in Standardbreds, which again have lower percentages of type I fibers than horses used for endurance events, such as Arabs.[160] The breeds with a high percentage of type I fibers are more suited for aerobic, long-lasting work while horses with a high percentage of type II fibers are best suited for exercise in which high-intensity bursts are needed. Within a single breed, the variation in the slow-twitch:fast-twitch (type I:type II) ratio is less marked than between breeds, and training-induced differences are mainly seen in the type IIA:type IIB ratio. Exact comparisons are, however, difficult because horses from different breeds are used for different purposes and they hardly ever perform comparable exercises. This is evident when maximal lactate concentrations after different events are compared (see Table 34.1). For faster breeds, it is possible to compare the metabolic effects of races (e.g. Thoroughbred or Standardbred racing) that may be considered as maximal effort, although differences in gait complicate these comparisons.

Table 34.2 Maximum oxygen uptake ($\dot{V}O_{2max}$) in different breeds (values are means ± standard error of the mean)

Metabolism during recovery from exercise

Lactate removal

After cessation of exercise, the rate of oxygen consumption remains elevated[167] and blood lactate concentration continues to increase, with peak concentrations attained 2–10 min post exercise. Lactate is an excellent energy source because it contains more than 90% of the energy in glucose. During exercise the main tissues that use lactate are the liver, which converts lactate back to glucose, and the heart in which lactate is used directly for energy. There also may be some utilization of lactate by type I muscle fibers. However, during recovery the major consumer of lactate is, due to its large mass, skeletal muscle with oxidation of lactate by all fiber types.[168]

The rate of lactate removal from blood depends on the metabolic state. At rest the need for energy is low, but even light exercise increases the oxygen consumption of muscles and thereby the oxidation of lactic acid.[168–170] Following high-speed treadmill exercise, the half-life of lactate is decreased by 50% in horses that exercise lightly in comparison to those that remain stationary.[169] The rate of lactate disappearance is independent of concentration which implies that the rate-limiting step in the process is saturable[169] (Fig. 34.11).

Glycogen synthesis

Recovery from exercise is metabolically characterized by resynthesis of energy stores depleted during exercise, especially that of glycogen. In horses, recovery of glycogen is typically slow; during the first 24 hours practically no repletion occurs and full recovery after exhausting exercise may take up to 3 days.[78,80,110,112] In horses, glycogen resynthesis appears to start in type IIB fibers,[112] and among the two glycogen forms, synthesis of proglycogen is favored during the early phase of recovery in both humans and horses.[141,171] In human athletes, consumption of a high carbohydrate diet enhances the rate of glycogen resynthesis, but similar abrupt changes in feed, especially the addition of soluble carbohydrates, are not practical in the horse because they may cause gastrointestinal dysfunction or even laminitis. The only means that has so far been found to enhance the rate of muscle glycogen synthesis is the intravenous administration of large doses of glucose (6 g/kg over 12 hours).[146,172]

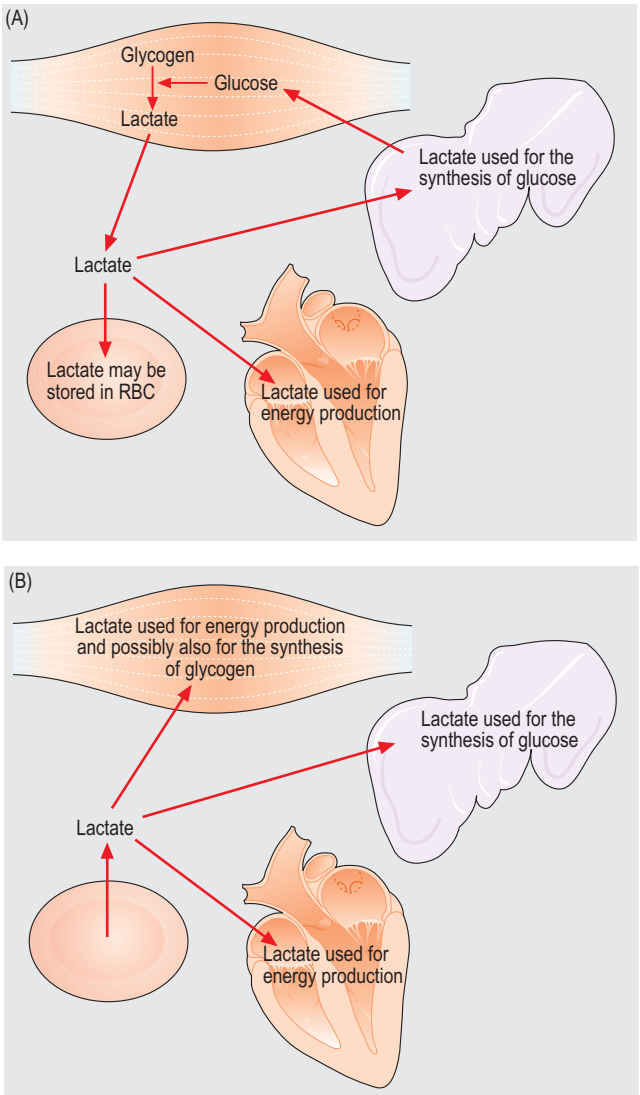

Fig. 34.11
During exercise (A) lactate is formed in the working muscles and the flow of lactate is from muscle cells into blood plasma and further into tissues such as heart and liver that may use lactate for energy or glucose production. In horses, a substantial proportion of lactate produced in muscle may also be taken up by red blood cells (RBC). During recovery (B) the direction of lactate flow is reversed, i.e. from RBC to plasma, and the main user of lactic acid is skeletal muscle. Light exercise during the recovery period that increases muscle energy requirements will also increase the rate of lactate disappearance.

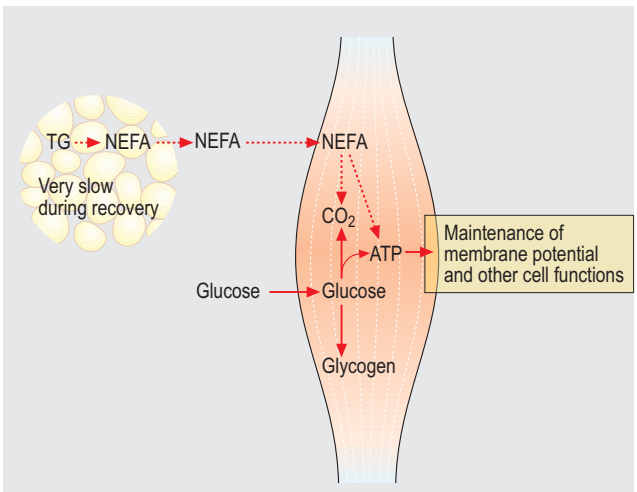

Fig. 34.12
During recovery the rate of lipolysis decreases, leading to low concentrations of fatty acids (NEFA) in plasma. Therefore, the predominant substrate for muscle metabolism is blood glucose. The use of glucose in the maintenance of cell functions will affect the availability of glucose for the resynthesis of glycogen.

The reasons for the slow rate of glycogen synthesis in the horse are not known, but in general the hormonal status immediately after exercise does not favor anabolic processes, such as the resynthesis of glycogen. During exercise, the concentration of insulin is reduced.[117,118] As insulin contributes to the activation of glycogen synthase as well as the transport of glucose into muscle by the insulin-activated glucose transporter (GLUT-4), low insulin status during the postexercise period does not favor glycogen resynthesis. Another possible factor may be a shortage of fuel during recovery. Skeletal muscle has to maintain its normal functions and only the available substrate (glucose) in excess of these demands is available for the resynthesis of glycogen. After exercise, catecholamine concentrations decrease within minutes and consequently lipolysis is inhibited and the plasma concentration of NEFA decreases to a very low level.[80] Therefore, the predominant substrate available for muscle will be glucose (Fig. 34.12).

Metabolic responses to training

Exercise training affects aerobic and anaerobic capacity and thus training effects are seen at both submaximal and maximal exercise intensities. Changes in aerobic capacity reflect increases in maximum oxygen consumption,[74,162,166,173,174] blood volume and red cell volume in young horses,[4] capillarization of all fiber types,[175] and increases in the mitochondrial density and activities of oxidative enzymes such as CS and HAD.[88,160,176–181] Such increases in aerobic capacity mean that the trained horse is able to run faster before the lactate threshold is reached and accumulation of lactate begins when compared to an untrained animal.[142]

The primary change in muscle fiber composition is from IIB/IIX → IIA and further training also may result in an increase in type I fibers.[177,180,182–184] Histochemical analysis show an increase in type IIA fibers, but recent use of myosin-

specific antibodies has revealed that after training muscles contain a high proportion of IIXA fibers.[185] The best Standardbred trotters have the highest type IIA:IIB fiber ratios and also the cross-sectional area of type II fibers tends to be smaller when compared to less well-performing horses.[175] In contrast, successful endurance horses have a high percentage of type I fibers with a large cross-sectional area.[186] Very intense training has been reported to increase the cross-sectional area of type II fibers.[187] The most important changes that describe training effects in skeletal muscle are increases in type I fiber area and capillarization, particularly the number of capillaries in contact with type I and type IIA fibers, and an increase in the oxidative capacity of type IIB fibers.[188,189] Some studies have also demonstrated an increase in muscle glycogen and triglyceride content after endurance training.[184]

Because of increased oxidative capacity, less glycogen is used and respiratory exchange ratio decreases during both high-[190] and moderate-intensity[57] exercise. Also due to high aerobic capacity, lactate accumulation in plasma at a given submaximal work level is lower.[91,] Studies in humans also demonstrate that the exercise-induced increase in muscle lactate concentration is mitigated by training[107] due to increased lactate efflux out of the muscle and a training-associated increase in plasma volume.

The changes in anaerobic capacity are more difficult to measure, but an increase in maximal accumulated oxygen deficit (MAOD) and lower accumulation of lactate in skeletal muscle were found in trained horses after a maximal sprint to fatigue, providing indication of an increase in anaerobic capacity with training.[162] These changes were accompanied by a significant increase in run time to fatigue during sprinting. The effects of training on blood lactate concentrations after maximal effort are controversial. Some studies show no differences[162] while others show significantly higher lactate concentrations after training.[91,120] As previously mentioned, studies in human athletes have demonstrated that training increases the quantity of MCTs on muscle membranes.[105,106] This increase in muscle MCT could contribute to higher blood lactate concentrations after training. Another factor that could modify blood lactate concentrations after training is an increase in muscle buffering capacity. Studies in horses have reported both an increase and no change in muscle buffering capacity with training.[162,176,191]

Training intensity and duration

Significant training effects are apparent even when the intensity of training exercise is low or moderate, but these changes mainly reflect an increase in aerobic capacity and reactions related to aerobic metabolism. Decreases in the rate of glycogenolysis, increases in oxidative enzymes and increases in oxygen extraction by tissues are evident after as little as 2 weeks of training,[173,174] sometimes even before any measurable changes in indices of muscle oxidative capacity can be detected.[190] In general, most of the training-induced increase in aerobic capacity occurs during the initial 6-week period of training.[165] However, further increments in $\dot{V}O_{2max}$ occur if a training stimulus is maintained.[165] The study by Hinchcliff et al,[162] however, clearly shows that high-intensity training is necessary for improvements in anaerobic capacity. It is possible that intense exercise is also necessary for maximum improvements in aerobic capacity because adaptive changes in aerobic processes appear to require hypoxia as an inducer of gene activity, e.g. the induction of erythropoiesis, capillary growth and the synthesis of glycolytic enzymes appear to be regulated by hypoxia.[192]

Detraining

Most of the changes in metabolism require synthesis of new proteins and thus require days or weeks to develop; these adaptations also persist for several weeks after the cessation of regular physical activity (detraining).[193,194] In general, adaptive training responses in skeletal muscle persist for 5–6 weeks after the cessation of regular physical activity.[180,184] Similarly, there is minimal change in maximum oxygen uptake after 2–4 months of detraining.[165,194] However, in the study by Butler et al,[194] lactate accumulation during intense exercise was higher after a 15-week period of detraining, indicating a decrease in aerobic capacity. The fiber type changes during detraining occur in reverse order to the changes during training.[180,184]

Effects of diet on metabolic responses

The chemical energy (i.e. ATP) required for muscle contraction is ultimately provided in the diet. Therefore, inasmuch as diet can influence the storage of glycogen and TG in muscle, there is an obvious relationship between dietary intake and skeletal muscle exercise metabolism. Indeed, studies in human athletes have unequivocally demonstrated that a high-CHO, low-fat diet will result in higher muscle glycogen concentration when compared to a more conventional, lower CHO diet.[195] Furthermore, there is a direct relationship between initial muscle glycogen stores and performance during moderate intensity (50–80% of $\dot{V}O_{2max}$) endurance exercise in humans.[196] Thus, for human athletes, dietary strategies that boost muscle glycogen stores enhance exercise performance. Conversely, a low-CHO, high-fat diet impairs endurance exercise performance, in part due to lower initial muscle glycogen concentrations.

Although there has been extensive study of the metabolic responses to exercise in horses, relatively few studies have examined the effects of diet composition on substrate metabolism and exercise performance. Traditionally, the high energy requirements of athletic horses have been met by diets high in hydrolyzable CHO (i.e. grains). In the past decade, however, there has been increased emphasis on use of alternative energy sources, such as fat and beet pulp, in equine rations and some data are available regarding the effects of such diets on the metabolic response to exercise.

High carbohydrate diets

As mentioned, only a modest increase in the glycogen content of muscle has been observed in horses fed diets rich in hydrolyzable CHO.[81–83] For example, Essén-Gustavsson et al[83] reported a 12% increase in the resting muscle glycogen content of Standardbred horses fed a diet containing approximately 2 kg of starch and sugar when compared to an isocaloric diet that provided about 1.3 kg hydrolyzable CHO per day. However, no beneficial effect on performance has been shown in horses after CHO-rich diets.[81–83] On the contrary, higher HR and blood lactate accumulation is observed during intense exercise in horses fed CHO-rich diets.[81,82] The underlying mechanisms of these responses are unknown but may be related to alterations in sympathetic outflow and circulating catecholamine concentrations. Interestingly, Jansson et al[197] reported higher HR during submaximal exercise in horses fed 1.5 kg of barley sugar per day when compared to an oat-based diet, suggesting that the form of CHO also may influence the HR response during exercise. There is also evidence that diets comparatively high in starch and sugar increase HR and excitability of horses at rest.[198]

Fat-supplemented diets

The inclusion of fat (as vegetable oil) in diets for athletic horses is now widespread and it is common for horses to receive up to 20% of total daily digestible energy (DE) from fat. However, the effects of dietary fat supplementation in horses on exercise metabolism and performance are somewhat controversial, in part because of the wide variability in the design and results of studies examining various physiological responses to dietary fat.

Fat supplementation in horses is characterized by an increase in plasma phospholipids and cholesterol and a decrease in plasma TGs.[199,200] Changes in the activities of lipoprotein lipase and the enzymes of β-oxidation also suggest that horses adapted to a fat-supplemented diet have increased capacity for the uptake and oxidation of fatty acids in muscle. Indeed, some recent studies have shown lower respiratory exchange ratio in fat-adapted horses during low and moderate-intensity exercise.[59,201] Pagan et al[59] also reported a decrease in glucose flux during low-intensity exercise in horses adapted to a diet providing 25% of DE from corn oil. Thus, fat supplementation enhances lipid oxidation and spares the use of endogenous CHO (plasma glucose, muscle glycogen) during moderate exercise. Theoretically, such a glycogen-sparing effect could improve exercise performance. However, the actual effects of fat supplementation on endurance exercise performance have not been reported.

The minimum (or optimum) level of dietary fat necessary for expression of these metabolic adaptations has not been established. Most studies have fed diets containing 3–12% fat (total diet on a dry matter basis) and in one study a dose–response relationship was detected between fat intake (3.0–10.8% fat) and heparin-released plasma lipoprotein lipase activity.[202]

The length of time required for metabolic adaptation to dietary fat is a somewhat contentious issue. Some nutritionists believe that a minimum of 10–12 weeks is required for adaptation.[217] However, metabolic adaptations to fat supplementation have been observed as early as 3–5 weeks after the start of supplementation.[59,199] Thus, whereas a 2–3 month period may be required for complete adaptation to a fat-supplemented diet, some of the metabolic responses are evident much earlier. In one study, the metabolic responses to fat supplementation were abolished within 5 weeks of withdrawal of the oil-supplemented diet.[199] Thus, the putative benefits of fat-supplemented diets in horses are dependent on continued use of such rations.

There is some evidence that fat supplementation also improves the performance of horses undertaking higher intensity exercise (e.g. race horses). Harkins et al[203] reported improved racetrack performance in Thoroughbreds fed a fat-supplemented diet and attributed this improvement to increased muscle glycogen content and glycogen utilization rate during exercise. Furthermore, Eaton et al[204] reported that a fat-supplemented diet resulted in a small but statistically significant increase in run time to fatigue and MAOD in horses undertaking treadmill exercise at an intensity equivalent to 120% of $\dot{V}O_{2max}$. However, in this study there was no corresponding change in resting muscle glycogen content or glycogen utilization rate during exercise. The mechanism for enhancement of high-intensity exercise performance with fat supplementation is unclear, although increased activation of glycolysis and glycogenolysis is a possibility, the data of Eaton and colleagues[204] notwithstanding.

Fat-supplemented diets for horses have lower hydrolyzable CHO (starch and sugar) content when compared to grain-based rations. These diets therefore provide less substrate (glucose) for muscle glycogen synthesis. However, although a drastic reduction in the soluble CHO content of the diet (< 10% of DE from starch and sugar) is associated with marked reductions in muscle glycogen content,[81] it appears that muscle glycogen content is largely unchanged when horses are fed diets containing moderate amounts of fat (up to 7.5% of total dry matter or 20% of DE).[84,198] However, in horses not adapted to a fat-supplemented diet, consumption of meals containing 7.5% fat (rapeseed oil) slows the rate of muscle glycogen replenishment.[84]

Sugar beet pulp

Non-starch carbohydrate feeds, such as sugar beet pulp (SBP) and soya hulls, are now commonly added to diets for athletic horses. The carbohydrate fraction of these feeds is devoid of starch, but rich in non-starch polysaccharides (fiber). SBP contains major fractions of pectins, arabinans and galactans that are extensively fermented in the hindgut.[205] Up to 3.0 g SBP per kg bodyweight have been fed to adult horses without any adverse effects on overall nutrient utilization or performance.[206] Replacing oats with plain SBP will reduce the glycemic and insulinemic responses to a meal.[206] However, when oats were replaced by molassed SBP there was no appreciable change in glycemic response although the postprandial increase in insulin was mitigated.[207]

Replacing oats with SBP also mitigates the rate of muscle glycogenolysis and the increases in muscle and plasma lactate in Standardbred trotters performing a treadmill exercise test that simulated a race.[207] Similarly, replacing oats with barley sugar resulted in a significant reduction in muscle glycogen utilization during intense exercise.[197] Therefore, a reduction in dietary starch, with replacement by SBP or barley sugar, modifies the muscle glycogenolytic response to high-intensity exercise. The mechanism of this apparent glycogen-sparing effect when oat starch is replaced by barley sugar or SBP is not known. Potentially, an increase in sugar intake results in enhanced use of plasma glucose for energy with a concomitant decrease in energy transduction from muscle glycogen.

Dietary protein

Studies in humans and in dogs have indicated that protein is an unimportant substrate during exercise, although under some circumstances amino acid oxidation may account for up to 5–10% of energy expenditure.[195] The contribution of protein to energy expenditure in horses during exercise is unknown, but it has generally been assumed that carbohydrate and fat oxidation predominate. On the other hand, the effects of dietary protein level on exercise metabolism and performance have received some attention. In one study of racetrack feeding practices, there was an inverse correlation between dietary protein level and race performance; for every 1 kg of crude protein (CP) ingested over recommended levels, there was a 1–3 s increase in race time.[208] However, these conclusions are questionable as the statistical analysis of the data was inappropriate. Subsequent laboratory investigations comparing metabolic responses in horses fed moderate (~10% CP; recommended levels) versus high (~18% CP) protein diets have yielded equivocal results. Miller et al[209] and Pagan et al[82] reported attenuated blood lactate accumulation during exercise in horses fed a high-protein diet. However, a subsequent study by Miller-Graber and colleagues[210] did not detect an effect of dietary protein level on lactate accumulation or muscle glycogenolysis during exercise.

More recently, Graham-Thiers and colleagues[211] have evaluated the effects of a restricted protein diet (7.5% CP with added lysine and threonine) on acid–base responses in horses subjected to repeated bouts of high-intensity exercise. When compared to a 14.5% CP diet, the restricted protein diet mitigated exercise-associated acidemia. However, quantitatively the effects were very small and the physiological significance remains to be determined (for further discussion, see Chapter 39).

Effects of pre-exercise feeding

The timing and composition of a meal consumed before exercise can influence metabolic response. Most notably, the hyperglycemia and insulinemia associated with the digestion and absorption of grain meals affect the mix of substrates utilized during a bout of exercise. Insulin is a potent inhibitor of lipolysis and fatty acid oxidation in skeletal muscle and also promotes glucose uptake into muscle via recruitment of the transporter protein GLUT-4 to the sarcolemma. Thus, hyperinsulinemia at exercise onset will suppress NEFA availability and lipid oxidation and increase reliance on carbohydrate stores (including plasma glucose) for energy transduction.

Accordingly, several equine studies have demonstrated that a grain meal (1–3 kg of oats, corn or a mixture of the two) consumed 3 hours or less before exercise results in hyperglycemia, hyperinsulinemia and decreased plasma NEFA concentration at the start of exercise, and a subsequent marked decrease in plasma glucose concentration during the initial period of exercise.[212–215] This decrease in plasma glucose concentration tends to be short-lived such that during prolonged moderate-intensity exercise (e.g. 60 min at 50% of $\dot{V}O_{2max}$), the plasma glucose concentration of grain-fed horses is not substantially different from horses fasted before exercise. On the other hand, plasma NEFA remains lower when compared to the fasted state throughout exercise. Jose-Cunilleras and colleagues[58] utilized isotopic tracer methods and indirect calorimetry to determine the effects of hay (alfalfa cubes; ~3 kg) and starch (cracked corn; 1.7 kg) feeding on glucose flux and substrate oxidation during exercise. The alfalfa cubes were consumed between 2 and 3 hours before exercise, while the cracked corn was ingested 90 min pre-exercise. Feeding corn before exercise resulted in increased utilization of blood-borne glucose and whole-body carbohydrate oxidation when compared to a meal of alfalfa or not feeding (Fig. 34.13).

The effects of pre-exercise grain feeding on endurance exercise performance in horses have not been reported. In humans, carbohydrate ingestion during exercise unequivocally improves performance during prolonged (more than 2 hours) moderate-intensity (> 50–60% of $\dot{V}O_{2max}$) exercise,

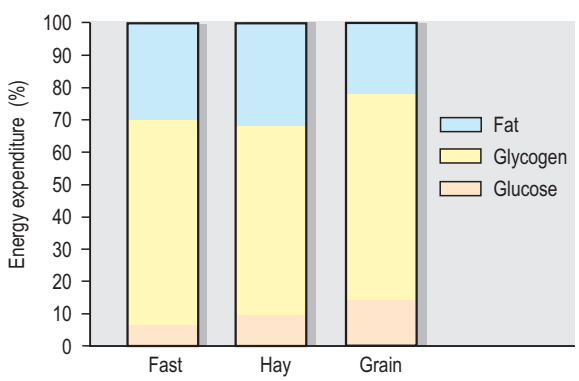

Fig. 34.13
Effects of pre-exercise feeding on the partitioning of energy expenditure in horses during the 5–30 min period of exercise at 50% of maximum oxygen uptake. Horses were either fasted or fed cracked corn or alfalfa cubes 2 hours before exercise. Grain feeding resulted in a significant increase in the caloric contribution from oxidation of glucose when compared to the fast and hay feeding trials. (From Jose-Cunilleras et al.[58])

presumably by maintaining glucose supply in skeletal muscle at a time when glycogen stores are depleted. On the other hand, the performance effects of pre-exercise glucose feedings in human athletes are more equivocal. For horses performing endurance exercise, the acceleration in carbohydrate oxidation (and suppression of fat oxidation) associated with grain feeding may result in premature fatigue as a result of carbohydrate depletion.

As demonstrated in the study by Jose-Cunilleras et al,[58] together with the results of earlier studies by Pagan & Harris,[215] forage meals (< 2–3 kg) consumed 2–3 hours before exercise have minimal effect on substrate availability and oxidation during sustained exertion. However, free choice consumption of hay in the 12–24-hour period before exercise may adversely affect performance because of an increase in bodyweight (gut fill). Large meals (hay or grain or a combination) consumed near the start of exercise also may result in a decrease in plasma volume as a result of fluid shifts into the gastrointestinal tract.[215] Such reductions in plasma volume could compromise cardiovascular and thermoregulatory function during exercise.

There is some evidence that a short-term reduction in forage intake is beneficial in horses undertaking high-intensity exercise. When compared to ad libitum hay consumption, restricting hay intake to ~ 1% of bodyweight for a 3-day period before a treadmill exercise test (2 min at 115% $\dot{V}O_{2max}$) resulted in a 2% decrease in bodyweight and a reduction in anaerobic energy expenditure during exercise, as evidenced by reduced oxygen deficit and plasma lactate concentrations. The reduction in bodyweight was attributed to a reduction in gut fill.[216]

In summary, small forage meals consumed 2–3 hours before exercise have minimal effect on substrate metabolism during exertion. However, meals containing hydrolyzable carbohydrate (starch and sugar) consumed within 3 hours of the start of exercise accelerate carbohydrate utilization and decrease lipid oxidation. Although the performance effects of these feeding practices are not known, this suppression in lipid oxidation may be detrimental during endurance exercise (e.g. endurance races; speed and endurance test of a three-day event).

CHAPTER 35

Endocrine alterations in the equine athlete

Kenneth Harrington McKeever and Mary Beth Gordon

Introduction

For the most part the domestic horse spends a good part of its day either eating or seeking food.[1] In feral horses the latter can involve treks over a wide range.[1] However, most horses spend the majority of their day eating, standing and occasionally exercising.[1] Exercise can range from running up and down the fence line in anticipation of the feed truck to athletic training for a variety of competitive endeavors.[1] Under resting conditions, the horse has a relatively easy job of maintaining the internal environment. However, whatever the activity, the performance of work or exercise is a major physiological challenge, a disturbance to homeostasis, that invokes an integrative response from multiple organ systems.[1] On a gross level there is a pairing of those systems associated with convective transport and those associated with the transduction of potential energy into kinetic energy.[1] Put another way, the response to exercise requires the transport of oxygen from the atmosphere to the cells in the working muscles where it is utilized in metabolic pathways generating ATPs for fuel utilization.[1] In reality, though, the adjustments to acute exercise require the co-ordination of several systems including the respiratory, cardiovascular, muscular, integumentary, renal, hepatic and the various organs of the digestive tract.[1–5] Each tissue or organ called upon to facilitate movement must function in co-ordination with others in a variety of classic feedback loops (Fig. 35.1). Multiple layers of control exist in the body to facilitate work. The first muscle contractions associated with work will alter mechanisms of autoregulation causing changes in local control of the local environment that are sensed peripherally. Longer work causes system-wide alterations that necessitate integrated whole-body responses requiring neural and endocrine mediation.

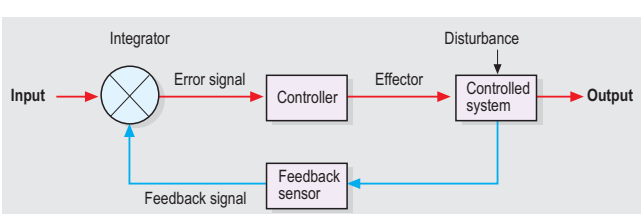

Fig. 35.1
Components of a controlled negative feedback system.

The most rapid mechanisms used to facilitate a co-ordinated response to exercise involve an integration of error signals in the periphery that are communicated via the nervous system to central command centers where adjustments are made to the respiratory and cardiovascular systems.[3–5] Some have suggested that the rapid adjustments in cardiopulmonary function at the onset of exercise can be accomplished primarily via a shift in autonomic tone with a withdrawal of parasympathetic tone and an increased sympathetic drive.[4,5] However, as exercise progresses beyond a few seconds, more sophisticated mechanisms are called upon to fine-tune the initial response to the disturbance of exercise.

Fine-tuning of the response to exercise that lasts longer than a few seconds is reliant on the regulation of several key variables governing the cardiopulmonary, vascular and metabolic response to exercise.[3–5] Regulation allows the internal environment to be maintained within relatively narrow limits so as to enhance optimal cell function. This type of classic regulation involves a multiple system response where some variables are controlled so that those most vital to the defense of the internal environment can be regulated.

This type of integrative response is slower than a neural response because it requires communication between systems that relies on the secretion of substances by one tissue or organ that are transported remotely to other tissues or organs to evoke a response to the disturbance.[3–5]

Endocrine system and hormones

By definition, a hormone is a substance that is produced and released by one organ or tissue and is transported via the blood to a remote target organ or tissue where it causes a physiological response.[2,5] Most hormones fall into two major categories: the steroid hormones and the non-steroid hormones. Steroid hormones include cortisol, aldosterone and the reproductive hormones testosterone, estrogen and progesterone.[2,5] The steroid hormones have a classic ring structure and are lipid soluble, a characteristic that allows them to diffuse across cell membranes.[2,5] Mechanistically, the steroid hormones exert their effect through direct gene activation that occurs after diffusion into the cell (Fig. 35.2).[2,5] Once across the cell membrane, they bind to receptors in either the cytoplasm or the nucleus.[2,5] This complex formed by the steroid hormone and receptor induces the DNA in the cell to produce mRNA which, when it enters the cytoplasm, is transcribed, resulting in the production of protein.[2,5] This protein results in the physiologic action of the hormone on cellular function.[2,5]

The non-steroid hormones are not lipophylic and thus, cannot pass through the cell membrane.[2,5] These hormones bind in a lock-and-key fashion to very specific receptors on the surface of the cell membrane (Fig. 35.3).[2,5] The hormone–receptor complex remains in the membrane, but is still able to activate the enzyme adenylate cyclase within the cytoplasm of the cell.[2,5] Activation starts a cascade that results in the active formation of the enzyme cAMP through the combination of adenylate cyclase and ATP.[2,5] The enzyme cAMP in turn activates specific inactive protein kinases which cause the conversion of inactive substrates into active substrates that have the capability to induce changes in cellular form or function.[2,5]

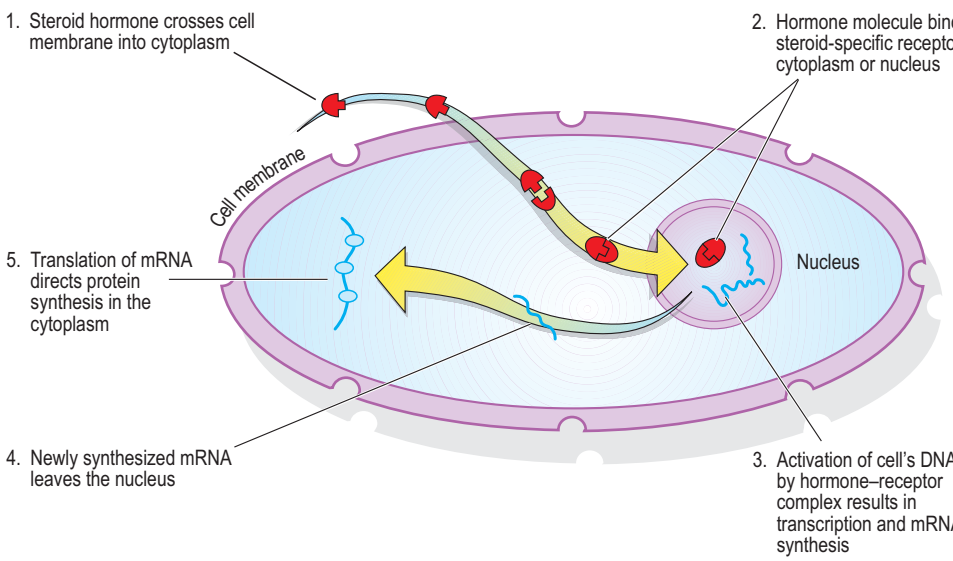

Fig. 35.2
Gene activation mechanism associated with the action of a steroid hormone.

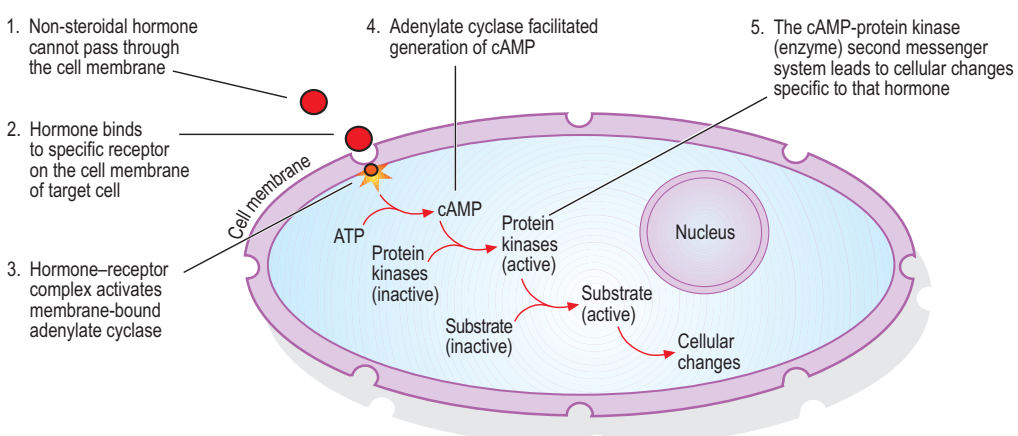

Fig. 35.3
Second messenger mechanism associated with the action of non-steroid hormones.

Release of most hormones is part of a controlled negative feedback system that keeps a specific variable within narrow limits.[2,5] The typical negative feedback system is composed of a variable that has an input or set point that is read or sensed by an integrator.[2,5] For the system to be in a state of balance or homeostasis, the input and output signals must be the same. If the input variable is changed by a disturbance, such as exercise, the integrator senses the mismatch and sends an error signal, usually via nerves, to the controller. The controller then alters the controlled system via an effector. In some cases the effector is a nervous signal; however, in some cases it is a hormone. The effector causes a change in the controlled system, inducing a change in the output that is sensed by the feedback sensor. The feedback sensor sends a signal to the integrator that then determines if the input matches the output of the system.

Physiological variables that are the most critical to normal function are regulated. *Regulation* refers to a phenomenon in which the output of a system remains relatively constant under many different disturbances. For example, mean arterial pressure, plasma osmolality, blood pH, Pco_2 and Po_2, plasma electrolyte ($Na,^+$ K^+ and Cl^-) concentrations, blood glucose concentration and body temperature are just a few of the major variables that are regulated and held within very narrow limits during exercise. Regulation of each of these variables is accomplished through a combination of neural and endocrine mechanisms affecting multiple control strategies. *Control* is a phenomenon where the output of the system constantly changes in order to manage a rate of functioning. In short, some physiological variables are controlled so that others may be regulated. The more rapid responses used to maintain homeostasis are usually mediated by neural control mechanisms with less rapid responses usually mediated by endocrine mechanisms.

For example, maintenance of systemic mean arterial pressure around a narrow set point is critical to cardiovascular performance.[4] Multiple systems are controlled to insure that MAP is sufficient to allow perfusion of all the working muscles as well as obligate tissues during exercise.[4] At the onset of exercise, there is a decrease in total peripheral vascular resistance (TPR) that results from the opening of blood vessels in the working muscles.[4] This allows for the increase in blood flow to those vascular beds.[4] However, there is an almost simultaneous increase in cardiac output which comes about through the matching of the input and output signals sensed by volume and baroreceptors placed at strategic points in the cardiovascular system.[1,4] Matching of the input and output signals (see Fig. 35.1) by the vasomotor center of the medulla (the integrator) results in an error signal via the autonomic nervous system (the controller).[1,4] A withdrawal of vagal tone and an increase in sympathetic drive results in the local release of norepinephrine (effector) which causes a rapid increase in heart rate and the force of contraction that raises cardiac output (the controlled system) enough to maintain MAP.[1,4] As exercise intensity increases the set point for MAP is increased; thus, higher intensity exercise usually requires more dramatic responses, including a decrease in blood flow to non-obligate tissues such as the splanchnic vascular beds.[1,4] The initial part of this response is mediated by neural mechanisms affecting the arteriole in those vascular beds.[1,4] However, higher intensity exercise also requires the added influence of endocrine effectors such as vasopressin and angiotensin II to cause sufficient vasoconstriction in non-obligate tissues to facilitate the rise in MAP needed for optimal cardiovascular function.[1,4] As such, one example of the role of the endocrine system during exercise can be seen in the regulation of MAP.[1,4] Longer term control of MAP can be affected by the duration of exercise which results in multiple strategies to control blood volume and defend cardiac filling pressure, cardiac output and MAP.[1,4]

Major endocrine glands and hormones

Pituitary gland

The pituitary is found at the base of the brain and is divided into three lobes: the anterior, intermediate and posterior.[2,5] Hormones of importance during exercise are produced and released by the anterior and posterior lobes.[2,5] The pituitary is vitally linked to the hypothalamus, an area of the brain with many very specific neural tracts that act as feedback sensors.[2,5] The hypothalamus also acts as the integrator in the controlled system, exerting control over the pituitary through neural and endocrine mechanisms.[2,5] The latter include various releasing hormones and inhibitory hormones and other substances.[2,5] The central location of this hypothalamic-pituitary axis makes it ideal for mediating the control of a wide variety of functions.[2,5]

Anterior pituitary hormones

Hormones produced by the anterior lobe of the pituitary include somatotrophin (growth hormone, GH, ST), thyrotrophin (thyroid-stimulating hormone or TSH), adrenocorticotrophin (ACTH), endorphins (EN), enkephalins, dynorphins, follicle-stimulating hormone (FSH), luteinizing hormone (LH) and prolactin.[2,5] The first three play an important role in growth and development in the young animal and metabolism in the adult animal. The endorphins, enkephalins and dynorphins are opiate-like peptide hormones that modulate pain reception and interact with the neural pathways of the hypothalamic-pituitary axis to influence releasing and inhibiting hormones.[6–8] FSH, LH and prolactin are considered hormones essential for normal reproduction and lactation.[2,5] New research in species other than horses has demonstrated that severe or prolonged exertion can alter their release and thus normal reproductive cycles.[2,5] Furthermore, prolactin appears to play an important role in the response to severe stress, interacting with many of the metabolic hormones.[2,5]

Somatotrophin (ST) Somatotrophin affects all the cells in the body, stimulating development and growth in younger animals. In mature animals it plays a vital role in muscle metabolism through its effects on protein synthesis and its role in fat and carbohydrate utilization.[2,5] The importance of somatotrophin in maintenance of normal physiologic function and its possible role in slowing or possibly even reversing the effects of aging can be seen in some younger adult humans, where somatotrophin 'deficiency' results in changes in appearance, decreased lean body mass, decreased immune function and other 'sequelae' of aging.[9,10] Amazingly, treatment of these individuals with recombinant human somatotrophin results in increased lean body mass, decreased body fat and increased muscle mass.[9,10] Chronic somatotrophin administration appears to increase strength and the ability to perform a battery of weight-lifting exercises in aged male humans.[9,10] While there have been no reported effects of ST on aerobic capacity, the increase in muscle mass and strength has been shown to benefit the quality of life in humans by increasing the ability to do daily tasks such as maintaining balance while walking and climbing stairs.[9,10] Those human experiments served as part of the justification for several recent studies of the efficacy of recombinant somatotrophin treatment in preventing or retarding functional decline in geriatric humans[9,10] and in geriatric horses.[11–14]

Researchers conducting equine studies[11–15] have asked 'quality of life' questions similar to those posed in experiments using aged humans.[9,10] While those studies demonstrated that equine ST (eST) therapy increases nitrogen retention and improves appearance in geriatric horses, they did not demonstrate any effect of chronic eST administration on bodyweight or the dimensions of several key muscles measured using ultrasonography.[13] Functionally, chronic eST administration did not alter aerobic capacity or several commonly used indices of exercise performance, at least not in unfit aged mares.[14] Furthermore, data from unfit geriatric horses indicated that eST did not alter lactate tolerance or cause an increase in maximal power that one would associate with an increase in muscular strength, a logical observation since there was no evidence of an increase in muscle mass.[14] Interestingly, studies of geriatric male humans have shown that recombinant somatotrophin therapy results in increased muscle mass and, in some cases, increased strength as measured in standardized tests performed with weight-lifting equipment.[9,10] However, while ST therapy does appear to increase strength in humans, there are no data to show that ST therapy alters maximal aerobic capacity or enhances endurance performance.[9,10]

More recent studies of younger horses have demonstrated that administration of eST prevents some of the bone demineralization that occurs in the first months of intense training.[16] Other studies found that there was minimal or no therapeutic benefit of administering eST to prevent tendon or cartilage injuries or to promote wound healing.[17–19] Another report demonstrated that eST does not alter aerobic capacity or markers of performance in young (~ 2 years) Thoroughbreds.[17,18] However, as with the studies of older horses, the experiments performed on younger animals had no way to evaluate the effects of eST administration on muscular strength; thus, data are needed to determine if eST alters strength and power.

