Notice
Medical knowledge is constantly changing. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the editors assumes any liability for any injury and/or damage to animals or property arising from this publication.

FOREWORD

Since time in memoriam, horses have been renowned for their athletic prowess and work capacity, and documenting and understanding the physiologic basis for these abilities has occupied many industrial-age equine scientists for more than a century. An integrative approach is essential to the elucidation of the mechanisms by which horses work, compete, or perform the various recreational activities that contemporary society asks of them. The performance or 'output' of an equine athlete is determined by many complicated interdependent biological processes. Understanding how these processes function and relate to each other is mandatory if the horse is to be effectively trained and managed during its working or competitive life. Such understanding is also pivotal to the clinical application of basic physiologic and pathologic principles, and is therefore necessary to ensure the successful diagnosis and management of exercise-related diseases in horses.

Modern day equine exercise science is generally regarded to have been born in 1967 with the publication of Sune Persson's doctoral thesis.[1] This was the first work that documented data generated from horses exercising on a high-speed treadmill. The subsequent widespread availability of such treadmills has had a great deal to do with defining the current state of knowledge with respect to basic and applied equine exercise physiology. The inception of the quadrennial International Conference on Equine Exercise Physiology (ICEEP) in 1982 has also provided a regular forum at which investigators can describe new fundamental and clinical findings pertaining to exercise in horses of all ages. Despite the great strides in equine exercise science that have been made in the last 35 years, it is important to recognize the contributions of the pioneers who helped develop many of the techniques upon which current scientific methodologies are based. These people also made fundamental observations that are still pivotal to much of the work that is being conducted today. Nathan Zuntz was a Berliner professor of animal science who, with a number of colleagues, notably Drs. Curt Lehmann and Oscar Hagemann, investigated the metabolism of horses during rest and work. These studies are truly extraordinary by today's standards. Zuntz and Lehmann built the first Laufband, or treadmill, and used a facemask and tracheotomies to measure oxygen consumption and carbon dioxide production in two horses at speeds up to 3.5 m/s.[2] Zuntz and Hagemann further refined these results by measuring oxygen consumption, carbon dioxide production, arteriovenous oxygen content difference, aortic blood pressure, tidal volume, heart rate and respiratory frequency in horses that were walking, trotting and walking backwards freely, and while pulling loads of 66–78 kg uphill, downhill and on the horizontal![3] These data were impressively similar to those that are determined under similar exercise conditions today.

The ability of the horse to increase its blood volume during exercise and the associated rise in hematocrit are two hallmarks of equine exercise or work, particularly in warmblooded horses. Scheunert, Krzywanek and Müller were the first to observe that hematocrit of horses could increase by up to 50 percent during exercise, and that the magnitude of this increase was related to workload.[4,5] Their observations were published in 1926. They also noted similar events in dogs and observed that splenectomy eliminated this exercise-related hemoconcentration. The contractile nature of the equine spleen was subsequently confirmed by Steger in 1938.[6] These phenomena are still the basis of various studies designed to evaluate different aspects of metabolism and the dehydration status of horses under different exercise conditions.

As well as the above cited work, interested readers are also referred to the work of two other teams of people in particular. First, Samuel Brody and colleagues conducted a seminal series of studies at the University of Missouri with the aid of a treadmill that they built. They focused on equine energetics, the efficiency of metabolism, nutrition, work and growth in the second quarter of the 20th century and published their findings in a collection of 66 Missouri Agricultural Experiment Station Research Bulletins. Among other things, Brody et al. showed that the caloric cost of movement per unit live weight, per unit horizontal distance covered, is not affected by the size of the animal and is independent of speed. He also demonstrated that minute ventilation is exponentially related to the energetic cost of work or exercise.

The Russian scientists Karlsen and Nadaljak published a series of papers from 1960–1965 that were, unfortunately, difficult to obtain. Karlsen, with Brejtsen, provided the first 'modern' documentation of the synchrony of breathing and stride frequencies[7] and, with Nadaljak, displayed great ingenuity in conducting the first field study of horses exercising at high speed.[8] Together these investigators recorded an oxygen consumption of 62.8 L/min in a Standardbred galloping on a track at 11.1 m/s.

I mention these things because, in the words of the famous Australian neurologist, Sir Sydney Sutherland (1910–93), it is important to 'honor those who go first even if those who come later go further'. In the 66 chapters in this book, the reader will find the latest information regarding the physiologic responses and adaptations of the various equine body systems to exercise and training. This information is also linked to exercise-related clinical problems of the same body systems. The chapters have been written by a number of contemporary experts in these fields. There are also sections on breed-specific activities and other 'applied' aspects of equine sports medicine. This book represents an ambitious and valuable contribution to the body of equine exercise-related physiologic and clinical literature. With it the reader has the opportunity to follow a subject from its basic principles to its current state of knowledge in both the physiologic and clinical or applied sense. Producing such a volume is a major undertaking and the principal editors and contributors are to be congratulated on their efforts. However, our knowledge base is incomplete; i.e., it is not perfect. When considered in terms of progress made over the last 120 years, one might even suggest that there have been few major

breakthroughs and that, rather, new information has come to light in an almost begrudging but inevitable fashion. In reality this is the essence of the scientific process and it is the principal reason that this book should prove to be so useful. It is also the main reason that such books need to be regularly revised and it is hoped that this will not be the only edition of this very complete and valuable text.

Warwick Bayly, College of Veterinary Medicine, Washington State University, Pullman, Washington

PREFACE

The diagnosis and treatment of disorders of the equine athlete is a specialty requiring not only the ability to recognize and treat clinical abnormalities, but also an understanding of the physiologic demands of exercise and requirements of competition and training. The science of equine exercise physiology has progressed to the stage that it now provides a sound, scientific basis for much of equine sports medicine. The current level of knowledge, while still incomplete and imperfect, of the physiologic processes underlying the acute responses to exercise and the mechanisms and effects of exercise conditioning, provides a sound, fundamental understanding of the workings of the equine athlete. Contemporary equine exercise physiology is comprised of not only the physiologic responses to exercise and training, but also nutrition, biomechanics, behavior and pharmacology. This fundamental knowledge informs our decisions regarding appropriate training, nutrition, care and treatment of the equine athlete.

We recognized that equine exercise physiology and equine sports medicine had advanced to the stage where there was a need for a comprehensive and integrated source of information for practitioners, students of veterinary medicine, graduate students in equine exercise physiology, residents in training and well-informed lay horsemen and women. This book attempts to meet that need. As with the first attempt at any major project, this book is imperfect and will not be all things to all readers. However, we hope that we have filled, at least partially, the requirement for a comprehensive source that integrates the basic and clinical sciences of the equine athlete.

Our belief in the importance of integrating both the basic and clinical sciences dictated the structure of this book. Each of the major body systems is described beginning with detailed coverage of the physiologic responses to acute exercise and to conditioning. This is then followed by one or more chapters describing the important clinical abnormalities of equine athletes. Our belief is that knowledge of the fundamentals of exercise science is essential for an understanding of the clinical abnormalities of the equine athlete. However, for those readers with little interest in the clinical abnormalities of athletic horses, the basic science chapters can be read alone and will provide a sound understanding of the physiology of equine athletic performance. Chapters in the last section of the book dealing with parasite control, veterinary aspects of training the various breeds of horse, aged athletes, and more, provide a pragmatic, utilitarian approach to the athletic horse.

Finally, we thank the colleagues and students with whom we have had the pleasure of working and who provided much of the knowledge contained within this book. Our profound gratitude is extended to the authors of sections of this book with an appreciation of the effort that was required to compile new comprehensive material on their designated topic. We hope that they, and the readers, are pleased with the final product.

CHAPTER 1

Integrative physiology of exercise

Kenneth W. Hinchcliff and Raymond J. Geor

The horse as an athlete

Comparative physiology

The horse is an extraordinary athlete, a characteristic that is the result of evolution of horses as grazing animals on the ancient prairies of North America. Survival in these open lands was enhanced by speed, to escape predators, and endurance, required to travel long distances in search of feed and water. These attributes are shared by pronghorn antelopes, another species that evolved on the prairies. The equid characteristics of speed and endurance were subsequently modified or enhanced by selective breeding by humans.

Horses were domesticated on more than one occasion, based on analysis of mitochondrial DNA from a wide variety of current domestic breeds and Przewalski's horses.[1,2] Domesticated horses were then selected and bred for certain traits, depending on the intended use. Large, heavy breeds of horses were bred for draft work, such as pulling plows, sleds or carts, or military work, such as the chargers that carried heavily armored knights into the battles of the Middle Ages. Lighter horses were bred for speed and endurance and were used for transportation, herding and sport. Horses have been bred or adapted to a large variety of uses. Thoroughbred race horses run at high speed (18 m/s, 64 km/h) over distances of 800 to 5000 meters, Standardbred horses trot or pace at high speed for distances up to 3600 m, Quarter Horses sprint for 400 m or less at speed as high as 88 km/h (see Chapter 32), sometimes around figure of eight courses delineated by barrels (barrel racing), and Arabians trot for up to 160 km in a single day during endurance events (and over longer distances during multi-day races). In contrast, draft horses pull huge weights (1000 kg or more) short distances in pulling competitions, Warmbloods perform elegant, but demanding, dressage routines, and ponies pull lightly laden jinkers or buggies.

Regardless of their size, provenance or intended use, all horses have in common an ability to perform physical activities, including running or jumping, at a level that surpasses that of most other animals of similar body size. The concept of body size is important as many physiologic variables, and especially the maximum values of these variables, do not scale directly with bodyweight but often more closely scale to an exponent of bodyweight.[3] Commonly, exponents range between 0.68 and 0.75. This exponent is derived empirically from the measurement of variables such as maximum running speed or maximum rate of oxygen consumption ($\dot{V}O_{2max}$). Typically, when expressed as a one-to-one function of bodyweight (i.e. per kg) values for many variables are much higher for smaller mammals. The necessity to scale variables allometrically has fascinating physiologic implications and interpretations.[3] However, direct comparison among species is to some extent specious from the point of view of depicting differences in physical capacity, given that the absolute values of these variables vary to such a large extent. Nonetheless, such comparisons are frequently made, if only to reinforce the magnitude of the maximal absolute values of these variables in the exercising horse (Table 1.1).

The athletic capacity of horses is attributable to a number of physiologic adaptations. In some cases these adaptations are not affected by training, for example lung size, whereas others change in response to training, for example blood volume (see Chapters 28 and 38). The superior athletic ability of horses is attributable to their high maximal aerobic capacity, large intramuscular stores of energy substrates and in particular glycogen, high mitochondrial volume in muscle, the ability to increase oxygen-carrying capacity of blood at the onset of exercise through splenic contraction, efficiency of gait, and efficient thermoregulation.

The maximal aerobic capacity ($\dot{V}O_{2max}$) of horses is approximately 2.6 times that of similarly sized cattle.[8] The larger aerobic capacity in horses is permitted by a larger

Table 1.1 Selected physiologic variables of athletic and non-athletic species[4–7]

Species	Bodyweight (kg)	Speed[a] (km/h)	Duration of exercise	$\dot{V}O_{2max}$ (mL O_2/kg/min)	HR[a] (beats/min)	Energy expenditure per day (kcal)
Thoroughbred race horse	450	64 (max)	2 min	180–200	240 (max)	30 000
Endurance race horse	400	15	12 h	180		38 000[b]

HR, heart rate; max, maximum value.

maximum cardiac output and stroke volume and higher hemoglobin concentration.[8] Maximum heart rate is not different between horses and cattle. In addition to the cardiovascular differences between cattle and horses, horses also have lungs that are twice as large as those of cattle with gas exchange surfaces 1.6 times those of cattle.[9] Thus, horses have structural adaptations that enhance oxygenation of blood in the lungs, oxygen transport capacity of blood and the ability to deliver oxygen to tissues. The oxygen transport chain, from air to muscle, of horses is suited to transportation of the large volumes of oxygen required to support the high metabolic rate of strenuously exercising horses.

Substrate is required to support these high metabolic rates during exercise. Substrate to support exercise is either carbohydrate or fatty acids. Oxidation of fatty acids is limited and reaches maximal values in other species at a work intensity of approximately 40–60% of $\dot{V}O_{2max}$.[10,11] It is likely that a similar phenomenon occurs in horses. Additional work above this exercise intensity is fueled solely by oxidation of carbohydrates, predominantly glycogen.[12] Horses have high intramuscular concentrations of glycogen, as do other athletic species such as dogs.[13] Muscle concentrations of glycogen in horses are approximately 140 mmol/kg of muscle (wet weight) compared with 80–100 mmol/kg in humans.[14] High intramuscular concentrations of substrate are important for fueling muscle contractions during exercise. The flux of glucose from blood into muscle and subsequently to the mitochondria provides only a small amount (< 10%) of the energy used during intense exercise,[15] probably because of limits to the rate of transportation of these compounds during exercise.[13] The presence of large amounts of readily available substrate in close proximity to mitochondria is therefore essential for horses to undertake strenuous exercise.

Mitochondria provide the energy for muscle contraction. The greater the quantity of mitochondria per unit of muscle weight, the greater is the oxidative capacity of muscle. Muscle of horses contains approximately twice the concentration of mitochondria as does muscle of cattle, a similarly sized animal but with a much lower aerobic capacity.[16] This greater aerobic capacity in muscle, when supported by adequate substrate availability and oxygen delivery, permits a higher whole animal maximal aerobic capacity.

Oxygen transport from the lungs to exercising muscle is achieved by the circulation. In addition to cardiac output, oxygen delivery is limited by the oxygen-carrying capacity of blood. Horses achieve rapid increases in the oxygen-carrying capacity of blood by increasing hemoglobin concentration through splenic contraction. Splenic contraction in anticipation of exercise and during exercise increases the circulating red cell mass without concomitant increases in plasma volume.[17] The resulting increase in hemoglobin concentration increases the oxygen-carrying capacity of arterial blood by up to 50% during intense exercise. The beneficial effect of this autoinfusion of red cells at the start of exercise is apparent in horses from which the spleen has been removed.[18–20] Splenectomized horses have lower hematocrits during exercise, altered systemic hemodynamics including lower right atrial and pulmonary artery pressures, and reduced capacity to perform strenuous exercise.

Energetically efficient gait is challenging for large animals because of the slow rate of contraction and low power output of their muscles.[21] However, the gait of horses is energetically efficient,[22] with the muscular work of galloping being halved by elastic storage of energy in muscle and tendon units.[23] For the forelimb, this use of stored energy and the subsequent catapult action mean that the biceps and brachiocephalicus muscles are less than one-hundredth the size that they would need to be were there no use of stored energy.[21]

In summary, a large number of physiologic and anatomic features act in concert to endow the horse with extraordinary athletic capacity. Optimal athletic performance is dependent

upon optimal integrated functioning of these physiologic and anatomic features.

Integrative physiology of exercise

The detailed responses of each body system to acute exercise and to repeated exercise (conditioning or training) are described in chapters throughout this book. These responses, although described in isolation for each body system, do not occur in isolation, but rather occur as a component of a complex and integrated response to exercise, the ultimate goal of which is to provide substrate for muscle contraction while maintaining homeostasis.

Exercise results in coordinated changes in almost all body systems. Fundamentally, exercise is associated with an increase in power output achieved by contraction of muscles. Contraction of muscles consumes adenosine triphosphate (ATP) and triggers an increase in metabolic rate to replace expended ATP. Increases in metabolic rate are dependent upon an adequate supply of substrate and, ultimately, oxygen. Energy production can be achieved for brief periods of time by anaerobic metabolism, but ultimately all energy production is linked to substrate oxidation and an adequate supply of oxygen.

Production of ATP during exercise is proximately dependent on supplies of substrate for oxidation and of oxygen. A schematic of factors influencing the supply of these fuels to muscle is depicted in Fig. 1.1. The important concept is that there are a number of steps in the process or transport chain by which each of these products is delivered to the muscle cell. Because these processes are sequential and often non-duplicative, a limitation in one process or function will limit the rate of the whole system. In some cases these rate-limiting steps may be modified by training, in which instance the rate of oxygen or substrate delivery will be increased, or may not be altered by training. The consequences of these differences are discussed below under 'Factors limiting performance'.

At the onset of exercise there is a coordinated response by a large number of body systems to increase fuel availability, maintain acid–base balance within acceptable limits, and limit body temperature. These responses include a large increase in flux of substrate, the nature of which depends on the intensity and duration of exercise. Increasing exercise

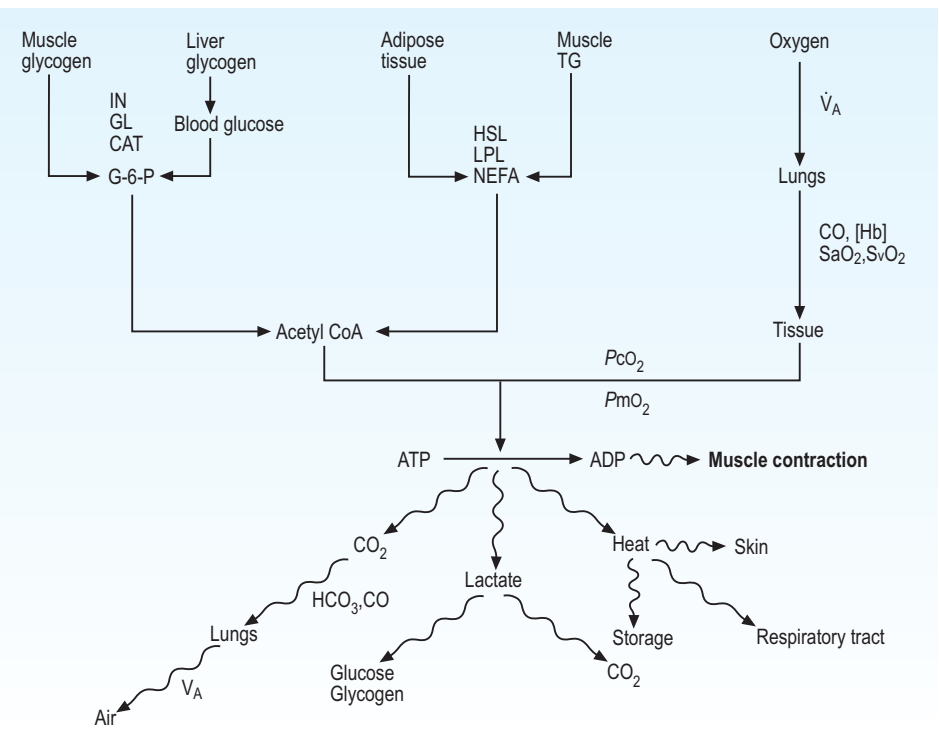

Fig. 1.1
Schematic of substrate and oxygen flux demonstrating the integrated and sequential nature of many processes. Substrate supply to produce ATP that powers muscle contraction is through both lipid and carbohydrate. Carbohydrate is provided from muscle glycogen by phosphorylase or from glucose in blood. Important controlling hormones are glucagon, insulin and the catecholamines, in addition to control by local physicochemical factors. Lipid substrate is provided from both intramuscular and adipose tissues, with the former being more important during exercise. Ultimately carbon molecules are delivered to the mitochondria wherein they are oxidized to produce carbon dioxide, heat and work. Oxygen delivery to the mitochondria is dependent upon a chain of events leading from the atmospheric air to the mitochondria. Muscle contraction is associated with production of work, carbon dioxide, heat and lactate (under conditions of anaerobic metabolism). ADP, adenosine diphosphate; ATP, adenosine triphosphate; CAT, catecholamines; CO, cardiac output; CoA, coenzyme A; CO_2, carbon dioxide; G-6-P, glucose-6-phosphate; GL, glucagon; [Hb], hemoglobin concentration; HCO_3, bicarbonate; HSL, hormone-sensitive lipase; IN, insulin; LPL, lipoprotein lipase; NEFA, non-esterified fatty acid; PcO_2, capillary oxygen tension; PmO_2, mitochondrial tension; SaO_2, arterial oxygen saturation; SvO_2, venous oxygen saturation; TG, triglyceride; V_A, alveolar ventilation.

intensity results in a greater proportion of total energy production being derived from carbohydrates in muscle (glycogen) and blood (glucose, either absorbed from the gastrointestinal tract or produced by the liver) than from fat (see Chapter 37). The supply of these substrates is controlled by the hormonal responses to exercise, which include a reduction in blood insulin concentration and increases in blood catecholamine, cortisol and glucagon concentrations (see Chapter 35). The net result is increased delivery of glucose to muscle from the blood as a result of increased hepatic glycogenolysis and gluconeogenesis. However, blood-borne glucose provides only a small proportion (< 10%) of carbohydrate used during intense exercise, the remainder coming from intramuscular stores of glycogen.

Oxidation of substrate during exercise is dependent upon a nearly constant supply of oxygen. Oxygen delivery to the muscle is dependent upon optimal functioning of the respiratory and cardiovascular systems, which are described in detail in this text (see Chapters 28 and 32). Increased oxygen delivery to muscle is achieved through increases in minute ventilation, alveolar ventilation, oxygen-carrying capacity of blood (secondary to splenic contraction), and cardiac output. Increases in values of these variables with exercise are roughly dependent on the relative intensity of exercise.

Aerobic metabolism and anaerobic glycolysis result in the production of waste products principal among which are carbon dioxide and lactate. Carbon dioxide is produced by the aerobic metabolism of carbohydrate or fat. Produced in the mitochondria of metabolically active cells, it diffuses into the blood wherein it is transported either as dissolved carbon dioxide or as bicarbonate (see Chapter 39). Transportation of the large amounts of carbon dioxide produced during exercise results in marked increases in venous partial pressure of carbon dioxide and venous blood bicarbonate concentrations.

Lactate, and associated H^+, is produced during anaerobic metabolism. A 3-carbon monocarboxylate compound, lactate moves out of muscles and into other tissues by diffusion and by active transport by monocarboxylate transporters. Lactate is metabolized to carbon dioxide and water in well-oxygenated metabolically active tissues, or is recycled to glucose and glycogen in the liver, kidney and inactive muscle cells (see Chapter 37). The hydrogen ions produced during anaerobic metabolism are buffered by intracellular buffers, including proteins, and by extracellular buffers, the most quantitatively important of which is bicarbonate. Despite this buffering, intense exercise induces a pronounced acidosis and acidemia with decreases in arterial and mixed venous pH and base excess, decreases in arterial bicarbonate concentration and marked increases in carbon dioxide tension in venous blood. The acidosis associated with maximal exercise is severe and tolerable only for short periods of time. Resolution of the respiratory acidosis occurs within seconds to minutes of the cessation of exercise, whereas metabolic acidosis is slower to resolve, taking 30–60 minutes.

Muscle contraction produces heat which if not effectively dissipated results in hyperthermia (see Chapter 41). The heat generated by an exercising horse is sufficient to raise its body temperature by 3–5°C. If exercise is prolonged and not accompanied by effective heat dissipation, the rectal temperature may exceed 42°C, a temperature associated with markedly increased risk of heat shock and illness. Heat generated in muscle is transported by the blood to the skin and respiratory tract, from where it is lost into the ambient air. Heat dissipation from horses is achieved by evaporation of sweat, evaporation of respiratory tract secretions and convective loss of heat in air moving over the horse's skin and respiratory membranes.

Physiology of training

Training is essential for horses to compete effectively and safely. All equine athletes undergo some type of training regimen to prepare them for the rigors of competition. Training prepares the equine athlete for competition by inducing the physiologic adaptations necessary to perform at a high level with minimal risk of injury, and by providing the appropriate behavioral and psychological factors essential for effective competition. In order to adequately prepare a horse for competition, the horse should regularly perform the type of activity that it will perform in competition at an intensity that will induce the physiologic changes needed to permit optimal performance.

Repetitive exercise induces a multitude of physiologic and anatomic adaptations in horses. The specific responses of each body system are dealt with in detail in the relevant sections of this book. However, there are a number of concepts that are common to many body systems.

The adaptive response

An important concept is that some physiologic processes, functions or anatomic structures are malleable and able to adapt in response to the stresses and strains imposed by repetitive exercise. Collectively, induction of these adaptive responses to exercise is called training or conditioning. Strictly speaking, training refers to changes in behavior induced by certain practices whereas conditioning refers to the physical changes that occur in response to repetitive exercise. However, the terms are often used synonymously.

The adaptive responses induced by repetitive exercise act to reduce the effect of the strain induced by the physiologic stressors associated with exercise. The body acts to minimize the disruption to homeostasis induced by exercise by increasing the capacity of the system to deal with the work imposed by exercise. For example, the stress of increased force production by muscle during exercise stimulates changes in muscle structure and function that act to reduce the stress on individual muscle fibers, while increasing the overall capacity of the muscle. This phenomenon is common to many, but not all, body systems and the cumulative effect is a change in body composition and capacity for physical work.

Mechanisms of training effects

Repetitive exercise (exercise training) results in a multitude of changes in the body at cellular, tissue, organ and whole organism levels. At the most fundamental level, training occurs through increased production of proteins, both structural and functional proteins. Accumulation of metabolites and waste products is believed to induce increased transcription of DNA specific for proteins, including enzymes, that control rate-limiting functions associated with these metabolites. Increased transcription, if associated with increased translation of mRNA to protein and appropriate post-translational events, results in production of more protein. The increased quantity or activity of the enzymes then results in an increase in the maximal rate at which the metabolites can be processed or waste products eliminated. At an organ level these changes result in an increase in function, usually associated with increases in organ size.

Principles of training

For training to be effective in inducing the desired conditioning, there must be a degree of 'over-reaching'. Over-reaching refers to the performance of an activity at a sufficient intensity and duration to induce some strain into the organism. Without this strain, there will be no conditioning effect.

It is also important to recognize that training is task specific. The task for which conditioning is desired must be performed. For example a horse trained to compete in endurance events will be poorly trained for sprint racing. Given the specificity of training, there are three principles of training expressed for human exercise physiology:[24]

1. Repetition
2. Summation
3. Duration.

To induce a training effect, there must be repetition of the training stimulus. The number of repetitions varies with the type and intensity of exercise. Summation refers to the total amount of work performed. To achieve some degree of over-reaching, the total amount of work performed must be sufficient to induce some strain. If tasks are performed without sufficient time for substantial recovery between repetitions, then the total amount of work needed to achieve a training response may be lower than if recovery is allowed to occur.[24] Finally, the training stimulus must be of sufficient duration to induce an effect.

These principles of training must be used in a thoughtful and planned manner in order to induce the maximum training response while reducing the risk of injury. The art of training involves the judicious use of exercise of various intensities and durations in order to induce the optimal adaptations that will permit successful competition while preventing injury or occurrence of overtraining.

Overtraining

Overtraining is a well-recognized syndrome in human athletes in which increases or maintenance of training intensity are associated with decrements in performance.[25,26] Diagnosis of overtraining in humans is complicated by the absence of any one definitive test, although psychological profiles including evaluation of mood are the most specific indicators of overtraining.[25] The situation is even more complicated in horses for which psychological and mood evaluation is not available. Overtraining in horses is characterized by decrements in performance and maximal rate of oxygen consumption.[27,28] Specific aspects of overtraining are addressed in other sections of this book.

Factors limiting performance

Maximal performance involves the coordinated optimal functioning of almost all body systems. In most cases, maximal performance requires that these body systems operate at or close to their maximum capacity. Conceptually, this integrated maximal function may be viewed as a pipeline. The maximum overall flow through the pipe is limited by the narrowest segment of the pipe. This analogy is often employed for oxygen transport during exercise and the system is viewed as one of tuned resistors, with no one individual element limiting the capacity of the system.[29] While this analogy is appropriate for healthy animals, it may not be so for animals with performance-limiting abnormalities, such as lameness or airway obstruction. In this instance, a single abnormality is sufficient to impair performance. Specific aspects of poor performance are dealt with elsewhere in this book.

For healthy horses the actual performance-limiting factor depends on the type of exercise and its duration. Standardbred or Thoroughbred race horses running at top speed are probably limited by oxygen transport. In these animals the malleable components of the oxygen transport chain (red cell mass, mitochondrial volume, muscle capillarity) have adapted to the extent that the capacity of these components approaches or exceeds the capacity of the non-malleable components, such as lung volume or tracheal diameter. A reduction in the capacity of the non-malleable component, for example a reduction in laryngeal diameter secondary to laryngeal hemiplegia, will reduce the capacity of the whole system. This has important consequences for a horse performing at maximal intensity. However, if the capacity of the non-malleable components exceeds that of the malleable components, then a reduction in capacity of the non-malleable component may not reduce performance, for instance in the case of a dressage horse with laryngeal hemiplegia. In this case, the disorder will probably not limit the physiologic capacity of the horse to perform its task (although the associated respiratory noise may detract from the performance).

For other types of performance, other factors are limiting. Three-day event horses may be limited by their capacity to thermoregulate, endurance horses by their capacity to maintain fluid and electrolyte homeostasis, and draft horses by the strength of their muscles. Clearly, the factors limiting exercise capacity of horses vary with the type and duration of

exercise. However, an understanding of what is likely to limit performance for each breed and use of horse is important not only in understanding the physiology of that form of exercise, but also in determining the likely causes of poor performance in animals with clinical disease.

CHAPTER 2

Clinical exercise testing: evaluation of the poor performing athlete

Eric K. Birks, Mary M. Durando and Ben B. Martin, Jr

Introduction

The widespread availability of high-speed equine treadmills at universities and major veterinary referral centers has led to the development of a number of programs that utilize a treadmill examination as part of the diagnostic evaluation of poor performance in equine athletes.[1–3] As a number of structural and/or functional abnormalities only manifest during intense exercise, appropriate diagnostic information for many of these potentially performance-decreasing problems are best obtained during controlled exercise afforded by a high-speed treadmill. This chapter will provide a discussion of the more common techniques utilized in the diagnostic workup of horses with athletic performance that is less than expected. A detailed flowchart of a typical performance evaluation protocol is shown in Fig. 2.1.

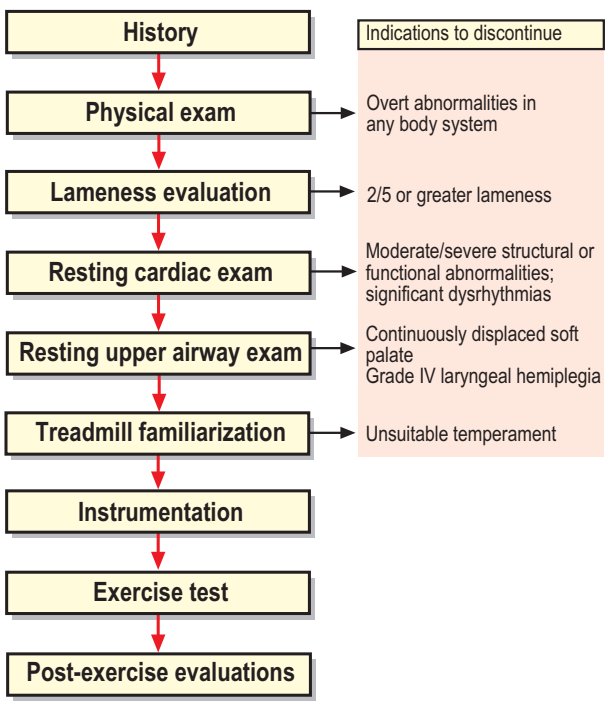

Fig. 2.1
An example of a diagnostic protocol for evaluation of horses with a primary complaint of poor athletic performance.

History

A thorough, accurate history is an essential initial step in attempting to identify the cause(s) of poor athletic performance. This includes not only a detailed description of the presenting complaint, but also the type/duration of any present or previous illnesses, any previous surgeries, present diet (including all supplements), present and past training protocols, and a complete performance record. Obtaining an accurate database requires that the individuals providing the information actually have the necessary specific, first-hand knowledge of the equine patient and any associated problems. Transportation providers, grooms, relatives, even absentee-owners, etc. are often unaware of the pertinent medical information that is required to assess the patient adequately.

For those patients that have been competing, a complete official performance record can often indicate whether an individual's performance has always been less than expected,

or if there has been a recent reduction in performance. Recent changes in competitive performance are often indicative of the onset of specific medical abnormalities, whereas poor performance throughout the individual's career may indicate that the expectations of the owners/trainers exceed the ability of the animal to compete at the desired level of performance.

Physical examination

The fact that a horse arrives at a referral center or university hospital with a primary complaint of 'poor athletic performance' indicates that up to the time of presentation no specific cause for reduced performance had been identified by any of the previous individuals examining the horse. However, this does not mean that a specific abnormality or illness is not present. Therefore, it is essential that a thorough physical examination of all body systems be conducted in order to rule out obvious organic disease or abnormalities. It is tempting to focus upon those systems most obviously involved in exercise (i.e. cardiovascular, respiratory, and musculoskeletal). However, abnormalities in virtually any system can also have an impact upon exercise performance.

Lameness evaluation

Although overt lameness is understood to impact severely on performance, the effects of mild-to-moderate lameness are often overlooked as a potential cause of diminished performance. As treadmill exercise can often mask or confuse all but the most severe lameness, treadmill evaluations are not indicated in lame animals. Additionally, the risk of potentially exacerbating an existing lameness does not usually warrant a high-speed treadmill evaluation. Instead, a thorough lameness examination, including diagnostic regional nerve blocks, radiographs, nuclear scintigraphy, or other imaging modalities, is indicated in these horses. Only if athletic performance continues to be less than expected after resolution of any causes of obvious lameness would a treadmill evaluation be indicated. Other abnormalities found during the physical examination, such as certain cardiac arrhythmias (e.g. atrial fibrillation), or overt lower airway disease, among others, should also be resolved before a treadmill evaluation.

In some cases, resolution of a specific cause of lameness may require significant rehabilitation time. Should multiple body system dysfunctions be suspected in addition to mild/moderate lameness, and if definitive diagnosis requires a dynamic evaluation, then a treadmill examination may still be indicated. This is particularly important if correction/treatment of any of these potentially performance-limiting dysfunctions also requires prolonged recovery time for return of normal function. Certainly, it is undesirable to exacerbate any diagnosed lameness, so the potential risk of further damage to the horse, as well as the safety of the treadmill personnel, must be weighed carefully prior to continuing with a high-speed treadmill examination. A compromise may involve a treadmill evaluation at reduced running speed.

Resting cardiac examination

A thorough examination of the cardiovascular system during resting conditions is critical to identify potential structural/functional abnormalities that may impact exercise performance.[4] This examination must include careful auscultation of the entire thorax to identify possible dysrhythmias, murmurs, or other abnormal heart sounds, along with possible evidence of primary or secondary pulmonary dysfunction. Peripheral pulse quality and venous distension should also be evaluated, as they may be important indicators of cardiovascular dysfunction. Heart rhythm should be evaluated by electrocardiography (ECG) (Fig. 2.2); cardiac structure and function are assessed with echocardiography. The ECG during rest should exhibit a regular sinus rhythm, although occasional second-degree atrioventricular block is considered a normal finding in healthy horses. Occasional premature beats are also acceptable, and not thought to

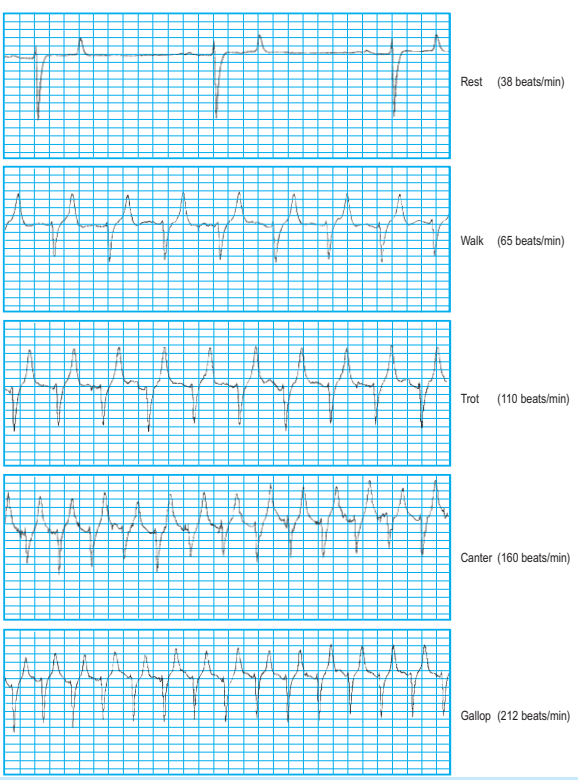

Fig. 2.2
Normal electrocardiograms (ECG) from horses without overt cardiac abnormalities. Heart rate ranges for each of the exercise intensities are given in the text.

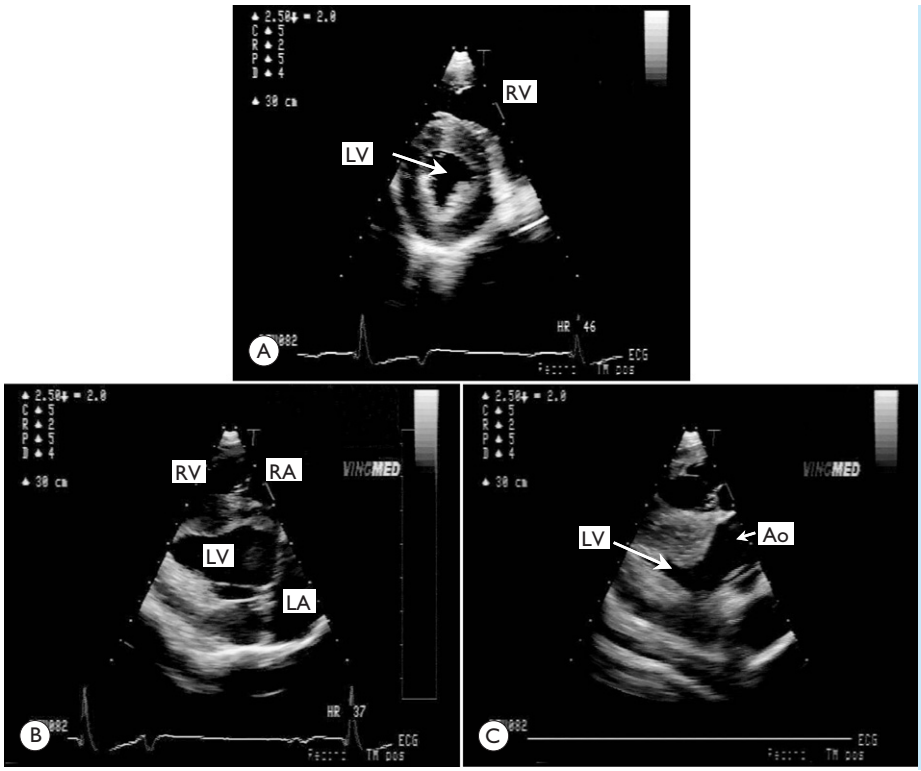

Fig. 2.3
Standard two-dimensional (2-D) echocardiograms from the right side. (A) Right parasternal short-axis view just below the level of the mitral valve. (B) Right parasternal long-axis four-chamber view of the heart. (C) Right parasternal long-axis view of the left ventricular outflow tract. Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

interfere with performance, as long as they disappear with exercise. A complete echocardiographic evaluation consists of two-dimensional (2-D) images to assess both structure and function (Fig. 2.3), M-mode images for measurements and calculated indices (Fig. 2.4), and Doppler studies to determine regurgitant blood flow. Detailed references have been published describing these echocardiographic techniques.[5–8] On a 2-D image, a normal heart should not have any evidence of chamber enlargement, and should have obvious thickening and inward motion of the ventriclar myocardium during systole. M-mode images from short axis views are used to measure ventricular and aortic dimensions and to calculate indices such as fractional shortening (FS). Fractional shortening provides an indication of cardiac contractility, and is calculated from measurements of the left ventricular internal diameter in systole (LVIDs) and diastole (LVIDd) taken from

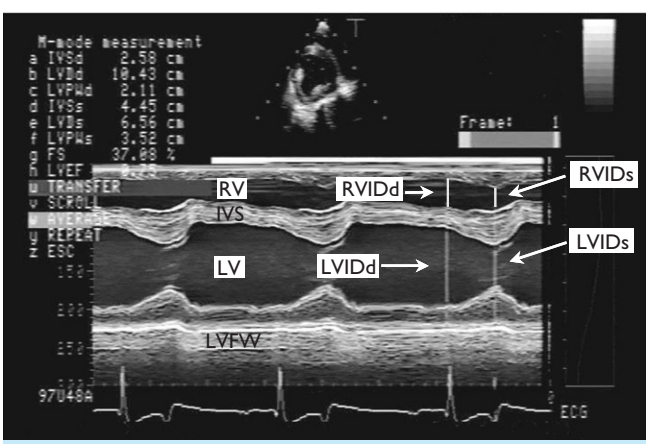

Fig. 2.4
Standard M-mode echocardiogram from a right parasternal short-axis view taken at the level of the chordae tendineae. Fractional shortening is calculated from this view. IVS, intraventricular septum; LVIDd, left ventricular internal diameter at end-diastole; LVIDs, left ventricular internal diameter during systole; LV, left ventricle; LVFW, left ventricular free wall; RV, right ventricle; RVIDd, right ventricular internal diameter at end-diastole; RVIDs, right ventricular internal diameter during systole.

Table 2.1 Values of selected cardiac dimensions at rest

Cardiac dimension	Average (range)
Ao	8.13 (6.9–9.2)
LVIDd	11.92 (9.7–13.1)
LVIDs	7.45 (5.8–8.8)
IVSd	2.85 (2.3–3.44)
IVSs	4.21 (3.16–5.16)
LVFWd	2.32 (1.72–3.40)
LVFWs	3.85 (3.00–4.62)
LAD	12.82 (11.30–14.52)
%FS	37.42 (29.41–44.67)

Ao, aorta; LVIDd, left ventricular internal diameter in diastole; LVIDs, left ventricular internal diameter in systole; IVSd, intraventricular septum in diastole; IVSs, intraventricular septum in systole; LAD, left atrial diameter; LVFWd, left ventricular free wall in diastole; LVFWs, left ventricular free wall in systole; FS, fractional shortening.
Data adapted from Durando and Young.[4]

M-mode images obtained at the chordal level immediately below the mitral valve, using the following formula:

$$FS = \frac{LVIDd - LVIDs}{LVIDd} \times 100$$

A number of investigators have measured normal heart chamber and wall dimensions.[7] A brief summary of the more commonly determined dimensions is given in Table 2.1.

Overt abnormalities identified at rest are often sufficient indication not to continue with a high-speed treadmill evaluation. These include, but are not limited to, atrial fibrillation, multiple ventricular premature depolarizations (VPDs), paroxysmal ventricular tachycardia, obvious abnormal ventricular wall motion, and/or significant valvular dysfunction. In some situations, a treadmill examination may still be indicated even with evidence of cardiac dysfunction. This is especially true when abnormalities in multiple systems are suspected, but require a dynamic examination for definitive diagnosis. With moderate/severe resting cardiac abnormalities, a high-speed treadmill examination may place the horse and/or personnel at risk. In these cases, a treadmill test may be conducted at reduced speed.

Resting upper respiratory tract evaluation

Endoscopic examination of the upper respiratory tract (URT) from the nostrils to the level of the carina should be conducted not only under passive resting conditions, but also during induced swallowing and with short-term nasal occlusion. Even without a definitive history of prior surgical intervention, a thorough visual examination of the entire URT should be completed, as the present owners/trainers may not be aware of all previous surgeries. Abnormalities in anatomy and/or function can have a significant impact upon ventilation during exercise, thereby contributing to reduced athletic performance. However, many abnormalities detected during an endoscopic examination are incidental findings that generally have little or no impact on exercise performance. Such insignificant findings would include, but are not limited to, hyperplasia of the pharyngeal lymphoid tissues (more common in younger horses), some asynchronous movement of the arytenoids, and mild flaccidity of the pharynx, epiglottis, and/or soft palate.[9,10] Abnormalities that are suggestive of possible ventilation impairment during exercise, and therefore warrant high-speed treadmill examination, would include moderate/severe flaccidity of the epiglottis, soft palate, and/or pharyngeal walls, asynchronous and/or asymmetric movement of the arytenoids, and intermittent displacement of the soft palate. Severe abnormalities observed during the resting examination, such as chronically displaced soft palate, grade IV laryngeal hemiplegia, or arytenoid chondritis, preclude a treadmill evaluation. Although it is often tempting to terminate the diagnostic work-up when mild/moderate upper respiratory tract abnormalities are identified, it must be stressed that a complete evaluation of all body systems should be conducted prior to rendering a definitive diagnosis of the cause of poor performance. Often multiple body systems have significant abnormalities,[1] and, when this is the case, repairing/treating only one of them without regard to other potential problems can lead to unrealistic expectations regarding improvement in athletic performance. The more commonly diagnosed upper respiratory tract abnormal findings are discussed in detail in Chapter 4.

The observation of a normal resting upper respiratory tract (Fig. 2.5), inconclusive evidence of soft palate displacement, or grade II/III laryngeal hemiplegia, are all indications for proceeding to a dynamic evaluation of the upper respiratory tract during a high-speed treadmill exercise evaluation.

Treadmill familiarization

Should the preceding evaluations of the patient reveal no obvious cause for reduced athletic performance or when potential dysfunction can only be diagnosed during exercise, a high-speed treadmill evaluation is indicated. Because the majority of individual horses have not been required to run

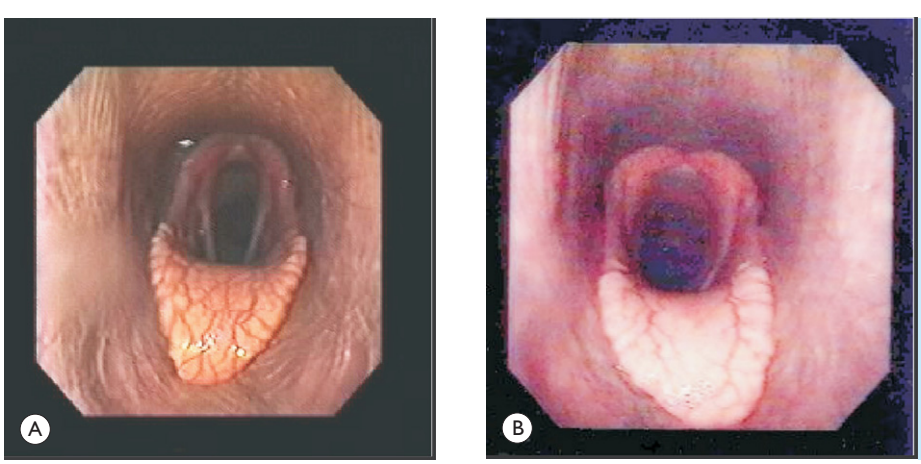

Fig. 2.5
Endoscopic views of an upper respiratory tract of a healthy horse during inspiration at rest (A) and during maximal exercise (B).

on a treadmill, the most important initial step in the process of a treadmill evaluation is to familiarize the horse to exercise on the treadmill. It cannot be stressed enough that the most essential part of the familiarization process is to have a competent horse-handling team; individuals familiar with the treadmill and skilled in handling fractious, excited, and often scared horses in an environment foreign to them. Although the philosophy regarding the familiarization process varies considerably among various referral centers and university hospitals, the most commonly employed system involves a 2–3 day process of non-exercising diagnostic evaluations and a multiple day familiarization protocol. However, this is not always the case, with several of the busiest centers employing a complete examination schedule conducted on an outpatient basis, all within 4–6 hours.

The initial stage of familiarization involves walking onto the treadmill platform repeatedly to allow the horse to become comfortable with its immediate surroundings. Then, several periods of starting and stopping the treadmill are utilized to help the horse become comfortable with the movement of the 'ground'. Once the horse becomes accustomed to walking as the treadmill is started, the speed can be slowly increased, encouraging the horse to change smoothly into gaits appropriate for the increased speeds, thus completing the initial familiarization stages. For those horses that routinely have ancillary running aids applied during competition (i.e. pacing harnesses, blinkers, head-check), additional familiarization should be conducted with these aids attached.

For most horses, the entire familiarization process is generally conducted over a time-span of less than an hour. Rarely, an individual horse will have a temperament unsuitable for familiarization in such a short time frame. In these cases, it may be decided to keep the horse at the facility for additional familiarization sessions, or at the discretion of the 'team', abandon any thoughts of high-speed treadmill evaluation! In the experience of most centers with high-speed treadmill evaluation capabilities, greater than 95% of the horses that reach the treadmill evaluation stage successfully complete the familiarization and proceed to the actual high-speed treadmill exercise evaluation.

Instrumentation

Following successful familiarization but prior to the actual high-speed treadmill evaluation, horses are instrumented to permit data collection during exercise. The most common monitoring instrumentation for diagnosing dynamic changes during exercise includes some type of ECG recording system, catheterization of a systemic artery (e.g. transverse facial artery), a means for monitoring core body/blood temperature, and placement of an endoscope to visualize the nasopharynx and proximal laryngeal structures. Occasionally, the presenting complaint may include the recent onset of exercise-induced pulmonary hemorrhage (EIPH). In these cases, the placement of a catheter to monitor pulmonary arterial pressures may be indicated.

To monitor the ECG during exercise, some form of telemetry system is generally utilized. A number of systems are commercially available, with the only requirement being the capability of recording a discernible ECG pattern during intense exercise. Because the horse is confined to the treadmill, it is not essential that a telemetry system be utilized; even a hard-wired system would be acceptable. It is, however, imperative that clear images of the ECG be recorded continuously during exercise and in the immediate post-exercise period. As previously noted, significant resting arrhythmias and/or myocardial dysfunction would preclude proceeding to a high-speed treadmill evaluation. However, several individual non-conducted beats or isolated VPDs are generally insignificant and will often not be apparent during exercise. The presence of this type of arrhythmia does not preclude the conduct of an exercise test.

A catheter placed in a systemic artery provides access to arterial blood during exercise. Sequential sampling of arterial blood during exercise is essential in evaluation of pulmonary gas exchange function as well as of exercise-related changes in blood electrolytes and acid–base status. Arterial blood gas values change extremely rapidly following exercise, within 5–10 seconds, thus precluding the use of virtually any post-exercise blood sample in the evaluation of lung gas exchange. The mechanics and exact placement of a systemic arterial catheter vary among the various facilities, with the most commonly utilized artery being the transverse facial artery. The type of catheter used is also a matter of individual preference, but most frequently some type of 20-gauge 'over-the-needle' catheter is utilized. In any event, the catheter must be securely attached to the horse (e.g. sutures or cyanoacrylate cement) and connected to extension tubing to permit collection of blood samples during treadmill exercise.

To temperature-correct measured blood gas values to those of the gas exchange region, it is essential that the blood temperature at the site of gas exchange be recorded. For the clinical treadmill examination, some type of rapid-responding thermocouple or thermister catheter must be placed in the central body core. This generally involves passing the temperature-monitoring catheter to the level of the heart via a jugular vein. Monitoring core body temperature is also of importance if heat dissipation abnormalities (e.g. anhidrosis) are suspected.[11,12] Figure 2.6 shows a catheter positioned in a transverse facial artery and a thermocouple catheter placed into a jugular vein.

Continuous visualization of the nasopharynx and proximal laryngeal structures during the high-speed treadmill examination is accomplished by placing a flexible endoscope through either of the nostrils to the level of the pharyngeal openings of the guttural pouches. While the exact type is not critical, a moderately flexible video or fiberoptic endoscope, 9–12 mm in diameter, with intense illumination and a wide field of view is most typically utilized. Some means of continuously recording the images obtained via the endoscope is also essential. Several commercial sources of veterinary video endoscopes are available, and are readily adapted to permit temporary fixation of the endoscope to the halter or bridle of the horse to maintain position during treadmill exercise.[10]

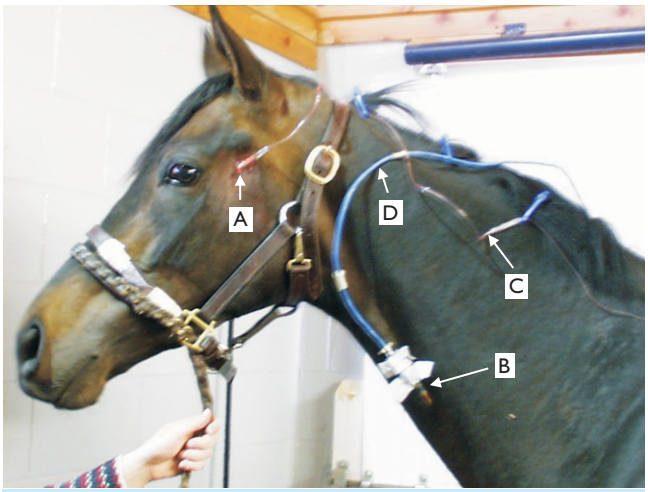

Fig. 2.6
Catheter placement for evaluation of arterial blood during treadmill exercise. (A) 20-gauge catheter secured with cyanoacrylate cement into the left transverse facial artery; (B) a thermocouple catheter passed via the left jugular vein; (C) catheter extension tubing to allow blood sampling during exercise; (D) thermocouple extension wire to allow recording of temperature signals from the sensor placed at the level of the right atrium.

Thorough diagnostic evaluation of the cardiopulmonary system during exercise may involve measurement of exercising pulmonary arterial pressures. Placement of a pressure-measuring catheter into the pulmonary artery, although somewhat invasive, is a relatively straightforward technique. A commercially available catheter introducer is placed into a jugular vein, and a pressure-monitoring catheter is passed through the introducer, advanced through the vein, the right atrium, the right ventricle, and into the pulmonary artery. Pressure waveforms are monitored during passage until the characteristic waveforms of the pulmonary artery are observed. Tip-mounted pressure transducer catheters are readily available, at modest cost, which permit not only accurate pressure measurements, but also simultaneous blood sampling, even during intense exercise. Although there are risks associated with the passage of a catheter through the heart, the associated problems rarely persist. These problems can include cardiac arrhythmias associated with myocardial irritation, thrombus formation, and possible damage to the myocardium and/or valve leaflets.[13] However, the diagnostic value of measuring pulmonary arterial pressure often outweighs the risks.

Recent reports also suggest that direct measurement of pressure changes within the right ventricle during exercise may provide valuable information regarding mild cardiac dysfunction. For these measurements, passage of appropriate pressure-measuring catheters into the right ventricle is identical to that described above for placement of a pulmonary arterial catheter except for the final positioning.[14]

Exercise tests

After placement of the necessary instrumentation described above, a standardized treadmill exercise test (STET) is conducted. Individualized STETs have been developed at various veterinary facilities; however, the differences are primarily related to equipment and/or personnel availability. A typical STET consists of a warm-up phase of walking, trotting, and moderate cantering (trotting/pacing in Standardbred race horses), followed by a high-speed test at as fast a speed as the individual horse is capable of sustaining for 1600 to 2400 meters. The exact intensity of the high-speed test is often dictated by the temperament of an individual horse, but in most cases speeds will approach 12–14 m/s. This generally represents 90–95% of the exercise intensity required to elicit maximum oxygen consumption in most fit athletic horses. Some clinical facilities conduct an additional high-speed test, 30–60 minutes following the first test, with the philosophy that a single test is not sufficiently strenuous to mimic racing conditions, and that two successive tests provide a better reflection of the fatigue and dynamic changes in certain variables associated with competition. Another commonly employed method of increasing exercise intensity during the STET is to elevate the treadmill to have the horses run uphill. While this does elicit greater exercise effort for any given speed than without treadmill elevation, it should be noted that different muscle groups are utilized during uphill exercise than on the flat. Therefore, this must be considered in the evaluation of potential performance-limiting abnormalities. It should also be noted that, for some horses, the inclusion of some uphill exercise during the STET may be appropriate. This is especially true for horses used in competitions that include jumping (i.e. steeplechasing, eventing).

During the high-speed test, the ECG and video images of the nasopharynx/larynx are continuously recorded. If pulmonary arterial pressures are being monitored, pressure waveforms are continuously recorded utilizing a computerized data collection system. Discrete samples of systemic arterial blood are collected anaerobically into heparinized syringes at various timed intervals during the test; a typical sampling protocol involves samples collected at rest, immediately following the warm-up period, after 30, 90, 150, 210 seconds of the maximal test, and within 60 seconds following cessation of exercise. The blood samples are tightly capped and stored on ice until analyzed, generally within 15 minutes of collection. Typical analysis would include blood gases (i.e. Po_2, Pco_2, pH), plasma electrolytes, hemoglobin concentration, lactate concentration, and multiple computed values (e.g. bicarbonate, base excess, total CO_2, anion gap, etc.).

In certain cases, part of the presenting complaint may include exaggerated noises associated with respiration. To help identify the source(s) of these reported respiratory noises, sounds associated with the upper respiratory tract and video images of the nostril region can be recorded during the treadmill examination.

Expected normal findings during STET

Normal ECG findings during exercise include a regular sinus rhythm with no ectopic beats. The heart rate is typically 60–80 beats/min during walking, 80–120 beats/min during trotting, 120–150 beats/min at a moderate canter (trot/pace in Standardbreds), 150–180 beats/min at a gallop (not maximal effort), and up to 220–240 beats/min at maximal effort. Heart rate and rhythm are also monitored during the immediate post-exercise period where the rate should drop to below 100 beats/min within 4–5 minutes, and have only occasional, transient sinus arrhythmias, second-degree atrioventricular block and/or isolated supraventricular or ventricular ectopic beats.[15]

The normal URT during a high-speed treadmill test will have little or no observable mucus. Additionally, during inspiration, arytenoid cartilages will fully abduct and move in synchrony, the epiglottis will remain on the floor of the nasopharynx (except during swallowing), the soft palate and walls of the nasopharynx should not adduct or in any way reduce the size of the nasopharynx, and the external musculature of the nostrils should expand the nasal openings during inspiration and maintain some tension (preventing fluttering) during exhalation.[9,16] Several researchers are attempting to correlate respiratory sounds with visual observations of pharyngeal/laryngeal abnormalities.[17,18] Published reports to date suggest that it may eventually be possible to obtain diagnostic information regarding certain URT abnormalities during routine exercise without a specific endoscopic treadmill examination. The caveat remains that such diagnostics would provide information only on the URT, potentially missing dynamic abnormalities in other body systems. Chapter 4 details abnormalities of the URT that are commonly associated with reduced athletic performance.

Arterial blood samples obtained during the treadmill examination are used to evaluate pulmonary gas exchange as well as electrolyte and metabolic changes associated with exercise. A number of these changes are related not only to the intensity but also to the duration of exercise. For these reasons, it is best to collect serial blood samples during the treadmill examination. Data for selected arterial blood parameters (those that exhibit the greatest exercise-related changes and thus are the most commonly utilized to diagnose related abnormalities) obtained during treadmill exercise in 119 clinically normal horses without evidence of cardiopulmonary or URT abnormalities are shown in Figs 2.7 and 2.8. Figure 2.7 shows average (± standard error of the mean) values for each of seven samples collected during the treadmill examination. Figure 2.8 shows the average values for the same variables but as a function of the maximum treadmill speed achieved by individual horses.

Core body temperature increases during exercise as a function of both exercise intensity and duration. Resting core body temperatures in a group of ~400 clinical cases averaged 37.3°C. The body temperature response to treadmill exercise is depicted in Fig. 2.7, while body temperature at the end of exercise plotted against maximum running speed for individual horses is shown in Fig. 2.8.

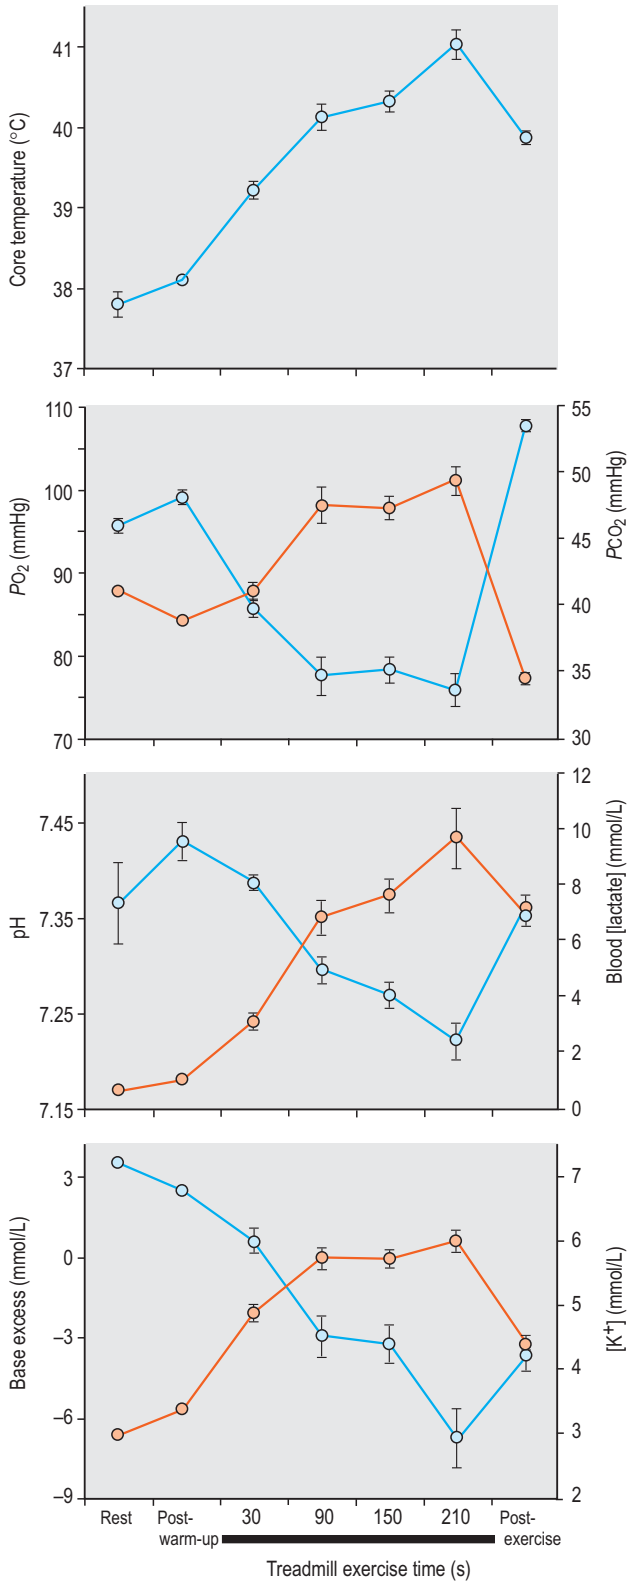

Fig. 2.7
Plots of selected blood variables at rest, following the warm-up period, during high-speed treadmill exercise at 12–13 m/s, and 30 seconds post-exercise. These data are from a subset of 34 individual horses from a total of 119 clinically healthy horses that completed a high-speed exercise test at a maximum speed of 12–13 m/s. Values are mean ± SEM. Left axis is used for values represented by blue lines; right axis for red lines.