Thyrotrophin (TSH) Release of TSH is stimulated by thyroid-stimulating hormone releasing hormone (TRH) which is produced in the hypothalamus.[2,5] Studies of humans and other species have demonstrated that acute exercise elicits mixed effects on TSH release.[20] The release of TSH appears to be linked to exercise intensity as mild and moderate exertion do not appear to have an effect on TSH release. However, there appears to be a threshold for stimulating TSH release, as plasma concentrations of this hormone increase only when exercise intensity exceeds 50% of $\dot{V}O_{2max}$ in humans.[20] This breakpoint is common to several hormonal systems including the observed increases in the catecholamines, ACTH, cortisol, PRA, etc., which may indicate that there is an interplay in the metabolic response to higher intensity exercise.[20–24] Interestingly, exercise duration beyond 40 minutes appears to cause an increase in TSH.[20] This observed increase during longer steady-state exertion is similar to the response of other metabolic hormones and may be related to substrate mobilization and attempts to prevent the onset of central fatigue mechanisms. In humans, repeated daily exercise also causes the release of TSH, suggesting the ratcheting up of metabolic function with exercise training.[5,20] Data on the effects of acute exercise and training on TSH in equine athletes are lacking.

Adrenocorticotrophin (ACTH) As with TSH, the release of ACTH is stimulated by corticotrophin-releasing hormone which is secreted by the hypothalamus.[2,5] A number of published papers have demonstrated that exercise causes an increase in ACTH in the horse; however, most of these only report postexercise values.[20,25–31] The major conclusion of most exercise studies has been that both high-intensity and endurance exercise cause an increase in ACTH and subsequent increase in cortisol.[20] Some researchers have attempted to characterize this as a stress response; however, if one looks at the role of cortisol in substrate mobilization and metabolic control during exertion, then one can see that the ACTH/cortisol response, if in the normal range, is an appropriate response to exertion.[20,25–32]

A more recent study demonstrated that ACTH increases in a curvilinear fashion with exercise intensity during controlled incremental exercise performed on a treadmill.[24] The ACTH response appeared to be highly correlated to the catecholamine and lactate responses to incremental exercise, all of which also increased in a curvilinear fashion.[24] When horses were exercised at steady-state speeds (80% or 110% $\dot{V}O_{2max}$), the ACTH response was rapid, with concentrations increasing in a linear fashion until the end of the exercise test.[24] Postexercise concentrations fell rapidly, returning to baseline within 60–120 min.[24] These responses are similar to those reported for humans and other species.[5,24]

The endorphins, enkephalins and dynorphins These peptides are released from the pituitary in response to pain or pleasure.[6–8] While some classify these substances as hormones, others classify them as neurotransmitters.[6–8] Nevertheless, these substances are naturally occurring opiate-like

pain suppressors that may allow a horse to tolerate higher intensity exercise.[6–8,31–34] The endorphins, enkephalins and dynorphins play a role in the response to physiological and psychological stress and appear to modulate pain perception.[6–8] As such, these hormones are markers of stress. However, since some sports medicine specialists have suggested that an overload of duration, intensity or resistance is needed for exercise training to elicit an adaptive response, then under controlled conditions, the endorphins may play an important role in allowing a horse to tolerate the progressive increases in exercise intensities or longer durations needed to invoke a training response. Mehl and co-workers[6–8] have demonstrated that a threshold exists for evoking an increase in plasma β-endorphin concentration. This threshold appears to correspond to ~ 60% of the speed eliciting $\dot{V}O_{2max}$. Interestingly, this is the same point at which one sees a curvilinear increase in the catecholamines, plasma renin activity, plasma lactate concentration and several other variables. This suggests a close interplay between these factors in the transition from low-intensity, primarily aerobic exercise to higher intensity exercise with an increasing anaerobic component.[21–24,35] Duration of exercise also appears to affect the magnitude of the endorphin response, with greater plasma concentrations as horses approach fatigue.[6–8] Training appears to alter the endorphin response to acute exertion with greater concentrations observed in the post-exertion peak occurring between 5 and 10 minutes post exertion.[36]

Posterior pituitary hormones

Hormones released from the posterior lobe of the pituitary include arginine vasopressin (AVP) and oxytocin. These two protein hormones are actually produced in the hypothalamus by specialized bundles of nerves.[2,5] Arginine vasopressin is synthesized in cells of supraoptic and paraventricular nuclei and stored in vesicles in the nerve endings located in the posterior pituitary. Vasopressin plays a role in blood pressure regulation and fluid and electrolyte balance. It is for this later role that some refer to AVP as antidiuretic hormone or ADH.[2,5] AVP plays a major role in the short-term and long-term control of cardiovascular function during and following exercise.[2,5] Oxytocin causes smooth muscle contraction in the epididymis of males and the uterus of females and also acts on mammary tissue, causing milk letdown in lactating mares.[2,5] Oxytocin does not appear to play a role in the response to exercise.

Arginine vasopressin (AVP) AVP is a posterior pituitary hormone associated with the acute and chronic defense of blood pressure, plasma volume and fluid and electrolyte balance.[1–3,37–39,41] The primary physiological actions of AVP include vasoconstriction and decreased free water clearance.[3,37–39,41] The mechanism for the release of AVP involves osmoreceptors in the supraoptic and paraventricular nuclei of the hypothalamus and cardiopulmonary baroreceptors in the atria of the heart.[2,3,37–39,41] Data from rats and other species have shown that a very small 1–2% decrease in cell volume in the hypothalamus or change in extracellular osmolality of 2–4 mOsm/kg will stimulate AVP secretion and drinking.[37–39] Exercise causes an increase in plasma AVP that is correlated with both duration and intensity.[21,35,37–40] Comparative data show that AVP is secreted during exercise in concentrations well above the threshold level associated with its antidiuretic effects, suggesting that its extrarenal actions are more important during acute exercise.[3,37–39,42–45] Extrarenal actions include AVP's action as a powerful vasoconstrictor and an important component in the control of blood pressure during exercise and its action on splenic blood vessels to prevent resequestration of the splenic reserve in the horse.[3,25,46] Interestingly, some studies suggest that drinking water, especially cold hypotonic water, during exercise may suppress AVP and thirst, leading to hypohydration.[38,39,41,47–49] However, sustained elevations in AVP stimulate thirst and drinking after exercise, cause a decrease in free water clearance by the kidneys and may influence the uptake of sodium and water from the colon.[3,38,39,41,49]

In exercising horses, plasma AVP concentration was recently reported to have increased from ~ 4.0 pg/mL at rest to ~ 95 pg/mL at a speed of 10 m/s.[45] It was also reported that the relation between AVP concentration and exercise intensity was curvilinear and did not plateau at speeds producing maximal heart rate.[45] Another recent paper reported that AVP increases during steady-state submaximal exercise in horses without a change in free water clearance.[42] However, the increase does not become significant until between 20–40 min of exertion.[42] Two possible explanations were given for the delay in AVP secretion in submaximally exercised horses.[42] First, a suppression of AVP secretion due to the volume overload sensed by neural pathways associated with the atrial baroreceptors and the hypothalamus.[3,42] Second, inhibition of AVP release by the increase in ANP concentrations at the beginning of exercise.[3,44] Nevertheless, an increase in AVP concentration was seen with prolonged exercise that appears to be related to sweat losses and decreases in body water that altered plasma osmolality and blood pressure.[3,44,45] Studies of humans have demonstrated that training alters the slope of the AVP response to acute exercise, suggesting a change in the sensitivity to the exercise challenge.[21,22,35,38–40,47,49] No studies have been published on the effect of training on the AVP response to acute exertion in the horse.

Thyroid

The thyroid is located in the neck in close proximity to the larynx region.[2,5] It plays a major role in the control of basal metabolic rate which has led some to refer to it as the body's 'thermostat'.[2,5] The two iodine-containing hormones produced by the thyroid, tri-iodothyronine (T3) and thyroxine (T4), act upon all cells in the body, affecting metabolic rate and subsequently energy metabolism.[2,5,20] The cells of the thyroid have three major actions when it comes to synthesis and secretion of T3 and T4: collection and transport of iodine, synthesis and secretion of the glycoprotein thyroglobulin into the intracellular colloid, and removal of T3 and T4

from thyroglobulin and secretion into the bloodstream.[2,5,20] The thyroid hormones circulate in the plasma in both a free and a protein-bound form with protein bound accounting for 99.98% of the circulating hormone and the unbound form being the active form able to act on cellular metabolism.[2,5,20] The thyroid also produces calcitonin, an important hormone in the control of calcium metabolism with potent effects on bone mineral density.[2,5,20]

Tri-iodothyronine and thyroxine

The release of these hormones is stimulated by TSH which, as previously mentioned, is released during exercise.[2,5,20] As with TSH, release of T3 and T4 is associated with both the intensity and duration of exercise in humans and horses.[5,20,50] Irvine[51] demonstrated that training increases the secretion rate of both T3 and T4 by approximately 65%. This would indirectly support the suggestion that TSH, which increases with training in humans and other species, is also increased with training in the horse. Training also increases the turnover rate of the thyroid hormones.[5,20]

Calcitonin

In addition to its control of metabolic rate, the thyroid is vital to calcium homeostasis.[2,5,20] For this function the thyroid synthesizes and produces calcitonin which plays a role in calcium homeostasis by either inhibiting osteoclast activity in bone or, through its action on the kidney tubules, causing an increase in calcium loss by actively inhibiting tubular reabsorption.[2,5,20] New bone is formed by osteoblasts and reabsorbed by osteoclasts. In young growing horses, both osteoclasts and osteoblasts are active; however, the activity of osteoblasts outpaces that of osteoclasts, allowing for bone growth and development.[2,20] To this end calcitonin appears to be more important in the young growing animal through its inhibitory action on the osteoclasts. Calcitonin is also important in the healing of fractures.[2] Chiba and co-workers[52] documented substantially elevated plasma calcitonin concentrations in racehorses with various fractures. Studies have also demonstrated that there is a period of bone demineralization in young Thoroughbreds in the first few months of training.[16] Growing and adult humans who exercise regularly have increased bone density.[5] While a great deal of work has examined markers of bone turnover, more data are needed to determine whether acute and chronic exertion affects plasma calcitonin concentrations.[9,52–56]

Parathyroid glands

The parathyroid glands, which are located in close proximity to the thyroid gland, regulate calcium homeostasis by synthesizing and secreting parathyroid hormone or parathormone (PTH) in response to a change in plasma calcium (Ca^{++}) concentration.[2,5,20] The hormone PTH has receptors in the intestinal tract, in the osteoclasts in bones and the tubules of the kidneys.[2,5,20] The action of PTH to stimulate osteoclast activity is antagonistic to calcitonin's inhibitory action. The resultant effect is a net bone reabsorption and the release of calcium and phosphate into the bloodstream.[2] Actions on the bone are relatively slower compared to PTH ability to alter both the uptake and excretion sides of the homeostatic balance equation by acting on the intestine and the kidney tubule.[2] Parathyroid hormone has a profound ability to enhance the enzymatic pathway that mediates increases in intestinal absorption of calcium and phosphate.[2,5,20] At the same time PTH can act on the kidney tubules where it enhances calcium reabsorption and phosphate excretion.[2,5] The increase in phosphate excretion counters the increased amount absorbed concurrent with the increase in calcium absorbed by the intestines.[2,5]

As with calcitonin, most equine research has focused on effects of repeated exercise on markers of bone turnover.[9,52–56] It is well recognized that nutritional influences can alter calcium and phosphate balance and bone metabolism. Thus, more work is needed to determine whether exercise intensity and/or duration are factors affecting PTH concentrations. Furthermore, data are needed to determine whether exercise alters the synthesis and secretion rate, receptor numbers and sensitivity and general interplay of PTH and calcitonin in bone metabolism.

Adrenals

The adrenal glands are multilayered organs that sit atop the kidneys.[2,5] Functionally, the primary layers are the adrenal medulla and the adrenal cortex.[2] The medullary portion of the adrenal produces epinephrine and norepinephrine which have the potential to affect most cells in the body.[2,5,20] In general, epinephrine potentiates the response to exercise, causing profound effects on central cardiovascular and respiratory function.[5,20] It can cause increases in muscle blood flow and can mobilize glycogen and free fatty acids to fuel exertion.[2,5,20] The adrenal cortex contains three specialized zones: the zona glomerulosa zona fasciculata and zona reticularis.[2] The cortex produces a multitude of steroid hormones that fall into three major categories: the mineralocorticoids (aldosterone), the glucocorticoids (cortisol) and the gonadocorticoids (androgens and estrogens).[2,5,20]

Hormones produced by the adrenal medulla (the catecholamines)

The release of the catecholamines has its origin in the fight-or-flight response.[57] This 'stress' response involves the local release of norepinephrine from the sympathetic nerve endings and a systemic release of epinephrine and norepinephrine from the adrenal medulla.[57] Receptors for the catecholamines are specialized and are divided into two primary categories, referred to as α and β-adrenergic receptors.[57] These two major categories are divided into subcategories, namely α_1 and α_2 and β_1 and β_2 receptors.[57]

Sympathetic nervous activity increases with intensity and duration of exercise; however, measurable changes in plasma

catecholamine concentrations are not apparent below 50–70% of maximal aerobic capacity.[57] Recent papers report that plasma catecholamine levels increase in a curvilinear fashion with increasing exercise intensity and are highly correlated with plasma lactate concentrations.[23,24,50] The measurable increase appears to coincide with the intensity where one would expect complete parasympathetic withdrawal.[19,20,22–24] These increases in the catecholamines enhance the increase in heart rate, force of cardiac contraction and thus cardiac output.[3,57] The catecholamines also play a role in inducing splenic contraction and the delivery of 6–12 liters of blood into the central circulation at the onset of exercise.[57,58] Even with this mobilization of reserve blood volume, the demands of exercise may exceed central cardiovascular capacity in the horse; thus, during high-intensity or long-duration exercise, the catecholamines contribute to the vasoconstriction that decreases blood flow to non-obligate tissues.[3,4,57]

The catecholamines are also vitally integrated into the respiratory response to exercise.[3,23,57,59,60,80] At the onset of exercise the β_2-adrenergic receptor action relaxes tracheal and bronchial smooth muscle, increasing airway diameter and decreasing airway resistance, and thus facilitating movement of greater amounts of air into and out of the lungs.[57] While the sympathetic system is not directly responsible for the control of ventilation during exercise, the increase in ventilatory drive associated with activation of the motor cortex can be enhanced during exercise by catecholamine secretion and augmentation of the sensitivity of chemoreceptors in the carotid bodies.[57] During high-intensity exercise ventilation may be further affected by catecholamine release; however, this is more a stress response than a 'normal' response to exercise.[57]

The catecholamines also have major effects on metabolic pathways associated with substrate utilization during exercise.[5,20,57] Increases in sympathetic activity, more specifically catecholamine concentrations, result in an increase in hormone-sensitive lipase and subsequently an increase in circulating free fatty acids.[5,20,57] Exercise-induced increases in the catecholamines also cause an increase in glycogen breakdown, resulting in elevations in blood glucose concentrations.[5,20,57] It has been suggested that one way in which warm-up exercises benefit the athlete is through activation of these metabolic pathways, allowing for elevated blood concentrations of glucose and free fatty acids prior to race-induced increases in utilization, thus facilitating delivery of substrate to tissues without a significant lag time.[5,20,57]

The above responses have been well documented during acute exercise; however, recent data suggest that exercise training alters adrenergic receptor numbers and sensitivity in selected tissues.[5,20,57] For example, β-adrenergic receptor numbers are unchanged in cardiac muscle with training, while α-adrenergic and muscarinic receptor numbers are reduced.[5,20,57] Both β-adrenergic receptor numbers and sensitivity are increased in skeletal muscle and in vascular and bronchial smooth muscle.[5,20,57] Changes in receptor number and sensitivity with training may be important with respect to adjustment of drug doses for the animal that has been trained extensively as opposed to an animal that is at the beginning of a training program or one that is being reconditioned following removal from training.[5,20,57]

Primary hormones produced by the adrenal cortex

Some sources suggest that more than 30 structurally distinct steroid hormones are secreted by the adrenal cortex.[2,5,20] Of those, the mineralocorticoid aldosterone and the glucocorticoid cortisol are the most important to the physiologic response to exercise.[2,5,20]

Aldosterone (ALDO) Aldosterone plays an important role in electrolyte homeostasis, in particular sodium and potassium balance.[2,3,5,20,61] It is well recognized that ALDO acts on the kidneys to enhance sodium (and chloride) reabsorption and potassium excretion.[3,5,20,61] It also acts on the intestines to facilitate the uptake of electrolytes and water.[3,5,20,61] Aldosterone release can be stimulated by decreases in plasma Na^+ or by increases in plasma H^+, plasma K^+, plasma ACTH and/or increased PRA.[3,38,39,61] However, the most potent of these stimuli is an increase in plasma K^+.[3,61] Studies of horses have attempted to identify factors that may stimulate the release of ALDO during exercise.[14,42,45,61–65] In one study plasma Na^+ was not significantly affected by exercise and thus, a decrease in plasma Na^+ did not appear to have been the primary stimulus for ALDO release.[42] The early mechanism for the release of ALDO appeared to have been a proportional increase in the plasma renin-angiotensin-aldosterone cascade where an increase in PRA results in the generation of angiotensin I and angiotensin II, with angiotensin II stimulating the production and release of aldosterone.[38,39,41,66–68]

The relationship between plasma aldosterone concentration and exercise intensity has been reported for horses running on a treadmill.[45] Aldosterone increased from concentrations around 20–50 pg/mL at rest to almost 200 pg/mL at a speed of 10 m/s.[45,69] A linear relation was found between exercise intensity and aldosterone concentration; however, unlike PRA, ALDO concentration did not reach a plateau at HR_{max}.[45] Another study found that during submaximal exercise, increases in plasma ALDO concentration paralleled changes in PRA; however, the magnitude of the increase in PRA (66%) was less than the relative increase (709%) in plasma ALDO concentration.[42] The authors concluded that factors other than PRA affected the release of ALDO in the horse.[42] Of all the parameters reported, a highly significant increase in plasma K^+ concentration may have served as the strongest stimulus for the release of ALDO.[3] An increase in plasma K^+ as small as 0.3 mEq/L can be sufficient to stimulate the secretion of ALDO, independent of the renin-angiotensin cascade, through the conversion of cholesterol to pregnenolone or at a later step in the biosynthetic pathway.[3] This is consistent with the acute homeostatic requirements of the horse since a major perturbation in electrolyte homeostasis observed during endurance exertion was an increase in plasma K^+ and not a drop in plasma Na^+.[45] As with humans, ALDO has a minimal role in the acute response

to exercise in horses; however, ALDO concentration remains elevated for hours after exercise and may affect the long-term reabsorption of sodium and water[40,70,72] by the kidneys and by the intestinal tract.[69,73]

Cortisol The major glucocorticoid secreted by the adrenal glands is cortisol; however, some cortisone, corticosterone and deoxycorticosterone are also produced and found in the plasma.[2,5,20] Thornton reported that deoxycorticosterone concentrations are very low in the horse.[20] Cortisol, cortisone and corticosterone can be found in a ratio of 16:8:0.5 in the plasma; thus, most exercise studies have focused on cortisol.[2,20] Cortisol undergoes diurnal variation with peak levels found in the early morning between 0600 and 1000 and lowest levels found in the late evening and night.[2,5,20] Some have characterized the glucocorticoids as 'stress' hormones.[2,5,20] However, they are released under a multitude of normal situations not characterized as stress.[2] Thus, it is the appropriateness of their release and the magnitude of their release that would indicate whether a given physiologic disturbance (or stressor) can be classified as a mere perturbation or a dangerous stress.

Release of cortisol allows an individual to tolerate and adapt to challenges to homeostasis that occur in everyday life.[5,20] To this end, the functional effects of cortisol fall into two major categories: substrate mobilization and immune modulation.[2,5,20] One such challenge is exercise where cortisol stimulates substrate mobilization by enhancing gluconeogenesis and the mobilization of free fatty acids.[5,20] At the same time cortisol release will decrease glucose utilization by some tissues, sparing it for use by the central nervous system.[5,20] One could speculate that such an action could delay the onset of central fatigue that occurs during endurance exertion when blood glucose concentrations drop.[71,72] Cortisol also causes an increase in protein catabolism with a resultant increase in the release of amino acids.[2,5,20] These building blocks of protein are thus available during exercise as a source of energy when glucose levels begin to drop.[2,5,20] They are available after exercise to repair tissues and for the synthesis of enzymes involved in many cellular pathways.[2,5,20] Cortisol also modulates immune function, acting as an anti-inflammatory agent and suppressing immune reactions.[2,5,20] Teleologically, these actions may be of benefit in the response to training. Overload through increased exercise intensity, resistance or duration is necessary for training to stimulate an adaptive response to exercise. The minor disruption of function and structure in the cells of the muscles results in protein accretion, substrate uptake and deposition, and other beneficial remodeling that increases the functional capacity of the cells. Cortisol's suppression of immune function and anti-inflammatory effects may actually provide a permissive environment for tolerating the slight amount of 'muscle damage' needed for training-induced remodeling.

Many studies have demonstrated that cortisol is increased in the horse during a wide variety of exercise activities, from racing to polo to endurance rides.[11,20,32,74–80] The release of cortisol in the horse appears to be affected by both intensity and duration of exercise.[20,79,80] However, excessive increases in cortisol concentrations following exertion can be a marker of too much exercise. Prolonged cortisol recovery times as well as either inappropriately high or low plasma concentrations of cortisol may be markers of overtraining in the horse. As mentioned above, postexertion effects of cortisol may elicit a permissive effect beneficial for training adaptation by preventing the immune system from eliciting an inflammatory and immune reaction to acute exercise.[11,81] Several studies of horses have followed cortisol levels for an extended period post exercise.[82–84] Those experiments demonstrated that exercise caused a six-fold increase in adrenal cortisol secretion and a 2–3-fold increase in plasma cortisol concentration. Urinary cortisol concentrations also increased threefold with a return to baseline levels by 10 hours post exertion.[82,83,84] The authors also noted a substantial increase in liver clearance of cortisol.

Interestingly, data are mixed as to the effects of training on the cortisol response.[20,79,80] Studies have suggested that peak postexercise cortisol concentrations are reached earlier in trained horses and that trained horses have a faster cortisol recovery time.[20,79,80] On average, peak cortisol levels were observed at about 30 minutes post exertion.[20,79,80]

Pancreas

The pancreas is a V-shaped organ that lies along the duodenum.[2,5,20] Structurally, most of the pancreas is composed of acini which function as exocrine cells, secreting digestive enzymes and bicarbonate into the small intestine via the pancreatic duct. The endocrine function of the pancreas is mediated by cells of the islets of Langerhans.[2,5,20] These specialized cells are arranged as branching cords surrounded by a large network or plexus of capillaries.[2,5,20] The cells are classified into three types: the α-cells which produce glucagon, the β-cells which produce insulin and the δ-cells which produce somatostatin.[2,5,20] Of those hormones, the most important during exercise are insulin and glucagon and their actions in the control of glucose metabolism.

Insulin

Insulin functions as part of the feedback system controlling blood glucose concentration.[2,5,20] Insulin is synthesized by the β-cells of the pancreas and is primarily a glucose 'storage' hormone because it facilitates glucose uptake by the cells, promotes glycogenesis and inhibits gluconeogenesis.[2,5,20,85,86] At rest insulin is the 'key' that opens the cellular door to allow uptake of glucose.[2,5,20] However, during exercise the working muscles take up glucose without insulin.[5,20] Thus, insulin is very important during the recovery from exercise when glycogen repletion is most active.[2,5,20,87–89]

The insulin response to acute exercise has been well documented with the horse, like humans and other species, suppressing insulin during exercise.[20,76–78,80,90–96] This suppression appears to have a threshold of 50% of $\dot{V}O_{2max}$ which coincides with the increase in catecholamines seen during exercise.[1,20] Recent more mechanistic studies have demonstrated the link between exercise-induced increases in sympa-

thetic drive and changes in insulin and glucagon secretion in the horse.[95,96] Functionally this allows the animal to increase gluconeogenesis to maintain blood glucose concentrations during exercise.[5,20,95,96] Glucose mobilized during exercise can be taken up by the muscles with insulin; however, endurance performance appears to be limited by central fatigue mechanisms more than peripheral fatigue.[5,20,95,96] Suppression of insulin and maintenance of blood glucose concentration prevent the onset of central mechanisms of fatigue.[6,71] Much of the recent work on the insulin response to exertion has centered on the composition and timing of pre-exercise feeding.[74,97–105] High-carbohydrate feeds are beneficial for optimal muscle glycogen synthesis to fuel exercise; however, the resultant increase in blood glucose seen after a horse eats a high-carbohydrate ration usually evokes an increase in insulin secretion.[102, 104–106] The goal of recent research has been to prevent this feed-induced spike in insulin that would tend to decrease blood glucose directly before or during exercise.[102,104–107] Training appears to alter the insulin response to exercise, enhancing the ability to synthesize glycogen during recovery.[20]

Glucagon

The functions of glucagon are in opposition to insulin in that it stimulates gluconeogenesis and inhibits glycogenesis.[2,5,20] Glucagon is one of many hormones needed for substrate mobilization and thus it increases during exercise in the horse.[76–78,85,108,109] As such, glucagon is important for maintaining glucose concentrations during exercise, a role that is especially important during endurance activities where a drop in blood glucose concentrations leads to the onset of central fatigue.[2,5,20] Published data from several studies have demonstrated that endurance horses have an increase in glucagon.[76–78] This increase in glucagon is also altered by exercise intensity and its release appears to be under the influence of the increases in sympathetic drive and the catecholamines.[96] Training appears to alter the glucagon response to exercise, enhancing the ability to mobilize glucose during exertion.[5,20]

Other pancreatic hormones

Other hormones produced by the pancreas and associated with both endocrine and exocrine pancreatic function may play an important role in modulating substrate disposition during and after exercise.[110] These hormones include pancreatic polypeptide, somatostatin of pancreatic origin, amylin and galanin.[110]

Pancreatic polypeptide Pancreatic polypeptide does not appear to affect insulin or glucagon concentrations. However, comparative studies have suggested that pancreatic polypeptide affects digestion.[110] Hall and co-workers[109] point out that pancreatic polypeptide (PP) inhibits pancreatic exocrine function and bile secretion, an observation that they considered appropriate for a horse during long-term exercise when food intake would tend to be minimal. Information regarding the effect of exercise on pancreatic polypeptide is minimal. However, in one study Hall et al[109] demonstrated that PP increases in the endurance horse from concentrations averaging 20 pmol/L at rest to levels as high as 102 pmol/L after an 80 km ride. Lower concentrations seen after a 42 km race would suggest a dependence on duration which may be related to the degree of hypoglycemia seen in the horses post exertion.[109] These results are similar to those seen in other species.[110] We are unaware of any published studies that have examined the effect of exercise intensity in the horse.

Somatostatin Somatostatin is produced in the hypothalamus, the gastrointestinal tract (see below) and the pancreas. It is well recognized that the somatostatin produced in the hypothalamic region of the brain inhibits somatostatin (i.e. growth hormone) as well as thyrotrophin release.[109] Somatostatin of pancreatic origin is produced by the δ-cells of the pancreas and functions locally, to alter pancreatic function, and regionally to possibly alter blood flow and also restrict nutrient absorption.[109] Hall and co-workers[109] have suggested that this fits with the well-documented reduction in splanchnic blood flow that occurs during exercise. A small but significant increase in somatotrophin concentration has been demonstrated during endurance exercise per se with no difference due to duration (42 versus 80 km).[109] This is consistent with studies of humans and other species.[110] Published studies of the horse have not examined the effect of exercise intensity on concentrations of somatostatin.

Amylin and galanin Amylin and galanin are two other substances produced by the pancreas that affect pancreatic function and influence pathways involved in insulin regulation.[110] Amylin is a 37-amino acid protein produced by the β-cells of the pancreas, whereas galanin is a 29-amino acid protein secreted by nerve cells in the pancreas.[110] These paracrine substances may be influenced by exertion; however, we are unaware of any published studies in horses or other athletic species.

Circulating gastrointestinal ('gut') hormones

Several other substances with endocrine and paracrine function are secreted by the digestive tract.[110] These substances alter digestive function and thus may influence digestion and the absorption of substrate during exercise.[110] Included in this complex array of modulatory substances are gastric inhibitory peptide (GIP), vasoactive intestinal polypeptide (VIP), gastrin, somatostatin, secretin, enteroglucagon, motilin, cholecystokinin (CCK, see also below), the enkephalins, the endorphins, substance P, gastrin-releasing peptide, neuropeptide Y, peptide YY and neurotensin.[110]

Gastric inhibitory peptide

This is a 42-amino acid peptide that has a dual action, inhibiting gastric acid production and stimulating insulin secretion.[110] Exercise does not alter GIP in humans; however, consumption of glucose during recovery appears to result in decreased concentrations of GIP in humans. Hall et al[109] reported that plasma GIP concentrations were not altered during endurance exercise (42 and 80 km). However, those

results should be looked at with caution as the authors had relatively low animal numbers. The longer endurance competition did result in a non-significant decline in plasma GIP concentration from approximately 75 pmol/L before exercise to 50 pmol/L after 80 km.[109] The decline in GIP and its insulin secretagogue action would be consistent with the substantial and significant suppression of insulin concentrations reported in those same horses.

Vasoactive intestinal polypeptide

A 28-amino acid peptide acting as a neurotransmitter that is secreted by nerve fibers in the GI tract.[110] Multiple actions of VIP include vasodilation, stimulation of glucagon secretion and enhancement of the stimulation of substrate release through lipolysis and hepatic glycogenolysis.[110] Endurance exercise has a pronounced effect on VIP secretions, with increases in plasma concentrations that appear to be affected by exercise duration.[109,110] Teleologically this fits with the energy substrate needs associated with prolonged exercise.

Gastrin

This is a 10-amino acid peptide that stimulates gastric acid secretion that is affected by prior ingestion of food.[110] Limited data are available on the effects of exercise on the plasma concentration of this hormone in the horse.[109] Human studies[110] have not reported increases in gastrin due to exercise but in a paper on horses by Hall et al,[109] while plasma concentrations of gastrin were not altered by a 42 km endurance ride, they were substantially increased following a longer 80 km ride. One would presume, though, that the horses in the longer ride went for a longer time without food intake and therefore, this increase in gastrin secretion would seem unwarranted. However, one wonders if this paradoxical increase contributes to excessive acid production and gastric ulcer formation when food is withheld from a horse for a long period of time.

Other gastrointestinal peptides with endocrine or paracrine actions

Most of these substances have not been studied in the horse; however, comparative studies have shown that they have localized action within the gastrointestinal tract. Many of these substances have been characterized as neurotransmitters that act on local tissues, altering membrane transport, stimulating motility and, in some cases, stimulating acid production.[110] For example, gastrin-releasing peptide is a 27-amino acid peptide that is also referred to as bombesin.[110] This protein stimulates gastrointestinal motility and the release of gastrin.[110] Secretin and enteroglucagon are both 29-amino acid hormones that inhibit acid secretion in the stomach.[110] Comparative studies have shown that there is an increase in peripheral blood collected after exercise in both humans and dogs.[110] Motilin has been shown to increase with exercise in humans.[110] This 22-amino acid peptide stimulates motility of the gastrointestinal tract.[110] Interestingly the enkephalins appear to have the opposite effect, decreasing motility.[110] Other peptides like substance P, neuropeptide Y and peptide YY appear to alter GI tract motility but little is known about changes during exercise.[110] Interestingly, the functional link between all the GI tract hormones appears to be their actions on motility and possibly transport.[110] These actions may make them inportant for the uptake of water, electrolytes and energy substrates during and after exercise.[110] Finally, neurotensin is a 10-amino acid GI hormone with an unknown role; however, studies have shown that it increases during exercise in humans when a glucose solution is consumed but not when water alone is consumed.[110]

Hormones related to appetite and energy balance

Maintaining energy balance is crucial for the optimal health and performance of exercising horses. The energy expended during exercise directly affects energy homeostasis, because the horse has to increase energy intake in order to compensate both for the energy lost during exercise and for the energy required for the recovery and repair of tissues. Although the neuroendocrine control of energy balance has been studied extensively in humans and rodents, it is just beginning to be examined in horses. Examples of some of the endocrine mediators measured to better understand the control of energy balance are the hormones leptin, adiponectin, ghrelin and cholecystokinin.

Leptin

Leptin is an adipocyte-derived hormone, a 16 kDa protein product of the *ob* gene, that acts as an indicator of energy balance.[111–113] Sensed levels of leptin influence neural transmission in brain pathways, affecting food intake and energy utilization.[114] Basically, high levels of leptin increase energy expenditure while decreasing food intake and vice versa.[114] Food intake is altered by leptin influencing responsive neurons in the brain that activate either a feeding or satiety system.[114] The feeding or orexigenic system contains neuropeptide Y, agouti-related protein, and other hormones and neurons that signal an animal to increase food intake while the satiety system involves neurons containing pro-opiomelanocortin and α-melanocyte stimulating hormone as well as others that decrease food intake.[115] Leptin increases energy expenditure by stimulating the sympathetic nervous system in brown adipose tissue, directly increasing the expression of uncoupling protein 1, and by possibly increasing the expression of uncoupling protein 3 in muscle.[116] Furthermore, leptin strongly stimulates triglyceride and fatty acid cycling by increasing lipolysis and fatty acid oxidation.[117] Leptin is secreted in proportion to fat mass,[117] although massively obese humans seem to be 'resistant' to leptin's slimming propensities.[111,119]

In horses, plasma leptin is positively correlated with percent fat mass and body condition score.[120,121] Leptin has also been found to have a seasonal variation in both young and old mares, with plasma leptin levels increasing in the summer and decreasing in the winter, in correlation to body-weight and percent fat mass.[122] Furthermore, 24-hour fasting decreases plasma leptin levels in young and mature mares.[123] Interestingly, one study showed serum concentrations of leptin were higher in geldings and stallions versus mares, which is incongruent with human literature in which females have higher leptin levels than males, with differences not completely explained by a greater percent fat mass in females.[121,124] In rats, recent research demonstrated that male rats had higher leptin concentrations in the blood than female rats.[125] The reason for the discrepancy between species is unclear.

With regard to exercise, there have been some interesting findings in humans on how the type and duration of exercise affect energy balance and leptin concentrations in the blood. To date, no such studies have been published in horses. In humans, however, studies involving short-term exercise (< 60 min) with varying intensities have generally shown no change in leptin concentrations due to exercise.[126,127] Studies that have reported changes in leptin concentration with short-term exercise have attributed the changes to hemoconcentration or circadian rhythm.[128,129] It is possible that short-term exercise does not cause a sufficient kilocalorie deficit to produce a disruption in long-term energy balance. Also, the interaction between other hormones (e.g. cortisol, insulin, glucose, epinephrine and norepinephrine) that fluctuate during exercise and have been found to either stimulate or inhibit leptin secretion remains to be determined.[1,129,130]

Long-term exercise (≥ 60 min) of varying intensities has been shown to decrease or cause no change in leptin concentrations.[131–133] Interestingly, studies showing reductions in leptin increased sampling times for up to 48 hours after exercise, with a reduction in the 24-hour mean and amplitude of the circadian rhythm of leptin.[130,134] It appears that long-term exercise, in well-controlled studies, provides enough of an energy deficit to decrease leptin levels, which in turn will increase food intake to help maintain energy balance.[135]

Training is another aspect of exercise that is of interest to scientists studying leptin concentrations and energy balance. Training regimens have had different effects depending on duration and intensity of exercise and subjects used. Briefly, training for less than 12 weeks generally causes no change in leptin levels, although type II diabetic individuals did show a reduction in leptin concentrations after 6 weeks of low-intensity walking and cycling, independent of body composition changes.[136,137] Training regimens for longer than 12 weeks can cause a reduction in fat mass, which lowers leptin levels, yet some studies report a reduction in leptin independent of fat mass changes.[138–140] Additionally, it appears that females are more sensitive to the training effect on leptin levels, with several studies showing female subjects, yet not their males counterparts, demonstrating lower leptin concentrations in response to training.[141]

Leptin has several potential roles in terms of the health of exercising horses. As a signal of energy homeostasis, leptin concentrations in horses can help scientists to determine if a horse is in positive or negative energy balance and can provide supportive data regarding a horse's body condition and percent fat mass. Negative energy balance is detrimental to exercise performance, reproductive status and overall health.[142] Furthermore, determining how exercise and training affect leptin concentrations in horses will allow better understanding of how horses regulate their energy balance so that training regimens and diets can be adjusted accordingly to optimize the health of the athlete.

Adiponectin

Adiponectin is another hormone secreted from adipocytes, with its role in metabolism related to the regulation of glucose, insulin and adipocyte metabolism.[143–145] In contrast with leptin, adiponectin levels are decreased in obese and insulin-resistant humans and animals.[146,147] With regard to exercise, adiponectin may have a role in the increased insulin sensitivity seen as a result of training in both humans and horses.[148–151] In a study of humans undergoing exercise training, however, plasma adiponectin concentrations did not change relative to the increased insulin sensitivity due to training.[152]

In horses, adiponectin is negatively correlated with percent fat mass in yearling fillies and mature mares.[120] The study of adiponectin in horses is of importance as it is likely related to the insulin resistance commonly seen in older horses and horses with pituitary adenomas. Studies have shown that older mares with impaired glucose tolerance were able to improve their insulin sensitivity with 12 weeks of training.[149] It would be of interest to determine if adiponectin has a role in this insulin-sensitizing phenomenon.

Ghrelin

Another hormone involved in the control of appetite and energy balance is ghrelin, a protein hormone secreted from the stomach which was first discovered as a potent growth hormone secretagogue.[153] Ghrelin has received most of its attention, however, due to its role in initiating food intake in humans and rodents.[154] In meal-fed animals, including humans, rodents and sheep, ghrelin increases before meal feeding in anticipation of the meal and will also increase during times of fasting.[155–157] In rats, ghrelin stimulates gastric acid secretion in the stomach.[158,159] Few studies to date have examined the role of ghrelin in relation to exercise, in any species. One study in humans, however, demonstrated that ghrelin levels did not change during submaximal aerobic exercise in healthy adults,[160] although the paper was focused on the relationship between ghrelin and growth hormone released during exercise and not that between exercise, ghrelin and food intake.

It would be valuable to attempt to study ghrelin in horses as it may have a significant role in helping horses to maintain

energy balance. In addition, high performing equine athletes often have problems with inappetance and gastric ulcers that may be related to abnormal ghrelin concentrations and ghrelin's stimulation of gastric acid.[161] Humans with anorexia exhibit higher ghrelin concentrations than their normal counterparts, with a presumed 'ghrelin resistance' contributing to the cachexia of this eating disorder.[162,163]

Cholecystokinin

The peptide hormone cholecystokinin (CCK), secreted from the small intestine, is involved in energy balance by signaling fullness and decreasing food intake in humans, rodents and ruminants.[164–167] To date, there has been little published data on cholecystokinin in horses but this hormone may play a role in the inappetance commonly seen in heavily exercised horses. In a study conducted in humans, exercise increased plasma CCK concentrations fourfold. Although CCK values returned to normal at the end of exercise, equine researchers have speculated that CCK concentration may increase in response to exercise in horses and remain elevated, contributing to a lack of interest in feed by some equine athletes.[168]

Finally, it must not be ignored that there is also an interaction between many of the above-mentioned hormones in relation to energy balance. For example, CCK enhances the effect of leptin administration on weight loss and the pair may directly decrease food intake.[169,170] Leptin and adiponectin, although expressed in opposite concentrations to one another, may be regulated similarly for short-term alterations, yet differently for long-term regulation.[112] Ghrelin, on the other hand, is upregulated during leptin therapy, although these increases in ghrelin are not able to overcome the food intake depression caused by leptin.[171,172] Hence, it is clear that these endocrine mediators should not just be studied in isolation but collectively to determine how they regulate various systems.

In conclusion, the regulation of energy balance in horses and how it is affected by exercise is a field that has yet to be investigated in depth. On the other hand, data published in humans and other species demonstrate the importance of such research, especially with regard to gastric ulcer syndrome and the inappetance commonly seen in heavily exercised horses and obesity and insulin resistance seen in many older horses. It is hoped that future research in this field will elucidate the characterization of energy balance in horses, how this equanimity is maintained in response to exercise and ways in which management practices can be changed to help horses remain in energy balance and achieve optimal performance and health.

Kidneys

Filtration of the blood and conservation of vital substances are the most obvious functions of the kidneys.[41,61] However, their close link with the control of cardiovascular function is more complex and multifaceted. The basic filtration unit is the kidney glomerulus.[41,61] Each of these glomeruli has a specialized group of cells referred to as the juxtaglomerular apparatus (JGA),[41,61] which has more specialized cells that act as feedback sensors in monitoring flow (and pressure), sodium and chloride concentration, and arterial P_{O_2}.[41,61] The major hormone produced by the kidney is renin, the activating substance in the renin–angiotensin–aldosterone cascade which has the potential to alter blood presssure, volume and tonicity.[41,61] The kidney also produces erythropoietin which acts on precursor cells in the bone marrow to stimulate red blood cell production. Both of these hormone systems play an important role in the defense of normal cardiovascular function.[41,61]

Plasma renin activity (PRA)

Renin is a hormone released by the JGA of the kidney. It facilitates the conversion of angiotensinogen into angiotensin I, which is converted in the lung to angiotensin II, a vasoconstrictor that also stimulates the production and release of aldosterone.[38,39,41,45,173] During exercise, PRA is a measure of the rate of angiotensin I generation.[38,39,41,45] Angiotensin I and angiotensin II are powerful vasoconstrictors involved in the control of MAP and blood flow during exercise.[38,39,41] After exercise, renin can directly affect renal function and angiotensin stimulates thirst and drinking, thus altering post-exercise fluid balance.[38–40,45,174] Three major mechanisms that may account for the increase in PRA during exercise are renal nerve stimulation via increased sympathetic drive, changes in renal blood flow and pressure associated with juxtaglomerular function, and changes in electrolyte (sodium and chloride) concentrations at the JGA in the kidney.[38–41,45,173]

Previous studies have measured PRA in horses at rest, after exercise training, during steady-state exercise or after brief maximal exercise.[42,45,61–65,68] A strong linear correlation exists between work intensity (and duration) and increases in PRA, and HR were reported up to treadmill speeds of ~ 9 m/s.[45] Above 9 m/s, HR and PRA reached a plateau and did not increase when speed was increased from 9 to 10 m/s.[45] In previously published studies of horses, PRA increased from 1.9 ± 1.0 ng/mL/h at rest to a peak of 5.2 ± 1.0 ng/mL/h at 9 m/s.[45] The observed concurrent plateau in PRA and HR rate supports the suggestion that the increase in PRA during exercise in the horse is linked to sympathetic drive. Such is the case in other species where mechanistic studies have demonstrated a correlation between renal sympathetic nerve activity and PRA.[38,39,41,173] During steady-state submaximal exercise, the major factor stimulating an increase in PRA early in exercise was an increase in sympathetic drive.[38,39,41,61] However, a secondary increase in PRA was seen in horses after 40 min of exercise and was most likely due to a decrease in plasma Cl^- concentration, which fell significantly during this period, and not plasma $Na,^+$ which remained constant.[42]

Functionally, an increase in PRA during exertion has been shown to result in an increased plasma angiotensin II concentration.[38,39,41,61] Interestingly, horses given the angiotensin converting enzyme inhibitor enalapril had significantly lower plasma angiotensin II and aldosterone

concentrations and pulmonary artery pressures during exercise compared to horses given a placebo.[68] These later observations demonstrate that the renin–angiotensin cascade plays a role in the control of blood pressure during exercise in the horse.

Erythropoietin

Erythropoietin (EPO) is a peptide hormone that is produced by the kidneys in response to hypoxia sensed by pericellular cells positioned in the vasculature of the renal matrix.[175–178] Recent papers have documented the effects of a variety of perturbations, including the effects of blood loss, acute exercise and altitude, on EPO production in humans.[175,176,179] If cardiopulmonary adjustments are insufficient to prevent hypoxemia and if the above-mentioned perturbations are large enough to cause a decrease in renal arterial partial pressure of oxygen (Pa_{O_2}), then plasma EPO concentrations increase and there is a subsequent stimulation of erythropoiesis in humans.[175,176,179] The resultant increase in red blood cell volume would be expected to couple with other compensatory mechanisms to return arterial P_{O_2} back up to normal levels.

McKeever et al[180] recently reported that acute exercise does not appear to stimulate an increase in plasma EPO concentration in normal horses. This is similar to observations made in several studies of humans which demonstrated that neither the intensity nor the duration of acute exercise alters plasma EPO concentrations in humans.[181–183] Teleologically this makes sense because one would speculate that if acute exercise caused substantial increases in EPO production and release, then repeated exercise (i.e. training) would cause a sustained increase in EPO.[184] Any such hypothetical repeated increase in circulating EPO concentration would be expected to cause a sustained stimulation of erythropoiesis. Taken a step further, this would eventually cause a red cell hypervolemia and potentially detrimental increases in blood viscosity. Mechanistically, the acidosis of exercise appears to inhibit EPO production.[185]

Altitude appears to cause a transient increase in plasma EPO production in humans and horses.[5,180,186,187] However, in horses, plasma EPO concentrations increased only during the first 3 hours of the first day at 3800 meters.[180] This is similar to studies of humans which have reported a 'temporary rise' in EPO concentrations in mountaineers at both 4900 and 7600 m.[186] One explanation for this rapid return to baseline concentrations is a rapid compensation of cardiorespiratory mechanism to the challenge of altitude that would tend to limit changes in Pa_{O_2} at the kidney.[186] Interestingly, exercise performed at altitude did not induce a secondary increase in plasma EPO concentration.[180] The authors concluded that hypobaric hypoxia positively affects EPO production in the horse rapidly upon the first day at altitude with a rapid return to prealtitude concentrations.[180] Their data suggest that horses have an innate ability to tolerate the acute challenges induced by exercise and altitude.

Interestingly, administration of recombinant human erythropoietin (rhEPO) has been shown to increase hemoglobin concentration and exercise capacity in humans with chronic renal failure.[188–190] Small doses of rhEPO have been found to increase hemoglobin concentration by 30% and increase endurance performance anywhere from 10% to 19% in healthy human subjects.[188–190] Purportedly, some human athletes and/or their trainers have decided to use higher than recommended doses of erythropoietin with the rationale that the more rhEPO injected, the greater the increase in aerobic capacity.[188–190] Injections of rhEPO have been shown to elevate resting hematocrit to levels greater than 55% in humans, which increases blood viscosity and clotting and enhances the risk for heart attack or stroke.[188,190] Rises in hematocrit increase blood viscosity and may have caused excessive increases in blood pressure and clotting problems related to the deaths of human athletes in Europe.[188,190]

Unfortunately, these practices have entered equine sports medicine, with clinicians, horse trainers and racing commission personnel reporting that this drug is being misused in race horses to improve performance through an increase in blood volume and oxygen-carrying capacity.[178,191,192] However, two major problems can develop in horses.[175,178,193] First, while the horse can tolerate hematocrits of 50–60% during exercise, no one knows what happens to a horse's cardiovascular system if the normal resting hematocrit is artificially elevated to values of 70–80%.[178,193] A large increase in resting hematocrit coupled with splenic reserve mobilization may produce dangerously viscous blood that may lead to sudden death during or after exercise.[178] If this increase in resting red blood cell volume were to be coupled with lasix-induced fluid losses the results could be devastating.[178] A second major potential problem associated with rhEPO misuse in the athletic horse is its reactivity with the horse's immune system.[178,193] Some horses have purportedly developed a life-threatening anemia associated with an immune reaction to both the exogenous rhEPO and the animal's own EPO.[178,193] Clinically, resting hematocrit has been seen to drop below 20% in horses reacting to rhEPO administration with some cases requiring blood transfusions to save the horse's life.[193]

Recently studies of splenectomized and intact horses have demonstrated that rhEPO administration in low doses causes substantial increases in resting hematocrit, red blood cell volume, maximal oxygen uptake, blood viscosity and selected hemodynamic variables during incremental exercise performed on a treadmill.[179,194] In splenectomized horses, administration of rhEPO in low doses (15 IU/kg) three times a week for 3 weeks increases resting hematocrit from 37% up to 46%.[194] The resulting 13% increase in red cell volume was associated with a 19% increase in $\dot{V}O_{2max}$ and substantial increases in blood viscosity.[194] Another study of intact horses also demonstrated that low-dose administration of rhEPO (50 IU/kg, three times/wk for 3 wks) increases red blood cell volume, $\dot{V}O_{2max}$ and the velocity at $\dot{V}O_{2max}$.[179] Viscosity was not measured in that study; however, postexercise hematocrits were in the low 70s and considered dangerously high.[179] Horses in that study also developed antibodies to the rhEPO (McKeever, unpublished data).

Heart and blood vessels

The heart and blood vessels play both a paracrine and endocrine role in the control of cardiovascular function.[3] While there are several mechanisms worthy of discussion, two hormones appear to play a major role during exercise: atrial natriuretic peptide and the endothelins.[3]

Atrial natriuretic peptide (ANP)

This is a hormone produced by the heart that is important in the regulation of blood flow and blood pressure during exercise.[3,195] Granules of ANP are stored within the walls of the atria and are released during atrial stretch.[3,196] Receptor sites for ANP have been identified in the posterior pituitary, the kidneys, vascular smooth muscle, adrenal cortex, heart and lung.[3,197] This hormone causes a rapid and profound vasodilation and a pronounced natriuresis.[3,197] ANP inhibits vasopressin, renin and aldosterone secretion and also inhibits the binding of aldosterone at the kidney tubule.[3,197]

On a practical level, ANP may be involved in accommodating the exercise-related shifts of blood volume in the horse.[3,44] Evidence for this is provided by two recent studies which demonstrated that plasma ANP increases in a linear fashion with increasing work intensity, from 5–10 pg/mL at rest to plasma concentrations exceeding 60 pg/mL at speeds eliciting $\dot{V}O_{2max}$.[3,197–199] Mean ANP concentration was strongly correlated with heart rate.[197] Furthermore, ANP increases during steady-state submaximal exercise, from ~ 10 pg/mL at rest to a peak of 40 pg/mL at 40 min, and remained elevated through 60 min of exertion.[3,42,200] Nyman and co-workers[199] presented similar peak plasma ANP concentration during steady-state exertion and reported that ANP concentrations were altered by hydration status. Horses that were hyperhydrated had the highest ANP concentrations during exercise compared to control and hypohydrated horses.[199] Another study found no differences between arterial and mixed venous ANP concentrations, suggesting that ANP is either not metabolized by the lung or is released from the left atrium at a rate matching pulmonary metabolism.[201] Even more recent work has examined the effects of exercise on ANP, with a special focus on its interaction between fluid and electrolyte status and other endocrine responses.[69,202] The authors concluded that ANP remains elevated post exercise and that this is a response to the exercise-induced increase in circulating blood volume rather than an interaction with vasopressin and the catecholamines.[69]

Endothelin

The endothelins are peptide hormones that have pronounced effects on neuroendocrine control of cardiovascular function.[203–206] The endothelins, ET-1, ET-2 and ET-3, are isoforms of a 21-amino acid polypeptide with pronounced effects on both central and peripheral control of cardiovascular function.[203–206] The three sequences of endothelin are structurally and pharmacologically distinct, arising from what has been called 'big endothelin', a 39-amino acid precursor molecule.[203–206] The half-life of ET-1 is very short, only a few minutes, which is consistent with its role in control of vascular tone.[205,206] Factors affecting the release and metabolism of endothelin include increased blood flow, vasopressin, angiotensin, shear stress and thrombin.[205–213]

Many studies have shown that ET-2 and ET-3 are limited in their vascular effects and that ET-1 has the most pronounced effect on peripheral vascular tone.[205,206,212,213] Endothelial cells produce ET-1 exclusively[205] and circulating levels of this hormone may play a role in certain forms of hypertension.[205,206,214] ET-1 and ET-2 (to a minor degree) are potent vasoconstrictors that can increase systemic arterial blood pressure and pulmonary arterial blood pressure and cause alterations in cardiac output and the distribution of blood flow in the peripheral circulation.[205,206] Thus, ET-1 may affect the redistribution of blood flow and control of blood pressure during exercise. ET-3 appears to play a role in modulating the release of vasopressin from the hypothalamus, and Rossi[205] has shown that ET-3 amplifies free water excretion independent of renal and systemic hemodynamic and osmotic clearance and/or circulating vasopressin concentrations.

Resting plasma concentrations of immunoreactive ET-1 measured in horses appear to be similar to the relatively low concentrations reported for other mammalian species such as the rat, dog, pig, cow and man[205,206,210,213,215,217] and horses.[198,204,218–221] Studies of ET-1 in horses have focused primarily on either understanding its role in horses with respiratory disease[218–221] or aging.[198,204] In some of those studies, ET-1 was found to be elevated in blood and bronchiolar alveolar lavage fluid in resting horses with respiratory disease.[219,220] Many recent experiments have only reported on samples obtained either before and after exertion[219,220] or at rest and at the speed eliciting $\dot{V}O_{2max}$.[204] However, one recent study has examined plasma ET-1 concentrations in the horse during exercise rather than just collecting blood samples before and after exercise.[204] Samples taken while the horses were running a GXT revealed that during exercise there were no changes in plasma ET-1 concentration and there were no alterations due to increases in work.[204] Interestingly, while plasma ET-1 concentration did not change with increases in exercise intensity, it did increase substantially in samples collected immediately after the exercise stimulus was withdrawn and in blood collected 2 min following cessation of running.[204] However, plasma ET-1 concentrations were back to normal by 10 min.[204] This rapid response may be physiologically significant as it coincides with the rapid recovery and transient decreases in cardiovascular function reported in other studies of horses that have involved protocols with a quick stop of the treadmill.[3,68]

Similar postexertion increases in plasma ET-1 concentration have also been reported in studies of normal humans and in studies where the subjects had various diseases affect-

ing the vasculature.[211–213,216] In one of those experiments even greater increases in plasma ET-1 concentrations were seen in dehydrated humans.[217] The greater increase in plasma ET-1 concentration due to volume depletion supports the suggestion that ET-1 plays a role in the modulation of vascular tone in the defense of mean arterial pressure.[206] Thus, the postexertion increase in plasma ET-1 concentration observed in horses[204] sampled before and after exercise is consistent with previously published reports on the hemodynamic and endocrine responses to exercise in horses.[3,62,228] An increase in plasma ET-1 concentration following rapid cessation of prolonged exercise, at a time when postexertion blood pressure would be expected to fall, fits with the neuroendocrine response to other perturbations affecting vascular fluid volume, cardiac filling pressure and mean arterial pressure. This would be an appropriate response in the regulation of cardiovascular function during the transition from exertion to recovery when heart rate, cardiac output and blood pressure are declining rapidly in the face of exercise-induced vasodilation of vascular beds supplying the muscles.[64]

A great deal of information has been published documenting elevated resting plasma ET-1 concentrations in humans and rats with diseases, in particular in humans with COPD and pulmonary hypertension.[203,206,210,211,213–223] Data reported by Benamou et al[219] demonstrated that postexercise ET-1 concentrations were substantially elevated in the bronchoalveolar lavage fluid of horses with EIPH. In another study Benamou et al[218] demonstrated that ET-1 type A receptors mediate the vasoconstrictor action of ET-1 in the pulmonary and systemic circulations of the horse. However, data from another study[221] suggest that ET-1 is not a mediator of the acute hypoxic pulmonary hypertension response to exercise, but may serve as a modulator of the acute response or slower phase of hypoxic pulmonary hypertension response to exercise. More work is needed to determine if ET-1 plays a role in the etiology of exercise-induced pulmonary hemorrhage (EIPH), especially since some feel that increases in pulmonary artery pressure during exercise may contribute to EIPH.[223,224]

Gonads and reproductive hormones

The reproductive hormones are essential for the health and well-being of a mare or stallion. However, exercise performance is not affected per se by the reproductive hormones. Nevertheless, recent human research has focused a great deal of attention on the effects of exercise on the female reproductive cycle and the interaction of prolactin, LH, FSH, estrogen and β-endorphin.[5] Human work has also examined the effects of acute exercise on the health of pregnant women. More work is needed in the horse to determine if exertion affects these hormones, especially in endurance horses and in pleasure horses that are ridden while they are in foal.

Endocrine mediation of short-term control of cardiovascular function

The cardiovascular response to exercise is dependent on a multisystem defense of blood volume, MAP and plasma tonicity.[3] These mechanisms insure adequate blood flow to the working muscles and obligate tissues along with the provision of adequate fluid volume for sweating and thermoregulation.[1,3,5,38–40] The maintenance of cardiovascular homeostasis during exercise is mediated by neuroendocrine mechanisms which insure the system can meet the increased demand for blood flow to the working muscles during exercise.[1,3,38–40]

The anticipation of exercise in humans and horses can invoke a withdrawal of parasympathetic control and an increase in sympathetic nervous activity resulting in an increase in heart rate, force of contraction, stroke volume and cardiac output. Rowell[4] suggests that the 'range of parasympathetic control of the heart by central command determines the level of exercise at which the activation of the sympathetic nervous system occurs'. In horses, resting HR averages 30–40 bpm.[3] Initial increases in heart rate up to ~120 bpm are associated with the withdrawal of parasympathetic tone.[3] However, further increases in HR during exercise, up to maximal HR between 200 and 240 bpm, are associated with increases in sympathetic activity and catecholamine release.[3] This increase in HR, coupled with increased stroke volume from 0.7 L at rest to almost 2 L, results in a rise in cardiac output from an average of 30 L/min at rest up to nearly 300 L/min during maximal exercise.[3] The cardiovascular system responds to exercise with dramatic increases in heart rate and force of cardiac contraction and subsequent increases in stroke volume and cardiac output.[4] These central cardiovascular responses are rapid and concurrent with venoconstriction and arterial vasodilation in the working muscles.[4]

Adjustments in peripheral vascular resistance that are mediated by the cardiopulmonary baroreflex cause a redistribution of blood volume from 'storage' in highly compliant venous capacitance vessels into the arterial side of the cardiovascular system, enhancing venous return.[4] In the horse there is the added component of splenic reserve mobilization which further enhances venous return and circulating red cell volume.[3,58] Splenic contraction is mediated by direct stimulation from the sympathetic nervous system, through the action of norepinephrine and epinephrine on α-adrenergic receptors.[58] From 6 to 12 liters of blood can be delivered into the central circulation at the onset of exercise, allowing the equine athlete to reach a maximal aerobic capacity (145–200 mL/kg/min in fit horses) that is almost three times greater than that of human athletes.[3,58] This extra volume is rapidly accommodated through arterial vasodilation which is mediated by increases in sympathetic

neural outflow and ANP and through local chemoreceptor mechanisms.[3,44] Resequestration of the splenic reserve is prevented by the action of vasopressin and the catecholamines on splenic arterioles.[46]

Mean arterial blood pressure increases with exercise intensity, a response essential for increasing cardiac output in the face of decreases in resistance in the vascular beds of the working muscles. Rowell[4] suggests that in addition to input from the cardiopulmonary baroreceptors, a functional arterial baroreflex and muscle chemoreflexes are essential for the regulation of heart rate, cardiac output and arterial pressure during exercise. Rowell[4] further suggests that the operating point of the arterial baroreflex is 'reset during dynamic exercise with adjustments in autonomic tone to compensate for the mismatch between cardiac output and vascular conductance'.

Modulation of the blood flow and blood pressure response to exercise involves input from both the high- and low-pressure baroreceptors. The low-pressure (cardiopulmonary) baroreceptors are volume receptors located primarily within the atria and the pulmonary circulation.[3,4] At the start of exercise, increased venous return results in atrial stretch, eliciting a neuroendocrine response by the cardiopulmonary baroreceptors. Nerves within the atria serve as stretch receptors, sensing volume overload or underload. The output from these nerves is conducted centrally via vagal afferents and integrated into the central control of peripheral vascular tone.[3,4] The endocrine component of this baroreflex involves the release of ANP, a hormone with potent vasodilatory properties and a reflex decrease in vasopressin release.[3,195]

Even with the mobilization of reserve blood volume, the demands of high-intensity or long-duration exercise may exceed central cardiovascular capacity. Baroreceptor control of arterial tone becomes vital to the maintenance of cardiac output and MAP and sympathetic-induced vasoconstriction decreases blood flow to non-obligate tissues during high-intensity exercise.[3,4] This response is even more pronounced during long-term exercise when fluid losses associated with sweating compromise vascular fluid volume and venous return. Without replacement or compensation, decreases in venous return associated with fluid losses can cause a decrease in cardiac output and decreased blood flow to the working muscles and to the vascular beds associated with thermoregulation.[3,4,40] To maintain MAP, the body compensates by increasing heart rate and contractility, a phenomenon termed cardiovascular 'drift' that is associated with an increase in sympathetic activity and circulating catecholamines.[57]

Exercise training produces chronic adaptations in the cardiovascular system that are mediated through changes in neuroendocrine control.[3,37,38,40] Work from several species has shown that exercise training produces an expansion of plasma volume.[40,65,72,225] Trained horses have significantly greater blood volumes than untrained horses[40,58,65,72] with increases in plasma volume of 30% observed after only 1 week of exercise training. Humans show significant alterations in sodium and water excretion that are attributable to repeated exercise-induced increases in plasma aldosterone concentration.[40] In the one study of the hypervolemic response in horses, the authors reported no change in resting plasma aldosterone concentration or sodium excretion; however, their measurements were taken at 1-week intervals and may have missed changes in sodium excretion that are reported to occur in the first days of training in humans.[65] A more recent study that focused on changes occurring during the first days of training demonstrates that plasma aldosterone concentration remains elevated for almost 24 hours during the first days of training.[72] It appeared that, as in humans, an aldosterone-mediated retention of sodium and water by the kidneys and digestive tract is a vital part of the hypervolemic response to training in the horse.[40,72]

Endocrine control of metabolism during acute exercise

Performance of exercise requires the transduction of potential or stored energy into kinetic energy and the endocrine system plays an integral role in the co-ordination of the mobilization and utilization of carbohydrates and free fatty acids.[226,227] The need for a rapid provision of metabolic substrates to fuel exercise and to prevent central fatigue is facilitated by a rapid increase in sympathetic drive and the rate of catecholamine release from the adrenal medulla. The degree of this response is correlated with both exercise intensity and duration.[2,5,20] At the onset of exercise the catecholamines (epinephrine and norepinephrine) act on the liver and muscles to increase the rate of glycogen breakdown (glycogenolysis).[2,5,20] This results in an increase in circulating blood glucose concentrations. The catecholamines also stimulate the release of hormone-sensitive lipase which acts on triglycerides to mobilize free fatty acids.[2,5,20] The latter are important for endurance activities where the use of fat to fuel exercise spares glycogen by offsetting the amount of glucose needed to fuel the activity.[2,5,20] However, fat cannot be used alone as a fuel source as 'fat burns in the flame of carbohydrates'. An increase in circulating catecholamines also inhibits insulin and stimulates glucagon release. As with the catecholamines, glucagon also stimulates gluconeogenesis and inhibits glycogenesis,[2,5,20] thus playing an important role in maintaining blood glucose concentrations during exercise and delaying the onset of fatigue.[2,5,20] Glucagon can also stimulate the breakdown of protein and release of amino acids which can be used as a fuel source by the liver.[2,5,20] The effects of the catecholamines and glucagon can be augmented by the release of cortisol. The latter is affected by the intensity and duration of the activity.[2,5,20] Cortisol thus is a metabolic hormone that stimulates gluconeogenesis, fatty acid mobilization and protein breakdown. In the case of the latter, amino acids not used to fuel exercise may provide resources for the synthesis of new proteins needed to repair muscle and replace enzymes used in the various metabolic pathways.[2,5,20]

CHAPTER 36

Nutritional management of the equine athlete

Raymond J. Geor

The owners, trainers and riders of horses engaged in competitive athletic events are motivated to apply management strategies that provide a performance advantage during competition. Such strategies may include novel nutritional interventions administered before or during an event. Although there may be merit in some of these approaches, more realistically nutrition has a larger impact on performance by supporting consistent conditioning and thereby promoting the physiologic and biochemical adaptations that will ultimately result in improved athletic performance. For any athletic horse, the primary goals of nutritional management should include:

- provision of substrates for maintenance of bodyweight and replenishment of energy reserves in working muscle and other tissues
- promotion of tissue adaptation, growth and repair
- promotion of general health and well-being
- application of competition feeding strategies appropriate to the athletic task.

Although these same general principles apply to all equestrian sports, actual feeding strategies may vary widely because of the different demands of training and competition. For example, whereas the consumption of a high-fiber (roughage) diet may be of benefit to an endurance horse via promotion of a large fluid reservoir in the hindgut, this strategy is not desirable in a race horse because excess gut fill may be energetically disadvantageous during high-intensity exercise. Similarly, the rationale for nutritional intervention immediately before and/or during competition will differ between disciplines. For an endurance athlete, feed consumption before and during a race may enhance energy supply and delay the onset of fatigue. On the other hand, for a race horse the consumption of a meal within 1–2 hours of the race start is less likely to substantially impact energy use and athletic performance.

This chapter provides an overview of the nutritional needs of athletic horses with suggested feeding strategies to meet these requirements. The dietary management of horses with chronic exertional rhabdomyolysis and the putative role of ergogenic feeding strategies and nutritional supplements are also discussed.

Nutrient goals

The overall goal of diet formulation is to develop a ration that delivers optimal amounts of all essential nutrients. The 1989 edition of the National Research Council's (NRC) *Nutrient requirements of horses* provides nutritional recommendations for all classes of horses, including those undertaking regular physical activity.[1] However, it is important to realize that these recommendations are considered to be minimal rather than optimal requirements. It should also be noted that there has been considerable research in the area of athletic horse nutrition since the last NRC publication, most notably in the area of dietary energy sources. Thus, while the 1989 NRC recommendations still provide a framework for ration formulation and evaluation, many nutritionists have developed their own set of nutrient standards that, based on more recent scientific literature and practical experience, provide optimal ranges of nutrients relative to the horse's physiologic state.

Energy

Undoubtedly, the most profound nutritional effect of regular physical activity is an increase in dietary energy needs relative to non-working horses. For bodyweight to be maintained, athletic horses must consume enough energy to cover

'maintenance' energy costs together with the energy costs associated with physical activity and the building and repair of muscle tissue. There are two primary considerations with respect to dietary energy in athletic horses: provision of sufficient energy to maintain bodyweight and condition; and the sources of energy (fiber and non-fiber carbohydrates, fats and oils, proteins) in the diet. The latter impacts body substrate stores, the metabolic response to exercise and, potentially, athletic performance. These issues are discussed later in the chapter (see Feeds for attainment of nutritional goals).

Estimating energy requirements

In most parts of the world, both energy requirements and the energy content of feeds are evaluated as *digestible energy* (DE). In North America, the horse industry uses the kilocalorie (kcal) as the standard unit of energy, whereas use of the kilojoule (kJ) predominates in Europe and much of the rest of the world (4.184 kJ = 1 kcal). Digestible energy is expressed as kcal (or kJ) per gram of substance or Mcal (or MJ) per kg.

Several definitions of the energy requirements for maintenance have been used. These include: the daily food intake that maintains constant bodyweight and composition of a mature horse with zero energy retention at a defined level of activity; and the amount of DE required for zero bodyweight change plus normal activity of non-working horses. The work of Pagan & Hintz[2] indicated that maintenance energy requirements varied linearly with bodyweight and not with metabolic body size ($W^{0.75}$). Therefore, these researchers developed the following equation for prediction of maintenance energy requirements of horses weighing 100–600 kg:

$$\text{DE (Mcal/day)} = 1.4 + 0.03\ W$$

where W is the weight (kg) of the horse. This equation overestimates the energy needs of large horses (< 600 kg) and ponies and miniature horses, and this author uses $W^{0.75}$ when estimating the maintenance energy needs of these animals. Alternatively, the NRC recommends that the following equation be used for estimating the maintenance requirement of horses with mature weights of more than 600 kg:

$$\text{DE (Mcal/day)} = 1.82 + 0.0383\ W - 0.000015\ W^2$$

Several factors can influence maintenance energy requirements, including the age, breed, gender and temperament of the horse, the level of activity, ambient conditions, and diet composition. Logically, therefore, 'book values' for maintenance energy needs based on these and other equations should only be considered a guide.

Similarly, there are no practical means for precise determination of the additional energy requirements of horses in exercise training. The intensity and duration of exercise, terrain, the weight of the rider and tack, the ability of the rider, the level of training of the horse, environmental conditions and diet composition will all influence overall energy needs. Pagan & Hintz[3] developed a prediction equation for the estimation of the DE required above maintenance using oxygen consumption ($\dot{V}O_2$) data collected from horses running on a level track:

$$\text{DE (kcal per kilogram of horse, rider and tack)} = \{[e^{(3.02 + 0.0065\ Y)} - 13.92] \times 0.06\}/0.57$$

where Y is the speed (meters per minute) and 0.57 accounts for the efficiency of utilization of DE. Although this equation may be useful for horses exercising on level ground and an even surface, the wider applicability of this approach is questionable given the need to measure running speed and the variation in terrain and footing conditions in which horses train and compete. Use of the equation developed by Pagan & Hintz[3] underestimated by 30–35% the daily energy requirement of horses exercised on a treadmill for 60–75 min at 50% of maximum aerobic capacity ($\dot{V}O_{2max}$).[4,5] In the future, the availability of systems for valid field measurements of oxygen consumption in horses undertaking different exercise tasks under a variety of conditions may facilitate development of more precise prediction equations. However, it is unlikely that such equations will account for all of the factors influencing energy requirements. As such, ongoing clinical assessment of bodyweight and condition will remain the most practical means for assessment of energy balance in horses.

In 1989 the NRC recommended that daily energy intake be increased 25%, 50% and 100% above maintenance requirements for horses performing, respectively, light, moderate and intense work. These recommendations were based on data from experimental studies, feeding surveys and practical experience. Light work might include equitation and other forms of pleasure riding, while horses engaged in racing, hunting, three-day events and endurance racing would fall into the intense category (Table 36.1). Although these guidelines are clearly very general in nature, the results of field studies in working horses have provided evidence that the 1989 NRC recommendations are a useful guide for estimation of energy needs in horses in moderate and intense work.[6,7] For Standardbreds (mean bodyweight [bwt] of approximately 450 kg) and Thoroughbreds (mean bwt 500 kg) in race training, the NRC recommendations are 28.8 Mcal/day and 33 Mcal/day.[1] Consistent with these recommendations, Gallagher and co-workers estimated DE intakes of 28–31 Mcal/day for Standardbreds[8] and 31–36 Mcal/day for Thoroughbreds[6] in North American race stables. Similar DE intakes were reported for Australian

Table 36.1 Estimated digestible energy (DE) requirements for a 500 kg horse at four different levels of activity

Activity*	Examples	DE requirement (Mcal/day)+
Maintenance	Horse at pasture	16–17
Light	Pleasure riding, equitation	20–21
Moderate	Reining, showjumper or hunter	25–26
Intense	Race horse, three-day event, endurance	32–34

* According to the 1989 NRC classification of activity level
+ Mcal = megacalorie

Standardbred and Thoroughbred race horses.[7] Taylor et al[9] reported that 420 kg Arabian horses undergoing treadmill exercise 3–4 days per week maintained bodyweight when fed 19–22 Mcal DE/day, equivalent to the NRC recommendation for horses in moderate work.

The effects of body condition and composition on athletic performance

In humans, there is a strong inverse relationship between body fat content and both sprint and endurance running performance. Although data from horses are limited, there also is evidence that body composition is an important determinant of athletic performance. Kearns et al[10] used B-mode ultrasound of the rump area to calculate percentage of body fat and fat free mass (FFM) in 14 racing Standardbreds. Males had less fat mass (7.4% bwt) when compared to the females (9.9% fat). Interestingly, percentage fat mass was negatively correlated to race performance in the males but not the female horses of the study, a finding consistent with data in humans. However, for both genders, FFM was negatively correlated with race time (i.e. the higher the FFM, the shorter the race time). The authors concluded that while a low fat mass is beneficial to race performance, it is more important to possess a larger FFM.[10] A larger FFM is indicative of a greater muscle mass and, therefore, greater potential force development. Using similar methodology, this research group has demonstrated that maximum aerobic capacity ($\dot{V}O_{2max}$) is also significantly related to FFM, independent of body mass.[11]

Lawrence and colleagues[12] also used rump ultrasound to assess the relationship between body composition and endurance race performance. The average body fat content of the horses of this study (7.8%) was similar to that reported by Kearns et al[10] for Standardbred race horses. Top finishers in a 150-mile race had a lower fat mass (by approximately 20 kg) when compared to horses that could not complete the event. Taken together, the results of these studies provide evidence that excess body fat is detrimental to sprint and endurance running performance.

On a more practical level, condition scoring is a useful clinical tool for the assessment of body fatness. Although several scoring systems have been used, the version developed by Henneke and colleagues at the Texas A & M University is the most widely used (Table 36.2).[13] There are a few studies that have reported body condition score (BCS) in horses involved in different activities. In the aforementioned study by Lawrence and co-workers,[12] the mean BCS of horses in an endurance race was 4.67 (using the 1–9 scale). Gallagher et al reported that Standardbred and Thoroughbred horses in training had, respectively, mean BCS of 5.7 and 5.0.[6,8]

Recent studies of endurance horses competing in the 100-mile Tevis Cup have provided evidence of a relationship between condition score and race performance.[14] The mean BCS of horses that successfully completed the rides was 4.5, whereas horses that were eliminated for metabolic failure (e.g. colic, heat exhaustion, synchronous diaphragmatic flutter or tying up) had a mean condition score of 2.9. Horses that were eliminated for non-metabolic reasons such as lameness and overtime had a mean condition score of 4.3. The researchers were careful to point out that their results may not apply to endurance competition as a whole, given the difficult nature of the Tevis Cup course. Nonetheless, the implication from these studies is that there is an optimal level of 'fatness' for horses competing in endurance events and that training and feeding programs need to be adjusted accordingly. Endurance performance of horses with a low BCS (e.g. < 3) may be limited by the supply of energy from fat reserves. In addition, a loss of lean tissue (muscle mass) may

Table 36.2 A body condition scoring system for horses (adapted from reference[13])

Condition	Score	Description
Poor	1	Severe emaciation; bone structure is prominent, including cervical and lumbar vertebrae
Very thin	2	Emaciation; bone structure is still prominent but cervical vertebrae barely visible
Thin	3	Neck thin; junction of neck, withers and shoulder accentuated; pelvic structure remains prominent; transverse processes of lumbar vertebrae cannot be palpated
Moderately thin	4	Ribs prominent; spine still apparent but not individual vertebrae; neck, withers and shoulder normal
Moderate	5	Ribs are not visible but easily palpated; neck blends smoothly into withers and shoulder; flat back
Moderately fleshy	6	Neck, shoulder and withers appear more filled and rounded; back area may have slight depression (crease) along spine; tailhead and ribs with some flesh coverage
Fleshy	7	Fat deposited over withers and neck; crease along spine more visible; flesh over tailhead and ribs is prominent and soft
Fat	8	Thickened neck; well-defined crease along spine; ribs difficult to palpate; fat accumulation over rump
Extremely fat	9	Bulging fat in neck, withers and shoulder; prominent crease down back; patchy fat over ribs

contribute to diminished performance in horses with poor body condition.