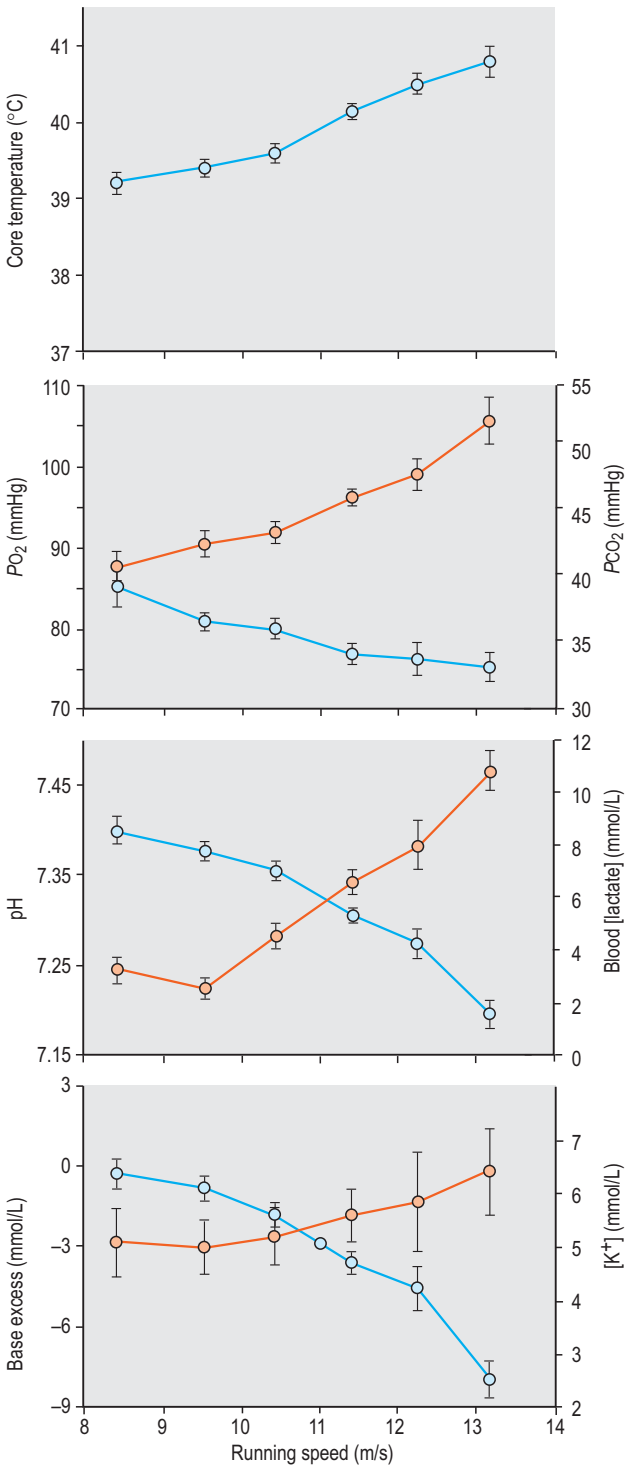

Fig. 2.8
Plots of the same blood variables as in Fig. 2.7 except, in this case, versus running speed. These values are those obtained from blood samples collected during the final 30 seconds of maximal treadmill exercise (i.e. the samples indicated in Fig. 2.7 at 210 seconds of treadmill exercise). The speeds indicated represent the maximal intensities attained by individual horses during treadmill tests. Values are mean ± SEM from a total of 119 horses determined to be clinically healthy that completed a high-speed exercise test: total number of individual horses at speeds of 8, 9, 10, 11, 12, and 13 m/s were 14, 19, 15, 25, 34, and 12, respectively. Symbols are as indicated in Fig. 2.7.

Immediate post-exercise assessment

Echocardiography

A resting cardiac examination is critical to ensure that the horse does not have overt disease as a contributor to decreased performance. On the one hand, subtle or paroxysmal abnormalities that might not be apparent at rest can significantly impact on exercise performance when maximal cardiac output is required. Conversely, some abnormalities appreciated at rest, such as a murmur with mild valvular regurgitation, might not negatively influence performance. As horses have a relatively high prevalence of murmurs and arrhythmias,[19–22] it can be a challenge to determine their significance as a cause of poor performance. Various abnormalities, such as systolic dysfunction, diastolic dysfunction, significant regurgitation, intracardiac shunts or dysrhythmias, can cause a reduction in athletic ability by reducing cardiac output. Some of these may be dynamic in nature, only exacerbated by strenuous exercise. Although the heart rhythm can be evaluated during exercise by telemetered ECG, myocardial function is much more difficult to evaluate, and, under most circumstances, this evaluation must be confined to the immediate post-exercise period.

In human medicine, immediate post-exercise stress echocardiography has been shown to be a very sensitive and specific indicator of exercise-induced myocardial ischemia and coronary artery disease.[23,24] Stress echocardiography consists of specific standardized views taken under resting conditions just prior to and immediately post-exercise. The corresponding images are displayed side-by-side in a continuous loop cine format at comparable heart rates, to compare wall motion and thickening from similar views before and after exercise. In humans, the left ventricular wall is divided into segments, and the wall thickening and motion pre- and post-exercise for each segment are evaluated and graded. The segments are scored normal, hypokinetic, akinetic or dyskinetic, and segmental dysfunction is considered to be a sensitive indicator of coronary artery disease and regional ischemia. To be most accurate, it must be completed within 2–3 min of cessation of exercise before values return to baseline. Recently, a similar technique has been advocated as a means of evaluating myocardial function in horses.[5] Normal myocardial function at rest is manifested by ventricular wall thickening and inward motion during systole with FS of approximately 30–40%. During exercise, the inward wall motion, wall thickening and FS should increase dramatically in response to the demand for increased cardiac output. This increased myocardial contractility persists very briefly into the post-exercise period. A recent study in exercising horses calculated myocardial contractility on the basis of dP/dt (the first derivative of the change in pressure with respect to time) via pressure catheters positioned in the left and right ventricles. Similar calculations have been used to assess both systolic and diastolic myocardial function in horses. This study

Table 2.2 Values for selected enzymes and proteins found in serum of clinically health horses

	Rest	Post-exercise
Total creatine kinase (CK) activity (U/L)	24.6 ± 6.9[a]	<1000[d]

LDH_5	2.3 ± 1.7[a]	
	3.4 ± 1.2[e]	3.1 ± 0.9[e]
Cardiac troponin I (cTNI) concentration (ng/L)	26 ± 11[b]	72 ± 57[b]

[a] From Fujii et al;[30] values are mean ± SD, n = 160.
[b] From Durando et al;[26] values are mean ± SD, n = 9.
[c] From Lumsden et al;[31] values are 95% confidence interval.
[d] From Martin et al;[1] upper limit for asymptomatic horses.
[e] From Rueca et al;[32] values are mean ± SD, for horses running >15 m/s.
[f] The designation BB, MB, MM_1, MM_2 is a term for the specific isoenzyme. BB is brain type, MM is muscular type, and MB is hybrid type (Fujii et al[35]).

demonstrated that contractility remains similar to exercising values for approximately 30 s, while the heart rate remains elevated.[14] Thus, for stress echocardiography to be a useful indication of exercising myocardial function, it must be performed within 30–60 s of the cessation of exercise.

Post-exercise blood samples, collected 1–4 h following the treadmill test, are evaluated for the activities of several circulating enzymes that can arise from damaged cells. The most commonly evaluated enzymes are creatine kinase isozymes (CK or CPK), aspartate aminotransferase (AST), and the lactate dehydrogenase (LDH) isozymes. In addition, the plasma concentration of cardiac troponin I (cTNI) has been evaluated.[25–27] Although not all of these enzymes are exclusively found in skeletal and/or cardiac muscle, unexpected differences between values in samples collected prior to the treadmill examination and those in the post-exercise samples can generally be attributed to abnormalities in either of these systems. Table 2.2 provides reference ranges for cTNI and the commonly measured enzyme activities, both at rest and post-exercise.

Differential cytologies of washes from either the trachea (TW) or the bronchoalveolar region (BAL) are frequently used to evaluate the potential contribution of lower airway disease to reduced athletic performance. Most clinicians agree that BAL fluid cytology is better correlated with specific lower airway abnormalities than is TW fluid and thus is the better sample to collect post-exercise.[28,29] However, the need for sedation and the more invasive nature of a BAL may preclude its use in some clinical settings, especially if the entire treadmill examination is performed in a single day on an outpatient basis. The cytologic profile of samples collected pre- and post-exercise will differ. Typical cell differential values for samples of TW and BAL fluid obtained before and approximately 1 h after treadmill exercise are given in Table 2.3.

Table 2.3 Normal values for cytology from tracheal and bronchoalveolar wash fluid

	Tracheal wash		Bronchoalveolar lavage	
	Rest[a]	Post-exercise[b]	Rest[c]	Post-exercise[c]
Nucleated cell differential

CHAPTER 3

Exercise testing in the field

David Evans

Introduction

Exercise tests of equine athletes can be conducted in a treadmill laboratory, or in the field. There are advantages and disadvantages for conduct of exercise tests in both these locations. Field investigations have the advantage of conduct of the test in the environment likely to be used in competition. The surface, gaits and speeds used in a field test are therefore more closely aligned to the demands that horses face during exercise in the 'real world'. Field tests also account for the effects of jockey or driver. These advantages can also be disadvantages, because they can contribute to difficulties in standardization of field exercise tests. This chapter presents some of the limitations of treadmill exercise tests, and describes techniques that have been used for field exercise tests in galloping, trotting and pacing horses. The rationale for making the effort to perform field exercise tests is discussed. There have been many remarkable field studies that have measured the electrocardiogram, collected arterial blood and measured tracheal pressures in galloping horses. However, it is not the intention of this chapter to review in detail all equine field studies. The scope of this chapter will be limited mostly to field studies of cardiorespiratory function, and to the use of field studies to conduct fitness tests in athletic horses.

Limitations of treadmill tests

The arguments for using high-speed treadmills to evaluate fitness and health of horses are obvious. The physical environment can be controlled, and conduct of exercise tests with precise design is possible. The speeds and durations of each step of an exercise test are highly repeatable. There is also easy access to horses at suitable times during and after exercise for cardiorespiratory measurements and blood collections.

Horses should be acclimated to treadmill exercise before clinical exercise testing.[1] However, responses to acclimation runs are unpredictable in individual horses. Figure 3.1 illustrates the variability of heart rates and plasma lactate concentrations during treadmill exercise in horses that were given four treadmill tests on consecutive days. Several studies have shown that physiologic responses to treadmill exercise do not replicate responses to field exercise. Heart rate (HR) and plasma lactate concentrations in Standardbred horses pulling a 10 kilopond draught load were lower on the treadmill than on the racetrack.[2] It was also reported that HR and blood lactate in trotters were lower during exercise on a level treadmill than during exercise on a racetrack (Fig. 3.2).[3] Heart rates were expressed as V200 and VHRmax, the velocities at which HRs were 200 beats per minute or had just reached maximal HR. Blood lactates were expressed as V4, the velocity at which blood lactate was 4 mmol/L. This value is sometimes referred to as VLa4. Stride frequency was lower and stride length was greater on the treadmill. Interestingly, this study also showed that there were no differences in any measurements on two sand tracks of 720 and 1250 m in length. A study of ridden Warmblood horses also found that heart rates and blood lactate concentrations were lower on the level treadmill at speeds of 6.5–9.4 m/s compared with exercise over ground. The treadmill speed had to be increased by approximately 10% or the treadmill incline increased to 1–2% to give the same heart rates as in the field.[4]

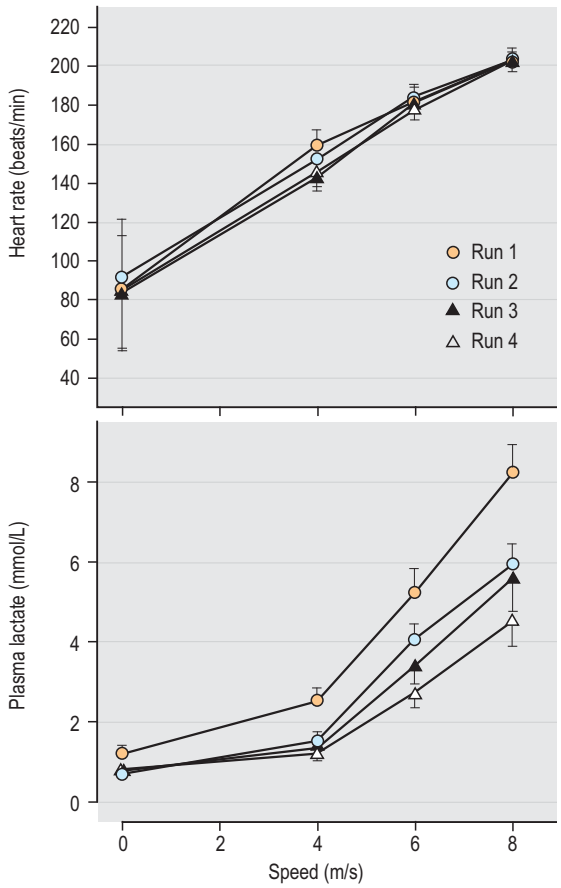

Fig. 3.1
Heart rates and plasma lactate concentrations (mean ± SEM) during treadmill exercise in six race horses that had four sequential acclimating runs over a 4-day period. Note the variability of heart rates during trotting at 4 m/s, and the high variability of plasma lactates at all velocities. From King et al,[1] with permission.

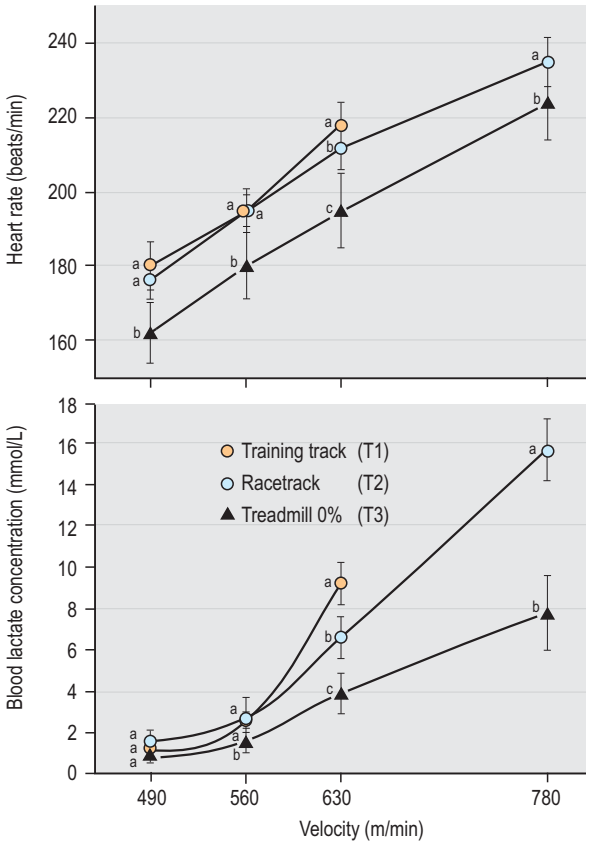

Fig. 3.2
Mean ± SD heart rate (HR) and blood lactate concentrations in five French Standardbred trotters at three different speeds during exercise tests performed on two different tracks (T1,T2) and on a non-inclined treadmill (T3). At each velocity, values with a different letter are significantly different. The treadmill tests produced lower HRs and blood lactate concentrations in most cases. From Couroucé et al,[3] with permission.

Locomotion during treadmill exercise is quite different to that on the track. As a consequence, even if horses are given tasks on treadmills that produce similar HRs, their gaits may be quite dissimilar. Stride frequencies at identical trot and gallop speeds are greater on a racetrack.[5] Design of treadmill exercise tests to replicate field exercise therefore seems to be a fruitless endeavor.

Treadmill exercise tests should be used when it is appropriate to do so, and field exercise tests also have a role in the management of athletic horses. In field tests, horses do not need acclimation, and the exercise is conducted in the physical environment that is more closely matched to that used in competition.

Field exercise tests

Heart rate and blood lactate measurements are the bases of an exercise test for athletic horses. Heart rates are usually expressed relative to a constant submaximal speed, such as V200, the velocity at which heart rate is 200 beats per minute. However, expression of the velocity at lower heart rates is equally valid, and some studies have used V140 and V170.

The blood lactate response to specific speeds of exercise has also been used in numerous studies of field exercise testing for assessing performance and fitness. Fitness has usually been described with speed at a lactate concentration of 4 mmol/L (VLa4). As the horse increases fitness, VLa4 increases. Alternatively, the blood lactate response to a single episode of submaximal exercise can be used. This 'one-step' approach might be more applicable in field tests. It obviates the need for time-consuming, standardized multiple increments of velocity, and the need for multiple collections of blood via a catheter secured in the jugular vein or by repeated venipuncture. Treadmill exercise tests have also measured the lactate 'break-point', the velocity at which blood lactate begins to accumulate in the blood,[6] but there has been no application of this technique in the field.

All exercise tests should attempt to answer a simple question for a trainer or owner of the horse. Ideally the exercise

test should be designed to answer one or more of the following questions:

1. Has the horse's fitness changed with recent training?
2. Is the horse 'fit' for its next race, where fitness refers to a horse that is healthy and suitably trained?
3. How does the fitness of horse A compare with horse B?
4. Does a horse with poor racing performance have suboptimal fitness?
5. Can an appropriate measure of fitness help with training of race horses?
6. Does a horse with suboptimal or unexpectedly poor performance have a disease? Is there evidence of a cardiac or respiratory limitation to performance?

Exercise tests to help answer all of these questions necessitate measurements of heart rate, oxygen uptake, and pulmonary ventilation. Nonetheless, blood lactate and heart rate measurements during or after suitable exercise tests can help with answers to questions 1, 3, 4, and 5. In the following sections, field exercise tests that have used heart rate and blood lactate measurements in Standardbred and Thoroughbred horses will be described.

There are several important principles to follow so that field fitness tests provide meaningful results and answer one or more of the above questions. First, the test protocol should be simple. Multiple steps of increasing speeds of exercise are frequently used in treadmill testing, but these forms of exercise testing in the field may not be popular with trainers because of the excessive time commitment. Exercise tests should also be easy to implement, and ideally should not disrupt normal training schedules.

There are several features of the exercise test that should be maintained wherever possible. These include consistency of:

1. Warm-up routine prior to testing
2. Rates and distances of acceleration during the exercise
3. Test distances or times
4. Speed during the exercise
5. Time after exercise at which blood is collected
6. Post-exercise activity
7. Environmental conditions.

The environmental conditions can be an important factor during the conduct of field exercise tests.[7] Heart rates and other variables were compared under high and low ambient temperature and relative humidity during a submaximal incremental field exercise test in horses tested in summer and in autumn. Heart rate was measured continuously, the other variables at rest and immediately after 4 minutes at 3.5, 4.5 and 7.0 m/s, separated by 3 minute rest intervals, and after 5 and 10 minutes recovery. Heart rates were significantly greater by a mean of 13 beats per minute during exercise in the hot versus cool conditions. It was concluded that differences in environmental conditions can affect assessment of exercise response. These factors must be considered when using fitness tests in the field. Sudden changes in environmental conditions might have considerable consequences for heart rates during exercise.

There has been slow adoption of the use of field exercise tests in commercial race-horse training establishments. Part of the reason for the slow adoption of these techniques has been the difficulty in the design and implementation of exercise tests in the field. Treadmills are useful because they help with the conduct of standardized exercise tests. However, few trainers use treadmills or have access to them. Understandably, some trainers might also have reservations about adopting new techniques that could disrupt busy training schedules.

However, many horse owners continue to be frustrated by lack of information about the fitness and performance capacity of their horses. Several recent studies have outlined new methods of performing exercise tests on racetracks. Some of these methods could easily be implemented in commercial training environments, so that they are a part of the routine management of the horses. The general approaches described below for use of heart rate and blood lactate measurements for fitness assessment can also be applied in endurance, event and other athletic horses. Ergospirometry, the measurement of breathing and oxygen uptake during exercise, is necessary for an ideal exercise test, but the technology is not yet suitable for routine use in the field.

Studies of heart rate in galloping horses

During the 1960s and 1970s, before the common availability of high-speed treadmills at research centers, there were many field studies with remarkable achievements. Telemetric electrocardiography was used widely in the 1960s and 1970s to study the HR and electrocardiogram (ECG) of race horses during exercise on racetracks.[8–13] Direct recording of the ECG with an on-board tape recorder was also used to study the heart rate during races.[14] These studies described typical heart rates during submaximal and maximal exercise in Thoroughbreds and Standardbreds. Studies of training exercise and races were included, as were descriptions of the recovery of heart rate after field exercise. Studies of heart rate were also combined with telemetry of arterial blood pressure at speeds up to 800 m/min.[15] These studies were mostly descriptive, and did not focus on design of exercise tests.

An exercise test typically consists of several bouts of exercise after a warm-up, which may or may not be separated by a rest period. Heart rate is usually measured during the exercise, and the velocity of each step of the exercise test is calculated by timing the event. The distances and durations of each step used in field tests have varied widely. Blood samples can be collected during rest periods after each step of the exercise test. Figure 3.3 shows a continuous record of heart rate over time during an exercise test in an Australian Thoroughbred event horse.[16] In this exercise test, each horse was exercised over a 450 m distance at speeds of approximately 250, 300, 450, and 600 m/min. Horses were given a brief period of walking between each step of the exercise test. Figure 3.4

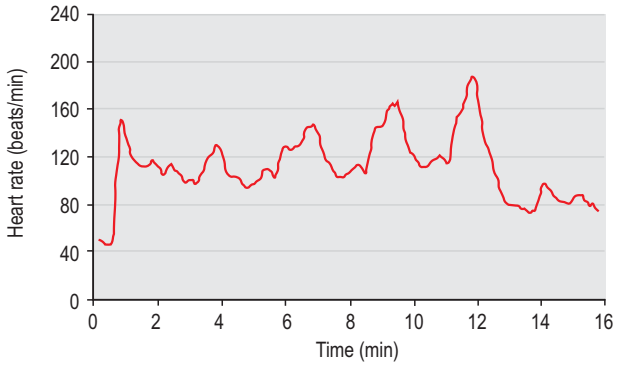

Fig. 3.3
Typical plot of heart rate versus time for the exercise test used in Thoroughbred event horses. There is an overshoot of heart rate at the commencement of the test (1 minute). The four heart rates during the four steps of the exercise test were recorded at 4, 7, 9 and 12 minutes. From Serrano et al,[16] with permission.

shows the use of a graph of heart rate and velocity for each step of the test to produce the typical linear relationship between heart rate and velocity. The graph also enables calculation of V200, the exercise velocity resulting in a heart rate of 200 beats per minute.[16] In this study of 17 horses, V200 ranged from 560 to 900 m/min. This wide range could reflect differences in inherent fitness, and differences in fitness due to training. An increase in fitness results in an increase in V200. Loss of fitness, cardiovascular and respiratory disease, lameness, and an increase in bodyweight could all cause a decrease in V200.

V200 can also be calculated with an incremental field exercise test in Thoroughbred race horses.[17] Commercial heart rate meters that log heart rate continuously and enable transfer of the data to a computer for analysis are suitable for this purpose. The exercise test consisted of about 1000 m trotting at 250 m/min, then galloping exercises at approximately 400, 460, 550, and 660 m/min for 600–800 m at each speed. Fine days and tracks in firm condition were used, and velocity was measured by stopwatch every 200 m of each step of the test. Mean HR and mean velocity were calculated for each 200 m section of the test.

This exercise test was used to investigate the influence of rider and track conditions, repeatability of V200 measurements and the effects of training on V200.[17] The HRs for the different sections of each step of the exercise test were all included, providing 17 HR and velocity measurements from one test. Figure 3.5 shows the relationship between heart rate and velocity in a Thoroughbred race horse using data obtained with this type of field exercise test. The method used in this exercise test has great potential. Use of a high number of data points should enable easy identification of outliers, and generation of a reliable line of best fit, as in Fig. 3.5. The technique also shows that it is possible to generate excellent HR–velocity relationships in field tests without use of protocols that necessitate strict adherence to steps of an exercise test with constant exercise speed. Trainers may more readily adopt this technique because it does not necessitate changes to training schedules, and it can be incorporated into the usual daily training routine. The methodology in this study demonstrates the importance of refining field exercise tests so that they are easy to undertake. The usual treadmill model of an exercise test, with an emphasis on 45–60 seconds of constant velocity exercise in order to achieve steady state conditions, may not be the most suitable method in the field.

The importance of taking into account the psychological state of the horse was also demonstrated.[17] In an excitable state, the slope of the regression line of HR on velocity was decreased because of high HRs during trotting. V200 was thus falsely high. This finding emphasizes the need for careful observation of horses during field exercise tests, and for questioning of trainers and jockeys concerning the emotional state of the horse during exercise. If in doubt, calculation of V200 should be delayed until the horse has completed a test in a relaxed state. The correlation between 31 values for

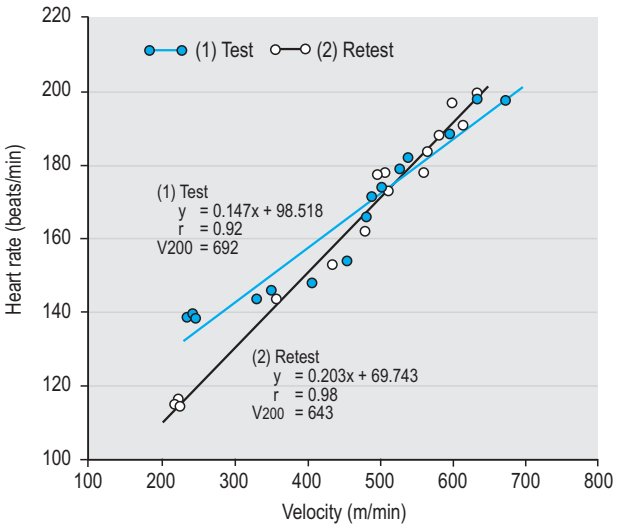

Fig. 3.6
Relationships between heart rate and velocity in a Thoroughbred race horse (1) exercising under field conditions after trotting in an excitable condition (●) and (2) when retested in a relaxed condition ( ). Note the pronounced increase in heart rates when trotting at 250 m/min in an excited condition. This effect has a marked influence on the slope of the line of best fit, which causes a false increase in V200. From Kobayashi et al,[17] with permission.

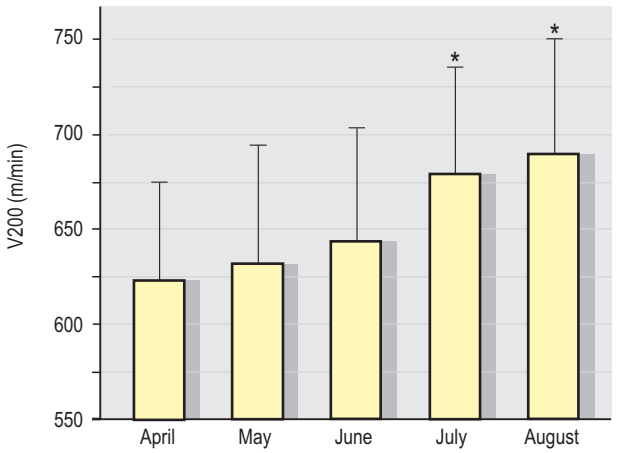

Fig. 3.7
Changes in V200 (± SD) as training progresses from April to August in 2-year-old Thoroughbreds. * Significantly different from April, May and June. From Kobayashi et al,[17] with permission.

V200 measured on two consecutive days was 0.88.[17] The differences in V200 were in the range of 0–50 m/min. Precision of V200 measurements in the field would probably be increased by use of more than one exercise test, and inspection of scatter plots to discard obvious outliers. These results suggest that the outliers will most likely be high HRs during trotting which could indicate excitability. Figure 3.6 shows the effect of excitability on heart rates during trotting, and the effect on V200. High HRs in this study were also associated with gait changes that were not 'smooth', and with phases of rapid acceleration. No major decisions about a horse's fitness or health should be based on the results of a single exercise test. Ideally, horses should be tested regularly, so that a record of results is established for an individual horse. If there is some doubt concerning the results in an individual exercise test, the test should be repeated.

As expected, the V200 was influenced by track type, with lower values on sand tracks than on grass or wood. Interestingly, the V200 was not significantly different in horses ridden by light (55 kg) and heavy (70 kg) jockeys in a crossover study.[17] However, the mean V200 was 35 m/min higher with light jockeys, and it seems sensible to avoid large differences in field studies of ridden horses.

One important rationale for field exercise tests is to accurately, reliably and precisely measure a variable or variables that indicate changes in state of training or health. Field studies of fitness have demonstrated that V200 in Thoroughbreds increased with training over a 5-month period (Fig. 3.7).[17] In 2-year-old horses, the average increase in V200 over the period was approximately 65 m/min, an increase of approximately 10%.

Telemetric electrocardiography has been used in combination with pneumotachography to measure heart rate, respiratory frequency, tidal volume, and respiratory gas flow rates in four Thoroughbred horses during field exercise at a speed of approximately 800 m/min.[18] Heart rate was also measured by telemetry during lunging exercise at the walk and trot, in combination with breath-by-breath measurements of pulmonary ventilation.[19] Studies of minute ventilation, flow rates, respiratory times and flow volume loops were conducted in normal horses and horses with airway diseases. Horses with bronchitis had higher heart rates during exercise than normal horses, as well as altered measurements of pulmonary ventilation. The authors concluded that the technique had considerable potential for diagnosis and evaluation of therapies. However, there has been little adoption of this method because of the limitations of the technology for measuring breath-by-breath respiratory gas flow rates during field exercise.

The results of many studies have demonstrated that higher than expected heart rates during submaximal exercise may be an indication of one of the following:

1. Lameness, or another painful condition
2. Dehydration
3. Exercise conducted in hot conditions
4. A loss of fitness, due to detraining or inappropriate training
5. Respiratory disease
6. Cardiovascular disease, or anemia
7. Increased body mass, or a greater percentage of bodyweight as fat or water
8. A physiologically inferior horse, probably due to a relatively small heart.

Ideal use of exercise tests therefore depends on regular use of heart rate measurements during the training months. Conduct of one exercise test in isolation is much less likely to provide meaningful information. Comparison of current

results with previous findings is most likely to give a trainer, veterinarian or owner information that can help manage the horse's training program. As well, the finding of a high heart rate during an exercise test may or may not indicate a problem with fitness or health. High heart rates during exercise, compared with recent findings in the same horse, are not a diagnosis. However, they are a warning sign, and such horses should be thoroughly examined to ascertain whether or not there is a new clinical or other condition that could explain the results. It is also best to be cautious about interpretation of unexpected findings. Tests should always be repeated if possible to confirm the validity of results.

Field tests of fitness in Standardbred horses

Field tests with multiple speeds and blood collections have been conducted in Standardbred trotters and pacers to assess performance on the basis of HR and blood lactate measurements. A simple exercise test for pacing horses consisted of four steps of exercise over 1000 meters.[20] Speeds of each step were 450–550, 600–700, 700–800, and greater than 800 m/min. The horse walked for 3–5 minutes between each of the four steps. Blood was collected into fluoride oxalate tubes 3 minutes after each step. Heart rates were also recorded during the exercise test to calculate V200. A plot of speed versus blood lactate was drawn. By drawing a line horizontal to the 4 mmol/L concentration, the VLa4 can be directly calculated. It was observed that superior horses had a lower blood lactate response to this exercise test.

In a study of Swedish Standardbred trotters, 10 horses performed a similar submaximal test on a track. The test consisted of five incremental heats at approximate speeds of 9.1, 9.5, 10.0, 10.5, and 11.1 m/s over 1000 meters. A blood sample was drawn from the jugular vein for plasma lactate analysis immediately after each heat. The plasma lactate response to exercise differed between horses, but no correlation was seen with a racing performance index in a small number of horses.[21]

Studies of larger numbers of horses that have a large range of racing abilities are more reliable. The relationship between VLa4, age and racing performance of Standardbred trotters has been investigated.[22] A total of 159 horses performed standardized exercise tests of three steps performed at increasing speeds. The velocity of the horses was measured with a tachometer on the sulky. Mean VLa4 values increased significantly ($P < 0.05$) with age between 2 and 4 years. Horses were defined as good performers (GP) when finishing between first and fifth place in a race or poor performers (PP) when finishing lower than fifth. VLa4 was significantly higher for GP than for PP ($P < 0.05$).

The VLa4 measurement is therefore a valid measurement for the evaluation of fitness in Standardbreds. The measurement could help trainers and owners to make more informed decisions about horses with poor performance, and assist with overall management of the racing career of a horse. Prospective owners may be more attracted to race-horse purchase if reliable measurements of fitness and performance capacity were more widely used. Veterinarians, trainers or owners interested in using these tests in Standardbred horses should develop their own exercise test routine on a single racetrack. It should also be noted that blood lactate concentration is likely to be increased by excitement during the test, and by 'pulling', an inefficient gait due to effort expended against restraint by the driver. Results from exercise tests in which horses pull hard against a jockey or driver should be regarded with suspicion, and the test repeated.

A review of exercise tests for French trotters exercising in the field concluded that track testing provided a more limited range of measurements than treadmill testing, but had the advantage of being performed in the horse's natural environment.[23] Various measurements such as heart rate during exercise and blood lactate concentration after exercise may be measured on the track, enabling calculation of physiological variables such as V200 and VLa4. Although VLa4 is calculated during submaximal intensity exercise, it is related to racing performance and seems to be the most important

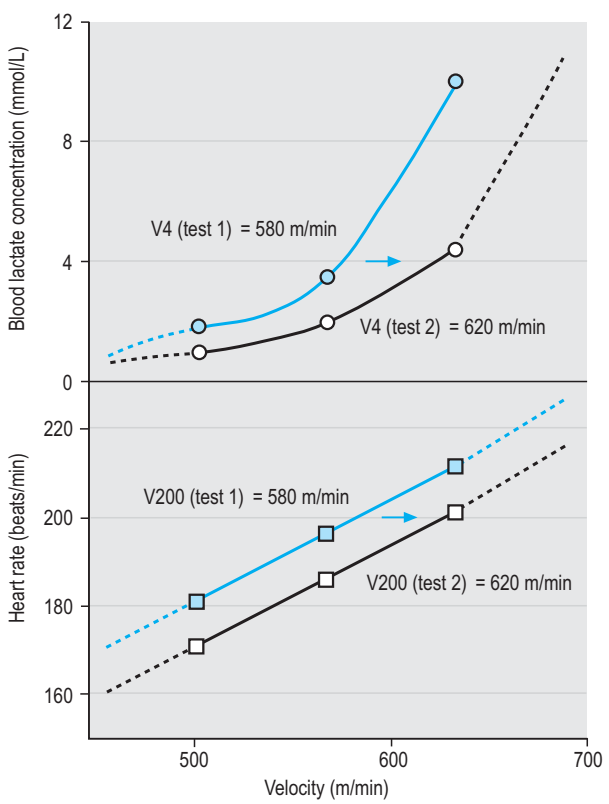

Fig. 3.8

There is a shift to the right with improved fitness. The heart rates and blood lactate concentrations during exercise at 500, 580 and 630 m/min are lower after training. V200 and V4 have increased. From Couroucé,[23] with permission.

measurement to assess changes in fitness.[23] There is a significant influence of age on measurements of heart rate (V200) and VLa4 in trotters. Reference values for heart rate and blood lactate responses to field exercise in French trotters of varying fitness and age have been described.[24] The use of a graphical display of heart rate and blood lactate concentrations at different speeds of field exercise to calculate V200 and V4 in a trotting horse is illustrated in Fig. 3.8.[23] This figure also shows the typical effect of training on the relationships; both curves shift to the right. Figure 3.9 shows the normal values for some heart rate and plasma lactate indices in relation to exercise velocity in trotters of various ages,[24] and the influence of training is described in Fig. 3.10. High heart rates during field exercise tests may be associated with lameness or respiratory disease. The potential use of field exercise tests as an aid to the clinical evaluation of athletic horses is illustrated in Fig. 3.11, which shows the effect of subclinical respiratory disease on heart rates and blood lactate concentrations during a submaximal field test in trotters.[23]

A submaximal field exercise test consisting of two bouts of 1600 meters has been used to assess fitness in Standardbred

pacing horses in two stables (A and B).[25] Five minutes of rest or walking between runs was allowed. Performance indices were compiled for each horse: number of race starts, number of race wins, number of race placings (1, 2 or 3), and lifetime earnings. Regression analysis was conducted to describe the relationship between plasma lactate concentrations and speed for tests one, two, and pooled results. Using the regression equation, observed (measured) minus expected (predicted) (O – E) lactate concentrations for tests were calculated and plotted against performance indices to determine their relationship. The association between lactate and velocity for the two tests was best described by exponential equations. This study found no relationship in either stable between O – E and performance indices (number of race wins, number of race placings, lifetime earnings and average $/start) for test run one, two or pooled lactates. At one of the stables there was a significant association between V4 (velocity predicted to produce a blood lactate concentration of 4 mmol/L) and log lifetime earnings ($r = 0.51$, $P = 0.05$) and log average $/start ($r = 0.54$, $P = 0.04$). There were no significant correlations at the other stable. It was concluded that a two-step determination method of V4 was a suitable method for studying limits to performance in pacing Standardbred race horses. A

From Couroucé,[23] with permission.

major advantage of the technique used in this study was that the test was easily incorporated into the normal training routines. It was also noted that the correlations might be higher if studies of associations between fitness indices and performance included more horses with a wider range of racing abilities. Another limitation of such studies is that they do not include horses that have been discarded from training due to poor performance early in their racing career. More studies are needed of the variability in fitness of young, unraced horses. Does fitness in young unraced horses predict future racing performance? Is the rate of change in fitness equal in all horses when they are trained? Large-scale field studies may offer the best opportunities to investigate these questions.

Metabolic measurements after maximal exercise

Tests of the blood lactate response to submaximal exercise such as those described above are indications of endurance ability, or stamina. Lactate tests measuring VLa4 or VLa10 (blood lactate at a velocity of 10 m/s) are unlikely to be highly correlated with the ability of a horse to accelerate at the start or finish of a race, or the ability of a horse to sprint 600–800 m.

High levels of 'anaerobic stress' are found in Thoroughbred horses after approximately 50 seconds of maximal field exercise.[26] After only 400 metres of field exercise near racing speeds the blood lactate concentration increased from less than 1.0 mmol/L to over 14 mmol/L,[27] values similar to concentrations found after races. This rapid increase in blood lactate concentration during maximal exercise also occurs in Standardbreds and polo horses.[28] Measurement of the blood lactate concentration after maximal exercise has been used to estimate anaerobic capacity, defined as the ability of an individual to resynthesize ATP via anaerobic metabolism. Markers of anaerobic metabolism in skeletal muscle include concentrations of plasma lactate and uric acid after maximal exercise.[29]

The blood lactate concentration after maximal exercise to fatigue does not change with submaximal treadmill exercise training,[30] or after high-intensity training.[31] As well, the blood lactate concentrations after maximal exercise were not correlated with race performance in trotters[32] or Thoroughbreds.[33] This measurement is therefore not a useful marker of fitness.

Relationships between racing performance and plasma lactate and uric acid concentrations after racing were investigated in pacing Standardbred race horses.[34] Twenty horses were tested after races of 1760 meters and 28 horses after races over 2160 meters. Blood samples were taken 30–60 minutes before and 8 and 30 minutes after a race. There were no significant differences between the race distances for pre-race and 8 minute post-race plasma lactates. Significant low correlations were obtained for plasma lactate concentration 8 minutes post-race and the number of race wins ($r = 0.29$, $P = 0.04$), number of race placings (first, second or third) ($r = 0.34$, $P = 0.02$) and lifetime earnings ($r = 0.29$, $P = 0.04$). There were no significant correlations between performance indices and plasma uric acid concentrations in races of 1760 meters. For races of 2160 meters, correlations were found between plasma uric acid concentration at 8 minutes post-race and the number of race wins ($r = 0.37$, $P = 0.06$). As well, there was a significant correlation between uric acid concentration at 8 minutes post-race and lifetime earnings ($r = 0.35$, $P = 0.07$). These results imply that only 10–15% of the variability in retrospective career performance in pacing Standardbreds can be explained by these metabolic markers of the muscle anaerobic response to racing. Blood or plasma lactate and uric acid responses to maximal exercise are not useful measures of fitness on their own, but they could be included in multifactorial studies.

A study of the relationships between racing performance and several physiologic measurements was also conducted in 25 Standardbred trotters.[21] Blood samples and muscle biopsies were obtained 5–10 minutes after racing. The biopsies were analyzed for fiber type composition and enzymatic profile and blood samples for plasma lactate and ammonia concentrations. Fiber type composition varied among horses

(range 9–27% for type I, 32–54% for type IIA, and 27–46% for type IIB). Fiber type composition, muscle enzyme activities, plasma lactate and ammonia responses to racing were not correlated to a racing performance index.

The rate of accumulation of lactate in blood during maximal field exercise over distances up to 400 meters is closely related to speed in Standardbred, Thoroughbred and polo horses.[28] It was suggested that this lactate measurement could be a useful index of fitness. However, it is unlikely that any physiologic measurement after brief, maximal intensity exercise to estimate anaerobic capacity will be more closely correlated with fitness than a simple measurement of maximal speed during 40–50 seconds of exercise. In conclusion, the blood lactate response to maximal exercise has limited usefulness as a measure of fitness in horses. However, the blood lactate response to moderate, or submaximal speed exercise, expressed as VLa4 or another similar index, is a useful technique for differentiating poor performers and good performers, and for monitoring the changes in fitness during training programs.

Blood lactate measurements in submaximal field tests of fitness in Thoroughbreds

A major difficulty with field exercise tests has been control of the exercise performed by the horse. Ideal standardized tests necessitate control of exercise speeds, duration of exercise, and rates of acceleration. Use of stepwise exercise tests has been usual in treadmill studies, with incremental speeds used. Such tests enable descriptions of the relationships between speed and variables such as heart rate, blood lactate concentration, and oxygen consumption. Field exercise tests of this sort are not very practical for Thoroughbred race horses, and alternative methods are needed. Conduct of racetrack exercise tests for measurement of VLa4 or VLa10 is especially problematic in Thoroughbreds because it is difficult to obtain constant track conditions and constant speeds during exercise. Measurement of the lactate responses to a single or pair of exercise bouts could be a superior approach to field exercise testing in Thoroughbreds.

A standardized, two-step exercise test has been used to investigate the blood lactate running speed relationship in nine Thoroughbred race horses.[35] Each horse completed a two-speed field test at intervals of 6–8 weeks to determine the running velocity (v) that resulted in blood lactate concentrations of 4 (v(4)) and 12 mmol/L (v(12)). Changes of v(4) and v(12) in a horse between two consecutive tests were used to assess the effects of training history. The percentage of days with gallop workouts between two consecutive tests showed a significant correlation with changes in v(4) ($r = 0.71$, $P < 0.01$) and v(12) ($r = 0.56$, $P < 0.05$). The number of gallop workouts ($r = 0.60$, $P < 0.05$) and the total time of training ($r = 0.58$, $P < 0.05$) also correlated with the change of v(4). Furthermore the percentage of days without training was negatively correlated to changes of v(4) ($r = -0.75$, $P < 0.01$) and v(12) ($r = -0.56$, $P < 0.05$). These results imply that increases in fitness, as measured with the blood lactate response to submaximal exercise in a two-step field test, are more likely in Thoroughbred horses that have more galloping than trotting exercise, and have a higher number of gallops in a time period. More days without training was associated with reduced fitness, and more training at higher speeds was associated with greater fitness.

An alternative approach is to determine the blood lactate concentration during a single bout of strenuous, submaximal exercise. An appropriate speed of the exercise must be chosen. The aim is to have an exercise test that is demanding for some horses, but achieved easily in others. Typical speeds for such tests are 800 meters in 65–70 seconds in a Standardbred horse,[20] and in 55–60 seconds in Thoroughbreds.[36] These speeds would need to be confirmed in an individual stable, because they will depend on the quality of horses being trained, and possibly on track size and surface conditions.

The use of a single blood lactate measurement after exercise has been validated as a measure of racing ability in Thoroughbred horses, and as a simple method of monitoring responses to treadmill training. A correlation of over 0.6 was found between retrospective career racing performance in Thoroughbreds, and blood lactate concentration 2 minutes after treadmill exercise at 10 m/s.[33] During a treadmill training program, the blood lactate concentration after treadmill exercise at 9 m/s gradually decreased over 9 weeks of training.[30] This response was similar to changes in VLa4. These results suggest that exercise tests with multiple steps may not be absolutely necessary for fitness evaluation in horses, and that measurement of the blood lactate concentration after a standardized, one-step test may suffice.

The feasibility of a one-step field test for assessment of fitness in Thoroughbred horses has been investigated.[36] Each horse completed a 1000 m warm-up at a slow trot of approximately 3–4 m/s prior to each test. Subsequently the horses completed an 800 m gallop with jockeys instructed to maintain a constant running speed in the range of 13 to 16 m/s. This range of speeds was selected as they correspond with the speeds frequently used in training Thoroughbreds on Australian tracks. The time for the 800 m and each of the four 200 m sections was obtained by stop-watch. All timing was conducted from the same position at each track by the same observer. Speed was determined from the total time for the 800 m gallop. At the completion of each gallop, the horse was trotted for 5 min, and then jugular venous blood was collected for blood lactate assays.

After inspection of the scatter plots of the relationships between blood lactate concentration and velocity for data from each racetrack, regression analyses were conducted to describe the line of best fit. Figure 3.12 shows the relationship between blood lactate after field exercise and exercise velocity on a sand racetrack in 21 trained Thoroughbred race horses.[36] The variability of the velocity during the exercise tests was expressed as the coefficient of variation (CV) of the

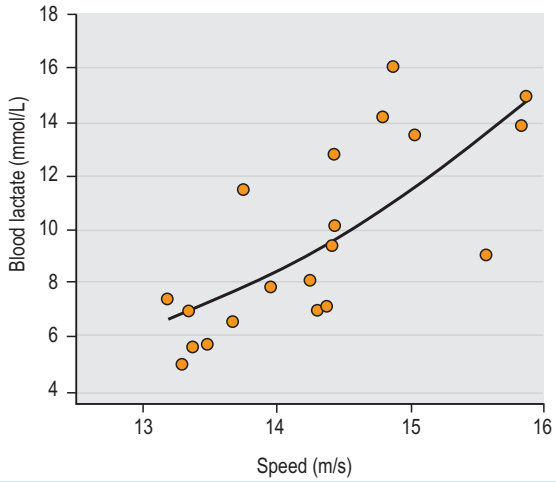

Fig. 3.12
Relationship between blood lactate concentration (mmol/L) after field exercise and velocity (m/s) during an 800 m exercise test on a sand racetrack in Thoroughbred horses. From Davie and Evans,[36] with permission.

times for the four 200 m sections of the exercise test. In horses tested more than once the result from the exercise test with the lowest CV was used in the regression analysis. Exercise tests were conducted at velocities in the range 13.2 to 15.9 m/s, and resulted in post-exercise blood lactate concentrations in the range 5.0 to 16.1 mmol/L. The mean speeds of the four consecutive 200 m sections of the exercise tests on the sand racetrack were 13.5, 14.6, 14.5, and 14.9 m/s. The jockeys were clearly unable to maintain a constant speed during the 800 m test.

A single step test that takes into account variability of velocity within a test, and is based on calculation of the difference between the measured and predicted lactate concentration, has potential application in field evaluations of fitness in Thoroughbred horses. Further studies are required to investigate whether the difference between the blood lactate response to exercise in an individual horse and the predicted concentration in a reference population is an accurate and reliable correlate of racing performance. Changes in this difference could also reflect changes in fitness over time.

The use of the difference between the measured and predicted lactate concentration as an index of the lactate response to exercise obviates the need for strict control over the target speed during the conduct of a field exercise test. Potentially it could be possible to conduct tests at any speed in an appropriate range, and compare the measured lactate concentration with the predicted concentration based on the equation for the line of best fit. This approach enables horses to be tested at different speeds, and comparisons between individual responses to exercise can be based on the rating. Superior English Thoroughbred race horses had a low blood lactate response to a single bout of exercise.[33] Therefore it could be expected that horses that consistently give a high 'rating' (that is, a high positive difference between measured and the predicted lactate concentration) could be expected to race poorly. Superior training in an individual horse should reduce the difference between measured and expected blood lactate concentrations.

The validity of results could be improved with some refinement of the technique. Accuracy and reliability of measurements could be improved if velocity did not increase during the exercise test. Anxiety or fear could also contribute to the variance, and these factors may not always be easy to recognize. The confounding effect of increases in speed may be more important in field tests that measure blood lactate concentration than in tests that measure heart rate, because the increase in speed can be related to the higher heart rate when the data are analyzed, as demonstrated in a study with Thoroughbred horses.[17]

A simple field exercise test for event horses has been described.[37] In this test, horses warmed up with 5 minutes of walking and then 6 minutes of trotting. Horses then galloped 400 m, 500 m, 600 m and 700 m/min over 1000 m with 5 min walking between these steps. This format enabled measurement of heart rates and blood lactate concentrations at each velocity of the exercise test, and calculation of V200 and VLa4. Such a test also assists horse trainers because it enables calculation of the velocity needed to train horses at a predetermined heart rate or blood lactate concentration.

A field exercise test with three steps was used with eight French Thoroughbred horses in France to investigate the use of heart rate measurements during and after track exercise as a suitable measure of changes in fitness.[38] The test consisted of a warm-up followed by three 3 min steps, one cantering and two galloping, followed by a recovery period. Heart rate was recorded during the entire test, and blood samples were taken during the 2 min rest periods following each step, and after the recovery period for the measurement of lactate concentrations. Fitness was described by the relationships between lactate concentrations, heart rate and velocity. The authors concluded that the efficiency score and the cardiac recovery index were good indicators of potential speed.

Total red cell volume measurements

Total red cell volume expresses the volume of erythrocytes in the circulation of the horse, including the volume in the spleen. Its measurement with dye dilution methods necessitates measurement of plasma volume and the induction of splenic contraction before the hematocrit (PCV) is measured, so that red cells sequestered in the spleen at rest are also measured. Splenic contraction has been induced by adrenaline (epinephrine) injections and moderately intense exercise.[39] Total red cell volume relative to bodyweight was significantly correlated with maximal trotting speed over 1000 m in 35 Swedish trotters ($r = 0.68$, $P < 0.001$).[40] These results suggest that this measurement is an important factor in the ability to trot rapidly, but there have been no studies of the relationship in other breeds. Unfortunately measurement of the total red cell volume in horses with a dye dilution

technique is not a simple procedure that can be readily applied in veterinary practice.

The hematocrit after maximal exercise in Thoroughbreds, which ranges from 60 to 70%, was not correlated with Timeform rating (a commercial measurement of relative racing ability) in English Thoroughbreds. It is not a valid fitness measurement.[33] However, the hematocrit can be measured after maximal exercise if results of resting hematology suggest that a horse is anemic. PCV should be greater than approximately 55% immediately after maximal exercise in trained Thoroughbreds. In Standardbred race horses overtraining was associated with a decrease in PCV measured after a 2400 meter time trial at maximal speed. Mean values were 56% in control horses and 52% in overtrained horses.[41] Total red cell volume did not decrease during overtraining, so the decrease in PCV may have reflected the decrease in velocity of the horses during the time trial, rather than a true decrease in the total red cell volume. A treadmill study has also found that onset of overtraining was not associated with red cell hypervolemia.[42]

Measurements of the hormonal response to intense exercise may be more useful for identifying the overtrained horse. Overtraining was associated with a decrease in the cortisol concentration measured after a maximal field exercise test in Standardbred pacers.[41] The exercise test consisted of 1200 meters pacing in 105 seconds, and then completion of the following 1200 meters in the fastest time possible. A decreased cortisol response to maximal exercise in the overtrained state was also found in a treadmill study of Standardbred horses.[43] The mean peak cortisol concentrations after intense treadmill exercise were 320 nmol/L before overtraining, and had decreased to 245 nmol/L when horses were overtrained. Overtraining should be suspected in horses with evidence of decreased performance in association with decreased bodyweight and plasma cortisol response to a standardized maximal or near-maximal velocity exercise.

Measurement of oxygen uptake in field exercise

Oxygen uptake is a fundamental measurement in any exercise test. It describes the rate of oxygen use in liters per minute, and is usually expressed relative to body mass. Calculation of oxygen uptake in the field necessitates measurements of air flow rates during breathing, and of oxygen and carbon dioxide concentrations in expired respiratory gas. The horse must wear a mask over its nose or face to enable these measurements. The technique is referred to as ergospirometry. In horses during maximal exercise, respiratory rates often exceed 120 per minute, and over 1500 liters of air are breathed per minute, at peak flow rates of 30–40 L/s or more at each nostril. Measurement of breathing (minute ventilation) and expired gas concentrations during intense exercise in horses is obviously a considerable technical problem, especially in the field.

Rates of oxygen uptake during submaximal exercise will depend on gait, economy of locomotion, body mass, and other factors. The maximal rate of oxygen uptake is the gold standard measurement for aerobic capacity. It is primarily limited by the maximal heart rate and cardiac stroke volume during exercise. A cardiac limit to performance can be best evaluated by measurement of oxygen pulse, the volume of oxygen ejected with each ventricular contraction. This measurement necessitates simultaneous measurement of oxygen uptake and heart rate during exercise.

A landmark study of heart rate, breathing and oxygen uptake in two trotters was conducted in Russia.[44] A truck carried equipment beside the trotting horses, which completed a stepwise exercise test with peak speeds of 11 m/s. Notable findings during exercise at 11 m/s were tidal volumes of 17 liters, pulmonary ventilation of 1200 L/min, and peak oxygen uptake of 64 L/min with a respiratory exchange ratio of 1.0.

The horse plus vehicle approach to field ergometry was also used in a study of four Quarter horses, one Appaloosa and one Thoroughbred at speeds ranging from 40 to 390 m/min, with and without a rider.[45] A tractor was used to pull a wagon, and on the wagon were the calorimeter and a gasoline generator. This study was conducted to enable calculation of the digestible energy intake needed to support the demands of exercise.

Field ergospirometry was described in 23 riding horses at a walk, trot and gallop, using an on-board oxygen sensor.[46] The key measurements of an ideal clinical exercise test were reported: heart rate, oxygen uptake, pulmonary ventilation, ventilatory equivalent for oxygen, oxygen pulse and economy of locomotion. The synchrony of stride and locomotion was noted, as was the transitory effect of swallowing on breathing. The limitation of the performance of the pneumotachometer and response times of the oxygen sensor probably precluded measurements at maximal speeds.

Field ergospirometry and blood lactate measurements were conducted in 12 Warmbloods in order to calculate the ratios of aerobic and anaerobic contributions to total energy output at speeds up to approximately 500 m/min.[47] Aliquots of expired gas were collected via tubes in the face mask, and the rider manipulated the bags that were used to collect the gas at each step of the exercise test. Oxygen debt was calculated from the oxygen uptake measurements made for 10 minutes after exercise, minus values before exercise. This value was referred to as the anaerobic contribution to energy output. It was reported that the percentages of energy expenditure that were anaerobic were 1%, 3%, 19%, and 30% at speeds of 100, 250, 350, and 530 m/min. This technology has not yet reported measurement of maximal oxygen uptake.

Breath-by-breath pneumotachography for clinical appraisal during field tests of ridden horses has made little progress in the last 20 years. A major technical challenge remains: specifically simultaneous measurement of heart rate, oxygen uptake and pulmonary ventilation during submaximal and maximal field exercise. Coupling of measurements of heart rate, breathing (pulmonary ventilation) and oxygen uptake during field

exercise will be a powerful technique for advancing knowledge in equine exercise physiology.

Tracheal stethoscopy

The use of tracheal stethoscopy in the field for the investigation of respiratory sounds in the horse has been described.[48] This technique has been used for the investigation of upper respiratory conditions such as idiopathic laryngeal hemiplegia. The technique has existed for many years, but has yet to find a place in routine clinical exercise testing in the field.

Conclusion

Heart rate and blood lactate measurements during standardized field exercise tests are relevant to the management of all athletic horses. These measurements can assist with performance prediction and evaluation of fitness changes, and can be used to alert owners and trainers to problems such as lameness and respiratory disease. More effort is needed to adapt new technologies and refine approaches to design of field exercise tests. It is unlikely that veterinarians, trainers or owners will be enthusiastic about equine fitness testing if the focus is not on simple approaches to field exercise tests. Simple tests, measuring the things that matter, is the approach in field studies in human sports laboratories. Heart rate and blood lactate measurements feature prominently in human field studies. Progress in technology transfer of applied exercise physiology might be greater if there was greater emphasis on field methods, using minimally invasive techniques. Every fitness test should answer a specific question, and results should be expressed in a way that helps a veterinarian, trainer or owner make more informed decisions about the training, fitness, health or management of horses.

A promising new technique for field fitness tests could be use of heart rate measurements in combination with measurement of velocity with differential global position system technology. Simultaneous logging of a horse's heart rate and velocity could be a powerful technique for field exercise tests.

The reliance on treadmills for most equine exercise research may have contributed to poor rates of technology transfer to equine veterinarians, trainers and horse owners. There are few established equine performance laboratories in the world, and many are located at considerable distances from racing populations. There will never be enough university-based treadmills to service all horses with sufficient facilities for fitness tests. Development of simple and user-friendly techniques for exercise studies of horses that do not depend on treadmills would therefore be a major advance.

New partnerships between equine exercise scientists and biomedical engineers could also generate new technologies for field studies. For example, field studies of breath-by-breath respiratory gas flows, and field ergometry, should be possible, building on the innovative studies performed in Germany.[18,46] The techniques for field ergomety have been developed for human athletes, and could be refined for use in horses. However, the technical challenge of reliably and accurately measuring respiratory flow rates of over 100 L/s in a horse galloping in the field at 1000 m/min has yet to be conquered. Field ergometry, coupled with measurements of heart rate, respiratory function and metabolic responses to exercise, would enable new fundamental studies in many areas of equine exercise physiology. Descriptions of the metabolic and energetic demands of different athletic events would be possible, and design of appropriate training programs would be facilitated. As well, clinical exercise testing would be more likely to be adopted by trainers and owners. Such 'high tech' clinical exercise tests would contribute to greater knowledge concerning limits to performance in different events (such as anaerobic or aerobic capacity, and maximal rates of oxygen uptake). Greater rates of technology transfer to industry participants are likely if researchers increase their use of normal horses in commercial training, and if technical developments free researchers from the constraints and limitations of treadmill fitness tests.

CHAPTER 4

Clinical exercise testing: overview of causes of poor performance

Ben B. Martin, Jr, Elizabeth J. Davidson, Mary M. Durando and Eric K. Birks

Introduction

Determining the cause of poor performance in equine athletes is difficult because many of the problems that cause poor performance are manifested only at medium- or high-speed exercise, and horses with poor performance may have multiple concurrent problems.[1,2] Comprehensive testing is often necessary to ascertain the definitive cause of poor performance. Traditional methods of evaluating horses with poor performance include performing a complete physical examination, a thorough lameness evaluation, and various clinicopathologic tests. However, the development of techniques for performing videoendoscopy during high-speed treadmill (HSTM) exercise, using telemetry to record exercising electrocardiograms, arterial blood gas sampling during exercise, post-exercise tracheal wash or bronchoalveolar lavage sampling for cytologic evaluation, and performing echocardiography immediately post-exercise, have combined to add a new dimension to the examination of horses with poor performance.[2–7] It is well known that multiple body systems may contribute to performance problems, including abnormalities of the upper respiratory tract, lower respiratory tract, cardiovascular, and musculoskeletal systems, as well as subclinical myopathies.[7]

Chapter 2 provided an overview of the diagnostic approach to poor performance in the horse, including the use of treadmill exercise testing. The purpose of this chapter is to describe the more common causes of poor athletic performance in the horse. The reader is referred to other chapters in this book for more complete description of the diagnosis and treatment of the conditions discussed.