Although further studies are needed in horses of different types, as a general recommendation the BCS of most athletic horses should fall between 4 and 6. The NRC recommendations should be used as an initial guide when making recommendations for DE intake in the face of changing work demands. Subsequently, however, frequent (e.g. weekly) assessment of bodyweight and/or BCS is necessary to determine the appropriateness of the feeding program; upward or downward adjustments in DE intake are often needed for maintenance of constant bodyweight. Trainers and/or owners should target a desired bodyweight or BCS, monitor these parameters on a weekly basis and adjust energy intake accordingly.

Protein

The dietary protein requirement of the horse is a function of the amino acid needs, the amino acid composition of the dietary protein and the digestibility of the protein. Horses have negligible ability to utilize non-protein nitrogen such that nitrogen needs must be provided in the form of protein or amino acids. Furthermore, it is thought that amino acids are not absorbed intact from the large intestine. Therefore, the horse's essential amino acid requirements must be met from protein sources that are digested in the small intestine. Whether, and to what extent, regular exercise increases the protein requirement is a controversial issue in both horse and human nutrition. Theoretically, higher turnover of muscle proteins in association with the rigors of regular exercise (oxidation of amino acids during exercise, protein synthesis to support muscle hypertrophy and tissue repair after exercise) and sweat nitrogen losses should increase protein requirements. Consistent with this hypothesis, studies in humans have demonstrated negative nitrogen balance at the onset of endurance training programs. However, within 7–10 days of the start of training the rate of leucine oxidation is attenuated and nitrogen balance approaches equilibrium, indicating adaptation in protein metabolism.[15] For the resistance-trained athlete, there also appears to be a homeostatic adaptation to the stress of exercise such that well-trained athletes require only marginally more protein than sedentary persons. For elite human endurance and strength athletes, a dietary protein intake that represents 14–15% of total energy intake (1.6–1.7 g protein/kg per day) has been recommended.[15] Protein intake above these levels has not been shown to be beneficial to human athletic performance.

Protein requirements of horses have been expressed as a function of bodyweight or in relation to DE intake. For maintenance, 1.3 g crude protein (CP) per kg bodyweight is recommended or approximately 40 g CP/Mcal DE daily. The NRC recommended that working horses receive the same dietary protein/calorie ratio, i.e. a race horse in intense training should consume twice the protein when compared to the non-trained state (2.5–2.6 g CP/kg/day or approximately 12% of dry matter intake).[1] This approach is practical with respect to ration formulation and the provision of dietary protein. However, some nutritionists have questioned the need for such high levels of dietary protein.[16,17] Specifically, it has been suggested that CP intakes greater than 2 g/kg bwt/day are detrimental to some forms of exercise because of the effects of excess dietary protein on heat production, acid–base balance, water requirements and, potentially, respiratory health. Oxidation of the phosphorus and sulfur in protein adds to the acid load on the body. In this context, Graham-Thiers and colleagues[16] evaluated the effects of a restricted protein diet (7.5% CP with added lysine and threonine) on acid–base balance in horses in moderate work. When compared to a 14.5% CP diet, protein restriction resulted in a slight increase in resting blood pH and mitigation of exercise-associated acidemia during repeated sprints. These effects may provide a performance advantage during exercise, although the actual effect of dietary protein level on exercise performance has not been determined.

There is evidence that dietary protein level alters urea metabolism in horses. In one study, horses consuming 1741 g CP per day (>3 g/kg bwt) excreted more urea in sweat and had higher plasma urea when compared to horses consuming 836 g CP per day[18] and it has been estimated that a change in dietary CP from 10% to 15% would increase water requirement by approximately 5% because of an obligate increase in urine production for clearance of endogenous urea loads.[17,19] Moreover, the higher urinary urea load could adversely affect the respiratory health of confined horses because urea is converted to ammonia, a known respiratory irritant.

Further research is needed regarding the protein requirements of athletic horses. Currently, a 10–12% CP diet is recommended for mature athletic horses. However, the recent studies by Graham-Thiers and co-workers[16] suggest that the 1989 NRC recommendations for dietary CP intake are not necessary for normal health and athletic function. Indeed, there may be advantages to a lower protein diet (8–10% CP), providing good-quality protein is fed.

Minerals and vitamins

Based on their daily requirements, minerals are usually classified as macrominerals (e.g. calcium, phosphorus, sodium, potassium and chloride) or trace elements (e.g. selenium, iron, zinc, copper). These nutrients are important in a large array of body functions. Several minerals and trace elements, such as magnesium, iron, zinc and copper, act as enzyme activators in glycolysis and oxidative phosphorylation. Minerals (electrolytes) are also critical to nerve and muscle function.

The classification of vitamins is based on their relative solubility: fat-soluble vitamins (A, D, E and K) are more soluble in organic solvents, whereas the B vitamins and vitamin C are more soluble in water. Most vitamins participate in processes related to muscle contraction and energy expenditure. Vitamins of the B complex group (e.g. thiamine, riboflavin, vitamin B_6, niacin, biotin and pantothenic acid) act as co-

factors for enzymes regulating glycolysis, the citric acid cycle, oxidative phosphorylation, β-oxidation of fatty acids and amino acid catabolism. Folic acid and vitamin B_{12} are needed for heme synthesis. The antioxidant vitamins (mainly vitamins C and E) participate in a buffer system against free radicals.

Many trainers, owners and veterinarians perceive that optimal mineral and vitamin nutrition is critical to successful athletic performance. One impression is that the rigors of training and competition promote excessive losses of these nutrients because of increased excretion or catabolism and, as a result, fortification of the diet is required to cover these losses. Moreover, there is often the opinion that increased consumption of various minerals and vitamins will improve physical performance and health. These perceptions, together with the aggressive marketing of supplements containing minerals and vitamins, appear to provide impetus for the extensive use of nutritional supplements in horses.

Macrominerals

Recommendations for macromineral (and trace mineral) intake by mature athletic horses are presented in Table 36.3. The requirements for dietary calcium (Ca) and phosphorus (P) are higher in athletic horses in comparison to their sedentary counterparts. Diets that contain inadequate levels of these nutrients or an imbalanced Ca:P ratio (i.e. Ca:P ratio < 1; high dietary P) may compromise bone integrity and predispose to injury during training and competition. Additional Ca and P are required for deposition in bone during modeling and remodeling, processes that are upregulated by the loading imposed on the bones of the limbs during exercise. It is also possible that calcium losses in sweat increase dietary requirements. However, assuming a calcium concentration in sweat of 100–120 mg per liter and daily sweat losses of 10 liters, these losses may be no more than 1–2 g per day.

Table 36.3 Estimated daily mineral needs of a 500 kg* horse at maintenance and in moderate-to-intense exercise training (adapted from references[1,40])

Mineral	Maintenance	Exercise
Sodium (g)	10	30–50¶
Potassium (g)	25	40–75¶
Chloride (g)	15	50–150¶
Calcium (g)	20	35–40
Phosphorus (g)	15	25–27
Magnesium (g)	7.5–9	10–15
Iron (mg)	320	460
Copper (mg)	80	115
Manganese (mg)	320	460
Zinc (mg)	400	575
Selenium (mg)	0.8–1.0	2.3–3.0
Iodine (mg)	0.8	1.15
Cobalt (mg)	0.8	1.15

* Assumes a dry matter intake of approximately 8 kg/day for maintenance and 11.5 kg/day for work.

¶ The sodium, potassium and chloride requirements of working horses are, in part, dependent on the extent of sweat fluid losses. The upper end of these values is recommended for horses in intense training in warm climates and during the summer months.

With respect to Ca and P requirements, the 1989 guidelines furnished by the NRC[1] assumed that if the nutrient: calorie ratio of the ration was maintained, the increase in feed intake needed to meet DE requirements for work would also supply the calcium required to replace sweat losses and support bone formation. However, the calcium needs of young horses in training (< 2 years) may be higher in comparison to mature athletic horses because of greater Ca turnover in bone.[20,21] Nolan and colleagues[21] reported that the training-associated increase in bone density in young Quarter Horses was enhanced by the consumption of diets that provided 150–170% of the NRC (1989) recommendations for Ca. In line with these findings, it has recently been suggested that diets for young horses in training should contain at least 0.4–0.45% Ca (versus the NRC recommendation of 0.34% Ca).[20] Higher levels of dietary calcium may also be beneficial in older horses. In one study, the increase in the mineral content of the metacarpus, assessed by radiographic photometry, in response to 12 weeks of treadmill training was greater in horses receiving a diet containing 0.7% Ca when compared to the current recommendation of 0.34%.[22]

Close attention should be paid to Ca:P balance in horse rations; the Ca:P ratio should be at least 1:1. It is not uncommon for athletic horses to be fed a diet with an improper Ca:P balance. This is particularly true for horses fed high cereal grain (not fortified with minerals), low roughage diets because most cereals are low in Ca and high in P. Although most grass hays contain moderate Ca content, the quantities fed may be insufficient to balance the low Ca content of the grain, resulting in an inverted Ca:P ratio (< 1). This type of ration can result in bone demineralization and pathology.[23] This problem can be averted by provision of a supplemental source of Ca or by including some legume hay in the diet. On the other hand, the Ca:P ratio of diets containing large amounts of legume hay can be greater than 3–5:1. However, such diets appear to be well tolerated by mature horses.

The NRC guidelines for Ca and P nutrition are based on the assumption that the efficiency of absorption for Ca and P is 50% and 35% respectively. However, several factors can influence the efficiency of absorption of these nutrients, including the Ca:P ratio, the form of Ca or P, the level of intake and the presence of inhibitors such as phytate and oxalate. Grains and cereal hays are high in phytates, while some tropical grasses are high in oxalates such that the efficiency of digestion and absorption of Ca and P in these feedstuffs is low. On the other hand, the efficiency of absorption of inorganic source Ca and P (e.g. calcium carbonate, dicalcium phosphate) may approach 70%. Due to the high variability in the availability of Ca and P from organic sources, most commercial horse feeds use inorganic sources of Ca and P to ensure adequate dietary levels of these nutrients. Similarly, inorganic forms of Ca and P should be added to 'homemade' rations for athletic horses (Table 36.4).

Scant data are available regarding the magnesium (Mg) requirements of athletic horses. In one study of endurance

Table 36.4 The composition of selected calcium and phosphorus supplements

Supplement	Calcium (%)	Phosphorus (%)	Magnesium (%)	Sulfur (%)
Calcium carbonate	39	–	0.05	–
Limestone	34	0.02	2.1	0.04
Oyster shells, ground	38	–	0.3	–
Dicalcium phosphate	22	19	–	–
Monosodium phosphate	–	22	–	–
Magnesium oxide	0–3	–	51–59	–

horses, serum magnesium concentrations were unchanged after an 80 km race.[24] Muscle (intracellular) magnesium content was unchanged in horses after intense trotting over 2600 m.[25] However, athletic horses may have slightly increased requirements for dietary magnesium to cover sweat losses (equine sweat contains 100–120 mg magnesium per liter). The NRC[1] recommends 0.1% dietary magnesium for maintenance or approximately 7.5–9 g/day based on a daily DM intake of 7.5–9.0 kg. As the magnesium content of feeds commonly consumed by horses is 0.1–0.3%, typical daily intake by athletic horses will be much greater than 7.5–9 g/day and should cover daily losses associated with sweating.

The dietary requirements for sodium, potassium and chloride are increased by physical activity because of the substantial sweat loss of these ions. The extent of these losses will depend on the intensity and duration of exercise, the training and heat acclimation status of the horse and the ambient conditions. A more detailed discussion on the effects of exercise on fluid and ion balance, strategies for electrolyte replacement and daily electrolyte requirements can be found elsewhere in this book.

Trace minerals

Few data exist regarding the effects of regular physical activity in horses on trace mineral requirements. With the exception of selenium, clinical signs consistent with a trace mineral deficiency are rare in horses fed typical diets. Nonetheless, several of the trace minerals are routinely supplemented to working horses. Most notably, iron, often in combination with copper, zinc and some of the vitamins, is widely given to athletic horses because of the perception that the provision of these nutrients will enhance erythropoiesis and oxygen-carrying capacity. In reality, there is no evidence that this practice results in altered red cell number or hemoglobin concentration, and iron deficiency anemia is a rare diagnosis in horses. Daily Fe losses of horses in training have not been reported. However, sweat contains a small amount of iron and other trace minerals such as zinc. Therefore, there is some rationale for increased provision of dietary Fe in working horses. Practically, however, common horse feedstuffs provide iron well in excess of requirements. The NRC maintenance requirement for iron is 40 mg/kg of diet (DM basis) or approximately 0.65 mg/kg bwt/day (320 mg/day for a 500 kg horse).[1] Forages usually contain 100 mg Fe per kg DM and most grains more than 50 mg per kg DM. Thus, a diet of 6 kg of hay and 5 kg of grain concentrate for a 500 kg working horse would provide approximately 850 mg Fe.

Selenium is a functional component of the intracellular enzyme glutathione peroxidase and, in concert with vitamin E, is important in the defense of cells against oxidant stress. Selenium deficiency is associated with development of nutritional myodegeneration. Selenium is also essential for the development of acquired immunity. Whether regular physical activity increases the Se requirements of horses is not known. However, single bouts of exercise[26] have been reported to increase erythrocyte glutathione peroxidase activity. This increase in enzyme activity may be a reflection of an increase in demand on this antioxidant system and, perhaps, an indication that working horses have higher Se needs relative to idle horses. The 1989 NRC[1] concluded that the Se requirement for mature idle horses was 0.1 ppm on a dry matter basis (0.1 mg/kg diet). Yet, many nutritionists now favor higher dietary Se for idle and working horses, in the range of 0.2–0.3 ppm, to account for variation in the efficiency of selenium digestibility and utilization and increased work demands (Table 36.3).

Vitamins

There is very limited information regarding the vitamin requirements of horses and even fewer data concerning the effects of habitual exercise on these requirements. Microbes in the large intestine synthesize the B vitamins and absorption from the large intestine has been demonstrated for several of the B vitamins.[27] In addition, an ample supply of the B-complex vitamins, with the exception of vitamin B_{12}, is provided by good-quality forage. Therefore, a combination of dietary intake and microbial synthesis in the hindgut should meet the B vitamin requirements of horses.

In recent years, there has been considerable interest regarding the role of vitamins C and E (and other antioxidant nutrients such as β-carotene and lipoic acid) in the mitigation of oxidative stress and lipid peroxidation in horses during exertion. Vitamins E (α-tocopherol) and C, along with glutathione, are important non-enzymatic antioxidants. Vitamin E is a lipid-soluble scavenger of reactive oxygen species (ROS) that is located in cell membranes, while vitamin C is located in the aqueous phase of cells where it scavenges free radicals and recycles vitamin E to its active form.[28]

Exercise causes a dramatic increase in oxidative metabolism and, therefore, the production of ROS. During prolonged

and/or strenuous exercise, the extent of ROS production may overwhelm antioxidant systems such that the susceptibility of cells and tissues to damage by ROS (lipid peroxidation) is enhanced, particularly in animals with inadequate endogenous stores of the antioxidant nutrients. Several research groups have investigated the relationship between exercise and plasma markers of oxidative stress in horses. For example, Hargreaves et al[26] reported an association between muscle cell 'leakage' (exercise-associated increases in the activities of creatine kinase [CK] and aspartate aminotransferase [AST]) and indices of antioxidant status in horses during 80 and 160 km endurance races. Specifically, plasma vitamin C and erythrocyte glutathione concentrations decreased during the races, while erythrocyte glutathione peroxidase was increased. On the other hand, Marlin and colleagues[29] reported no change in plasma vitamin C after a 140 km race, but significant decreases after 16 h of recovery. In both studies, no changes in plasma α-tocopherol concentrations were detected. However, Marlin et al[29] demonstrated a negative correlation between pre-race plasma α-tocopherol and total red cell glutathione and end competition total barbituric acid reactive substances (TBARS), and suggested that horses with low antioxidant reserves may be more prone to lipid peroxidation from ROS during endurance exercise.

The NRC[1] recommended a dietary vitamin E concentration of 80–100 IU/kg DM for all classes of horses. Whether or not higher amounts of dietary vitamin E are beneficial in athletic horses is unresolved. Siciliano et al[30] demonstrated a decrease in plasma and muscle α-tocopherol concentrations in working horses fed a diet supplemented with 80 IU α-tocopherol per kg DM, whereas plasma concentrations were maintained when horses were supplemented with 300 IU/kg DM. Similarly, plasma concentrations of α-tocopherol were significantly higher in hard-working polo ponies fed a diet providing 300% of the current NRC recommendation for vitamin E (240 IU/kg versus 80 IU/kg diet).[31] In both studies, however, there was no association between dietary vitamin E and the serum activities of CK and AST in response to exercise. Further research is needed to better define the vitamin E requirements for different classes of athletic horse. In the meanwhile, it is recommended that athletic horses be fed a diet providing at least 100 IU vitamin E per kg DM. Intensely working horses (e.g. race and endurance horses) may benefit from higher levels of vitamin E (200–250 IU/kg diet). Most equine feedstuffs contain less than 50 IU/kg DM. Therefore, supplemental vitamin E must be added to horse rations to meet requirements.

As horses have L-gluconolactone oxidase, the enzyme required for the synthesis of vitamin C (ascorbic acid) from glucose, there is no dietary requirement for this nutrient. However, the demand for ascorbic acid may be increased by regular exercise because it is thought to spare tissue vitamin E by reducing the tocopheroxyl radical and restoring the radical scavenging activity of vitamin E.[32] Although there have been several studies on the effects of ascorbic acid metabolism and supplementation in athletic horses,[29,31,33–35] no consensus has emerged regarding a dietary requirement for horses under performance stress. Dietary supplementation with ascorbic acid (5–10 g/day) does result in higher serum ascorbate concentrations relative to non-supplemented horses.[29,31] However, the effects of these higher ascorbate concentrations remain unclear. In two equine studies, there was no effect of ascorbic acid supplementation on exercise-induced increases in serum CK activity.[31,33] One concern with high-level ascorbic acid supplementation is the potential for suppression of endogenous synthesis.

Water

The NRC guidelines recommend 2–4 liters of water per kg of DM intake.[1] However, diet, ambient conditions and level of activity will modify these needs. Horses maintained on an all-forage diet will consume approximately 3.6 liters of water per kg of DM intake, whereas the water-to-feed ratio for horses fed a typical hay and grain diet is about 3:1.[1] Water intake by horses living in warm climates (> 25–30°C daytime temperature) may be increased by 15–30%, whereas heavy work in warm to hot ambient conditions may increase the need for water by as much as 200–300% due to large sweat fluid losses.

Feeds for attainment of nutritional goals

For horses in training, a combination of forage and energy concentrate is generally required to achieve nutritional goals. In some situations, a vitamin-mineral supplement is added to the ration. Several guiding nutritional principles should be used in the development of a feeding program for an athletic horse. In general, the main considerations in ration formulation are:

- provision of adequate fiber (roughage) to maintain normal gut and digestive function (and perhaps limit the development of behavioral disturbances)
- targeting an overall energy density that will allow energy requirements to be met at typical fed intakes
- supplying sufficient hydrolyzable carbohydrate to maintain muscle glycogen concentrations
- provision of the optimal amounts and balance of the other essential nutrients (i.e. protein, minerals, vitamins)
- the inclusion of only the highest quality feedstuffs.

The four main sources of energy in horse rations are:

1. fermentable carbohydrates (components of dietary fiber or roughage, including hemicellulose, that cannot be digested by mammalian enzymes but can be fermented by micro-organisms, primarily in the hindgut, i.e. cecum and large colon)
2. hydrolyzable carbohydrates (simple sugars and starch) that are digested by mammalian enzymes in the small intestine, yielding hexoses
3. oils and fats

4. protein (not primarily fed as an energy source because metabolism of amino acids to useable energy is inefficient).

Knowledge of the horse's digestive physiology and the impact of diet composition and meal size on the efficiency of digestive processes are important in the selection of an appropriate ration and feeding strategy. The horse evolved as a grazing animal and its gastrointestinal tract, with a well-developed cecum and large colon, is highly adapted to the utilization of fiber-rich feeds that are consumed on an almost continuous basis.[36] The hindgut (cecum and colon) comprises approximately 64% of the total (empty) volume of the gastrointestinal tract, whereas the stomach (7%) and small intestine (25%) have a relatively small capacity. Similar to other mammalian species, the small intestine is the major site of digestion of protein, fat and hydrolyzable carbohydrates. However, as further discussed below, the horse has a limited ability to digest and absorb hydrolyzable carbohydrates (particularly starch) in the small intestine. Large concentrate meals may overwhelm the digestive capacity of the small intestine and promote the flow of undigested hydrolyzable carbohydrate to the large intestine. This not only reduces the efficiency of feed utilization but also increases the risk for digestive disturbances associated with excessive and uncontrolled fermentation of the undigested hydrolyzable carbohydrate in the large intestine.

Roughage/dietary fiber

From the preceding discussion, it is clear that forage (roughage) should always be the foundation of an equine ration. Although a requirement for dietary fiber has not been established in horses, some long stem roughage is important for maintenance of normal hindgut function and thus for normal digestion. There also is evidence that diets low in long stem fiber favor development of certain stereotypies.[37–39] Therefore, adequate dietary roughage may be important for prevention of some undesirable behavioral traits, particularly in horses kept in confinement. Some trainers prefer to feed low-roughage diets because such rations may reduce the weight of ingesta in the intestinal tract ('dead weight'), thereby providing an energetic advantage during some forms of exercise. The possible benefits of this practice should be weighed against the increased risks of gastrointestinal dysfunction (e.g. colic, gastric ulcers) and behavioral abnormalities when horses are fed low-roughage diets.

Meyer has suggested that performance horses be fed at least 0.5 kg of roughage per 100 kg bwt (0.5% of bwt).[40] However, this author recommends *at least* 1.0 kg forage per 100 kg (i.e. 5.0 kg for a 500 kg horse). One survey of Australian race horses indicated that forage intake is often less than this minimum recommendation. In that study, mean daily forage intake was 3.3 kg and 4.1 kg for Thoroughbreds and Standardbreds, respectively.[7]

Pastures and different forms of conserved forages (i.e. hay, chaff, hay cubes, haylage) are the primary source of roughage in horse rations. Although several factors can affect the nutrient value of conserved forages, the most important is the stage of maturity at the time of harvest (Fig. 36.1). The energy content, digestibility and palatability of forage all decrease with increasing maturity. Therefore, forages harvested at an early stage of plant maturity should be fed to working horses to maximize nutritional value and intake of the offered quantities (Table 36.5). An exception to this recommendation is the feeding of a very high-quality alfalfa, which may not contain adequate fiber (specifically, acid detergent fiber [ADF]) for normal hindgut function. Figure 36.2 illustrates how the energy content of the forage affects the relative proportions of forage and energy concentrates required to meet the energy needs of an athletic horse.

The relative use of grass, legume or cereal (usually oaten) hays and the different forms of preserved forages made from these species often depends on availability and personal preference. Legume hays such as alfalfa usually have higher energy, protein and mineral (particularly calcium) content when compared to the grass species. These differences will influence the type and quantity of energy concentrate to be fed with hay. For example, as discussed above, the total diet should provide 10–12% crude protein. Therefore, when feeding alfalfa the protein content of the concentrate can be

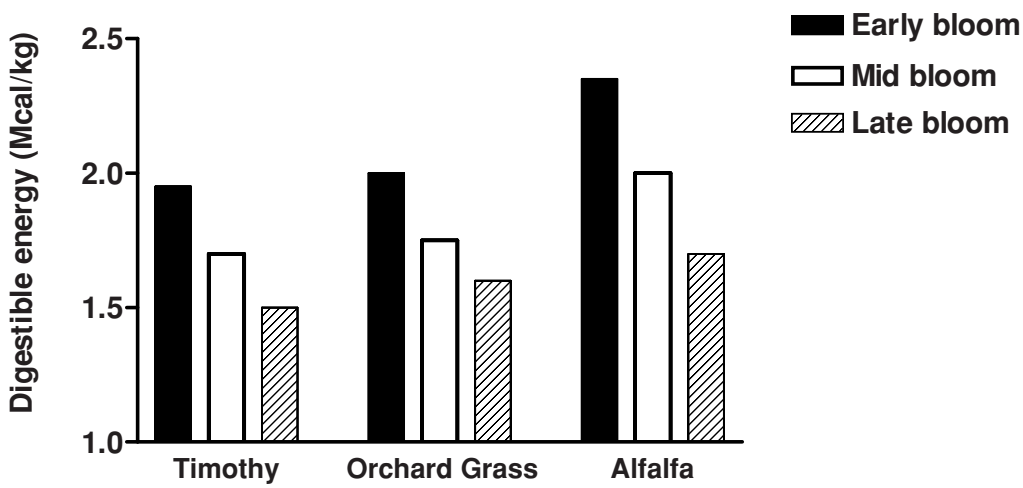

Fig. 36.1 The effects of maturity at the time of harvest on estimated digestible energy content of timothy, orchard grass and alfalfa hay.

lower than when grass hay is fed. In addition, a higher roughage-to-concentrate ratio is possible when high-quality (energy) forage is fed. However, even within a plant species the nutrient composition of preserved forage can vary greatly depending on growing conditions, plant maturity and harvesting methods. Thus, proximate analysis (including crude protein, neutral detergent fiber and macrominerals) should be performed when practical to best guide ration balancing and the selection of an appropriate energy concentrate.

Preserved forages should also be free of contaminants such as molds. Hay that is baled at high moisture content is likely to heat and become heavily contaminated with molds that can exacerbate chronic airway diseases such as recurrent airway obstruction and inflammatory airway disease. In areas with high rainfall during the growing and hay-making season (e.g. the UK), the feeding of ensiled hay or 'haylage' (50–60% DM) is sometimes practiced. Haylage is a suitable alternative to hay providing that it is stored correctly and fed in sufficient quantity to ensure adequate fiber intake. One concern with haylage is the potential for clostridial growth and production of botulinum toxin.[41] Haylage should be examined carefully for the presence of mold and other contaminants before feeding and sealed haylage bales should be fed within a few days of opening. Hay cubes and pellets, 'complete feeds', or the feeding of forage that has been thoroughly soaked in water can also aid in minimizing exposure to dusts and molds when managing chronic airway disease.

Daily feed intakes in mature horses (on an as-fed basis) range between 1.5% and 3.0% of bodyweight, although a more typical intake for a performance horse is between 1.8% and 2.2% (i.e. 9–11 kg for a 500 kg horse). Accordingly, the energy requirements of horses performing light athletic activities (e.g. pleasure riding 2–3 times per week) can, in most instances, be met by forage alone. Other essential nutrients may be provided in the form of a vitamin-mineral or vitamin-mineral-protein supplement. On the other hand, horses in moderate and intense training are unable to meet energy needs if forage is the only energy source. Therefore, energy concentrates must be fed to increase the caloric density of the diet and ensure that energy requirements are met within the confines of a realistic daily dry matter intake.

Energy concentrates

Cereal grains

Traditionally, cereal grains such as oats, corn and barley (alone or in combination) have been a source of energy in rations for athletic horses. Starch, a hydrolyzable carbohydrate, is the primary component of cereal grains. Oats are approximately 47–50% starch while the starch content of corn and barley is between 60% and 66% (Table 36.5). Digestion of starch in the small intestine yields glucose, the substrate for liver and muscle glycogen synthesis. As muscle glycogen is a primary fuel during exercise, the provision of some hydrolyzable carbohydrate (starch and/or sugar) in the diet of an athletic horse is important for replenishment of glycogen reserves. However, there is evidence that the horse has a limited capacity to digest and absorb starch (and perhaps other simple carbohydrates) from the small intestine. Low production and secretion of pancreatic amylase[42,43] and a limited capacity for mucosal monosaccharide transport[44] are factors that may contribute to this apparent constraint in small intestinal carbohydrate digestion. Regardless of the

Table 36.5 Nutrient composition of some feedstuffs used in horse rations

Feed	Dry matter %	DE (Mcal/kg DM)	CP %	Acid detergent fiber %	NSC %	Fat %	Ca %	P %
Alfalfa hay, early bloom	90	2.5	20	32	22	–	1.4	0.3
Alfalfa hay, full bloom	91	2.2	17	39	21	–	1.2	0.25

DE = digestible energy; CP = crude protein; NSC = non-structural carbohydrate; Ca = calcium; P = phosphorus
All nutrients expressed as a percentage in feed dry matter.
Primary source of data is 1989 NRC.

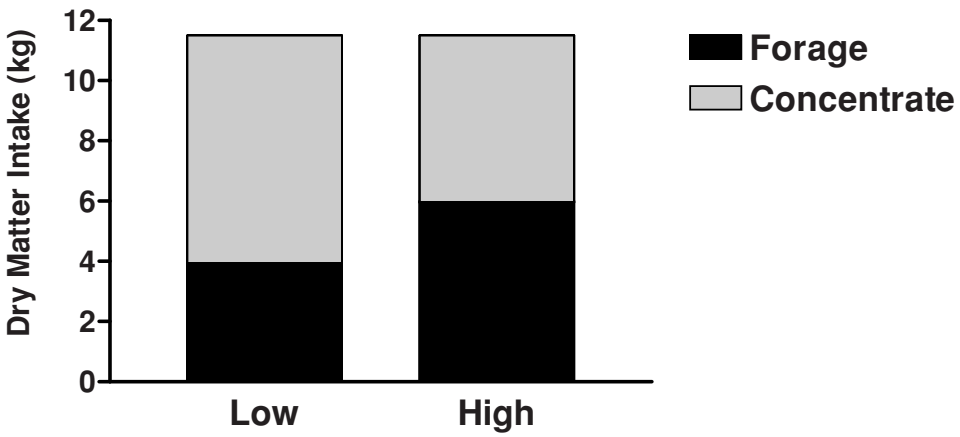

Fig. 36.2 The effects of forage energy content on the proportions of hay and energy concentrate required to meet the energy requirements of a 500 kg horse with daily digestible energy (DE) needs of approximately 30 Mcal/day. This example assumes a daily dry matter (DM) intake of 11.5 kg or approximately 2.2% of bodyweight. **Low** = hay with DE content of 1.5 Mcal/kg DM; **High** = hay with DE 2.0 Mcal/kg. The DE content of the energy concentrate is 3.3 Mcal/kg. The diet proportions in these two scenarios are: Low (4 kg hay and 7.5 kg concentrate or a ratio of 35:65); High (6 kg of hay and 5.5 kg of concentrate or a ratio of 52:48).

mechanism, with the ingestion of large grain meals a substantial proportion of the ingested starch may escape hydrolysis in the small intestine with a resultant delivery of this substrate to the hindgut. Rapid fermentation of starch in the hindgut by lactate-producing bacteria can result in lactate accumulation, excess gas production, cecal and colonic acidosis and increased risk of intestinal disturbances.[45,46] Epidemiological studies have identified the level of grain feeding as a risk factor for colic. Tinker et al[47] reported odds ratios of 4.8 and 6.3 (relative to no episode of colic) for horses fed, respectively, 2.5 kg/day and more than 5.0 kg/day of concentrate. Similarly, Hudson and colleagues[48] reported that recent (within the previous 2 weeks) changes in the type of grain or concentrate fed or feeding more than 2.7 kg of oats per day was associated with increased risk for an episode of colic. High-starch (grain) diets have also been implicated in the pathogenesis of some forms of chronic exertional rhabdomyolysis.[49]

While it is necessary to feed some hydrolyzable carbohydrate to athletic horses to ensure an adequate supply of substrate for glycogen replenishment, several strategies can be employed to mitigate the risk of digestive disturbances attributable to heavy grain (starch) feeding. First, it is advisable to limit the size of individual grain-based meals to avoid 'starch bypass' to the large intestine. Second, only cereal grains with high pre-cecal starch digestibility should be included in energy concentrates for horses. Third, energy concentrates for athletic horses should make more use of non-starch carbohydrates (e.g. sugar beet pulp) and vegetable fats. Inclusion of these alternative energy sources facilitates a reduction in the level of starch feeding without compromising the caloric density of the ration.

A suggested upper limit of starch intake in a single meal is between 2 and 4 g starch per kg bodyweight (0.2–0.4% of bwt per feeding),[43,50] although one nutritionist has suggested that 2 g/kg per meal is the safe upper limit.[46] Thus, if a concentrate feed contains 50% starch (e.g. plain oats) the maximum recommended amount of concentrate per feeding is approximately 2 kg for a 500 kg horse. Pre-cecal starch digestibility varies with the type of grain and the nature of any mechanical or thermal processing. For example, whereas oat starch (at up to 3 g/kg per meal) has a pre-cecal digestibility of greater than 90%, approximately 35% of an equivalent dose of cornstarch reaches the cecum undigested.[46] Similarly, the pre-cecal digestibility of unprocessed barley is substantially lower when compared to oats. However, heat treatments such as micronization, extrusion and steam flaking significantly improve the pre-cecal starch digestibility of barley and corn. Overall, oats appear to be the safest source of starch for horses, although barley and corn are acceptable if they are subjected to some form of heat treatment.

Fats and oils

The addition of fat to horse rations is now commonplace. Although animal fat (tallow or lard) has been fed to horses, palatability and digestibility[51,52] are inferior when compared to vegetable oils. Therefore, most commercial fat-supplemented concentrates for horses contain a vegetable oil such as soy, corn or canola. Other oils that may be used in equine rations include peanut, safflower, coconut, linseed or flaxseed. Vegetable oils are highly unsaturated and contain approximately three times as much DE as oats and 2.5 times as much as corn. Other sources of fat used in horse rations include stabilized rice bran (18–22% fat), flaxseed meal (40% fat) and copra meal (8–9% fat). Vegetable oils are both highly digestible (90–100%)[53] and palatable,[52] although there can be slight variation in the acceptance of the different oils. For example, Holland et al[52] demonstrated that corn oil is preferred over soy, peanut and cottonseed oils. Rice bran (as a powder or an extruded pellet) is also well accepted by horses and is commonly fed at a rate of 0.5–2.5 kg per day to

mature horses, providing 90–500 g fat per day. Rice bran is rich in phosphorus and has an inverted Ca:P ratio, but many commercial rice bran products contain added calcium (e.g. calcium carbonate) to correct this imbalance. Alternatively, a mineral supplement can be added to the ration to ensure an appropriate Ca:P ratio (at least 1:1) in rations containing rice bran.

Fat is often added to the diet to increase the energy density of the ration, which can offer an advantage when dry matter intake limits provision of adequate energy to maintain condition ('hard keeper' horses). Alternatively, substitution of fat for a portion of the grain in an energy concentrate allows for a decrease in hydrolyzable carbohydrate intake. This strategy is advocated for horses with some forms of chronic exertional rhabdomyolysis (see below).

Fat is also added to the diet of athletic horses because of the reputed benefits of fat-supplemented diets on exercise performance, specifically that performance is improved by *fat adaptation*, a set of physiologic responses to the consumption of a high-fat diet during training that confer advantages to the horse during exercise.[54] As discussed in Chapter 34, there is evidence that a fat-supplemented diet is associated with an increased capacity for fat oxidation during exertion, as shown by a lower respiratory exchange ratio during low and moderate intensity exercise.[55,56] However, this effect of fat supplementation on fuel selection is not evident at higher workloads, reflecting the high dependence of horses on carbohydrate metabolism during moderate and high intensity exercise.[55] Nonetheless, the increase in fat oxidation and decrease in carbohydrate oxidation (carbohydrate sparing) evident during low intensity exercise in fat-supplemented horses should be beneficial during endurance exercise, although the actual effect of fat supplementation on endurance performance has not been reported.

It should also be noted that the level of fat supplementation used in the aforementioned research studies (approximately 20–25% of DE from fat)[55,56] is considerably higher than that commonly practiced by horse owners and trainers (4–15% of DE from fat). Whether these lower levels of fat supplementation confer similar metabolic advantages during exercise is unknown.

The ideal amount of dietary fat for horses has not been determined, nor is there much information regarding the effects of fatty acid chain length or degree of saturation on metabolism and health in horses. Kronfeld[53] has stated that horses can safely consume diets containing up to 15–20% vegetable oil by weight (on a total diet basis), providing the horse is adapted to this level of fat inclusion over a 2–3-week period. However, one study demonstrated a decrease in total tract fiber digestibility in horses fed a 14% soy oil diet.[57] Commercially, the level of fat or oil added to a concentrate is often limited by manufacturing constraints (e.g. poor pellet quality when large amounts of oil are included in pelleted feeds; greasy appearance of concentrate mixes). Therefore, fat-supplemented concentrates designed for performance horses usually contain between 5% and 14% fat (as fed), providing between 8% and 30% of the DE. However, as these concentrates are fed with forage, the amount of fat on a total diet basis is much lower (approximately 3–8% fat or 4–15% of the DE from fat assuming a 50% concentrate, 50% forage diet). These levels of fat supplementation carry minimal risk of negative associative effects such as a decrease in fiber digestibility.

Many horse owners and trainers add vegetable oil to existing rations. A suggested upper limit of oil supplementation is 100 g per 100 kg bwt per day. For reference, one standard measuring cup contains 250 ml (8 fluid ounces) of oil (~200 g) and provides approximately 1.67 Mcal (6.7 MJ) of DE. For a 500 kg horse in moderate work (daily DE needs of 26 Mcal), the inclusion of 500 g of oil per day will provide about 16% of the DE requirements. There should be a gradual introduction to oil feeding to avoid digestive disturbances (loose and oily feces). Initially, 1/4–1/2 cup of oil/day can be added to the ration. Over a 2–3-week period, the amount of added oil can be increased to 2–2$\frac{1}{2}$ cups/day, divided into at least 2–3 feedings.

One concern with the addition of vegetable oils (or rice bran) to an existing diet is the potential for nutrient imbalances. Commercial energy concentrates with added fat are fortified to maintain appropriate nutrient-to-calorie ratios and are designed to complement the forage source. On the other hand, the on-farm addition of a substantial amount of oil (e.g. 400–500 g per day) to an existing ration may result in an unbalanced diet. Consultation with a nutritionist is recommended in these situations. Supplementation with vitamin E (100–200 IU per 100 g of added oil) is recommended for prophylaxis against oxidant stress when oil is directly added to the ration. This practice may not be necessary when rice bran is the source of added fat as it contains substantial quantities of vitamin E and other natural antioxidants.

Non-starch carbohydrates

There are two main types of non-starch polysaccharides used in equine rations: simple sugars; and highly digestible sources of fiber (so-called 'fermentable fibers'), particularly sugar beet pulp (SBP) and soya hulls and, to a lesser extent, citrus pulp. Simple sugars in the form of molasses (a mixture of glucose, sucrose and fructose) are often added to grain mixes at 6–8% by weight. In general, these sugars are well utilized by the horse, as shown by pronounced glycemic responses following the administration of glucose, sucrose or fructose at dosages of 1.0–2.0 g/kg bwt.[58]

SBP contains major fractions of highly digestible fiber fractions, including pectins, arabinans and galactans, which are readily fermented by equine hindgut microflora[59] Digestibility studies have demonstrated that, in contrast to the fibers in traditional roughage sources, the fibers in SBP and soya hulls are extensively degraded within the time that such a feedstuff would be resident in the gut.[60] This high digestibility accounts for the higher energy value of these feedstuffs when compared to hay. It has also been demonstrated that the addition of 30% SBP to the ration increases the digestibility of the hay portion of the diet.[60] SBP

is available in two forms, molassed (i.e. molasses is added to the beet shreds, generally at the 5% level) or non-molassed, and can be fed alone or as a component of a concentrate mix. When fed alone, it is recommended to soak the beet shreds in water for 3–4 hours before feeding. Soya hulls are generally included in pelleted feeds.

SBP or soya hulls can be included as a substitute for cereals (starch) in energy concentrates. Studies in horses have demonstrated that up to 3.0 g SBP per kg bwt per day (i.e. 1.5 kg for a 500 kg horse) may be fed to adult horses without any adverse effects on overall nutrient utilization or performance.[61–63] Indeed, as discussed in Chapter 34, there may be metabolic advantages of diets that include non-starch polysaccharides such as SBP, including a muscle glycogen-sparing effect during moderate and heavy exercise.

Although the feeding of straight grains or sweet feed mixes to athletic horses remains a popular practice, there is increasing emphasis on use of energy concentrates in which some starch and sugar has been substituted by fat and/or a fermentable fiber such as SBP and soya hulls (so-called 'fat and fiber' feeds). Such diets may reduce the risk of gastrointestinal disturbances and, as discussed below, are useful in the nutritional management of horses with chronic exertional rhabdomyolysis. Figure 36.3 compares the sources of digestible energy in a traditional race horse diet (forage plus grain) and a diet in which a fat and fiber energy concentrate is fed.

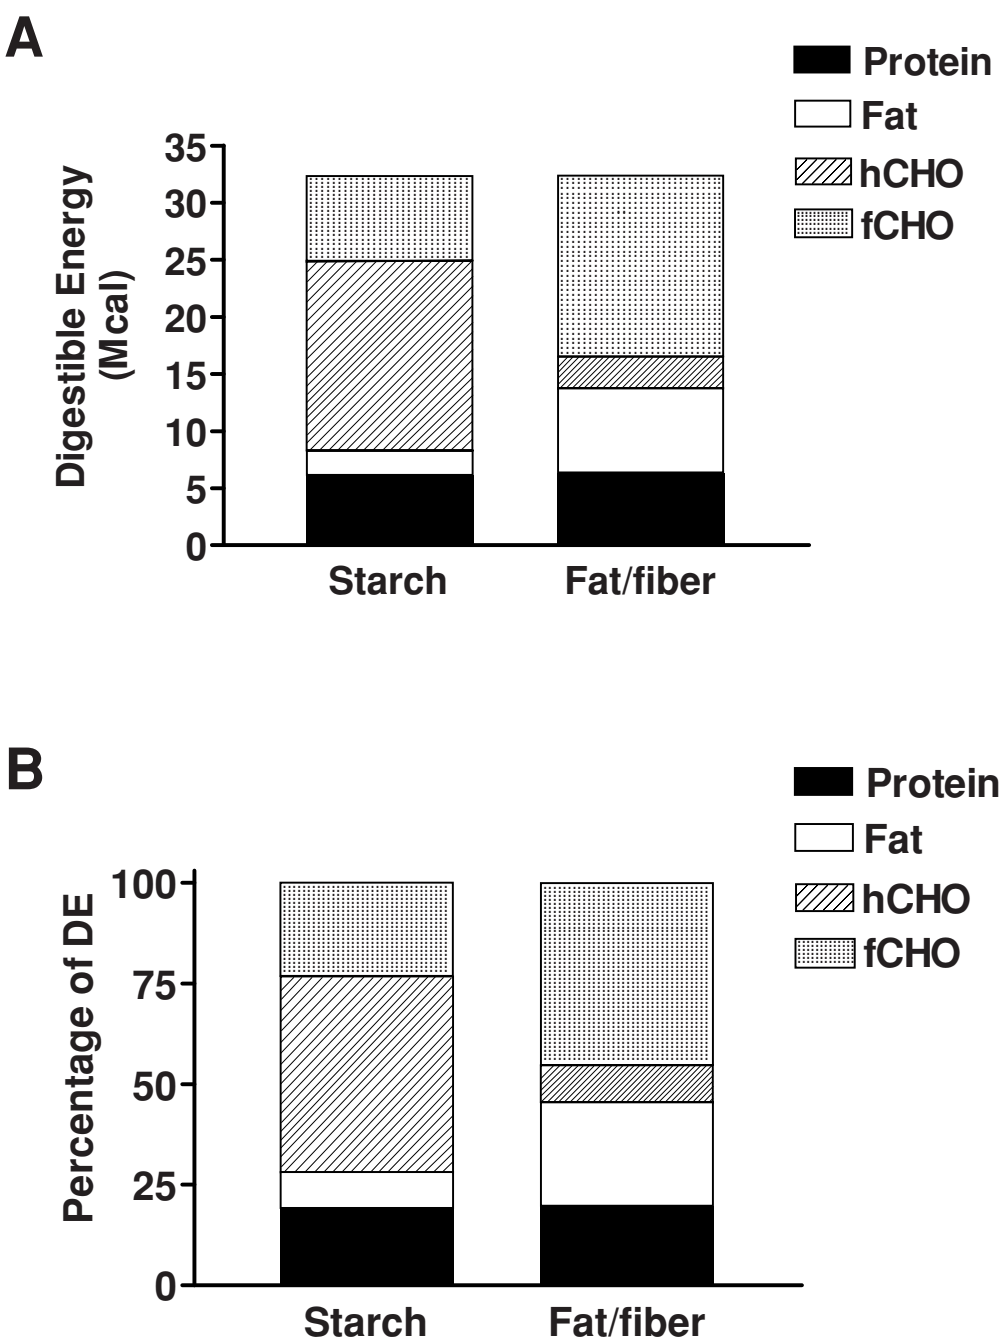

Fig. 36.3 Graphical representation of the sources of energy in a traditional grain and hay diet (**Starch**) and a contemporary fat and fiber energy concentrate and hay diet (**Fat/fiber**) fed to a 500 kg racehorse requiring approximately 32 Mcal of digestible energy (DE) per day. Both diets include 6 kg of mid-bloom timothy hay and, on a total diet basis, provide 12% crude protein. For Starch, the horse is fed ~ 7 kg of an energy concentrate composed of oats (57%), cracked corn (37%) and sugar cane molasses (6%). The same quantity of energy concentrate is fed in Fat/fiber (~ 13% fat), the primary ingredients of which are beet pulp, rice bran, soy hulls and vegetable oil. Graph A depicts estimates of the absolute DE provided by protein, fat, hydrolyzable carbohydrate (hCHO; starch and sugar) and fiber carbohydrates (fCHO) in the respective diets. Graph B shows the percentage contribution of the four energy sources to the total DE intake. Note the dramatic reduction in hCHO intake in the Fat/fiber when compared to the Starch diet.

Special considerations: horses with chronic exertional rhabdomyolysis

Special considerations are needed in the selection of energy concentrates for horses with two forms of chronic exertional rhabdomyolysis (ER): polysaccharide storage myopathy (PSSM) and recurrent exertional rhabdomyolysis (RER). Although the pathogenesis of PSSM and RER is distinctive[64] (see Chapter 27), there is increasing evidence that diets low in starch and higher in fat are beneficial in the management of both conditions.[49,65–68]

Quarter horses and related breeds with PSSM have enhanced insulin sensitivity, as demonstrated by a more rapid clearance of blood glucose after intravenous glucose loading[69] or the feeding of grain meal,[70] and this increase in insulin sensitivity is probably a contributing factor in the development of excessive muscle glycogen storage. Thus, diets high in starch and/or sugar may promote clinical expression of the disease by providing substrate for glycogen synthesis, and the cornerstone of dietary management for horses with PSSM is a severe restriction of hydrolyzable carbohydrate (starch and sugar) intake. There is also emerging evidence that beyond the simple removal of hydrolyzable carbohydrate from the diet, additional clinical improvement occurs when fat is added to the ration. It has been hypothesized that an increase in dietary fat alters intracellular glucose metabolism and glycogen synthesis in horses with PSSM,[49] although as yet there is no direct evidence in support of this hypothesis. Whether similar metabolic mechanisms contribute to the glycogen storage syndrome recognized in draft breeds (equine polysaccharide storage myopathy, EPSM) is not known. However, there is evidence that an increase in dietary fat is also beneficial in the management of horses with EPSM.[65,66]

The role of diet in the pathogenesis of RER is less clear. As with PSSM, there is evidence that a reduction in starch intake and increase in fat supplementation can be beneficial.[49,67,68,71] However, experimental studies in a small group of RER-affected Thoroughbreds have demonstrated that dietary energy source (i.e. the relative amounts of starch and sugar versus fat) is only important when total caloric intake is high (> 28–30 Mcal DE per day for a 500 kg horse).[67,68,71] Specifically, when daily calorie intake was moderate (~21–22 Mcal/day) diet composition had little influence on exercise-associated increases in plasma creatine kinase (CK) activity.[67,68] However, postexercise CK activity was significantly higher in horses consuming a hay and grain (starch) diet that provided 28.8 Mcal of DE per day when compared to an isocaloric diet low in starch with 20% of DE supplied by fat.[71] It has been suggested that high-calorie, high-starch diets are associated with a more nervous disposition in horses. This association may explain the relationship between dietary starch level and subclinical or clinical tying up in RER-susceptible horses given that stress and excitement are apparent trigger factors for the condition.[64] In support of this hypothesis, RER-affected horses fed the low-starch, high-fat diet had lower resting heart rates and, subjectively, a less excitable temperament when compared to observations made in the same horses while consuming the high-starch diet.[67,68,71]

In general, there should be a reduction in hydrolyzable carbohydrate intake and increased reliance on fat and fermentable fibers as energy sources. With respect to PSSM, the diet should be devoid of grain (starch) and sugar such that on a total diet basis, less than 15% of DE is supplied by hydrolyzable carbohydrate. There is some controversy with respect to the amount of supplemental fat required for management of PSSM.[49] A suggested target is 20% of DE as fat; however, in some horses this can be difficult to achieve at very high daily DE intakes (> 30 Mcal/day). 'Easy keeper' horses with PSSM that are only in light work will maintain condition on a diet that is predominantly medium-quality hay (supplied at approximately 1.5% of bwt), with a small quantity of fat (e.g. 0.5–1 kg rice bran per day or 1/2–1 cup of oil), and a vitamin–mineral supplement. Lush pasture and legume hays (alfalfa) should be avoided because these forages can supply a substantial quantity of sugar. Possible options for meeting the energy needs of affected horses in harder training include the provision of larger quantities of rice bran (e.g. 1–2 kg/day), a combination of hay pellets and vegetable oil (up to 100 g per 100 kg bwt/day), or a 'fat and fiber' energy concentrate. As mentioned, the latter utilizes a combination of vegetable fats (oils and/or rice bran) and fermentable fiber (SBP and/or soya hulls). Some of these feeds provide less than 10% of DE from hydrolyzable carbohydrate and 20% of DE as fat.

A typical race horse with RER is consuming greater than 30 Mcal of DE per day, with much of the energy supplied by starch. Indeed, it is not uncommon for race horses to consume 5–8 kg/day of a grain concentrate and this level of starch intake appears to contribute to an increased frequency of tying-up episodes.[49,71] Therefore, as with PSSM, a lower starch, higher fat and fermentable fiber diet is indicated in the management of horses with RER. One recommendation for race horses in intense work is a diet that provides no more than 20% of DE from hydrolyzable carbohydrate, with a minimum of 20% DE from fat (Fig. 36.3).

These dietary interventions are not a panacea for the prevention of PSSM and RER. As discussed in Chapter 27, a number of other management changes are needed for the successful management of horses with chronic ER. For example, along with strict dietary control, daily exercise is critical to the successful management of horses with PSSM, while strategies for reduction of stress and excitability are important in the management of RER-susceptible horses.

Putative ergogenic feeding strategies and supplements

Beyond provision of a diet that meets the energy and nutrient requirements of an athletic horse, horse owners often apply different feeding strategies or administer a variety of nutritional supplements in an attempt to enhance a horse's

performance during competition. The term *ergogenic* means 'work generating';[72] thus, an ergogenic nutritional supplement or feeding manipulation is one that enhances work performance (e.g. an increase in speed, endurance or strength). A plethora of nutritional supplements are marketed for use in horses, often on the basis of performance enhancement. However, with rare exceptions, there is little or no scientific basis for these claims because there are no data available regarding the efficacy of a given supplement in horses. Instead, the rationale for use is most often based on data from studies in humans or other species.[73]

This section provides a brief overview of the effects of selected feeding strategies or nutritional supplements that have been purported to enhance athletic performance of horses. The reader is also referred to Chapter 34 for discussion on the effects of fat supplementation, dietary protein content and pre-exercise feeding on exercise metabolism and performance.

Manipulation of carbohydrate supply

In humans, it is universally accepted that carbohydrate availability to skeletal muscle is an important determinant of exercise performance, particularly during moderate intensity exercise lasting 1 hour or more.[74,75] Low muscle glycogen concentration before exercise is associated with decreased performance, whereas high muscle glycogen content enhances endurance performance.[74,76] Similarly, an increase in blood glucose availability by ingestion of glucose or glucose polymers before and/or during exercise enhances the performance during prolonged moderate intensity exercise.[75,76] Therefore, feeding strategies that increase pre-exercise muscle glycogen content and enhance blood glucose supply to skeletal muscle during exercise are ergogenic in human athletes. This is especially true for events lasting more than 60–90 min.

The effect of carbohydrate supply on exercise performance in horses is less well studied but, similar to humans, there is evidence that glucose availability and muscle glycogen content are important determinants of performance during moderate and intense exercise. Time to exhaustion in horses running at 6–7 mph was decreased by 35% when pre-exercise muscle glycogen content was 70% lower than normal.[77] Anaerobic work capacity in horses, as assessed by the run time until fatigue during a 'supramaximal' treadmill exercise test, was decreased by approximately 28% when muscle glycogen content was 60–70% lower relative to a control treatment.[78] Thus, similar to humans, low pre-exercise muscle glycogen content is associated with decreased exercise performance in horses. On the other hand, an increase in blood glucose availability has been demonstrated to enhance performance in horses undertaking moderate intensity exercise. In two studies of horses running on a treadmill at 50–60% of $\dot{V}O_{2max}$, the time to fatigue was increased by 14–20% when glucose availability was increased by intravenous administration of glucose (2–3 g/min).[79] These data have generated interest in the development of nutritional strategies for horses that optimize pre-exercise muscle glycogen content or glucose availability during exercise.

Muscle glycogen storage

In humans, the term 'glycogen loading' refers to maximization of muscle glycogen stores prior to a competitive event in which performance is limited by the depletion of muscle glycogen stores. The original CHO loading protocols, pioneered by Bergström & Hultman,[74] involved a 3–4-day depletion phase of hard training and a low carbohydrate diet, followed by a 3–4-day loading phase of high carbohydrate intake and exercise taper. This protocol resulted in a more than 50% increase in glycogen content, hence the term 'muscle glycogen supercompensation'. More recent studies have shown that well-trained athletes are able to achieve similar muscle glycogen supercompensation without the need to undertake a glycogen-depletion phase.[80] Accordingly, the more practiced method for glycogen loading in human athletes involves 3 days of exercise taper and high carbohydrate intake (7–10 g/kg bwt per day).[81]

Research in horses has indicated that only modest (~10%) increases in muscle glycogen content can be achieved through dietary manipulation.[77,82,83] For example, Essén-Gustavsson et al[83] reported a 12% increase in the resting muscle glycogen content of Standardbred horses fed a diet that provided approximately 2 kg/day of starch and sugar when compared to an isocaloric diet that provided about 1.3 kg/day of hydrolyzable carbohydrate. An increase in muscle glycogen content of this magnitude was not associated with improved performance during moderate intensity exercise.[82,83] These observations notwithstanding, a number of glycogen or 'carbo' loader products are marketed for use in athletic horses.

One possible reason for the apparent disparity in capacity for glycogen supercompensation between humans and horses is a difference in hydrolyzable carbohydrate intake. In humans, a daily carbohydrate intake of 7–10 g/kg bwt is required for a substantial increase in muscle glycogen content.[81] For a 500 kg horse, an equivalent carbohydrate dose would require the consumption of 7–10 kg of oats (~50% starch) per day. Such a high grain (starch) intake is not realistic for most horses, nor recommended given the risks of gastrointestinal dysfunction associated with high starch intake.

Although an increase in muscle glycogen content is perhaps not achievable in horses, it is still desirable to apply dietary and management practices that optimize glycogen resynthesis after exercise such that low glycogen does not prevail at the start of the next exercise session. Following exercise in horses that depletes muscle glycogen content (middle gluteal m.) by greater than 50–60%, complete glycogen replenishment is achieved by 24 hours when glucose (6 g/kg) is administered intravenously.[78,84] In contrast, oral administration of a glucose polymer (3 g/kg bwt) within 60 min of the completion of glycogen-depleting exercise does not accelerate glycogen replenishment.[85,86] Similarly, when horses are fed meals with high hydrolyzable carbohydrate

content (grain), the rate of muscle glycogen replenishment is not different[87] or only slightly faster[88] when compared to horses fed a hay diet. Studies in humans, on the other hand, have shown that carbohydrate ingestion during the postexercise period substantially enhances the rate of muscle glycogen resynthesis.[75] Over a 6–12-hour period following exercise, the ingestion of carbohydrate at a rate of 0.7–1.0 g/kg bwt every 2 hours results in muscle glycogen synthetic rates of 5–8 mmol/kg/hr and complete glycogen replenishment is achieved within 24 hours. By comparison, the maximum rate of muscle glycogen synthesis in horses after exercise that results in a 40–70% decrease in glycogen content is approximately 1.5 mmol/kg/h,[87–89] and as much as 48–72 hours is required for complete replenishment.[88,89] As discussed, the horse appears to have a limited capacity for the digestion of hydrolyzable carbohydrates and this may limit systemic glucose availability, thereby restraining the rate of muscle glycogen resynthesis.

The performance implications of the slow rate of glycogen replenishment in horses are likely dependent on the type of athletic activity. In a study of Thoroughbreds fed a hay and grain concentrate diet, the muscle glycogen loss sustained during training gallops (19–25% decrease) was fully restored within 2–3 days.[90] Thus, in situations where intense exercise bouts occur at 3-day intervals, as is typical in the conventional training of Thoroughbred race horses, muscle glycogen content can be well maintained. However, for horses competing in multi-day events (e.g. three-day event) or multiple heats on a single day (e.g. Standardbred race horses), inadequate glycogen replenishment may adversely affect subsequent exercise performance. For these horses, small grain meals (e.g. 1–1.5 kg for a 500 kg horse) should be provided at frequent intervals (e.g. every 3 h) during the first 12 hours of recovery. Limiting the size of the grain meals and increasing the frequency of feeding should minimize the risks of digestive disturbance.

Enhancement of blood glucose supply during exercise

The only practical means for enhancement of blood glucose availability during exercise is the pre-exercise feeding of a meal high in starch and/or sugar or the intragastric administration of a glucose or glucose polymer solution. For endurance horses, similar strategies could be applied at rest stops during races. However, there is some controversy regarding the merits of these pre-exercise dietary interventions. It has been argued that the suppression in lipid oxidation associated with pre-exercise carbohydrate ingestion may be detrimental to performance because an accelerated rate of carbohydrate oxidation will result in premature depletion of endogenous carbohydrate stores (see Chapter 34). Certainly, there is evidence that the hyperglycemia and hyperinsulinemia consequent upon grain ingestion or intragastric glucose administration alter substrate selection during moderate intensity exercise. The consumption of a grain meal (~2 kg corn) 2 hours before exercise[5] or the oral administration of glucose (2 g/kg bwt) 1 hour pre-exercise[91] increases the rate of blood-borne glucose utilization and the rate of whole-body carbohydrate oxidation in horses during treadmill exercise at 50–55% $\dot{V}O_{2max}$. Conversely, the rate of whole-body lipid oxidation is suppressed under these conditions,[5,91] most probably as a result of an insulin-induced suppression in lipolysis.

It must be emphasized that the effects of pre-exercise carbohydrate ingestion (grain meals or glucose solutions) on exercise performance have not been determined in horses. Although speculative, it is possible that the pre-exercise ingestion of hydrolyzable carbohydrate is beneficial for events requiring moderate and intense exercise. However, for more prolonged, lower intensity exercise, such as that required of the endurance horse, the suppression in lipid oxidation associated with pre-exercise carbohydrate ingestion may be detrimental to performance (see Chapter 34). Therefore, for endurance events it is recommended that no grain be fed in the 3-hour period before competition exercise. Further research is required to determine the metabolic and performance effects of various pre-event (and mid-event) feeding strategies.

Alterations in dietary fiber intake

The horse's large intestine contains a fluid volume equivalent to 8–10% of bodyweight, with 10–20% of total body sodium, potassium and chloride.[92,93] There is limited evidence that a portion of this fluid can be absorbed during prolonged exercise, thereby partially offsetting sweat fluid losses.[92] Accordingly, some nutritionists advocate a high-fiber diet for endurance horses because such diets should increase the size of the hindgut fluid reservoir. Indeed, Meyer et al[92] demonstrated that feeding a high-fiber diet (hay only) when compared to a low-fiber diet (a complete feed composed of grain, bran and beet pulp) to ponies resulted in greater water content of the large intestine (183 and 101 mL/kg bwt for the high- and low-fiber diets, respectively). Warren and co-workers[93] also reported an approximately 15% increase in estimated gastrointestinal tract fluid volume when horses were fed a high-fiber (54% neutral detergent fiber [NDF], 31% ADF) when compared to a low-fiber diet (31% NDF, 19% ADF). Whether such an increase in gut fluid volume is beneficial to thermoregulatory function and performance is unclear. In the study by Warren and co-workers,[93] neither the loss of bodyweight nor the decrease in plasma volume differed between dietary treatments during 45 min of low intensity exercise. Furthermore, as discussed by Kronfeld,[17] the putative benefits of a high-fiber diet in terms of improved water balance and thermoregulatory function must be weighed against energetic disadvantages associated with an increase in hindgut weight (bowel ballast). For example, in a 500 kg horse, an extra 4 kg in hay intake can be estimated to increase bowel ballast by between 10 and 24 kg. On balance, there is little justification for very high-fiber diets in endurance horses and as for other equine athletes, a diet that provides roughage at about 1.5% of bodyweight is recommended.

Anecdotally, many race horse trainers limit hay intake in the day leading up to races or, alternatively, eliminate hay

from the diet and instead feed a 'complete' beet pulp-based diet. There is some evidence that a short-term reduction in forage intake is beneficial in horses undertaking high-intensity exercise. When compared to ad libitum hay consumption, restricting hay intake to ~1% of bodyweight for a 3-day period before a treadmill exercise test (2 min at 115% $\dot{V}o_{2max}$) resulted in a 2% decrease in bodyweight and a reduction in anaerobic energy expenditure during exercise, as evidenced by reduced oxygen deficit and plasma lactate concentrations. The reduction in bodyweight was attributed to a decrease in bowel ballast (gut fill).[94] The practical implications of these findings are uncertain given that many race horses do not consume more than 1% of bwt as roughage. Furthermore, a more drastic reduction in roughage intake (e.g. less than 0.75% bwt) is not recommended because, as previously discussed, low-fiber diets may predispose horses to gastrointestinal dysfunction (e.g. gastric ulcers, colic).

Nutritional ergogenic supplements

Although electrolyte, vitamin and mineral (especially iron) supplements are the most widely used in horses, the use of supplements touted to enhance performance is also common.[73] Yet, very few of these substances have been the subject of scientific studies designed to evaluate their metabolic and performance effects. The following discussion is restricted to some supplements that have been evaluated in the horse. The effect of sodium bicarbonate administration on exercise performance is discussed elsewhere in this book.

Creatine

Creatine (methylguanidine-acetic acid) is a compound derived from amino acids that is stored primarily in skeletal muscle at typical concentrations of 100–150 mmol/kg dry weight (dw) of muscle. About 60–65% of this creatine is phosphorylated. Creatine phosphate (CP) provides a rapid but brief source of phosphate for the resynthesis of adenosine triphosphate (ATP) during intense exercise and therefore helps to maintain normal ATP/ADP homeostasis. Other functions of CP metabolism include the buffering of hydrogen ions produced during anaerobic glycolysis.[72] As both ADP and hydrogen ion accumulation are factors that may contribute to development of fatigue during sprint exercise, the size of the skeletal muscle CP store may be an important determinant of performance during high-intensity exercise. Therefore, nutritional manipulations leading to increases in total muscle creatine and CP might be expected to have an ergogenic effect during intense exercise.

The use of creatine supplements by human athletes is widespread; according to one estimate, 80% of the athletes competing in the 1996 Olympic Games were using a creatine supplement.[95] There is support for an ergogenic effect of creatine supplementation in human athletes engaged in repeated sprints, probably related to an increase in the rate of CP resynthesis during recovery between bouts of exercise. However, oral creatine supplementation is not considered ergogenic for single-bout or first-bout sprints or for prolonged, submaximal exercise. The evidence is inconclusive for effects on muscle strength although creatine supplements are widely used by body builders and weight lifters.[96]

Studies in humans have demonstrated that a daily creatine dose of 20–25 g (~250 mg/kg bwt/day), divided into four doses, results in increased muscle creatine concentrations, with an apparent upper limit in creatine storage of 150–160 mmol/kg dw. About 20% of the increased muscle creatine content is stored as CP and saturation occurs 2–3 days after the start of supplementation.[96] The increase in muscle creatine content is greatest in those subjects with a low initial concentration. Lower daily doses of 3 g/day (~40–44 mg/kg bwt) will achieve a slower loading over 14–28 days and elevated muscle creatine stores can be maintained by continued daily supplementation of 2–3 g creatine.[97] Creatine is transported into muscle against a high concentration gradient, via saturable transport processes that are stimulated by exercise[98] and by insulin.[99]

There are two published reports of oral creatine supplementation in horses.[100,101] Sewell & Harris[101] demonstrated that, in contrast to humans and dogs, creatine is poorly absorbed in the horse. The intragastric administration of 50 mg Cr per kg bwt resulted in an increase in plasma creatine concentration from 40 to 100 fmol/L after 4–6 h. By comparison, the same dose in humans results in plasma concentrations of 800–1000 fmol/L.[73] Furthermore, the administration of creatine at 150 mg/kg per day (divided into three doses) for 13 days had no effect on muscle creatine content.[101] In a randomized, crossover design, Schuback et al[100] fed Standardbred trotters 25 g creatine monohydrate twice daily (total daily dose of ~100–120 mg/kg bwt) for 14 days. Before and after the period of supplementation, horses completed an incremental treadmill exercise test until exhaustion. There was no significant effect of supplementation on plasma or muscle creatine concentrations, nor an effect on treadmill run time and the muscle metabolic response to exercise.[100] Thus, creatine supplementation in the horse at dosages shown to be effective in humans has failed to result in an increase in muscle creatine content. Without a change in muscle creatine content, creatine supplementation is unlikely to exert an ergogenic effect in horses. The reason for the apparent low bioavailability of orally administered creatine in horses has not been determined. It is possible that, as an herbivorous animal, the horse's gastrointestinal tract is not adapted to the absorption of creatine.

L-Carnitine

L-Carnitine is a component of the enzymes carnitine-palmityltransferase I, carnitine-palmityltransferase II and carnitine-acylcarnitine translocase that are involved in the transport of long-chain fatty acids across the inner mitochondrial membrane.[102] As such, long-chain fatty acid oxidation is carnitine dependent and, therefore, it has been proposed that increased availability of L-carnitine by supplementary ingestion might up-regulate the capacity to transport fatty acids into the mitochondria and increase fatty acid oxidation.[72] This augmentation in fat oxidation could be of

benefit during endurance exercise. Another role of carnitine is to act as a 'sink' for acetyl-CoA units produced during high-intensity exercise. The conversion of acetyl-CoA to acetylcarnitine maintains CoA availability and decreases the ratio of acetyl-CoA:CoA. As such, an increase in carnitine availability could enhance substrate flux through the citric acid cycle and increase the activity of pyruvate dehydrogenase, which is otherwise inhibited by high levels of acetyl-CoA. These mechanisms would serve to increase oxidative metabolism of glucose, decrease lactate production and perhaps enhance performance during exercise tasks that might be limited by excess hydrogen ion and lactate accumulation.[72]

However, the weight of evidence from human studies indicates that oral carnitine supplementation has no effect on muscle carnitine concentration. In addition, there is no evidence that muscle carnitine content limits fat oxidation other than in patients with inborn errors in metabolism that result in inadequate muscle carnitine. This is also likely to be the case in horses as the carnitine content of equine skeletal muscle is 2–3-fold higher when compared to human muscle.[103] Supplementation studies in humans have failed to demonstrate an effect of carnitine on measures of fat oxidation or muscle metabolism during exercise.[72,102]

Studies in humans[104] and in horses[105,106] have demonstrated that the oral bioavailability of L-carnitine is poor. In horses, large oral doses of L-carnitine (10–60 g) are required to effect an approximate doubling in plasma carnitine concentration.[105] Importantly, supplementation at these levels for 58 days had no effect on muscle carnitine content. In a subsequent study, intravenous doses of 10 g L-carnitine were administered daily for 26 days.[106] These infusions resulted in peak plasma carnitine concentrations 30-fold higher when compared to pre-injection values and concentrations remained three-fold higher after 6 h. Yet, there was no change in muscle carnitine content. Thus, from the available data there is no evidence that muscle carnitine content in horses is enhanced as a result of oral or intravenous L-carnitine supplementation.

Although the weight of evidence suggests that L-carnitine is unlikely to be ergogenic in horses, a recent study has provided evidence that supplementation during conditioning may augment training-associated skeletal muscle adaptations.[107] In a small group of 2-year-old Standardbred horses subjected to a 10-week conditioning program, supplementation with L-carnitine (10 g/day per os) was associated with significant increases in the percentage of type IIA muscle fibers and the intensity of periodic acid-Schiff staining (an indicator of intrafiber glycogen content) when compared to untreated control horses.[107] The mechanism of these effects is unclear and somewhat perplexing, given that previous studies have failed to demonstrate a change in muscle carnitine content in horses receiving an identical carnitine dosage. Further studies are required to determine the performance implications of these apparent carnitine-induced muscular adaptations.

Amino acids

Amino acid or 'refined' protein supplements are often touted for their ability to 'build' muscle mass or, in the case of the branched-chain amino acids (BCAA) (leucine, isoleucine, valine), enhance endurance performance by modifying factors that contribute to central fatigue.[108,109] In addition, it has been proposed that BCAA supplementation during exercise may provide carbon intermediates for the citric acid cycle at a time when endogenous carbohydrate reserves are depleted, thereby delaying the onset of fatigue.[72]

The 'central fatigue' hypothesis proposes that increased brain serotonin contributes to fatigue development during prolonged moderate-intensity exercise.[109] The increase in brain serotonin synthesis occurs as a result of increased transport of free (unbound) tryptophan across the blood–brain barrier. Key to this increase in tryptophan uptake is an increase in the plasma ratio of free tryptophan to BCAA,[109] which may increase for two reasons. First, as blood free fatty acid (FFA) concentration rises during exercise, the FFA compete with tryptophan for binding sites on albumin and the FFA displace some of the tryptophan molecules from albumin; therefore, free tryptophan concentration increases. Second, an increase in the oxidation of BCAA in muscle results in a decrease in blood BCAA concentration. As BCAA and tryptophan compete for carrier-mediated entry into the central nervous system, an increase in the free tryptophan-to-BCAA ratio leads to increased tryptophan transport. Therefore, it has been theorized that BCAA supplementation could reduce the exercise-induced increase in brain tryptophan uptake and thus delay fatigue.[109] Interestingly, when horses were infused with tryptophan (100 mg/kg, i.v.) during submaximal exercise, run time to fatigue was decreased by ~15% relative to the placebo treatment, providing evidence that an increase in circulating tryptophan adversely affects endurance performance in horses.[79] However, the oral ingestion of a tryptophan solution that markedly increased plasma free tryptophan concentration and estimated brain tryptophan uptake had no effect on time to exhaustion in exercising humans.[110] Furthermore, in this and other studies, the ingestion of large quantities of BCAA also had no effect on endurance performance.[72,110] These data cast some doubt on the 'central fatigue' hypothesis and suggest that BCAA supplementation is not ergogenic during dynamic exercise in humans.

BCAA supplements are marketed for use in horses, but there are no published data regarding their effects on exercise performance per se. Glade[111] reported that BCAA supplementation mitigated the increase in blood lactate during exercise. However, the exercise test involved treadmill walking and the applicability of these results to equine athletic activities is questionable. More recent studies have failed to demonstrate a beneficial effect of BCAA supplementation in horses. The administration of a mixture of L-leucine (9 g), isoleucine (4.5 g) and L-valine (9 g) to Standardbreds 1 h before training had no measurable effect on energy metabolism during intense exercise.[112] Similarly, there were no changes in plasma biochemical variables during and after exercise in horses fed BCAA three times per week for 5 weeks.[113]

Several studies in humans have demonstrated that increased amino acid availability early in the postexercise period modifies protein metabolism in skeletal muscle.[114–117]

Specifically, hyperaminoacidemia resulting from ingestion or intravenous infusion of amino acids increases postexercise muscle protein synthetic rate and prevents the exercise-induced increase in protein degradation. Thus, postexercise amino acid or protein supplementation may promote anabolism in skeletal muscle during conditioning. Neither the effects of exercise in muscle protein metabolism nor the effect of postexercise amino acid or protein supplementation on these processes have been investigated in horses.

Antioxidants

As discussed, exercise has been linked with an increase in free oxygen radical species that may cause cellular damage. Thus, it has been postulated that supplementation of athletes with antioxidants such as vitamin E or vitamin C will increase antioxidant status and confer protection against free radical-associated damage. Although there is evidence in humans that antioxidant supplementation provides some degree of protection during periods of increased stress, such as a sudden increase in training load (see Packer 1997 for review),[32] overall the literature on the effects of antioxidant supplementation is confusing and no clear recommendations have emerged for supplementation strategies in human athletes. Similarly, the performance effects of large-dose antioxidant supplementation in horses are unclear. On the other hand, there is evidence that antioxidant supplementation of horses with recurrent airway obstruction improves antioxidant status and moderates airway inflammation.[118]

CHAPTER 37

Metabolic diseases of athletic horses

Seppo Hyyppä and A. Reeta Pösö

Exhausted horse syndrome

- Occurs in events that require sustained (endurance) exercise.
- Clinical signs include depression, hyperthermia, delayed recovery of heart rate, muscle fasciculations and soreness, shortened stride and increased capillary refill time.
- Treatment focuses on correction of fluid and electrolyte deficits and aggressive cooling of the overheated horse.
- Despite extensive supportive care, severely affected horses may die.

Recognition

In events that require sustained exercise, horses are sometimes pushed past their performance limit and show signs of what has been termed the exhausted horse syndrome.

History and presenting complaint

The syndrome begins with subtle signs of distress: changes in the sensory state and attitude of the horse, mild muscle soreness and small inconsistencies in gait. If exercise is continued, signs will become more and more pronounced. Muscles start to show localized hardening and pain on palpation, the gait becomes stiff and stilted, muscle spasms and cramps may occur, as may synchronous diaphragmatic flutter. Severely affected horses are often unwilling to continue to exercise and are depressed. They may even show inco-ordination (ataxia) or become recumbent.

Physical examination

Temperature, heart and respiratory rates are elevated and after cessation of exercise show a delayed return to resting values. Although the heart and respiratory rates of an exhausted and a non-exhausted horse may be similar immediately following exercise, these rates return to normal (heart rate under 60 bpm, respiratory rate under 25 breaths/min) within 10–20 minutes of recovery in the non-exhausted horse but not in the exhausted one. Rectal temperature may be 42°C or higher. However, measured rectal temperature may be lower than true body temperature if the horse has diminished anal sphincter tone. Respiratory rate is elevated in an attempt to increase respiratory heat loss; heart rate is elevated to maintain cardiac output. Auscultation of the heart may reveal cardiac irregularities, capillary refill time is increased and both pulse pressure and jugular distensibility are decreased. Dehydration is expressed clinically as decreased skin turgor, sunken eyes, dry mucous membranes, firm, dry feces and decreased urine output. Mild signs of dehydration usually become apparent at a body water deficit of 4–5%. Subjectively, the sweating response may appear inappropriate relative to the level of hyperthermia (e.g. a patchy appearance or, in severe cases, a hot and dry coat). Despite significant dehydration, affected horses often are not interested in water or feed. Intestinal stasis commonly occurs with decreased or absent boborygmi, poor anal tone and, occasionally, colic.

In severely affected horses, a number of serious complications may develop immediately or over the following 1–4 days. These include exertional rhabdomyolysis, renal failure secondary to muscle necrosis and myoglobinuria, hepatic dysfunction, gastrointestinal dysfunction, laminitis and central nervous system disorders. Despite intensive supportive care, the horse may die.