Upper respiratory tract

Laryngeal hemiplegia (LH)

History

The most common complaints associated with LH are exercise intolerance and a high frequency inspiratory noise. Horses with LH are more commonly affected on the left side.[1,2] These horses typically have a grade III or grade IV LH, using the grading system previously published.[8]

Physical and videoendoscopic examination

Palpation of the larynx may be informative, as the muscular process can frequently be palpated secondary to atrophy of the cricoarytenoid dorsalis muscle. On resting endoscopic

evaluation, the arytenoid may be paralyzed or hang slightly in the airway (Figs 4.1–4.3). These horses are good candidates for treadmill evaluation because function during strenuous exercise helps to select the patients in which surgical correction is most likely to be successful.[8]

Treatment

Surgical intervention is the treatment of choice for LH when the arytenoid collapses into the airway (grade IIIC, grade IV). This may include placement of a prosthesis alone, or in combination with a ventricular saculectomy or cordectomy.[9,10] Surgical correction of grade II or IIIA or B is most often unsuccessful. Ideal surgical candidates are those with either grade IIIC or grade IV LH. Reported surgical success rate for grade IIIA and IIIB is 20–25%, versus 70–75% for grade IIIC and grade IV.[3] Horses with incomplete collapse of the affected arytenoid should continue to race or train until they become a grade III or IV. Attempts at cutting the recurrent laryngeal nerve in horses with partial collapse of the arytenoid to hasten progression to grade III or IV have met with limited success.

Prognosis

Treatment of uncomplicated LH carries a good prognosis for return to work and decrease in exercise intolerance, although some horses will continue to make an abnormal respiratory noise.[10]

Retroversion of the epiglottis

History

Horses have a history of significant exercise intolerance and of making a very loud gurgling, honking noise at medium to high speed.[11,12] This condition is uncommon, occurring in only 10 of 2100 horses examined at the University of Pennsylvania, New Bolton Center between 1992 and 2002.

Videoendoscopic examination

The resting videoendoscopic examination is usually normal, while videoendoscopy during exercise reveals an epiglottis that curls up in the center and rises directly dorsally to occlude most of the airway during inspiration (Fig. 4.4). There is a characteristic inspiratory noise.

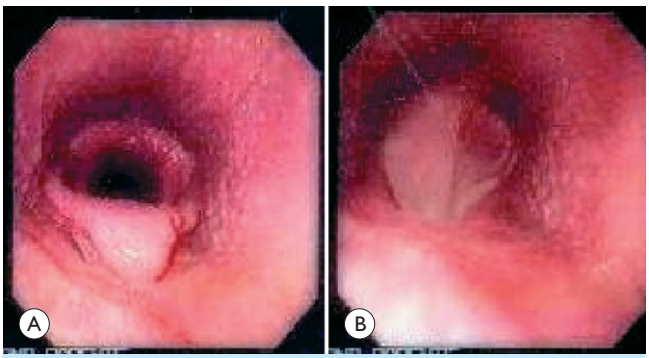

Fig. 4.4
Endoscopic view showing retroversion of the epiglottis during high-speed treadmill exercise upon exhalation (A) and inhalation (B).

Treatment

Several surgical treatments have been attempted including epiglottectomy, augmentation of the epiglottis, and placement of a suture to mimic the genio-hyoideus muscle.[11] The latter appears to have some promise, while the first two techniques have not been useful in the management of this condition.

Prognosis

The prognosis for return to previous performance ability is poor. Horses may, however, be used as pleasure horses that exercise at low to medium intensity.

Dorsal displacement of the soft palate (DDSP)

History

Most horses have a history of racing well for three-quarters of a mile, making an expiratory gurgling noise and slowing down rapidly. These two historical facts lead many clinicians to make a presumptive diagnosis of DDSP. Endoscopic examination immediately after racing or training is usually unrewarding. DDSP is the most common pharyngeal dysfunction in racing horses. Sport horses may also be hindered with DDSP. Retrospective analysis of 80 sport horses presented for poor performance identified this abnormality in six horses.[12]

Videoendoscopic examination

Resting videoendoscopy may be normal or suggestive of a problem. Examination of the pharynx during occlusion of the nostrils can provide useful diagnostic information. In particular, the time taken for the palate to displace and then return to its normal position should be noted. Prolonged displacement is suggestive of DDSP. After the endoscope has

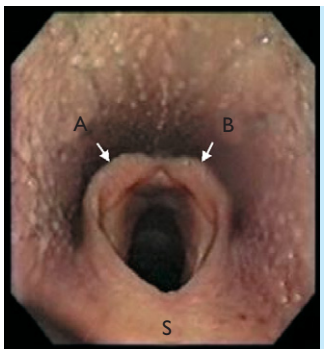

Fig. 4.5
Endoscopic view of a dorsally displaced soft palate (DDSP) at rest. The pharyngeal surface of the soft palate (S) and the arytenoid cartilages (right, A; left, B) are shown.

been removed from the trachea during examinination for tracheal mucus or blood, horses will frequently displace and then quickly replace the palate. This examination often provides an opportunity to examine the free border of the palate for ulcers or evidence of a previous surgery (notch or scar). Some practitioners feel that there is an association between an ulcer of the soft palate free border and DDSP during high-speed exercise. However, this is not a consistent finding in horses subjected to treadmill evaluation. DDSP (Fig. 4.5) may or may not be evident during a single exercising videoendoscopic examination; exercise to fatigue may be necessary to demonstrate the abnormality in some horses. Thirty to thirty-eight percent of horses may not make a respiratory noise during displacement, making diagnosis difficult.[5,13] DDSP can occur alone or in combination with other abnormalities. In one study, when DDSP occurred it was observed alone in 49% of horses and combined with at least one other abnormality in 51% of horses.[13]

Treatment

Surgical intervention is usually recommended when conservative management treatments, such as a tongue-tie, figure eight nose band, overcheck, can, spoon bit or anti-inflammatory throat sprays, have been unsuccessful. Various surgical interventions have been used in the treatment of DDSP, including radical myectomy,[14] sternothyroideus myotomy,[15] sternothyrohyoideus myectomy,[16] or staphylectomy,[17] with success reported to be 60–64%.[13–17] Because DDSP frequently occurs with other upper respiratory tract (URT) diseases, it is imperative that other upper respiratory conditions be identified and treated.[1,13]

Prognosis

The prognosis is guarded for successful return to athletic performance.

Axial deviation of the aryepiglottic folds (ADAF)

History

Horses with ADAF have a history of exercise intolerance and usually make a medium frequency, inspiratory noise during

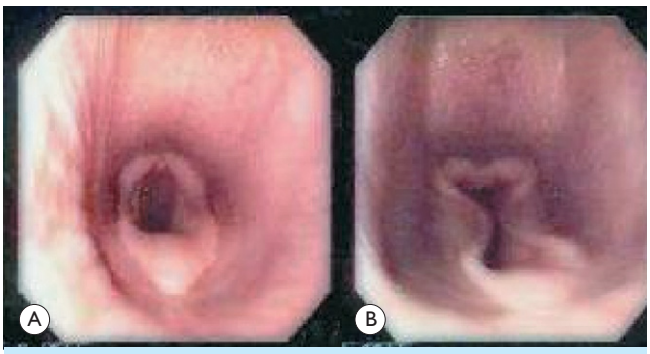

Fig. 4.6
Endoscopic view of axial deviation of aryepiglottic folds (ADAF) during high-speed treadmill exercise during exhalation (A) and inhalation (B).

exercise. ADAF occurs only at high speed and is characterized by axial collapse of the membranous fold extending between the corniculate process of the arytenoid cartilage and the lateral edge of the epiglottis (Fig. 4.6).[18] Some consider that ADAF represents a manifestation of the dysfunction that results in intermittent dorsal displacement of the soft palate (DDSP), but this remains uncertain.[18] ADAF occurred in 6% of cases examined videoendoscopically during a high-speed treadmill examination, and when ADAF was observed, it occurred alone in 64% of horses and in combination with another upper airway abnormality in 36% of horses.[1,18]

Videoendoscopic examination

Resting videoendoscopy is usually normal. Exercising videoendoscopic examination reveals collapse of the aryepiglottic folds (Fig. 4.6) alone or in combination with other URT abnormalities.

Treatment

Trans-endoscopic laser resection of the aryepiglottic folds is considered to be the treatment of choice.[18] Seventy-five percent of horses that received laser resection of the aryepiglottic folds successfully returned to racing 3 weeks to 3 months following treatment. However, with conservative treatment consisting of 2–12 months' rest, 50% of the horses in a recent study returned to successful racing.

Prognosis

The prognosis is excellent in ADAF alone. The prognosis with combined abnormalities is dependent upon the specific abnormalities.

Pharyngeal collapse (PC)

History

Horses with PC have a history of moderate to severe exercise intolerance and a low frequency, raspy inspiratory or roaring

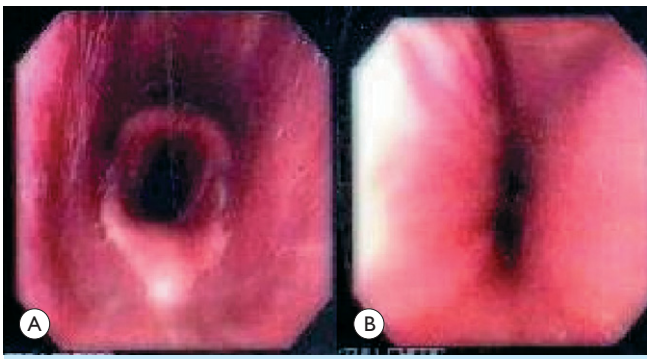

Fig. 4.7
Endoscopic view showing pharyngeal collapse (PC) during high-speed treadmill exercise. A, during exhalation, B, during inhalation.

noise. This abnormality has been identified in race horses[5] and sport horses,[12] and in 11.5% and 27% of horses completing a high-speed treadmill evaluation.

Videoendoscopic examination

As PC can only be identified during exercise,[5] a high-speed treadmill examination is required for diagnosis. Videoendoscopically, pharyngeal collapse can be classified as dorsal, lateral or circumferential (Fig. 4.7).[12] Severely affected horses struggle and it may be necessary to stop the test early. Elevated head and neck carriage such as that seen in Hackney ponies or American Saddlebreds can further increase the severity of PC.

Treatment

Conservative management of long-term rest (4–6 months), non-steroidal anti-inflammatory medication and a short course of oral corticosteroids may be successful in young, immature horses. The disease is most often career-ending in older (> 3 years old) race horses and sport horses. In horses that are maximally collected or have significant flexion of the neck during exercise (Hackneys, American Saddlebreds) it may be necessary to change careers.

Prognosis

In moderate to severe cases, the prognosis for any type of strenuous performance is poor. In rare instances, a young horse may mature out of the problem. In older horses, return to prior function is unlikely.

Lower respiratory tract

Lower respiratory tract (LRT) diseases can affect horses of any breed or discipline. In performance horses, exercise-induced pulmonary hemorrhage (EIPH) and inflammatory airway disease (IAD) are the two most common LRT diseases.[19] EIPH has been reported in 60–100% of performance horses.[19,20] IAD has been reported in 20–76% of horses receiving an endoscopic examination and transtracheal aspirate[21] or tracheal wash via the endoscope.[19] Certainly, many other LRT diseases/abnormalities are observed in horses. However, most of these are associated with generalized illness rather than non-specific complaints of 'poor athletic performance'.

History

Signs of EIPH can include epistaxis (rarely) after exercise[22] or, quite commonly, blood observed in the trachea post-exercise.[23–26] Coughing, increased swallowing, and/or prolonged recovery from exercise may occur following EIPH, but most often no signs are apparent. Signs of IAD in race horses (generally younger athletic animals subject to bouts of intense exercise) include coughing, mucus accumulation in the airways, exercise intolerance, prolonged recovery from exercise, nasal discharge, and worsening of signs when the weather is very hot, humid or cold. Perhaps the most common sign of IAD is exercise intolerance with or without other signs of respiratory disease.[27] Horses often have a history of fading at the 3/4 pole or in the home stretch.[27] EIPH and IAD may exist separately or together, and may occur with or without URT and/or cardiac dysfunction.

Physical examination

Often there are no abnormal findings during a resting physical examination. Horses with EIPH or IAD may or may not have abnormal lung sounds and a cough may or may not be elicited in horses with IAD. Some horses with a history of sudden, profuse epistaxis have been shown to have atrial fibrillation. Careful auscultation of the heart must be performed as a number of cardiac abnormalities can cause or exacerbate pulmonary problems.

Diagnostic tests

Both EIPH and IAD are best evaluated endoscopically following exercise. Blood visualized in the trachea and/or bronchi, or erythrocytes in tracheal or bronchoalveolar lavage (BAL) fluid, indicate EIPH. Although not directly diagnostic, visualization of large quantities of mucus in the airways is generally considered suggestive of IAD.[19,27]

Cytologic evaluation of samples obtained from the trachea or lower airways can often be of use in diagnosing pulmonary abnormalities. Lavage fluid may be collected from the trachea percutaneously or via an endoscope (transtracheal wash: TTW) or from the bronchial-alveolar regions (BAL). The ideal time for collecting post-exercise TTW and/or BAL samples is still debated, but most studies indicate that samples collected 45–90 minutes following exercise are the most suitable.[28] Numerous erythrocytes, in the absence of trauma, in lavage fluid (either TTW or BAL) indicate acute EIPH.[29] Hemosiderophages in lavage fluid indicate previous bleeding into

the airways, and, in horses in active competition, this finding is considered indicative of previous (in the past 1–21 days) episodes of EIPH.[19]

Normal values for differential cytologic evaluation of TTW and BAL fluids are presented in Chapter 2. Although the interpretation of differential cytologies in samples of lung fluid is still debated, an increase in the number or percentage (> 30%) of neutrophils is considered suggestive of IAD.[19,27]

As outlined in Chapter 2, systemic arterial blood samples can be used to evaluate lower airway function, as well as the functional significance of abnormalities in other body systems. While not specifically indicative of lung abnormalities, taken in conjunction with other clinical data, arterial blood gases can be of clinical importance and aid in diagnosis. It is important to keep in mind that arterial oxygen partial pressure (Pa_{O_2}) significantly lower than expected during exercise can occur not only from altered lower airway gas exchange, but also from reduced ventilation secondary to upper airway obstructions. Similar caveats are necessary when evaluating other arterial blood parameters. Thus, arterial blood gas values must be interpreted in light of results from the diagnostic tests pertaining to other body systems.[30]

Treatment

Treatment for EIPH has included the use of environmental management, pre-race administration of furosemide (frusemide), vitamin C, conjugated estrogens, vasodilators, and nasal strips. The effect of any of these treatments on EIPH remains controversial.[20,23] Treatment for IAD has two goals. The first is to decrease inflammation and the second is to increase the diameter of the distal airways. These goals are accomplished via the administration of inhaled corticosteroids and bronchodilators. These medications may be administered using several metered dose inhaler (MDI) systems (Equine AeroMask, Torpex, and the Equine Haler). The most versatile of these is the AeroMask, as it can deliver medication via MDI devices, nebulizer solution or dry powder inhaler. The Torpex device presently is used only to deliver albuterol sulfate. The Equine Haler can deliver any aerosolized drug using human MDI devices.[31]

Prognosis

Recent reports suggest that EIPH occurs in most, if not all, race horses.[23] Thus, simply finding evidence of EIPH does not suggest a reduced prognosis for future performance. However, the effects of repeated episodes of EIPH have yet to be critically evaluated. The current supposition is that each episode of EIPH results in increased scarring of the lung, leading to reduced gas exchange potential and thus reduced athletic potential. At the present time, no data exist that directly demonstrate any chronic effects of EIPH on athletic performance. Although epistaxis has not been positively correlated with the severity of EIPH, the general perception is that epistaxis indicates severe EIPH. Horses in which repeated episodes of epistaxis have been observed are generally retired from athletic competition.

The prognosis for managing early-recognized IAD is good. Treatment with bronchodilators and local anti-inflammatory agents generally leads to successful return to previous athletic performance.

Cardiovascular system

Abnormalities of the cardiovascular system can have a significant adverse effect on athletic performance, primarily via a reduction in cardiac output. Although less commonly recognized than diseases affecting the respiratory or musculoskeletal system, with the advent of newer diagnostic techniques for evaluation of cardiac function during and immediately after exercise, cardiac diseases are being diagnosed more frequently.[1,32] It can be difficult to determine the cardiovascular contribution to exercise intolerance, as frequently horses can have no, or only very subtle abnormalities at rest, while displaying significant abnormalities at near maximal effort. Conversely, 'normal' horses can have a relatively high prevalence of both murmurs and dysrhythmias,[32–36] which may be physiologic, disappear with exercise, and not contribute to reduced performance. Therefore, the significance of these findings may be unclear. For this reason, as discussed in Chapter 2, an evaluation during exercise is critical. Abnormalities can be divided into disturbances in cardiac rhythm, systolic or diastolic dysfunction, valvular regurgitation, and intracardiac shunts.

Dysrhythmias

Atrial fibrillation

History

In general, dysrhythmias more commonly contribute to performance problems than other types of cardiac dysfunction, and atrial fibrillation is the most common dysrhythmia associated with poor performance. Atrial fibrillation (AF) can be paroxysmal or sustained, with paroxysmal being implicated frequently as a cause of poor racing performance.[37–39] Epistaxis has been associated with AF.[40] This may be due, in part, to the alterations in left atrial, and hence pulmonary arterial pressures.[39] Dyspnea, hyperpnea and severe exercise intolerance have also been associated with AF, which decreases maximum cardiac output (under strenuous exercise conditions) by reducing left ventricular filling.[41,42] Horses with either paroxysmal or sustained AF frequently have no underlying detectable cardiac pathology.[43] These horses are excellent candidates for conversion to sinus rhythm, and once converted, should return to their previous level of performance. The large atrial mass and high resting vagal tone contribute to the development of AF. Electrolyte abnormalities (particularly K^+ depletion) have also been associated with development of AF. Therefore it is very important to ascertain drug administration history, such as the use of loop diuretics (e.g. furosemide (frusemide)).

Fig. 4.8
Electrocardiogram (ECG) from a horse with atrial fibrillation. The ECG was obtained at rest and the heart rate was 50 beats/min. For all ECGs, a base apex lead system has been used, and paper speed is 25 mm/s.

Clinical findings and diagnosis

It is important to perform a complete cardiac evaluation of any horse in AF to determine the presence of underlying cardiac disease. Auscultation will reveal an irregular rhythm. Pulses will be irregular, of varying intensity, and pulse deficits may be palpated. If no underlying cardiac disease is present, heart rate will be within a normal range or only mildly elevated.[41] ECG will show an irregular R–R interval, no P waves, and fine to coarse fibrillation waves (Fig. 4.8).

Treatment and prognosis

The treatment of choice for uncomplicated AF is oral quinidine sulfate.[43] If the duration of AF is short (< 2 weeks) and no cardiac pathology exists, intravenous quinidine gluconate can be tried. Most horses without significant cardiac disease can be successfully converted to normal sinus rhythm. Although some horses revert back into AF, the likelihood of recurrence is higher in horses with AF of greater than 4 months' duration or those with evidence of underlying cardiac pathology.

Supraventricular and ventricular extrasystoles

History

Dysrhythmias other than AF, while less well recognized, can certainly decrease athletic capacity.[44,45] Both ventricular and supraventricular extrasystoles can decrease cardiac output, and thus maximal performance ability. Ventricular tachycardia (VT), defined as more than three consecutive ventricular extrasystoles, may be sustained or paroxysmal. While sustained VT is easily recognized, and has a clear-cut effect on performance, it might not be recognized on resting examination if it is paroxysmal and/or exercise-induced; however, these horses may demonstrate a sudden fall off in performance during a race. The influence on performance of premature depolarizations, whether supraventricular or ventricular in origin, can be more difficult to determine. When detected infrequently, and at rest, they are of questionable significance if they disappear with exercise. However, ectopic beats occurring during exercise interfere with normal cardiac function, and may be more significant.[32] If ectopic beats occur during maximal effort, or as the horse is speeding up or slowing down on the treadmill, they can decrease cardiac output enough to affect performance. Certainly, if ectopic beats are numerous there is likely to be an adverse effect on exercise performance. The immediate post-exercise period is a time of autonomic nervous system imbalance. Consequently, dysrhythmias, including occasional premature beats, are frequently observed during the post-exercise period. These dysrhythmias probably do not affect performance.

Clinical findings and diagnosis

If no rhythm disturbances are present at rest, the results of physical examination and electrocardiographic and echocardiographic tests may be normal. ECG examination during exercise is required to detect cardiac rhythm disturbances in these cases. If uniform VT is present at rest, a rapid, regular rhythm, with changes in intensity of heart sounds, will be ausculted. Pulse deficits may be present. A jugular pulse may be evident. Premature beats present at rest will be detected as occasional early beats, corresponding to the premature depolarizations. A compensatory pause may be heard after the premature beat if it is ventricular in origin, and pulse deficits may be present. The heart sounds may be variable in intensity, with the ectopic beat having an increased intensity. Paroxysmal VT present only during maximal exercise requires exercising telemetric ECG to diagnose. ECG will show abnormal QRS complexes occurring in a rapid regular rhythm. ECG findings associated with uniform VT include a series of abnormal, widened QRS complexes with a regular R–R interval (Fig. 4.9). P waves will not be associated with the QRS, and may not be visualized if buried in the preceding QRS–T complex. With premature depolarizations, the ECG will reveal an underlying regular rhythm, with occasional premature QRS complexes causing an irregular R–R interval. If the premature complexes are supraventricular in origin, the QRS complexes will typically be normal in appearance and a P wave will be seen associated with it, although the P–R interval may differ from others (Fig. 4.10). Usually there will

Fig. 4.9
Electrocardiogram from a horse with ventricular tachycardia. This horse was at rest with a heart rate of 120 beats/min. Note the P waves buried in differing portions of the QRS–T complex.

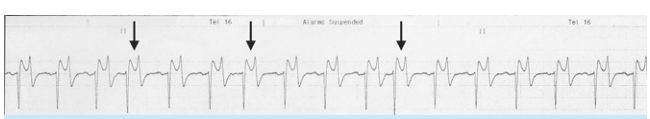

Fig. 4.10
Electrocardiogram (ECG) from a horse showing supraventricular premature depolarizations (SVPD; also known as atrial premature contractions, APC) (arrows). This ECG was obtained after exercise and the heart rate was 95 beats/min.

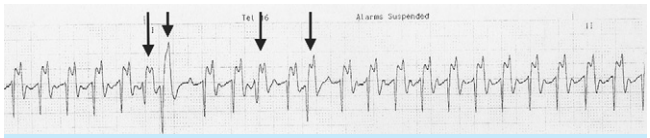

Fig. 4.11
Electrocardiogram (ECG) from a horse demonstrating ventricular premature depolarizations (VPD; also commonly called ventricular premature contractions, VPC) (arrows). Note compensatory pauses following VPD. This ECG was obtained immediately post-exercise and the heart rate was 160 beats/min.

not be a compensatory pause following the early beat. If the premature beat is ventricular in origin, the QRS complex will vary in configuration, and no P wave will be seen in association with it (Fig. 4.11). Ventricular premature depolarizations frequently are followed by a compensatory pause. While these arrhythmias may reflect primary myocardial disease, they may also be associated with hypoxemia, ischemia, electrolyte or metabolic disturbances, certain drugs, respiratory disease and toxemia.

Treatment and prognosis

Regardless of cause, rest for 4–8 weeks is recommended. Specific therapy is dependent on the type of dysrhythmia and whether underlying pathology is identified. In some cases of premature depolarizations, treatment with corticosteroids has been successful. If the premature complexes are frequent, anti-arrhythmic therapy can be instituted. Horses in VT may require specific anti-arrhythmic therapy along with correction of the primary problem.[44] Criteria for treatment include a sustained rapid rate (> 100 beats/minute), multifocal VT, R on T phenomenon, or if the horse is exhibiting clinical signs associated with the arrhythmia. Prognosis is favorable for most arrhythmias, if proper rest and correction of the underlying problem is accomplished.

Bradyarrhythmias

History and clinical findings

Severe bradyarrhythmias are not common. However, when present, they can cause weakness, syncope or profound exercise intolerance. Advanced second degree atrioventricular (AV) block, third degree AV block or sinus arrest not abolished by an increase in sympathetic tone or a decrease in parasympathetic tone are usually indicative of primary myocardial disease, although they are possibly associated with electrolyte or metabolic abnormalities.

Treatment and prognosis

Treatment consists of correcting the underlying cause, if one can be determined. Vagolytic drugs are not usually successful in restoring sinus rhythm. Corticosteroids may be used to decrease inflammation. However, the definitive treatment in most circumstances is a pacemaker. Although successfully used in horses, placement of a pacemaker is not practical in most instances.

Myocarditis/myocardial dysfunction

History

Clinical signs associated with myocarditis are dependent on the severity of the myocardial dysfunction, and can range from congestive heart failure with obvious clinical signs at rest, to subtle exercise intolerance that only manifests at maximal workloads.[32,46] Horses presenting with more severe cardiac dysfunction are not challenging to diagnose, as they are likely to have physical examination findings suggestive of heart failure, murmurs, and/or dysrhythmias. Horses with exercise-induced myocardial dysfunction are more difficult to diagnose, and may appear normal at rest, but may present with a history of fatigue and tiring early in a race.

Clinical findings and diagnosis

Clinical signs of congestive heart failure include a jugular pulse, ventral edema, tachypnea and rapid, weak pulses. Auscultation of these horses may reveal tachycardia with possible dysrhythmias and/or murmurs. Echocardiographic examination may demonstrate a moderate to severe decrease in fractional shortening, with chamber enlargement. If murmurs are present, Doppler examination may confirm valvular regurgitation. In horses that are less severely affected, the physical examination may be normal. The resting echocardiogram is also likely to be normal, or show only a mild decrease in the fractional shortening, with slightly less than normal thickening and inward motion of the myocardium. In these horses, it is critical to perform an exercise stress test to determine whether there is exercise-induced myocardial dysfunction.[32] Rather than the expected increase in fractional shortening, wall thickness, and inward wall motion, affected horses may have no change, or a decrease in these parameters (hypokinesis, dyskinesis, akinesis) immediately after high-intensity exercise.

Treatment and prognosis

Treatment of horses with exercise-induced myocardial dysfunction should include stall or pasture rest. If a non-infectious cause of myocarditis is suspected, corticosteroids may be useful. Prognosis is fair to good for return to function for these horses, with adequate rest.

Valvular regurgitation

Horses have a high prevalence of cardiac murmurs, many of which are physiologic or 'innocent' murmurs. However, even those associated with valvular regurgitation may not cause exercise intolerance unless the amount of regurgitation is moderate to severe. Mitral insufficiency is the abnormality

most likely to cause a decrease in athletic ability because of resultant left atrial enlargement and elevation in pulmonary artery pressure. Horses can successfully compete with significant tricuspid and aortic insufficiency unless accompanied by other abnormalities such as chamber enlargement, dysrhythmias, and mitral regurgitation.[33]

Ventricular septal defects

The effect on performance of ventricular septal defects (VSD) depends on the size, number, location, and type of work the horse must do. A small restrictive VSD might not impair performance at all, whereas a large one might decrease not only athletic potential, but life expectancy as well. Typically, if the VSD is < 2.5 cm in two perpendicular views, with a peak shunt velocity of > 4 m/s, and no other abnormalities are detected, performance will not be affected, although these horses might not be the most elite of race horses.[33,47]

Vessel thrombosis

Venous thrombosis, particularly jugular vein thrombosis, is a very common occurrence that does not usually impact performance. In most circumstances, collateral circulation develops if the vein does not recanulate. However, if severe and/or bilateral, so that venous drainage from the head is impaired, swelling and edema in the head and pharyngeal region may result, which may decrease athletic performance.[48] Although not common, thrombosis of the terminal aorta and/or iliac arteries can severely limit performance. It may be apparent at rest, with lameness, weak peripheral arterial pulses and slow filling of the saphenous vein in the affected hindlimb.[48] Exercise will often exacerbate clinical signs. Thromboses are definitively diagnosed with ultrasound of the suspected affected vessel.

Myopathies

Exertional rhabdomyolysis and subclinical myopathy

Exertional rhabdomyolysis (ER), recurrent exertional rhabdomyolysis (RER) and subclinical myopathy (SCM) can affect performance horses, with ER occurring in 2.8% of all horses and SCM occurring in 15.2% of horses with no clinical evidence of myopathy.[1,2] Horses with any of these conditions may have exercise intolerance. Although there are many causes of muscle disease in the horse,[49] this section will focus on ER, RER and SCM.

History

Horses with ER or RER may have signs of stiffness, muscle cramping, pain, muscle fasciculation, and weakness or exercise intolerance.[49] Horses with SCM typically do not exhibit any signs associated with ER or RER.[1] In fact, they usually appear clinically normal and the only pertinent information may be a history of poor performance or exercise intolerance.[1,2] A history should include the horse's recent exercise regimen, whether the horse has had a recent episode of 'tying up', the results of any diagnostic test, a listing of all medications and supplements administered to the horse, any present or prior lameness problems, and any history of respiratory problems.[49] Any horse with a recent bout of ER or RER (i.e. within 14 days) should not be subjected to a high-speed treadmill examination. In our experience, these horses have a recurrence of ER soon after treadmill schooling. Historically, young Thoroughbred females are the most likely to have RER, and this is thought to have a genetic component.[1,50]

Physical examination

During clinical episodes of ER, affected horses typically exhibit signs of pain, sweating, anxiety, muscle cramping, muscle atrophy, and unwillingness to walk (or lameness).[49] Dark colored urine may be present. One muscle group (e.g. the triceps group) or multiple groups of muscles may be affected. Horses with SCM may not exhibit any clinical signs and the diagnosis is based on laboratory findings. Close examination of the general muscle distribution and symmetry is important. Palpation of all large muscle groups should be done, along with running a blunt instrument gently over the neck, epaxial and gluteal muscles looking for excess fasciculation, wayward fasciculation or excessive guarding of muscle groups. Any of these adverse reactions may suggest primary or secondary muscle pain or muscle pathology.[49]

Diagnostic tests

If there is evidence of increasing lameness or of ER during any portion of the schooling for the high-speed treadmill evaluation, the examination is discontinued. Otherwise, the horse receives a complete HSTM examination and is monitored for post-exercise lameness and ER. If lameness is increased or if there is evidence of ER, appropriate management should be implemented.

The two most common serum or plasma enzymes evaluated are creatine kinase (CK) and aspartate aminotransferase (AST). Samples for CK and AST analysis are taken before and after exercise. It has been suggested that samples be collected 4–6 hours after exercise, when CK activity peaks.[52] However, other sample times are frequently employed for logistical or convenience reasons. For samples collected 30 minutes following exercise, a serum CK activity less than 1000 IU/L has been considered normal. In a recent retrospective study, 10/348 horses experienced clinical signs of ER.[1] CK activities in these horses 30 minutes post-exercise were 20 000–120 000 IU/L. In the same report, serum CK activities were elevated (15 000–220 000 IU/L) in 59/348 horses that had no obvious clinical signs of ER.

Elevations in AST can result from damage to both muscle and liver.[49] Post-exercise AST activities reach maximal

values later than does CK, and AST has a longer half-life; therefore activities can remain elevated as long as 2 to 3 weeks after insult.[52] Both CK and AST should be evaluated before and after treadmill exercise to determine if there has been any recent evidence of muscle damage.

An additional diagnostic test that may be helpful in cases of recurrent ER is nuclear scintigraphy. Nuclear scintigraphy may indicate the presence of deep muscle damage even with normal circulating muscle enzyme activities. This deep muscle damage may help explain subtle lameness or performance problems.

Treatment

Treatment of acute severe ER includes supportive care such as intravenous fluid therapy, acepromazine maleate, and monitoring of the CK activities. Clinical signs generally subside within a few hours of onset. Horses should not be returned to work until their muscle enzymes have returned to normal. Management of recurrent ER has included changing training methods, oral and injectable acepromazine, long warm-up periods, oral phenytoin, oral dantrolene sodium, acupuncture, afternoon turnout, and racing the horse from the field, along with numerous other methods. To date, none of these methods has been entirely satisfactory. Horses fed a high carbohydrate diet are more likely to have ER or RER.[53] In support of this, it has been suggested that a useful management technique to limit ER is feeding a low soluble carbohydrate, high fat diet.[49]

Prognosis

The prognosis for successful management of ER or RER is guarded. Horses responding to dietary management can have a good prognosis, as long as the dietary requirements are maintained throughout the remainder of the horse's career.

CHAPTER 5

Muscle physiology: responses to exercise and training

José-Luis L. Rivero and Richard J. Piercy

Muscular response to exercise

Overview

The skeletal musculature of the horse is highly developed and adapted to match the animal's athletic potential. In contrast to most mammals, in which 30–40% of body weight consists of muscle, more than half of a mature horse's body weight comprises skeletal muscle.[1] Total muscle blood flow in horses that are exercising at a level when O_2 consumption is at a maximum (VO_{2max}, 134 ± 2 mL/min/kg) has been estimated at 226 L/min, which represents approximately 78% of total cardiac output.[2] Such exercise therefore requires the co-ordinated application of many different body systems under the control of the nervous system (Fig. 5.1). Metabolites and oxygen reach skeletal muscle fibers via the respiratory, cardiovascular and hematologic systems; in turn the muscle fibers produce energy in the form of ATP which, via the contractile machinery, is converted into mechanical work. The structural arrangement of the musculoskeletal system provides the means with which to harness this energy to move the horse's limbs in a characteristic rhythmic pattern that is well established for each gait.

Equine muscle is considerably heterogeneous; the diversity reflects functional specialization and adaptive plasticity and has been studied extensively over the past 30 years. Muscle biopsy in particular has resulted in a greater understanding of the response of this tissue to exercise and training. Much of this work is summarized in the excellent review by Snow & Valberg[3] and therefore this chapter focuses specifically on new data obtained in the past decade, while assessing earlier studies from a later perspective.

Methodology

Percutaneous needle biopsy technique

Equine muscle physiology has centered around use of percutaneous needle biopsy (Fig. 5.2), a technique originally described for the M. gluteus medius by Lindholm and Piehl.[6] Although this muscle is very active during exercise[7] and shows considerable adaptation to training,[3] care must be exercised in interpreting data from a single biopsy,[8] because of the muscle's heterogeneity.[9,10] Other locomotory muscles (e.g. semitendinosus, biceps femoris, longissimus lumborum, triceps brachii and cleidocephalicus) can also easily be biopsied using the same technique. Muscle samples are useful for studies in vivo and in vitro using a range of morphologic, biochemical, and physiologic techniques. Muscle samples for histochemistry are frozen in isopentane precooled in liquid nitrogen. Samples for biochemistry are immersed directly in liquid nitrogen. In addition, a portion of the sample may be directly fixed for electron microscopy, thereby allowing measurement of capillary[11] and mitochondrial density.[12] Biochemical and physiologic studies can also be made on dissected and skinned single fibers.[13–15]

Laboratory methods

Biochemical analysis of homogenized equine muscle samples has enabled the study of broad metabolic responses to exercise and metabolic adaptation to training (see reference[3] for a review) through analysis of selected muscle enzyme activities, their substrates and intermediary metabolites. However, a limitation of this technique is that it does not enable differentiation between the various individual fiber types or the study of important morphologic features such as fiber size, capillary density and myonuclear location. Some of these disadvantages can be overcome by analyzing single fibers biochemically.[16,17] Histochemical evaluation of muscle, combined with image analysis,[18] has also provided invaluable information about the contractile and metabolic properties of equine muscles, specifically regarding fiber types, oxidative and glycolytic capacities, fiber sizes and capillary density.

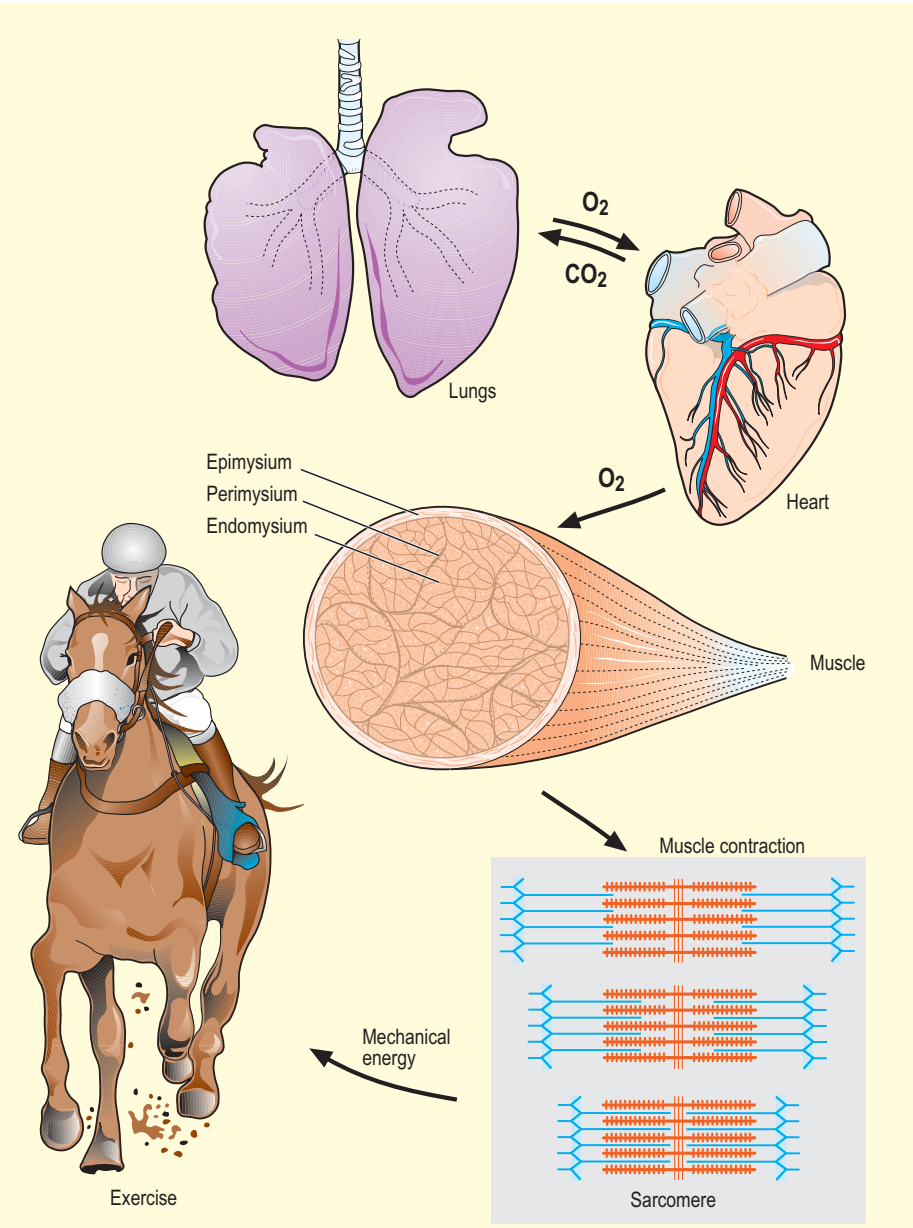

Fig. 5.1
Interaction between the main body systems (respiratory, cardiovascular, hematologic and muscular) involved in exercise. In the sarcomere, the thick myofilaments (myosin) are red and the thin myofilaments (actin) are blue.

However, subjective visual assessment of qualitative histochemical reactions (Fig. 5.3A,B) has until recently limited the application of these methods.[19] In recent years, more objective and quantitative histochemical methods have been applied to equine muscle.[20]

Cellular and molecular diversity within equine muscle has also been addressed, via study of myofibrillar and non-contractile proteins by immunohistochemistry,[21,22] gel electrophoresis,[23] a combination of both techniques,[24–26] and by enzyme-linked immunosorbent assay.[27,28] The past few years have seen the production of a considerable number of monoclonal antibodies to contractile and non-contractile muscle isoproteins, some of which can be used effectively in horse muscle via immunohistochemistry.[29–31] The technique's specificity provides, among other things, a more objective way to assess muscle fiber type (Fig. 5.3C).[32] Electrophoretic methods for the quantification of myosin isoforms have also recently been validated in the horse (Fig. 5.3D)[33] and immunoelectrophoresis has enabled the specific identification and relative quantitation of certain muscle-derived proteins.[34]

A major goal for future studies will be to refine molecular biology techniques and apply them to the field of equine exercise physiology in general and equine muscle physiology in particular. Northern blotting, reverse transcription followed by polymerase chain reaction and in situ hybridization will provide the means with which to study the molecular diversity of muscle proteins at the transcript (mRNA) level and before too long, microarray technology will enable a more global approach. This should prove invaluable when examining exercise and training effects, since altered transcript concentrations precede changes in protein expression.[35] Hence, during the early phase of transformation between fiber types,

Fig. 5.2
(A) Percutaneous muscle biopsy needle; this needle, which has an outer diameter of 6 mm, was first introduced by Bergström[4] and was further modified with finger and thumb rings by Henckel.[5] (B) Site for the collection of biopsy specimens from the right gluteus medius muscle according to Lindholm & Piehl;[6] this fixed site is located one-third of the distance along a line running from the tuber coxae to the root of the tail. (C–E) An illustration of the various steps for the needle biopsy technique; (C) the needle biopsy, together with the internal cutting cylinder, is inserted into the muscle; (D) once within the muscle, the cutting cylinder is partially withdrawn so that the window is opened up, allowing muscle to enter the slot, and a piece is then cut by pushing down the internal cylinder; (E) between 50 and 150 mg of muscle tissue are usually acquired.

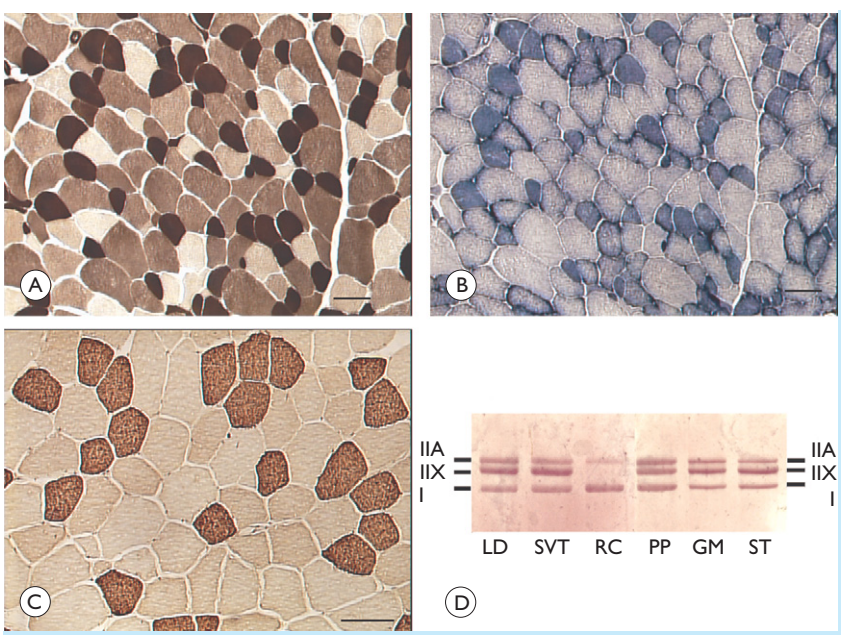

Fig. 5.3
Illustration of three integrated approaches for investigating skeletal muscle samples in horses: histochemistry (A, B), immunohistochemistry (C) and gel electrophoresis (D). (A) Transverse section of a gluteus medius muscle biopsy stained for demonstration of adenosine triphosphatase activity after acid preincubation (pH 4.4); the differential staining allows identification of the various fiber types. (B) Serial section of the previous sample stained to demonstrate succinic dehydrogenase activity; this histochemical stain is performed to allow examination of the oxidative capacity of myofibers. (C) Transverse section of the same sample stained by immunohistochemistry with a monoclonal antibody to the β-slow (type I) myosin heavy chain isoform; this method enables more objective delineation of muscle fiber types than histochemistry. (D) Coomassie blue staining to show myosin heavy chain composition of whole-muscle extracts on 8% sodium dodecyl sulfate polyacrylamide gel electrophoresis; isoforms are identified as IIA, IIX and I going from the slowest (highest) to the fastest band. LD, M. latissimus dorsi; SVT, M. serratus ventralis thoracis; RC, M. rhomboideus cervicis; PP, M. pectoralis profundus; GM, M. gluteus medius; ST, M. semitendinosus. Scales in A–C, 50 μm.

isoform-specific mRNA should be detectable some time before the associated protein.

Other techniques

In addition to cellular and molecular techniques, non-invasive analysis, such as nuclear magnetic resonance and electromyography,[36,37] is being increasingly applied to examine the effects of exercise and training on the neuromuscular system. Furthermore, electromyography, force plate and gait analysis have applications for assessing muscle activation patterns during locomotion.[7,38]

Muscle structure and function

Morphology

Development Most skeletal muscles are derived from paraxial mesodermal tissue following its condensation into segmentally arranged somites. Cells of certain lineages become compartmentalized within each somite as it differentiates: the dorsolateral compartment, known as the myotome, contains two subsets of myogenic precursor cells. The cells of one subset are destined to become the axial musculature, whereas cells of the other subset migrate into the periphery to form the muscles of the body wall and the limbs.[39] Myogenic precursor cells differentiate to form myoblasts. These fuse to become discrete populations of myotubes that subsequently fuse into myofibers (see Fig. 6.2).[40] At the same time, α-motor neurons establish their connections at neuromuscular junctions. Embryonic myogenesis shares many similarities with the regeneration of mature myofibers following injury, a subject that is covered in more detail in Chapter 6.

Gross anatomy Locomotor muscles are generally located proximally on the appendicular skeleton, thereby reducing the weight of the lower limb and decreasing the energy necessary to overcome inertia when the limb swings back and forth.[41] Movements of the distal limb are mainly passive and result from the release of elastic energy of the digital flexor tendons and suspensory ligament when the limb is unloaded.[42] However, myofibroblasts (with contractile properties) have been observed in these tendons.[43] Movements of the proximal limb result from active muscular contraction.[44] In general, most locomotor muscles are active during the propulsion stage of the stance phase of the stride in each limb.[45] Quantitative electromyography shows that muscles within the same group have significant differences in their activities when exercising at constant speed; furthermore, muscle activity, as measured by electromyography, is positively correlated with running speed.[46]

More than 90% of a muscle is made up of myofibers, with the rest consisting of nerves, blood vessels and the fat and connective tissue that separates the individual fibers (endomysium), the fascicles (perimysium) and the whole muscle (epimysium; Fig. 5.1). The connective tissue merges with both the origin and the insertion tendons of the muscle, as well as with internal tendons in compartmentalized muscles. Blood vessels and nerves course within the perimysium. Capillary arrangement in the skeletal muscle is optimized for oxygen delivery to tissue during exercise;[47] usually several capillaries are located within close proximity, sometimes circumferentially but more often running parallel to each fiber. The internal muscular architecture varies considerably both within and between equine muscles.[21,48,49] For example, different fiber lengths and pinnation angles have a significant impact on the power output and the degree of shortening of specific muscles, in accordance with their specific function.[50]

Histology The skeletal myofiber is an elongated cell (generally believed to be between 30 and 100 mm in length) with tapered ends. Fibers vary from 10 to 100 μm in diameter and are multinucleated (Fig. 5.4A). The nuclei are normally located at the fiber's periphery, in a subsarcolemmal position. Although the cytoplasm contains other organelles found in many cell types, it is mostly taken up by the contractile apparatus that consists of the contractile proteins and their supportive structures that are grouped together as myofibrils. In longitudinal sections, individual muscle fibers have numerous cross-striations (dark and light bands), that are orientated perpendicular to the fiber's long axis (Fig. 5.4B). Lighter I bands alternate with darker A bands. Within the I band there are dense striations called Z disks.

Ultrastructure The repeating unit between two adjacent Z disks is known as a sarcomere, the unit of muscular contraction. Each sarcomere includes half the I band on each side of the A band (Fig. 5.4C,D). I bands contain only thin filaments (8 nm diameter), whereas the A bands contain both thin and thick (15 nm diameter) filaments. Within the A band, the H band is defined as the central area where the thick filaments do not overlap with thin filaments (Fig. 5.4D). The central darker portion of the H band is designated as the M line (Fig. 5.4D). Transverse section of the sarcomere at the overlapping zone between thick and thin filaments reveals each thick myofilament surrounded by thin myofilaments in a hexagonal lattice arrangement (Fig. 5.4E). Muscle contraction occurs when, within each sarcomere, thin myofilaments slide over the thick myofilaments, bringing the adjacent Z disks closer together. Hence upon contraction, the I band shortens and the H band starts to disappear.

Thick filaments contain myosin and other myosin-binding proteins. Sarcomeric myosins have two heads and a long tail and consist of two heavy chains and two pairs of light chains (Fig. 5.5A). The myosin head is the motor domain that contains the adenosine triphosphate (ATP) binding site, the actin-binding site and the myofibrillar ATPase enzyme. The major components of the thin filaments are tropomyosin, the troponin complex (consisting of three subunits: troponin C (TnC), troponin T (TnT) and troponin I (TnI)), and two helical filamentous strands of actin (F-actin), made up of polymerized globular actin monomers (G-actin) (Fig. 5.5B). Elongated tropomyosin dimers lie within the major groove of the actin filament, spanning seven actin monomers; each troponin complex is also associated with a seven-actin repeat. The elongated NH_2-terminal of TnT extends for a considerable

length from each tropomyosin molecule, spanning the gap between adjacent molecules.

Mitochondria are located beneath the sarcolemma and between myofibrils (Figs 5.6, 5.7). This intimate relationship means that ATP produced during oxidative phosphorylation is readily available for the contractile machinery. Intramuscular substrates, such as glycogen and lipids, are also stored between the myofilaments and under the sarcolemma (Fig. 5.7). Numerous other proteins, including myoglobin, glycolytic enzymes and various intermediate filaments are distributed throughout the cytoplasm.

The sarco(endo)plasmic reticulum (SR) of skeletal myofibers is an intracellular membranous system located between the myofibrils (Figs 5.6, 5.7), but has no physical continuity with the external surface membrane (sarcolemma). Much of its tubular network is orientated longitudinally to the myofibrils. The SR contains, amongst other molecules, a large amount of the enzyme Ca^{2+}-ATPase, the protein calsequestrin and the calcium release channel (ryanodine receptor or RYR1). At the AI junction of the sarcomere, the SR tubules become confluent and form terminal cisternae orientated perpendicularly to the long axis of the cell (Fig. 5.7D). Two adjacent cisternae are separated by a structure known as the T-tubule, which is a long tubular invagination of the sarcolemma, communicating directly with the extracellular space. Together the three structures make up a triad (Figs 5.6, 5.7).

The motor end-plate (see Fig. 5.11B) is a specialized region on each fiber, where the α-motor neuron interdigitates with the sarcolemma. The postsynaptic membrane contains numerous acetylcholine receptors. The remainder of the sarcolemma contains a variety of specific membrane proteins that function structurally and as channels, pumps and hormone receptors. Myofibers have a cytoskeleton of various intermediate filament proteins that link the contractile apparatus with a complex of proteins at the sarcolemma, known as the dystrophin-associated complex (see Fig. 5.14). Between the sarcolemma and the extracellular matrix is the basal lamina (Fig. 5.7E) which is generally closely apposed to the sarcolemma except where it leaves the sarcolemma to course over the surface of satellite cells (Fig. 5.8; see also Fig. 6.2).

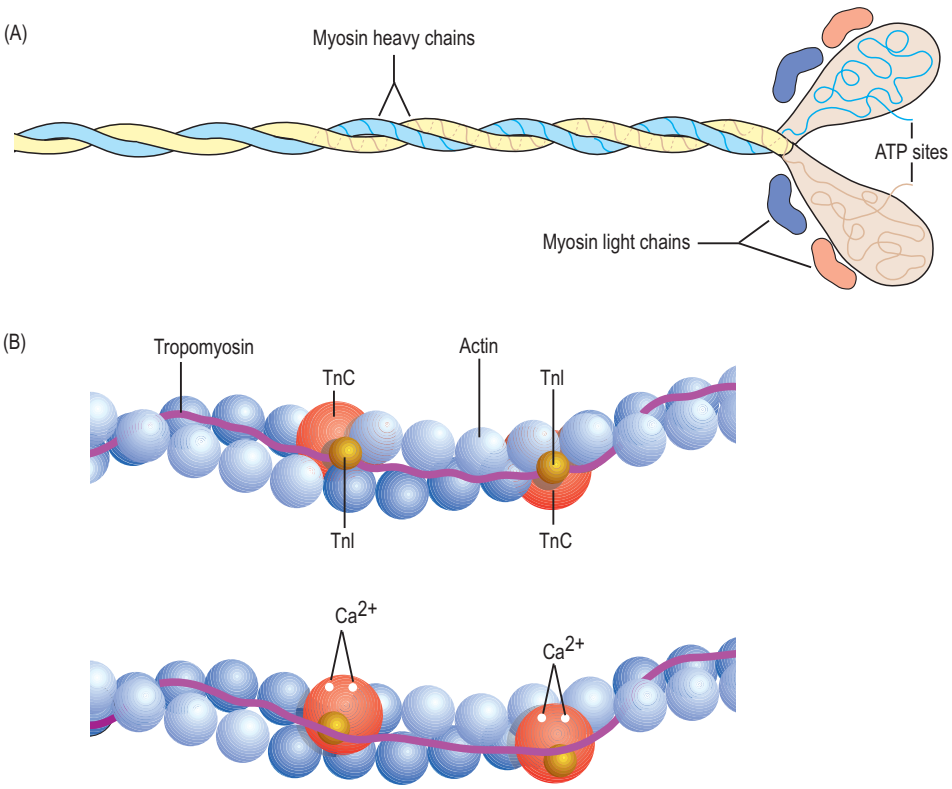

Fig. 5.5
(A) Diagram of the myosin molecule illustrating the α-helical coiled-coil tail, the folding of each heavy chain to form a globular head, the site of ATP hydrolysis, and the location of the four myosin light chains (regulatory and essential). (B) Model of the troponin–tropomyosin–actin that make up the thin myofilaments, during muscle relaxation (upper) and contraction (bottom). In the relaxed state, the inhibitory region of troponin (TnI, colored yellow) is attached to actin and tropomyosin, whereas troponin C (TnC, colored orange) is bound to Mg^{2+}. In this conformation, myosin cannot bind. In the contracted state, two Ca^{2+} ions bind to TnC, which in turn interacts with TnI. A conformational change to the troponin–tropomyosin complex exposes the myosin binding sites, thereby allowing the power stroke to occur.

General muscle physiology

The motor unit A motor unit consists of an α-motor neuron and the skeletal muscle fibers that it innervates (Fig. 5.9).[51] Since each time an α-motor neuron fires, the entire motor unit contracts, coarser movements are generated in those muscles that have many muscle fibers making up motor units (such as the locomotor muscles) compared with those with few (such as the extrinsic eye muscles). Muscle fibers within one motor unit are generally all of the same histochemical type, but they are normally widely distributed between fibers from other motor units and therefore give rise to the characteristic checker-board pattern that is apparent when using certain histochemical stains (see Fig. 5.3A). This is evident in denervated muscle (Fig. 5.10A,B) where there may be selective loss and atrophy of fibers of one histochemical type (Fig. 5.10A) or in reinnervated muscle following disease or injury, by patterns of fiber grouping (Fig. 5.10C).[52] Large-diameter α-motor neurons innervate fast-twitch fibers whereas smaller ones tend to innervate slow-twitch fibers.

Contractile force for a particular muscle is partly regulated by the rapidity of neuron discharge: muscle fibers contract with a twitch following a single discharge of a motor neuron but sustained contraction (tetanus) results from repetitive neuron firing. The force of a contraction increases with the rate of discharge up to a maximum limit that is determined by the properties of the muscle. Furthermore, a process known as recruitment, which reflects the gradual inclusion of larger motor neurons as greater force is required, also regulates force (see below). Relatively weak and slow contractions required for maintenance of posture therefore involve small-diameter α-motor neurons and slow-twitch fiber types, whereas locomotion and rapid movements rely on recruitment of larger diameter α-motor neurons and fast-twitch fibers.

Muscle proprioception Proprioception is the term given to the mechanism underlying the self-regulation of posture and movement through stimuli originating in sensory receptors embedded in joints, tendons, muscles and the labyrinth of the ear. In skeletal muscles and tendons these receptors are known as spindles and Golgi tendon organs and each type has been well characterized in the horse.[53–56] Signals derived within these sensory receptors are conveyed via a variety of well-defined reflex pathways that generate specific motor responses.

Muscle spindles consist of specialized intrafusal muscle fibers surrounded by a connective tissue capsule and lie parallel to regular muscle fibers (Fig. 5.11A). Sensory nerves (type Ia and type II) terminate on the intrafusal fibers in specialized sensory endings and generate afferent signals that are relayed to the spinal cord via the dorsal horn. Type Ia nerves carry both dynamic (rate of stretch) and static (amount of stretch) afferent signals whereas type II nerves sense only static muscle length. Motor innervation to the muscle spindle is provided by γ-motor neurons, which regulate the sensitivity of muscle spindles to muscle stretch. Golgi tendon organs are located within the connective tissues of tendons, joint capsules and muscles. They lie in parallel with the direction of mechanical force that they measure and from them, afferent type Ib fibers convey proprioceptive signals to the spinal cord.

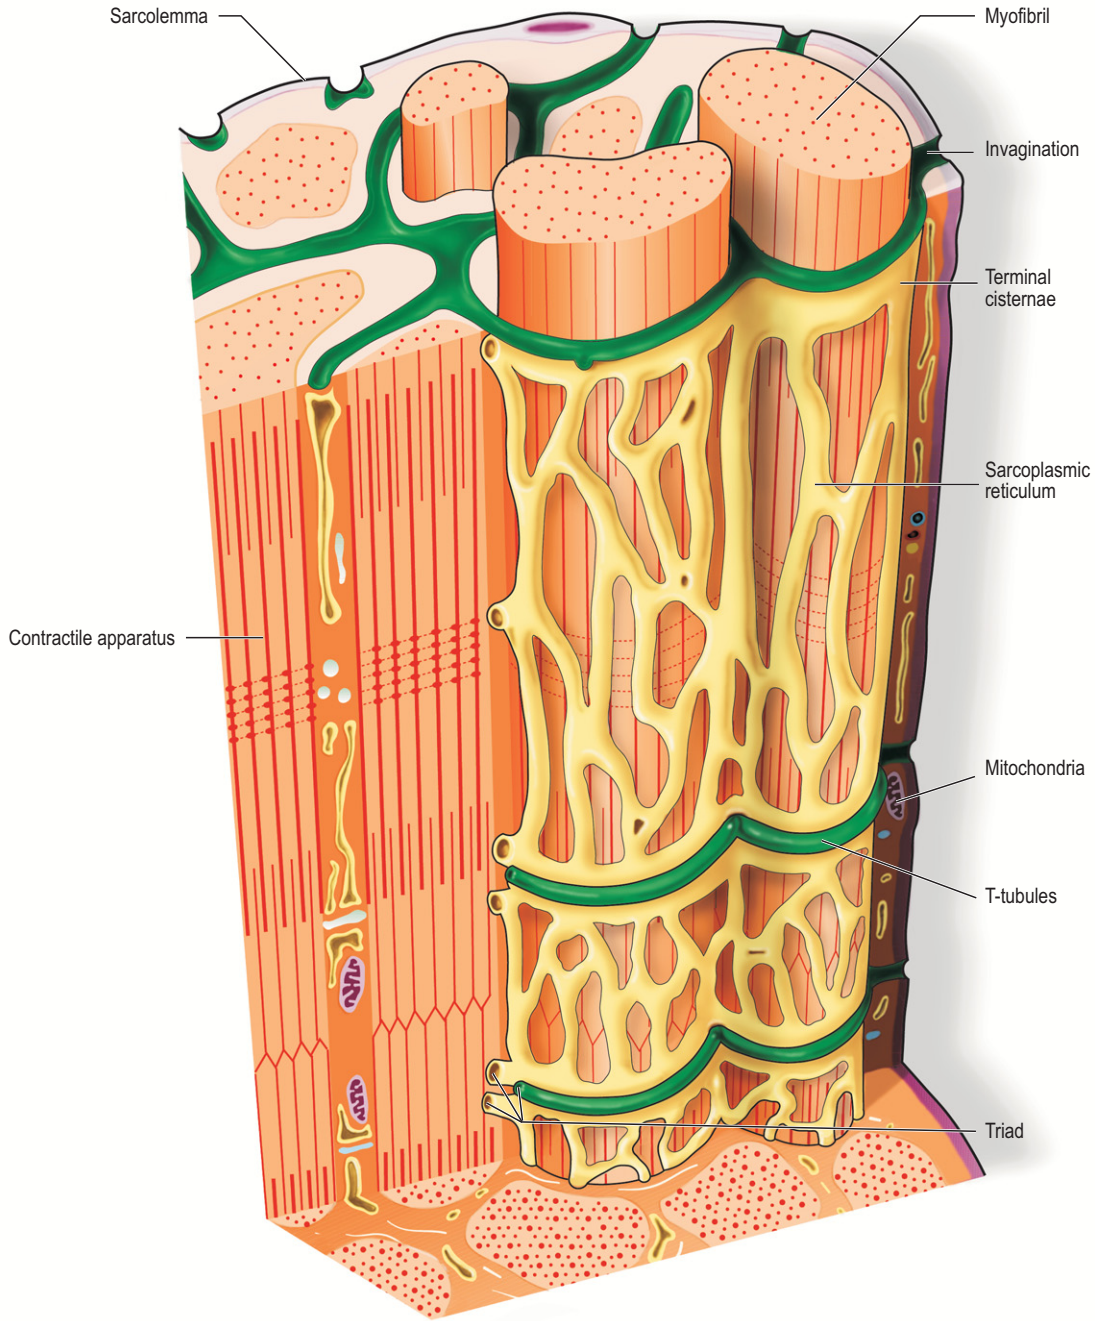

Fig. 5.6
Diagrammatic representation of the internal structure of a muscle fiber. Myofibrils are surrounded by the net-like tubular sarcoplasmic reticulum (SR); the SR converges at the junction between A and I bands of sarcomeres to form terminal cisternae. Between each pair of terminal cisternae there is an invagination of the sarcolemma called the T-tubule. Together, the three structures make up a triad. Mitochondria are dispersed between myofibrils.