Laboratory examination

In an exhausted horse, routine hematology reveals increased packed cell volume and plasma protein concentration due to dehydration. Serum or plasma biochemical analysis may

show normo- or slight hyponatremia, hypokalemia, hypocalcemia (ionized), hypochloremia and associated metabolic alkalosis.[1] Three-day event and combined driving horses have metabolic acidosis until excess lactate is oxidized. As a result of muscle exertion or damage, increases in muscle enzyme activity and plasma phosphorus concentration may be evident. Plasma creatinine values may be elevated, suggesting a reduction in glomerular filtration rate because of dehydration. Urine samples appear dark due to myoglobin, hematuria, proteinuria and glycosuria.[2,3]

Necropsy examination

Necropsy findings include skeletal and myocardial muscle damage, gastrointestinal ulceration, renal necrosis and sometimes renal infarction as well as laminitis.[4]

Treatment and prognosis

Therapeutic aims

Cooling the overheated horse and fluid therapy to replace fluid losses and to assist in restoration of circulating blood volume are essential components of therapy.

Therapy

Exercise must cease to minimize further damage and a horse with marked elevation in rectal temperature (41°C or greater) should be cooled down as quickly as possible. Repeated application of cool or cold water by sponges or by hosing down and ventilation via a natural breeze or a fan will enhance heat loss via convection and evaporation. Ice-water enemas can be effective in a severely compromised patient. Cooling should continue until the body temperature is reduced to nearly normal (< 39°C).

For mildly affected horses, rest together with cooling out and access to water, salt and feed may be sufficient, but if no improvement occurs within 30 minutes, fluid therapy is required. In severe cases, fluid therapy should be started immediately. Under most circumstances, it is better to treat a horse in the field and not to attempt a trailer ride until it has been rehydrated. The severely dehydrated horse will need 30–80 L of fluid. In many cases, however, after the first 15–20 L the horse will start to drink and eat and be able to restore the remaining deficit itself.

Oral administration offers the advantages of speed and convenience and can be used if the horse has normal gut sounds. Via nasogastric tube, 5–8 L of fluid can be given every 30–60 min until the horse shows signs of improvement. Oral administration can be started immediately after exercise, because consumption of 10–15 L of cool (~ 16°C) water within 3–5 min of completing exercise is not harmful.[5] Isotonic solutions containing sodium, potassium, calcium, chloride and glucose are often well tolerated and fairly rapidly absorbed. Commercial electrolyte powders should be those formulated for horses. For example, electrolyte formulations designed for use in calves with diarrhea usually contain bicarbonate, lactate or citrate. Therefore, these preparations are not the best choice for the treatment of horses with exercise-induced dehydration because of their alkalinizing effects. Hypertonic solutions should also be avoided, because they may cause a transient reduction in plasma volume due to movement of water into the bowel lumen.[6] Oral administration should be halted if any discomfort or gastric reflux becomes apparent.

If the horse is severely compromised, gut sounds are absent or gastric reflux is evident, intravenous (i.v.) fluids are indicated. An i.v. catheter should be placed in a jugular vein. The rate of fluid administration will depend on the extent of hypovolemia and dehydration. In severely affected horses, a second catheter may be inserted to facilitate a rapid rate of fluid administration (~ 20 L/h) during the first hour. In less compromised patients, 8–10 L/h is a suitable initial rate of fluid administration. Preferred fluids are isotonic or only slightly hypertonic solutions containing sodium, potassium, chloride, calcium and glucose (e.g. Ringer's solution with 5% glucose). An alternative is 0.9% saline with glucose and potassium added: 1–3 g of potassium chloride/L and 5–10 g of glucose/L.[4] The added glucose will also assist in the replacement of energy deficits. Because these horses often have metabolic alkalosis, lactated Ringer's solution or sodium bicarbonate solution is not the best choice, especially in a severely compromised patient. In hypoproteinemic horses (e.g. secondary to diarrhea or renal disease), colloids and/or plasma may be necessary to limit development of pulmonary or peripheral edema.[7]

Sometimes non-steroidal anti-inflammatory agents (NSAIDs) and phenothiazine derivatives such as

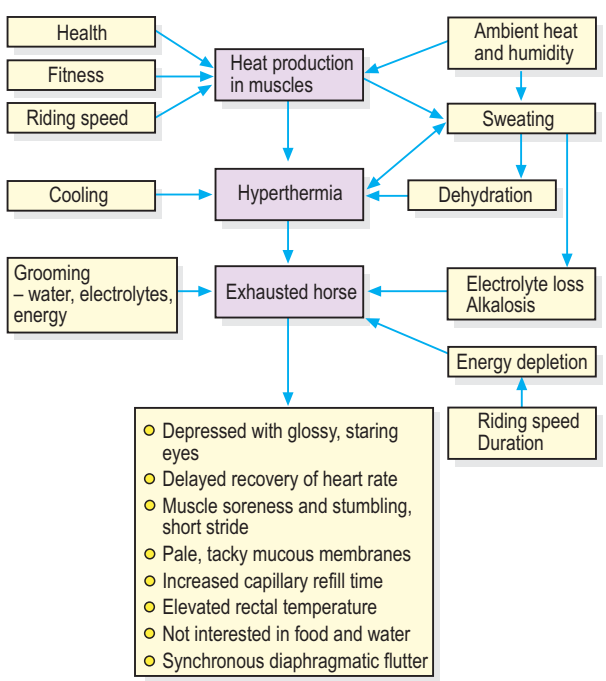

Fig. 37.1
Both internal and external factors contribute to dehydration, electrolyte loss and overloading which, if untreated, may lead to the exhausted horse syndrome.

acepromazine are required to control muscle pain and anxiety. As dehydration and hypovolemia increase the risk for NSAID toxicity, these agents should be administered only in conjunction with fluid therapy. Flunixin meglumine (0.5–1.0 mg/kg), phenylbutazone (2.2–4.4 mg/kg) or ketoprofen (0.5–1.0 mg/kg) can be used. Parenteral dimethylsulfoxide (DMSO) may be administered for its anti-inflammatory effects.[7] Corticosteroids may be indicated in severe cases with shock and possible pulmonary edema. Heparin (30 000 IU three times daily s.c.) may be useful to prevent or treat the effects of hypercoagulability.[7]

About 50 g of a non-iodized salt (NaCl) and 25 g of potassium chloride should be added to the grain/concentrate and fed twice a day for several days. During treatment the horse should be moved as little as possible and severely affected horses should be rested for several weeks afterwards.

Prognosis

Prognosis is good for mildly and moderately affected horses, but severely affected horses may die.

Etiology and pathophysiology

The main underlying causes of the syndrome are dehydration, electrolyte loss and overheating. Depletion of energy stores in endurance horses, especially during 100 km or longer rides,[8] and high lactate production in event and driving horses may contribute to the onset of exhaustion.

Dehydration occurs as a result of heat dissipation. Physical exercise leads to considerable heat production, because only 20–25% of the energy utilized in muscles is converted to mechanical energy. Evaporation of sweat is the most efficient means of heat loss during exercise and may be the only means of heat dissipation in a hot environment. The amount of sweat produced depends on the horse's size and fitness, on work intensity and the environmental conditions. Under cool climatic conditions, horses may sweat 5–8 L/h but in hot weather sweat production may amount to 10–15 L/h when activity levels are maintained at a high rate (e.g. 15 km/h). During endurance competitions, horses routinely lose 4–7% of their bodyweight but in hot conditions, net water loss may be about 40 L or close to 10% of bodyweight.[9] Respective values during the endurance phase of three-day eventing range from 2% to 4% of bodyweight under normal conditions[10] and in hot conditions deficits greater than 9% of bodyweight have been reported.[11] During sweating, water is mainly lost from the extracellular fluid and the consequent decreases in blood and plasma volumes[12] can reduce perfusion in skeletal muscle and in other vital organs. Inadequate tissue perfusion leads to inefficient oxygen and substrate transport, and hampers thermoregulation. If severe, this cardiovascular compromise may contribute to impaired renal function and partial renal shutdown.

Sweating-induced dehydration is always accompanied by electrolyte loss. Equine sweat is isotonic or slightly hypertonic relative to plasma and contains high concentrations of sodium, potassium and chloride and also some calcium and magnesium.[9] Abundant sweating will incur significant ion deficits; these will lead to alterations in skeletal muscle ion content, increasing the potential for muscular dysfunction and contributing directly to fatigue.[13]

Because of sweating, the most consistent acid–base alteration associated with endurance horses in a hot environment is metabolic alkalosis. These horses exercise at moderate work intensities at a fairly constant speed between 10 and 20 km/h and rely almost totally on aerobic energy metabolism, producing very little or no lactate. Typical plasma lactate concentrations during such exercise are 1.0–3.3 mmol/L.[14] The degree of metabolic alkalosis is dependent on the severity of hypochloremia and hypokalemia.[4] Hypochloremia is associated with an increase in plasma bicarbonate because in the kidney when chloride concentration is low, bicarbonate (HCO_3^-) is resorbed. As plasma sodium concentration tends to decrease due to loss in sweat, the kidney conserves sodium at the expense of potassium and hydrogen ions, which also contributes to the alkalosis.[4] Potassium, magnesium, and calcium depletion associated with metabolic alkalosis may alter membrane potential and neuromuscular transmission, contributing to gastrointestinal stasis, cardiac arrhythmias and muscle cramps and spasms including synchronous diaphragmatic flutter.[9]

The situation differs during the endurance phase in three-day eventing and the marathon phase in combined driving, during which anaerobic metabolism significantly contributes to energy transduction, plasma lactate concentrations are very high (up to 38.5–40.2 mmol/L)[15,16] and horses develop metabolic acidosis. After exercise, the acidosis is resolved through oxidation of lactate during a 30-min to 2-h period. Thereafter, metabolic alkalosis prevails.[10]

In an effort to maintain blood volume, significant dehydration and electrolyte loss result in impairment in the efficiency of sweating and evaporative cooling. Heat dissipation is markedly compromised when dehydration is severe (> 10% of bodyweight).[17] If exercise is continued, the thermoregulatory system will be overwhelmed and this will lead to an excessive elevation of body temperature (hyperthermia). Ultimately this may cause life-threatening heat stroke, with damage to the central nervous system. Heat stroke is more often observed in three-day horses and combined driving horses that do fast anaerobic work at a high rate of heat production, but it may also occur in endurance horses.

Epidemiology

Exhausted horse syndrome is most often seen in association with long-distance riding, but may also be seen in horses competing in the endurance phase of three-day eventing or in the marathon phase of combined driving, in which horses perform moderate- and high-intensity exercise for a period of 1–2 hours, depending on the level of competition. As ambient temperature and humidity and the duration of exercise increase, the incidence of exhausted horse syndrome rises. For example, in 160 km endurance rides, about half the

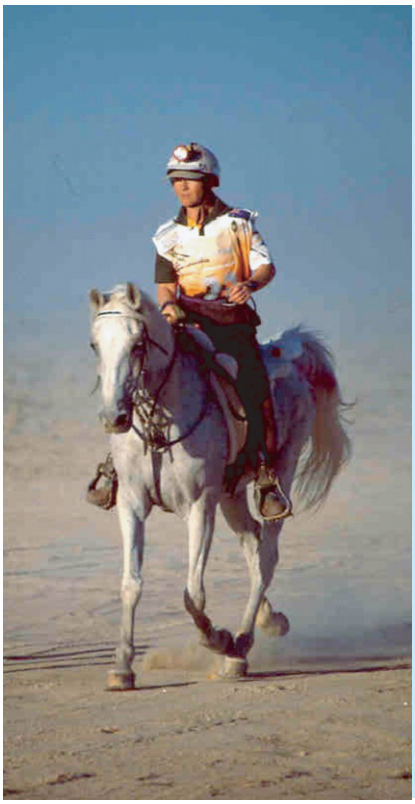

Fig. 37.2 Endurance ride is a competition to test the speed and endurance ability of a horse. But equally important is the horsemanship of the rider so that he understands the physiology of the horse and can take care of him during a competition. Horse and rider approaching the first veterinary check point in good condition during the World Endurance Championship 1998 in the United Arab Emirates. (Photo by S. Hyyppä.)

horses may retire from the competition or be eliminated at veterinary checks.[18]

Prevention

The first prerequisite for a successful endurance competition is that the horse is truly fit and healthy. Mild, undetected lameness may cause a horse to compensate and overuse some muscle groups. Pain also may lead to peripheral vasoconstriction and poor blood flow. These factors may contribute to the onset of exhaustion. But even fit and healthy horses may be over-ridden. Therefore, in the heat of competition riders have to keep a cool head and be alert to any changes in the condition of their horse.

During transport, a horse typically experiences substantial loss of weight (approximately 3 kg/h of transport) and will become dehydrated.[5] The horse therefore requires sufficient time to recover from a long trailer ride such that hydration state and electrolyte balance are normal at the start of the event.

Hyperhydration prior to exercise has been shown to be beneficial in human athletes who exercise for prolonged periods, but it is difficult to achieve in horses because they refuse to drink excess amounts of water and electrolyte solutions voluntarily. Such fluids can therefore be supplied only by nasogastric intubation or intravenously. This may, however, be forbidden by doping regulations.

Athletic horses do not regulate their salt intake according to need, at least not when offered salt from salt blocks.[19] It is therefore wise to include salt and other electrolyte supplements in their diet. Electrolyte loading by feeding supplemental electrolytes for several days prior to competition is not effective because the kidneys readily excrete excess electrolytes within a few hours of administration. Nevertheless, electrolytes administered in the few hours immediately before a prolonged exercise competition may be of benefit if adequate water is also ingested.[6]

During the endurance ride, it is critical to give the horse a chance to drink as often as possible. Horses should be taught to drink electrolyte solutions because plain water, although better than nothing at all, is inadequate. Water intake without electrolyte replacement exacerbates dilution of sodium in the extracellular fluid such that the osmotic thirst stimulus is mitigated. An isotonic, polyionic electrolyte solution that replaces some of the electrolyte deficit is therefore more beneficial. Frequent sponging of the horse with cool water will assist in evaporative heat loss and cool the horse. However, riders should keep in mind that especially during warm and hot climatic conditions, even when a horse is a good drinker, it is impossible to compensate for all the losses during the ride. It is therefore important to monitor the horse very carefully and adjust the speed accordingly or retire from the ride if necessary.

In the endurance phase of three-day eventing and in the marathon phase of combined driving, the sequence of the competitions does not allow for proper rehydration because the 10-minute rest occurs towards the end of the ride. It is unlikely that fluid consumed at this point will be absorbed in time to significantly assist rehydration and thus improve performance. On the contrary, if a large volume of fluid is given, the extra weight that the horse must carry could limit performance during the last part of the competition. Therefore, in hot weather, the best strategy is to use the rest periods to effectively cool the horse.

During the recovery period, the fullest restoration of fluid losses can be achieved by the inclusion of salts in the ration and by allowing free access to both isotonic electrolyte solution and water. Achieving complete replenishment of fluid and electrolytes is important because in the case of multiday rides, horses may fail to replenish bodyweight losses overnight and may enter the next day's competition with some degree of dehydration. Our own studies have shown that a persistent bodyweight deficit of 2% or more impairs performance on the following day.[12]

Good veterinary supervision is vital to prevent horses from being over-ridden by excessively ambitious riders. At vet gates, horses must be carefully monitored when deciding whether they are 'fit to continue'. Attending veterinarians should also be well prepared to handle any metabolic disorders and other problems that may occur.

Synchronous diaphragmatic flutter (thumps)

- Occurs in events that require sustained exercise.
- Clinical signs include a rhythmic convulsive motion in one or both flanks that is synchronous with each heart beat.

- Treatment consists of fluid therapy to replace loss by sweating.
- It is not a life-threatening condition, but may lead to more dangerous metabolic problems if exercise is continued.

Recognition

History and presenting complaint

Synchronous diaphragmatic flutter (SDF) is evident as a rhythmic movement, twitching or convulsive motion in one or both flanks of the horse that is synchronous with each heart beat. Signs of dehydration and exhaustion often accompany SDF.

Laboratory examination

Typical laboratory findings include hypocalcemia (ionized), slight hyponatremia, hypokalemia, hypochloremia, hypomagnesemia and hyperphosphatemia. Hemoconcentration and metabolic alkalosis are also commonly observed.

Treatment and prognosis

Therapy

Synchronous diaphragmatic flutter may resolve on its own and no treatment is required provided the animal is eating and drinking voluntarily. If treatment is required, calcium administered by slow intravenous injection will frequently result in rapid recovery. Normally 100–300 mL of 20% calcium borogluconate is sufficient.[20] The heart must be continuously auscultated during this procedure for assessment of heart rate and rhythm: if irregularities develop, calcium administration should be discontinued.

When SDF occurs in association with sustained athletic stress, many horses will also respond to treatment with isotonic or slightly hypertonic polyionic fluids (Ringer's with 5% glucose; regular saline with some glucose and potassium added: 1–3 g of potassium chloride/L and 10 g of glucose/L) administered intravenously.[4] This treatment offers less chance of cardiac problems than with the i.v. 20% calcium borogluconate infusion.

Prognosis

Synchronous diaphragmatic flutter is not a life-threatening condition but does indicate an electrolyte imbalance which, if allowed to progress, may lead to more dangerous metabolic problems.

Etiology and pathophysiology

Alterations in acid–base and electrolyte balance may alter the membrane potential of the phrenic nerve, allowing it to discharge in response to an electrical impulse associated with atrial depolarization. Such stimulation is possible because the phrenic nerve, which originates in the cervical spine, courses over the atria before terminating in the diaphragm.

After prolonged exercise, particularly in the heat, large quantities of sodium, potassium and chloride and also some calcium and magnesium are lost in sweat[9] and horses develop metabolic alkalosis. Alkalosis increases binding of calcium to albumin and thus less calcium is present in ionized form. In addition, stress and subsequent increases in cortisol may lower calcium levels. The resultant hypocalcemia, especially that of ionized calcium, affects sodium channels in neurons and results in a lowered threshold potential of the phrenic nerve, thus allowing depolarization.[9]

Synchronous diaphragmatic flutter often occurs following a rest stop because if the horse is rehydrated without electrolyte intake, the water replenishment further dilutes Ca^{++} and K^{+} and exacerbates metabolic alkalosis.

Epidemiology

Synchronous diaphragmatic flutter is most often associated with sustained athletic stress but may also be seen in colic, lactation tetany, shipping, blister beetle toxicosis and urethral obstruction.[21] It may occur following administration of furosemide and sodium bicarbonate.[22]

Prevention

Dietary supplementation with calcium and other electrolytes is recommended in horses used for prolonged exercise tasks. However, excessive calcium feeding (e.g. alfalfa hay diets) is generally not recommended because high calcium intake may reduce the activity of calcium homeostatic mechanisms. During prolonged exercise, frequent consumption of balanced ion solutions to avoid extreme electrolyte depletion will reduce the incidence of SDF as well as that of other metabolic problems.

Synchronous diaphragmatic flutter is a sign of metabolic problems and exercise should be discontinued to prevent development of more serious disorders. In endurance competitions, SDF is a sufficient reason for elimination of the horse from the competition.

Hormonal disturbances

Endocrine dysfunction as a cause of reduced performance in horses is poorly documented. Much has been made of hypothyroidism and adrenal exhaustion, but few data support their existence.

Thyroid gland

Hypothyroidism

- Controversy exists over its true incidence in sport horses.
- Clinical signs attributed to hypothyroidism include weight gain, poor performance and myopathies.

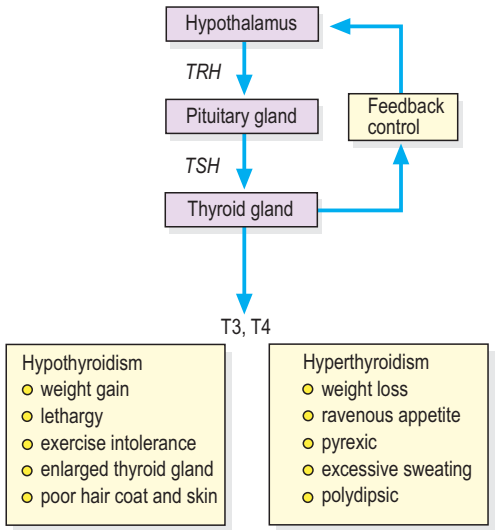

Fig. 37.3
Release of thyroid hormones is under the control of hypothalamic and pituitary hormones, with the release of those being under negative feedback regulation by thyroid hormones. Both low and high concentrations of thyroid hormones may be harmful as indicated by the signs of hypo- and hyperthyroidism.

- Diagnosis should never be based on a single low thyroid hormone value.
- Treatment consists of ascertaining adequate dietary intake of iodine and supplementation with thyroid hormones.

Recognition

Hypothyroidism is defined as a deficiency in thyroid activity. It has been identified as a cause of poor performance and myopathies in racing horses.[23]

History and presenting complaint

Clinical signs frequently attributed to hypothyroidism include weight gain, lethargy, poor coat and skin, cresty neck, exercise intolerance, exertional rhabdomyolysis, laminitis, fertility problems, agalactia, retarded growth and enlarged thyroid glands (goiter).[24,25] In most adult horses the thyroid glands, which are located at the dorsal aspect of the trachea just distal to the pharynx and made of two discrete firm lobes connected by a narrow isthmus, are barely detectable by palpation.

Signs similar to those attributed to hypothyroidism are seen in adult horses after thyroidectomy. These include reduced resting heart and respiratory rates, resting body temperature and cardiac output, but increased blood and plasma volumes.[26] Thyroidectomized horses develop edema of the rear limbs, a dull and coarse coat and lethargy.[27] After thyroidectomy, changes occur also in blood lipid concentrations: triglycerides and total cholesterol increase and non-esterified fatty acids decrease.[28]

Laboratory examination

Diagnostic testing is often limited to measurement of total and free tri-iodothyronine (T3) and thyroxin (T4) concentrations. In the circulation, the thyroid hormones are bound to plasma proteins, with free thyroid hormones constituting only about 1% of the total. Reported reference ranges for normal horses are 0.32–1.23 nmol/L for total T3 and 15–74 nmol/L for total T4 concentrations.[29] However, hypothyroidism should never be diagnosed on the basis of a single low value, because several factors influence the concentrations of T3 and T4. Circulating levels show some diurnal variation, because thyroid-stimulating hormone (TSH) is released in a pulsed manner and mainly in the afternoons.[30] Thyroid activity increases as horses acclimatize to colder climates and decreases as horses acclimatize to warmer climates. After a high carbohydrate diet, serum T3 increases and serum T4 decreases[24] and prolonged food restriction results in decreases in total and free T3 concentrations.[31] González and co-workers[32] reported a sudden increase in T3 in response to an acute race stress and Irvine[33] reported T4 to increase with training. In mares, stage of estrus cycle also affects T4 concentrations.[24] Most importantly, any concurrent disease condition may lead to a decrease in circulating serum T3 and T4. Furthermore, certain medications, including phenylbutazone and corticosteroids, will lower thyroid hormone concentrations.[30,34]

Diagnostic confirmation

Hypothyroidism may be confirmed by a thyroid-releasing hormone (TRH) stimulation test, e.g. 1 mg of synthetic TRH injected intravenously.[29] Four hours after TRH injection in healthy horses, serum total T3 and T4 concentrations are more than double that before injection.[29] Similarly, T3 concentration increases fivefold (peak at 2 h) and T4 more than twofold (peak at 4 h) after administration of TSH, (5 IU intravenously).[29,36,37] Primary thyroid deficiency may be confirmed by minimal response to stimulation.[26] Unfortunately, in practice situations the use of these function tests is limited by the availability and cost of TSH and TRH.

Treatment and prognosis

Therapeutic aims

The first step in formulation of a treatment plan is to ascertain that dietary intake of iodine is adequate. The NRC

Table 37.1 Serum T4 and T3 concentrations in a population of clinically healthy horses by age group[35]

Age	T4 (μg/100 mL)		T3 (ng/100 mL)	
	Mean	Min–max	Mean	Min–max
1.5–4 months	4.0	2.9–5.3	193	135–270
2–5 years	1.9	1.2–2.9	120	72–180
6–10 years	1.7	1.3–2.2	86	48–118
11–25 years	1.6	0.9–2.2	84	47–145

recommends a minimum daily intake of 0.1 mg/kg of feed.[38] If correction of dietary deficiency does not solve the problem, replacement hormone supplementation is indicated.

Therapy

Because T3 is formed from T4 by deiodination, supplementation with T4 should be effective unless there is a deiodination defect. An oral dose of 5–20 μg T4 per kg bodyweight once daily has been recommended[26,30] and if T3 is to be used, a recommended oral dose is 0.6 μg/kg twice daily.[26] Clinical response to therapy will take at least 2 weeks. Hormone levels should be monitored periodically and thyroid function and dosages reassessed. Overdosage should be avoided because it may lead to loss of muscle mass, poor performance, muscle strain and hyperexcitability.[39]

Prognosis

Thyroid hormones have a wide array of functions but are not essential for life in adults. Supplementation therapy will usually alleviate clinical signs of hypothyroidism and improve performance.

Etiology and pathophysiology

Hypothyroidism can result from abnormalities in the formation, secretion, transport or metabolism of thyroid hormones. Primary hypothyroidism results in inadequate production of T3 and T4 by the thyroid gland. This can result from a deficiency (< 1 mg/day) but also from excess (> 35 mg/day) iodine intake. Some supplements, particularly those containing kelp, are extremely high in iodine.[24] Additionally, malnutrition (hypoproteinemia), ingestion of goitrogenic feeds (e.g. raw soybeans, cabbage, turnip, rapeseed, white clover) and a catabolic state due to excessive training or chronic disease may cause hypothyroidism.[24,38,40] In secondary hypothyroidism, there is a deficiency of TSH from the pituitary gland and in tertiary hypothyroidism an inadequate quantity of TRH is released from the hypothalamus.

Epidemiology

Congenital hypothyroidism of foals is a well-established entity,[41,42] but controversy exists over its true incidence in adult horses.[43] Although no controlled studies have confirmed an association between serum thyroid concentrations and poor performance, on the basis of an apparent response to exogenous thyroid hormone treatment many practitioners consider hypothyroidism to be a real clinical syndrome.

Prevention

Ascertain that dietary intake of iodine is adequate.

Hyperthyroidism

- Occurs due to high iodine intake or thyroid tumors.
- Clinical signs include weight loss despite ravenous appetite, elevated body temperature, excessive sweating and polydipsia.
- Blood samples show increased thyroid hormone concentrations.
- Treatment consists of ascertaining appropriate dietary iodine intake, antithyroid treatment or unilateral thyroidectomy.

Recognition

Hyperthyroidism is defined as an excess in thyroid activity.

History and presenting complaint

One or both thyroid glands may be enlarged. The horse may be emaciated, tachycardic, pyrexic, polydipsic, enophthalmic and alopecic, and sweat excessively. The horse may also be hyperexcitable and have a ravenous appetite.[42]

Laboratory examination

Blood samples show increased thyroid hormone concentrations.[44]

Diagnostic confirmation

A tri-iodothyronine suppression test may be effective to confirm the diagnosis.[44] In mares, high thyroid hormone levels without clinical signs may be evident during pregnancy.[30]

Treatment and prognosis

When hyperthyroidism is suspected, the first step is to ascertain that dietary intake of iodine is acceptable. In mature horses daily iodine intake should not exceed 35 mg per day. In addition to feeds, other products such as leg paints and shampoos containing iodine can be the source of excess iodine. If the problem is not solved after dietary correction, antithyroid treatment such as 1 g potassium iodide orally per day can be tried.[30] If this treatment is ineffective, a unilateral thyroidectomy may be considered.[44] If severe distress from thyrotoxicosis occurs, glucocorticoids may alleviate the signs.[30]

Etiology and pathophysiology

Horses may develop accelerated thyroid hormone production due to high iodine intake,[30] and hyperthyroidism has also been reported in elderly horses with thyroid adenoma or adenocarcinoma.[44,45]

Epidemiology

Hyperthyroidism is rare; it may be associated with thyroid tumors, which are moderately common in aged horses.[45] In race horses, cases of hyperexcitability associated with hyperthyroidism have been reported.[46]

Prevention

Ascertain that dietary intake of iodine is not excessive.

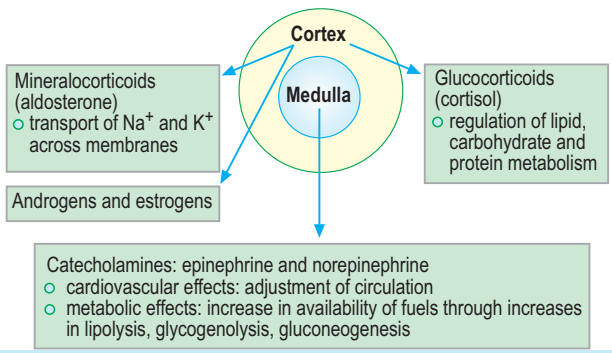

Fig. 37.4
The hormones produced by the adrenal cortex and medulla and their primary effects on metabolism, electrolyte balance and cardiovascular system.

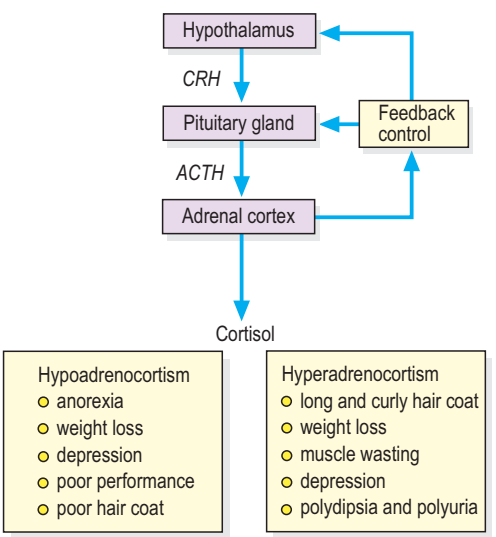

Fig. 37.5
Hypothalamic and pituitary hormones that are under feedback regulation by circulating cortisol control the release of cortisol from the adrenal cortex. Hypoadrenocorticism may be due to colic, endotoxemia or intensive training and also may be caused by cessation of exogenous glucocorticoid or anabolic steroid administration. Pituitary adenoma (equine Cushing's disease) is the most common cause of hyperadrenocorticism in horses. These tumors secrete ACTH, thereby resulting in hypercortisolemia.

Adrenal glands

Adrenal exhaustion (hypoadrenocortism, adrenal insufficiency, steroid letdown syndrome, Addison's disease)

- May develop after discontinuation of prolonged administration of glucocorticoids or anabolic steroids, colic and endotoxemia, or hard training.
- Clinical signs include depression, anorexia, weight loss and poor performance.
- Diagnostic confirmation requires an ACTH stimulation test.
- Treatment consists of avoidance of stress and supplementation with small quantities of corticosteroids.

Recognition

History and presenting complaint

Clinical signs attributed to adrenal exhaustion include depression, anorexia, weight loss, mild abdominal discomfort, poor coat and lameness. In adrenalectomized rats, exercise induces a less pronounced increase in muscle lactate concentrations, a less pronounced decrease in liver and muscle glycogen concentrations, much lower blood glucose concentrations and decreased exercise time to fatigue when compared to intact rats.[47]

Laboratory examination

Serum chemistry may be normal or hyponatremia, hypochloremia, hyperkalemia or hypoglycemia may be found. Measurement of cortisol levels is complicated by a number of factors that affect cortisol release in response to emotional and particularly physical stress, and is further complicated by circadian and ultradian fluctuations in total and free plasma cortisol concentration.

Diagnostic confirmation

Confirmation of the diagnosis requires an adrenocorticotrophin (ACTH) stimulation test, e.g. 25 IU synthetic ACTH intravenously.[48] In healthy horses 2–4 hours after an ACTH injection, plasma cortisol concentration is more than twice that before injection but in adrenal exhaustion, plasma cortisol concentration will be diminished.[49–51]

Treatment and prognosis

Treatment consists of strict avoidance of any stress. Small daily quantities of corticosteroids may be helpful.

Etiology and pathophysiology

Most cases involve sudden cessation of exogenous glucocorticoid or anabolic steroid administration following prolonged treatment regimens.[49,52] Naturally occurring adrenal exhaustion may be secondary to adrenal atrophy following conditions such as colic and endotoxemia, as the gland is a shock organ.[53] In normal Thoroughbred horses, hard training and racing at a high level may cause a decline in basal and ACTH-stimulated cortisol concentrations.[50] Moreover, poorly performing red cell hypervolemic Standardbred horses have lower cortisol concentrations than do untrained or normally performing horses.[51] Furthermore, in red cell hypervolemic horses, ACTH injection results in a smaller increase in plasma cortisol concentration than in trained normovolemic horses, which suggests that adrenal exhaustion may be a component of this syndrome.[51]

Cortisol deficiency reduces exercise capacity by depressing energy mobilization. Lipolysis is reduced, which in turn reduces the amount of free fatty acid available for aerobic energy metabolism. Gluconeogenesis decreases, which reduces carbohydrate availability. Cortisol deficiency also causes diminution of the important permissive effect of glucocorticoids on catecholamine action and causes apathy via direct neural effect.[46]

Epidemiology

Adrenal exhaustion is poorly documented in horses.

Hyperadrenocorticism (Cushing's disease)

- Primarily due to pituitary (pars intermedia) tumors.
- Clinical signs include long curly-hair coat, weight loss, muscle wasting, polydipsia, polyuria and poor performance.
- The most consistent clinicopathologic finding is hyperglycemia.
- Treatment with a serotonin antagonist or a dopamine agonist may ameliorate clinical signs.

Recognition

History and presenting complaint

The condition most often occurs in horses older than 12 years. They usually present with a history of weight loss, muscle wasting, lethargy and an abnormally long curly-hair coat that fails to shed at the appropriate time. Horses are often polydipsic and polyuric. Mares may show abnormal estrus cycles. Recurrent infections due to immune suppression and chronic laminitis have also been associated with the disease.

Laboratory examination

The most consistent finding is hyperglycemia, which in many cases also results in glucosuria and osmotic diuresis. A blood sample may also reveal neutrophilia and hyperlipemia. Blood cortisol concentration may be elevated, but this is not a consistent finding. Couetil et al[54] have suggested that plasma ACTH concentration determined with a commercial human radio-immunoassay can serve as a sensitive indicator of Cushing's disease in horses and ponies.

Necropsy examination

Post-mortem examination reveals a variably sized tumor of the intermediate lobe of the pituitary and hypertrophy of the adrenal cortex.

Diagnostic confirmation

Diagnosis should be confirmed by laboratory tests because neglect, poor dental care, parasites and other underlying systemic illnesses may lead to many of the same clinical signs. Confirmation may be achieved through detection of a poor response to a dexamethasone suppression test (DST) and an exaggerated response to an ACTH stimulation test.[55] A TRH response test and glucose tolerance test may also be used.[56]

Treatment and prognosis

Treatment is usually attempted with the serotonin antagonist cyproheptadine or the dopamine agonist pergolide mesylate. Clinical experience has indicated that pergolide is the treatment of choice. An initial dose of 0.001 mg/kg per day (0.5 mg/day for a 500 kg horse) is recommended. The horse should be re-evaluated (e.g. with a DST) after 4–8 weeks of treatment. If there has been no clinical improvement, the dose may be increased by 0.25 mg per day until improvement in clinical signs or results of a DST. When an effective dose is established, the horse is maintained on that dose for life. The results of cyproheptadine treatment have been less consistent. The recommended dose for initial treatment is 0.25 mg/kg once daily. If no improvement occurs, the dose may be increased to 0.5 mg/kg once daily or 0.25 mg/kg twice daily.[55,56]

These drug treatments do not affect tumor size, but may reduce the secretion of ACTH and other peptides. Signs caused by excess ACTH will usually be ameliorated in 6–8 weeks. Horses with long thick hair coats that do not shed should be body clipped.

Etiology and pathophysiology

Chronically elevated blood cortisol has a number of potential effects. It may lead to hyperglycemia via stimulation of gluconeogenesis. Muscles become more prone to fatigue and often exhibit marked weakness and wasting. A high cortisol concentration may contribute to polyuria and polydipsia by antagonizing antidiuretic hormone activity, and promote immunosuppression and mediate the development of lamini-

tis. Hypercortisolemia may also cause polycythemia with inappropriately increased blood viscosity, which places an increased load on the cardiovascular system.[46] In addition, the tumor mass of the pituitary adenoma can impinge upon surrounding structures, resulting in a variety of neurologic abnormalities.

Epidemiology

Adrenal tumors are almost unknown in horses as a cause of hyperadrenocorticism. However, pituitary adenomas, which are commonly reported in older horses, are associated with increased ACTH production, resulting in hyperadrenocorticism accompanied by an increase in circulating cortisol.

Problems associated with training programs

Surveys indicate that the most common reason why young race horses are withheld from training and racing is some form of lameness, with respiratory disease the next most common cause. However, when no apparent abnormality can account for the alleged poor or reduced performance, an evaluation of the management and training program is indicated. Critical assessment of training programs can be difficult because even within a given equine sport, there is wide variation in successful training programs.

Over-reaching (overloading, short-term overtraining)

- Occurs due to short-term maladaptation to training.
- Clinical signs include decreased appetite, irritability, muscle soreness and reluctance to exercise.
- Treatment consists of rest for up to 2 weeks.
- Training program needs to be evaluated to prevent recurrence.

Recognition

History and presenting complaint

Short-term maladaptation to training that causes fatigue and poor performance due to insufficient metabolic recovery is called over-reaching. As for true overtraining, the condition is characterized by immediate or delayed onset of muscle soreness, stiffness and performance decrement, and by decreased appetite, as well as behavioral changes (irritability), including a reluctance to exercise.

Laboratory examination

Blood samples may show increased activity of muscle enzymes (aspartate aminotransferase (ASAT), creatine kinase (CK) and lactate dehydrogenase (LDH)).

Treatment and prognosis

The problem is solved with up to 2 weeks of rest and proper nutrition. In horses, recovery of glycogen stores is slower

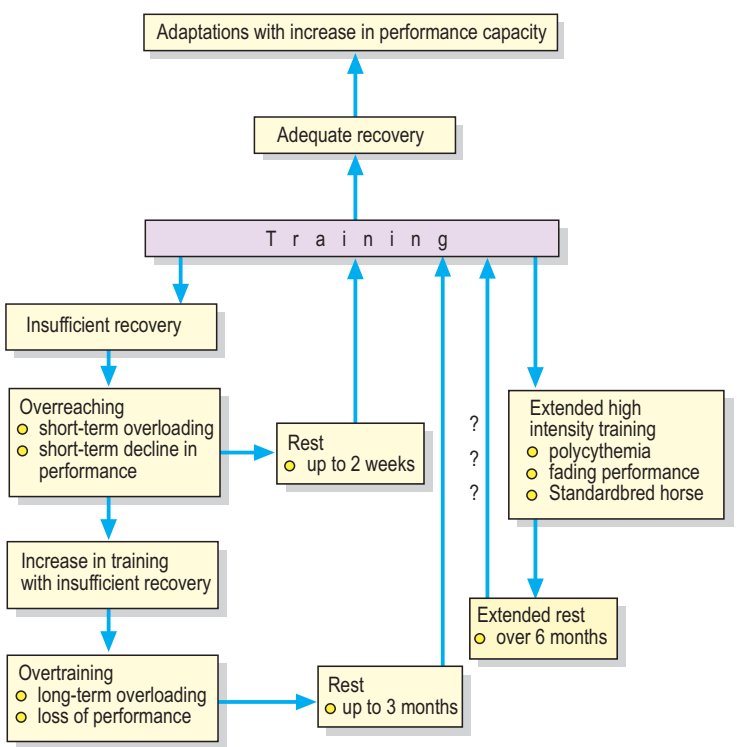

Fig. 37.6
A balanced training program leads to adaptation and increase in performance capacity while an overly strenuous training load, with insufficient recovery between training sessions, may cause loss of performance. In Standardbred trotters, training-induced red cell hypervolemia may signal the end of a successful racing career.

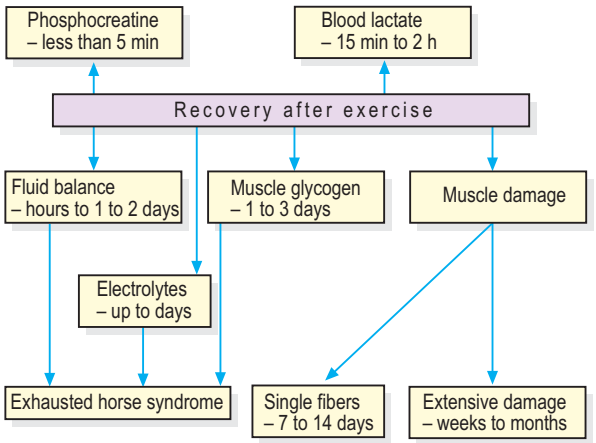

Fig. 37.7
Energy stores and fluid and electrolyte balance recover within minutes to 2–3 days following strenuous exercise, but repair of muscle damage may require weeks.

than in other species and may take up to 3 days.[57] For the most part, muscles repair themselves in up to 7–10 days and in doing so, produce an adaptation or training effect.

Etiology and pathophysiology

This condition occurs when the volume of training is too great or the interval between workouts is too short, resulting in acute or cumulative depletion of energy stores and damage to muscle cells. Recovery usually occurs within a few days.[58]

Epidemiology

Young horses at the beginning of their training are especially susceptible to this condition when too much is attempted too soon. It may, however, also occur in well-trained horses if training is dramatically increased or the workout routine altered.

Prevention

A new exercise program should begin slowly, with increases in intensity or duration of a workout schedule being accomplished gradually. As a general rule, to minimize the risk of over-reaching, horses should not perform the same type of strenuous conditioning exercise on consecutive days.

Overtraining (long-term training-competition recovery imbalance, staleness)

- Occurs due to long-term imbalance between training and recovery.
- Clinical signs include decreased performance capacity, weight loss and behavioral changes.
- Treatment consists of rest for up to 3 months.
- Training program needs to be evaluated to prevent recurrence.

Recognition

Overtraining is defined as a loss of performance ability, despite the maintenance of or an increase in training effort, which cannot be explained by any discrete pathology. Athletic performance deteriorates and affected horses must reduce or cease training for variable periods of time to allow recovery.[59]

History and presenting complaint

The syndrome has been characterized by decreased performance capacity and loss of weight, as well as behavioral changes (irritability), including a reluctance to exercise.[48] Affected horses often show clinical signs consistent with psychic stress, including a nervous demeanor, tachycardia, muscle tremor, sweating and diarrhea. These signs may occur before a race or in connection with training. Poor appetite is another common clinical sign in overtrained horses. Horses may also have increased susceptibility to infections, which in human athletes has been attributed to decreased concentrations of glutamine,[60] but no such decrease has been detected in horses.[61]

Laboratory examination

No single change occurs with sufficient consistency to identify the individual horse which is overtrained. Therefore, as yet no specific biological markers have been identified to help predict the onset of overtraining.[58,62] The serum activities of AST and CK are often increased due to muscle damage, but because muscle damage can occur in horses that have not been overtrained, an increase in AST or CK activity cannot be used as a definitive marker of overtraining.[58,62] In overtrained human athletes, increased concentrations of urea have been taken as an indication of increased protein catabolism, but such changes have not been detected in the horse, suggesting that in horses overtraining is not associated with proteolysis.[62]

Diagnostic confirmation

Signs of overtraining persist after 2 weeks of a reduced training load. However, because chronic fatigue can be the presenting symptom of many diseases, any medical conditions that cause chronic fatigue must be excluded.

Treatment and prognosis

An extended rest for 30–90 days is needed to reverse overtraining.

Etiology and pathophysiology

In training, the concept of progressive loading is applied to continually challenge body systems to adapt such that they are better able to perform the tasks demanded. Adaptation to any workload imposed at one point will not be seen until some point in the future, because the body requires time to respond. Overtraining is an imbalance between training and recovery, exercise and exercise capacity, stress and stress tolerance. Incorrect nutrition may contribute to the overtraining syndrome. Chronic fatigue, lack of training progress and injuries are common outcomes.

The physiologic features of overtraining are still poorly understood. In addition to depletion of energy stores and damage to muscle cells, it probably involves endocrine imbalance. Hormones are essential for physiologic reactions and adaptations during exercise and influence the recovery phase after exercise by modulating anabolic and catabolic processes. In overtrained human athletes, disorders of hormonal regulation at pituitary–hypothalamic level, adrenal exhaustion and a consequent reduction in blood cortisol, downregulation of peripheral and perhaps central β-adrenergic receptors and also downregulation of neuromuscular transmission have been claimed to occur.[63–65] Also in overtrained horses postexercise plasma cortisol concentration is reduced,[66] but both increased and decreased adrenocortical responsiveness to ACTH administration have been reported.[48,62]

Epidemiology

Overtraining is primarily related to a sustained high training load, such as that undertaken by Standardbred and Thoroughbred race horses.

Prevention

Increase in training load should be moderate, so that the horse has time to respond to the present load before any new requirement is imposed. Monotonous training should be avoided. After strenuous exercise, recovery is essential to allow time for training gains to take place and to permit further heavy work. Even when the training load is increased, the program for light exercise days should not be increased. Every third to fifth week should be considerably easier than the rest of the training program, to allow time for full recovery.

No two horses react the same to an equivalent exercise regimen. Each horse should therefore be monitored daily by measurement of resting heart rate and rectal temperature, by palpation of legs and muscles for swelling and soreness, by assessment of gait for any irregularities and by observance for any change in attitude or appetite. If any irregularities are noted, training volume should be reduced or a short rest period given. Adequate nutrition must be maintained.

Training-induced polycythemia (red cell hypervolemia, erythrocytosis)

- Occurs in association with long-term high-intensity training.
- Clinical signs may be absent except for a history of a rapid decline in performance after several years of racing.
- Blood samples show excessively high working hematocrit and hemoglobin values.
- Treatment consists of rest over 6 months, but polycythemia may signal the end of a successful racing career.

Recognition

Polycythemia has been described in Standardbred trotters. The condition is defined as a postexercise elevation of red blood cell count, packed cell volume and hemoglobin concentration above those levels considered normal.

History and presenting complaint

Horses are usually presented with a history of a rapid decline in racing performance after 3–4 years of racing.[67]

Physical examination

Polycythemic horses are often free from symptoms at rest, although Persson & Forssberg[68] have suggested an association between polycythemia and T-wave abnormalities in the electrocardiogram. The performance of affected horses in a submaximal standardized exercise test is similar to that of normovolemic horses, but polycythemic horses have reduced exercise capacity during racing.[67] Polycythemic horses and normovolemic horses show no differences in oxygen uptake, the maximum difference in arteriovenous oxygen content, heart rate, stroke volume, cardiac output or systemic arterial pressure, but polycythemic horses show higher pulmonary arterial pressure.[69] The latter may contribute to the high incidence of exercise-induced pulmonary hemorrhage in red cell hypervolemic horses.[69]

Laboratory examination

High postexercise values for hematocrit (> 65%) and hemoglobin concentration (> 240 g/L) suggest that polycythemia could be the problem. However, dehydration must be ruled out because a reduction in plasma volume will induce increases in red blood cell count, hematocrit and hemoglobin concentration.

Diagnostic confirmation

Diagnosis should be confirmed by measurement of total red cell volume. This involves measurement of postexercise hematocrit and plasma volume, the latter by use of the Evans blue dye dilution method.[70] For normovolemic adult trotters, red cell volumes are between 60 and 90 mL/kg[71] and for hypervolemic horses (4 years and older), between 90 and 115 mL/kg.[67]

Examination of middle gluteal muscle biopsy samples may yield useful information. Muscle capillary density is lower in red cell hypervolemic horses, while mitochondrial volume, estimated from NADH tetrazolium dehydrogenase activity in type II B muscle fibers, is higher in red cell hypervolemic when compared to normovolemic horses.[72,73]

Treatment and prognosis

As polycythemia seems to be a very persistent condition in Standardbred trotters, it has been suggested that its recognition may signal the end of a successful racing career.[67] Practitioners report that phlebotomy (4–5 L) will improve performance capacity of horses for only 2–3 weeks. Six months or more of rest without high-intensity training will usually reduce the red cell volume, but as training is resumed the condition frequently recurs. Castrating intact males to reduce circulating testosterone levels has also been suggested to be beneficial.

Etiology and pathophysiology

The etiology of this condition is not known. Intermittent hypoxia associated with regular strenuous exercise is thought to stimulate erythropoietin release and red cell production. This increase in red cell mass is presumably an important mechanism of training-associated increases in athletic capacity. Indeed, a significant correlation exists between blood volume and kilometer time in trotters. On the other hand, marked increases in blood viscosity associated with red cell hypervolemia may increase peripheral resistance, decrease cardiac output and impair tissue oxygenation.[74] These effects may underlie the reduction in athletic performance observed in trotters with polycythemia. Affected horses have lower muscle capillarization that may hamper the efflux of lactate from contracting skeletal muscle.[72,73]

Stallions are more likely to develop polycythemia than are mares and geldings, because on average they have a significantly higher red cell volume, due to high testosterone production. Abuse of erythropoietin and anabolic steroids may also cause or contribute to secondary polycythemia.[75,76]

Epidemiology

Polycythemia associated with prolonged fast work training has been reported in Standardbred trotters, but in other horse breeds it appears to be rare.[58,62,67,70,77] Training-induced polycythemia with impaired racing performance was first described in Scandinavia.[70] Typical features for the athletic career of these horses are intensive training with much high-intensity work, frequent racing (30 or more races per year) and a long racing career (up to 10 years).

CHAPTER 38

Body fluids and electrolytes: responses to exercise and training

Kenneth Harrington McKeever

The exercising horse produces a tremendous amount of metabolic heat. This byproduct of the transduction of potential energy into kinetic energy can raise core body temperature in the horse from 37°C at rest to temperatures exceeding 42°C in a matter of minutes.[1–6] Normal cellular function, however, requires active and efficient ways to keep core body temperature within narrow limits. To do this a horse must move heat produced in the muscles to the periphery.[1,2,4–6] Other mammalian species, like the rabbit and dog, have an enhanced countercurrent brain bloodflow mechanism that couples with panting to provide for cooling of the brain while permissively allowing heat storage in the rest of the body and a rise in body temperature.[5,7,8] Horses and humans are the only species that cool primarily through the evaporation of sweat.[1,5,7,8] Sweating can produce tremendous fluid and electrolyte losses that, if uncompensated for, can lead to cardiovascular and thermoregulatory instability. These fluid deficits and their effects are even more pronounced during endurance exercise and exercise performed during periods of high environmental temperature and humidity.[1–3,5–7] Recent work focused on preventing thermal injuries in horses has documented findings similar to those published in the human sports medicine literature, namely that maintenance of fluid and electrolyte balance prevents dehydration and provides thermoregulatory and cardiovascular stability.[3–12] Data demonstrate that optimal fluid and electrolyte balance delays the onset of fatigue. The present chapter reviews the current literature on the effects of exercise on fluid balance and renal function in horses.

Body fluid compartments

Like all animals, the body of the horse is primarily composed of water and electrolytes. Those solutions are compartmentalized within and outside the cells. This combination of intracellular and extracellular water is referred to as the total body water (TBW). The TBW accounts for 50–70% of bodyweight, or 250–350 kg of the bodyweight of a typical 500-kg horse.[1,2,9] TBW can be measured using various indicator dilution techniques, stable isotope techniques, and bioelectric impedance technologies.[1,2,9] Each of these techniques has advantages and disadvantages, with the use of stable isotope infusion being one of the most accurate and bioelectric impedance technology the least reliable. The TBW is divided by cell membranes into two primary fluid compartments, the intracellular fluid compartment (ICF) and the extracellular fluid compartment (ECF).[1,2,8] Approximately two-thirds of the TBW (~200 L) is contained within the cells of the body leaving one-third of the water in the ECF space (~100 L). According to Carlson,[2] the latter is further compartmentalized into fluid contained within the vascular space, the interstitial fluid space, the lymphatics, and transcellular fluids. This last category includes the fluid content of the gastrointestinal tract, which represents a large reservoir of fluid.[2]

The vascular space or total blood volume is filled with a mixture of fluid and cells, the latter primarily red blood cells, but also including white blood cells and platelets. Thus, the total blood volume (BV) is the combination of the plasma

volume (PV) and the red cell volume (RCV) or stated as a formula:[2] BV = PV + RCV. Blood volume varies from breed to breed, with age, body composition, hydration status, and training status.[2,13] Across breeds, studies have reported total blood volumes ranging from 61 mL/kg in draft horses to 137 mL/kg in race horses.[1,2,9] In the average 450-kg horse, total BV would be about 36 L, PV ~16 L and RCV around 20 L.[1,2,13]

The eloquent work of Persson[13] and many others[2,14–16] has shown that there is a strong relationship between red blood cell volume and aerobic performance in the horse. Oxygen uptake and delivery is dependent on both optimal volume to insure cardiac filling pressure and an optimal number of red blood cells to carry oxygen. Much focus has been placed on the need to have red blood cells to carry oxygen to the working muscles. However, while RCV and PV are usually looked at independently; they are interdependent in the optimization of blood flow during exercise. Blood flow can be affected by changes in viscosity; thus, too many red blood cells and not enough plasma can cause a substantial change in viscosity, as well as other factors related to resistance to flow. The values for BV, PV, and RCV in the literature also vary with the differing methodologies used in different laboratories to measure and/or calculate total blood volume.[2,13–16] For the most part, studies of equine blood volume have not used direct measurement of BV. Instead, they have generally used dye or indicator dilution techniques to measure PV and then calculated (Formula 1) BV using the measured PV and hematocrit (HCT):[2,13–16]

$$BV = \left(\frac{PV}{100 - HCT} \right) \times 100$$

The measurement of PV using dye or indicator dilution techniques requires the use of an indicator that stays within the vascular compartment for a long enough time to reach full steady-state distribution without substantial removal through the metabolism of the dye by the tissues.[2,15] Ideally, this requires an indicator that binds to a large molecule that does not readily leave the vascular compartment. Two substances commonly used to measure PV in the horse are indocyanine green (IC-green or cardiac green) dye and Evans Blue dye.[2] While IC-green dye has been used to measure plasma volume in the horse, one must caution that because it is rapidly cleared from the vascular compartment, it is better suited for the repeated injections required for the measurement of cardiac output. The rather short half-life of IC dye means it can be cleared before reaching full distribution affecting the accuracy and repeatability of PV measurements in the horse. Evans Blue dye binds to albumin and thus, has a relatively long half-life and stays for the most part in the vascular compartment.[2,13,15] However, one must caution that albumin can shift out of the vascular compartment if there is an increase in hydrostatic pressure induced by manipulations such as exercise or adrenaline infusion. Thus, the measurement of PV using the Evans Blue dye dilution technique requires that a horse be standing relatively quietly and unperturbed by exercise or pharmacological manipulations for the 15- to 20-min mixing period between collection of a blank plasma sample and injection of the dye and the collection of a postinjection blood sample.[2,15] Anything that disturbs the steady-state of the cardiovascular system affects distribution of the dye; therefore, one should view with extreme caution published studies reporting PV, BV, and RCV values calculated using a postinjection sample obtained after exercise as the readings can be skewed in two ways.[13] First, decreases in PV due to water shifts out of the vascular compartment caused by increases in hydrostatic pressure that would give artificially high concentration of the dye and, second, errors caused by the loss of dye from the vascular compartment due to extrusion of albumin out of the bloodstream by the same increases in hydrostatic pressure.[3,17–20] Plasma volume can decrease 15–20% after only three 1-min steps of an incremental exercise test;[17] therefore, errors in the measurement of plasma volume due to non-steady-state sampling would also affect the calculation of BV and RCV using the above formula.

Another factor that must be considered in the calculation of total BV in the horse is the splenic reserve volume. The horse is somewhat unique compared to most other mammalian species in that the spleen is a very capacious and capricious organ, storing between 6 and 12 L of red-cell-rich blood at rest.[2,13,19,20] Splenic blood typically has a hematocrit of ~65–75%.[2,13] Thus, studies of total BV become somewhat problematic because measurement of the total circulating BV requires an accounting for the splenic reserve volume, a measurement that requires mobilization of the splenic red cell reserve. Most studies to date have utilized exercise or infusion of adrenaline or an α-adrenergic agonist drug to cause splenic contraction, with a blood sample obtained for the measurement of hematocrit after the accommodation and the mixing of the extra volume of blood. Complete mixing takes only 1–2 min; however, in many studies, the hematocrit used to calculate BV and RCV was taken at the end of or after an incremental exercise test.[13,16] While this is an accepted way to cause splenic contraction and a viable way to *estimate* the contribution of the splenic reserve to the total circulating blood volume, the resulting hematocrit values are skewed upward by the dynamic fluid shifts caused by the changes in flow and hydrostatic pressure induced by the exercise or pharmaceutical manipulation. Therefore, the hematocrit used to calculate total BV would reflect both the contribution of splenic reserve mobilization and reductions in plasma volume and would be an overestimation of total blood volume. This is essentially an offset error and, because acute reductions in PV caused by exercise-induced fluid shifts are linked to exercise intensity,[3,17–19] the fluid shifts that lead to this overestimation only become a problem if a study's experimental design uses different exercise intensities to measure the hematocrits used in comparisons between treatment groups or comparisons made before and after training. For example, if one calculates BV using a hematocrit obtained at the 10 m/s step of a treadmill test it will yield a different result than the value calculated using the hematocrit collected at the 11 or 12 m/s step of an incremental treadmill test.

As mentioned above, the absolute value for resting plasma volume can be determined using Evans Blue dye. However, measurement of PV during exercise and any resulting

Example 1 Calculation of the percent change in plasma volume using uncorrected hematocrit as in humans

$$\%\Delta PV = \left(\frac{100}{100 - HCTb}\right) \times \left[100 \times \frac{(HCTb - HCTa)}{HCTa}\right]$$

$$\%\Delta PV = \left(\frac{100}{100 - 43}\right) \times \left[100 \times \frac{(43 - 45)}{45}\right]$$

$$\%\Delta PV = \left(\frac{100}{57}\right) \times \left[100 \times \frac{(-2)}{45}\right]$$

$$\%\Delta PV = (1.8) \times [-4.4]$$

$$\%\Delta PV = -7.9$$

decreases are problematic because of mixing time, the requirement for steady-state conditions, and the potential for overwhelming the vascular space with dye through repeated injections. Percent changes in PV can be measured using changes in protein concentration.[17] However, because some protein leaves the vascular compartment, this method tends to underestimate the reduction in PV.[17] To get around these methodological problems, studies of human athletes[21–23] have utilized changes in hematocrit to calculate percent changes in PV (Example 1). Absolute volume changes in liters are then calculated using the previously measured absolute resting PV determined using Evans Blue dye.[21–23] The calculation of percentage change in PV using hematocrit is feasible because red blood cells do not leave the vascular compartment like protein molecules and any change in their concentration must be due to changes in plasma volume.[21–23] In humans, the calculation is simple and involves the use of a pre-exercise hematocrit (HCTb) and hematocrits measured during or after exercise (HCTa).[21–23] For example, if the hematocrit measured before exercise (HCTb) was 43 and the hematocrit measured in a blood sample obtained after 10 min of exercise was 45 then the change in plasma volume is –7.9%. Thus, one can see that a relatively small change in hematocrit represents a much larger change in plasma volume.

However, it is important to note that the use of this formula requires that there is no addition of red blood cells to the central circulation or change in the size of the cells.[21–23] The latter has been shown to not be a problem if exercise duration is less than 120 min.[23] The former makes the use of this formula problematic for those doing horse research because the spleen adds RBCs to the central circulation. Fortunately, McKeever et al. have developed a correction factor obtained after comparing sequential blood samples taken from splenectomized and intact horses.[17] These studies demonstrated that the spleen contracts very rapidly with both the extruded volume and cells accommodated and mixed with the central circulation within the first one to 1.5 min of exercise.[17] Changes in hematocrit from the point of full mixing onward paralleled each other in both groups of horses. Thus, the changes in hematocrit from that point on were due to decreases in plasma volume caused by fluid shifts and loss of water from the vascular compartment.[17] More importantly, the difference between the pre-exercise and the 2-min values for hematocrit in the intact horses represented an offset due to splenic reserve mobilization that could be used as a correction factor.[17]

Example 2 Calculation of the percentage change in plasma volume using corrected hematocrit in horses[17]

HCTb = 35

HCTraw = 58

HCT2min = 20

HCTa = HCTraw – HCT2 min = 58 – 20 = 38

$$\%\Delta PV = \left(\frac{100}{100 - HCTb}\right) \times \left[100 \times \frac{(HCTb - HCTa)}{HCTa}\right]$$

$$\%\Delta PV = \left(\frac{100}{100 - 35}\right) \times \left[100 \times \frac{(35 - 38)}{37}\right]$$

$$\%\Delta PV = \left(\frac{100}{65}\right) \times \left[100 \times \frac{(-3)}{37}\right]$$

$$\%\Delta PV = (154) \times [-5.41]$$

$$\%\Delta PV = -12.2$$

Example 2 demonstrates how to use hematocrit in the horse to calculate percent changes in PV. For example, if a horse had a resting hematocrit (HCTb) of 35 and the hematocrit measured at 2 min of exercise (HCT_{2min}) was 55 then the difference between the two would be the calculated correction factor (HCT_{2min}) to be used to correct all the hematocrits measured after the 2-min point of exercise onward. Thus, in Example 2, if the uncorrected hematocrit obtained at 15 min of exercise was 58 (HCT_{raw}), then the value for HCTa to be used in the formula would be obtained by subtracting the correction factor from the uncorrected hematocrit.

Plasma osmolality and the concentration of key electrolytes

Normal cellular function is vitally linked to maintenance of fluid, electrolyte and acid–base balance within a narrow range.[2,3,23–26] Thus, the composition of both the plasma within the vascular compartment and the fluid within the intracellular fluid space is tightly controlled.[2,3,23–26] Key to maintenance of the internal environment is a regulation of overall plasma osmotic concentration or osmolality as well as the concentration of key electrolytes such as sodium, potassium, chloride.[2,3,23–26] Sodium is the major anion contributing to osmolality and is the major cation in the extracellular fluid space.[2,3,23–26] Potassium on the other hand is the primary cation found within the cells.[2,3,23–26] Other important cations include calcium and magnesium, both primarily intracellular ions.[2,3,23–26] When considering exercise, it is the

Table 38.1 Electrolyte composition (mEq/L) of plasma, interstitial fluid, intracellular fluid (muscle), and sweat

Electrolyte	Plasma	Interstitial fluid	Skeletal muscle cell	Sweat
Cations

Protein	14	0	50	
Other	7	7	84	

calcium found within the muscle in the tubular sarcoplasmic reticulum that is important.[2,3,23–26] This calcium plays a vital role in the process of excitation contraction coupling. Magnesium found within the cells is an important cofactor in many of the reactions involved in various metabolic pathways.[2,3,23–26] Major anions include chloride, bicarbonate, and the phosphates.[2,3,23–26] Normal values for resting concentrations of the major electrolytes found in plasma, interstitial fluid, intracellular fluid and sweat can be found in Table 38.1. All of the electrolytes contribute to the osmotic concentration of the body fluids, a variable that is tightly regulated to prevent cell dehydration or cell swelling.

The osmotic concentration or osmolality of the plasma is essentially the same as that of the rest of the interstitial fluids.[27,28] Normal plasma osmolality in the horse and most other mammals averages 290 mOsm/L.[2] Plasma osmolality is the total number of dissolved particles in solution, independent of the elemental species making up that solution.[27] Plasma osmolality reflects the osmolality of both the extracellular fluid space and the intracellular fluid space[27] and is important for two reasons. First, large molecules in solution exert osmotic force across semipermeable membranes such as capillaries and cell membranes. Thus, plasma osmolality is a measure of the total 'osmotic pull' or osmotic force that is exerted by the sum of freely-moving particles in solution exerting an effect on water in surrounding tissues.[27,28] Because water tends to move down a concentration gradient from an area of low concentration to an area of high concentration, an increase or decrease in plasma osmolality has the capacity to dramatically alter normal cellular function by causing fluid shifts into and out of the cells, shifts that can decrease cell function.[27,28] Second, a change in osmolality reflects expansion or contraction of the extracellular fluid compartment.[27,28] Optimal cardiovascular function is highly dependent on fluid volume status and mechanisms associated with the maintenance of plasma osmolality and extracellular fluid volume serve as one of the first lines of defense in the regulation of cardiac filling volume and pressure and ultimately mean arterial pressure and the ability to perfuse the tissues.[19,27,28]

During exercise the horse can lose tremendous volumes of hypertonic sweat presenting a serious challenge for maintaining the volume and the composition of the body fluids.[1,2,19] Dramatic changes can compromise cellular function.[28] It can also compromise cardiovascular stability through a reduction in venous return and cardiac output. Therefore, it is vitally important that the body regulates plasma osmolality within very narrow limits.[28] Defense of osmolality is vitally intertwined with the defense of extracellular fluid volume, plasma volume, and cardiac filling pressure.[19,28] Thus, defending plasma osmolality involves an integrative response of multiple systems including the cardiovascular, neural, endocrine, and renal systems.[6,10,19,27–30] Changes in plasma osmolality are sensed by specialized cells within the supraoptic and paraventricular nuclei of the hypothalamus.[19,27–29] These osmoreceptors are very sensitive and changes in plasma osmolality as small as 2 mOsm/L can evoke a change in the synthesis and secretion of the hormone arginine vasopressin (antidiuretic hormone) by the posterior pituitary.[29] Changes in circulating vasopressin concentration occur rapidly and can cause dramatic alterations in renal handling of water within minutes, thus correcting volume deficits and swings in the concentration of osmotically active substances through losses of plasma water or electrolytes in the sweat.[29,30] Vasopressin also stimulates thirst and drinking, which ultimately affects water balance and osmolality.[29]

Plasma concentration versus plasma content

When considering the effects of acute exercise on changes in key electrolytes one must distinguish between changes in the concentration versus changes in the total content of those electrolytes.[23,31] By definition, the concentration of a substance is the amount of solute in a given volume of solvent. Content, on the other hand, is the total amount of that solute in the fluid compartment or body depending on the focus of analysis. For example, normal plasma concentration sodium is 140 mEq/L or, put another way, there are 140 mEq of

sodium per liter of plasma. Plasma content of sodium would be obtained by multiplying the concentration of sodium by the plasma volume:[23,31]

$$\frac{140\ \text{mEq}}{\text{Liter}} \times \frac{26\ \text{Liters}}{1} = 3640\ \text{mEq}$$

Calculation of changes in the content of key electrolytes and other substances allows one to determine if changes in the concentration of a substance is the result of addition or loss of the substance or just due to changes in plasma water.[23,31] When viewed on a whole body level, changes in content allow one to make calculations giving insight into how concentrations of tightly regulated plasma constituents are affected through routes of intake or loss that affect whole body balance of said constituent.[23,31] Acutely, calculation of relative or percent changes in the content of plasma volume and the plasma constituents gives one insight into the dynamic changes that occur in response to the challenge of exertion.[23,31] To that end, human exercise physiologists for years have used key formulae to calculate percentage changes in plasma volume and percentage changes in the content of various plasma constituents during exercise (Example 3).[21–23] If one knows the resting plasma volume then once one calculates the percentage change in the content of a plasma constituent one can calculate the total amount of that substance lost during exercise from the vascular compartment.[23,31]

On a practical level, calculation of changes in the content of various plasma constituents can give insight into their disposition. An example of this would be an examination of sodium and chloride losses during short-term versus endurance exercise. Plasma sodium and chloride concentrations are held within vary narrow limits. During short-term exercise plasma sodium and chloride concentrations undergo minimal changes.[31] However, the plasma content of sodium and presumably chloride decreases suggesting the fluid shifts that occur during short-term exercise involve an isotonic shift of fluid.[31] During longer-term exertion there can be minimal changes in plasma sodium concentration but content can change dramatically.[23,31] With chloride there is a dramatic disproportional decrease both in the plasma concentration and content due to large amounts lost in the sweat.[23,31] Measuring total content lost gives a more complete picture of how much supplementation must occur to replenish exercise related losses. When one looks at changes in plasma potassium concentration and content one sees a different picture. Both the concentration and content of potassium go up during high-intensity exercise. When one looks at the change in content one can see that the change in concentration is due to both the loss of plasma water and the addition of potassium to the plasma when it leaks out of the contracting muscle cells.

Effects of acute exercise on fluid and electrolyte balance

Hypothetically, fluid and electrolytes can shift from the intracellular space to the extracellular space as well as between each of the compartments through active, passive, and facilitative mechanisms.[6–8,11,18,19,23,32,33] This dynamic exchange of fluid and electrolytes between compartments moves nutrients and waste products, provides fluid and electrolytes for the production of sweat and allows the horse to defend the internal environment of the cells.[6–8,11,18,19,23,32,33] To maintain cellular homeostasis the horse must regulate blood volume, blood pressure, and the osmotic composition of the intracellular and extracellular fluid compartments. Acute fluid and electrolyte shifts have differing functional significance related to the timing of the response during exercise. Early shifts appear more related to a system-wide redistribution of blood and fluid from capacitance vessels and the interstitial space so as to increase venous return and augment cardiac output.[6–8] Later responses provide fluid and electrolytes for the production of sweat and thermoregulation[6,11,17,23] Finally, decreases and depletion of fluid stores lead to dehydration, thermoregulatory, and cardiovascular instability and fatigue.[6,11,17,23] This latter challenge stimulates an expansion of plasma volume and the contents of the various electrolytes, a beneficial adaptive response known as a training-induced hypervolemia.[6,11,17,23]

Intercompartmental fluid shifts at the onset of exercise

Senay[34] demonstrated, in humans, that in the first seconds at the onset of exercise, there is a rapid net movement of protein

Example 3 Calculation of percent change in the content of a plasma constituent using corrected hematocrit[31]

HCTb = Resting hematocrit

HCTa = Corrected hematocrit

Cnb = Resting concentration

Cna = Postconcentration

Co = Content of soulute

$$\%\Delta Co = \frac{Cna - [HCTa\ (100 - HCTb) \times (Cnb)]/HCTb(100 - HCTa)}{HCTa(100 - HCTb) \times (Cnb)/HCTb(100 - HCTa)} \times 100$$

and fluid from the interstitial space and lymphatics into the vascular compartment.[34] This inward flux of protein and water causes a transient, short-lived increase in plasma volume, an intercompartmental shift of body fluids that couples with a redistribution of blood from the venous capacitance side of the vascular system to the arterial side to provide adequate venous return to maintain cardiac filling pressure.[6–8,34] This important redistribution of blood and fluid from the capacitance side of the vascular system is important because of the need for extra venous return at a time when there is rapid vasodilation in the working muscles.[6–8,34–36] Similar phenomena have been demonstrated in dogs and probably also occur in horses.[35,36] Studies[37] have demonstrated a shift in the albumin to globulin ratio in the horse consistent with an inward flux of fluid from the interstitial space. At rest albumin is the primary protein found in the vascular space and globulin represents the most prevalent protein found in the lymphatics.[37] This dramatic change in albumin to globulin ratio suggests that the horse experiences a similar influx in fluid at the onset of exercise as described in humans.[34,37] Plasma is also added to the central circulation upon mobilization of the splenic reserve.[13,17] Splenic blood is rich in red blood cells, with a hematocrit between 65 and 75%.[13,17] However, this also means that there is an addition of plasma to the central circulation. Splenic blood volume averages range from 8 to 12 L; thus, there is an addition of a 1.6 to 3.6 L plasma to the central circulation in addition to the volume added by intercompartmental fluid shifts.[13,17] This extra volume of plasma serves a role in cardiovascular control and it also increases circulating protein that provides extra buffering capacity to the central circulation.[13,17]

Plasma volume decreases rapidly after this initial intercompartmental redistribution of water and electrolytes.[6,17,18,23,32,33,38] These secondary fluid shifts are caused by significant increases in mean arterial pressure and consequentially capillary hydrostatic pressure that cause water, electrolytes, and a small amount of protein to be extruded from the vascular compartment.[6,23] Studies of horses[17,19,20] performing moderate incremental exercise have demonstrated that this decrease in plasma volume is rapid and intensity dependent with a 15 to 20% decrease observed after only four 1-min steps of an incremental exercise test (Fig. 38.1). This movement of water and salts bathes the interstitial space, where it can be taken up into the working muscles, used to form sweat, or returned to the vascular compartment.[17,19,20] In mammals there is a dynamic flux of fluid into and out of the vascular compartment that is governed by Starling forces (Fig. 38.2).[2,6–8,11] Net filtration and reabsorption across a vascular bed is the sum of forces affecting the movement of fluid and osmotically active substances in both the arterial and venous capillaries.[2,6–8,11] These forces include the capillary and interstitial hydrostatic pressures and the capillary and interstitial oncotic pressures. On the arterial side of the resting capillary bed, hydrostatic pressure and

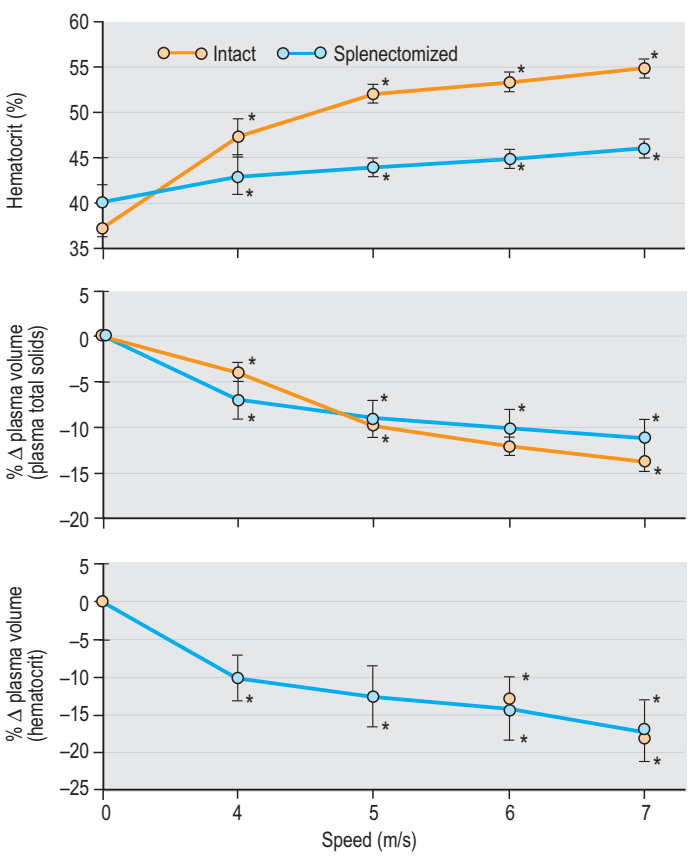

Fig. 38.1 Percentage change in plasma volume during incremental exercise. Values are means ± SE for hematocrit, percentage change in plasma volume calculated using total solids (i.e. protein) and percentage changes in plasma volume calculated using corrected hematocrit. (Reproduced with permission from McKeever et al.[17])

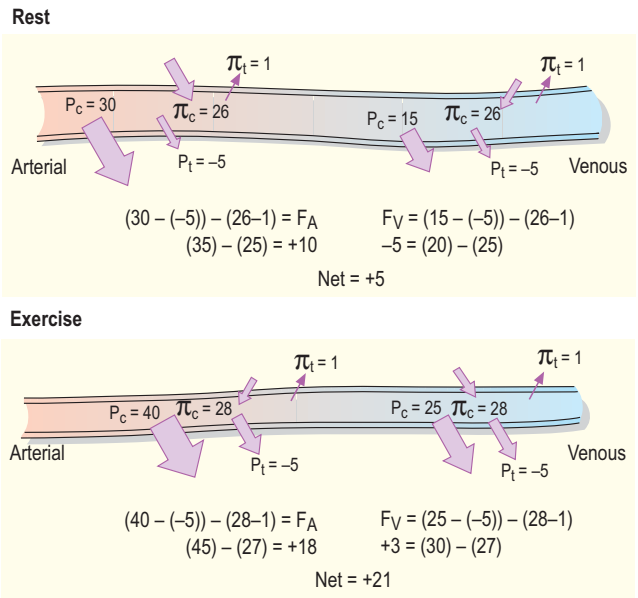

Fig. 38.2 Starling forces affecting the movement of fluid in and out of the vascular compartment. Rest: at rest, the balance of forces on the arterial side of the capillary bed is positive (+10), favoring an outward movement of fluid. On the venous side of the capillary bed the balance of forces is negative (–5), favoring the inward movement of fluid. However, the net difference between the arterial and venous sides of the capillary beds is positive (+5) and thus not all the fluid is returned to the bloodstream. The excess must be returned via the lymphatic system. Exercise: during exercise, hydrostatic pressure increases in both sides of the capillary bed enhancing the movement of fluid outward into the interstitial space for transport and for sweat production. Thus, during exercise, lymphatics play an important role in returning fluid not lost as sweat.