Electrical and ionic properties of the sarcolemma
The sarcolemma maintains the interior of the fiber at a negative potential (the membrane potential) when compared to the extracellular fluid while the fiber is in a resting state. The negative potential is derived from the disequilibrium of ionic concentrations (mostly Na^+ and K^+) across the membrane and is generated partly by the action of the Na^+/K^+ ATPase pump, which extrudes three Na^+ ions for every two K^+ ions taken up. This results in the cytoplasm having a much higher K^+ concentration but much lower Na^+ concentration than the extracellular fluid. The remainder of the membrane potential is derived from the tendency of ions to diffuse down their electrochemical gradients across the semipermeable membrane.

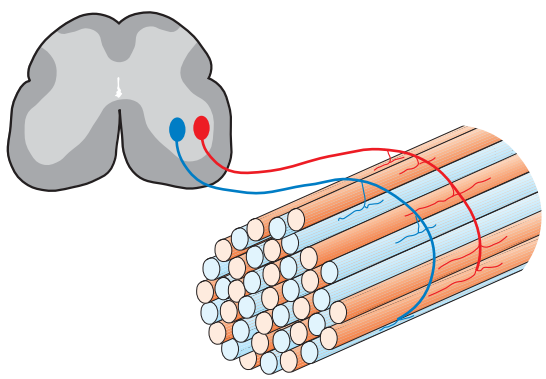

Fig. 5.9
Diagram illustrating the organization of motor units. A motor neuron from the ventral horn of the spinal cord supplies the motor innervation to a group of muscle fibers with similar contractile and metabolic properties.

Acetylcholine released from presynaptic nerve terminals at neuromuscular junctions (end-plates; Fig. 5.11B) binds to acetylcholine receptors and increases the conductance of the postjunctional membrane to Na^+ and K^+. The inward movement of Na^+ down its concentration gradient predominates, causing a transient depolarization (about 20 mV) in the end-plate, known as the end-plate potential. This depolarization is sufficient to activate sarcolemmal voltage-gated Na^+ channels (mutated in hyperkalemic periodic paralysis – see Chapter 6, p. 92), which open and therefore elicit propagation of an action potential along the membrane. Following this, and in response to depolarization, voltage-gated potassium channels open, resulting in the downswing of the action potential. The action potential therefore conducts rapidly along the sarcolemma in a wavelike fashion, away from the neuromuscular junction.

Excitation-contraction coupling Action potentials are conducted into the interior of muscle fibers via the T-tubules and there activate voltage-gated channels known as dihydropyridine receptors (DHPR). Unlike in cardiac muscle, very little calcium enters the muscle fiber from the extracellular space (via the DHPR).[57] Instead, a mechanical link between DHPR and the SR Ca^{2+} release channel (ryanodine receptor, RYR1) at the junctional feet of the triads results in the release of calsequestrin-bound Ca^{2+} from the SR's interior (Fig. 5.12). A positive feedback loop, known as calcium-induced calcium release, is responsible for further activation

of RYR1 with the result that the calcium concentration within the cytoplasm increases about 100-fold from a resting concentration of approximately 50 nM.[57] The anatomical location of the terminal cisternae results in Ca^{2+} being released adjacent to the overlapping contractile apparatus.

Binding of Ca^{2+} to high-affinity binding sites on troponin C causes a conformational change to the troponin–tropomyosin complex (see Fig. 5.5B). This results in the exposure of the myosin-binding sites on F-actin and allows the myosin globular head to attach, as ATP is hydrolyzed, thus forming the crossbridge. Force generation, and the resulting shortening of the sarcomere are the result of a conformational change of the myosin head. Adenosine diphosphate and inorganic phosphate are displaced by actin, which is followed by dissociation of the actin–myosin bridge due to the binding of ATP to myosin again. The crossbridge cycle continues while the cytoplasmic Ca^{2+} concentration remains high. Relaxation is achieved when the Ca^{2+} is resequestered within the SR via the action of the Ca^{2+} ATPase pumps (see Fig. 5.13 for a summary).

Force transmission The force that is generated in the crossbridge cycle is transmitted via the contractile apparatus to intermediate filament proteins that act to maintain and stabilize the muscle fiber's shape during contraction. These intermediate filaments provide a structural link first to the sarcolemma and then to the extracellular matrix via a group of proteins known as the dystrophin-associated protein complex (Figs 5.14, 5.15).[58] Contractile forces are transmitted from each muscle fiber via the extracellular matrix and the connective tissues of tendons, and ultimately to the bones of the skeleton.

Oxygen availability ATP replenishment in (predominantly) oxidative fibers requires a readily available source of oxygen that is provided by the O_2-binding heme protein known as myoglobin.[59,60] The P_{50} for equine myoglobin (the PO_2 when it is 50% saturated) is about 2.4 mmHg at physiological temperatures and pH,[61] and therefore far to the left of hemoglobin and close to the PO_2 of muscle cells. During exercise, oxygen demand rises dramatically and is met by a 20–30 times increased blood flow through the muscle capillary beds.[2] Capillary dilation results partly from autonomic control and stretch imposed by the higher blood pressure, but also follows the local production of vasoactive substances that include potassium, adenosine and nitric oxide. The latter is produced by nitric oxide synthase, found both in the

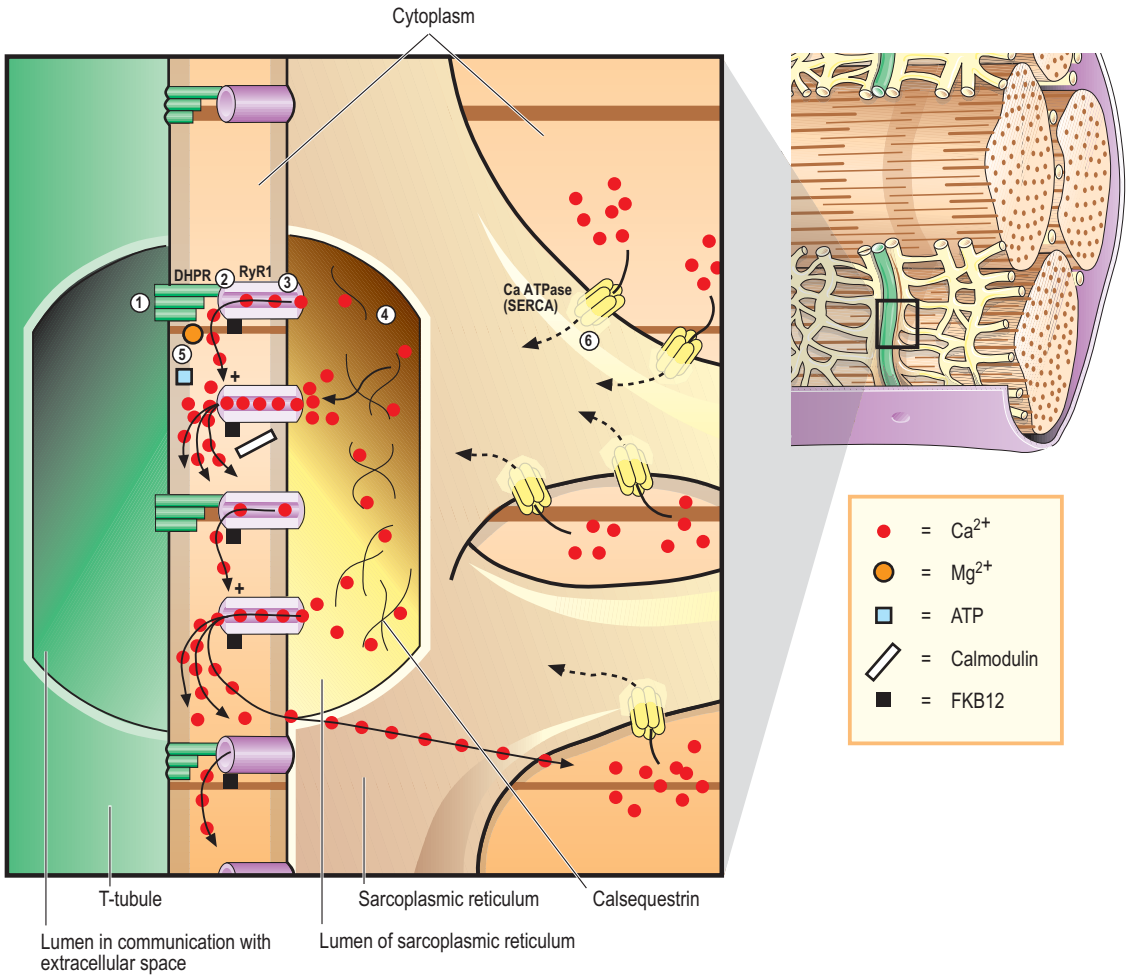

Fig. 5.12
Depolarization of the T-tubule membrane during the action potential activates voltage-gated Ca^{2+} channels (1) (dihydropyridine receptors) in the wall of the T-tubule. A mechanical link (2) with ryanodine receptors (RyR1) (3) located in the wall of the sarcoplasmic reticulum causes them to open and release calsequestrin-bound Ca^{2+} ions from the lumen of the SR (4). This Ca^{2+} stimulates further Ca^{2+} release via the calcium-induced calcium release mechanism. The process is modulated by other factors within the cytoplasm that include ATP, calmodulin and Mg^{2+} (5). After release into the cytoplasm, calcium activates the contractile apparatus by binding to troponin-C (Fig. 5.13). Reuptake into the SR occurs via the Ca^{2+}-ATPase pumps (6).

endothelium of the capillaries and bound to the dystrophin-associated protein complex within the contracting muscle fibers themselves (Fig. 5.16).[62]

Energy provision for muscular functions

Muscles cannot contract without a biochemical source of energy provided by the cleavage of high-energy phosphate bonds within ATP. In addition to the normal cellular metabolic requirements and the energy required for ion pumping up concentration gradients, ATP is required in the contractile crossbridge cycle: at the head of each myosin there is an ATP molecule that becomes hydrolyzed and releases energy (E) in a reaction catalyzed by the enzyme actomyosin ATPase:

$$ATP + H_2O \rightarrow ADP + Pi + H^+ + E$$

where ADP = adenosine diphosphate and Pi = inorganic phosphate.

Aerobic pathways Within mitochondria, β-oxidation of free fatty acids (FFA), the tricarboxylic acid (TCA) cycle and oxidative phosphorylation (via the electron transport chain) combine to produce ATP aerobically (Fig. 5.17; see also Fig. 28.25). During the process, the coenzymes nicotinamide adenine dinucleotide (NAD) and flavin adenine dinucleotide (FAD) are reduced to $NADH_2$ and $FADH_2$, respectively. Subsequently, $NADH_2$ and $FADH_2$ are reoxidized to NAD and FAD via the electron-transport chain in which oxygen acts as the final hydrogen acceptor to form water. Oxygen dissolved within the cytoplasm and bound to myoglobin is rapidly used up and hence must be replenished. Functional oxidative phosphorylation therefore depends on the dense capillary network between muscle fibers (Fig. 5.18). Acetyl-CoA is the substrate for the TCA cycle and its complete oxidation allows the formation of 12 molecules of ATP. Acetyl-CoA is derived from pyruvate, following anaerobic metabolism of glucose and glycogen within the cytoplasm (glycolysis) (Fig. 5.17); at

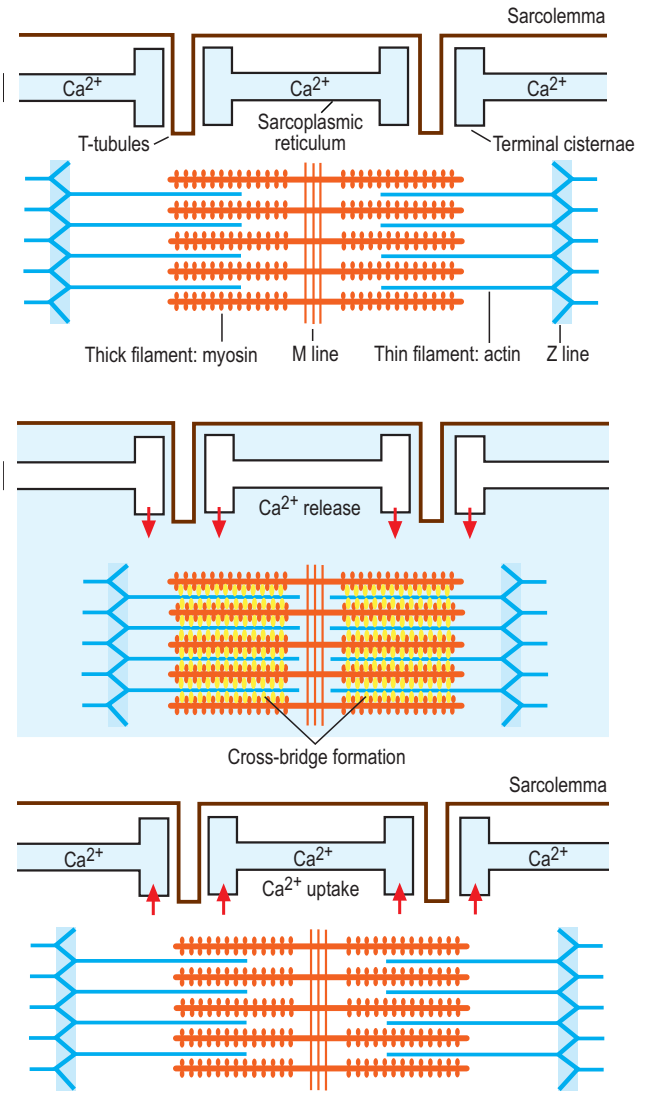

Fig. 5.13
Diagram illustrating excitation–contraction coupling and the role of calcium in the contractile mechanism. (Top) Calcium (light blue) stored in the SR during the relaxed state of the muscle. (Middle) A wave of depolarization moves along the sarcolemma and alters the membrane potential of the T-tubules. The altered membrane potential culminates in movement of Ca^{2+} ions into the cytoplasm from the SR (see Fig. 5.12). Thin filament inhibition is removed, allowing the globular heads of myosin to interact with actin and form a crossbridge that results in shortening of the total length of sarcomere. (Bottom) Muscle relaxation is achieved when Ca^{2+} is pumped back into the SR.

submaximal exercise intensities, most pyruvate produced via glycolysis is transported into mitochondria and is converted to acetyl-CoA. Thirty-six molecules of ATP are produced in the complete breakdown of glucose via these pathways. However, acetyl-CoA might also be derived from the oxidation of fatty acids, following their mobilization from the liver or adipose tissue. β-oxidation of FFA is highly efficient, as complete oxidation provides up to 146 molecules of ATP.

Anaerobic pathways In addition to the pathways described above, additional anaerobic mechanisms exist for ATP replenishment in muscle. They can be divided into two different mechanisms. The first system involves high-energy phosphate transformations involving the coupling of the creatine kinase (1), adenylate kinase (2) and AMP deaminase (3) enzyme systems:

1. ADP + phosphocreatine → ATP + creatine
2. ADP + ADP → ATP + AMP
3. AMP + H_2O → IMP + NH_3

The enzymes that catalyze these reactions help buffer ATP concentrations at the expense of lowering the cellular concentration of phosphocreatine and free ADP, while increasing the concentrations of creatine, adenosine monophosphate (AMP) and inosine monophosphate (IMP). These reactions occur in active muscles at top speeds, but provide only a small amount of ATP for a few seconds. Deamination of adenosine nucleotides leads to the production of ammonia (NH_3), uric acid and allantoin.[63]

The second anaerobic pathway involves glycolysis acting independently from the oxidative pathways. Glycolysis requires glucose-6-phosphate as a substrate, which may be derived from the phosphorylation of glucose by hexokinase or by the mobilization of stored intracellular glycogen that is metabolized first to glucose-1-phosphate via glycogenolysis (Fig. 5.17) and then converted to glucose-6-phosphate. Blood glucose is transported across the sarcolemma by means of specific glucose transporters that include GLUT-1 and GLUT-4 (Fig. 5.18).[64] GLUT-1 is normally located within the sarcolemma and provides basal glucose requirements; however, GLUT-4 receptors translocate to the sarcolemma in vesicles, in response to insulin or the demands of exercise (see Fig. 6.14, p. 91). The glycolytic pathways result in the formation of two pyruvate molecules which, in the absence of oxygen, are converted to lactate.

Integration of aerobic and anaerobic pathways Aerobic production of ATP is a relatively slow but highly efficient process, while anaerobic pathways produce energy rapidly but relatively inefficiently. Although both pathways are generally active during exercise, the relative contribution within each muscle depends on the nature, intensity and duration of the activity, the muscle's fiber type composition, the availability of oxygen and substrates and the relative concentrations of intermediary metabolites that may potentially activate or inhibit selected enzymes.[63,65] Hence, at the beginning of low-speed exercise, when oxygen is abundant, energy production depends largely on the degradation of glycogen via aerobic pathways.[63] Within a few minutes, glucose and FFA concentrations rise in the blood and following 20–30% glycogen depletion, there is a shift towards β-oxidation of FFA.[66] With higher energy demands, the muscle ATP/ADP ratio decreases, providing a stimulus for energy production via anaerobic mechanisms. The activity of the key regulatory glycolytic enzyme phosphofructokinase increases, resulting in greater production of pyruvate via glycolysis. The point where the availability of oxygen becomes a limiting factor in oxidative phosphorylation is reflected by partial reoxidation of $NADH_2$, as more and more pyruvate is converted to lactate. As exercise intensity increases, a greater proportion of the energy is supplied by the anaerobic pathway. The point when the increased rate of latacte production can be detected in the plasma is known as the anaerobic threshold. This threshold varies and depends on several factors

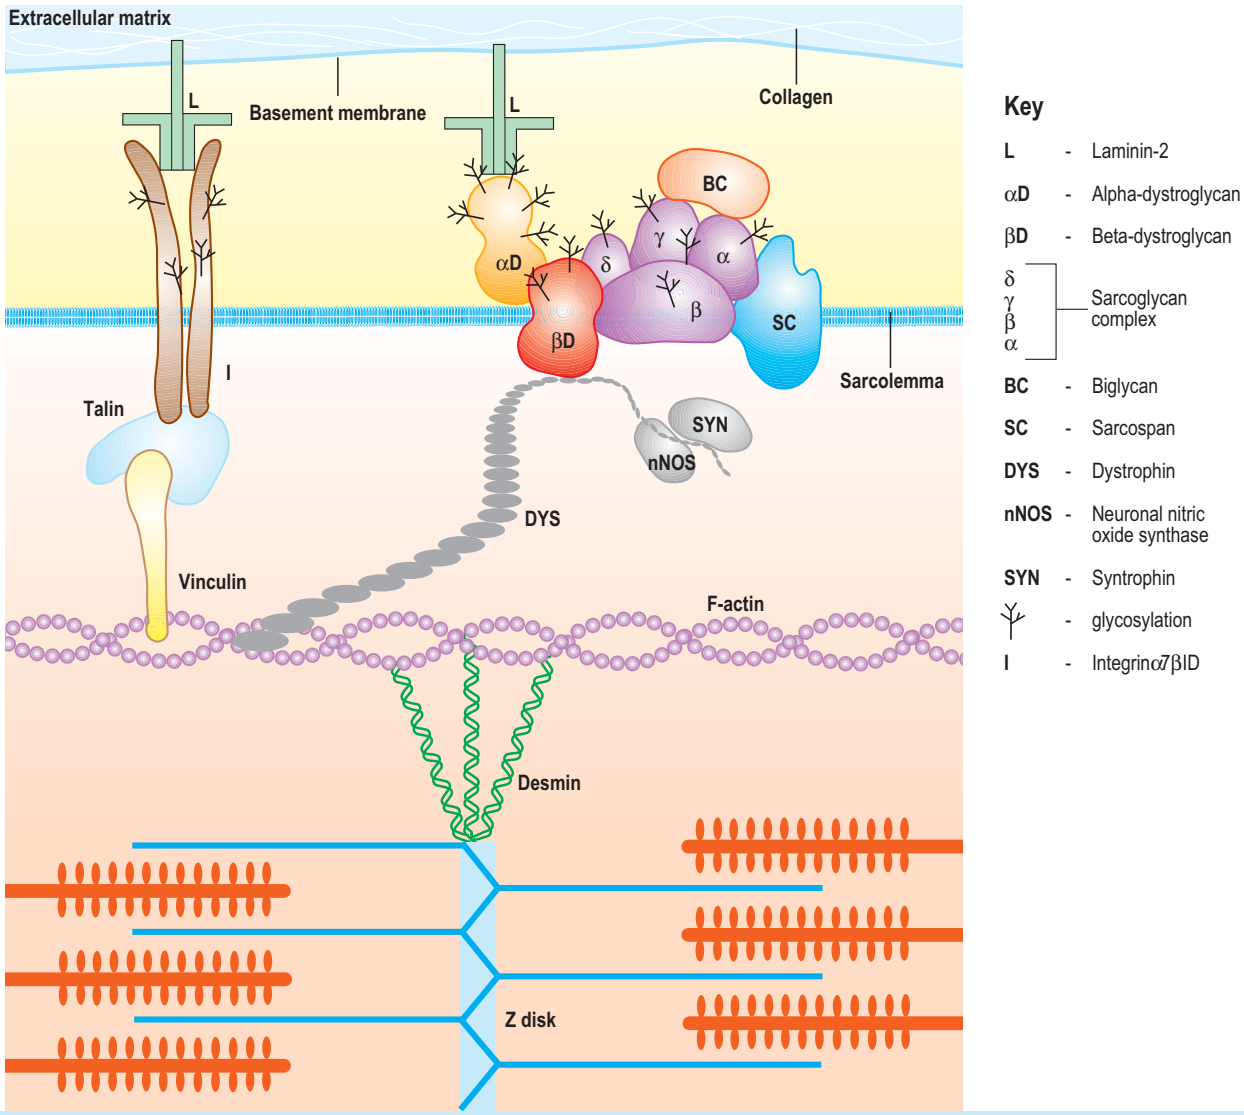

Fig. 5.14
Interconnections between the contractile apparatus, the dystrophin-associated complex (DAC) and the extracellular matrix. Further structural support is provided by integrin molecules that span the sarcolemma. Note nNOS makes up part of the DAC. In addition to a structural role, the DAC likely has a role in cell signaling.

including the muscle's fiber type composition and the level of fitness. Furthermore, the diet plays an additional role; for example, a fat-rich diet promotes oxidative energy production via FFAs,[67] thereby increasing the oxidative capacity of muscle[68] and sparing glycogen.[69] However, other substrates also influence the pathways employed during energy production: for instance, it has been shown that energy production can be steered towards that derived from glucose by the provision of additional glucose during exercise.[70]

Muscle heterogeneity

The ability of muscle tissue to perform efficiently in spite of very different types of exercise of varying duration is significantly enhanced by a muscle's heterogeneity. This functional flexibility is partly derived from the regulation of nervous control but also from the combined properties of the different fiber types.

Muscle fiber types

Fiber type differentiation There are important differences in the morphologic, physiologic, and biochemical properties of fibers both within and between muscles. These differences form the basis for the classification of fiber types. Better understanding of the expression patterns of groups of proteins within individual fibers has allowed refinement of fiber type classification in recent years. For example, myofibrillar proteins exist as different isoforms encoded by separate genes that are expressed in a myofiber type-specific

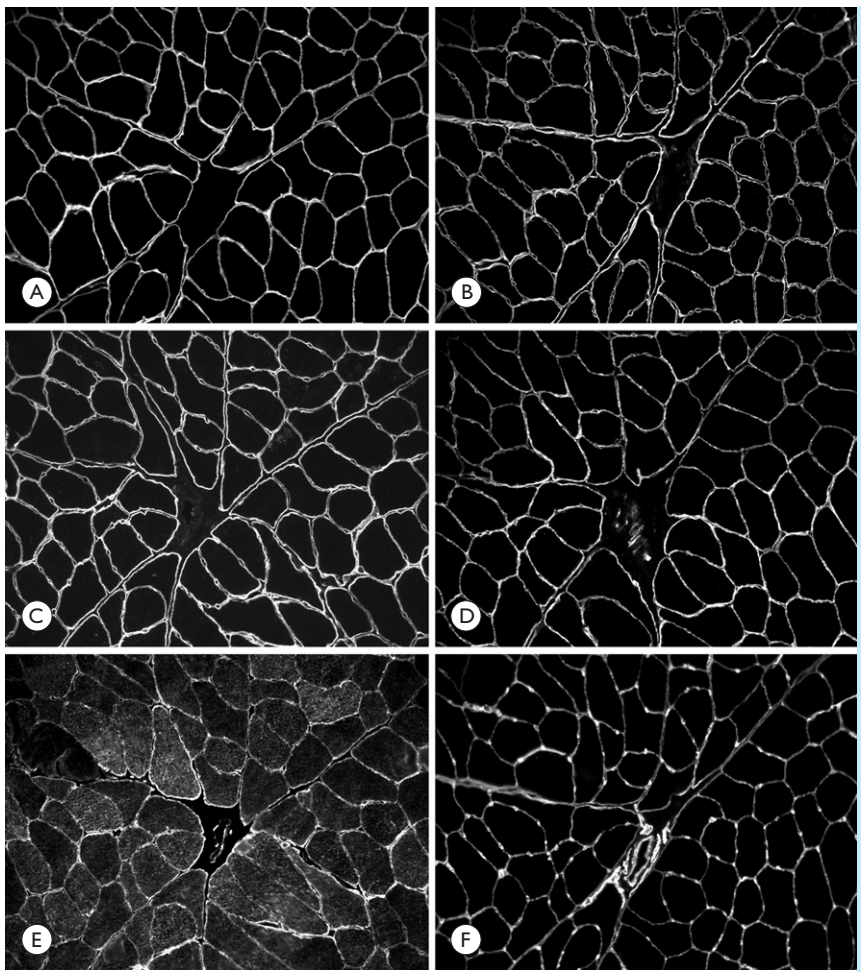

Fig. 5.15
Immunofluorescence labeling of serial 7 μm sections from the gluteus medius muscle of a normal Thoroughbred, showing proteins that link the contractile apparatus to the extracellular matrix. (A) Beta dystroglycan; (B) laminin alpha-2; (C) dystrophin; (D) integrin alpha-7-beta-1d; (E) desmin; (F) collagen IV. Working clockwise from desmin (E), contractile force is conveyed via dystrophin (C) to the dystrophin-associated complex (A and B) and ultimately to the extracellular matrix (F). Integrin alpha-7-beta-1d likely also plays a structural role. Compare with Figs 5.14 and 5.16. Note the capillaries located around each muscle fiber, and a central blood vessel that are also localized with the collagen IV antibody in (F).

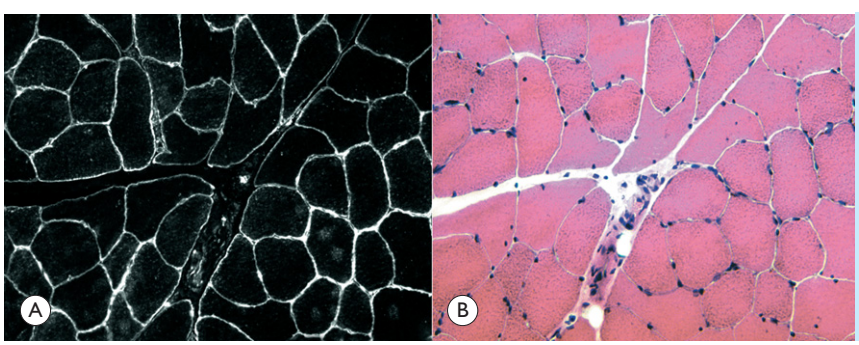

Fig. 5.16
Serial 7 μm (A) and 10 μm (B) sections from the gluteus medius muscle of a normal Thoroughbred. (A) Immunofluorescence labeling of neuronal nitric oxide synthase (nNOS). (B) Hematoxylin and eosin stain. Note the sarcolemmal distribution of nNOS, and compare with Fig. 5.14 and Fig. 5.15.

and co-ordinated manner.[71] Fiber types can best be differentiated by analyzing the specific myosin heavy chain (MyHC) isoform(s) expressed by each fiber, since MyHC composition closely reflects each fiber's phenotype.[20] Three MyHC isoforms have been characterized in adult equine skeletal muscles at the protein level: they are designated as types I, IIA and IIX[34] or IID[31] (henceforth IIX). The differential distribution of these MyHCs defines three pure fiber types containing a single isoform (types I, IIA and IIX) and two hybrid fiber types coexpressing two isoforms (I+IIA and IIAX) (Fig. 5.19). Hybrid IIAX fibers exist in equine locomotor muscles as a significant and stable population.[31,32] Recent studies have demonstrated either minimal (fewer than 0.6%)[72] or no expression of the MyHC-IIB isoform in the horse;[34] hence the fibers classified as type IIB in earlier studies are now more appropriately classified as type IIX.

Muscle fiber type properties Certain relevant differences between the various equine skeletal muscle fiber types

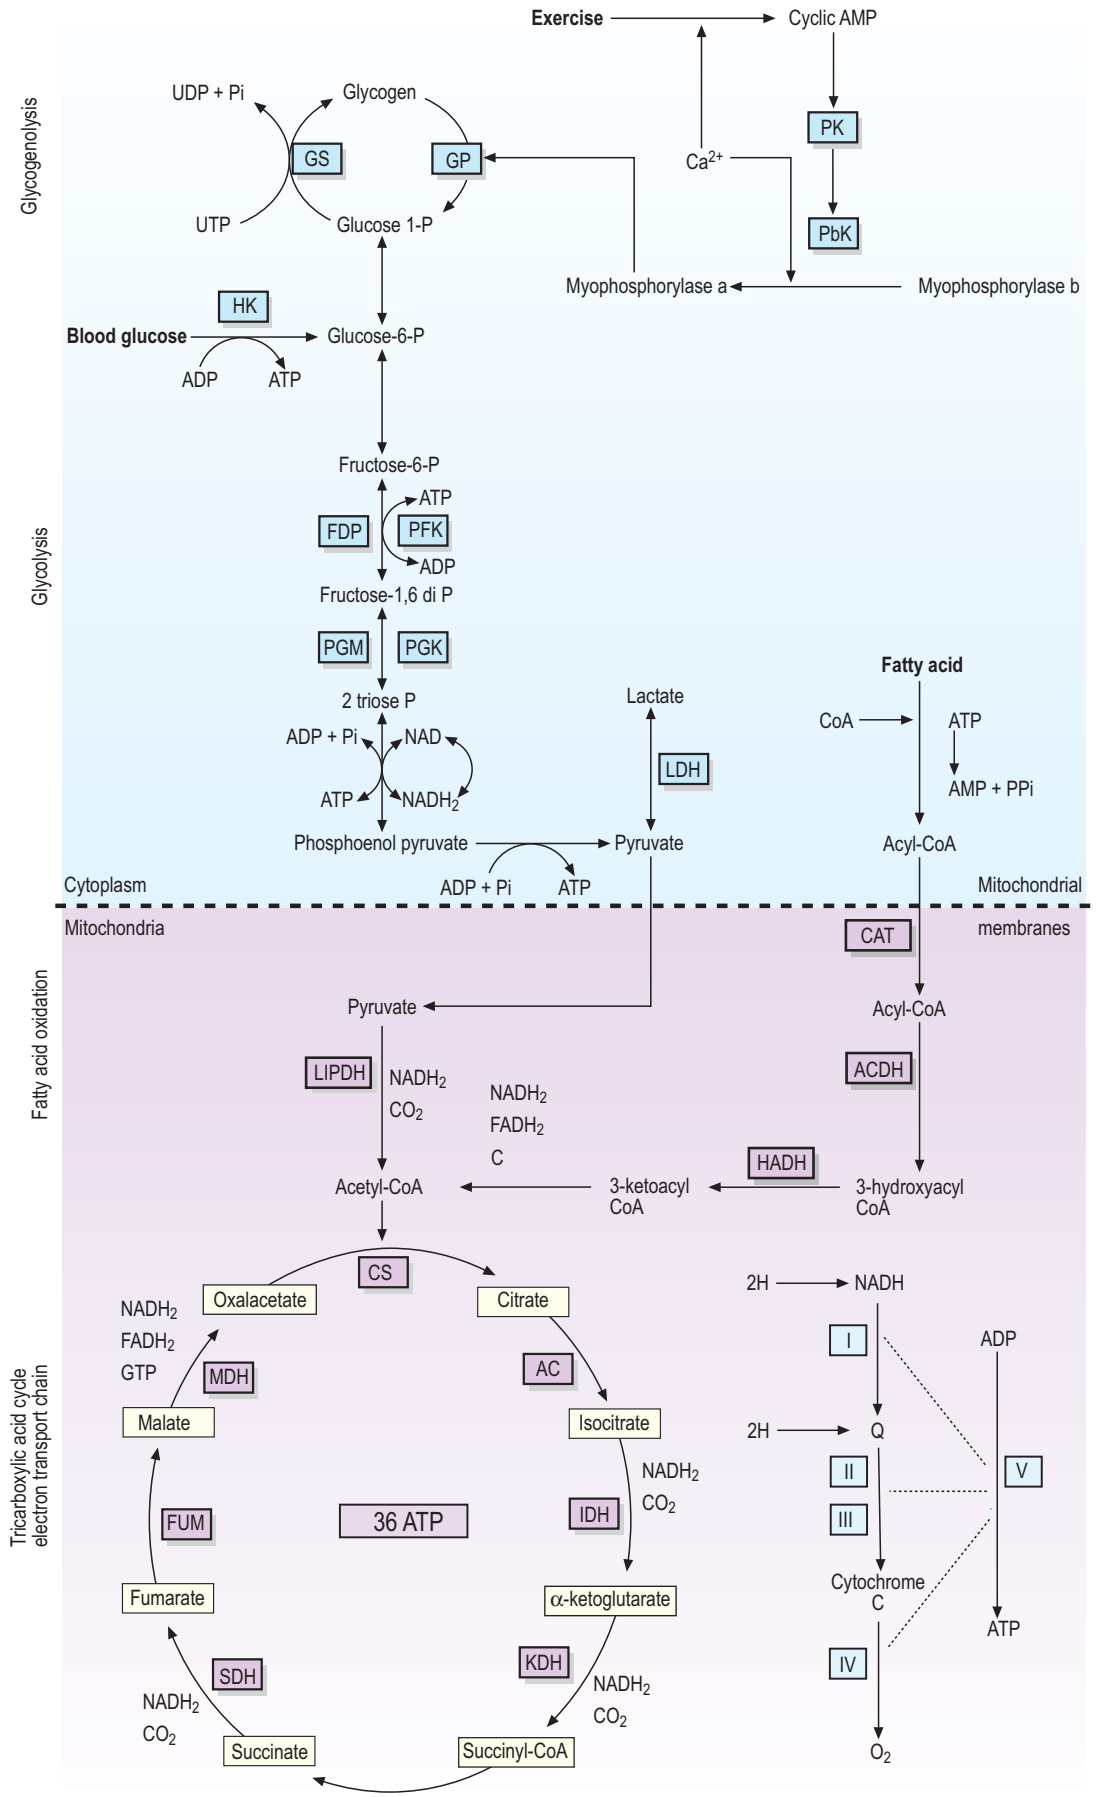

Fig. 5.17
Diagram summarizing the integration of metabolic pathways in muscle cells. Abbreviations: AC, aconitase; ACDH, acyl-CoA dehydrogenase; ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; CAT, carnitine acyltransferase; CoA, coenzyme A; CS, citrate synthase; FAD, flavin adenine dinucleotide; FDP, fructosediphosphatase; FUM, fumarase; GP, glycogen phosphorylase; GS, glycogen synthetase; GTP, guanosine triphosphate; HADH, 3-hydroxyacyl-CoA-dehydrogenase; HK, hexokinase; I, complex I; II, complex II; III, complex III; IDH, isocitrate dehydrogenase; IV, complex IV; KDH, ketoglutarate dehydrogenase; LDH, lactate dehydrogenase; LIPDH, lipoamide dehydrogenase; MDH, malate dehydrogenase; NAD, nicotinamide adenine dinucleotide; PbK, phosphorylase b kinase; PFK, phosphofructokinase; PGK, phosphoglycerate-kinase; PGM, phosphoglycerate-mutase; Pi, phosphate; PK, protein kinase; PPi, pyrophosphate; SDH, succinate dehydrogenase; V, complex V; UDP, uridine diphosphate; UTP, uridine triphosphate.

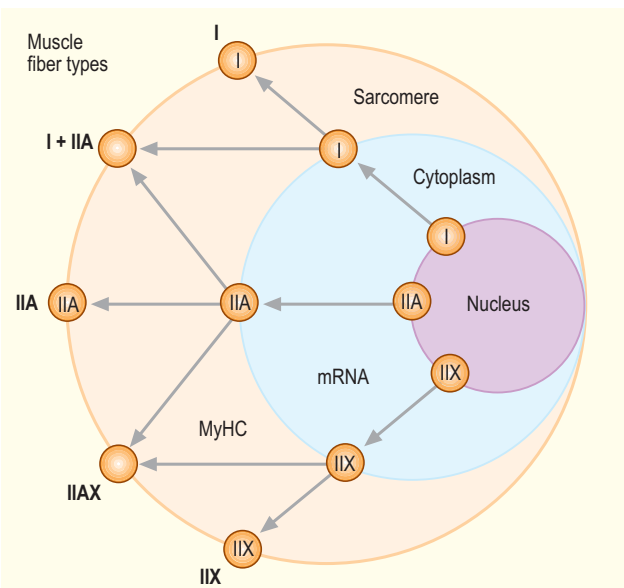

Fig. 5.19
Diagram illustrating the relationship between muscle fiber phenotype and the regulation of gene expression for the separate myosin heavy chain isoforms in adult horse skeletal muscle. Horses only express three myosin heavy chain isoforms: one slow or type I and two fast termed type IIA and type IIX. The differential expression of these isoforms defines three major fiber types, each containing a single isoform (i.e. types I, IIA and IIX) and two intermediate hybrid fiber populations containing either slow and fast IIA isoforms or the two fast isoforms.

are illustrated in Figure 5.20 and summarized in Table 5.1. When studied in combination, these differences allow more objective delineation (Fig. 5.21) and represent the considerable interdependence of contractile, metabolic and morphologic features. Type I fibers have a MyHC isoform that hydrolyzes ATP slowly, resulting in a slow crossbridge cycle, together with a small cross-sectional area, a high number of capillaries and a high oxidative capacity. However, their glycolytic capacity and glycogen content are relatively low. Together, these properties make type I fibers highly efficient and economical in producing slow repetitive movements and sustaining isometric force, but not significant power generation. In contrast, type II fibers have MyHC isoforms that create fast crossbridge cycling and therefore develop force rapidly. Within the type II group, type IIX fibers have a maximal velocity of shortening that is three times higher than that of IIA fibers.[14] Hence, IIX fibers are adapted for high power outputs for a limited time because they have a low oxidative capacity and limited oxygen availability (as reflected by their large cross-sectional area and relatively low capillary supply). Type IIA fibers, however, have a considerable number of both capillaries and mitochondria and rely on glycolytic and oxidative metabolism; they are therefore able to sustain high power outputs for longer than IIX fibers. Hybrid IIAX fibers are intermediate in their properties.[20] Although classified according to the MyHC composition, it is important to remember that other protein isoforms vary, each closely correlating with the fiber's function and with one another. Furthermore, fibers also differ with respect to other factors, such as the availability of high-energy phosphate,[74] GLUT-4

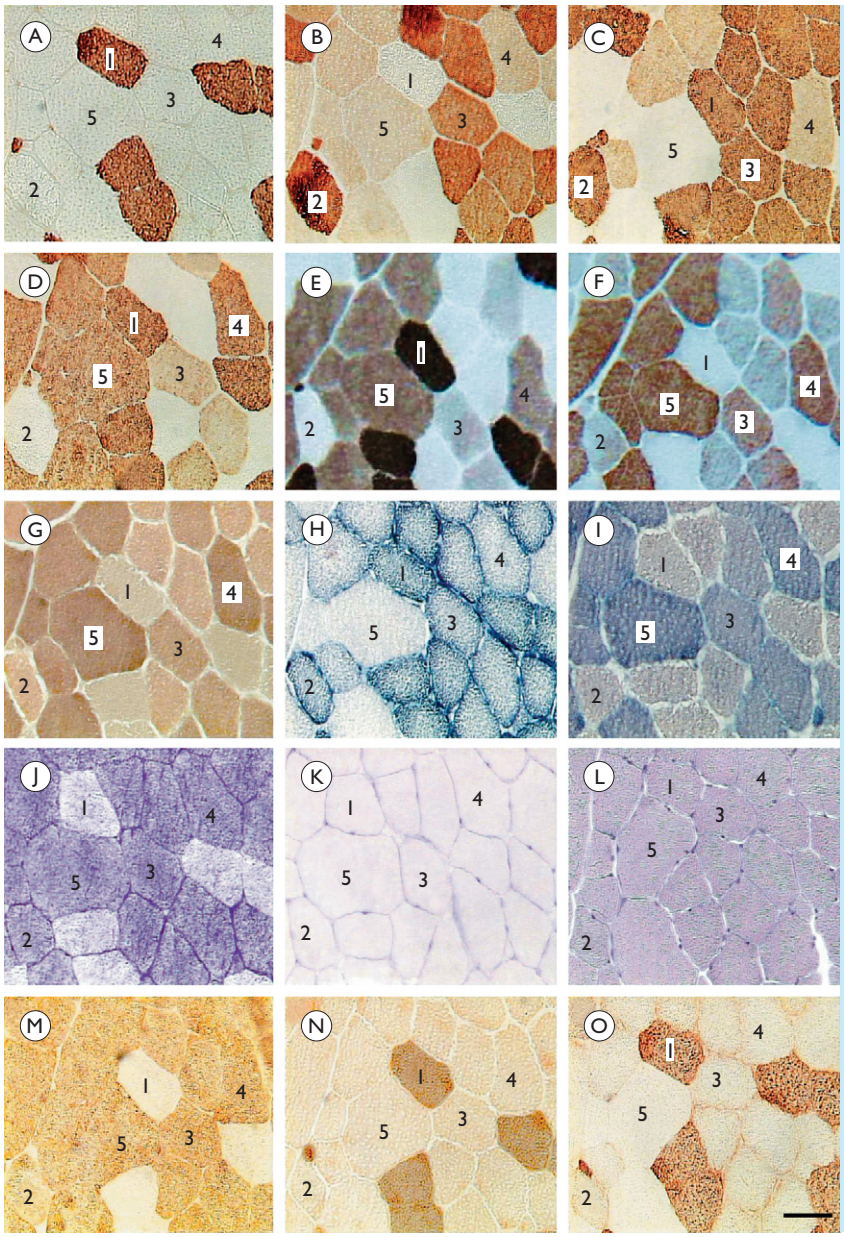

Fig. 5.20
Serial cryosections of adult horse M. gluteus medius stained by immunohistochemistry, enzyme histochemistry and histology. (A–D) Sections were stained with a number of monoclonal antibodies against specific myosin heavy chain (MyHC) isoforms: BA-D5 (A, anti MyHC-β/slow), SC-71 (B, anti MyHC-IIA), BF-35 (C, anti MyHCs β/slow and IIA), and S5-8H2 (D, anti MyHCs β/slow and IID/X). (E–G) Sections were assayed for myofibrillar actomyosin adenosine triphosphatase activity after acid (pH 4.4, E) and alkaline (pH 10.45, F) preincubations, and by Blanco and Sieck's quantitative histochemical procedure (G).[73] (H–I) Sections assayed for succinate dehydrogenase and (H), glycerol-3-phosphate dehydrogenase activities (I) and periodic acid-Schiff (PAS) for selective staining of glycogen (J). (K–L) PAS with α-amylase digestion, for visualizing capillaries (K) and hematoxylin and eosin for visualizing myonuclei (L). (M–O) Sections were stained by immunohistochemistry with monoclonal antibodies specific against SR Ca^{2+}-ATPase (SERCA) isoforms and phospholamban: CaF2-5D2 (M, anti-SERCA1a), MA3-910 (N, anti-SERCA2a) and 05-205 (O, antiphospholamban). The fibers labeled 1, 2, 3, 4 and 5 are types I, IIA, IIAx, IIaX and IIX, respectively. Calibration bar 50 μm.

protein expression (Fig. 5.22),[64] the calcium sensitivity of force production[15] and carnosine and taurine contents.[75–77]

Muscle fiber recruitment Although muscle can be separated into individual fiber types, the basic functional unit of skeletal muscle remains the motor unit (see section above on general muscle physiology). Motor units are commonly classified according to the MyHC profile of their constituent fibers (hence I, IIA and IIX; Fig. 5.23). This is possible because fibers within a single motor unit show relatively homogeneous, although not identical, biochemical and histochemical properties.[78] Although the motor unit's structure, function and hence role in motor control have been studied extensively in experimental animals, they have not been widely studied in larger mammals. However, specific muscle fiber type recruitment has been examined in horses by observing glycogen depletion patterns during and after exercise of varying intensity and duration (Fig. 5.24).[3] In horses, it appears that motor units are selectively recruited in a specific pattern that changes according to the gait, in addition to the intensity and duration of exercise. For the maintenance of posture, only type I motor units are recruited. As intensity and duration increase, further motor units are recruited, in the rank order: I → IIA → IIAX → IIX. Type IIX motor units are only recruited at near-maximal exercise intensity (sprint and jumping) and during extremely prolonged submaximal exercise.[63]

Muscle fiber type distribution between and within muscles Fiber-type composition varies extensively between muscles and in accordance with the functional requirements of the muscle.[79] For example, significant components of the forelimb musculature consist of postural type I fibers, while propulsive muscles of the hindlimb contain a high proportion

Table 5.1 Quantitative fiber type features of equine skeletal muscle. Values are mean ± SE of 208 individual fibers.

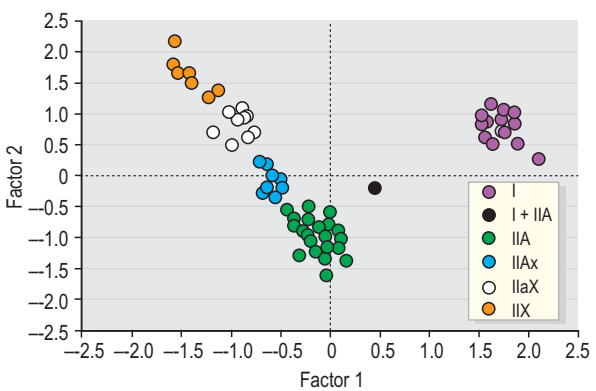

Fig. 5.21
Principal component analysis of muscle fiber type features in a representative sample (*n* = 82 fibers) to show graphically the spatial discrimination of myosin heavy chain (MyHC)-based fiber types. This scatter plot shows the spatial distribution of a set of equine muscle fibers upon the basis of muscle variables included in Table 5.1; this analysis resulted in an optimal discrimination (100%) of all muscle fiber types; Factor 1 axis discriminates between type I (right) and type II (left) fibers, whereas Factor 2 axis discriminates type IIA (bottom) and IIX (top) fibers.

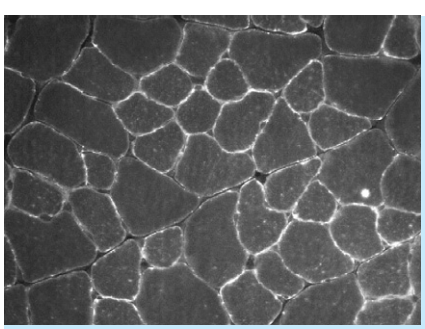

Fig. 5.22
Transverse section of rat extensor digitorum muscle samples labeled by immunohistochemistry with a monoclonal antibody to GLUT-4 (glucose transport protein). Note the higher intensity of staining in the periphery of the smaller fibers (presumably types I and IIA) compared with the larger ones (presumably IIX and IIB).

of fast-twitch type II fibers (Fig. 5.25A,B). Variation is also seen between muscles belonging to the same synergic group. For example, most of the triceps muscle mass consists of type II fibers, but the medial head is composed of nearly all type I fibers.[80] Significant regional variations in fiber composition within a muscle have also been reported in several horse

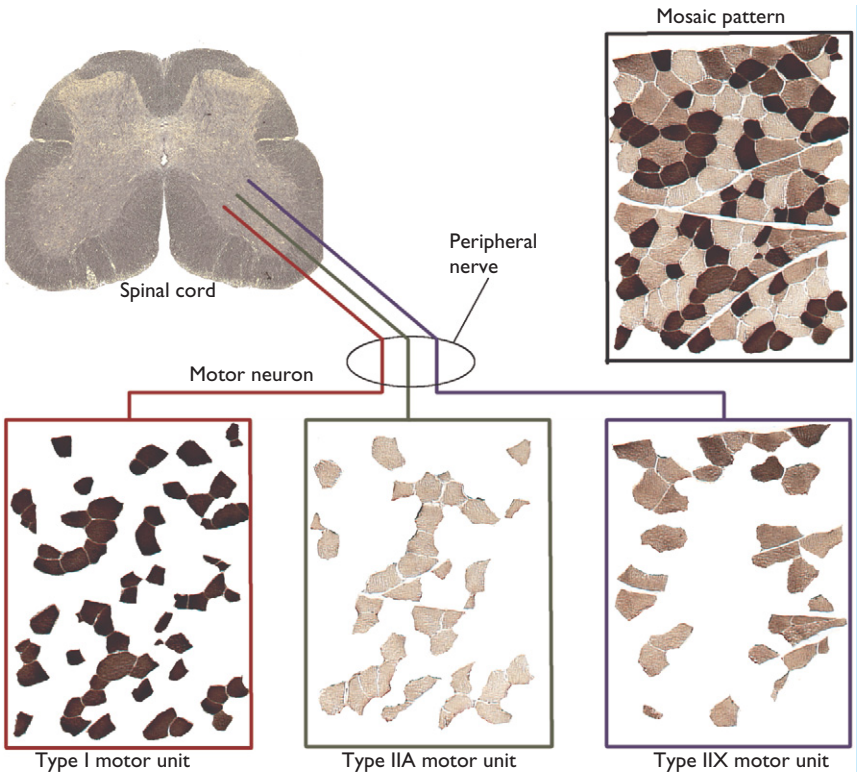

Fig. 5.23
Diagram showing the spatial distribution of muscle fibers integrating three different motor units classified according to myosin heavy chain isoform expression as types I, IIA and IIX. Note how muscle fibers within each motor unit are dispersed between those of others resulting in the characteristic mosaic or checkerboard distribution seen in transverse section.

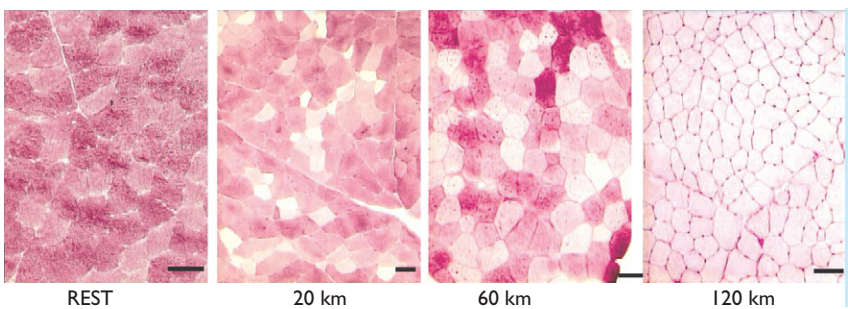

Fig. 5.24
Transverse sections of gluteus medius muscle biopsies (6 cm depth) to show muscle glycogen depletion patterns in a horse competing in an endurance ride of 120 km. Note the increase in the number of myofibers without glycogen when the intensity and duration of the exercise increase. Bars, 75 μm.

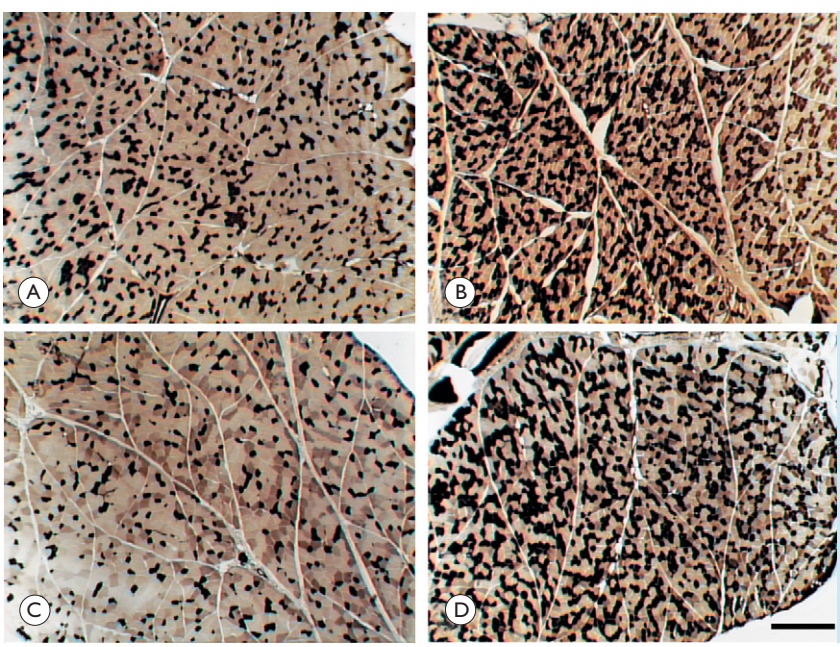

Fig. 5.25
(A, B) Transverse sections stained for myofibrillar adenosine triphosphatase activity after acid preincubation (pH 4.4) demonstrating the differential muscle fiber type composition in two locomotor muscles with different functions: M. semitendinosus (A) vs M. rhomboideus cervicis (B). Note the higher percentage of type I fibers (black staining) and the lower proportion of types IIA (white) and IIX fibers (gray) in the rhomboideus muscle compared with the semitendinosus muscle. (C, D) Transverse sections stained with myofibrillar adenosine triphosphatase activity after acid preincubation
(pH 4.4) from two muscle samples removed from the equine gluteus medius muscle at two different sampling depths: 2 cm (C) vs 8 cm (D). Note the higher percentage of type I fibers and the lower proportion of type IIX fibers in the deeper region of the muscle than in the superficial region. Scale bar, 1000 μm.

muscles.[8,9,24,25,32,48,49,81] Most locomotory muscles have greater numbers of oxidative type I and type IIA fibers in the deep portions and a predominance of glycolytic type IIX in more superficial portions (Fig. 5.25C,D). This compartmentalization reflects the relationship between structure and function: the deeper regions appear best suited for posture maintenance and low-level but longer duration muscular activity, whereas the more superficial regions are involved with short-duration, rapid, propulsive force generation. In general, groups studying equine muscle physiology have formed conclusions based on data derived from a single biopsy sample site (see reference[3] for review of relevant citations); however, it is apparent that this approach may be too simplistic. Several studies by the first author's group have demonstrated a greater muscular response to training in the deeper region of the M. gluteus medius compared with more superficial regions.[82–84]

Relationship to performance Some studies in horses have shown that performance is correlated with selected muscle characteristics (see reference[3] for a review). Unsurprisingly, endurance capacity is correlated with (1) high percentages of type I and IIA fibers[85] and (2) high activities of oxidative enzymes,[86] whereas sprint capacity is correlated with high percentages of type II fibers.[87] It is therefore feasible to differentiate the endurance potential of horses based on the fiber type composition of certain muscles,[88] although different conclusions have been obtained in Thoroughbreds[81] and Trotters.[89,90] Nevertheless, trotting speed is highly dependent on the ability of muscle to produce energy via anaerobic glycolysis.[89] Interestingly, some myofiber properties are correlated with kinematic profiles. For example, stride length and frequency are positively correlated with both the percentage of IIA fibers[91] and fiber size.[92] The stance time of the stride is inversely correlated with the percentage of IIX fibers[93] and fiber diameter.[92] Furthermore, some relevant muscular adaptations to training occur with concomitant modifications in the temporal characteristics of the trot.[94]

Control and regulation

Myogenic factors Multiple factors, both myogenic and non-myogenic in origin, regulate the expression of proteins that comprise the various muscle-specific organelles in each muscle fiber (Fig. 5.26) and, in combination, these factors also regulate the percentage of individual fiber types found within each muscle. During development and maturation (and regeneration following injury – see Chapter 6) these factors change, resulting in a significant alteration in protein expression. However, generally, the myogenic lineage from which a muscle fiber develops defines the ultimate fiber type.[71] All fibers during embryonic development express an embryonic MyHC isoform. At birth, some fibers are found to express type I MyHC: these are destined to become mature type I fibers in the adult. Other fibers express a neonatal MyHC isoform that is gradually replaced by either IIA or IIX, or both MyHCs: these subsequently become type II fibers in the adult. Horse skeletal muscle has also been found to express the α-cardiac MyHC isoform,[31] but its significance is unclear. The influence of genetic factors on equine muscle fiber types is clearly illustrated by dramatic variations observed between different breeds of horses (Fig. 5.27)[79,95,96] and between separate genealogical bloodlines within the same breed.[97] Furthermore, there is a tendency for fiber type ratios (type I : type II) to be inherited.[87,98] During growth and maturation, muscle fibers change in their size and histochemical properties: there is a gradual conversion of fast to slow phenotype that is especially pronounced in the first year postpartum,[99] but that may continue until about 6 years of age[100–102] or older.[103]

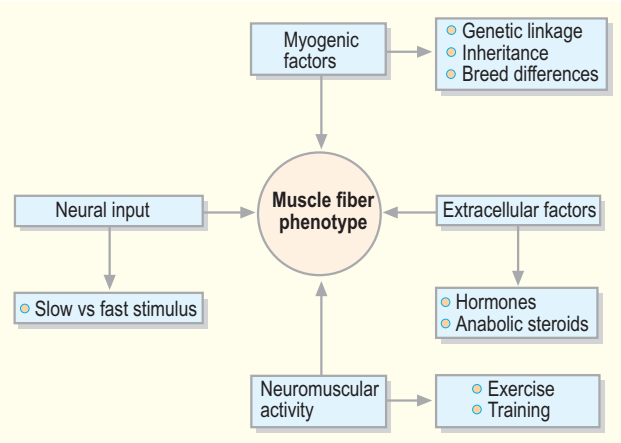

Fig. 5.26
Schematic diagram summarizing regulation of muscle fiber type. Fiber type is determined by a combination of four factors: (1) the myogenic lineage from which the muscle fiber developed; (2) the innervating motoneuron that regulates fiber type via patterns of activity and basal activity and/or via other mediators such as neurotrophic factors; (3) activity levels influenced by exercise and training; and (4) extracellular factors. The extracellular factors include hormones (e.g. thyroid hormone and growth hormone), growth factors (e.g. insulin-like growth factor and anabolic steroids), substrate availability (e.g. β-guanidinoproprionic acid), and various other currently unidentified factors such as certain extracellular matrix proteins.

Non-myogenic factors In addition to the underlying myogenic lineage, additional factors influence muscle fiber phenotype. Muscle fibers are syncyteal (multinucleated), with their myonuclei arranged peripherally throughout the length of the fiber. The volume of cytoplasm associated with a single nucleus is known as the myonuclear domain.[104] Hence, each individual nucleus regulates the expression of proteins within a particular cytoplasmic region. In horses, myonuclear domains of type I fibers are smaller than those of IIX fibers, but similar in size to those of IIA fibers (Fig. 5.28).[20] These observations have been related to the different activity patterns of the various fiber types:[105] the more active type I fibers have a higher rate of both protein synthesis and protein turnover than the less frequently recruited faster fiber types.

Neural input also has a significant influence on muscle fiber growth and type (fast/slow, glycolytic/oxidative) through altered regulation of gene expression.[106] This is convincingly demonstrated by dramatic changes observed in muscles follow-

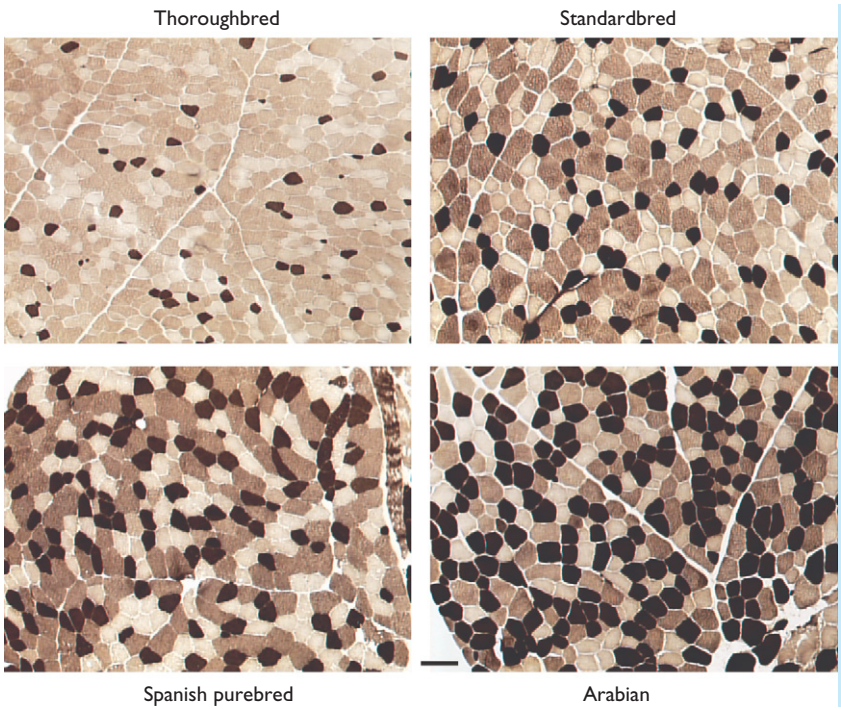

Fig. 5.27
Transverse sections of M. gluteus medius specimens stained with myofibrillar adenosine triphosphatase after acid preincubation (pH 4.4), removed at the same depth, from four different breeds of athletic horse. Note how the percentage of type I (oxidative) fibers and the fiber size increases from the fastest breed (Thoroughbred) towards the slower, more endurance-suited breed (Arabian). Bar scale, 150 μm.