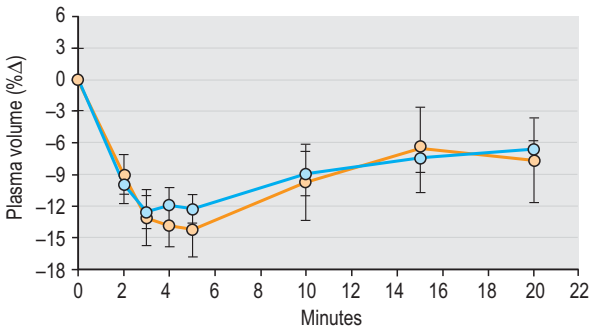

Fig. 38.3 Changes in plasma volume with steady-state exercise. Initial drop in plasma volume (0–3 min) due to fluid shifts, secondary changes due to fluid loses. (Reproduced with permission from McKeever et al.[17])

interstitial oncotic pressure outweigh interstitial pressure and intravascular oncotic pressure.[2,6–8,11] This favors a net movement of fluid out of the vascular compartment. However, resting venous oncotic forces outweigh the other forces and favor a movement of fluid back into the vascular space.[2,6–8,11] Some fluid is not returned via the influx into the venous capillaries and is returned through the lymphatic system.[2,6–8,11] During exercise, the balance of Starling forces is greatly affected by a larger increase in arterial hydrostatic pressure.[2,6–8,11] At the arteriole level this amounts to a ~20 mmHg increase in hydrostatic pressure enhancing the net force of fluid outward.[2,6–8,11] On the venous side of the capillary beds, hydrostatic pressure is also elevated with a tendency for a net positive outward force. This means that more fluid is shifted into the interstitial space when compared to rest. This extra dynamic outward flux of fluid has a functional significance and is beneficial as it can either be excreted as sweat or returned to the vascular compartment via the lymphatics. The net result is a decrease in plasma volume and a dynamic flux of fluid that provides for removal of metabolic waste products and for removal of heat produced during exercise.[2,17,20] The key here is that the decrease in plasma volume seen at the onset of exercise[2,17,20] is dynamic and intensity dependent (Fig. 38.3) and occurs before the onset of sweat losses.[17,20] However, plasma volume decreases seen after these initial fluid shifts are the result of reductions in total body water caused by sweating.[1,2]

Fluid and electrolyte losses associated with longer acute exercise

Exercise continued beyond a few seconds causes pronounced hemodynamic changes and, because of sweat production, fluid and electrolyte losses.[1,2,6] Evaporative cooling via sweating is by far the most efficient way to remove a large amount of heat from the body.[1,2,4–6,39] But this ability to maintain body temperature comes at a cost to the cardiovascular system. First, a portion of blood flow that could be used to supply the working muscles is redistributed to the skin to transport heat from the core to the surface.[5–8] At moderately heavy work intensities limited circulating blood volume and cardiac output cause transient alterations in cardiac filling volume and mean arterial pressure that are sensed respectively by the cardiopulmonary baroreceptors (volume receptors) and by the high pressure baroreceptors.[5–8] Optimal perfusion of working muscles requires that the cardiovascular system keeps mean arterial pressure within narrow limits.[5–8] However, there is an upward change in the set point during exercise that removes the check on the system that would tend to limit an increase in cardiac output. Rowell[7,8] has suggested that a feedforward mechanism allows blood pressure to increase during exercise via integrated responses of the above mentioned two layers of defense.[7,8] Control of mean arterial pressure during increasing exercise intensity necessitates shunting of blood away from non-obligate tissues.[6–8,35,36] These non-obligate tissues include the splanchnic and renal vascular beds.[6–8,35,36,40,41] The changes in vascular tone are so pronounced that they are facilitated by both nervous system and endocrine effector signals.[6–8,40,41] Interestingly, these neural

and endocrine factors (catecholamines, plasma renin activity, vasopressin etc.) influencing vascular tone in the splanchnic and renal vascular beds increase at intensities above 50–60% $\dot{V}O_{2max}$,[6–8,29,33,40,42–45] in most cases prior to any substantial loss of sweat. These adjustments in cardiovascular function and renal blood flow thus appear to be a response to the 's tress of exercise' itself rather than fluid and electrolyte imbalance.[40]

As exercise progresses, acute fluid shifts from the vascular compartment to the interstitial space provide water for sweat production.[6–8] Sweat loss causes a net reduction in total body water and a decrease in plasma volume that, if not replaced by water intake, eventually results in decreased venous return and cardiac filling pressure.[6–8] The horse has evolved to have a large reservoir of fluid in its digestive tract.[6] This is not an inconsequential amount as the horse can utilize fluid from the large colon as well as fluid contained in its cecum. Thus, in the wild the horse does not need to stop to drink while running from a predator. There are limits to these fluid reserves and the horse produces a huge volume of hypertonic sweat that eventually can lead to a compromised vascular volume. The cardiopulmonary volume receptors sense the drop in cardiac filling pressure and volume. To keep cardiac output constant the resultant fluid-loss-induced decrease in stroke volume must be countered by an increase in heart rate.[6–8] This tachycardiac adjustment to progressive fluid loss is referred to as cardiovascular drift.[6–8] More dramatic reductions in flow to non-obligate tissues can occur if increased heart rate cannot compensate for the decrease in cardiac filling pressure. Sweat-induced reductions in total body water initially come at the expense of plasma volume; however, as exercise progresses water loss causes a progressive cellular de-hydration.[1,2,4–6,9,39,45] The resultant cellular fluid deficit eventually leads to decreased cell function, fatigue, and a failure to thermoregulate properly.[46,47] Other problems can be caused by significant simultaneous electrolyte losses.[2,4,5,39,45–47]

Along with heavy sweat production comes loss of electrolytes which stimulates a variety of endocrine responses which function to correct the concentration of these vital substances.[6] Human sweat is hypotonic, that is, the concentration of sodium is less than that found in the plasma.[2] While prolonged exercise can result in severe electrolyte disturbances recent research has shown that they are much less frequent in humans compared to those seen in horses.[2,6,45–47] Equine sweat, on the other hand, is hypertonic and excessive sweat loss can rapidly result in severe problems related to both the hypovolemia and to the resulting electrolyte imbalance.[1,2,39] Several papers have documented that severe electrolyte loss can lead to weakness, muscle cramps, acid–base imbalance, and decreased performance.[2,5,6,45–47] Interestingly, trained humans appear to start sweating earlier and in greater amounts than untrained individuals exercising at similar relative work intensities.[6,26,48] Trained human athletes also appear to have a more hypotonic sweat[11,48] that results from aldosterone's action on the sweat glands.[19,20,25,26,48] Studies have not yet demonstrated similar training-induced adaptations in the neuroendocrine control of sweating and fluid balance in horses.

Sweat losses and the combined effects of exercise and environment

The transduction of potential energy into kinetic energy is a rather inefficient process with only 20–30% of potential energy effectively utilized for work.[5] The rest is heat that must be liberated from the body.[5] In general, the greater the exercise intensity of the event, the greater the heat load generated and the greater the need for heat dissipation.[5] Even under mild ambient conditions, the exercising horse is presented with a significant thermoregulatory challenge that requires an integrated response to transport heat from the core to be transferred to the environment.[5] The major method for the transfer of heat from the body involves sweating and evaporative cooling.[5] Evaporative cooling is several times more effective than other routes of heat exchange. Because evaporative cooling is so essential, the horse appears to have evolved with several species specific adaptations that enhance the ability to move fluid from the vascular compartment to the sweat glands and ultimately to the exterior as sweat.[5] First, as previously mentioned, increases in hydrostatic pressure during exercise enhance fluid shifts from the vascular compartment to the interstitial space, increasing the availability of fluid for sweat production.[5,6,19,20] Second, the sweat gland of the horse is very simple compared to the well-organized sweat glands seen in humans.[5,39] Therefore, sweat excretion is a less complex process. Additionally, the equine sweat gland, unlike the human sweat gland, is not responsive to aldosterone and thus it cannot conserve sodium.[39] Put simply, the equine sweat gland almost acts like a funnel to allow a hypertonic solution of electrolytes to move from the interstitial space to the surface. Teleologically, producing a hypertonic sweat may be beneficial as the solvent drag would tend to facilitate the movement of a greater amount of water outward. The extra salt in the sweat, as well as the protein lather in, also alters the evaporation point of the sweat possibly enhancing evaporative cooling. Functionally, this is significant as the horse has a less favorable surface area to volume ratio when compared to humans. The down side to these adaptations is the potential for large fluid and electrolyte deficits.

Recent articles have reported that during submaximal exercise, under conditions of high heat and humidity, sweat losses in horses can exceed rates of 12 L per hour.[5,39,45,49,50–56] This large volume of sweat results in proportional decreases in body weight, total body water, and plasma volume. This, in turn, can compromise venous return, cardiac filling pressure, cardiac output, and the ability to thermoregulate. Thermoregulatory stability requires a large cardiac output and peripheral blood flow to carry heat from the core of the body to blood vessels in the skin.[5] At the same time, the heart must pump blood to the working muscles, to the brain, and to other 'obligate' tissues that cannot suffer from reduced perfusion. To maintain cardiac output during intense exercise, baroreflexes

cause selective vasoconstriction and blood flow redistribution.[6–8] This reduces blood flow to non-obligate tissue beds like the viscera and kidneys and allows for increased blood flow to the working muscles.[7,8] As core heat accumulates, various feedback mechanisms cause blood flow to increase to the skin to enhance the transport of heat from deep in the core of the body to the surface.[5] If exercise proceeds for a long enough time, sweat loss leads to progressive dehydration and loss of plasma water from the bloodstream. Dehydration causes a decrease in circulating blood volume and cardiac stroke volume. A horse can keep going despite this reduction in vascular fluid volume; however, to maintain cardiac output, heart rate must increase ('cardiovascular drift').[5–8] When dehydration cannot be compensated for by cardiovascular adjustments, body temperature rises and is soon followed by decreased performance and fatigue. Maintaining cardiac output and mean arterial pressure (MAP) is vital to keeping perfusion pressure at the level needed to distribute flow to the working muscles, skin, and other obligate tissues. Thus, at the onset of exercise both mean arterial blood pressure and skin blood flow are defended.[5–8,19] However, as a horse becomes dehydrated MAP is defended preferentially at expense of skin blood flow and thermoregulation, adding to the resulting increase in body temperature.[5–8,19]

Several laboratories have observed that, even under cool conditions, endurance exercise performed in the field or on a treadmill laboratory will cause a substantial rise in core temperature, a substantial amount of sweat production, and a dramatic loss of total body water.[1,2,5,39,45,49,50–56] In field trials, it has been documented that even with the combination of proper hydration, adequate sweating, and maximal rates of evaporative cooling, a horse's body temperature can reach 105–106°F during endurance rides performed under moderate climatic conditions.[1,2,5,39,45,49,50–56] Under hot humid conditions, evaporative cooling becomes ineffective because sweat will not evaporate. The resulting hyperthermia can cause fatigue, cramps, heat stroke, and other thermal injuries.[1,4–6,10] Thus, in a hot and humid environment, even a well hydrated horse can encounter potential life-threatening situations in a relatively short time. However, most of these injuries can be prevented with proper feeding, adequate watering, and advanced planning of exercise training sessions and athletic events.

Almost all studies reporting sweat electrolyte concentrations in horses during exercise demonstrate that the horse loses a large amount of key electrolytes.[1,2,5,39,45,49,50–56] The range of sweat electrolyte concentrations varies with older studies suggesting tremendous sodium and chloride losses.[2] The magnitude of electrolyte loss reported in some studies is questionable and most likely is a function of the methodologies utilized. Older studies relied on sweat scrapings and other sampling techniques that overestimate actual losses. Several newer papers have utilized more refined methods adapted from human research, preventing the errors due to evaporation of water or addition of salt from areas already contaminated by prior sweating.[49,50–56] Nevertheless, more recent studies still demonstrate that equine sweat is hypertonic to plasma and that without replacement there are substantial electrolyte deficits in horses competing in endurance activities. While sodium and chloride are the primary electrolytes lost in equine sweat, other key electrolytes like magnesium and calcium are lost.[39] Most important is a disproportional loss of chloride ions that can potentially lead to a serious metabolic alkalosis.[9,39] The loss of sodium can become an even greater problem during recovery if a horse drinks too much water.[9] As with human marathon runners, some endurance horses can develop a hyponatremia that, if untreated, can lead to collapse and death.[47] Thus, provision of water as well as electrolyte supplements is warranted after endurance activities accompanied by large fluid and electrolyte losses.

Thirst, drinking, and electrolyte intake

Hormonal changes stimulate thirst and drinking and it is well recognized that the horse has a finely tuned regulatory system to maintain fluid and electrolyte balance.[1,2,6,19] Mechanistically, thirst can be stimulated by increases in circulating concentrations of angiotensin, arginine vasopressin (AVP), and by changes in the concentration of calcium and other electrolytes in the cerebrospinal fluid.[6,24–26,28,57–60] These systems are modulated by changes in osmolality sensed by the paraventricular and supraoptic nuclei of the hypothalamus.[6,24–26,28,57–60] Thus, a small increase in plasma osmolality will result in the release of AVP by the posterior pituitary.[6,24–26,28,57–60] These drives for thirst and drinking are finely tuned for the resting horse; however, it has been documented that strenuous, high intensity, exercise can paradoxically suppress thirst and the central drive for drinking behavior in humans, dogs, and more recently horses.[6,24–26,28,57–60] Mechanistically, it appears that early in exercise there is a suppression of AVP release associated with the role the cardiopulmonary baroreceptors play in the accommodation of fluid shifts and the mobilization of the splenic reserve.[19,61] Comparative studies of dogs, humans, and other species have also shown that there is a general suppression of the drive for drinking, as well as additional suppression of thirst and drinking during exercise when cold hypotonic water passes by nerves in the mouth and throat.[6,24–26,28,57–60] This suppression of drinking behavior may be a protective mechanism – an ingrained defensive behavior that prevents an individual from stopping for water while on the run from a predator. Horse owners and veterinarians monitoring endurance events have reported a similar suppression of drinking in horses.[6,9,10,23] In many cases, endurance horses will not drink at the end of a race and some clinicians have reported that this suppression of thirst and drinking behavior can last for several hours after exercise.[1,2,10,23] Unfortunately, this is the time when rehydration should be taking place. In some cases, it is the horse

with the most severe fluid and electrolyte deficit that is the one that will not drink right away or is the one that will consume a volume that is not sufficient to replace the amount of water lost during competition.[10,23] Some researchers have speculated that there is a threshold where severe dehydration itself accentuates this paradoxical suppression of drinking.[26,28,57–60] Interestingly, recent research demonstrated that endurance horses could be taught to drink warm water with electrolytes during competition without a resulting suppression of thirst and drinking.[62–66]

An equine athlete can usually recover from moderate acute exercise-induced fluid and electrolyte losses. And, in most cases, fluid and electrolyte losses following acute exercise can be compensated for through the provision of adequate water, a normal diet, and a salt and mineral supplement.[10,67] However, some scenarios can potentially cause problems for competing animals.[10,67] One scenario might result from larger-than-normal fluid and electrolyte losses resulting from exercise in hot or hot and humid conditions. In this case, fluid losses may need to be replaced rapidly to avoid thermal injuries.[10] Competition following long periods of trailering to an event with limited amount of water supplied for drinking while in transit presents another scenario for problems.[10] In this case, a horse owner should provide access to water prior to competition.[10] If the distance to the event is long, one should consider providing opportunities for drinking at rest stops along the way.[10] Another situation that can result in severe dehydration can occur when there is limited recovery time between phases during three-day competitions or other multiple event competitive formats.[10] Logistics of these events may prevent an animal from drinking enough water or prevent a horse from getting adequate electrolytes via dietary replacement.[10] Clinicians monitoring the status of competing horses should insure that all animals have had an ample opportunity to recover between days, phases, or heats of a competition.[10]

The amount of water consumed by a horse varies with the individual, diet, climate, and amount of exercise.[10,66] The National Research Council guidelines for feeding horses recommend 2–4 L of water per kilogram of dry matter feed intake.[10,67] This amount can increase 15–20% for horses in warm environments.[10,66] For example, a recent paper reported that non-exercised horses in Arizona consumed between 30 and 40 L of water in the hot months of June and July.[14] Water intake may increase 300% or more with prolonged exercise and some studies have documented that an active horse can consume 100 liters of water per day under some conditions.[1,2,39,62]

Renal function during exercise

Alterations in renal blood flow and renal function vary with both the duration and the intensity of exercise.[6,40,68–70] In general, exercise affects both renal blood flow and the delivery of water and electrolytes to the kidney and it affects

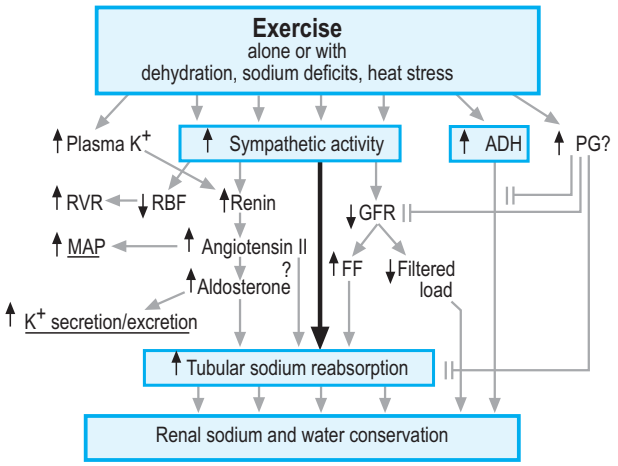

Fig. 38.4 Renal response to high-intensity exercise. (Reproduced with permission from Cooper Publishing Group, Traverse City, MI[40]). FF, filtration fraction; GFR, glomerular filtration rate; MAP, mean arterial pressure; PG, prostaglandins; RBF, renal blood flow; RVR, renal vascular resistance

mechanisms associated with the tubular reabsorption of water and electrolytes.[6,40] Acute and chronic renal responses to exercise are part of an integrative defense of blood volume, blood pressure, and osmolality.[6,40] Zambraski[40] suggests that the alterations in renal function are both a response to the stress of exercise alone and also to perturbations in fluid and electrolyte balance (Fig. 38.4). Acute demands of exercise result in a decrease renal blood flow, sparing cardiac output so as to allow the cardiovascular system to meet the increased circulatory demand associated with exertion.[40] Post-exertional changes in renal function, on the other hand, are part of a long-term mechanism to restore lost water and electrolytes.[6,40] The kidneys also function as major effector organs in the adaptive expansion of plasma volume and electrolyte content balance referred to as the hypervolemic response to exercise training.[6,40]

Effects of exercise on renal blood flow

During submaximal exercise absolute renal blood flow (RBF) is not reduced in humans or horses.[40,71] However, it has been documented that low- intensity exercise results in a reduction of renal blood flow as a percentage of cardiac output.[40,71] For example, Hinchcliff et al.[71] reported that renal blood flow averaged 15 mL/kg/min and did not change during exercise. However, because cardiac outpit increased, RBF did decrease as a percentage of cardiac output, dropping from 23% at rest to 6% during exercise.[71] High-intensity exercise, on the other hand, causes substantial reductions in absolute renal blood flow in swine, horses and humans, but not in normal dogs.[6,40,72,73] Renal vasoconstriction appears to occur when work intensities exceed a threshold of 50–60% of $\dot{V}O_{2max}$,[6,40] a point coincident with detectable increases in renal nerve activity, circulating catecholamines, and plasma renin activity.[6,40–42]

Schott and co-workers[72] were the first to demonstrate that high- intensity exertion causes a reduction both in absolute RBF and relative RBF (i.e. RBF expressed as a percentage of cardiac output) in the horse. Absolute RBF decreased from 9.0 L/min to 2.4 L/min when horses were exercised at a speed shown to produce an oxygen uptake that was 100% of $\dot{V}O_{2max}$.[72] Amazingly, RBF decreased as a percentage of cardiac output from 22% at rest down to 0.09% during maximal exercise.[72] This reduction in RBF resulted in a substantial drop in glomerular filtration rate and subsequently a drop in urine flow, and the excretion of solute-free water and various electrolytes. Interestingly, a follow-up study demonstrated that phenylbutazone and furosemide did not appear to alter the renal response to high-intensity exercise.[73]

Effect of exercise on glomerular filtration rate, filtration fraction

Blood flowing through the renal artery is filtered through millions of glomeruli in the kidney.[40] The glomerulus is part of the nephron, the basic structural unit of the kidney.[40] It is a complex structure made up of the afferent artery, Bowman's capsule, and the efferent artery.[40] Algebraically, glomerular filtration rate is representative of the sum of the action of all the nephrons, and is autoregulated over a wide range of kidney blood flow. As with RBF, the effects of exercise on glomerular filtration rate (GFR) in the horse varies with the intensity of the exercise.[71–73] GFR has been shown to increase or decrease during submaximal exercise depending on hydration status.[40] In studies where the subjects were hyperhydrated, GFR did not change during submaximal exertion.[40] However, when individuals were euhydrated or hypohydrated, changes in GRF were intensity and/or duration dependent, changing the most when individuals performed high-intensity exercise.[40] Interestingly, while RBF can be dramatically reduced during exercise, studies of humans show that decreases in GFR do not necessarily parallel the decreases in RBF.[40] Thus, glomerular filtration is somewhat protected in the face of exercise-induced reductions in RBF with a resultant increase in filtration fraction (i.e. the ratio GFR/RBF).[40]

Zambraski[40] has suggested some possible mechanisms to explain the exercise-induced increase in filtration fraction (FF) observed in humans and other species. First, maintenance of glomerular hydrostatic pressure and preservation of GFR through greater constriction of the efferent arteriole relative to the afferent arteriole.[40] However, data from comparative species are lacking or have not fully supported this hypothesis. A second hypothesis for exercise-induced increases in FF postulated that changes in glomerular capillary Kf simultaneous to decreases in glomerular capillary hydrostatic pressure would 'assist in maintaining GFR'.[40] While not directly tested, this mechanism fits teleologically with data from human and animal studies documenting exercise-induced increases in substances that affect Kf, such as vasopressin, the prostaglandins, and angiotensin II.[40]

The effects of exercise on GFR and FF appear to be similar in the exercising horse and in exercising humans. Hinchcliff and co-workers[71] reported that, as in humans, there appear to be no alterations in GFR or FF during standing control or submaximal (50–60% $\dot{V}O_{2max}$) exercise in horses. In that study, creatinine clearance (GFR) ranged between 2.0 and 2.5 mL/min/kg and FF averaged 23%.[71] High-intensity exercise, on the other hand, produces a significant decrease in GFR and a significant increase in FF in the horse.[72] Schott and co-workers[72] demonstrated that GFR decreased 73% from a mean of 1.9 mL/kg/min to 0.5 mL/kg/min during exercise performed at an intensity shown to produce $\dot{V}O_{2max}$. As with humans, horses performing high-intensity exercise had significant increases in FF from 16% at rest to 23.2% following running.[72] While drugs like furosemide and phenylbutazone affect renal blood flow, they do not appear to alter GFR and FF in the horse during submaximal or maximal exercise.[73] These observations were interpreted to suggest that the renal prostaglandins play a minimal role in mediating changes in GFR and RBF in the horse during exercise.[73]

Renal tubular function and excretion during exercise

In simple terms, the kidneys filter the blood at the glomerulus and then selectively reabsorb or secrete essential and non-essential substances in the tubules.[6,40] Normal fluid and electrolyte homeostasis requires the kidneys to eliminate excess water and electrolytes or if there is a deficit, to reabsorb those vital components of the blood.[6,40] Alterations in GFR and/or tubular handling of water and solutes ultimately affects the volume of urine produced and the rate volume of essential electrolytes excreted over a given period of time.[6,40] Studies of humans, dogs, and horses have demonstrated that changes in tubular handling of water and solutes varies with work intensity.[6,40] These changes appear to be secondary to alterations in renal blood flow, GFR, and the filtered load of a given substance.[6,40] We are aware of only a few studies of the effects of exertion on renal tubular function. One study (Fig. 38.5) examined the effects of 1 h of submaximal exercise on endocrine changes and renal tubular function[74] and the others examined the effects of high intensity exercise on renal function during and after exercise.[72]

During submaximal exercise, performed at an intensity below 60% $\dot{V}O_{2max}$, urine flow increases in humans and horses.[40,69,71] However, in horses, while low intensity exercise resulted in a significant 45% increase in urine production, the total volume of extra water lost (~6 mL/min) was reported to be small compared with the increased volume lost as sweat.[72] McKeever et al.[74] reported that the increase in urine flow was due to an exercise-induced increase in osmotic clearance induced primarily by a natriuresis and a kaliuresis.[74] The increase in sodium excretion appeared to be medi-

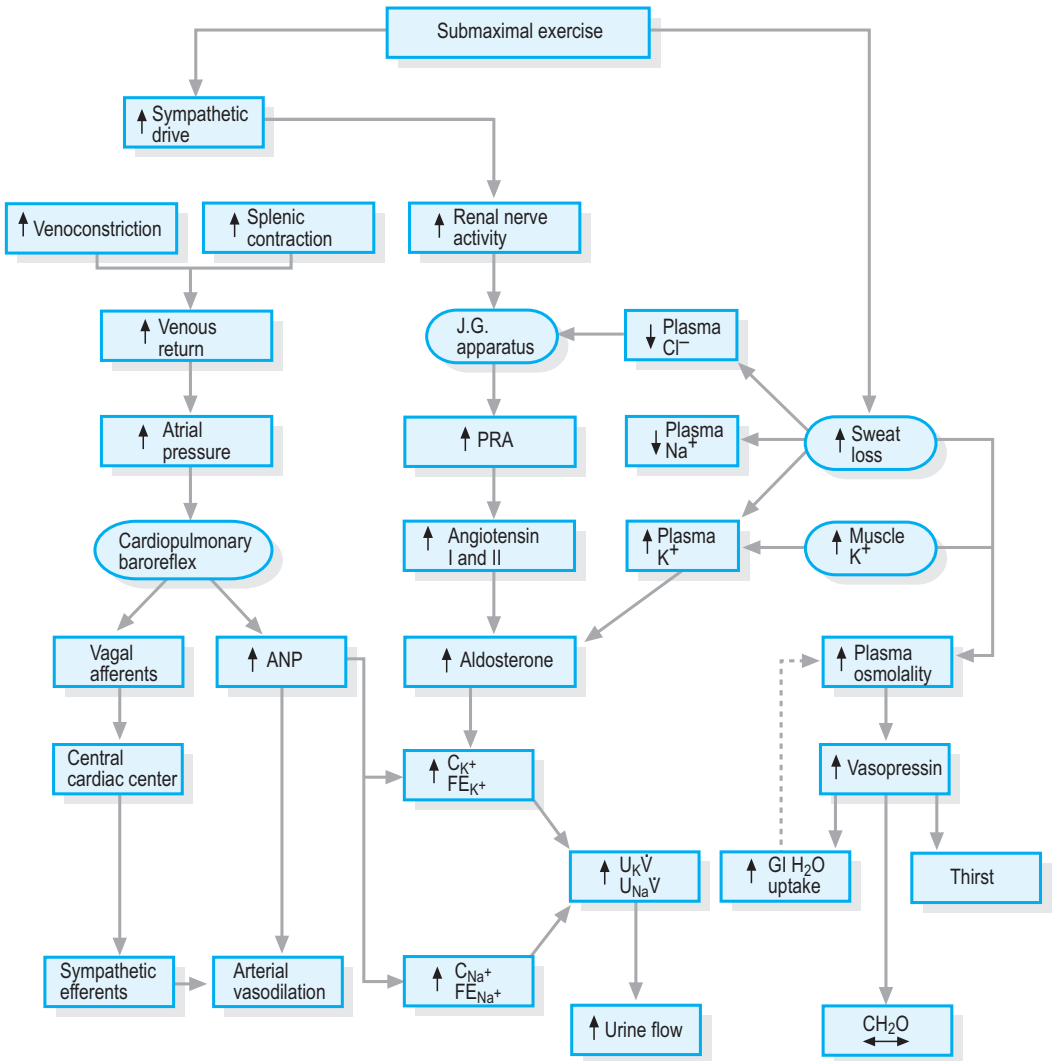

Fig. 38.5 Renal, cardiovascular, and endocrine response to low-intensity exercise in the horse. ANP, atrial natriureteric peptide; C_{K^+}, potassium clearance; C_{Na^+}, sodium clearance; FE_{K^+}, fractional excretion of potassium; FE_{Na^+}, fractional excretion of sodium; GI, gastrointestinal, JG, juxtaglomerular (apparatus); PRA, plasma renin activity; $U_K\dot{V}$, potassium excretion; $U_{Na}\dot{V}$, sodium excretion. ated by a concomitant increase in plasma atrial natriuretic peptide (ANP).[74] Even so, the total amount of sodium lost via renal excretion was minimal. The authors suggested that, during exercise, ANP (a potent vasodilator) functioned primarily to facilitate decreased vascular resistance in the working muscles[74] so as to accommodate increased atrial pressure caused by exercise-induced increases in venous return. The relatively small but significant increase in sodium excretion observed in horses and humans during the early part of a bout of endurance exercise appeared to be a minor secondary response to the potent cardiovascular action of this hormone.[74]

Interestingly, the authors of that same study demonstrated that there was a significant kaliuresis as well as the aforementioned natriuresis and suggested that the increase in potassium excretion was due primarily to a rise in plasma aldosterone concentration.[74] The increase in plasma K^+ concentration seen in submaximally exercised horses coincided with an increase in plasma aldosterone concentration.[74] The authors speculated that because there were limited decreases in plasma Na^+ concentration, the increases in aldosterone release may have been primarily in response to the rise in plasma K^+ concentration.[74] This phenomenon has been demonstrated by other researchers, who have shown that the most potent stimulus for aldosterone secretion is an increase in circulating potassium.[74] Functionally, this prevents excessive increases in plasma K^+ concentration, which can alter electrophysiological gradients in the muscles and other tissues.[74] Several studies have documented that excessive increases in plasma K^+ concentration appear to be one of many factors contributing to the onset of muscle fatigue.[6,74] Thus, the reported increase in plasma aldosterone release and the kaliuretic action of ANP may function to limit an excessive rise in plasma K^+ concentration during lower-intensity exercise.[74]

Another major problem associated with exercise in the horse is an excessive and disproportional loss of chloride via the sweat.[74] McKeever et al[74] demonstrated that renal chloride losses decrease when plasma chloride concentrations fall. Similar reductions in chloride excretion are also seen in exercising humans.[6,40] As Na^+ and K^+ excretion increased in submaximally exercised horses, the authors suggested that mechanisms affecting the conservation of those electrolytes could not have been responsible for the increase in Cl^- reabsorption.[74] Interestingly, the same horses became alkalotic during the hour-long bout of exercise.[74] Thus, the authors suggested that based on other reports,[40,74] renal mechanisms affecting reabsorption of Cl^- and secretion of HCO_3^- by the antiporter in the apical membrane of the intercalated cell of the cortical collecting duct may have led to conservation of chloride.[40]

Lastly, solute-free water clearance does not appear to be altered by submaximal exercise in the horse despite significant increases in plasma osmolality and plasma vasopressin concentrations.[74] Similar observations have been made in exercising humans.[40] This paradox has several possible explanations. First, a decrease in renal blood flow potentially could decrease the filtered load of solute-free water available for reabsorption by the action of AVP on the collecting ducts.[40] This explanation would not be supported by the observation that submaximal exercise does not affect absolute RBF or GFR.[6,71] It may, however, be possible that the extrarenal functions of vasopressin are more important during exercise and actions on the kidneys are overridden. Such functions may include vasopressin's role in vasoconstriction of vascular beds in non-obligate tissues, its role in central mechanisms that stimulate thirst and drinking, and its action on the gut.[6,25,75,76] In the gut, vasopressin appears to act on the epithelium of the large intestine enhancing the uptake of sodium and water.[75] This protective effect would aid in the limitation of exercise-related fluid deficits more than potential reductions in free water clearance.

High-intensity exercise appears to have effects that are dramatically different from submaximal exertion. Sodium excretion is dramatically reduced during high-intensity exercise in horses, pigs, and humans.[6,40,71] Inconsistent changes in sodium excretion have been observed in the exercising dog.[40] Several mechanisms could be responsible for the decrease in sodium excretion including: (i) a decrease in filtered load of sodium; (ii) activation of the renin–angiotensin cascade; (iii) elevation of plasma aldosterone concentration; and (iv) direct neurogenic control.[40] In the first instance, a change in filtered load sodium would mean that less solute would be presented to the tubules for reabsorption. This would require a reduction in GFR; as this does not change in humans, pigs, or horses,[6,40,71] it does not appear to be a viable mechanism for the decrease in sodium excretion. More recent information has been published that shows that the decrease in sodium excretion is not blocked by pharmacological blockade of the renin–angiotensin cascade.[40] Aldosterone concentration increases in the horse without a change in sodium excretion.[74] In other species, the observation that sodium excretion rapidly returns to baseline after exercise suggested that aldosterone was not the mediator of the antinatriuresis seen during exercise.[40] The speed of the recovery has been further interpreted to suggest a neural mechanism.[40] This theory is consistent with a reported intensity-dependent increase in renal sympathetic nerve activity during exercise.[40] Zambraski[40] and others have suggested that, based on all the current evidence, the mechanism behind exercise-induced increases in sodium reabsorption is primarily direct neurogenic control.

Schott et al.[72,73] reported that urine flow almost stopped during supramaximal exercise and was still below pre-exercise levels in the period immediately after exercise. High-intensity exercise also caused a decrease in urine osmolality and osmotic excretion.[72,73] Interestingly, one would have predicted a significant reduction in electrolyte excretion; however, there were only non-significant reductions in the bulk excretion of K^+ and Cl^- during exercise and no change in Na^+ excretion, despite a reduction in urine flow.[72] This response contrasts with changes observed in other species.[40] One explanation for this aberrational finding may be the design of the experiment. In the experiment, exercise was performed during part of one of the 15-min collection periods.[72] Data for the entire 15-min collection period were pooled and included a postexercise period characterized by diuresis, natriuresis, and kaliuresis (see below). These post-exercise changes may have offset any exercise-induced decreases in electrolyte excretion that should have occurred with a reduction in RBF and urine flow.

High-intensity exercise appears to also affect urinary pH, an observation of interest to racing chemists.[77] Gerken et al[77] reported that high-intensity exercise caused a transient reduction in urine pH that lasted for up to 60 min of recovery. The authors suggested that the more acidic urine may affect the results of the battery of tests used to detect foreign substances.[77] More interestingly, they suggested that alkalinizing agents like sodium bicarbonate may alter postexertion pH, thus further complicating drug detection efforts.

Post-exercise changes in renal function

While the studies of Schott et al.[72,73] did not document a change in tubular function, the authors did report a substantial postexercise increase in urine flow. Data were consistent with a diuresis, kaliuresis, and natriuresis.[72,73] Excretion rates for these substances returned to baseline by 30 min of recovery. The authors suggested that the increase in sodium and potassium excretion was most likely due to an increase in atrial natriuretic peptide, which had been shown to increase during exercise in the horse.[72] Long term, the adaptations to exercise training involves reduction in 24-h urine output and an expansion of plasma volume with a concomitant increase in the content of sodium in the vascular compartment.[14,78]

Adaptive response to repeated exercise (training)

Training-induced hypervolemia

Repeated exercise or training usually evokes an adaptive response that better prepares the horse's various physiological systems for subsequent bouts of acute exertion.[6,11,14,48,79] Disturbances in fluid and electrolyte balance require a two-phase response, with the early phase resulting in the replenishment of acute fluid and electrolyte losses and a secondary or adaptive phase that results in an enhanced ability to cope with future systemic disturbances.[6,11,14,48] This 'hypervolemic' response to training is an adaptive response that involves a beneficial increase in blood volume due to an increase in plasma volume.[48] The training-induced hypervolemia is beneficial because it enhances both cardiovascular and thermoregulatory stability during the challenge of acute exercise.[48,80] The increase in total body water provides extra fluid that insures cardiovascular stability by providing the extra volume needed to maintain venous return and thus cardiac output.[6,48] Thermoregulatory benefits are two-fold, including an increase in the ability to increase skin blood flow to enhance transport of heat from the core to the surface and an increase in the amount of fluid available for sweat production and evaporative cooling.[48] Functional evidence for the latter benefit can be seen in studies of humans that have demonstrated that trained individuals have an earlier onset to sweating and produce more sweat compared to untrained individuals exercising at the same relative submaximal work intensity.[48] It is likely that there are similar training-induced changes in cardiovascular function and thermoregulation in the horse.[80]

Mechanistically, the retention of water and electrolytes that leads to a training-induced hypervolemia reflects the effort of multiple systems to defend volume, plasma osmolality, and blood pressure.[6,11,14,19,48] Comparative studies have demonstrated that approximately 60% of the mechanism behind the hypervolemic response is related to stimuli associated with the demands of thermoregulation[48] The remaining 40% of the response appears to be related to mechanisms directly associated with exertion.[48] These mechanisms counter acute fluid and electrolyte losses by stimulating the intake of water and by reducing renal losses of water and electrolytes (Fig. 38.6).

Interestingly, rats, humans, dogs, and horses all expand their plasma volume in response to exercise training.[14,48,79,81] However, there are profound species differences in the mechanism behind the hypervolemic response to exercise training. Dogs expand their total body water through drinking, in fact, water is consumed at a greater rate than an observed training-induced natriuresis and diuresis.[81] Cooling in dogs involves a large loss of respiratory water and saliva, which results in acute increases in plasma tonicity and osmolality.[81] Thus, dogs must either drink to take in water to dilute the hyperosmotic hypertonic plasma or they must use renal mechanisms to excrete the excess electrolytes sensed in the plasma.[81] Humans and horses on the other hand, lose a large amount of electrolytes in their sweat; therefore, there is a drive to replenish fluid and electrolytes to defend both volume and tonicity.[14,48,78]

In horses and humans, drinking during and immediately after exercise at best only slows or partially counters the development of a fluid deficit, but does not counter any electrolyte deficit.[14,48,78] Studies of horses and humans are mixed as to the role of water and electrolyte intake in the long-term response to exercise training.[14,48,78] Humans use both an increase in thirst and drinking and renal mechanisms to increase net fluid retention.[48] Drinking in humans, however, does not account for all of the net water retention, with most of the actual expansion of total body water coming through renal mechanisms.[48] One recent study of the horse reported that water intake increased with training; however, the authors did not measure renal losses or conduct a balance study that would determine if the amount ingested contributed to an expansion of plasma volume.[6] Other studies have shown that exercise training does not alter water intake in the horse.[14,78] Instead, they reported that the horse appears to rely on renal mechanisms and an overall reduction in urine water loss[14,78] to retain the sodium and water needed to expand plasma and blood volume.

In both humans and horses, this decrease in urine output seen with training is due to alterations in postglomerular mechanisms rather than a change in filtration rate.[14,48,78]