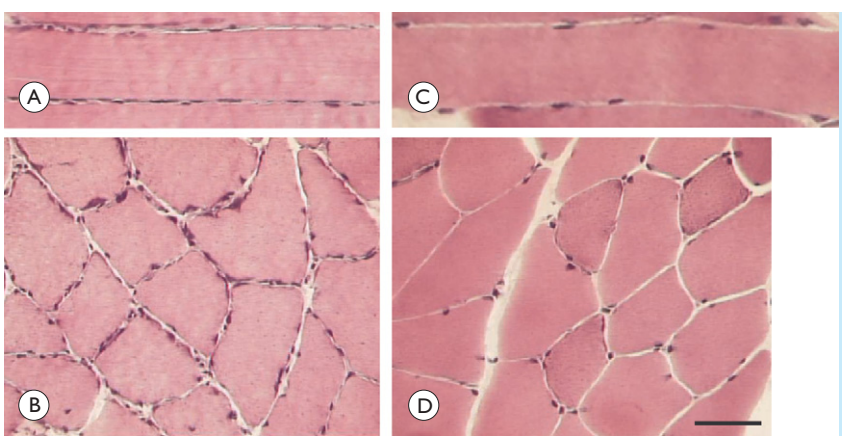

Fig. 5.28
Representative images of longitudinal (A and C) and transverse (B and D) sections stained with hematoxylin and eosin of a muscle containing predominantly slow fibers (type I) (M. sacrocaudalis dorsalis medialis, A and B) compared with a muscle containing predominantly fast-contracting (type II) fibers (superficial region of the M. longissimus lumborum, C and D). Note the increase in myonuclear number in the fibers from the slow-contracting muscle compared with the fast-contracting muscle. Scale bar, 50 μm.

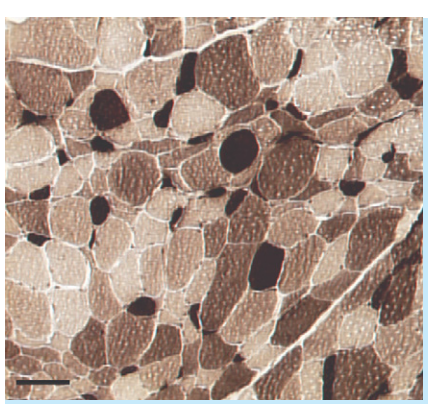

Fig. 5.29
Transverse section of a M. vastus lateralis muscle sample from a horse with denervation atrophy (femoral paralysis) stained with myofibrillar adenosine triphosphatase after acid preincubation. Note selective angular atrophy of some type I (black) and type IIA (white) fibers, while other type I and IIA fibers, presumably belonging to other motor units, are of normal size. Bar, 50 μm.

ing denervation (Figs 5.10, 5.29). Such regulation is particularly evident in slow type I fibers, because their basal neurogenic dependence is significantly greater than faster fiber types (type I > IIA > IIX).[51] Additional factors that are known to influence myofiber diversity include hormonal and drug (anabolic steroid)-induced changes,[3,100–102] that may vary depending on the underlying fiber type.[107] Of particular interest, and as discussed in the sections that follow, neuromuscular (contractile) activity associated with exercise and training has a significant impact on fiber type adaptation and the expression of fiber-specific protein isoforms.

Muscular responses to exercise

When aerobic metabolism can meet energy demands (during submaximal exercise), oxygen uptake correlates with increas-

ing speed.[65] However, the slope of the linear relationship may vary according to the load, incline, track surface and ambient temperature.[65] At a certain point energy demand outstrips oxygen uptake and the shortfall must be met by anaerobic metabolism.[65] Muscle fatigue may occur during either aerobic or anaerobic exercise: in the following sections, we consider the major metabolic changes that occur within muscle, that are believed to contribute to the development of fatigue.

Aerobic exercise

Muscle and liver glycogenolysis starts to occur soon after the start of aerobic exercise. Glucose derived from the liver is subsequently transported into myofibers to join the glycolytic cascade via glucose-6-phosphate formation (see Fig. 5.17). However, although elevated glucose-6-phosphate concentrations have been detected after submaximal exercise in horses,[108] circulating epinephrine (adrenaline) released during exercise stimulates the release of FFAs from adipose tissue and/or liver stores, which partially inhibit glucose utilization during moderate-intensity exercise.[109] Nevertheless, during prolonged submaximal exercise, blood glucose may still account for up to 25% of the total energy output.[63] This reliance on glucose derived mainly from the liver results in an early sparing of muscle glycogen. As energy demands increase, higher rates of pyruvate oxidation tend to cause a further shift towards FFA β-oxidation. The overall effect is that muscle glycogenolysis declines over time during aerobic exercise, whereas FFA oxidation increases.[66]

Although lipids are the predominant fuel utilized during prolonged submaximal exercise, fatigue occurs long before the complete metabolism of lipid deposits.[3] At submaximal workloads, fatigue has been associated with intramuscular glycogen depletion (Fig. 5.30)[63] because FFA oxidation cannot produce sufficient ATP without a source of pyruvate. During prolonged activity, glycogen depletion patterns occur in parallel with the progressive recruitment of fiber types, i.e. initially in type I fibers, then in IIA and finally in glycolytic IIX (see Fig. 5.24). Therefore, muscular fatigue does not occur at the same time in all fibers but in a progressive manner that results in gradual compromise to performance. Following exercise, glycogen repletion occurs in the reverse order (i.e. IIX → IIA → I) and may take up to 72 hours,[110] or sooner with the administration of dextrose[111] or nandrolone.[112]

Although glycogen depletion appears to play a major role in fatigue onset during aerobic exercise, a variety of other factors are also implicated, including AMP deamination, hyperthermia, dehydration, electrolyte depletion and lack of motivation.[63,113,114] The onset of fatigue itself may be hard to assess objectively but recent evidence suggests that electromyography may prove useful in the experimental setting.[36]

Anaerobic exercise

The effects of high-intensity exercise on horse skeletal muscle and development of fatigue have been comprehensively reviewed by Snow & Valberg.[3] In recent years, further research has confirmed many previous observations and provided new insight on mechanisms underlying the onset of fatigue. The functional demands imposed by high-intensity exercise require the recruitment of most motor units within a given muscle; at this time, intramuscular glycogen and blood glucose act as the predominant fuels to replenish ATP during anaerobic glycolysis. In addition, some ATP is derived from the deamination of adenosine nucleotides. In contrast to aerobic metabolism, there is relatively little reliance on FFA oxidation.

Lactate accumulation and pH decline Limitations imposed by oxidative metabolism result in greater amounts of the end-product of glycolysis (i.e. pyruvate) being converted to lactate rather than acetyl-CoA; in the process, NAD is used to regenerate more ATP. As a consequence, muscle lactate concentrations increase during anaerobic exercise.[89,90,115–117] This rise is correlated with the proportion of type II fibers within muscles.[118] Initially, intracellular lactate accumulation is removed from the cell by active transport into the blood (see Figs 5.18, 5.31).[119] Saturation of this mechanism results in a sudden exponential rise in intracellular lactate accumulation, known as the anaerobic threshold, that generally occurs when the plasma lactate concentration reaches about 4 mmol/L.

The rise in intracellular lactate, together with free H^+ ions, results in a significant reduction in cytoplasmic pH[120] that has been suggested to be the major cause of fatigue during anaerobic exercise (Fig. 5.30).[63] Muscle pH may decline to as low as 6.25–6.50 and lead to impairment of both structure and function. Significant disturbance to both mitochondrial and SR ultrastructure has been documented in horses that exhibit

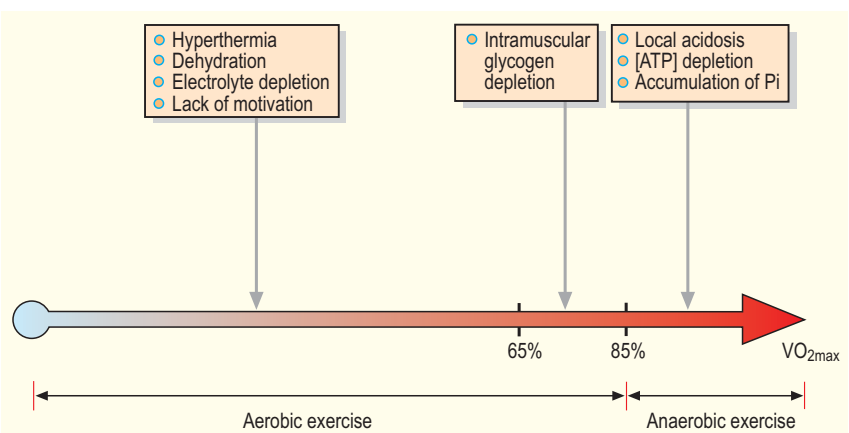

Fig. 5.30
Schematic diagram summarizing the main causes of fatigue during or after exercise of different intensity and duration. Intramuscular glycogen depletion is considered to be the main cause of fatigue during aerobic exercise (work loads between 65% and 85% of VO_{2max}). At lower exercise intensities, however, hyperthermia, fluid and electrolyte depletion and poor motivation have been suggested to be the primary factors in initiating fatigue. Causes of fatigue during supramaximal anaerobic exercise include local acidosis, ATP depletion and accumulation of pyrophosphates (Pi).

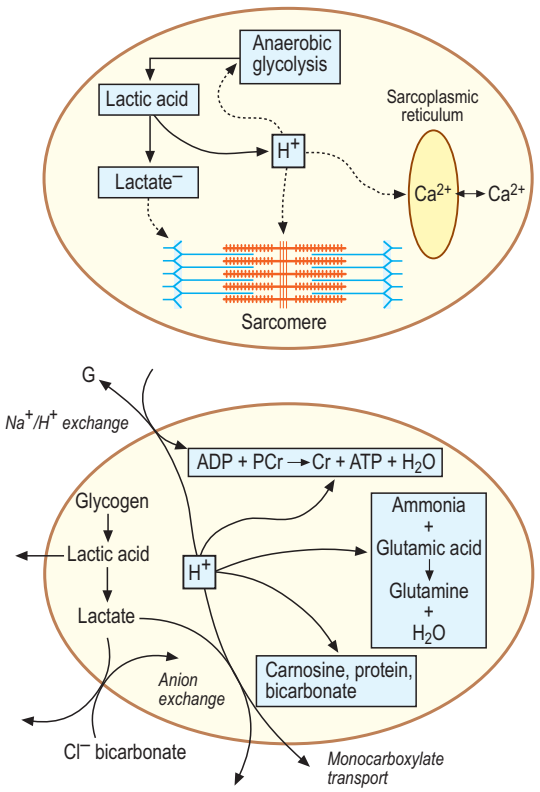

Fig. 5.31
Schematic diagrams illustrating intramuscular acidosis and buffering capacity of muscle (according to Hyyppä & Pösö).[118] (Upper) Performance inhibition (dotted arrows) caused by the accumulation of protons and lactate anions. (Lower) Diagram summarizing the major regulatory mechanisms that control intramuscular pH (explained in reference[118]).
PCr = phosphocreatine; Cr = creatine.

fatigue during maximal exercise.[121] Low pH leads to dysfunction of the excitation–contraction coupling mechanism, due to impairment of the SR calcium release channel (RYR1), together with decreased reuptake of calcium into SR during relaxation.[120] Low pH also inhibits the glycolytic enzyme phosphofructokinase, thereby diminishing ATP production.[118]

A fall in cytoplasmic pH is partially overcome by a buffering system within myofibers (Fig. 5.31). Dynamic buffering of H^+ occurs during the hydrolysis of phosphocreatine in reactions catalyzed by creatine kinase and by glutamine synthetase; static physicochemical buffering is provided by various proteins, bicarbonate, inorganic phosphate and carnosine.[118,122] Race horses have been shown to have a higher muscle buffering capacity than humans,[123] thought to be associated with their myofibers having high carnosine concentration.[76] Muscle carnosine content appears to be influenced by β-alanine bioavailability[124] and is greatest in glycolytic IIX fibers.[76,124]

Nucleotide depletion Since initial observations by Snow and co-workers,[125] numerous studies confirm a decline in muscle ATP concentration during anaerobic exercise,[17,74,89,126] suggesting that ATP regeneration can be insufficient to meet energy demands.[76] Depletion of muscle ATP concentration has also been implicated as a primary cause of fatigue during maximal effort in horses,[63] and a correlation between muscle nucleotide stores after racing and performance has recently been reported.[74] The fall in ATP occurs in parallel with a rise in IMP concentration,[74,126] the latter being a particularly prominent response in equine muscle due to high underlying AMP deaminase activity.[127] High concentrations of IMP within muscle therefore act as a marker for depletion of total nucleotide stores, given that reamination of IMP to ADP and finally restoration of ATP is a slow process, that may take up to 1 hour.[125] ATP depletion and formation of IMP within muscles working maximally are closely correlated with the production of ammonia,[90,115] uric acid[126] and allantoin,[63] all of which may be detected in the plasma. Theoretically, low levels of nucleotides in some fibers would impair the optimal functioning of all ATP-dependent muscular processes. However, because nucleotide depletion occurs concurrently with a rise in muscle lactate and free H^+ concentrations,[74] it is still unclear which of these two mechanisms plays the more significant role in the development of fatigue.

Glycogen depletion Muscle glycogen concentration declines rapidly during maximal exercise[117,126] to an extent that varies between 30% and 50% depending on the number and frequency of exercise bouts.[125] Glycogen depletion occurs most rapidly in the glycolytic low oxidative IIX fibers and occurs simultaneously with lactate formation.[3] Although glycogen depletion is not considered to be a major factor contributing to fatigue during anaerobic exercise,[63] it has recently been demonstrated that decreased muscle glycogen availability diminishes anaerobic power generation and hence the capacity for high-intensity exercise in horses.[128,129]

Other muscular changes Other factors that, though not necessarily contributing directly to fatigue, may result in reduced performance are reviewed by Snow & Valberg[63] and include increased intracellular potassium concentrations,[130] a stochiometric modification to the proportions of free carnitine and acetylcarnitine,[131] increased formation of alanine from pyruvate[132,133] and significant changes in the free intracellular amino acid pool.[134] Additional factors that are implicated include a reduction in calcium SR uptake through decreased Ca^{2+}-ATPase activity[135] and a rise in muscle temperature occurring during high-intensity exercise.[120]

Muscular response to training

Overview

Equine skeletal muscle has considerable potential to adapt during training, largely mediated by the structural and functional plasticity of myofibers. These long-term adaptations occur independently from the immediate or short-term physiologic responses to either aerobic or anaerobic exercise and are associated with altered rates and regulation of transcription of specific genes and consequently a change in the amount or isoform of proteins expressed within muscle fibers.[136]

Depending on the nature (type, frequency, intensity and duration) of the stimulus (exercise training), the adaptive

response can take the form of: (1) hypertrophy, when myofibers increase in size but otherwise retain their basal structural, physiologic and biochemical properties; or (2) remodeling without hypertrophy, where myofibers do not enlarge but acquire markedly different enzymatic and structural characteristics, often accompanied by changes in the microvasculature; or (3) a mixed response, i.e. remodeling in conjunction with hypertrophy (Fig. 5.32). Furthermore, the modality and amplitude of the response depend significantly on the basal muscle profile before training.[137] This is because the increased contractile activity that is associated with training induces a change towards slow and oxidative muscle profiles. Hence fast-twitch fibers (and therefore muscles that contain a higher proportion of glycolytic fibers) can show a relatively greater training adaptation than slow-twitch fibers. This response is particularly prominent in young inactive horses, which have a high percentage of glycolytic (low oxidative) pure IIX fibers (Fig. 5.33A,B), in contrast to active but more mature horses which have muscle fiber type profiles that are more oxidative (Fig. 5.33C,D). Although it can be hard to differentiate altered fiber properties caused by growth and training, specific training effects have been delineated in growing foals[99] and young horses.[83,84,138–141] Overall, muscular adaptations with training have important physiological implications that influence power generation, shortening velocity and resistance to fatigue.

Muscular adaptations to training

Muscle fiber size

The effects of training on equine muscle fiber size are still controversial. In general, the adaptive response of equine skeletal muscle to early and long-term exercise training takes the form of remodeling with minimal, if any, muscle fiber hypertrophy (see references[3] and [142] for reviews). However, specific muscle fiber hypertrophy can be stimulated with bursts of muscle activity against high resistance[83,143] and by prolonged stretch beyond normal resting length.[12,84] Six months of conventional jump training in competitive showjumpers also induces a selective hypertrophic growth of type II fibers, with minimal switching between myofiber phenotypes.[144] Other longitudinal studies have also reported significant and early (less than 3 months) increases in the mean cross-sectional areas of type I and/or IIA fibers after training.[72,82,145,146] This is partially explained by the simultaneous fiber type conversion in the direction IIX → IIA → I, since IIX and IIA fibers show greater cross-sectional areas than type I fibers (see Table 5.1). In contrast, in other studies of Standardbreds and Thoroughbreds, minimal changes[5,19,147,148] or a reduction in type II fiber cross-sectional area[139,149–151] have been reported. These observations are hard to reconcile with the prominent increase in muscle mass, especially in the hindquarters, that is generally observed in horses after most training programs.[3,143] When considered together, the only explanation for an increase in muscle mass, despite either no change or a reduction in fiber size, is a parallel increase in the number of muscle fibers (hyperplasia) that has previously been demonstrated in human beings.[152]

Muscle fiber type transitions

Muscle fiber type distribution and MyHC composition are strongly influenced by training (Figs 5.34, 5.35). Studies on endurance training in horses have demonstrated (by myofibrillar ATPase histochemistry) increases in the fraction of type IIA fibers, with concomitant decreases in IIX fibers[82,95,149,150,153,154] together with a relative reduction in MyHC-IIX and increase in MyHC-IIA.[84] In addition, several endurance training studies in horses have reported fiber transitions beyond type IIA fibers, i.e. an increase in hybrid I+IIA

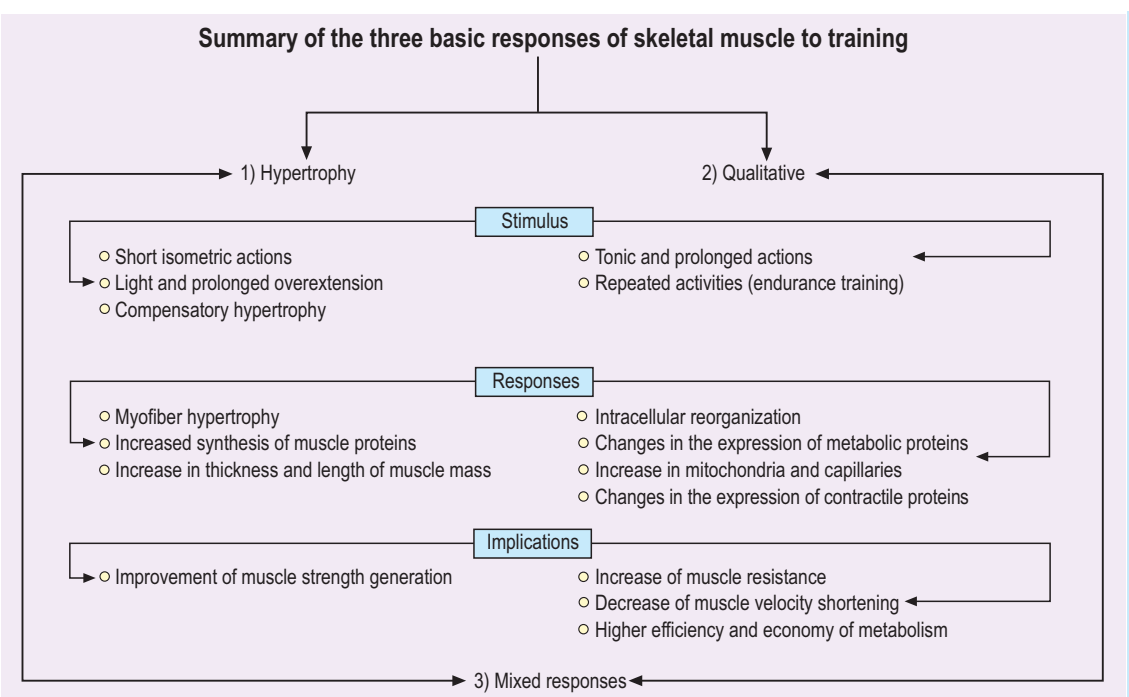

Fig. 5.32 Summary of the three basic responses of skeletal muscle to training: (1) hypertrophy, (2) remodeling without hypertrophy, and (3) remodeling with hypertrophy. Possible stimuli and the nature of the responses and physiological implications are indicated.

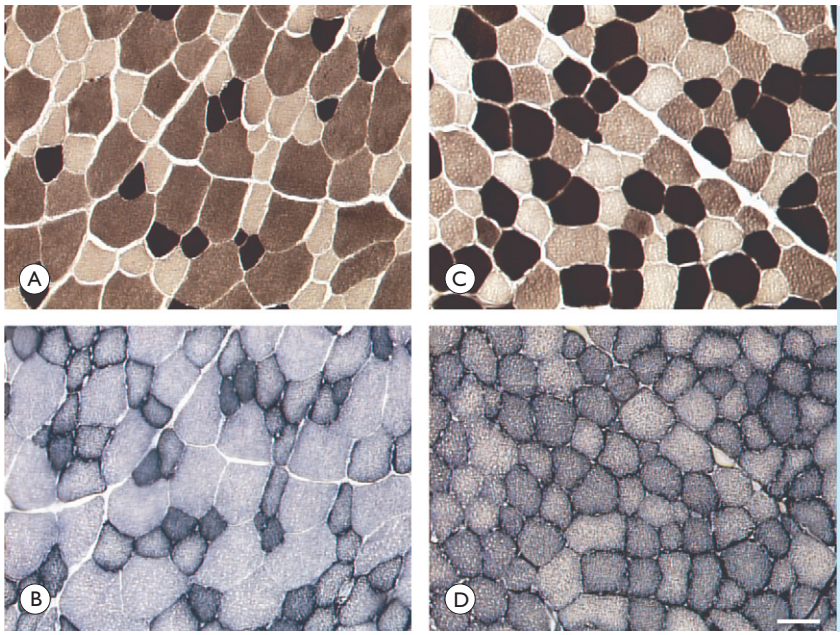

Fig. 5.33
Transverse serial sections of gluteus medius muscle biopsies stained with myofibrillar ATPase after acid preincubation at pH 4.45 (A and C) and succinate dehydrogenase (B and D) in a young adult (3 year old) and untrained Andalusian horse (A and B), and in an adult and regularly trained (10 year old) Andalusian horse (C and D). Note that the young animal has a lower proportion of type I fibers and a higher percentage of low-oxidative type IIX fibers than the adult horse; furthermore, differences in fiber size are much more pronounced in the young animal than in the adult. This therefore may explain the broader range of adaptive responses to training in young untrained horses than in adults or regularly trained animals. Bar, 50 μm.

fibers, and pure type I fibers.[5,82,84,155] Fiber type transitions during resistance training appear to resemble qualitatively those observed in endurance training. Hence, strength training in horses has been shown to result in an increase of both the IIA : IIX fiber ratio[141,145] and, when training is long enough, the I : II fiber ratio.[83] Similarly, sprint training in horses has been shown to cause increased numbers of type IIA and decreased numbers of type IIX fibers,[156] with corresponding alteration to the respective MyHC content.[72,157] In contrast to endurance and strength training, a specific decrease of type I fibers has been reported as an early, and probably transitory, response to high-intensity training.[156,157]

When these various training studies are considered in combination, it is reasonable to assume that fiber type transitions occur in a graded and orderly sequential manner and typically change from faster, more glycolytic fibers to slower and more oxidative fiber types, i.e. IIX → IIAX → IIA → IIA+I → I.[137] A dose–response relationship between the duration (in total) of the training program and the magnitude of induced changes has recently been demonstrated at the molecular level.[83,84] This relationship can be explained more readily in terms of a threshold for the type IIX → IIA transition during the early phase of training, and then a further threshold for the type IIA → type I transition. Thus, a single fiber is capable of a complete fast-to-slow transforma-

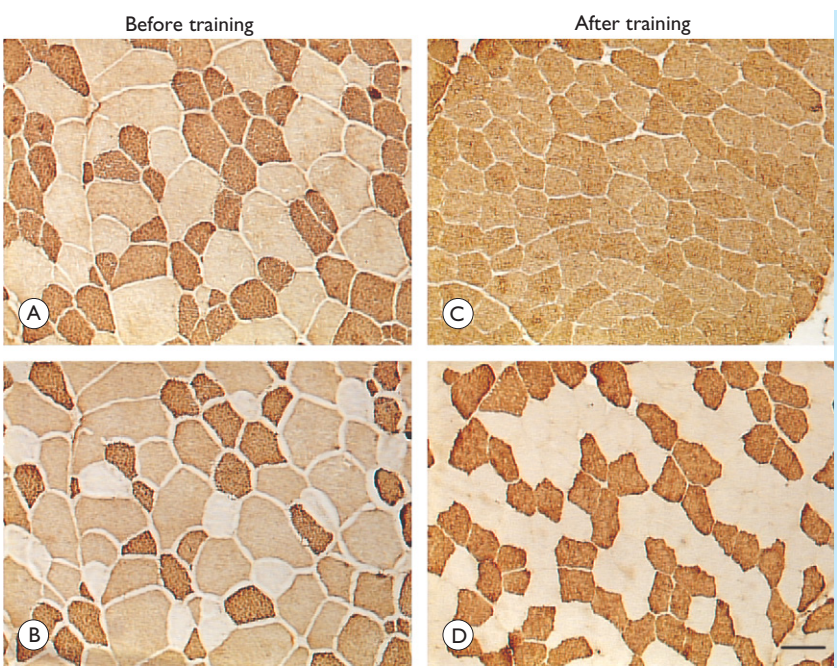

Fig. 5.34
Transverse serial sections of M. gluteus medius biopsies (depth, 6 cm) of the same horse before (A and B) and after (C and D) a long-term endurance training program (9 months in total). (A and C) Sections are stained by immunohistochemistry with a monoclonal antibody to types I or IIA myosin heavy chain isoforms; note that almost all muscle fibers express either or both of these isoforms after training. (B and D) The same sections stained by immunohistochemistry with a monoclonal antibody specific to type IIA myosin heavy chain isoform; note the significant increase in the number of fibers expressing this isoform after 9 months of training. Scale, 50 μm. Details of the training program are described in reference[84].

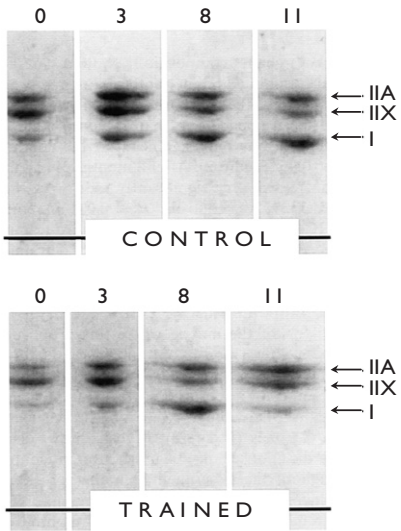

Fig. 5.35
Eight percent sodium dodecyl polyacrilamide gel electrophoresis of muscle samples from the gluteus medius muscle of a control horse (upper row) and a trained horse (bottom row) throughout an experiment to investigate the effects of prolonged endurance exercise training and detraining program. 0, pre-training; 3 and 8, after 3 and 8 months of training; 11, after 3 months of detraining. More details of the experiment in Serrano & Rivero.[83] The three myosin heavy chain isoforms are identified as I, IIA and IIX. Note the effect of training on the relative densities of the I and IIX bands, indicating a fiber type transition in the order IIX → IIA → I.

tion in response to a sufficiently long physiological training stimulus. Although many reports have investigated the training response shown by muscle fibers in terms of the MyHC component, it is important to remember that many other protein isoforms, such as the sarcomeric isoproteins, the regulatory proteins of the thin filaments and the calcium regulatory proteins of the SR, change in parallel.[158]

Metabolic changes and increased capillary density

Perhaps the most commonly detected and earliest muscular adaptation to training is an increase in the activity of enzymes of aerobic metabolism, such as selected enzymes of the TCA cycle, the electron transport chain and fat oxidation.[72,84,86,100,156] These changes are associated with increased mitochondrial and capillary densities (Fig. 5.36).[12,82,93,159,160] The latter response promotes improved oxygen diffusion and more expeditious removal of waste products (such as CO_2).

The activities of key anaerobic enzymes, such as phosphofructokinase and lactate dehydrogenase, either do not change or decrease following training.[3,72,84,86] Although training also results in an increase in the activity of AMP deaminase and other enzymes of the purine nucleotide cycle, such as creatine kinase (discussed in reference[3]), the concentration of total nucleotide stores is not affected by training.[156] Training has also been shown to result in a modest increase in muscle glycogen storage[84,148,161] that may well be associated with reduced levels of glycolytic enzymes, since the capacity to mobilize endogenous glycogen is partially influenced by the absolute activity of anaerobic enzymes expressed within muscle fibers.[64] In experimental animals, training is known to increase the sensitivity of glucose uptake across the sarcolemma, via increased GLUT-4 expression in muscle.[162] In horses however, moderate-intensity exercise training increases middle gluteal muscle GLUT-4 protein content, but this change is not reflected in an increase in sarcolemmal glucose transport activity in postexercise muscle samples.[163] Furthermore, the transfer of FFAs from the vascular to the intracellular compartment is also enhanced with

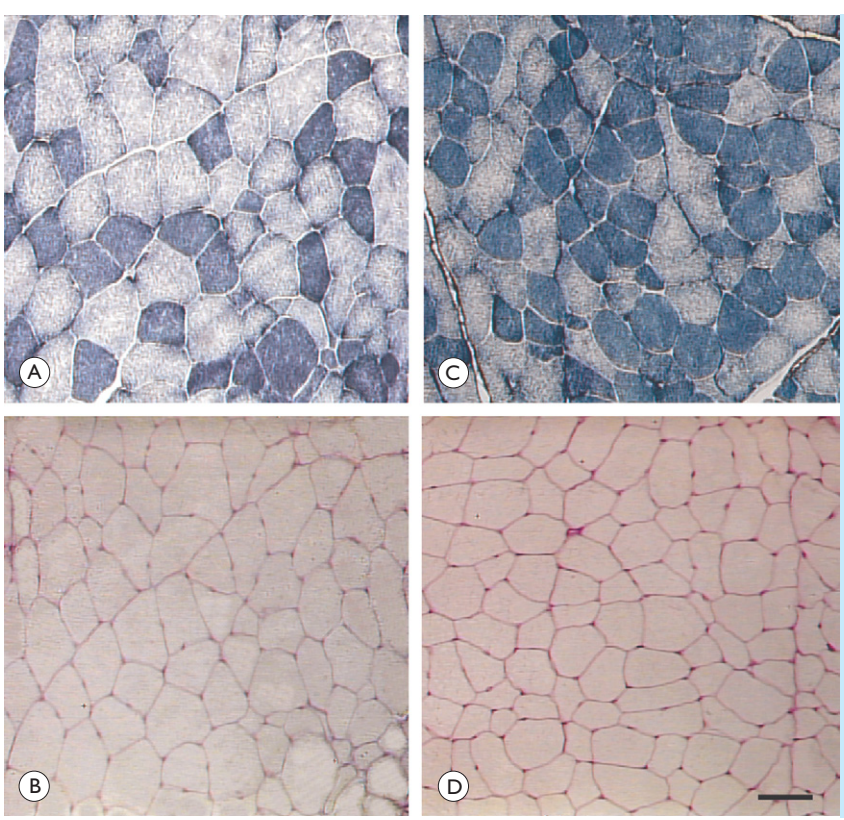

Fig. 5.36
Transverse serial sections of muscle biopsy samples of the M. gluteus medius from the same horse removed before (A and B) and after (C and D) 9 months of prolonged endurance training. (A and C) Sections are stained with succinate dehydrogenase to demonstrate the oxidative capacity of individual muscle fibers; note the increase in the number of fibers with dark staining after training. (B and D) Sections are stained with the α-amylase PAS to visualize capillaries; note the increased capillary density (e.g. number of capillaries per mm^2) after the training program. Scale, 75 μm.

endurance training, via an increase in extracellular (interstitial) albumin concentration.[164]

Physiological adaptations and buffering capacity

Significant effects of training on electrical membrane properties and ion channels have recently been reported in horse skeletal muscle.[165–167] Short-term exercise training of moderate intensity results in an increase in the density of Na^+/K^+-ATPase pumps, measured by oubain binding assays, together with an attenuation in K^+ efflux from working muscles during high-intensity exercise. Although physiologic implications of these training-induced adaptations are unclear, enhanced ionic control at the sarcolemma may result in myofibers that are better able to respond to the rate of motor neuron discharge.[168] Additional responses following physical conditioning include increased SR calcium uptake and Ca^{2+}-ATPase activity and an attenuation of the exercise-induced decline of both calcium uptake and Ca^{2+}-ATPase activity.[169]

Several studies have reported an increase in buffering capacity of equine skeletal muscle after a few weeks of sprint training.[170–172] This increase may be due to (1) increased incorporation of myofiber protein, (2) higher muscle carnosine concentrations or (3) increased creatine phosphate concentrations.[118] However, no differences in muscle carnosine concentration were found between trained and untrained Thoroughbreds.[173]

Detraining

Adaptive training responses of skeletal muscles are maintained through 5–6 weeks of inactivity,[12,148,150] but not beyond 12 weeks.[82–84,174] This maintenance of the trained phenotype during inactivity appears more prolonged in horses than other athletic species. It has been suggested that expression of the MyHC-IIX gene constitutes a default setting that may be altered (decreased) by chronic increases in contractile activity (i.e. training), and compensated for by increased expression of MyHC-IIA.[175] In line with this hypothesis is the observation reported in horses that a return to sedentary activity levels following a prolonged period of endurance training results in normalization of expression of MyHC-IIX, via a slow-to-fast fiber type transformation in the order I → IIA → IIX (Fig. 5.35).[84] These detraining-induced changes in MyHC phenotype occur in parallel with a reversion of the muscle's size and metabolic and capillary characteristics to pre-training levels.[84] Thus, fiber sizes decrease, together with a decline in mitochondrial density, aerobic enzyme activities and glycogen content, and an increase (normalization) of anaerobic enzyme activities.

Possible mechanisms underlying muscular adaptations to training

Skeletal muscle responds to altered functional demands by specific quantitative and/or qualitative alterations in gene expression (Fig. 5.37), provided that the stimuli are of sufficient magnitude and duration.[158] Repeated or persistent elevation of neuromuscular activity (i.e. during exercise and training) induces a series of concerted changes in gene expression, evoking either myofiber hypertrophy or myofiber remodeling, or both.[136] Myofiber hypertrophy is characterized by a generally co-ordinated increase in abundance, per fiber, of most protein constituents. To a limited extent, this process includes the selective and transient activation of specific genes immediately following the onset of work overload. The major events however, underlying muscle hypertrophy involve a general and non-specific augmentation of protein synthesis within cells. Remodeling of myofiber phenotype, with minimal or no hypertrophy, is the typical muscular response to prolonged training in the horse.[84] During this type of adaptation, myofibers undergo a striking reorganization, with selective activation and repression of many genes. Thus, switching among different myofibrillar isoproteins occurs in a graded and orderly sequential manner.[158] These changes occur in parallel, but not simultaneously over time, and correspond to the changes observed in enzymatic profiles, cytosolic proteins and membrane receptors and transporters.

The complexity and pleiotropic nature of the physical and metabolic stimuli presented to myofibers during contractions that ultimately result in altered gene regulation have been reviewed by Williams & Neufer.[136] Acetylcholine released from motor neurons and other signaling molecules of neural origin bind to cell surface receptors on myofibers and trigger intracellular events that may be linked to altered gene expression and hence to appropriate modifications (Fig. 5.38). Additional signals are probably derived from contracting myofibers experiencing mechanical stresses that perturb the sarcolemma and extracellular matrix, as well as exerting tension via intermediate filaments on the cytoskeleton, organelles and the nucleus.[176] Changes in the intracellular concentrations of ions and meta-

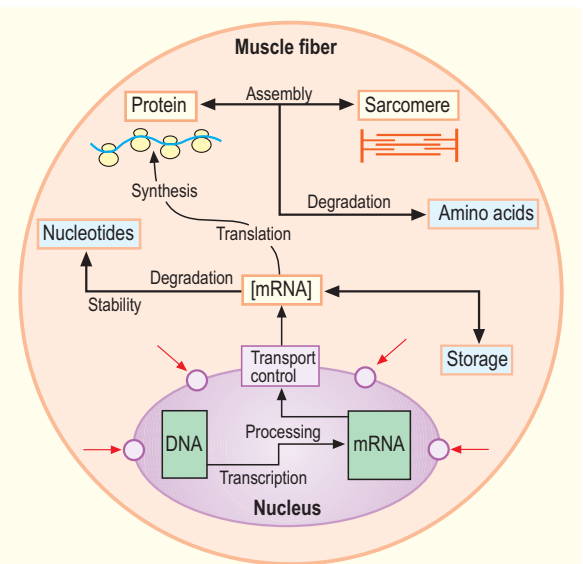

Fig. 5.37

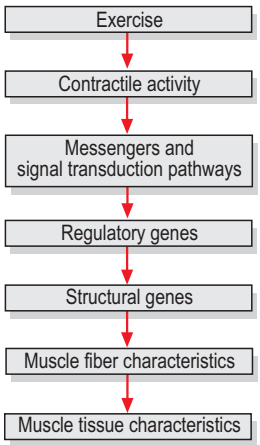

Fig. 5.38
Steps in the cascade of events by which exercise and increased neuromuscular activity lead to physiologically relevant changes in the characteristics of skeletal muscle.

bolites during chronic muscle contractions have also been implicated in the activation of signaling pathways.[64] These messengers include alterations in calcium concentration, acidosis during anaerobic exercise, the marked reduction in phosphorylation potential of the adenylate system ([ATP]/[ADP_{free}]), a depletion of the redox state (NADH/NAD), and hypoxia. Among all these factors, the imbalance between energy requirement and energy supply is perhaps the most important signal triggering an appropriate adjustment in contractile and metabolic protein expression.[177] Recent years have seen significant advances in our understanding of the signaling mechanism by which the information contained in specific action potential patterns is decoded by the transcriptional machinery of muscle fiber nuclei.[178] For example, Ras-mitogen-activated protein kinase[179] and calcineurin[180] signaling have recently been implicated in the α-motor neuron induction of slow muscle fiber phenotype, but not muscle growth. Conversely, a protein kinase B-dependent and rapamycin-sensitive pathway controls myofiber growth but not fiber type specification.[181]

Specific genes that regulate skeletal muscle following contractile activity include most genes that encode sarcomeric and cytosolic proteins, and enzymes of the glycolytic pathway, TCA cycle, the electron transport chain and fat oxidation.[136] There are, however, special signals for control of mitochondrial genes. These pathways require co-ordinated induction of some nuclear genes encoding mitochondrial proteins, as well as increased expression of genes located within mitochondrial DNA. The factors that promote angiogenesis in skeletal muscle in response to training have not been clarified although they may be related to a chronic increase in muscle capillary blood flow and the corresponding endothelial shear stress, as well as increased capillary wall tension.[182] Hudlicka and colleagues speculated that endothelial stress may disturb the luminal surface, resulting in the release of bound proteases that damage the basement membrane and contribute to an increase in basic fibroblast growth factor release.[182] Subsequently, the growth factors may enhance vascular growth and satellite cell proliferation.[183] However, much information is still unclear, including the influence of training intensity and duration on neovascularization and the mechanisms that underlie the increase seen in intramuscular substrates in response to long-term endurance training. These latter adaptations may be related to either (1) increased glucose and FFA availability (via GLUT-4 and albumin respectively), (2) a lower utilization of these substrates for energy production or (3) possible artefacts imposed by experimental design (i.e. they may be a reflection of increased dietary intake of soluble starches and fat from a parallel change in diet for horses in training).[3]

Implications of training-induced changes to the physiologic response to exercise

The main physiologic consequence of increased muscle mass in response to training is to produce a muscle with a greater peak force capacity, because force output is proportional to total cross-sectional area of the fiber mass recruited.[168] At slow speeds, this adaptation has an impact on gait, causing a marked reduction of both stance time and stride duration.[95] Additionally, such an adaptation has a significant impact on the performance of showjumpers via enhanced power output from the hindquarters.[144] Furthermore, because increased power output results in a greater ability to accelerate and may increase stride length, these training adaptations (strength rather than endurance) may be important for race horses competing over short distances.[3] However, enhanced power through training comes with the cost of a corresponding decline in aerobic potential, because the increased mass of recruited fibers and concomitant rise in ATP utilization occur simultaneously with a relative inability of oxygen to diffuse into the larger fibers.[150]

From a physiologic standpoint, remodeling of myofiber phenotype with minimal or with no hypertrophy, in response to training, produces a muscle that is much more resistant to fatigue but with an intrinsic decrease in maximal velocity of shortening. The rise in resistance to fatigue corresponds to each myofiber's increased oxidative capacity. The reduction in contractile speed is associated with the switch of muscle fiber types and the increased expression of slow MyHC and other contractile protein isoforms.[14] In a similar but reciprocal fashion to that described for strength training, some conventional training programs of young race horses produce a decrease in the size of type II fibers[151] and a corresponding decline of both speed and force of contraction.[63] Clearly a balance must be acquired at a level most appropriate for the intended use of the horse: in general, training programs in race horses should be aimed at the development of muscle properties that optimize an equilibrium between speed, stamina and strength.

Following endurance training, exercise at submaximal intensities elicits optimal delivery of oxygen and bloodborne substrates, an early activation of oxidative metabolism with a lower utilization rate of endogenous carbohydrates and an increased reliance on fat oxidation as an energy source. Muscle glycogen sparing is underlying the delay in the onset of fatigue during this type of exercise. It seems highly probable that all these metabolic adaptations are largely responsible for the increased endurance in the trained state and the lower propensity for individual muscles to fatigue as measured electromyographically following 8 weeks of aerobic conditioning.[36] The increased oxidative capacity, which is observed in skeletal muscle after training, occurs concurrently with increased maximum oxygen uptake[12] and a significant reduction in the

net rate of muscle glycogenolysis and anaerobic metabolism.[184] As a consequence, in the trained state, the speed at which a horse begins to accumulate lactate increases gradually (i.e. there is a delay in the onset of lactate accumulation, and ATP depletion).[63,140,141] This is accomplished by enhanced muscle buffering capacity and more efficient excitation–contraction coupling. Hence collectively, endurance may be enhanced by a wide variety of related factors that delay the onset of fatigue during anaerobic exercise.

CHAPTER 6

Muscle disorders of equine athletes

Richard J. Piercy and José-Luis L. Rivero

Veterinarians have long recognized muscle diseases of athletic horses, but only recently have there been significant advances in our understanding of the etiopathogenesis underlying these disorders. These achievements can be attributed to various factors including: (a) recognition of similarities between human and equine muscle diseases; (b) greater awareness that muscle has a limited pathological response despite different mechanisms of injury; (c) subdivision of diseases based on breed susceptibility and histopathology; and (d) the application of molecular and cellular investigative techniques. Future developments should lead to more accurate diagnostic tests and better treatments, thereby enabling the veterinarian to provide an improved service, while benefiting from a more clinically rewarding experience.

General response of muscle to trauma and disease

Muscle tissue has a limited pathological response to different insults whether traumatic, ischemic, exercise induced or due to underlying disease. Cell membrane damage causes abnormal ion fluxes and osmotic imbalance that rapidly perturbs fiber homeostasis. Normally the resting myoplasmic Ca^{2+} concentration is maintained at a concentration that is 60–100 times lower than that of the extracellular fluid (Chapter 5). Membrane damage allows Ca^{2+} to enter the cytoplasm from the interstitium, causing activation of destructive cellular proteases and inhibition of mitochondrial respiration.[1,2] Necrotic cell death is often associated with inflammatory responses including the chemotaxis of neutrophils and macrophages and collagen deposition. However, in certain muscle diseases, fibers die without marked inflammatory responses in which case apoptosis may be responsible.[3]

Muscle's remarkable regenerative capacity is usually associated with a characteristic sequence (Fig. 6.1). Following injury, ruptured myofibers retract, forming a gap between the stumps and allowing access for inflammatory cells via capillaries.[4] 'Contraction bands', condensations of cytoskeletal and sarcomeric material, plug the myofiber stumps and prevent further damage prior to plasma membrane repair.[5,6] Satellite cells, a subpopulation of adult skeletal muscle stem cells[7] that are normally relatively undifferentiated, quiescent and located between the myofiber's sarcolemma and its basement membrane (Fig. 6.2), are responsible for regeneration. Growth factors cause satellite cell activation, division and differentiation within 24 hours.[8] The cells migrate into the damaged region and over a period of about 5 days, fuse to form multinucleated myotubes (often within the basal lamina of the damaged fiber).[9] As the proteins of the myofilaments mature, myotubes gradually differentiate into myofibers,[5] a process taking several months during which histopathology reveals immature fibers of variable sizes and with internally located nuclei (Fig. 6.3).[10] Basement membrane damage results in more extensive fibrosis that may impede reinnervation and revascularization and hence regeneration.[9] Scarring may hinder action potential proliferation; however, this is overcome by sprouts from nearby axons piercing interposed scar tissue and creating new neuromuscular junctions (Fig. 6.4).[9]

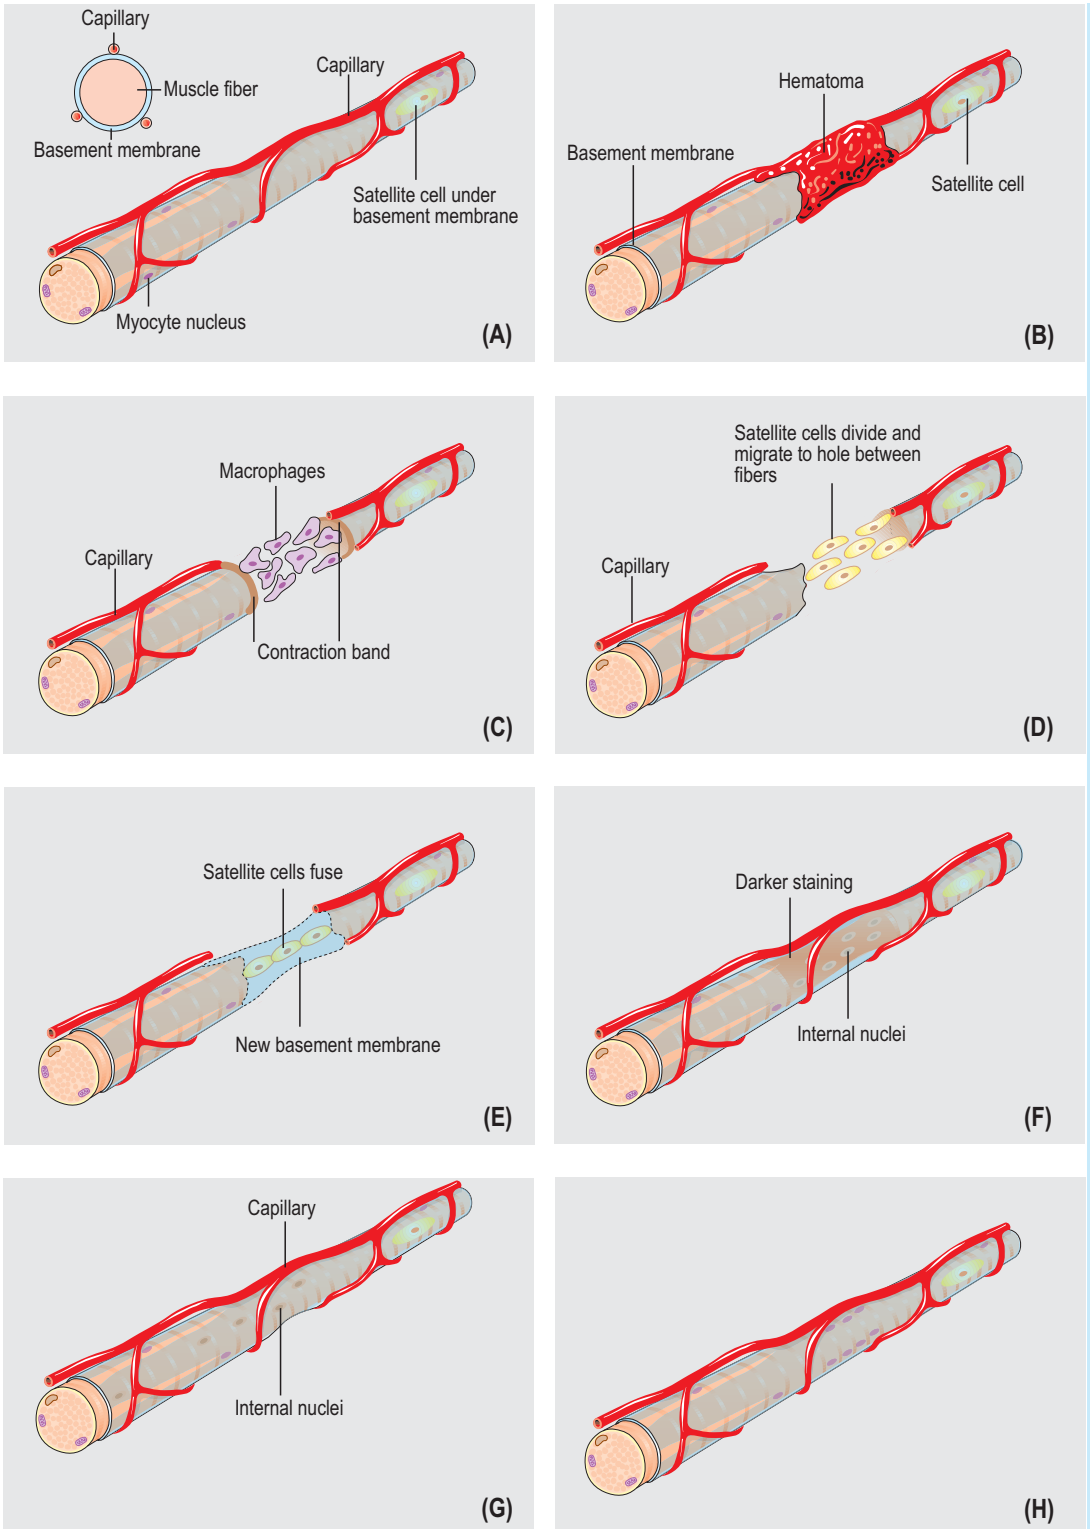

Fig. 6.1
Repair and regeneration in muscle following damage and disease. (A) Normal muscle fiber surrounded by a basement membrane that covers the occasional satellite cell together with a rich network of capillaries. (B) Damage causes myofiber disruption that may or may not involve the basement membrane and hematoma formation, depending on severity. (C) Myofiber stumps retract and the ends become plugged with the contraction band, made of sarcomeric proteins. Macrophages migrate into the (remnants of the) basement membrane cylinder within the first 24 hours and engulf and remove damaged tissue. (D) Satellite cells become activated (12–24 hours following injury), proliferate, differentiate into myoblasts and migrate to the damaged region. By days 2–3, satellite cells align and bridge the gap, fusing between the fiber stumps (E). The process continues over the next week as narrower, more differentiated myotubes with internally located nuclei form (F) followed by more mature myotubes (G). Nuclei return to the normal subsarcolemmal location over several months (H).

Muscle damage caused by trauma, strains and tears

- Muscle damage caused by strains or tears is common in athletic horses.
- The site of damage dictates the signs that may include lameness or back stiffness.
- Plasma CK and AST activities may be mildly elevated.
- Ultrasound, thermography and scintigraphy can aid diagnosis.
- Rest and non-steroidal anti-inflammatories often bring full return to function.

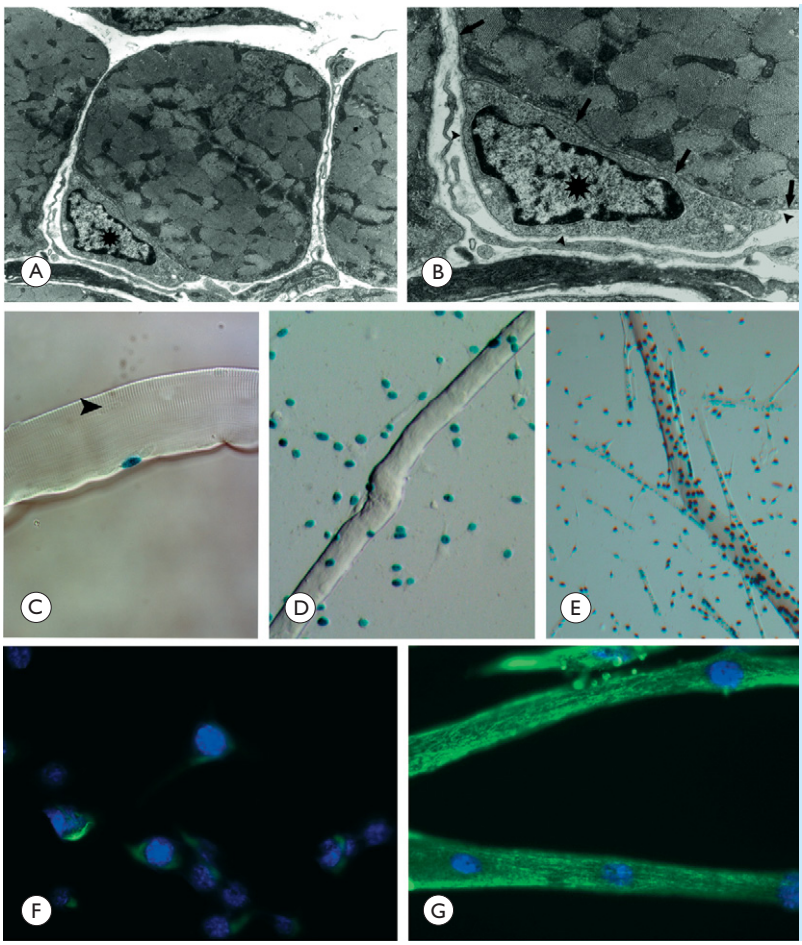

Fig. 6.2
Satellite cells in vivo and in vitro. (A) Satellite cell in situ on the sarcolemmal surface of a 9-day-old B10 mouse muscle fiber. Notice the patchwork-like distribution of myofibrils in the muscle fiber and the satellite cell nucleus marked with an asterisk. (B) Higher power view of the satellite cell from (A) showing the sarcolemma (arrows) and the basement membrane (arrowheads). (C) Single muscle fiber in culture following its isolation from a transgenic mouse that expresses lacZ (blue staining) in satellite cell nuclei in response to Myf5 transcription factor expression;[231] notice the fiber striations and the unlabeled subsarcolemmal myonuclei (arrowhead). (D) Single fiber from a transgenic mouse (as in C) following several days in culture. Notice the proliferation of satellite cells. (E) Following several further days in culture, satellite cells begin to fuse into myotubes. (F) H2K myoblasts in culture labeled with a monoclonal antibody to the muscle-specific protein, desmin (green); nuclei are stained blue with the chromosomal DNA marker 4,6-diamidino-2-phenylindoledihydrochloride hydrate (DAPI). (G) H2K cells as in (F) following their differentiation and fusion into myotubes.

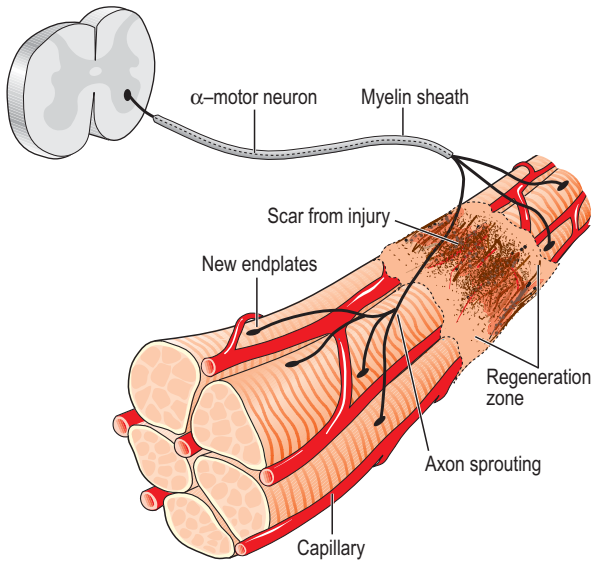

Fig. 6.4
Diagrammatic representation of resprouting of an α-motor neuron following injury to a group of myofibers. Axon sprouts penetrate interposed scar tissue forming new end-plates, thereby reinnervating the myofiber stumps.

Recognition

History and presenting complaint

Delay in the onset of inflammation after trauma may complicate the history, but pain may be evident in showjumpers and eventers (both prone to lumbar and gluteal strain) as unwillingness to jump or turn sharply[11] or in other animals as mild to moderate lameness or stiffness. Generally injuries occur during exercise but severe muscle damage can follow prolonged recumbency[12] or direct trauma.[13,14]

Physical examination

In acute stages, palpation reveals painful muscles with focal heat, swelling and edema. Trauma, secondary to impact injury, may be associated with overlying skin damage. In more chronic cases an organizing hematoma and/or a scar may be palpable. Certain lacerations and muscle tears may manifest as an abnormally held limb, unusual gait or an inability to bear weight.[14,15]

Special examination

Radiography may rule out bony abnormalities such as avulsion fractures. Thermography, scintigraphy and ultrasound can aid diagnosis and lesion localization and help assess healing.[16–18]

Laboratory examination

Plasma muscle enzyme activities may be increased in the early stages.

Diagnostic confirmation

In some cases establishing a definitive diagnosis may be difficult, but confirmation is aided by ruling out skeletal injury.

Treatment and prognosis

Therapeutic aims

Minimizing further damage while allowing for repair and regeneration of the damaged muscle and providing analgesia are critical.

Therapy

Adequate rest followed by gradual return to exercise is essential. Severe injuries may require immobilization in casts or splints. Non-steroidal anti-inflammatory drugs (NSAIDs) (e.g. phenylbutazone 4.4 mg/kg i.v. or p.o. q 12 h for one day followed by 2.2 mg/kg p.o. q 12 h for several days; or flunixin meglumine 0.5–1.1 mg/kg i.v. or p.o. q 12 h or q 24 h) provide analgesia and may reduce fibrosis. Massage, electrical stimulation and swimming may speed recovery.

Prognosis

The prognosis for most muscle strains and tears is good, although fibrosis may cause mechanical lameness.[19] When severe, or where tearing occurs near the myotendinous junction, the prognosis for return to full function becomes guarded.

Prevention

Although traumatic injuries are hard to prevent, exercise-induced injuries are less likely when horses are warmed up before work and exercise schedules are intensified gradually.

Exertional rhabdomyolysis syndromes (during acute and between intermittent episodes; acquired, idiopathic, defective calcium regulation, polysaccharide storage myopathy)

- Both acquired and inherited forms of exertional rhabdomyolysis exist.
- Overexertion is a common acquired cause.
- Likely inherited causes include a disorder of defective myofiber calcium regulation and another associated with abnormal muscle polysaccharide accumulation.
- Environmental effects probably modify the phenotype in genetically susceptible animals.

- Severity ranges from subclinical to life threatening.
- Pain may be severe.
- Plasma CK and AST activities are moderately to markedly elevated.
- Myoglobinuria may cause renal tubular damage and acute renal failure.
- Muscle biopsy is indicated in animals with histories of multiple episodes.
- In acute cases, rest and intravenously administered isotonic fluids and analgesics form the mainstays of treatment.
- Dietary management can prevent episodes recurring in some horses.

There are many historical, somewhat speculative reports suggesting different possible causes of equine exertional rhabdomyolysis (ER).[20] A large number of causes is unsurprising given the numerous acquired and inherited forms in humans.[21] However, since certain types of equine ER appear to have underlying genetic causes, the intermittent and varying severity of phenotype in these animals may be explained by the influence of modifying genes and environmental factors, factors that in the past were determined to be the primary etiology. Episodes of rhabdomyolysis not generally associated with exercise may be of toxic, infectious, immune-mediated or iatrogenic origin and are not included in this chapter but are discussed in detail in general medicine texts.[12,22]

The recent identification of certain specific forms of ER means that classification can now be based on the underlying etiopathogenesis. In the text that follows, the clinical sections have been written in a manner aimed at the investigation of a case with unknown etiology, when there are generally two presentations. The first is that of an animal with acute signs requiring emergency medical treatment. The second scenario is a clinically normal horse with a history of several episodes of ER or a history of poor performance. The clinical investigation and management for each situation differ, even though the underlying cause may be the same and for this reason they are considered separately.

Acute exertional rhabdomyolysis

Recognition

History and presenting complaint

Often the history includes training or management changes. The complaint may vary from a mild stilted gait to severe stiffness, sweating or recumbency.[23] However, most animals are mildly or moderately affected.

Physical examination

During an attack, horses with ER show varying clinical signs. Mildly or moderately affected animals are tachycardic, with firm painful hindlimb, epaxial and gluteal musculature causing gait stiffness.[23] In some, pain localization may be difficult or pain may be manifest in other ways: male horses, for example, may frequently posture to urinate[24] and other horses exhibit colic. Pigmenturia may be evident, especially in more severe cases (Fig. 6.5). These animals are often extremely painful, tachycardic, hyperthermic and tachypneic; they sweat profusely and may be totally unwilling or unable to move.[23] These horses have widespread muscle involvement and may become recumbent. The worst affected animals may show signs compatible with underlying shock and disseminated intravascular coagulation.

Fig. 6.5 Urine containing myoglobin (brown discoloration) from a horse with severe rhabdomyolysis (plasma CK activity > 700 000 IU/L).

Special examination

The history, clinical signs and clinicopathologic investigation (see below) are usually sufficient to establish a diagnosis of ER but scintigraphy may be helpful to localize and quantify muscle involvement in certain cases.[16]

Laboratory examination

Blood samples Routine clinicopathologic changes in mild cases usually consist solely of elevations in the activities of the muscle-derived enzymes CK and AST. CK is the most convenient and specific marker of acute muscle damage and peaks at 4–6 hours following muscle damage and (unless the damage continues) starts to decline, with a half-life of approximately 12 hours (Fig. 6.6).[25] AST activity peaks about 24 hours after an episode and may remain elevated for several days to weeks.[12,24] Although both CK and AST activities rise in proportion to the degree of muscle damage, they do not always reflect the severity as assessed clinically[12] or the prognosis. Other markers, sometimes used experimentally to assess muscle damage, such as serum myoglobin concentration or aldolase, LDH and carbonic anhydrase III activities, offer few if any clinical advantages over the measurement of CK and AST.

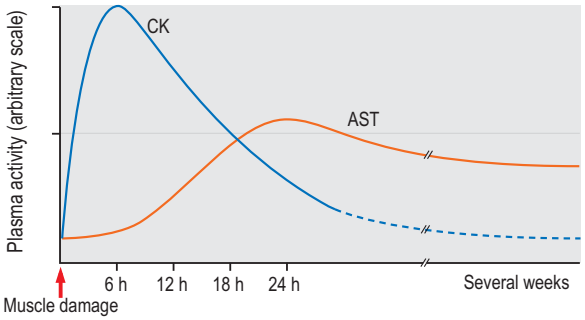

Fig. 6.6
Diagrammatic representation of changes to serum CK and AST activity following an acute brief episode of rhabdomyolysis.

More severe cases have additional less-specific abnormalities. Hyperkalemia may reflect the release of potassium from damaged muscle fibers. The hematocrit and total protein may rise due to intracompartmental fluid shifts. High serum creatinine concentration suggests the possibility of acute renal failure. Complex acid–base abnormalities are sometimes present as the usual hypochloremic metabolic alkalosis[26] shifts to metabolic acidosis if shock ensues. Widespread hematological and biochemical abnormalities are evident in terminal cases.

Urinalysis A urine sample collected early during treatment may, with microscopic examination, reveal urinary casts, a useful indicator of tubular necrosis and impending acute renal failure, prior to the plasma creatinine concentration rising.

Reagent strip analysis of urine does not differentiate myoglobin from hemoglobin, so specific assays are required to determine the cause of any pigmenturia.[12] However, measurement of urinary myoglobin concentration is not usually necessary in an animal with significantly elevated serum muscle enzyme activities. Mild pigmenturia is a normal finding in some horses following high-intensity exercise.[27]

The calculation of electrolyte clearance ratios (see below) during an episode of ER may help evaluate renal function,[28] but should not be used to determine whether electrolyte imbalances were responsible for precipitating the attack.

Necropsy examination

Histopathological assessment often reveals widespread muscle involvement, even in non-locomotor muscles. Occasionally there may be focal muscle involvement so a wide selection of muscles should be sampled, including several epaxial muscles, forelimb and hindlimb locomotor muscles and psoas.

Diagnostic confirmation

In the acute form the disease may be confused with colic, laminitis, tetanus, hyperkalemic periodic paralysis and some cardiac arrhythmias. However, usually these diseases are readily distinguishable by additional signs, specific tests and the lack of significantly elevated serum muscle enzyme activities. Occasionally sedentary horses may present with classic signs of rhabdomyolysis with markedly elevated serum muscle enzyme activities. In these animals underlying genetic susceptibility, more usually associated with exertional forms of the disease, is possible because other events such as stress may precipitate attacks. Toxic, infectious or immune-mediated causes should also be considered.[12,22,29]

Treatment and prognosis

Therapeutic aims

The therapeutic goals are to minimize further muscle damage, establish and maintain diuresis, correct underlying systemic abnormalities and provide analgesia. Early treatment is essential.[30]

Therapy

Management Exercise should be stopped and the horse rested in a deep-bedded stall. In very mildly affected animals gentle hand walking is sometimes recommended.

Fluid therapy Mildly affected animals, in which vital signs are close to normal, can recover without intravenous fluid therapy. However, they should be monitored for signs of deterioration. In moderate to more severe cases, however (even in those without clear pigmenturia), establishing diuresis and preventing or treating hypovolemia is the priority because myoglobin is nephrotoxic. Large volumes of isotonic fluids are usually effective (0.9% NaCl or lactated Ringer's solution infused intravenously at 100–150 mL/kg/24 h). The addition of sodium bicarbonate to fluids, though rarely necessary,[26] is generally only indicated in a horse with metabolic acidosis when the urine remains acidic despite fluid therapy, because myoglobin is significantly more nephrotoxic when in acidic urine.[31]

In rare cases, isotonic electrolyte solutions, even when administered rapidly, cannot compensate for the worsening hypovolemia. This state is reflected by a climbing heart rate and hematocrit, accompanied by a steady or occasionally falling total plasma protein and serum albumin concentrations as widespread muscle lysis and inflammation allow water and proteins to leave the vasculature and enter the interstitium and damaged muscle fibers. These animals often die despite intensive therapy.

Diuretics If there is little or no urine production during appropriate intravenous administration of fluids, attempts should be made to invoke diuresis. Furosemide (frusemide) is generally effective (0.5–1 mg/kg i.v. or i.m. q 12 h). Careful monitoring and adjustment of fluid rates are essential to ensure that diuresis does not cause or exacerbate hypovolemia. Diuretics are not recommended in animals not receiving fluids.

Absence of urination for several hours despite fluid therapy and furosemide (frusemide) suggests oliguric renal failure, in which case renal blood flow may be increased with dopamine (3–5 μg/kg/min diluted in 5% dextrose intravenously) to promote diuresis. Close monitoring of heart rate and the ECG is required because of the risk of tachyarrhythmias.

Analgesia In mild to moderate cases NSAIDs (e.g. phenylbutazone 4.4 mg/kg i.v. or p.o. q 12 h for one day followed by 2.2 mg/kg p.o. q 12 h for several days; or flunixin meglumine 0.5–1.1 mg/kg i.v. or p.o. q 12–24 h) medication

is all that is necessary; however, clinicians should monitor renal function given the drugs' nephrotoxicity. In severe cases more potent analgesics such as butorphanol (0.1 mg/kg i.v. or i.m. q 4–6 h) may be required. In the worst cases the pain is very difficult to relieve.

Other therapy Acepromazine (0.04–0.11 mg/kg i.v. or i.m. q 8 h) has been advocated for its vasodilatory effects within the musculature; however, it should be used with caution in hypovolemic animals. Corticosteroids (e.g. dexamethasone 0.02 mg/kg i.v. q 24 h for 1–2 days) are sometimes used to stabilize membranes, but their efficacy is unproven.

Dantrolene, a drug that limits release of Ca^{2+} from the sarcoplasmic reticulum (SR) via the skeletal muscle ryanodine receptor (RYR1),[32] has been used in the acute stages of idiopathic rhabdomyolysis[33] but pharmacokinetics[34] suggest that the dose and the frequency of administration were unlikely to have resulted in beneficial drug concentrations (when compared with those required to effect a response in humans).[35] Although dantrolene administration has been associated with causing weakness in some horses,[36] emerging experimental evidence suggests that it may be indicated in the prophylaxis or treatment of the acute stages of the form of ER associated with abnormal calcium regulation. As yet, however, the dose required to limit RYR1 release of Ca^{2+} in horses is unknown, as the drug has not been tested. We therefore recommended that clinicians await efficacy trials, particularly given the high cost of the drug.

Prognosis

The prognosis for most horses with mild to moderate acute episodes of ER is good for recovery, but horses with an underlying genetic susceptibility will always be prone to future episodes. For horses in shock, the prognosis is poor. Many horses that develop acute renal failure, if treated early, recover.

Prevention

Refer to the section below that covers investigation and management of horses between episodes.

Exertional rhabdomyolysis (between intermittent episodes)

Recognition

History and presenting complaint

Histories are often compatible with recurring episodes of rhabdomyolysis as described above. Often, a horse is presented because there is no good explanation for the rhabdomyolysis and owners believe that some underlying factor is responsible. Some horses may present with histories of poor performance.[37]

Physical examination

Often animals appear normal when examined.

Special examinations

Exercise testing An exercise test may be helpful in horses with no evidence of ongoing muscle damage (by measuring serum CK and AST activities), but is potentially dangerous in ER-susceptible animals so sound clinical judgment is critical. Exercise testing is contraindicated in animals with evidence of recent muscle damage. The sensitivity and specificity of exercise tests have not been evaluated and the intermittent nature of the disease may result in a negative test in a susceptible animal.[12]

Ideally, a positive test should provoke a subclinical episode of rhabdomyolysis that can be detected via a rise in CK activity between pre- and 4-h post-exercise serum samples. Titrating the amount and type of exercise can be difficult, but should be based on the horse's history and level of fitness. Bouts of maximal exercise appear less likely to precipitate episodes[38,39] and are therefore not recommended. Generally, 10–20 minutes of moderate exercise (trot and canter) on a lunge line or a treadmill is appropriate. Ideally, a normal horse should be evaluated in a similar manner for direct comparison, because some normal animals show a rise in CK activity post exercise; a rise in plasma CK activity of less than 250% has been regarded as normal.[12]

Laboratory examinations

Blood samples Despite a normal physical examination, elevations in plasma CK and AST activities suggest recent muscle damage. A high plasma AST activity without a concomitant elevation in plasma CK activity may indicate that muscle damage has occurred within preceding weeks. However, given that AST is not a specific marker for muscle disease, careful evaluation of the hemogram and biochemistry profile, and if necessary further tests, are indicated to rule out hepatocellular disease.

Electrolyte clearance ratios Clearance ratios are calculated to assess whole-body electrolyte status. Electrolytes and creatinine concentrations are measured in a urine (free catch or catheterized) and serum sample from the same animal. Ratios determined following collection of a single urine sample give similar results to those obtained with a 24-hour pooled (volumetric) urine sample, except for magnesium,[40] but accurate measurement requires urinary acidification (e.g. addition of concentrated nitric or hydrochloric acid)[40,41] to dissolve any suspended crystals. Horses should not eat between collection of the samples.[42]

The fractional clearance for each electrolyte ($FC_{(electrolyte)}$), is calculated as follows.[28]

$$FC_{(electrolyte)}\% = \frac{[electrolyte]_{urine}}{[electrolyte]_{plasma}} \times \frac{[creatinine]_{plasma}}{[creatinine]_{urine}} \times 100$$

where the square brackets represent the concentration (the acidification dilution factor should be factored in). There are wide variations for normal values in veterinary literature,[28,40,41,43,44] probably from differences in management,

sampling and analysis. Normal ranges for FC(sodium) have been reported as 0.04–0.52%; for potassium, 35–80%; for chloride, 0.7–2.1%; and for phosphate, 0–0.2%.[45] However, the identification of wide daily fluctuations in clearance ratios in the same horse, despite standardized management, casts doubt on the test's relevance.[44,46]

Plasma vitamin E and selenium Most ER-susceptible horses are not deficient in vitamin E or selenium, but measuring plasma vitamin E and selenium concentrations may demonstrate deficiencies in animals on poor planes of nutrition or from selenium-deficient areas.

Muscle biopsy A muscle biopsy is indicated in an animal with several unexplained episodes of ER. The technique is described in Chapter 5. The biopsy site is based on the physical examination, but epaxial, gluteal and semimembranosus muscles are most commonly chosen.[29] Ideally, a fresh muscle sample should be snap-frozen in isopentane cooled in liquid nitrogen,[10] but since this is not usually practical, a compromise is necessary. Good results can be obtained when a sample is sent overnight to a suitable laboratory, wrapped in moist but not dripping gauzes (0.9% saline), and chilled (not frozen) on icepacks.[29] Formalin fixation, though more convenient, is unsuitable for histochemical investigation and leads to more artefact; it does allow morphological assessment, however, and has enabled a diagnosis to be reached in cases of polysaccharide storage myopathy (PSSM).[47]

Histopathological lesions of idiopathic cases and ER associated with defective calcium regulation are highly variable and depend on severity and the time between the biopsy and the last bout of rhabdomyolysis (Figs 6.7, 6.8). Mild inflammation with hypercontracted and swollen fibers, interstitial edema and occasionally hemorrhage is seen in single episodes of acute rhabdomyolysis and during the first 24–48 hours following a new episode in animals with histories of recurring episodes (Fig. 6.7A). In this latter group, there may be hyaline degeneration, edema, scattered swollen fibers, fiber fragmentation, necrosis and macrophage infiltration and signs of regeneration (occasional fibroblasts with large nuclei and prominent nucleoli, myotubes and mature fibers with centrally located nuclei) within the same section.

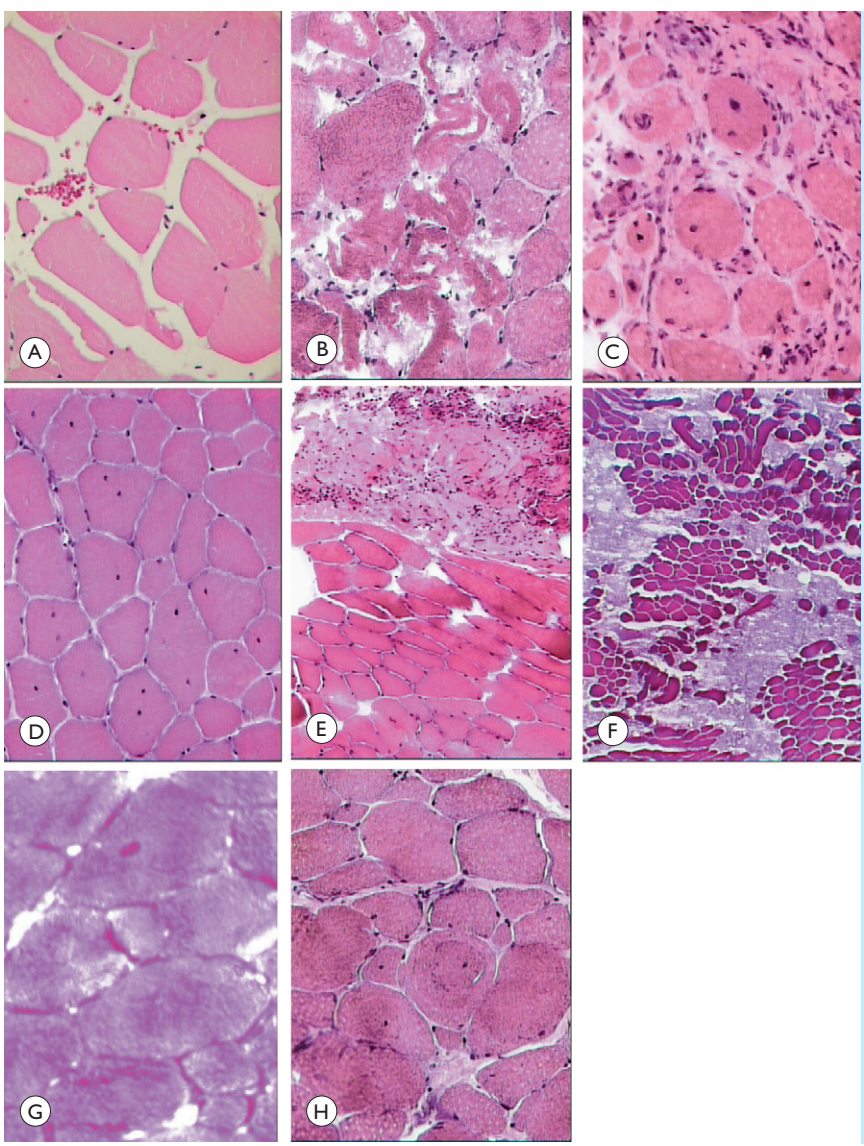

Fig. 6.7
Transverse sections stained with hematoxylin and eosin of the hindlimb and epaxial musculature of horses with idiopathic recurrent ER. (A) Several large, rounded and hypercontracted fibers are shown with diffuse interstitial edema and abundant hemorrhage. (B) Focal hyaline degeneration of type II fibers. (C) Severe myopathic changes characterized by increased fiber size variability, hypercontraction and degeneration, macrophage infiltration and abundant fibroblasts with large nuclei and prominent nucleoli. (D) Mature fibers with internalized nuclei that have regenerated following damage within the previous 1–2 months. (E) A scar is shown in the top of this frame, indicating ineffective muscle repair in an animal after recurrent rhabdomyolytic episodes. (F) Extensive ineffective muscle repair with massive loss of myofibers and replacement by connective tissue. (G) A fiber (top) with an intracytoplasmic mass, probably an aggregate of intracellular calcium. (H) Signs of regeneration including a whorled fiber towards the center.

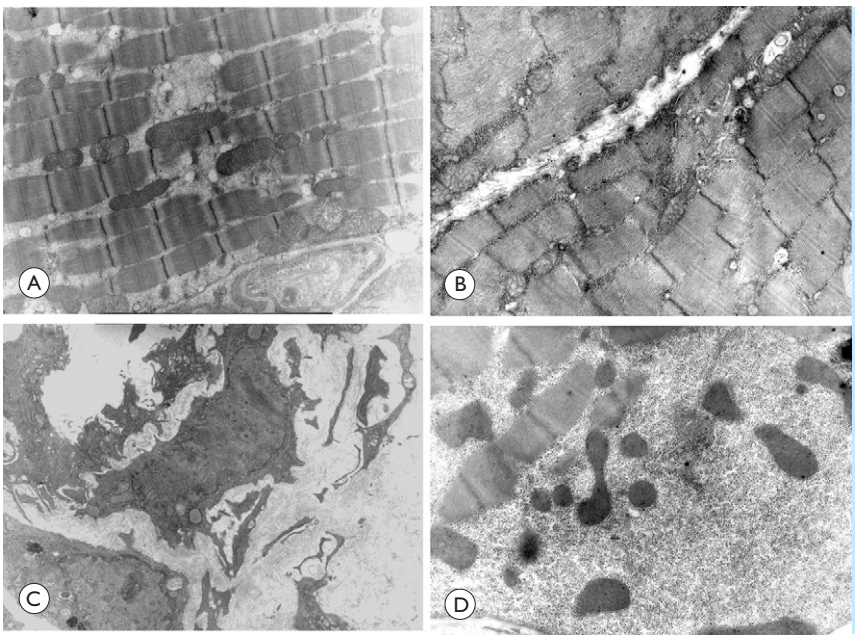

Fig. 6.8
Electron micrographs of muscle from horses with idiopathic recurrent ER. (A) Myofibrillar degeneration with loss of contractile material, dilated terminal cisternae and swollen mitochondria with different electrodensities and abnormal cristae; × 16 800. (B) Loss of myofibrillar architecture with abundant Z-line streaming; × 22 400. (C) Macrophage infiltration; × 11 200. (D) Loss of contractile material with abundant glycogen; × 25 200. (Courtesy of Drs Sucre and Finol from the Universidad Central de Venezuela.)

Additionally, in severe cases, fibrosis, scars and fat infiltration and/or substitution are common (Fig. 6.7E,F).[23,48–50] Fast-twitch (type II) fibers are usually more severely affected than type I. Scattered fibers with subsarcolemmal and/or intracytoplasmic masses, possibly of calcium, are occasionally present (Fig. 6.7G).[51] Other signs of regeneration, such as whorled fibers (Fig. 6.7H), may be observed.

Common electron microscopic lesions found in idiopathic recurrent cases of rhabdomyolysis include myofibrillar disruption with loss of contractile material, streaming of Z disks, dilated SR, enlarged and rounded mitochondria with dilated matrices and degenerated cristae, macrophage infiltration and increased granular deposits of glycogen (Fig. 6.8).[39]

The changes described above are non-specific and reflect the general pathologic processes explained at the beginning of this chapter. Additional histopathologic changes associated with PSSM[47,52,53] include: (a) a heterogeneous distribution of periodic acid-Schiff (PAS) stained intrafibrillar glycogen with subsarcolemmal vacuoles; (b) PAS-positive inclusions; and (c) α-amylase-resistant PAS-positive inclusions (i.e. consistent with abnormal polysaccharide) (Fig. 6.9). The PAS-positive and α-amylase-resistant inclusions are observed in type II fibers, do not stain with ATPase and SDH histochemistry, and have a slight eosinophilic light blue appearance with hematoxylin and eosin stains, magenta to dark blue with PAS and magenta with α-amylase-PAS.[52,54,55] The morphology of these inclusions, as multiple intracytoplasmic 'lakes' and/or as larger or more confluent accumulations totally or partially replacing the fiber in transverse section, is consistent with similar changes recognized in formalin-fixed, paraffin-embedded muscle from affected animals.[56]

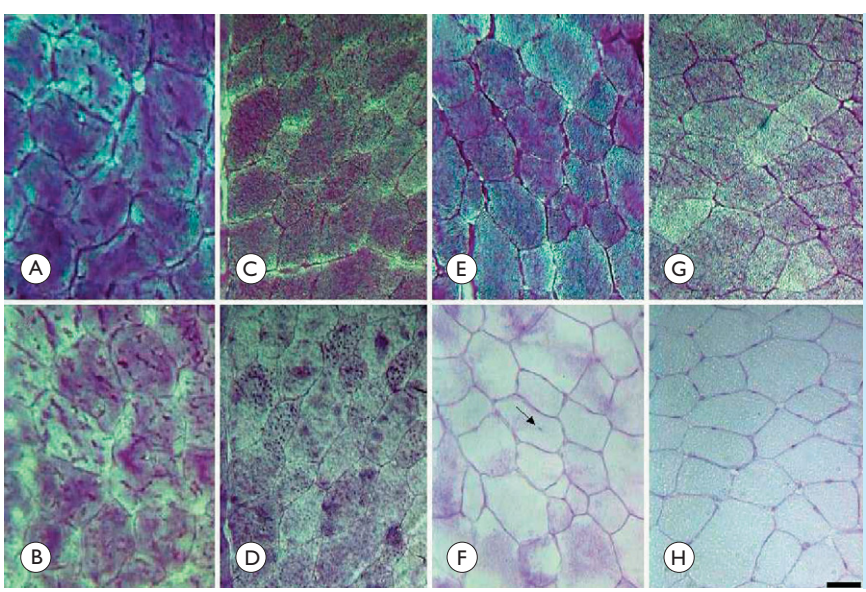

Fig. 6.9
Serial sections stained with PAS (A, C, E and G) and α-amylase-PAS (B, D, F and H) of longissimus lumborum muscle (A and B) and gluteus medius (C and D) muscle from the same horse with PSSM, of gluteus medius muscle from a Standardbred with idiopathic recurrent ER (E and F), and of gluteus muscle from a normal control Standardbred (G and H). Note the high glycogen content and the dark PAS-positive inclusions in muscle from the horse with PSSM (A–D), the lack of PAS-positive material after amylase digestion in idiopathic ER (F) and control (H) horses, as well as the low intensity of the PAS stain in the control (G). An internalized nucleus is present in (F) (arrow). Bar = 25 μm.

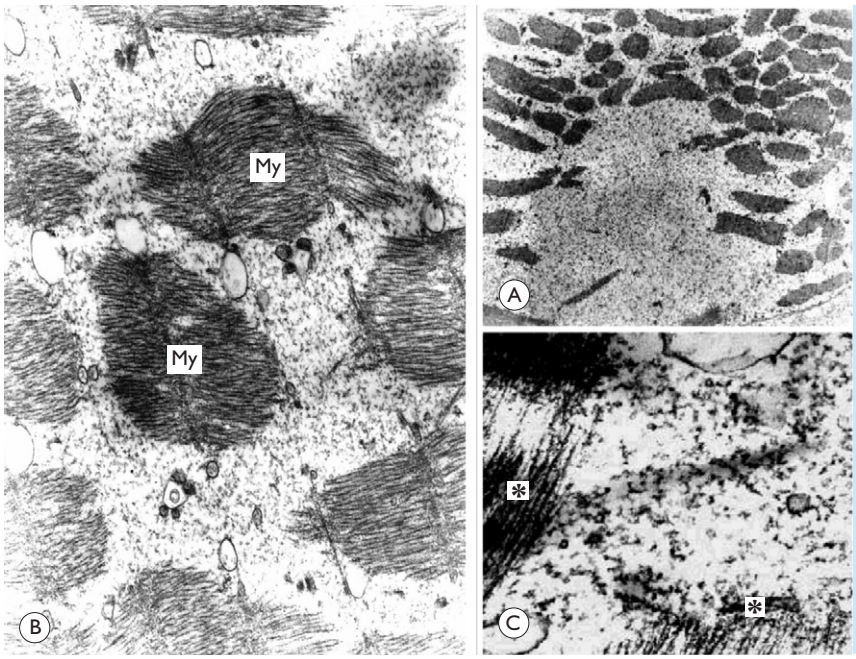

Fig. 6.10
Transmission electron micrographs of M. longissimus lumborum biopsies from horses with polysaccharide storage myopathy (PSSM). (A) A large intracytoplasmic irregular aggregate of granular material is distributed between myofibrils with massive disruption of their normal arrangement (× 20 000). At higher magnifications (B, × 37 000) the inclusions appear to consist of β-particles of glycogen disrupting myofibrils (My) and (C, × 65 000) large aggregates of filamentous material (asterisks).

Pathological features of PSSM may also be observed by electron microscopy (Fig. 6.10). Muscle damage is usually extensive and consists of numerous fibers containing varying degrees of myofibrillar disruption and both loss and disruption of contractile material, characterized by irregular myofibrils and striation patterns. Filamentous material consisting of disrupted contractile proteins and probably abnormal polysaccharide are present amongst excessive granular glycogen.

Although PSSM was originally identified in Quarter Horses,[52] it has also been described in other breeds.[54–58] Even though PAS-staining accumulations that remain following amylase digestion are regarded as a specific feature of PSSM and the disease's hallmark[29,53] they are sometimes absent.[56] Some investigators have overcome this lack of sensitivity by making the same diagnosis based on histopathologic evidence of *myopathy* in combination with excessive deposits of glycogen.[57] Excessive glycogen accumulation occurring prior to the deposition of abnormal polysaccharide is representative of milder and earlier pathologic changes in certain human polysaccharide storage diseases,[59] so there is some justification for this approach. Characteristic PAS-positive, amylase-resistant inclusions are only detectable in (genetically susceptible) PSSM Quarter Horse foals at 3 years of age, some time after their enhanced insulin sensitivity is detectable.[60] However, care must be exercised, given that the PAS staining intensity as quantified by photometry (and hence glycogen content) of muscle from horses with other (idiopathic) causes of ER is higher than in normal controls (Fig. 6.9).[54]

Additional tests Additional experimental tests used further to differentiate etiologies include glucose tolerance testing for diagnosis of PSSM and contracture testing of muscle and calcium fluorescence testing of cultured muscle for the diagnosis of recurrent ER due to disordered calcium regulation.[61–64] However, with the exception of glucose tolerance, these tests require specialist facilities and the expertise of a dedicated laboratory. Further study may result in some of these tests becoming clinically useful in the future.

Diagnostic confirmation

Reaching a diagnosis of ER is not usually difficult but categorizing the disease according to the etiology may be much harder. Both acquired and inherited causes should be considered in an animal with acute signs; in a horse that presents following multiple episodes, underlying genetic predisposition is more likely, although acquired forms should not be overlooked. Certain acquired causes may be obvious from the history (e.g. overexertion) and specific testing may identify other forms.[35,53] Of the disorders that are probably inherited, definitive diagnosis for PSSM can now be made by muscle biopsy. Unfortunately, other cases (away from the research setting) continue to contribute to a large idiopathic category, a situation in common with the diagnosis of human ER.[65] Identification of specific genetic abnormalities responsible for familial forms of ER should provide the means for definitive genetic testing in the future.

Prevention

The association of a disease with a considerable number of anecdotal treatments usually reflects current and historical inability to establish the precise etiology and the treatments' questionable or limited efficacies. Such is the case for the prophylactic treatment of ER where a wide variety of preventive treatments exist,[66] with only a few having been scrutinized objectively.

Diet Despite apparent differences in etiology and pathogenesis[64] the substitution of a proportion of dietary calories derived from soluble carbohydrate, with additional fat, reduces the severity of episodes of ER via poorly understood

mechanisms in both Thoroughbreds with dysfunctional calcium regulation[67] and horses with PSSM.[68,69]

High-fat diets have a calming effect on horses[70] and are associated with lower plasma cortisol concentrations during exercise;[71] since stress has been associated with ER in Thoroughbreds[66] the calming effect may explain the rapid prophylactic efficacy of high-fat diets in recurrent ER caused by abnormal calcium regulation.[67] There is currently conflicting evidence as to whether high-fat (low-carbohydrate) diets reduce the excessive glycogen accumulation in muscle in horses with PSSM[72,73] so further work is required to clarify the attractive hypothesis that the beneficial effect of fat in PSSM is a shift of energy metabolism from the assumed dysfunctional glucose uptake/glycogen synthesis pathways towards β-oxidation.

Most studies have investigated the beneficial effect of a diet that contains approximately 20% fat, together with a reduction in soluble carbohydrate (grain) intake.[67] Increased fat in the diet can be achieved by the addition of vegetable oil (up to approximately 1 g/kg bodyweight per day or 1.1 mL/kg bodyweight per day). Rice bran (15–20% fat) can also be used as a substitute source in animals that find the oil unpalatable[74] or a combination may be suitable in some animals. Forage intake should be at least 1% of bodyweight, but some authors recommend that fast-growing lush pastures and high-quality sweet hays should be avoided.[74] Alfalfa pellets and beet pulp may also be used. Horses should be introduced to higher fat diets over several weeks and the dietary intake of minerals and vitamins should meet recommendations. In particular, owners should ensure that the calcium : phosphorus ratio in the diet is adequate, as rice bran and high-fiber products such as beet pulp contain excessive phosphorus relative to calcium. There are several high-fat, low soluble carbohydrate feeds commercially available.

Exercise Evidence suggests that a regular daily exercise program with changes introduced gradually, and preferably daily access to pasture, may help horses that are susceptible to intermittent episodes of ER.[66,68]

Electrolyte therapy Electrolyte supplementation is appropriate in animals that have been identified as deficient by specific testing. There is no rationale for the once popular administration of sodium bicarbonate to horses to prevent episodes, because most affected animals do not have underlying acid–base disorders prior to exercise and become alkalotic during exercise.[26,67]

Antioxidant supplementation Vitamin E (1–6 IU/kg/day α-tocopherol) and selenium (1–2 mg/day) supplementation in food are indicated when deficiencies have been confirmed.[35,74]

Prophylaxis Numerous drugs are administered prophylactically, but most are used with unproven efficacy. The recent identification of separate disease etiologies may result in properly controlled drugs' trials in the near future (see comments on the use of dantrolene in the section on treatment of acutely affected horses, above). One group has reported the use of phenytoin[35] but it is expensive, it interacts with other drugs and may cause sedation, ataxia, focal seizures and recumbency.[35] Therefore, until further studies prove the drug's efficacy in horses with a well-established underlying etiology, the authors suggest its use only as last resort.

Etiology and pathophysiology

Acquired causes

Although important as specific causes in normal horses, some apparently acquired causes may be associated with underlying genetic predisposition to ER.

Overexertion Extreme or unaccustomed exercise predisposes horses to rhabdomyolytic attacks. Muscle damage in such cases may include a combination of physical damage incurred during excessive eccentric contractions, metabolic exhaustion and oxidative injury.

Eccentric contraction Delayed-onset muscle soreness in humans is associated with damage caused by excessive eccentric contractions (contraction during muscle lengthening).[75] Stiffness and pain, usually experienced 1–2 days following such exercise, is initially most evident at the myotendinous junction and then spreads throughout the muscle. Although the mechanism is poorly understood, there are prominent signs of damage within a muscle following eccentric contractions that include disruption of sarcomeres and damage to the excitation–contraction coupling mechanism and the sarcolemma.[76] This damage is reflected by (sometimes considerable) elevations in serum muscle enzyme activities[77,78] and triggers a local inflammatory response accompanied by edema and the sensitization of nociceptors.[75]

Whether horses experience this syndrome is unknown. Exercising horses are most likely to encounter eccentric contractions during downhill exercise and jumping. Given that muscle damage in humans generally occurs when the type or extent of eccentric contractions are unaccustomed and that adaptation occurs with training,[76] it seems sensible to introduce horses gradually to these types of exercise.

Metabolic exhaustion Exceeding the level of training either by excessive endurance exercise or overexertion when galloping is a common cause of acute ER in horses.[24] Exhaustion during endurance exercise results in heat retention, fluid and electrolyte loss, acid–base imbalance and intramuscular glycogen depletion.[79] Although the causes are numerous and likely involve electrolyte imbalances and hyperthermia, in certain cases a presumed underlying factor is the deficiency of ATP, which results in an inability to maintain ion homeostasis. In turn, a corresponding rise in intracellular calcium concentration precedes the final common pathways, leading to muscle fiber death described at the beginning of this chapter.

Oxidative injury Increased oxygen utilized during exercise leads to proportionate increases in free radical production (Fig. 6.11).[80] Free radicals are widely believed to cause post-exercise stiffness and fatigue in muscle, through several deleterious mechanisms that include the peroxidation of lipid membranes. Cell damage is normally minimized by the action of a complex cascade of free radical scavengers and antioxidants, including vitamin E and the selenium-dependent enzyme, glutathione peroxidase. When antioxidants fail to quench free radicals sufficiently, the body is subjected to so-called 'oxidative stress'.[80]

Although evidence suggests that exercise-induced oxidative stress occurs in horses, particularly when ambient

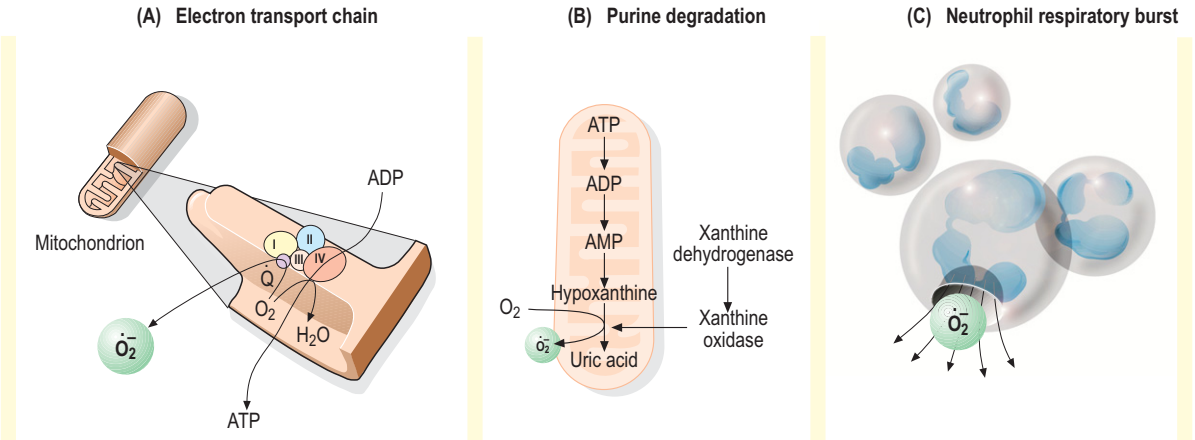

Fig. 6.11
Diagrammatic representation of free radical formation via the electron transport chain in mitochondria (A), via hypoxanthine degradation after ischemia (B) and during the neutrophil respiratory burst (C).

temperature and humidity are high,[81] there is no clear association with muscle damage.[82] This is corroborated by studies demonstrating that antioxidant supplementation fails to attenuate exercise-induced elevations in plasma CK activity,[83–85] and a lack of studies demonstrating antioxidant deficiencies in horses prone to ER. Instead, higher serum and muscle vitamin E concentrations and serum glutathione peroxidase activity were detected in ER-susceptible Standardbreds compared with controls (although prior supplementation could not be ruled out as a potential cause).[86]

In adult horses, vitamin E or selenium deficiency has been associated with nutritional myodegeneration (white muscle disease) of the masseter muscle[87] and was implicated in horses with rhabdomyolysis, colic and myocardial disease.[88] In growing foals, nutritional myodegeneration is characterized histopathologically by changes that are sometimes seen in horses with ER.[89] However, such changes likely reflect the general response of muscle to cycles of degeneration and regeneration, rather than damage caused specifically by oxidative stress.

There is therefore no good evidence that oxidative stress plays a primary role in ER, particularly given the apparent high incidence of the disorder in horses on excellent planes of nutrition.[35] Despite this, during conditions likely to result in significant oxidative stress, such as very strenuous or prolonged exercise, antioxidant deficiencies may exacerbate muscle damage caused by other mechanisms. Horses from selenium-deficient regions or animals on poor diets that are denied access to green pasture are most at risk.

Electrolyte imbalance Published and anecdotal reports of improvement following correction of electrolyte clearance ratios[45] underlie continued interest in this area.[35] In a group of 38 ER-susceptible Thoroughbreds, about a third had potassium clearance ratios of less than 30% or low chloride clearance.[90] These differences could potentially reflect differences in the handling of electrolytes by ER-susceptible animals but horses prone to ER exhibit the same dietary-induced alterations to electrolyte clearance ratios as normal animals.[40] Much attention has been directed at potassium, because low muscle potassium concentrations can precipitate rhabdomyolysis in other species.[91] Erythrocyte potassium concentration has been measured in attempts to investigate whole-body potassium stores: results indicate both low[92] and normal[90] erythrocyte potassium in horses with ER. However, the significance of either study is questionable given that erythrocyte potassium concentrations do not correlate with muscle or plasma potassium concentrations in horses.[90,93,94] Compared with normal animals, lower dry weight muscle potassium concentrations were detected in ER-susceptible horses.[90] However, characteristic muscle histopathological changes, seen in humans with potassium deficiency,[91] are generally not observed in muscle from horses with ER[90] so it is hard to draw conclusions.

The primary influence of altered electrolyte status as a cause of ER is better studied prospectively in normal horses, rather than retrospectively in horses known to be susceptible to the disorder. In comparison with controls, normal Thoroughbreds administered furosemide (frusemide) and sodium bicarbonate developed lower plasma calcium, chloride, magnesium and potassium concentrations. Following exercise, serum CK activity was found to be significantly higher in the treated group.[95] Some evidence therefore suggests that electrolyte imbalance may play a role in the development of certain forms of the disorder.

Hormonal influence In experimental animal models sex hormones influence the degree of disruption and post-damage inflammatory response in skeletal muscle. For instance, estrogen is known to have a protective effect following eccentric contraction and ischemia reperfusion injury.[96] It is intriguing therefore that many studies report a higher incidence of ER in female horses compared with males.[66,97–102] No correlation has been found between the stage of the estrus cycle and plasma CK activities in Thoroughbreds in training,[103] suggesting that a direct association of female sex hormones with ER is unlikely. As yet, therefore, the higher incidence of ER in females remains unexplained.

Hypothyroidism is associated with subclinical elevations of serum CK activity[104] and rarely causes ER in humans.[105] Although a cause of poor performance in horses,[106] hypo-

thyroidism has not been associated with ER in horses.[39,64,103,107–109] Other signs associated with hypothyroidism in horses, such as alopecia, lethargy and excessive fat accumulation,[110,111] are not frequently seen in ER-susceptible horses. Furthermore, given its rarity, it is unlikely that hypothyroidism is associated with ER in most animals.

Infectious causes Equine herpes virus 1 (EHV1) infection was proposed as causing an outbreak of ER in a training yard, where several horses seroconverted to the virus.[112] Equine influenza virus (EIV) has also been diagnosed by seroconversion as the potential cause of certain equine myopathies.[98] Both EIV and EHV1 infections are common in groups of young race horses and although the acute-phase response to viral infection may cause transient arthralgia and myalgia, and therefore stiffness, rhabdomyolysis is not a common feature of these diseases. As with other acquired causes, viral infection may modify the phenotype of genetically susceptible horses.

Inherited causes

Recurrent exertional rhabdomyolysis due to defective calcium regulation The term 'recurrent exertional rhabdomyolysis' (RER) has recently evolved to define a disease reported in Thoroughbreds with aberrant myofiber calcium regulation and caffeine-hypersensitive muscle.[38,113,114] Although possible, it should not be assumed that this syndrome is common to all Thoroughbreds with intermittent bouts of ER. It is also unclear whether this disease is unique to Thoroughbreds: certain similarities in vivo and in vitro suggest that other breeds, such as Standardbreds,[99] may share a similar, if not identical disorder, particularly if the suspected autosomal dominant inheritance, reported in families of Thoroughbreds with uncharacterized ER,[115] is confirmed in horses with defective calcium regulation. Use of the word 'recurrent' leads to further confusion given that recurring episodes are a prominent feature of several ER disorders. Until a more practical diagnostic test becomes widely available and the disease's etiology is understood, it may be safer to qualify the diagnosis.

In the remainder of this section, the abbreviation RER(c) is used for horses in which caffeine hypersensitivity has been established; RER refers to the broader group of horses, mostly Thoroughbreds but including some other breeds, in which there is reasonable evidence for the same etiology.

Defective calcium regulation Speculation that ER may be related to a defect in calcium regulation[116–118] was strengthened by a report of elevated resting intracellular calcium concentrations in muscle from ER-susceptible horses by Lopez et al.[33] However, recent calcium fluorescence experiments using cultured equine myotubes from Thoroughbreds with RER(c) found no difference in resting calcium concentration when compared with controls.[63] This disparity may reflect differences in case selection, active disease processes in the former study or the less differentiated nature of myotubes in culture compared to mature muscle.

Muscle from some Standardbreds and Thoroughbreds that are susceptible to RER is, however, hypersensitive to agents that induce calcium release from the SR (Fig. 6.12) such as caffeine, a potent activator of RYR1.[99,119] Caffeine can be used to identify humans, pigs and dogs that are susceptible to malignant hyperthermia (MH) when stressed or under halothane anesthesia, because lower caffeine concentrations elicit contraction in biop-

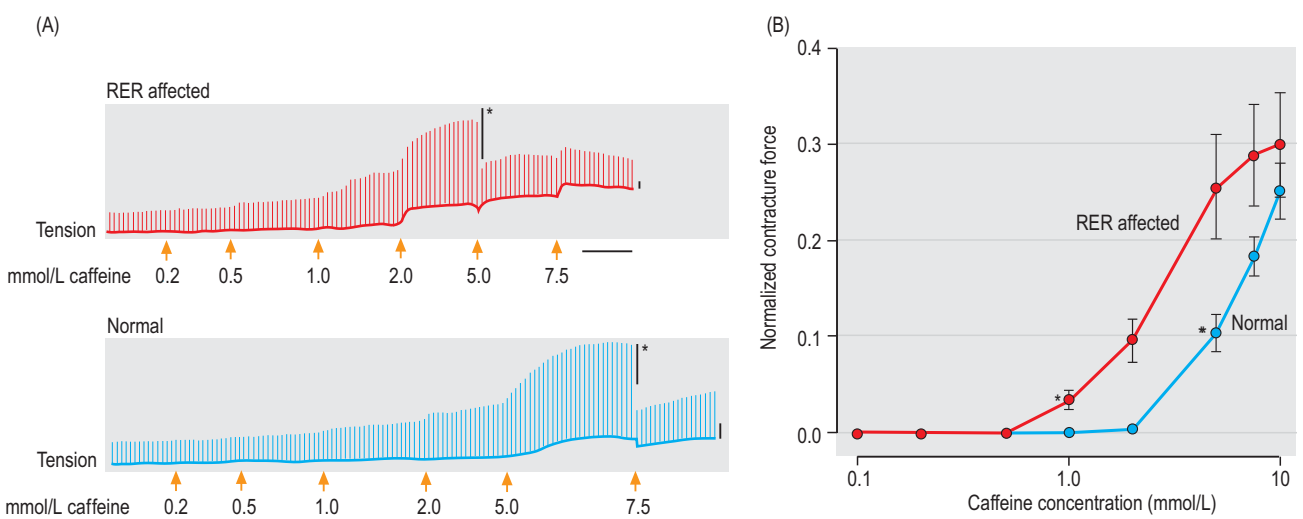

Fig. 6.12
(A) Tension (baseline) record for a caffeine contracture experiment performed on isolated intercostal muscle preparations from a normal horse and a Thoroughbred with RER(c). Twitches (vertical deflections) were elicited via electrical stimulation at 0.05 Hz and caffeine was added to the bathing solution as indicated by the arrows to obtain the final concentration as noted. Horizontal bar = 5 min; heavy left vertical bar = 0.5 N/cm;^{2} heavy right vertical bar = 1.0 N/cm.^{2} Asterisk = recorder gain change. Notice that caffeine elicits a change in baseline tension in muscle from the RER(c)-affected horse at between 1 and 2 mmol/L caffeine, whereas the baseline does not change until the bathing solution contains 5.0 mmol/L caffeine for the control muscle. (B) Contracture force versus caffeine concentration for muscle bundles from clinically normal horses (n = 12; blue line) and RER(c)-affected horses (n = 10; red line). Contracture force was normalized to the preceding tetanus for both groups. Asterisks show force of contracture thresholds > 0 at 1.0 mmol/L and 5.0 mmol/L caffeine for RER(c)-affected and clinically normal horses respectively. (Reproduced from Lentz et al[113] with permission.)

sied strips of muscle from subjects with MH compared to that of normal subjects.[120–122] Humans and pigs with MH are also susceptible to exercise- or stress-induced rhabdomyolysis;[123,124] conversely, MH-like reactions have been reported in several breeds of horse during or following anesthesia.[117,125–127] Some, but not all studies report ER-susceptible horses with muscle that tests positive for MH, perhaps because case selection included horses with different types of ER:[116,117,127] recent evidence now confirms that caffeine hypersensitivity is not a feature of muscle from horses with PSSM.[64,119]

In pigs, dogs and in most humans, MH is associated with mutations in the gene encoding RYR1,[122,128,129] but abnormal RYR1 ligand binding, characterized in vesicles prepared from the muscle of MH pigs,[130] is not a feature of similar vesicles from horses with RER(c).[131] Furthermore, whereas lower concentrations of caffeine elicit calcium release from the SR of RER(c)-susceptible Thoroughbreds when compared with normal horses, the same is not true for 4chloro-m-cresol, a RYR1 agonist with higher specificity.[63] Finally, characteristic clinical and histopathologic features seen in other human myopathies caused by RYR1 mutations are not seen in muscle from horses with RER(c).[29,132] Hence a mutation in the gene encoding RYR1, though not ruled out, appears less likely.

Caffeine-hypersensitive muscle is not exclusively found in human MH patients with RYR1 mutations: the same abnormality is reported in MH patients with mutations in other genes, such as the gene that encodes the α1-subunit of the L-type voltage-sensitive calcium channel (dihydropyridine receptor).[133] At least three more genes are implicated in human MH, based on linkage mapping;[129] furthermore, given that other proteins regulate calcium release from the SR (Fig. 5.12)[134] another, as yet unidentified gene may be the cause. Alternatively, since MH-like attacks and caffeine-hypersensitive muscle are reported in humans with other diseases,[135] horses with RER(c) may have an unrelated defect.

Defective kinetics of contraction/relaxation Muscle from RER-susceptible Thoroughbreds contracts more rapidly than normal muscle in vitro.[99] Furthermore, authors have detected abnormal relaxation, though they disagree as to whether relaxation is hastened or slowed.[99,113] The SR Ca^{2+}- ATPase pump is a major determinant of relaxation following contraction, but SR Ca^{2+}-ATPase pump activity is normal in extracted SR vesicles from horses with RER(c).[131] Abnormalities of the contractile apparatus could also explain some of the experimental findings in horses with RER(c). However, when compared with normal horses, there was no difference in its calcium sensitivity or in the myofibrillar ATPase activity.[114]

Diet and temperament High carbohydrate diets lead to more severe muscle damage in horses with RER(c),[38,67] while high-fat diets are protective.[67] Though unexplained, one possibility is that a high-fat diet may result in the stabilization of sarcolemmal membranes but the rapidity of the protective response[67] suggests that this is less likely. As stress is known to instigate MH in other species,[124] evidence suggests that the protective response may relate to dietary-induced alteration in temperament[70,71] (see section on prevention above).

Polysaccharide storage myopathy Since the first detailed report of PSSM in Quarter Horses,[52] a comparable disease has been recognized in other breeds.[54–58] Although similar histopathologically and sometimes associated with ER, some affected non-Quarter Horse breeds have neuromuscular weakness, muscle atrophy and abnormal hindlimb gaits characteristic of 'shivers'.[136] Abnormal muscle polysaccharide is also identified as an incidental finding.[56,57] Phenotypic variation caused by the effects of modifying genes and the environment is frequently encountered in human muscle diseases, so these may well be allelic disorders. Most work on pathophysiology has been in Quarter Horses, so here they are considered separately.

Quarter Horses Glycogen and abnormal polysaccharide accumulation are seen in several human muscle diseases known as glycogenoses, many of which are caused by abnormal regulation or deficiencies of glycolytic or glycogenolytic enzymes; others are idiopathic or caused by lysosomal dysfunction.[59] Early experiments suggested that Quarter Horses with PSSM displayed impaired lactate production[52,137] similar to humans with glycogenolytic or glycolytic enzyme deficiencies.[138] However, recent experiments using more stringent exercise tests demonstrated normal or exaggerated lactate production.[139] Affected Quarter Horses do not have detectable abnormalities in either glycolytic enzyme activities or their regulation,[52,140] and their oxidative metabolism appears functional since they can maintain low plasma lactate concentrations during long-term submaximal exercise.[139]

Glycogen is a branched three-dimensional molecule formed by glycogen synthase that adds straight 1,4 glucose linkages, and branching enzyme, that adds 1,6 linkages after every seventh glucose molecule (Fig. 6.13). The formation of abnormal polysaccharide, though not well understood, may be related to an abnormal increase in the glycogen synthase: branching enzyme ratio.[59] High muscle glucose-6-phosphate concentrations (found in PSSM muscle both before and after exercise[139]) may stimulate glycogen synthase activity[141] without a corresponding rise in branching enzyme activity, thereby altering their ratio and causing filamentous abnormal polysaccharide to form. Abnormal polyglucosan accumulates in tissues of humans with branching enzyme deficiency,[142] a fatal disease identified in a group of Quarter Horse foals,[143] but branching enzyme activities are normal in Quarter Horses with PSSM.[144]

Excessive muscle glycogen and polysaccharide may be associated with abnormal increased glucose uptake rather than diminished utilization.[61] Muscle's glucose uptake is controlled primarily by insulin in a process of facilitated diffusion via GLUT-4 receptors (Fig. 6.14A).[145] A separate, but poorly understood mechanism recycles GLUT-4 receptors when insulin concentrations diminish.[146] Compared with normal animals, Quarter Horses with PSSM clear glucose from plasma more rapidly following its intravenous injection (Fig. 6.15) and have reduced peak plasma glucose concentrations after oral carbohydrate intake.[62] Affected horses have lower resting serum insulin concentrations and lower insulin : glucose ratios than controls both before and after glucose infusion.[61] Enhanced insulin sensitivity in affected animals is demonstrated by a more rapid decline in plasma glucose concentration and prolonged hypoglycemia following intravenous insulin administration compared with controls.[61] Hence, although glucose uptake specifically into muscle has not been investigated, because skeletal muscle is the greatest insulin-sensitive tissue, horses with PSSM probably have enhanced skeletal muscle glucose uptake, a hypothesis strengthened by similar observations in transgenic mice

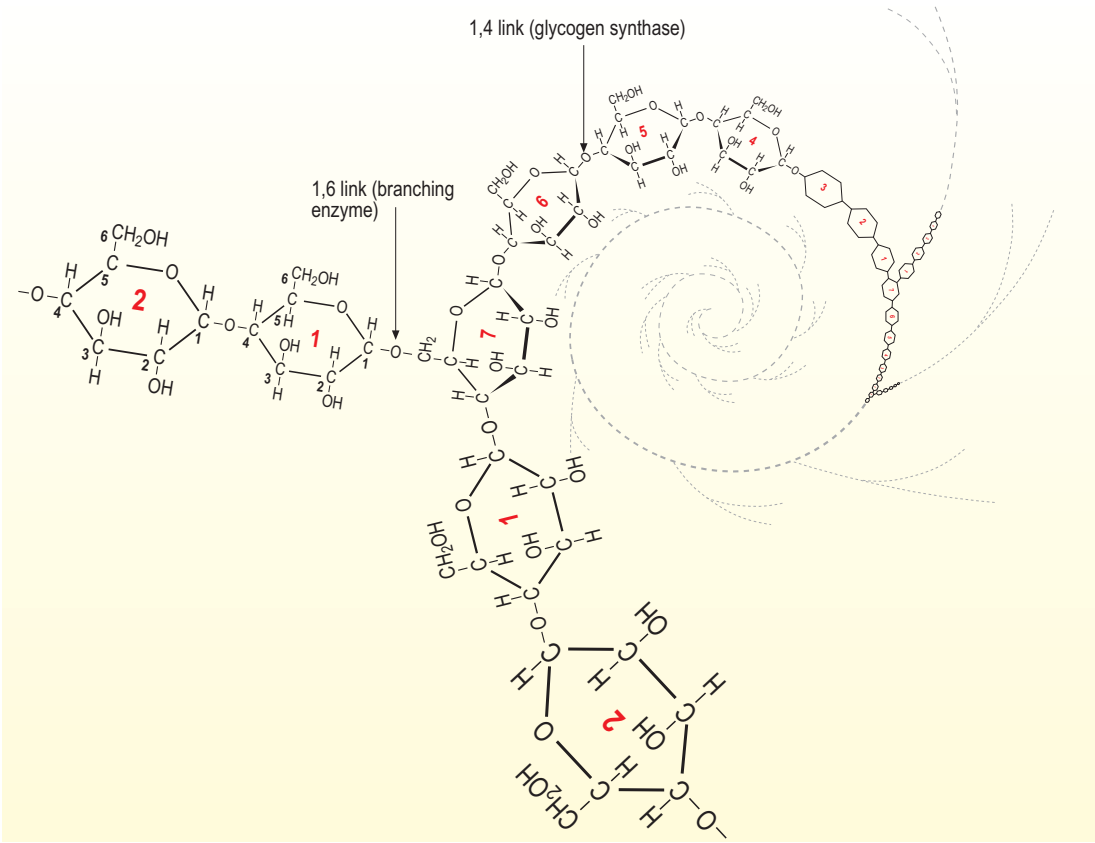

Fig. 6.13 Diagrammatic representation of the three-dimensional structure of glycogen. Note that glycogen is composed of chains of glucose molecules joined enzymatically via 1-4 linkages (glycogen synthase) and 1-6 linkages (branching enzyme).

that overexpress GLUT-4 receptors.[147] Whether muscle from horses with PSSM has greater numbers of sarcolemmal GLUT-4 receptors or whether they persist for longer within the sarcolemma following their translocation from the cytoplasm remains to be determined.

Exercise results in insulin-independent translocation of a separate pool of GLUT-4 receptors to the sarcolemma via poorly understood pathways (Fig. 6.14B).[148–150] After exercise, enhanced insulin-independent glucose uptake is maintained for several hours due to delayed GLUT-4 transporter recycling.[151] A second phase of increased glucose uptake results from enhanced insulin sensitivity in a mechanism that may be modulated by glycogen.[150,151] Normal horses fed grain following exercise show enhanced glucose clearance compared to non-exercised horses; a similar, but diminished enhancement occurs in horses with PSSM together with a relative decline in their insulin sensitivity.[62] One possible explanation is that glycogen's control over the regulation of insulin sensitivity is defective in affected horses. Alternatively, because horses with PSSM have greater post-exercise muscle

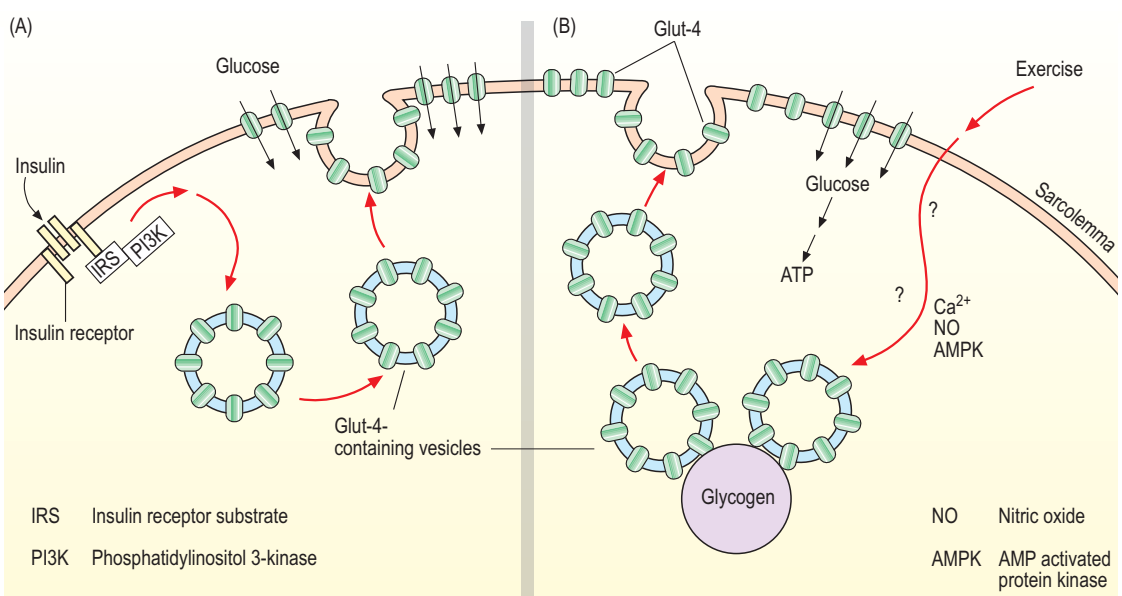

Fig. 6.14 Diagrammatic representation of insulin-dependent translocation of vesicle-bound GLUT-4 receptors from the cytoplasm to the sarcolemma (A) and the similar translocation of GLUT-4 receptors in response to exercise (B). Either way, GLUT-4 receptors at the sarcolemma result in increased rates of glucose uptake.

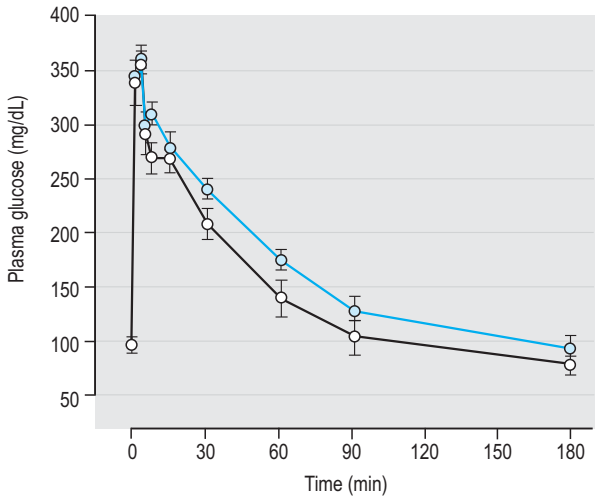

Fig. 6.15
Mean plasma glucose concentrations in six horses with PSSM (black line) and 10 healthy control horses (blue line) immediately before (time 0) and at various times after i.v. glucose injection. Glucose concentration from 0 to 180 minutes was significantly ($P < 0.001$) lower in horses with PSSM than in controls. Bars represent SEM. (Reproduced from de la Corte et al[61] with permission.)

glycogen stores than normal horses,[139] their stimulus for glucose reuptake may be less intense.

Other breeds In 1931 Carlström noted high glycogen concentrations in draft horses that developed rhabdomyolysis following a day of inactivity, proposing that the myopathy was related to a build-up of lactic acid.[152] Subsequent analysis does not support this hypothesis[139,153] and it seems most likely that this disease was probably PSSM[55,57] that, like in Quarter Horses, has been associated with excessive glycogen accumulation and amylase-resistant polysaccharide in muscle.[55,154] As with Quarter Horses, researchers have not identified glycolytic enzyme deficiencies in other affected breeds;[72] plasma glucose clearance and insulin sensitivity have yet to be investigated.

Various human glycogenoses affect tissues other than skeletal muscle, including the heart.[59,155] PSSM has been diagnosed as an incidental finding in a number of draft horses with seemingly unrelated diseases and in a few with sudden (perhaps cardiac-related) death. However, of nine draft horses examined, amylase-resistant polysaccharide was identified in the (otherwise histologically normal) myocardium of only one Belgian.[57] Quarter Horses with PSSM do not have overt cardiac disease[52] although histopathological assessment is lacking.

Epidemiology of exertional rhabdomyolysis syndromes

Characterizing horses as susceptible to ER by measuring serum CK activity is practical but cannot distinguish groups based on the underlying etiology. This drawback is partially overcome by grouping horses by breed or type, a method used in several studies.

Idiopathic cases Idiopathic ER has a worldwide distribution. Studies indicate that between 4.9% and 6.7% of racing Thoroughbreds can be affected during a single season[66,102] with the disorder probably inherited as an autosomal dominant trait with variable expression.[115] Subjective impression that ER occurs more frequently in young fillies has been confirmed by several studies.[66,102,109] Additionally, it was found that Thoroughbreds that were nervous or lame were more likely to develop episodes of rhabdomyolysis.[66,102] Another study that examined ER in polo ponies in the UK and the US also found a high incidence,[156] particularly in animals with an excitable temperament. In both Thoroughbreds and polo horses, the disease resulted in significant time away from training or competing.[66,102,156] Evidence suggests that ER also has a genetic component in Swedish Standardbreds.[101]

Polysaccharide storage myopathy The familial basis of PSSM in Quarter Horses may be autosomal recessive.[157] A retrospective epidemiological study of Quarter Horses with PSSM (diagnosed histopathologically) found that horses were prone to rhabdomyolysis when affected by respiratory disease. The age of onset varied between 3 months and 14 years and unlike in Thoroughbreds, there was no association with either gender or temperament.[68]

In a group of 37 draft-related horses (referred to a veterinary teaching hospital in the US with various diseases), when examined at necropsy, between 45% and 66% had signs compatible with PSSM (depending on diagnostic criteria).[57] The growing number of breeds diagnosed with PSSM now includes Quarter Horses,[52] Warmbloods, Morgans, Standardbreds and Arabians,[56] Haflingers,[58] Anglo-Arabians and Andalusians.[54] In addition, if the classification criteria for diagnosis of PSSM are relaxed, the list includes Thoroughbreds and ponies.[69] PSSM has been reported in North America and Europe.[54,57,68]

Hyperkalemic periodic paralysis

- Genetic disorder seen in Quarter Horses and related breeds descended from the stallion Impressive.
- Caused by a mutation in the α subunit of the skeletal muscle sodium channel.
- Autosomal dominant inheritance.
- Homozygotes are more severely affected than heterozygotes.
- Signs vary from subclinical to severe.
- Weakness is the predominant physical sign, although muscle spasm and fasciculation may occur.
- Life-threatening complications include cardiac arrhythmias secondary to hyperkalemia and asphyxiation due to laryngospasm.
- Prophylactic dietary and therapeutic management can reduce the frequency and severity of attacks.

Recognition

History and presenting complaint

Hyperkalemic periodic paralysis (HYPP) episodes occur intermittently, last several minutes to hours, and are more

common in young adults or foals. Affected horses are well muscled, particularly over the hindquarters, and appear normal between episodes. Episodes often follow sleep or may be precipitated by stress, cold weather and sometimes exercise.[158] Evidence suggests that the condition is more common in young males[159–162] although this has not been confirmed experimentally.

Physical examination

Clinical signs vary, with homozygotes being more severely affected than heterozygotes. Myotonia is often brief or unapparent; however, third eyelid protrusion is sometimes seen along with spasm of certain facial muscles and, more commonly, muscle fasciculation.[163] Laryngeal or pharyngeal spasm may occur, causing pharyngitis, dysphagia and occasionally severe dyspnea.[164] These signs are more common in young homozygous foals,[164] but in adults may present as abnormal respiratory noise during exercise.[165] More characteristic, especially in older horses, are signs of weakness, such as swaying or buckling, a stilted gait, dog sitting, collapse or recumbency.[160] Respiratory muscle weakness and increased muscular effort may be manifest as shallow tachypnea and sweating. Horses remain alert, responsive and unpainful.[158,163] Death, when it occurs, may be the result of the dyspnea associated with laryngospasm or, more commonly, cardiac arrhythmia (ventricular fibrillation) due to underlying hyperkalemia;[166,167] horses that are under or recovering from anesthesia appear particularly at risk.[168,169]

Special examinations

Electrocardiography Consistent with hyperkalemia, during episodes the ECG reveals smaller, wider P waves, increased amplitude of T waves and widening of QRS complexes.[162,170–173] Between episodes the ECG is normal.[162]

Endoscopy Endoscopy may reveal pharyngeal collapse and edema, dorsal displacement of the soft palate, bilateral laryngeal paresis and persistent opening of the guttural pouch ostia.[158,165]

Electromyography Electromyography reveals abnormalities such as doublets and characteristic myotonic discharges (Fig. 6.16).[174]

Laboratory examination

Serum biochemistry During an episode, clinical pathological changes usually, but not always,[159,169,175] include hyperkalemia (5.5–12 mEq/L).[162,176] Elevated total serum protein concentration (7.0–9.0 mg/dL) suggests fluid compartmental shifts.[162,177] Serum CK and AST activities are normal to moderately elevated.[162,178]

Muscle biopsy Muscle histopathology is not normally indicated and often appears normal, but may reveal centrally located vacuoles in type II fibers, excessive fiber size variation, occasional internal nuclei, moth-eaten fibers, connective tissue proliferation and fiber degeneration.[51,161,162] Electron microscopy reveals distension and proliferation of the SR and copious networks of transverse tubules.[158]

Diagnostic confirmation

The differential diagnosis includes colic, ER, laminitis, cardiac disease, tetanus, botulism, seizures and upper airway obstruction. Myotonic discharges, observed during EMG examination, are also seen in the rare disorders known as myotonic dystrophy and myotonia (see later sections).[179–181] Recognition of weakness and muscle fasciculations in

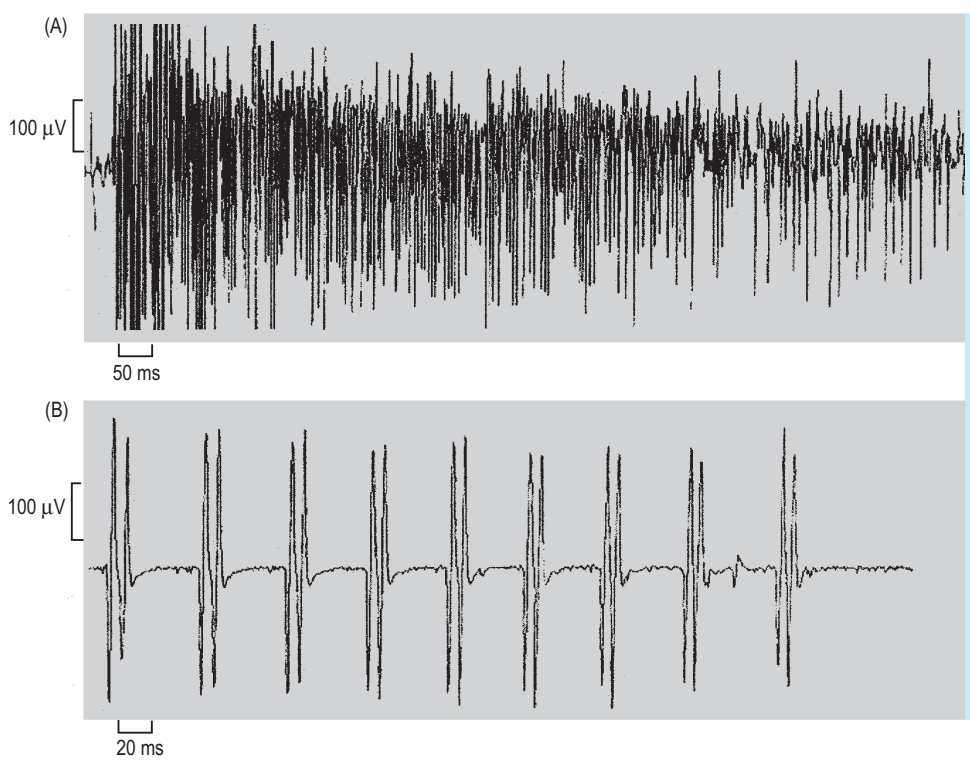

Fig. 6.16
Electromyographic features of HYPP-affected muscle. (A) Myotonic discharges and (B) trains of doublets recorded in an HYPP-affected horse while clinically normal. (Copyright of Jonathan M Naylor BSc PhD, Saskatoon, Canada. Reproduced with permission.)

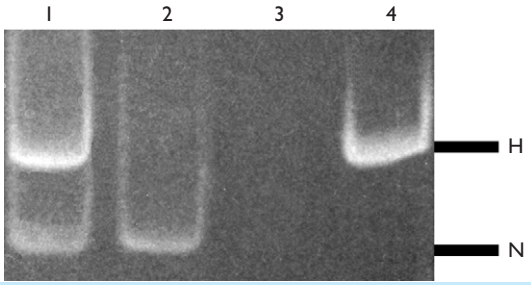

Fig. 6.17
Restriction fragment length polymorphism analysis for the testing of HYPP. Complementary DNA primers are used to amplify by polymerase chain reaction (PCR) a portion of extracted genomic DNA that contains the HYPP mutation. The PCR product is digested with a specific (restriction endonuclease) enzyme and is loaded into separate lanes of an agarose gel, containing ethidium bromide, which fluorescently labels the DNA. The enzyme cuts the DNA into a shorter fragment (which migrates more quickly and hence further down the gel) only if the sequence is normal (N). DNA from mutated alleles remains uncut, and therefore migrates more slowly in the gel (H). In lane 1 the extracted DNA contains both mutated (H) and normal (N) sequences, hence the animal is a heterozygote (H/N). In lane 2, all the DNA has been cut by the enzyme, hence both alleles must be normal (N/N). Lane 3 is a PCR control with no added DNA. In lane 4 none of the PCR-amplified DNA has been cut by the enzyme, hence both alleles must be mutated and the animal is homozygous (H/H). combination with hyperkalemia in an Impressive-related Quarter Horse should leave little doubt that the animal has HYPP. Hyperkalemia itself, though not always present, may be due to other causes such as recent exercise, a hemolyzed blood sample or, more rarely, renal failure.

Diagnostic confirmation via the potentially fatal potassium chloride challenge test[158,162,176,182] has been rendered obsolete with the advent of genotyping. Electromyography, a useful ancillary test with a reported sensitivity of 90%,[183] can support the diagnosis before DNA test results are available. Abnormal EMG signals can be detected both during and between episodes and in HYPP-positive horses undergoing treatment.[183,184]

Definitive diagnosis can only be achieved by mutational analysis of the sodium channel α subunit gene, which determines an animal as heterozygous or homozygous (Fig. 6.17). Any sample containing DNA (for example, tissues removed at necropsy) could be used but whole blood (in EDTA) or a plucked hair sample (containing roots) is preferred. The American Quarter Horse Association recommends testing foals born to unclassified parents; those related to Impressive are identified with their established genotype on registration certificates. Note that a horse may be heterozygous for HYPP but display weakness and collapse for some other reason and that the test only identifies the single specific mutation seen in all horses to date with HYPP.[185]

Treatment and prognosis

Therapeutic aims

Therapy is aimed at systemic abnormalities, specifically the life-threatening hyperkalemia and, if present, the dyspnea.

Therapy

Mild cases require stall rest or hand walking together with grain or a sweet-feed meal or orally administered corn syrup.[163] Horses should be observed closely for worsening signs. More severely affected animals with prominent weakness or auscultable cardiac arrhythmia require aggressive medical therapy. Severe dyspnea may require emergency tracheotomy.

Emergency treatment during an attack Intravenous calcium gluconate given slowly, diluted in isotonic fluids (0.2–0.4 mL/kg of 23% calcium gluconate in 2 liters of 5% dextrose) raises membrane threshold potential, reducing the likelihood of an action potential despite the muscle cells' relatively depolarized state.[158] Cardiomyocytes are also protected.[186]

Intravenous administration of potassium-free fluids containing dextrose triggers insulin release and hence glucose movement followed by potassium, intracellularly. Intravenous administration of insulin has been advocated but should be done with dextrose-containing fluids to avoid hypoglycemia; doses are not well established.[158] A mild alkalosis from sodium bicarbonate administration should also promote intracellular potassium movement. One author recommends 0.9% NaCl containing 0.5–1 mL/kg 1.3% $NaHCO_3$ and 0.5–1 mL/kg 50% dextrose.[163] Other treatments aimed at reducing hyperkalemia include β-adrenergic agonists[158,187] to stimulate the Na/K ATPase pump, which reduces the resting membrane potential. These drugs are rarely necessary, though, and may increase the risk of cardiac arrhythmia.[169]

Phenytoin ameliorates skeletal muscle signs probably by altering sodium channel activity through the influence of cytoplasmic free fatty acids;[188,189] however, serum phenytoin concentrations should be monitored. Note that phenytoin does not reduce serum potassium levels[166] and is not usually required.

Prognosis

Most mildly to moderately affected animals will respond well but if hyperkalemia is severe and not treated promptly, sudden cardiac death may occur. Asphyxiation is possible in cases with laryngospasm as is aspiration pneumonia, particularly in nursing foals. Evidence suggests that in many animals the signs can be controlled successfully but given the underlying genetic abnormality, horses remain susceptible for life.

Prevention

Management and dietary changes Horses that suffer repeated attacks often benefit from long-term management

changes and prophylaxis. In some cases a change in diet and avoidance of the cold and stressful events, such as transportation, may suffice.

Feed modification reduces the number of attacks.[159] Many horses do well when maintained principally at pasture but when not practical, they should always have access to hay and concentrate feed should be divided and given several times daily. High potassium-containing forages such as brome hay and alfalfa should be avoided, as should canola and soybean oil, molasses and certain potassium-containing mineral supplements. Late bloom timothy hay, sugar beet pulp and barley or oats are suitable alternatives, although calcium supplementation may be required to ensure appropriate calcium : phosphorus ratios.[190]

Prophylaxis

Acetazolamide (2–4 mg/kg q 12–14 h p.o.), a carbonic anhydrase inhibitor, is widely used in horses. It prevents attacks induced by experimental potassium challenge[191] and anecdotal evidence suggests that the drug is useful in the field.[163,178] Carbonic anhydrase inhibition in renal proximal convoluted tubules decreases reabsorption of sodium ions via an indirect inactivation of luminal H^+-Na^+ antiporters, thereby enhancing sodium for potassium exchange in the distal tubules and promoting potassium excretion.[186] However, some have doubted this explanation for acetazolamide's efficacy, suggesting that other mechanisms, such as the stimulation of insulin secretion, may be involved.[158,192,193] Other potassium-wasting diuretics such as hydrochlorothiazide have also been tried in horses but experience is limited.[194]

Etiology and pathophysiology

Etiology

A disease resembling human HYPP was reported in Quarter Horses in the mid 1980s[160,195] but the etiology of human HYPP was then unknown. In the early 1990s, several groups confirmed that human HYPP is caused by mutations in a gene encoding the α subunit of a sodium channel expressed only in skeletal muscle.[196,197] Linkage of equine HYPP to a single locus[198] and identification of a single base pair substitution in the equine sodium channel α subunit gene quickly followed.[199] Unlike in humans, in equine HYPP all identified cases have the same mutation,[185] the substitution of a cytosine for a guanine residue, causing the amino acid phenylalanine to be replaced by leucine in the cytoplasmic end of the IVS3 transmembrane domain (Figs 6.18, 6.19) of the encoded 260 kDa protein.[199]

As in the human disorder, equine HYPP is inherited in autosomal dominant fashion.[177,200] The different severity of homozygotes compared to heterozygotes is a reflection of the codominance of the mutated and wild-type alleles. As with many diseases, phenotypic severity varies between heterozygotes, perhaps due to the modifying influence of other genes or environmental effects. One group has reported a correlation of disease severity with the ratio of mRNA from affected: wild-type (unaffected) alleles,[201] although this finding has not been confirmed at the protein level.

Pathophysiology

Transient myotonia The skeletal muscle sodium channel associated with HYPP lies in the sarcolemmal (and T-tubule) membrane and allows sodium to enter the fiber during action

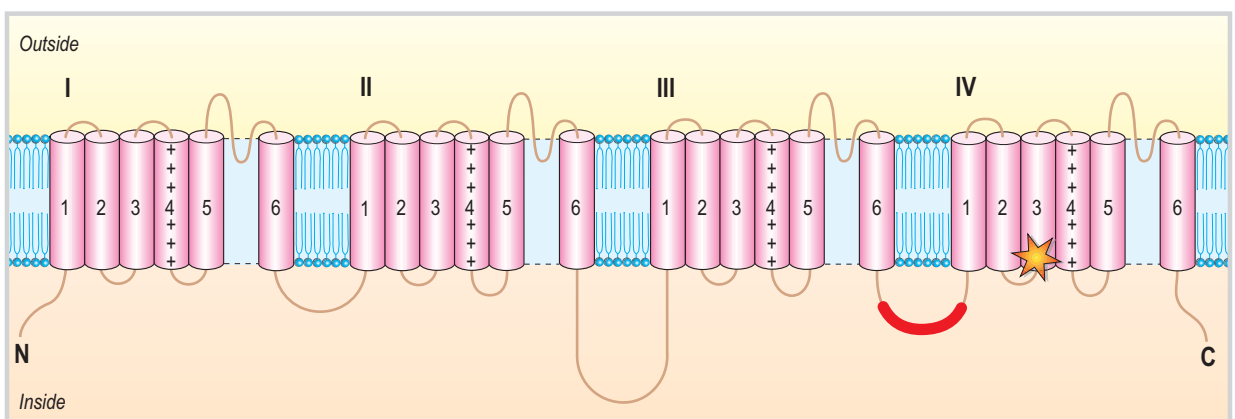

Fig. 6.18
Diagrammatic representation of the equine sodium channel α subunit. The protein contains four domains (I–IV), each containing six transmembrane hydrophobic segments (1–6) that combine to form a channel in the sarcolemma. Segment 4 in each domain contains a high density of charged amino acids that participate in sensing voltage changes across the sarcolemma. The phenylalanine to leucine mutation is located close to the cytoplasmic surface of segment 3 in domain IV (asterisk). The spanning region between III-S6 and IV-S1 is believed to participate in channel inactivation (colored red).

Fig. 6.19
Comparison of IVS3 amino acid sequences of various species. Standard single letter codes for each amino acid are used and amino acids with similar properties are shown with the same background color; hence polar-negative amino acids are red, polar-neutral amino acids are green, non-polar aliphatic amino acids are white and non-polar aromatic amino acids are purple. Glycine and proline tend to have structural properties in biological membranes and are colored brown. Note the significant conservation of either amino acid sequence or amino acid type within the structural domain between species. Such conservation usually reflects the functional and structural importance of the region to the protein. Also note the replacement of phenylalanine (F) by leucine (L) (circled in red), in horses with HYPP.

potential conduction (see Chapter 5). In vitro studies demonstrate dysfunctional inactivation of the mutant channel and an increased open probability, hence abnormal influx of sodium while at rest (Fig. 6.20).[202,203] Although individual fibers vary, in HYPP-affected fibers, the resting potential is higher (less negative) than normal.[145] Blocking sodium channels in HYPP muscle with tetrodotoxin returns the membrane potential towards normal (more polarized) but has no effect on the resting potential in normal muscle.[145] The closer proximity to the threshold potential in HYPP muscle results in more readily elicited action

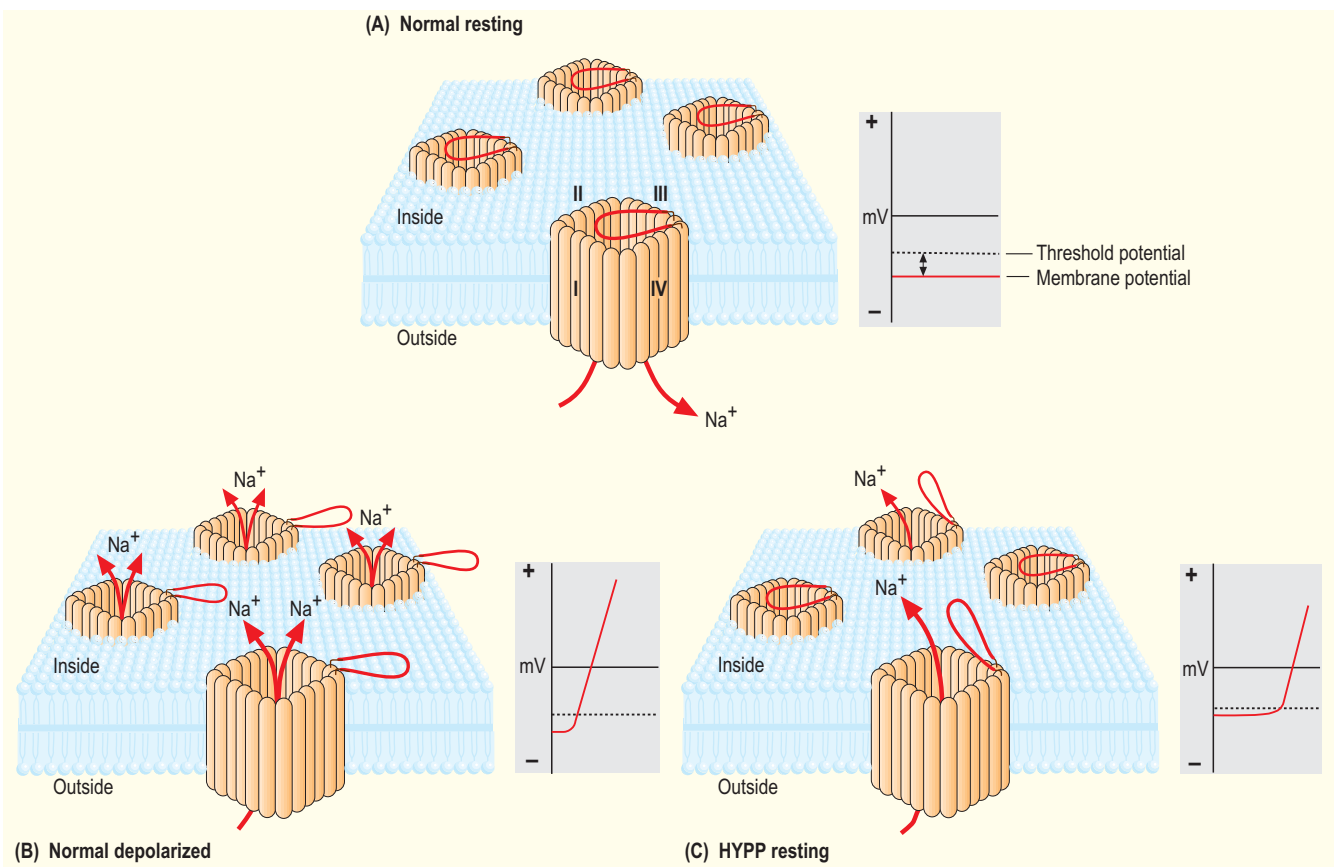

Fig. 6.20
Diagrammatic explanation for the pathophysiology of HYPP. In a normal resting muscle cell, sodium channels are inactive and closed and the resting potential lies some way below the threshold potential (A). A regional change in voltage activates sodium channels, causing them to open, allowing sodium to enter the fiber (the upswing of the action potential) (B). In muscle fibers from horses with HYPP, some sodium channels have abnormal inactivation and remain open, despite the fiber's resting state. Sodium can enter the fiber down its concentration gradient. This results in the fiber's resting potential being close to the threshold potential (C) and hence more readily elicited action potentials.

potentials, explaining the transient myotonia and muscle fasciculations. Fibers from younger horses with HYPP have higher resting potentials than older horses and muscle cooling raises the resting potential. These observations explain the higher incidence of HYPP episodes in young horses and during cold weather.[145]

Weakness Following rapid depolarization of the action potential, sodium channels normally close in response to the now positive membrane potential. In addition, voltage-gated potassium channels open, allowing potassium to leave the muscle fiber and return it to its resting potential. Failure of mutant sodium channels to inactivate prevents repetitive trains of action potentials[203,204] (required for Ca^{2+} release), causing the weakness that is the predominant sign in affected horses.

Hyperkalemia can be both the consequence and the cause of an attack Most horses are hyperkalemic during or immediately following an episode, probably due to voltage-gated potassium channels remaining open, allowing continual potassium efflux. Hyperkalemia itself raises the fiber resting potential and promotes an open sodium channel configuration, thereby exacerbating the condition[205,206] or, as demonstrated by the formerly used potassium challenge test,

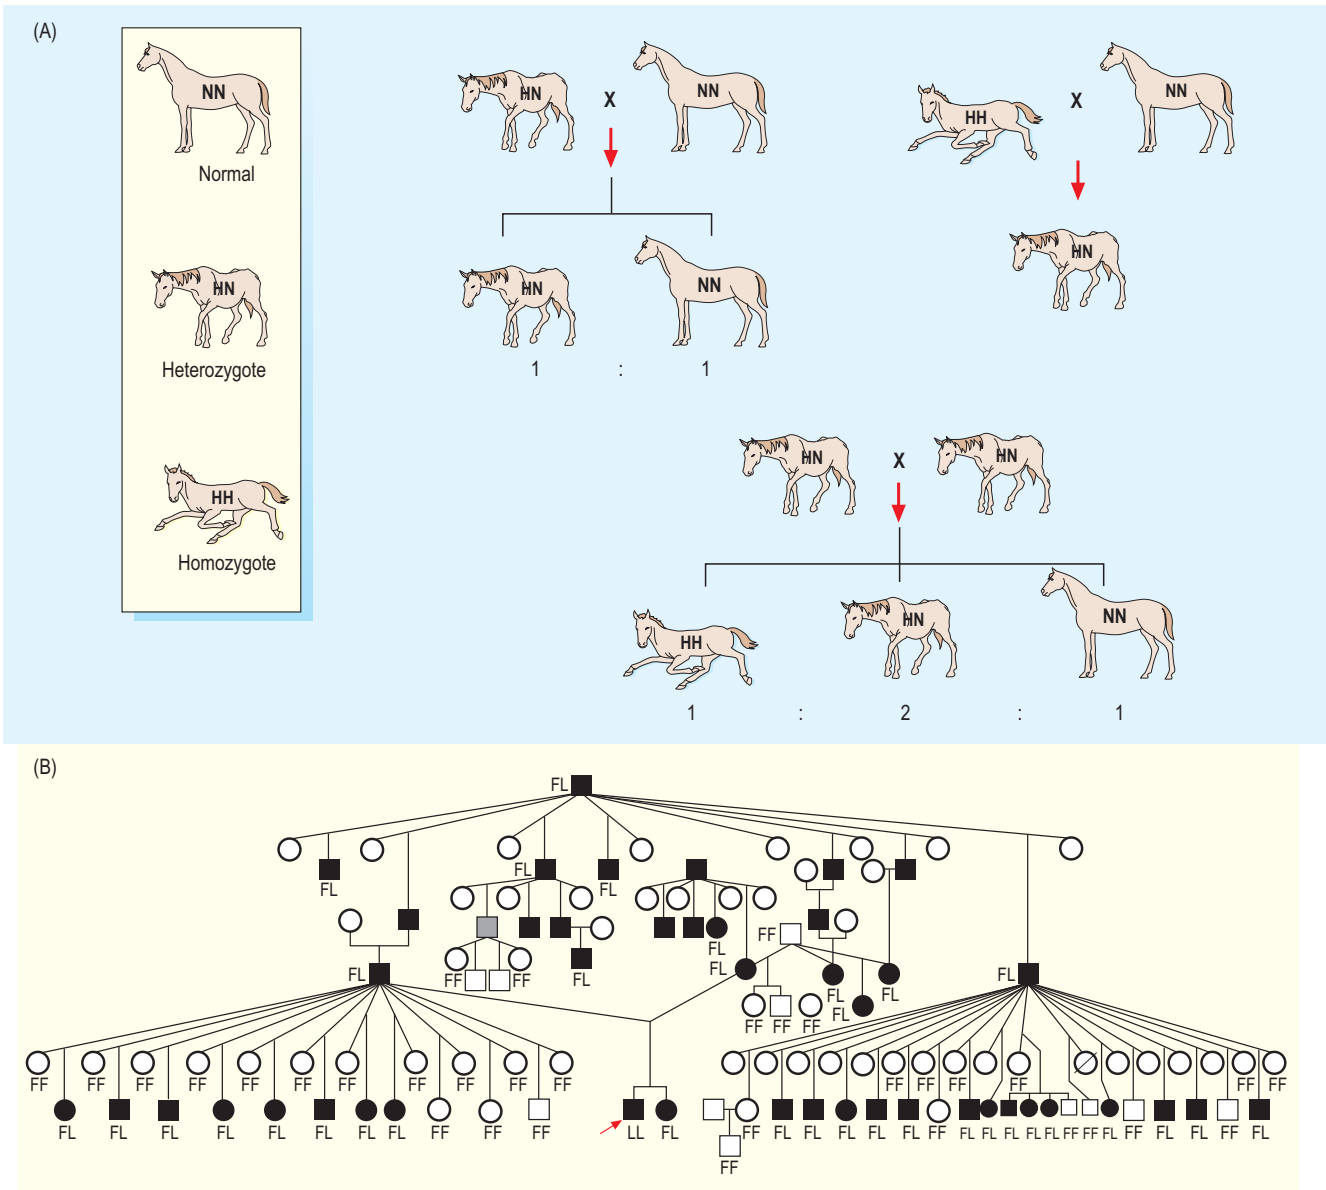

Fig. 6.21
(A) Diagrammatic representation of matings between horses with HYPP and normal animals. (B) HYPP Quarter Horse pedigree. Horses are shown typed for the normal allele of the sodium channel (phenylalanine (F)) and the allele that causes HYPP (leucine (L)) in the sodium channel region IVS3. A homozygous affected horse is indicated by an arrow. The horse represented by a gray symbol has an unknown status. Squares represent males and circles represent females. Black symbols represent horses with the HYPP phenotype and open symbols represent normal horses. (Reproduced from Rudolph et al[199] with permission.)

precipitating an attack. Spontaneous recovery often follows attacks, perhaps as a result of the kidneys' correcting the hyperkalemia or a local rise in muscle temperature.[163]

Muscle hypertrophy Horses with HYPP typically have hypertrophied muscles and this favorable trait in halter classes likely resulted in the maintenance and propagation of the mutation in the gene pool until a rule change by the American Quarter Horse Association.[184] The mechanism causing the hypertrophy is not understood, but may relate to myotonia-induced gene expression.

Exercise intolerance Experiments show that despite the hypertrophic muscles, horses with HYPP have reduced exercise tolerance compared with normal animals and produce relatively more lactate during exercise.[207] Even when weakness or muscle fasciculations are absent, exercised homozygotes exhibit intermittent laryngospasm, pharyngeal collapse, hypoxia, hypercapnia and ventricular premature contractions.[208]

Epidemiology

The spontaneous mutation that first occurred in Impressive (born 1969) spread via line breeding throughout the Quarter Horse population (Fig. 6.21). Within the US the frequency of affected heterozygotes in 1996 was believed to be 4.4%.[185] Dominant inheritance has led to cases in Quarter Horse-related breeds such as Appaloosas, American Paint horses and crosses. Although seen predominantly in North America, HYPP has also been reported in Impressive-descended Quarter Horses in Australia.[171]

Myotonia

- Equine myotonia is very rare and likely has a genetic cause: the sarcolemmal chloride channel has been implicated.
- Percussion dimpling and prolonged muscle contractions are present from an early age.
- Electromyography reveals frequent myotonic discharges.
- No successful treatment or prophylaxis has been reported.
- The prognosis for life in myotonia is fair to good, though athletic potential is likely to be poor.

Although horses with HYPP may exhibit (usually transient) myotonia, several case reports describe more prolonged myotonia. As in HYPP, some cases are probably associated with mutations in genes encoding sarcolemmal ion channels.[181] In humans, the phenotype varies depending on the channel involved and the mutation, but there is considerable overlap. Early literature combined equine myotonia with myotonic dystrophy but on close evaluation of the disease descriptions, it is clear that at least two myotonia-causing disorders exist.

Recognition

History and presenting complaint

Gait abnormalities and stiffness that are worst following a period of rest may be apparent early in life.[181]

Physical examination

Examination reveals symmetrical muscle hypertrophy and percussion causes localized muscle spasm and prolonged dimpling.[181,209] Animals with myotonia are not expected to deteriorate significantly with time.

Special examinations

Electromyography Changes are similar to those observed in HYPP (Fig. 6.16).[181]

Muscle biopsy Histopathology will likely be normal or show mild myopathic changes including excessive fiber size variation and internally located nuclei.[209]

Diagnostic confirmation

The main differential is myotonic dystrophy, which is characterized by severe muscle histopathological changes, endocrine abnormalities and progressive clinical signs. Affected horses share similarities with the prolonged myotonia of humans with chloride channel disorders[196] but the equine chloride channel gene has not been identified. Certain mutations in the human sarcolemmal sodium channel α subunit gene are manifest as myotonia rather than periodic paralysis: direct sequencing, rather than the routine HYPP DNA test would be required for definitive diagnosis of a sodium channel disorder in affected horses.

Treatment and prognosis

There are no reports of successful treatment. The prognosis for athletic function is poor but the prognosis for life may be good.[181]

Etiology and pathophysiology

Although the etiology is unknown, clinical descriptions and comparison with human diseases suggest that a sarcolemmal chloride channel mutation probably causes equine myotonia.[181,196] In human chloride channelopathies, reduced muscle chloride conductance causes membrane potential to rise, resulting in membrane hyperexcitability and hence myotonia.[197]

Epidemiology

The disease, which may be inherited, has been reported in a Thoroughbred filly in the US.[181]

Myotonic dystrophy

- Myotonic dystrophy is rare and probably has an underlying genetic cause.

- Percussion dimpling and prolonged muscle contractions are early signs.
- Horses with myotonic dystrophy may develop tendon contractures, kyphoscoliosis and testicular atrophy.
- Electromyography reveals myotonic discharges in certain muscles.
- Muscle histopathology reveals moderate to severe dystrophic changes.
- Successful treatment has not been reported and euthanasia may be necessary.

Recognition

History and presenting complaint

Horses are usually presented early in life with stiff gaits and prolonged contraction of certain muscles.

Physical examination

Animals are alert and responsive, with marked muscular hypertrophy particularly in the gluteal region and hindlimbs. Percussion dimpling is readily elicited in many animals and prolonged contraction may follow spontaneous or induced movements (Fig. 6.22). Weakness, manifest as knuckling or stumbling, may also be seen. Signs may progress to include tendon contractures, kyphoscoliosis, a pendulous abdomen, colic and testicular atrophy.[179,180]

Special examination

Electromyography Myotonic discharges are common in some but not all muscles, as are high-frequency electrical bursts during needle insertion, movement or following percussion.[179,180] Motor unit potentials in the thoracic paraspinal muscles of one animal were polyphasic and reduced in amplitude, but normal in the gastrocnemius.[180]

Laboratory examination

Hematology and biochemistry Hematology and biochemistry values may become abnormal with age.[210] CK and AST activities have been reported to be both normal and raised in affected horses. Some animals have endocrine abnormalities.[179,180]

Muscle biopsy Mild to severe dystrophic changes such as fiber-size variation and fiber-type grouping, increased perimyseal and endomyseal connective tissue, necrosis with inflammatory cell infiltration, internally located nuclei and whorled fibers may be seen (Fig. 6.23). There may be selective type I muscle fiber hypertrophy with moth-eaten fibers and ring bands.[51,179,180,210–214]

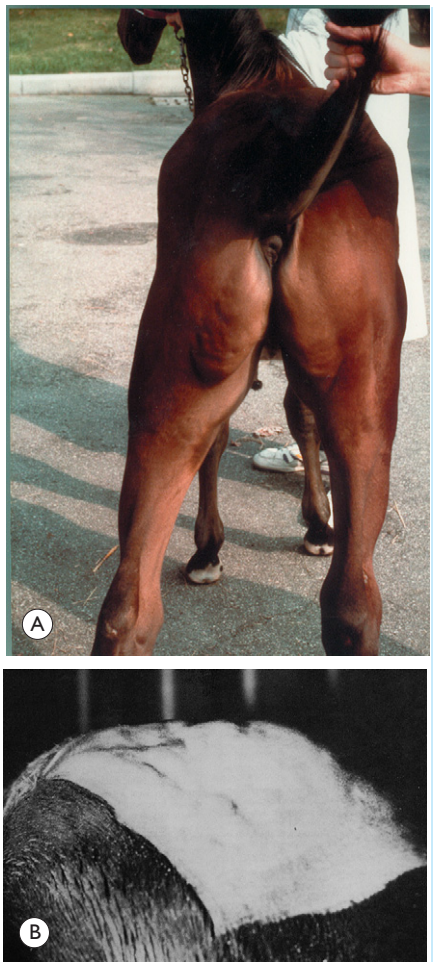

Fig. 6.22

(B) Percussion dimpling following clipping in the gluteal musculature of a 1-month-old Quarter Horse colt with myotonic dystrophy. (From Reed et al[179]. Reproduced by permission of John Wiley & Sons Inc.)

Diagnostic confirmation

The main differential is equine myotonia. Additional clinical signs and muscle biopsy will aid in the diseases' differentiation.

Treatment and prognosis

There are no reports of successful treatment.

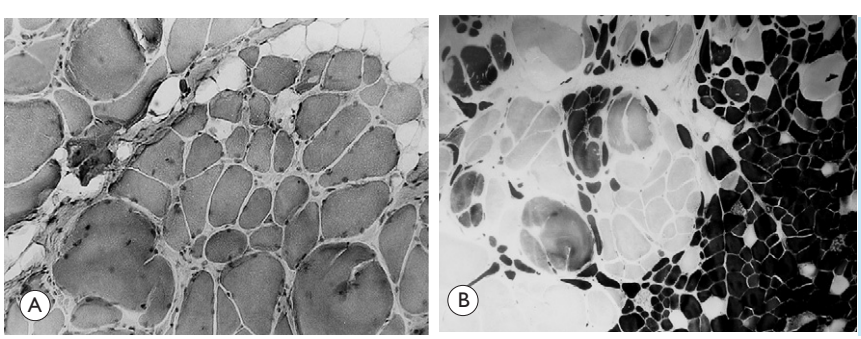

Fig. 6.23

(B) ATPase staining at alkaline pH. Compare with Fig. 5.20F, p. 60). Note the marked variation in fiber size with type I hypertrophy and fiber type grouping. (Courtesy of Prof Mario Cipone, University of Bologna, Italy.)

Prevention

Owners should be advised with regard to breeding affected or related animals, as the disorder may be genetic in origin.

Etiology and pathogenesis

The etiology and pathogenesis have not been established. There are several inherited forms of myotonic dystrophy in people, one of which is caused by mutations in a gene encoding a protein kinase,[215,216] although other genes are also implicated.[217] In humans, endocrine disorders including hyperinsulinemia and hypogonadism are common.[218,219]

Epidemiology

The condition has been reported in Quarter Horses and in a horse of Anglo-Arab-Sardinian descent.[179,180,210]

Mitochondrial myopathy

- Rare cause of severe exercise intolerance.
- Light exercise causes pronounced lactic acidemia.
- Diagnosis is achieved via muscle biopsy and measurement of mitochondrial enzyme activities.
- Reduced activity of mitochondrial enzyme complexes are probably associated with mitochondrial or genomic DNA mutations.
- There is no treatment and prognosis is poor.

Recognition

History and presenting complaint

The most likely history will include severe exercise intolerance. Mitochondrial myopathies in people are associated with exercise-induced myalgia and cramps.[220]

Physical examination

In the reported case, the Arabian appeared normal at rest.[221] However, human patients frequently have additional cardiac and central nervous system involvement.[222]

Special examination

Exercise test Light exercise resulted in stiff, short strides, profuse sweating and metabolic acidosis due to marked lactic acidemia (Fig. 6.24). Oxygen consumption was reduced, but PVO_2 increased. The horse was unable to exercise for more than 6 minutes and recovery was prolonged.[221]

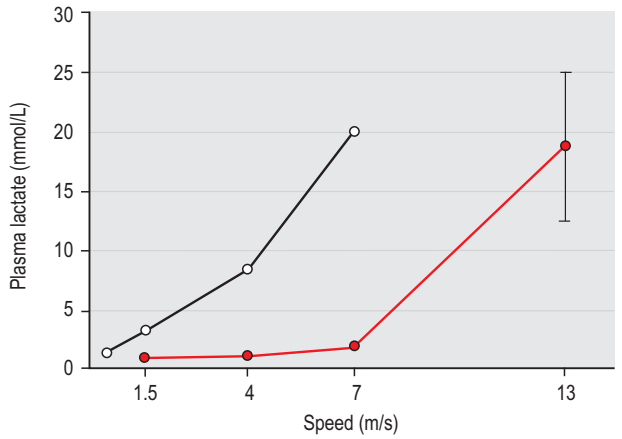

Fig. 6.24
Graph showing rise in plasma lactate concentration in a control horse (red line) and in a horse with a mitochondrial myopathy (black line) according to the speed of the treadmill. Notice that the affected horse produces large amounts of lactate even at slow treadmill speeds. (From Valberg et al.[221] Reproduced by permission of John Wiley & Sons Inc.)

Laboratory examinations

Hematology and biochemistry Routine hematology and biochemistry analysis, including CK activity, was normal in the reported horse at rest.[221] However, given the multiple systems involvement in humans,[222] other cases may have variable abnormalities.

Muscle biopsy Mild myopathic changes may be evident. In humans, classic findings include intense red-staining subsarcolemmal deposits of mitochondria in a few fibers with modified Gomori's trichrome stain – so-called 'ragged

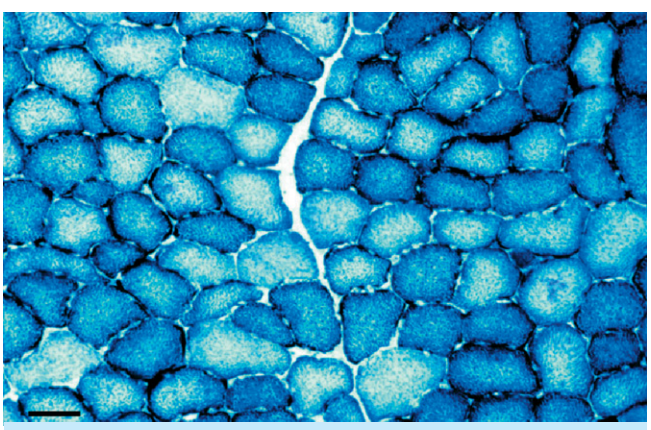

Fig. 6.25
Light microscopic transverse section of gluteus medius muscle stained with nicotinamide adenine dinucleotide tetrazolium reductase from an Arabian horse with suspected mitochondrial myopathy. Note the dark staining (mitochondria), particularly towards the rim of many myofibers, including the paler glycolytic fibers.

red fibers'. However, normal trained horses have abundant subsarcolemmal mitochondria, which can appear similar. Histochemical staining of NADH-dehydrogenase (complex I), succinate dehydrogenase (complex II) and cytochrome oxidase (complex IV)[10] may be abnormal, suggesting respiratory chain enzyme dysfunction (Fig. 6.25). Electron microscopy may reveal extensive subsarcolemmal and intermyofibrillar mitochondria with distorted or concentric cristae.[221]

Biochemical analysis of mitochondrial oxidative enzymes Mitochondrial respiratory chain enzyme activities are analyzed in mitochondrial preparations from affected muscle. The following enzyme activities should be measured by a specialist laboratory and compared with controls; in the reported horse, complex I enzyme activities were significantly reduced.[221]

Citrate synthase	(matrix enzyme)
NADH-dehydrogenase	(complex I)
Rotenone-sensitive NADH – cytochrome-c-reductase	(complex I and III)
Succinate – cytochrome-c-reductase	(complex II and III)
Succinate dehydrogenase	(complex II)
Cytochrome oxidase	(complex IV)
ATP-synthase	(complex V)

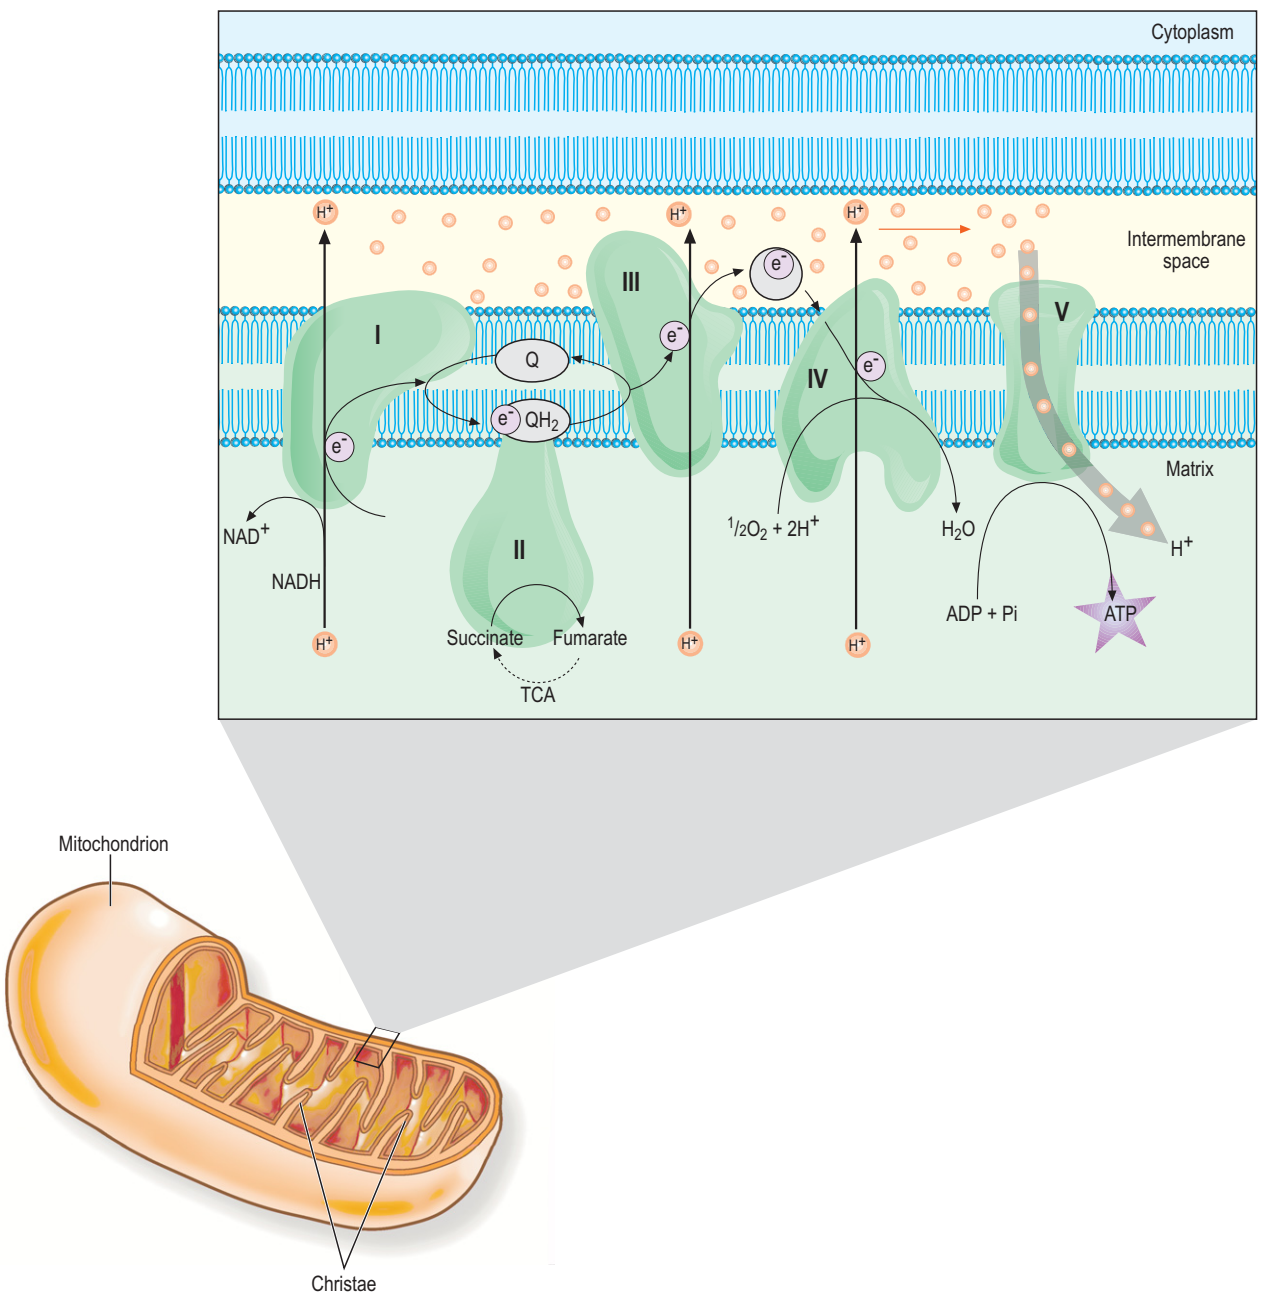

Fig. 6.26
Diagrammatic representation of the mitochondrial respiratory chain in mitochondria. The enzyme components of each complex are located in the inner membrane. Protons accumulate in the intermembrane space and their energy is harnessed to regenerate ATP (via ATP synthase). Q = ubiquinone.

Diagnostic confirmation

Other much more common causes of exercise intolerance should be ruled out before diagnosing mitochondrial myopathy. In their absence, severe exercise intolerance and unusually pronounced exercise-induced lactic acidemia should prompt muscle histopathological investigation and measurement of mitochondrial enzyme activities. Mutational analysis of mitochondrial or genomic DNA enables definitive diagnosis in humans; the complete equine mtDNA sequence is now available.[223]

Treatment and prognosis

The prognosis depends on the degree of respiratory chain compromise, but is likely to be poor as there is no treatment. Affected animals are very unlikely to be athletic.[221]

Etiology and pathophysiology

Etiology

The respiratory chain enzyme complexes that produce ATP during oxidative phosphorylation are located in the folded cristae of the inner mitochondrial membranes (Fig. 6.26). In humans, the proteins that make up complex II are encoded by genomic DNA, whereas the other complexes are encoded by genes in both genomic DNA and mtDNA,[222] hence mitochondrial myopathies may be caused by mutations in either.

Pathophysiology

Mutations in mtDNA occur spontaneously or are inherited from the mother, because mitochondria are maternally derived. Within individuals, different tissues may contain normal and mutated mitochondria in varying amounts (heteroplasmy). If sufficient normal mitochondria exist, oxidative phosphorylation defects go unrecognized, but become evident in tissues when mutated mtDNA predominates, especially when ATP requirements are high, as in muscle. In muscle, defective oxidative phosphorylation results in greater emphasis on anaerobic glycolysis for energy production and correspondingly, a rise in lactate production. In humans, mitochondrial diseases often affect multiple systems, although postmitotic tissues, such as the central nervous system and muscle, are over-represented, probably because of inability to select against abnormal mitochondria in affected cells.[222]

Fibrotic myopathy

- Mechanical hindlimb lameness characterized by the foot abruptly slapping the ground at the end of the anterior phase.
- Congenital and acquired forms have been recognized.
- Most horses have a history of trauma to the affected limb.
- A fibrotic mass may be palpable in the semitendinosus or other hamstring muscles.
- Transection of the mass or tibial insertion tenotomy results in return to normal function in some horses.

Recognition

History and presenting complaint

Horses present with unilateral or occasionally bilateral hindlimb lameness. There may be a history of injury, trauma or intramuscular injection in the affected limb.[224]

Physical examination

The mechanical lameness, which does not respond to analgesics, is most obvious at the walk or slow trot and is characterized by a sudden cessation of the anterior phase of the stride, with the hoof abruptly slapping the ground. At faster gaits the lameness may disappear. Taut muscles containing a firm, fibrous mass may be palpable in the bellies or myotendinous junctions of the semitendinosus (most commonly), but also the semimembranosus, biceps femoris and gracilis muscles (Fig. 6.27).[19,224–226]

Special examination

Ultrasound may help locate sites of fibrosis[227] and radiography can identify ossification.[19,224] Electromyography may suggest denervation that can be confirmed by muscle biopsy.[228]

Diagnostic confirmation

Other causes of hindlimb lameness should be considered. Mild stringhalt is sometimes confused with fibrotic myopathy

Fig. 6.27 Palpating the hamstring musculature for evidence of fibrotic myopathy. (Photograph courtesy of Dr Kenneth Hinchcliff, Ohio State University, USA.)

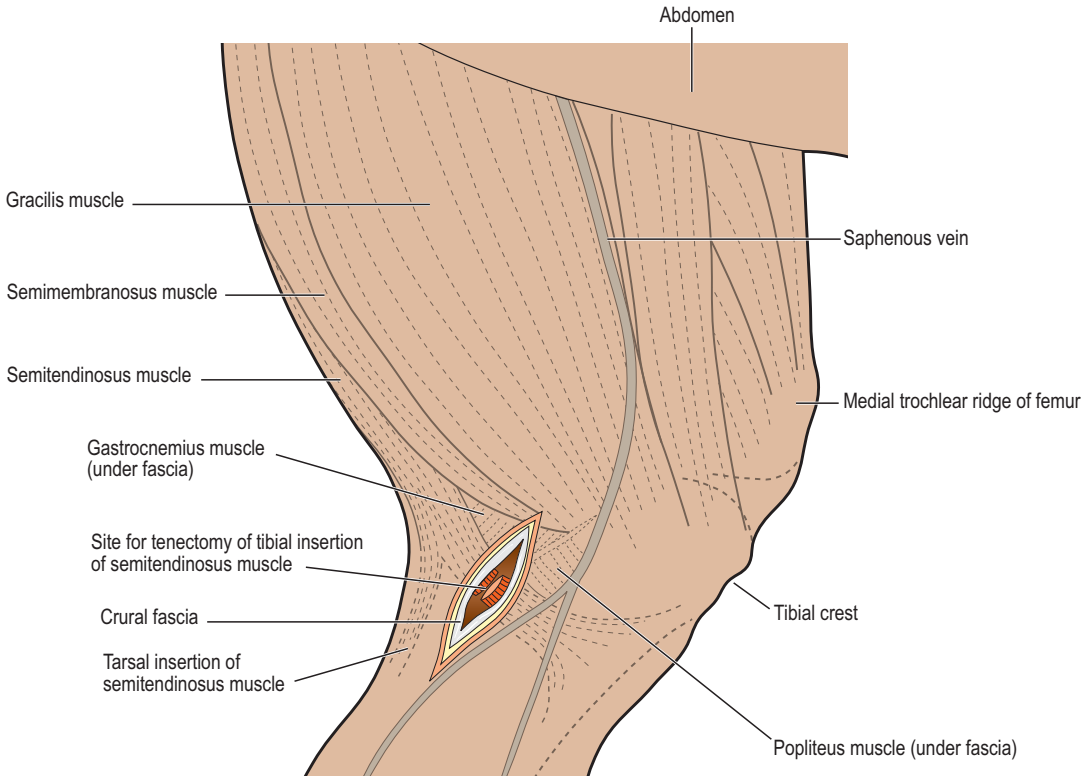

Fig. 6.28 Diagrammatic representation of the medial aspect of the hindlimb showing the semitendinosus tibial insertion tenotomy site with regional anatomy.

but stringhalt is associated with abnormal sudden upward flexion of the limb. In most cases of fibrotic myopathy the gait is pathognomonic.

Treatment and prognosis

Therapeutic aims

The main aim is to restore the normal mechanical function of the limb.

Surgery Transection[226] or excision[224] of the fibrotic mass or tenotomy of the tibial insertion of the semitendinosus muscle are described.[19,229]

Muscle transection Although usually performed under general anesthesia, transection of the fibrotic mass using a bistoury knife has been performed in the standing horse under local anesthesia. Postsurgical drainage is maintained with a Penrose drain inserted through a second incision, ventral to the first, and healing occurs via second intention. Light exercise is resumed the day after surgery.[22,226]

Tibial insertion tenotomy under general anesthesia The tendon of insertion of the semitendinosus muscle is palpated medially (with the horse in lateral recumbency and the affected limb down), caudodistal to the femorotibial joint (Fig. 6.28). The tendon is exposed and transected following vertical skin incision caudal to the medial saphenous vein. Closure is routine and tension sutures are placed in the skin. Residual healing occurs via second intention if dehiscence occurs. Mild exercise is recommended 2 weeks postoperatively with full exercise allowed after 6 weeks.[19,230]

Analgesia Treatment consists of NSAIDs (e.g. 2–3 mg/kg phenylbutazone i.v., q 12 h p.o.) postoperatively for 2–3 days.

Prognosis

Tenotomy is reported to result in fewer complications and have greater success.[19,224] Results depend on which muscles are affected and are better when only the semitendinosus muscle is involved.[229]

Etiology and pathophysiology

This disorder is seen worldwide in athletic horses and is often associated with trauma during work (particularly Quarter Horses) or from fences or ropes. Fibrosis following intramuscular injection has also been described[224] as has denervation atrophy (e.g. sciatic nerve entrapment following fracture of the greater trochanter).[228] In young animals, the disorder may be congenital.[19]

The hamstring musculature supports the stifle during the early stance phase of the gait cycle, enhances propulsion in the late phase and controls the limb's momentum during the swing phase of the stride. Limited range of movement imposed by fibrotic muscle causes an abrupt termination of the swing phase.

CHAPTER 7

Skeletal physiology: responses to exercise and training

Allen E. Goodship and Roger K.W. Smith

Introduction

Role of the skeleton

The mammalian skeleton provides protection for vital organs, a reservoir of minerals and a structural support for the body. Its major role, however, is provision of structural support and a means of locomotion using jointed bones together with muscles, tendons and ligaments. These components have evolved to optimize posture and locomotion for the lifestyle of individual species. The type of joints and position of muscle and tendon attachment relative to lever arms and fulcra provide an optimal mechanical advantage. As a structure the skeleton has evolved to provide maximum strength with minimal mass. The skeleton comprises a series of morphologically distinct elements – bones. The shape and size of these individual bones are determined by genetic and functional factors to prove an appropriate structure for functional demands with low risk of failure and without incurring excess energy expenditure. The demands for energetic efficiency are greater in animals evolved for high-speed locomotion, such as horses.

The horse has not only evolved to become a high-speed animal, but has also been the subject of selective breeding as an elite animal athlete. The Thoroughbred race horse is a prime example of selection for speed. However, it has been suggested that this selection process has reached its limit on the basis of classic race times remaining similar for many years. The Thoroughbred has arisen from a somewhat limited gene pool and this may have resulted in a plateau of performance.[1] This is in contrast to the performance of human athletes in which records are broken almost year on year. However, an alternative explanation is that training methods to condition race horses have not developed to optimize the capacity of the adaptive responses of the musculoskeletal system. In human athletics the application of sports science has undoubtedly contributed to the enhancement of performances over recent years. Equine sports science is not yet developed or applied to the same extent. In addition, many training systems continue to be based on empirical and traditional methods.

The skeleton has a unique capacity to respond to changes in mechanical loading in the short term and can, therefore, optimize for energetic efficiency in relation to changes in mechanical demands. There is a need not only to understand these mechanisms in general but to apply the information to specific training regimens for equine athletes.

Skeletal requirements for the horse

The requirements for the skeleton in the horse are, in common with other animals, related to functional demands, imposed by both evolutionary process and short-term conditioning. Domestication and the varied requirements for man's interaction with this species have resulted in a wide range of breeds and types of horse, with great variation in conformation. Selective breeding has resulted in adaptation of this species for the different specific purposes. Some breeds are massive and the bones are relatively high in mass to accommodate needs for strength and endurance but they are not able to sustain high speeds. Others have been selected for speed, the Thoroughbred race horse perhaps being the best example of skeletal development for speed. As such, the requirements for the skeleton in these horses are those of low mass and high strength.

The 'design' of the equine skeleton is a refinement of the basic mammalian pattern. The horse is an unguligrade

animal, a member of the order Perissodactyla, the odd-toed ungulates standing on the hoof of the third digit. The major muscle masses of the limbs are positioned proximally to reduce the energy required to move the limb as it swings backward and forward in cursorial locomotion. Muscle forces are transferred to distal bones across joints by means of long tendons. The tendons and ligaments have also evolved to play a major role in the energetic efficiency of locomotion, many acting as energy-storing springs.

Bone mass is also minimized at the distal extremities and safety margins decrease toward the distal extremity of the limbs. This has been related by Currey[2] to the incidence of fractures in race horses[3] being higher in the distal bones than those located proximally.

Selection for high-speed gait is also reflected in the morphology of the equine skeleton. The lever arms at the elbow and hock result in small muscle contractions producing fast extensive movement of the lower limb segments.

Skeletal refinements in the elite equine athlete are basically fine tuning of this general pattern. New methods of analysis of skeletal conformation are being used to assess the level of performance in several different types of horse.[4] However, these systems have not yet been perfected any more than many other methods for identifying potential winners at an early age. With advances in understanding of the factors that optimize efficiency and the development of complex computer modeling systems, it may eventually be possible to identify athletic performance of individual horses at an early age.

The ability to select and train elite equine athletes must result from a sound understanding of many aspects of the pathobiology of the horse, from the cell and molecular level to that of the whole animal. One of the most important systems in relation to locomotor performance is the musculoskeletal system. The major structural support tissue is bone.

Bone as a tissue

Bone as a tissue is a member of the family of connective tissues. These are characterized by being a composite of cells and extracellular matrix. The matrix in the case of bone is a composite of an organic, predominantly collagenous component and an inorganic hydroxyapatite component.

Bone cells and interactions

Adult bone tissue comprises three major populations of cells, each with a specific functional role but with both cell-to-cell interactions and also cell–matrix interactions. It is the coordinated interaction of the activities of these cell populations that optimizes the morphology of bones in relation to changing mechanical demands. Understanding these mechanisms and applying the principles to training regimens has the potential to improve performance and minimize injury in conditioning of equine athletes.

Osteoblasts

These cells are derived from local lining cells. The flattened mononuclear cells become plump when activated and synthesize bone matrix in the form of osteoid (Fig. 7.1). The osteoid then becomes mineralized over a period of weeks to form bone matrix. In rapidly forming surfaces some osteoblasts are entrapped in their own matrix and these then become osteocytes (Fig. 7.2). The osteoblasts communicate with osteoclasts and enable activation of osteoclasts to allow bone resorption. Osteoblasts also produce colony-stimulating factor that increases numbers of pre-osteoclasts from mononuclear precursors in the bone marrow and also osteoclast activation factor that activates the pre-osteoclasts and initiates resorption of bone matrix (Fig. 7.3). The coupling of bone resorption and subsequent bone formation has recently been shown to involve a receptor on the osteoblast cell membrane known as RANK ligand (RANKL) which binds to RANK present on the surface of pre-osteoclasts and induces activation of the intracellular cascades to activate the osteoclasts. The RANKL can also bind to a protein called 'osteoprotegerin,' OPG, which prevents binding with and activation of osteoclasts. Thus a regulation of coupling of these cells

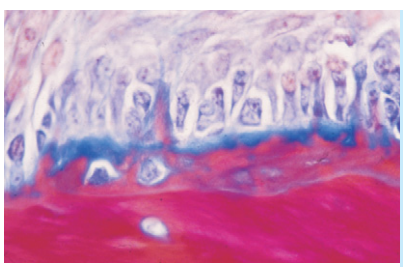

Fig. 7.1
A photomicrograph of bone showing the bone-forming cells called 'osteoblasts'. The blue staining matrix is the precalcified osteoid. Cells can be seen becoming entrapped in matrix to become osteocytes.

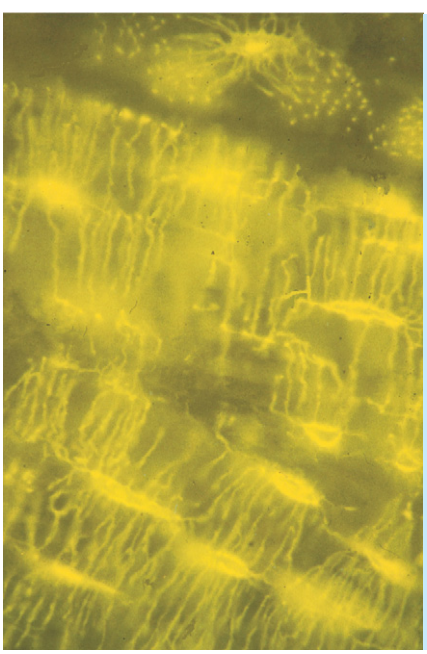

Fig. 7.2

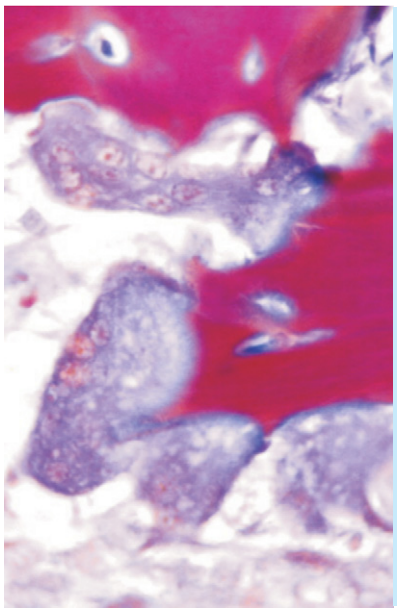

Fig. 7.3
A photomicrograph showing bone resorption by osteoclasts.

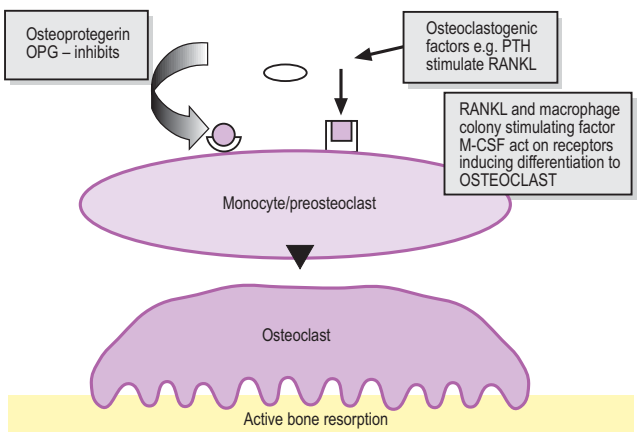

Fig. 7.4
Coupling of the bone remodeling cycle.

and associated amounts of bone resorption and formation is effected by this system (Fig. 7.4).[5,6] Other systemic factors can also influence this system; for example, parathyroid hormone (PTH) can 'blunt' OPG influence. The osteoblasts can also secrete collagenase, an enzyme that removes the surface layer of osteoid, unmineralized bone matrix, on bone surfaces and allows osteoclasts access to the bone matrix. Boyde et al used in vitro systems to measure bone resorption activity of osteoclasts and also to show the interactions between osteoblasts and osteoclasts.[7] Hormonal influences on calcium metabolism and bone resorption act indirectly on receptors on the osteoblast which in turn regulates osteoclast recruitment and activity. Thus the osteoblast is central to the control of the bone modeling and remodeling process.

Osteoclasts

These cells are derived from circulating monocytes. They are multinucleate cells (Fig. 7.3) which, when activated, reside on a bone surface with a ruffled border to isolate the local environment between the cell and the bone surface. The perimeter of the cell membrane forms a seal against the underlying bone involving adhesion molecules, the integrins to isolate the local environment beneath the cell which is then lowered in pH by an active proton pump generating hydrogen ions.[8] The pH falls to around 2–3 and the bone matrix and embedded osteocytes are resorbed, forming a resorption pit, and the resorption products are trafficked through the cell.[9] As indicated above, this process is regulated by the osteoblasts, which in turn communicate with the third population of cells – the osteocytes. The bone-resorbing osteoclasts are also influenced directly by some specific hormones such as calcitonin.

Osteocytes

These cells arise from osteoblasts that become trapped in the bone matrix within lacunae. They are cells with many long cytoplasmic processes within small tunnels in the matrix called canaliculi (Fig. 7.2). Processes from adjacent cells connect by means of gap junctions allowing cell-to-cell communication. A recent finding by Skerry and co-workers has been the identification of glutamate transport systems involved in osteocyte cell signaling.[10] This transmitter also operates in the central nervous system, where complex interneuronal signaling occurs. The presence of such a signaling mechanism among osteocyte bone cells provides supporting evidence that this population of cells plays a role in the overall perception of mechanical environment on a bone and co-ordinates an appropriate response to ensure optimal bone size and architecture.

The osteocytes and their cell processes are surrounded by extracellular fluid. The mechanical loading of a bone results in deformation and movement of this extracellular fluid within the matrix around the cells. Extracellular fluid contains ions and the movement of this ionic fluid with respect to the charged surfaces of the matrix induces electrical potentials. These electrical charges are referred to as 'streaming potentials' which are also thought to influence the cell activity and provide a putative mechanotransduction pathway.[11,12] The gap junctions linking cell communication are also modulated in number by mechanical loading of bone and thus may play a role in regulation of bone form in response to functional demands.[13]

The networks of osteocytes also communicate with the surface lining cells and osteoblasts. Thus the integration of the cell populations by the osteoblasts provides a complex but extremely sensitive mechanism to enable bone mass and architecture to be optimized for the changing mechanical demands throughout life.

Lining cells

Quiescent bone surfaces are covered by lining cells which have the capacity to respond to both mechanical and biological signals and are activated to change shape into plump, metabolically active osteoblasts. These cells are found in the osteogenic layer of the periosteum or endosteum; these membranes comprise a deep cellular layer and a more superficial fibrous layer (Fig. 7.5). Some pluripotent cells have been demon-

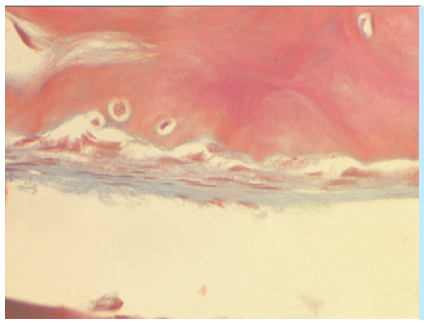

Fig. 7.5
Lining cells on a bone surface – periosteum, comprising a fibrous outer layer and an osteogenic or cambium inner layer of cells.

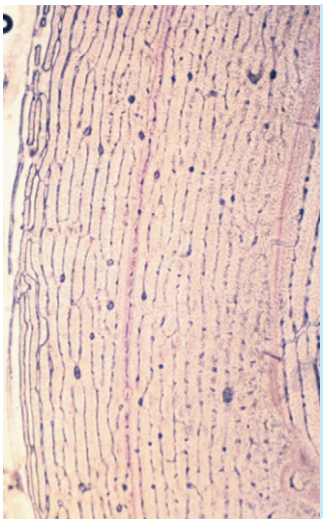

Fig. 7.6
Photomicrograph of a transverse section of laminar bone.

strated in the osteogenic cellular layer and these have been shown to have the capacity to differentiate into other connective tissues such as cartilage. There is currently considerable interest in the various types of pluripotent cells in the adult as a source of 'stem' cells that play a role in tissue regeneration. These quiescent lining cells are activated by mechanical or hormonal stimuli to generate a bone-forming front of metabolically functional osteoblasts involved in a modeling or remodeling process to maintain or restructure the matrix.

Bone matrix

The extracellular matrix of bone is composed of two major components: first, the collagenous organic component of predominantly type I collagen, imparting high tensile strength, and second, the inorganic salt hydroxyapatite, imparting high compressive strength. The apatite crystals are deposited onto the collagen and gradually become orientated in a preferred direction with age.[14]

As a composite material, bone matrix is anisotropic and the architecture of the matrix in relation to the osteocytes forms the basic unit of structure, termed the lamella. The architecture of the lamellae can be observed under polarized light microscopy as the collagen is a birefringent material. The architecture of these bone lamellae in different geometrical arrangements forms the basis of the different histological types of bone. Concentric circumferential lamellae form osteons and when these are formed in the original development of the bone they are termed 'primary osteons'. A similar architecture is also seen in the secondary osteons that are formed to repair damage such as micro-cracks or infill porosities within the cortex. Lamellae formed around vascular networks or plexi result in laminar or the less regular plexiform bone often seen in ungulates like the horse (Fig. 7.6). This type of bone allows very rapid increases in cross-sectional area with later consolidation.[2] Lamellar bone can also form circumferential lamella on the entire periosteal and endosteal surfaces of individual bones (Fig. 7.7).

In embryological development and in the early stages of fracture repair a rapidly forming bone with irregular lamellae, coarse collagen fibers and large osteocyte lacunae is seen. This is called 'woven' bone and is rapidly remodeled to the various types of organized lamellar bone, such as primary and secondary osteonal bone, previously termed 'Haversian' bone (Fig. 7.8).

Bone morphology has been related to the mechanical loading requirements of different specific bones. For example,

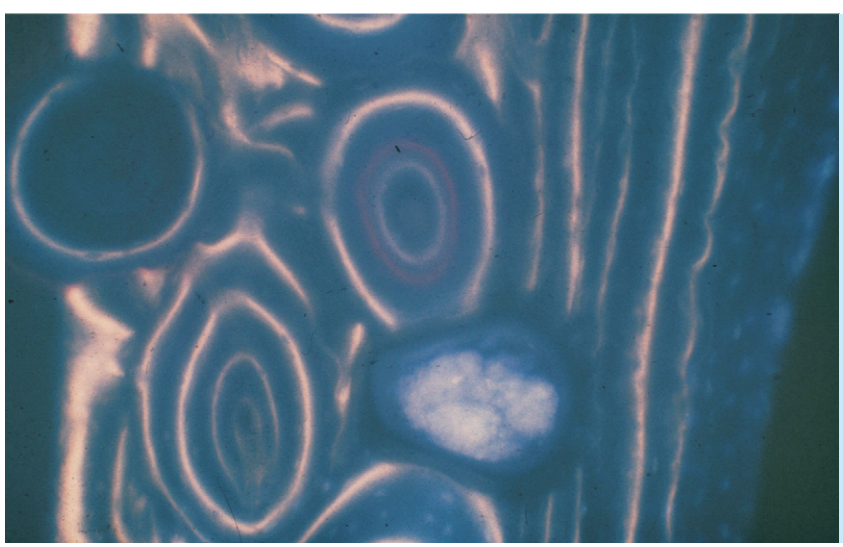

Fig. 7.7
Photomicrograph of a transverse section of cortical bone to show secondary osteons at different stages of formation in the process of remodeling and endosteal circumferential lamellar bone.

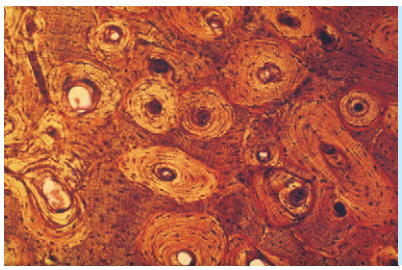

Fig. 7.8
Photomicrograph of a transverse section of highly remodeled secondary osteonal cortical bone.

the orientation of collagen fibers in the cranial and caudal cortices of the radius reflects the mechanical requirements of this bone. Strain gauge studies have shown that this bone is loaded in both compression and bending with principal tensile strains aligned with the long axis of the bone in the cranial cortex and principal compressive strains aligned to the long axis in the caudal cortex.[15] The arrangement of collagen fibers in relation to this pattern of loading has been demonstrated by Riggs et al.[16] This has been supported by a comprehensive analysis of matrix morphology in the equine radius by Mason et al, in which the analysis of primary bone and bone within secondary osteones of the cranial and caudal cortices of the radius were arranged appropriately to optimize for the pattern of functional loading.[17] Mason et al also confirmed a predominant longitudinal arrangement of collagen fibers in the cranial cortex of this bone, to resist the functional tensile strains at this location.[17] Any consistent changes in the magnitude and pattern of loading induce a modeling response in which the bone cell activity will modify the matrix to maintain the optimization of the overall bone architecture in relation to the new prevailing loading conditions. Matrix, and embedded osteocytes, can be removed by osteoclasts and new matrix formed by osteoblasts. This coupled cellular activity allows bone as both a material and structure to be changed in terms of mass and distribution throughout life.

Matrix molecular composition

Bone matrix comprises approximately 65% inorganic mineral, largely hydroxyapatite, and 35% organic material and water.

As with all connective tissue matrices, there is a high proportion of water in the order of 25%, dependent upon type of bone. The remaining matrix is predominantly type I collagen together with a small proportion of minor collagens and non-collagenous proteins, including proteoglycans and glycoproteins. Some growth factors such as TGF-β and bone morphogenetic proteins are also present in abundance within bone matrix; these peptides act as biological signaling molecules for mitogenesis and differentiation of bone-forming cells. They are released with osteoclastic resorption of the matrix and can act in autocrine and paracrine manner on the osteoblasts.

Bone matrix components include osteonectin, bone sialoprotein, osteopontin and osteocalcin, a protein that can be used in blood assays together with collagen propeptides that have been investigated as a non-invasive method to monitor bone cell activity during growth, development and training of horses.[18,19]

Material properties

The material properties of bone matrix vary and are largely related to the degree of mineralization, particularly with respect to modulus of elasticity. Bone such as the tympanic bulla, with a very high mineral volume fraction and density, has a high modulus eminently suitable for conduction of sound, whereas deer antler is low in mineral content and has a low modulus, again appropriate to avoid fracture in its role in fighting. Bone matrix is an anisotropic brittle elastic material and the elastic modulus is related to the level of mineralization. The influence of mineralization on material properties has also been evaluated during growth and maturation. In immature horses the level of mineralization is low and increases to a higher level with maturation to adult equine bone. With development and increased mineralization there is a significant correlation with changes in mechanical properties; it is suggested that such changes may be measured non-invasively using ultrasound transmission systems. This would provide the potential to monitor material properties of bone during growth and possibly during training.[20]

The material properties and morphology of specific bones determine the structural properties of the individual skeletal elements. Thus changes in the mechanical competence of bones as structures may be a consequence of either changes in the material properties of the constituent tissue or an alteration in the structural distribution of the material in relation to the magnitude and distribution of the loads applied at a particular time. The dynamic nature of bone tissue provides the ability to optimize structure in response to changes in matrix material properties.

Mechanical characteristics

Bone tissue as a material contributes to the mechanical characteristics of the individual skeletal elements. The architectural arrangement of the material is predominantly related to the general functional requirements of the particular skeletal elements. In the long bones the diaphysis is tubular to resist the functional loading patterns of bending and torsion. In engineering terms these loading patterns can be sustained with maximum strength and minimal material by tubular structures with the material distributed at a distance from the neutral axis. For example, if a solid beam is subjected to bending, one surface will experience tensile stresses and the opposite surface compression stresses. At some plane between

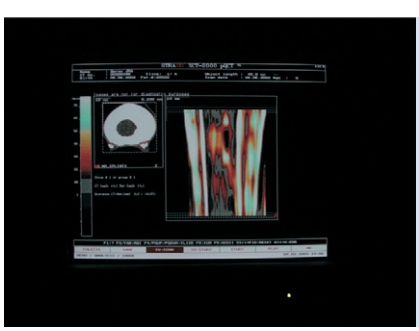

Fig. 7.9

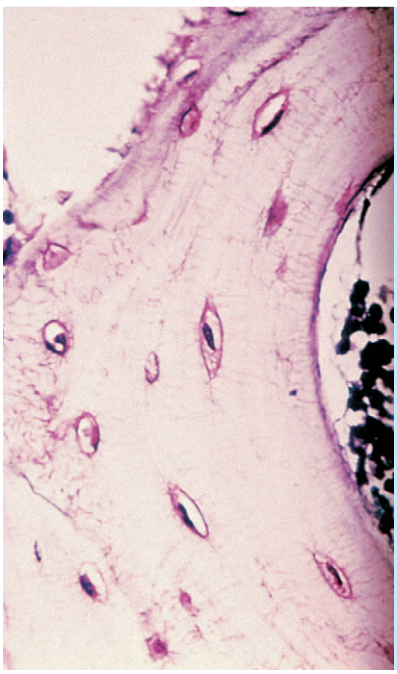

Fig. 7.11
Photomicrograph of histological section of a bone trabeculum to show lamellar bone structure.

these two surfaces there will be neither tensile nor compressive stresses (the neutral axis), thus no material is required in this region. When bone tissue organizes into the components of the skeleton, its structure is based on optimization of energetic efficiency. Thus to minimize the mass of material, bone is not present in the medullary cavity (Fig. 7.9). The relative thickness of the cortices also reflects the loading patterns of a particular bone. These changes may be measured using radiographic and ultrasound transmission techniques.[21]

At the extremities of the long bones and in short bones the functional loads are predominantly those of axial compression. This is reflected in a different architecture with a thin cortical shell supported by internal cancellous bone (Fig. 7.10). The plates and rods of bone are termed trabecula and formed of aligned bone lamellae (Fig. 7.11). These rods and plates are not randomly arranged but strategically placed in relation to the trajectories of principal compressive and tensile stresses. In the cancellous bone of the epiphyses, underlying the articular surfaces of the synovial joints, the trabecula are orthogonal (perpendicular) to the articular surface. This architecture of the plates and rods again allows the use of minimal material to provide maximum strength and minimize energy requirements for locomotion. In short bones that are loaded predominantly in compression, the internal structure is of strategically arranged bony trabecula. Some short bones, such as the calcaneus, are subjected to bending moments. The internal cancellous architecture reflects this with arcades of trabecular bone arranged orthogonally to resist the principal compressive and tensile stresses. Nature reflects the calculated stress-related bracing seen in some engineering structures such as the Fairbairn crane in which the loading and principal stresses resemble those of the femur (Fig. 7.12).

The increased diameter of the bones in the regions of the epiphyses and the presence of subchondral trabecular bone act both to reduce stresses on the articular cartilage and provide a compliant structure to absorb impact loads. Thus any changes in the compliance of the trabecular bone will influence the loading of the overlying cartilage and can indirectly induce changes in the articular cartilage.

Bone as a structure/organ

Adult bone form is determined by a combination of genetic and environmental influences. Fell demonstrated that certain anatomic features of the developing skeleton are formed as a consequence of inherent genetic control whereas others require a functional loading to form.[22] An elegant study by Chalmers investigated the development of a mouse femur implanted into the spleen when at the cartilage anlage (precursor) stage of development.[23] This cartilaginous bone precursor developed into a bone with the basic form of the femur but lacked the architectural refinements seen in the normal adult mouse femur. The refinements, such as a waisted femoral neck, cortical thickness and trabecular architecture, are induced as a consequence of functional loading and are determined by the prevailing loading conditions (Fig. 7.13).

Comparison of the structure and stress distribution of the Fairbairn crane and proximal femur.

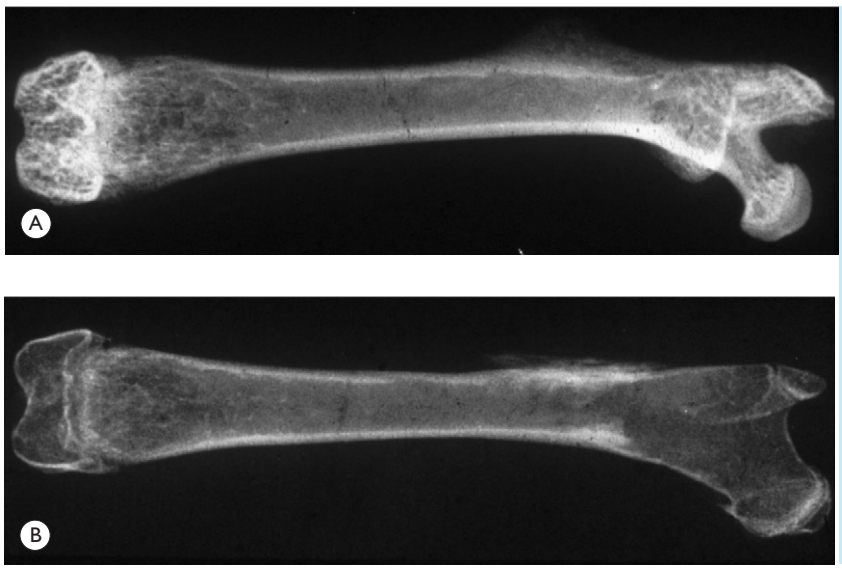

Fig. 7.13
Radiographs of mouse femora, showing the adaptations to functional environment (A) from the basic genetic template (B). Adapted from Chalmers et al 1962.

There is a dynamic interaction between the loads imposed on the skeleton and the morphology of the bones at any point in time throughout life. It is therefore important to appreciate these interactions in order to condition the skeleton for the demands of athletic performance and to understand the modes and mechanisms of failure.

Skeletal development

Growth

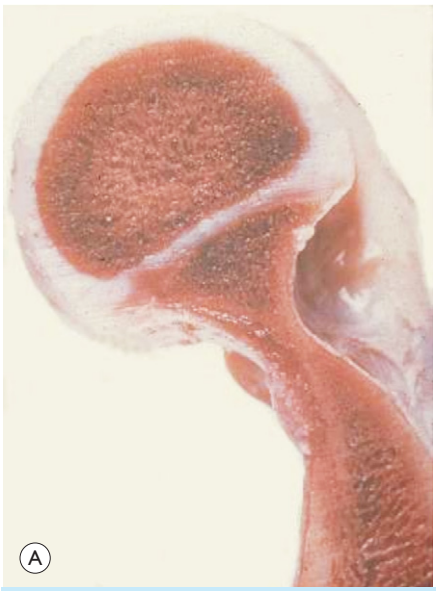
Ossification

The skeleton is developed both pre- and postnatally. The majority of the bones of the skeleton, particularly the appendicular skeleton, are preformed as miniature replicas in hyaline cartilage. This has the advantage of enabling rapid three-dimensional growth. The material and structural properties of hyaline cartilage are adequate to support the low level of loading prevailing in utero. In preparation for the postnatal changes in loading with gravitational and muscular forces, a more appropriate material must replace the hyaline cartilage. This is accomplished by vascular invasion, calcification and removal of cartilage and replacement with lamellar bone. This process is endochondral ossification. In a few sites of the skeleton, for instance the bones of the vault of the skull, bone is formed by direct ossification of a fibrous type I collagen scaffold. This process is intramembranous ossification.

The bones associated with locomotion are formed by both endochondral and intramembranous ossification. This allows simultaneous longitudinal and circumferential growth of the bones.

Endochondral ossification The initial vascular invasion of the cartilage replica occurs in the midshaft. In this region the chondrocytes within the lacunae undergo hypertrophy and the extracellular matrix becomes calcified. It is now thought that the endothelial cell invasion occurs in the non-calcified territorial and pericellular matrices following cell death[24] and that cell death in the growth plate occurs through an apoptotic pathway.[25] The calcified cartilaginous matrix is then removed by chondroclasts derived from vascular cells and replaced by woven and then lamellar bone. These spicules of bone become strategically organized and form the cancellous bone structure of the metaphysis, termed the primary spongiosa. In human growth this has been suggested by Byers et al as a critical component of the growth process and the development of the mineralization of the primary spongiosa may be of importance in relation to bone-altering disease in later life.[26] These authors also suggest that the secondary spongiosa retains a constant bone mineral volume throughout development. Thus in the developing horse the mechanical loading from exercise during growth and maturation could affect the level of mineralization of the primary spongiosa.

Simultaneously with the longitudinal growth, the fibrous layer covering the replica bone, the perichondrium, initiates ossification of the fibrous tissue and forms a cuff of bone which develops to form cortices of the tubular diaphysis. This process forms the 'primary' ossification center and is followed by further vascular invasion at one or both ends of the developing bone to form secondary ossification centers. The secondary ossification centers are separated from the primary center by plates of hyaline cartilage known as the growth plate or physis. This process allows for both circumferential and longitudinal growth and enlargement of the bone. The longitudinal growth occurs by utilizing the interstitial growth potential of hyaline cartilage in the proliferative zone of the growth plate. The physis has a distinct structural pattern relating to specific functional activities. The epiphyseal side of the plate is characterized by a resting zone of randomly arranged cells within an extracellular matrix. These cells give rise to the zone of proliferation in which the chondrocyte population is actively dividing. These cells then align into palisades extending toward the metaphysis, with the cells closest to the metaphysis showing hypertrophy of the lacunae. In this zone of hypertrophy the matrix becomes



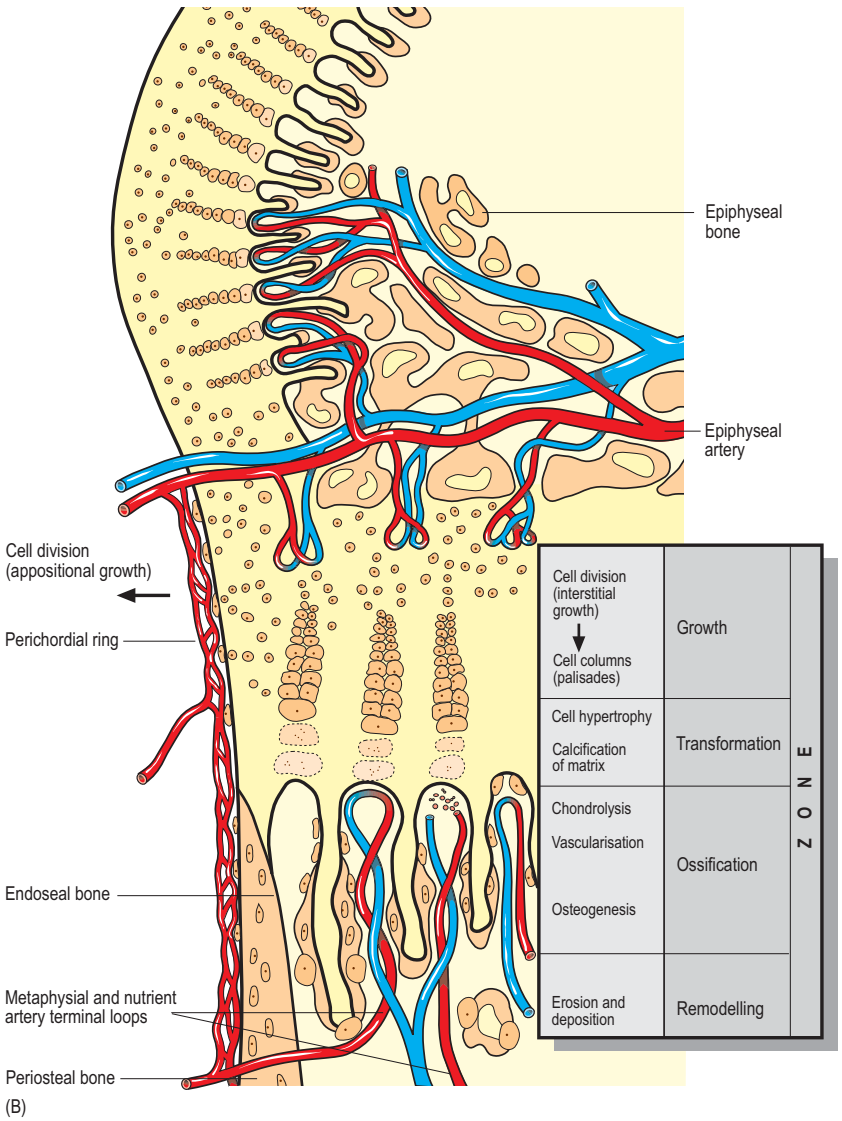


Fig. 7.14
(A) The growing spheroid and discoid physes in an immature growing long bone sectioned longitudinally. (B) Diagram to show the arrangement of palisades in the two physes.

calcified and is removed by chondroclasts. Osteoblasts then deposit woven bone on the calcified cartilage scaffold. This tissue is rapidly remodeled to lamellar bone and forms the trabecular rods and plates of the spongiosa that support the metaphyseal cortex. The width of the physis is increased by appositional growth from the overlying perichondrium. The physis can be described as a discoid physis contributing to the increase in longitudinal growth and width of the metaphysis. The epiphysis also acts as a spheroid physis to increase the size of the epiphysis by radial growth. The early articular cartilage is thick and arranged in a similar pattern to the physeal plate with the proliferating chondrocytes close to the articular surface and a radial arrangement of palisades toward the center of the epiphysis (Fig. 7.14). The secondary ossification centers and spheroid physes form the cancellous bone that supports the articular cartilage. Abnormalities in the process of ossification can lead to specific orthopedic conditions such as angular deviations of the limbs and osteochondral dysplasias.

The limited thickness of the physis in normal animals allows growth without excessive deformation of the cartilage which would result in angular deformations of the growing bone. In some conditions where ossification is inhibited and the cartilaginous component of the physis increases in thickness, limb deformities occur during growth. A classic example is dietary rickets. Rapid growth can also result in angular deformities of the long bones.

Intramembranous ossification As the bones increase in length there is also an increase in overall width of the metaphysis and diaphysis of the bone, accomplished by appositional bone growth on the periosteal surface. In the developing bone a cuff of periosteal bone is formed. The periosteum comprises an outer fibrous layer and an inner osteogenic 'cambium' layer. In this osteogenic layer cells differentiate into osteoblasts which deposit osteoid directly onto collagen type I fibers. This process ultimately forms lamellar bone. In ungulates the type of lamellar bone formed is laminar or plexiform bone. This primary vascular bone is capable of a rapid increase in cross-sectional area. In this type of bone a rapid appositional growth occurs with subsequent infilling of lamellae within the laminae of the vascular network.[27] Thus bone growth occurs to the age of skeletal maturity by means of these two processes.

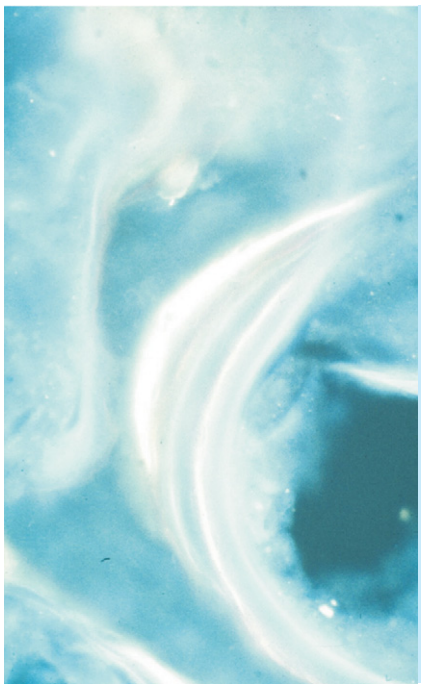

Fig. 7.15
Photomicrograph of a fluorochrome-labeled section of trabecular bone, showing apposition on one surface indicating a modeling change in architecture.

Modeling and remodeling

During the processes of both bone growth and adaptation to changes in loading, the shape or architecture of the bone is changed by cellular activity to remove and form bone. Unlike cartilage, bone cannot increase in size by interstitial growth; only by these processes of removal and formation of bone surfaces can the relative proportions of curvatures and the positions of tuberosities be maintained. Changes in shape result from removal and formation of bone at the same time but at different locations; this process is termed modeling and allows changes in three-dimensional tissue space (Fig. 7.15).

Modeling is determined both by growth and by mechanical loading. As a long bone increases in length the flared metaphysis is narrowed into the diaphysis by bone resorption on the periosteal surface and bone formation on the endosteal surface. In the diaphyseal region increase in bone width during growth occurs by periosteal appositional growth and endosteal bone resorption (Fig. 7.16).

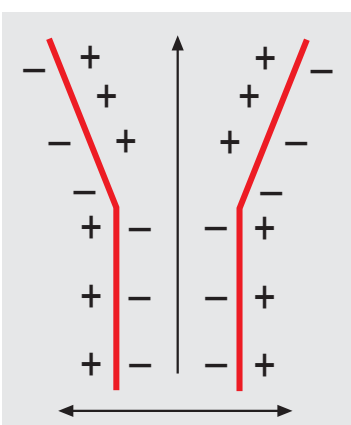

Fig. 7.16
Diagram of modeling changes at metaphysis and diaphysis during growth.

Within the bone matrix microdamage can occur as a consequence of repeated loading cycles. Repetitive loading in many inert materials results in accumulation of microdamage and ultimately, the gross fracture of the structure. Although bone is a structural material it is living and there are cell-to-cell and cell-to-matrix interactions. Thus changes in matrix can initiate cellular responses to maintain and adjust the matrix. Microdamage is a stimulus to induce osteoclastic resorption of the damaged matrix followed by deposition of lamellar bone by osteoblasts. This dynamic repair process occurs throughout life and during normal functional loading of the skeleton. It is termed remodeling and involves the resorption and removal of bone at the same site but at different points in time (Fig. 7.7). Bone that is formed in remodeling is called secondary bone. These secondary osteons continue to increase in level of mineralization for several weeks after formation of the osteon has been completed. The secondary bone is not as strong as primary bone but is stronger than the damaged matrix. The remodeling process results in the formation of 'secondary osteons'. The initial resorption is effected by a cutting cone of osteoclasts traveling longitudinally within the cortical bone, followed by lining osteoblasts that secrete the new circumferential lamellar bone with entrapment of osteoblasts within the matrix to become the osteocytes within the circumferential lamellae (Fig. 7.17). A glycoprotein layer is formed between the newly formed secondary osteon and the adjacent bone tissue which forms the cement line.

Bones as structures

Individual bones have specific morphologic features related to their functional contribution to the skeleton as a whole. The types of bones can be divided broadly into long bones, such as the femur, humerus, radius, tibia and the metacarpal/tarsal bones, short bones, such as the carpal, tarsal and distal phalangeal bones, and flat bones, such as the scapula, and some bones of the skull and pelvis. In addition, some bones are not directly involved in the structural support of the body but contribute to the mechanical arrangements of tendons in facilitating the change in direction of tensile forces. These bones, often associated with tendons, are the sesamoid bones, of which the patella, proximal and distal (navicular) sesamoids are examples.

The long bones can be divided into regions: the epiphyses, metaphyses and diaphysis. These regions show different morphologic arrangements of the bone tissue. The epiphyseal and metaphyseal regions comprise a thin cortical shell of compact bone supported by internal cancellous bone, sometimes termed spongy or trabecular bone. This internal arrangement of bone tissue comprises plates and rods of bone with spaces or cancelli filled with marrow or fat. The bone tissue in these areas often shows a definite pattern of trabecular arcades. This arrangement of internal spongy bone is also seen in the short bones. The geometric pattern is particularly noticeable on radiographs and especially those of the proximal femur and calcaneus (Fig. 7.18).

The internal structure of spongy bone has been of interest to scientists, engineers and surgeons since the time of Galileo. In the 1890s comparisons were made between the pattern of

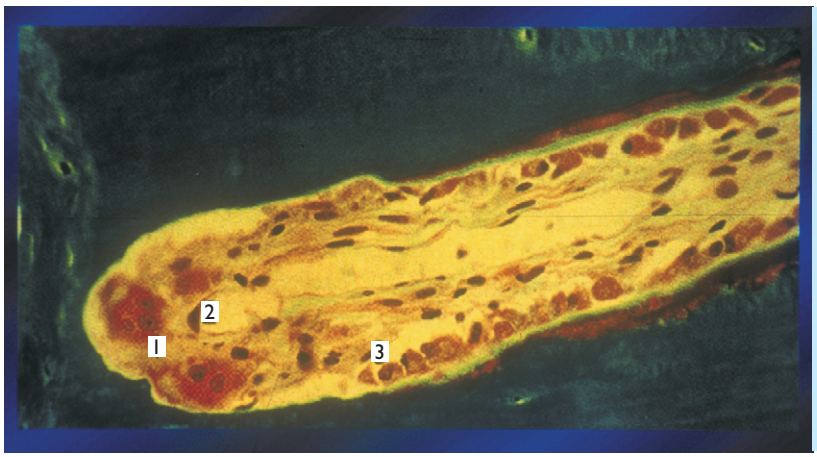

Fig. 7.17

cancellous bone and analysis of stress trajectories in engineering structures. The proximal region of the femur with the femoral neck and head is loaded in a manner very similar to that in engineering structures like the Fairbairn crane and the trabecular architecture reflects the lines of principal tensile and compressive stresses calculated for these structures (see Fig. 7.12).

Recent developments in technology have allowed the distribution of principal strains to be measured in the living skeleton and the data from such studies have provided supporting evidence that these bone trabeculae are strategically placed to optimize the strength of the structure with minimal mass of tissue. In animals this is important to reduce the energetic cost of locomotion. The thickness and structural density of trabecular bone also reflect the magnitude of the loads taken in that region of the bone. This has been shown in training studies; for example, the trabeculae in the dorsal region of the third and radial carpal bones are thicker than those in the more palmar regions in horses that have been trained for peak athletic performance. These observations can be used in diagnosis of bony changes related to mechanical loading of the skeleton. The site-specific changes, such as those in the carpal bones, are often found to be related to predilection sites of skeletal injury and pathology so knowledge of these interactions can enhance diagnostic and prognostic clinical skills.

The arrangement of bone tissue in the diaphyseal region of long bones is markedly different. This region is similar to a tube, hence the term tubular bone. The wall of the tube comprises compact cortical bone, of differing thickness, and a medullary cavity containing blood vessels, marrow and fat. This arrangement of bone reflects a different mechanical loading pattern; whereas in the short bones the loads are predominantly compressive loads, in the long bones spanned by tendons and ligaments there are large bending and torsional moments in addition to compressive loading.

Again, the biologic drive is to reduce the energetic costs of locomotion, whilst ensuring adequate structural strength to avoid failure during physiologic loading levels. In engineering design these requirements to provide maximum strength in bending and torsion using a minimal mass of material are met by a wide-diameter, thin-walled tube. This essentially places the material at the greatest distance from the neutral axis, where there are neither tensile nor compressive stresses. In long bones the medullary cavity represents the average neutral axis relative to the loading pattern of the bone. Thus strength is maximized and mass minimized to reduce the energy costs associated with moving the limb. In animals evolved for high-speed locomotion there is a high biologic drive to reduce energy costs. In engineering structures the material type, mass and distribution all contribute to the ability of the structure to resist functional loads. However, to allow for occasional overload a safety margin is normally incorporated into the design, such that the structure will not fail as a consequence of occasional overload. Studies have shown that the skeleton also incorporates a safety margin although this is not uniform in relation to skeletal location. The neck of the femur in humans is known to be able to withstand about five times bodyweight. The disadvantage of a safety margin is the additional mass of material. This becomes significant in the more distal regions of the limb since additional mass increases the momentum of the swinging limb and this in turn would result in a significantly increased energy requirement in decelerating and accelerating the limb, particularly in high-speed equine athletes.

Currey, analyzing data from Vaughan & Mason, showed that a higher incidence of fractures during racing occurred in the more distal bones of the limb and hypothesized that this could be explained by a lower safety margin in the more distal limb bones.[3]

Although the diaphysis of long bones is essentially tubular, the distribution of bone in terms of cortical thickness may be non-uniform around the circumference of the bone. This reflects different levels of resistance to bending in different planes and the associated distribution of bone mass.

Factors controlling shape and size

Genetic influences

Both between species and within species, the variation in the specific geometry of individual bones is a consequence of two main factors. First, a genetic component that will control a basic bone mass. Second, a response to prevailing mechanical conditions which will modify the basic genetic pattern in relation to both the magnitude and the distribution of loads applied to the particular bone.

Disuse will result in a tendency toward the genetic basic bone mass. Abnormal loading will induce a concomitant abnormality in the size and shape of the bone. Chalmers in 1962 demonstrated these controling factors by transplantation of the cartilage precursor of the mouse femur to the spleen, where it developed with adequate blood supply but devoid of mechanical input.[23] Although the basic shape of a femur could be recognized, this bone lacked the refinements in both mass and architecture exhibited by the normal functionally located bone in littermates (see Fig. 7.13). Further evidence that certain anatomic features of specific bones were genetically predetermined and others were formed as a consequence of local stimuli was provided by Fell using isolated limb buds from developing embryos in organ culture.[22] Genetic modification of a basic anatomic skeletal pattern is often seen in relation to attaining specific conformation for either visual or functional requirements. Even within specific breeds of horse certain genetic strains are evident and linked to differences in bone mass and architecture. Other factors influenced by selective breeding, which could be described as genetic modification, such as muscle mass, may have an indirect influence on bone mass as a consequence of increased levels of mechanical loading of the bones. As both a tissue and a structure, bone has the property of functional adaptation.

Environmental influences

Other factors such as nutrition and hormonal environment may also influence the ability of a bone to attain the full genetic potential. However, one of the most potent environmental influences on bone mass and architecture is the prevailing mechanical environment.

Functional loading of bone refines the inherent genetic form. The levels of mechanical input can vary throughout life with an associated response in terms of skeletal adaptation.

Both during growth and maturation and in the skeletally mature adult, bone responds to mechanical loading. The relationship of the pathophysiology of functional adaptation to training and conditioning regimens in general and in the horse in particular is important in maximizing performance and minimizing skeletal injury. In determining the aspects of functional loading that influence the bone cell populations and consequently are important in controling the architecture of the skeleton, it was essential to be able to quantify the functional environment of the skeleton.

Although techniques were available to measure strains on cadaveric bone, using photoelastic coatings, stress coat and electronic strain gauges, it had not been possible to quantify the effects of loads on the living skeleton until the cyanoacrylate tissue adhesives became available. In the early 1970s Lanyon & Smith[28] and van Cochran[29] made the first measurements of strain in the living skeleton. The ability to bond foil rosette strain gauges to living bone allowed both the magnitude and distribution of the principal strains on the surfaces of a number of bones to be measured during activities such as locomotion. From these measurements it was possible to determine the loading patterns of different specific bones. For example, the radius in quadrupeds is loaded in bending with principal tensile strain aligned to the long axis of the bone on the cranial cortex and principal compressive strain aligned to the long axis of the bone on the caudal cortex,[16] whereas the tibia showed a significant component of torsional loading.[30] The physiologic loading pattern of these long bones can be used in determining the appropriate fixation methods to treat fractures in these bones.

Strain distributions on the surface of bones with defined internal trabecular arcades again provide confirmatory data to show the strategic alignment of the trabeculae of spongy bone with the directions of principal tensile and compressive strains.[31] This technique increased the understanding of the response of bone to changes in mechanical demands, a mechanism called functional adaptation.

Functional adaptation of bone

General principles

The bony skeleton provides structural support for the body throughout life and also enables locomotion by virtue of the linked skeletal elements forming a system of rigid levers upon which forces can be exerted by muscles through tendons and ligaments. Articulations between the individual bones allow energetically efficient movement. The basic genetically determined bone mass is optimized for energetic efficiency and to accommodate the loads imposed. Thus throughout life as the activities change, the process of functional adaptation enables the appropriate adjustments to be made to the mass and architecture of the skeleton. The biologic signals that induce bone cell activity and control the adaptive process are

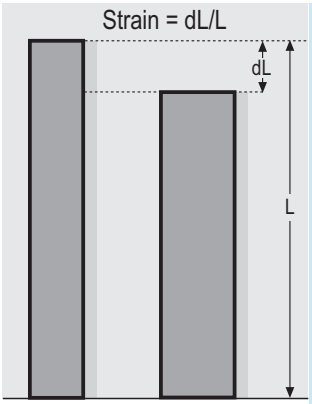

Fig. 7.19
Diagram to show deformation or 'strain'.

related to the deformation of the tissue as a consequence of the loads applied by muscles and gravity. Deformation is termed 'strain' and is the change in length in relation to the original length (Fig. 7.19). Although the response of bone to mechanical loading has been known for some time, the ability to quantify imposed changes in mechanical environment of the skeleton and relate these to the consequent biologic response of the bone has only been possible using the technique of in vivo strain measurement.

Dynamic strain similarity

By applying strain gauges to the living skeleton of a variety of species, from fish through reptiles, birds and mammals, including the horse and human, the level of bone deformation during peak physiologic activity has been shown to be remarkably similar.[32] Thus it was hypothesized that bone had evolved in this wide range of species to optimize to a threshold level of deformation, irrespective of histological structure. A simple strain-controlled feedback loop was proposed. If an increase in loading resulted in an elevated strain above the threshold value, this triggered the bone cell populations to synthesize bone matrix to increase the mass of bone and thus for the new loading conditions to reduce the increased levels of deformation back to the threshold values. In the event of a decrease in loading and consequent level of deformation, the bone cells would respond by activating a net bone resorption and decrease bone mass.

Optimization of mass and architecture (Wolff's Concepts)

In the event of a persistent change in the normal pattern of loading, the bone strain patterns would be altered and this persistent change in strain distribution would initiate a redistribution of bone through a modeling response to alter the architecture of the bone as a structure. Such changes may involve structural optimization by changes in both the distribution and mass of bone.

Early studies in which the strain on the skeleton was increased and an adaptive response was evoked supported the theory of a strain control feedback mechanism. The characteristics of the mechanical osteogenic stimulus were elucidated by a series of studies in which bones were subjected to known strain characteristics and the consequent osteogenic response was measured. These studies were of two basic types: those in which a defined mechanical regimen was imposed on a bone following surgical intervention and those in which an exercise regimen was applied to the intact skeleton. Increased loading of parts of the skeleton induced by removal of adjacent bone or by attachment of loading devices to isolated bones allowed the imposition of a specific strain environment. The early studies inducing increased loading by removal of an adjacent bone and consequent overloading of the remaining ones by normal locomotion demonstrated an adaptive response to increase the overall cross-sectional area and thus restore the strain levels to the functional optimal values, thus supporting one of Wolff's hypotheses.[33,34]

Osteogenic mechanical stimuli

The nature of the mechanical stimulus that elicited an osteogenic response was investigated by a more controlled study of specific mechanical variables and their influence on adjustment of bone mass and architecture.

Such studies involved the use of implants attached to the bone and used to impose controlled mechanical stimulation. These experiments elucidated some of the osteogenic aspects of the strain environment. During normal strain distributions, such as those occurring during walking, the level of osteogenic response, in terms of increased cross-sectional area of bone, to imposed strains was found to show a high correlation with the rate of bone deformation.[35] This suggests that training using a normal type of exercise requires a high loading rate to elicit an osteogenic response. A more refined method of studying the exact nature of mechanical signals that stimulate bone formations was developed by using isolated segments of bone. Ideally an organ culture might be used for such studies but culture of bone is difficult in terms of culturing a significant mass of true ossified tissue and the absence of the hormonal regulation and its interaction with mechanical cues precludes such models.

Using isolated bone models in vivo, it was possible to define in a more specific manner the strain characteristics that induced bone formation.[36] The effect of numbers of cycles of loading applied on a daily basis was investigated, together with the effect of magnitude of the imposed strain. It was shown that there was a 'dose–response' effect with strains below the normal physiologic threshold inducing bone resorption and a consequent decrease in cross-sectional area and those above the physiologic threshold showing an increase related to strain magnitude. From these experimental studies a number of mathematical models were derived in which it appeared that there was a window of strain magnitude that retained bone mass with neither resorption nor formation. This was termed the 'lazy zone'.[37] Strain magnitudes outside this zone induced either bone resorption or bone for-

mation. Interestingly, Rubin & Lanyon investigated the relationship between the number of loading cycles imposed on a daily basis and the resultant effect on bone mass in terms of bone mineral content and cross-sectional area.[36] This work showed that a maximal effect on bone mass could be attained with only 36 cycles of loading at 0.5 Hz each day. Any additional cyclical loading did not attain a greater effect on bone mineral density or cross-sectional area. Bone mass was shown to be maintained with as few as four loading cycles per day, whereas complete cessation of loading resulted in a decrease in bone, predominantly by endosteal resorption leading to a reduced cortical thickness, together with some increase in cortical porosity. This study suggests that short periods of osteogenic cyclical deformation can induce a maximal adaptive response. In terms of conditioning bone in equine athletes this might be interpreted as a short period of daily trotting. The stimulus appears to require cyclical deformation as the application of constant load did not induce bone adaptation.[38]

Hillam & Skerry developed a non-invasive method of loading the rat forearm and used this model to demonstrate that mechanical loading could modify the normal modeling patterns seen during growth.[39] A short period of cyclical loading changed a bone resorption surface to a bone-forming surface. The applied loading induced an aberrant strain distribution. This model was also used by Mason et al in determining the gene activation patterns associated with mechanical loading and putative signaling molecules in the transduction and integration of mechanically induced bone remodeling.[40] Forwood & Turner used a similar approach by applying a bending moment to the rat tibia and confirmed the response to high strain rate cyclical deformation in a mammalian model. This suggests the principles can be extrapolated to other species, including the horse.[41]

Thus the principles of these findings have implications for the training of young horses using a diverse exercise regimen. Perhaps on the basis of this evidence, horses that are used for competitive events that involve movements outside the natural range on a frequent basis should be introduced to such exercises at an early age when the architecture of the skeleton could be influenced to adapt to these loading demands and thus resist damage and failure in adulthood. Events such as jumping, dressage, trotting, racing and pacing may be candidates for such practice. However, any training regimens must be introduced over an adequate time period with a graded increase to accommodate adaptation and avoid damage.

Rate of adaptation

Adaptation to loading in bone can be initiated by short periods of cyclical loading. Therefore, to prolong this type of exercise or to introduce long periods of such exercise too rapidly, particularly on a hard surface, may lead to induction of microcracks and ultimately the gross fracture of the bone. Damage even to the delicate internal architecture of the trabecular bone with subsequent stiffening, particularly of subchondral regions, may reduce the absorption of high impact loads and inflict damage upon the overlying articular cartilage (Fig. 7.20).[42] Mechanical factors may thus initiate a cascade of events leading to degenerative joint disease. The joint must be considered as an organ and changes to one component tissue or structure will impact on the whole joint.[43] Interestingly, Chen et al observed differences in heel strike transients between races with different incidence of degenerative joint disease so it is possible that conformation may influence the transmission of impact transients in equine limbs and predispose to degenerative joint disease. This localized adaptive hypertrophy of trabecular bone can be seen following imposed exercise regimens, for instance the dorsal regions of the third and radial carpal bones.[45] Furthermore, with an osteogenic exercise regimen given for only a short period each day, these localized bone changes occur extremely rapidly.[46] This localized change in loading can induce a change in both bone and cartilage, the osteochondral unit. Increased exercise in the adult horse results in a thickening of the trabecula of the subchondral bone, a thickening of the subchondral plate and a thickening of both the calcified and hyaline layers of the overlying articular cartilage.[47] Experimental studies have also shown the sensitivity of cancellous bone to changes in mechanical loading and these data can be indirectly related to training methods in the horse.[48]

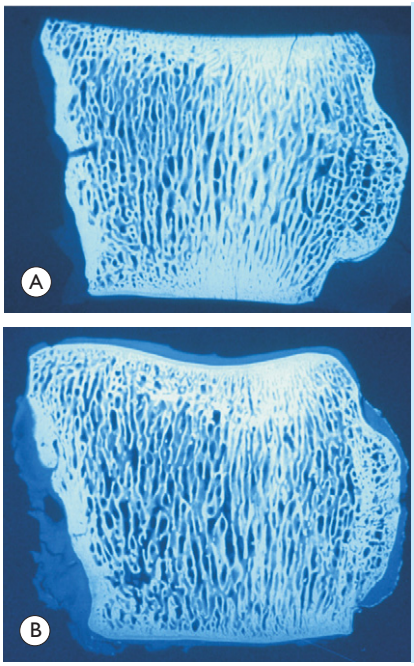

Fig. 7.20 Photomicroradiograph to show localized adaptive hypertrophy of trabecular and subchondral bone to imposed exercise (A) compared to control (B).

These morphological changes result in a change to the mechanical properties of the microstructure which can be measured by indentation techniques[49] and micromechanical testing of single trabeculae.[50] The adaptation within a bone in relation to a very specific pathway of load transmission through the bones of the skeleton is seen particularly well in the carpal bones where significant differences are found between the dorsal and palmar regions of these bones. Long-term loading with associated stiffening of the bone in the dorsal region may relate to the common occurrence of cartilage fibrillation and breakdown in this region.

Microdamage

Horses that are given this type of training regimen, especially if the training is imposed over a short period of time, show the clinical signs of 'bucked shins'. If the training is based upon a structured increase in duration of short periods of exercise that induces high bone strain, the bone will adapt and the physiologic adaptation will condition the bone for athletic exercise rather than a pathophysiologic response leading to 'bucked shins'. This response is also seen in racing greyhounds and can lead to overt fractures.

Microcracks

Accumulation of microcracking within the bone matrix results in a remodeling response in which the secondary bone has inferior properties to primary bone. Crack formation is seen as a fractal pattern of matrix damage (Fig. 7.21). Microcracks have been demonstrated in several species of athletic individuals such as the horse[51,52] and the racing greyhound.[53] Cracks can be observed by bulk staining the bone prior to histological sectioning in order to confirm that the cracks are not processing artefacts. The cracks can be seen as stained defects within the matrix (Fig. 7.21). When the level of magnification is increased these defects in the bone matrix can be seen to continue at an ultrastructural level (Fig. 7.22). This damage to bone matrix through which the delicate processes of the osteocytes pass can potentially alter the interaction between cell and matrix and cell-to-cell communication. Processes such as generation of streaming potentials by movement of ionic fluid through the macro-, micro- and nanoporosities of bone will be altered. These changes may be the cause of the known response to microdamage such as apoptosis and osteonal remodeling. Experimental studies using the non-invasively loaded rat

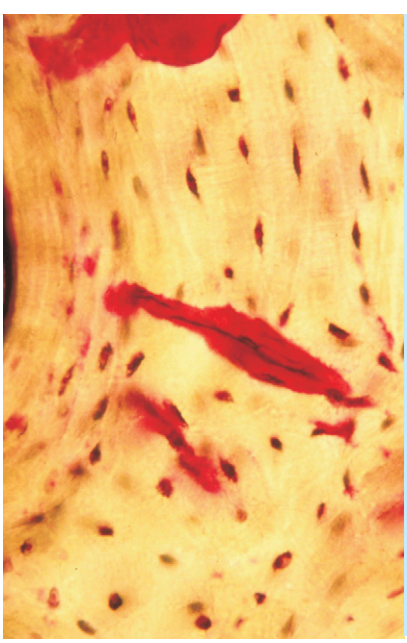

Fig. 7.21 Photomicrograph of a section of cortical bone stained to show a microcrack within the matrix.

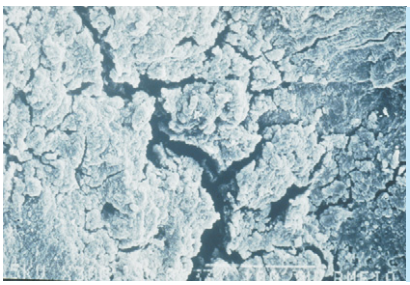

Fig. 7.22 Scanning electron micrograph of a microcrack in bone matrix, showing the fractal pattern of damage.

antebrachium have demonstrated that a rapid application of osteogenic cyclical loading will lead to a change in structural stiffness, indicating a plastic postyield deformation of the bone. The bone will fracture if such loading is continued. However, if bones treated in this way are examined histologically a short time after loading has stopped, an increased porosity is seen as osteoclastic cutting cones target the intracortical damage. A predominance of secondary osteons is found on examination after a longer period of time.

Once primary bone has been remodeled the bone type has been permanently changed. These changes, seen in the experimental model used by Bentolila et al, are closely related to those seen in studies on the induction of sore/bucked shins using a high volume of high strain rate exercise.[54] The effect on subsequent adaptation and failure of highly remodeled bones compared to those in which a gradual adaptation of primary bone has been induced is not really known. Epidemiological studies on race track fractures and relation to training methods are few. One such study by Wood et al (personal communication) has shown that certain types of training regimens are associated with a higher odds risk of fatal failure related to commencement of training at an earlier age. Short bursts of high-speed training in the months before racing reduces the fracture risk (Parkin personal communication). This appears to agree with marker data showing increased bone formation with short periods of fast work.[55] Also Boston & Nunamaker[56] report the advantages of short-distance breezing rather than long-distance gallops in reducing 'bucked shins'.

Osteocyte apoptosis

In addition to the overt fracture of the matrix at the ultrastructural to gross level, there is an effect of this type of loading-induced damage on the cellular component of the bone tissue. Osteocytic apoptosis rates are modified and some effects are also seen on gene expression.[57] Interestingly, estrogen treatment also modulates osteocyte apoptosis.[58] Recent observations by Ehrlich et al that mechanical cues to bone cells are mediated through the estrogen receptor may explain this commonly observed response.[59]

Remodeling

The consequence of exercise-mediated microdamage through a rapid imposition of cyclical mechanical loading is seen either as

overt fracture or, more often, as an increase in formation of secondary osteons to limit crack propagation and replace damaged matrix. However, secondary bone has been shown to be inferior in terms of material properties and may compromise mechanical properties of the bone as a structure.

Thus the avoidance of undue secondary osteon formation may prevent the reduction of the mechanical properties of the overall bone structure. Controlled osteogenic exercise during training would induce a more gradual adaptive response and increase the bone mass with minimal damage of the matrix, thus preserving the mechanical properties of the skeletal structure and reducing the risk of catastrophic failure. Training regimens that appear to optimize bone adaptation without matrix damage comprise short periods of high-intensity exercise.

In physiologic loading exercise at a high rate of deformation was found to be a potent osteogenic stimulus.[46,56] However, strain distributions that differed from those experienced during normal physiologic activities may elicit osteogenic responses at subphysiologic strain magnitudes. It has been suggested that these represent an 'error' signal which, if only imposed occasionally, does not lead to modeling changes; however, a repeated imposition of these unusual strain distributions can induce structural changes in bone architecture. An example is seen in the serving arms of professional tennis players where bone mass can be approximately 30% higher than the non-serving arm.[60] Thus an abnormal gait, particularly if inducing high strain rates, will induce an osteogenic response.

In the horse the level of bone deformation increases as a function of locomotor speed. Thus, as the speed of the walk increases so too does the level of bone deformation. This is also seen in the trot, with an extended trot leading to abnormally high rates of bone strain. In the horse, as speed increases there is normally a change in gait which is controlled by energy efficiency drives; the levels of oxygen increase with speed but there is an optimal speed at each gait for oxygen utilization. At speeds beyond the optimal, the utilization of oxygen becomes less efficient and this leads to a gait transition and further optimal levels of oxygen utilization for the new gait.[61] In addition, at the gait transition the level of bone deformation is reduced.[62] This may represent a means of controling bone mass and also reducing damage due to fatigue loading of bone.

Safety factors

As with most structures, the skeleton can withstand occasional overloads. In designing a structure such as a bridge there is a built-in safety factor to accommodate unforeseen overload. The level of overdesign is related to a balance between risk of overload and cost of materials. The architecture of the skeleton has been shown to follow very similar principles to those seen in engineering of structures. An excess of material would minimize risk of structural failure but carry a high cost in terms of energy requirements. These factors may explain the findings that bones toward the proximal region of the limbs have a higher safety factor than those at the distal extremity. For instance, the human femur is able to withstand loads of five times normal bodyweight.

Site-specific fracture incidence

In the horse, an animal evolved for high-speed locomotion, the energy costs of additional mass at the extremity of a long limb, acting like a swinging pendulum, would be high. Currey analyzed the incidence of fractures in race horses reported by Vaughan and showed a higher incidence in the more distal bone of the limb where safety factors would be reduced to decrease energy costs.

Exercise studies in horses have shown a reduced level of functional adaptation in the more distal bones together with an increase in fracture toughness. This may represent a different mechanism to limit crack propagation and consequent fracture.[63]

Gross fractures

As with any structure, a single overload can result in a monotonic failure. Since bone exhibits functional adaptation the mass and architecture are adapted to meet the prevailing magnitude and distribution of load. However, a single excessive load that is greater than the given safety factor will result in failure. The type of failure in terms of damage of the structure at a gross and microscopic level will depend upon the energy and velocity of crack propagation.

When the bones are subjected to load distributions different from those to which the bone has adapted, failure can occur at much lower levels. This type of failure may be seen when limb movements are unco-ordinated such as during recovery from anesthesia or at the end of periods of strenuous activity when muscles are fatigued and limbs loaded asymmetrically (Dow, personal communication).

The risk of fracture may also be increased if a new type of exercise is introduced suddenly without an appropriate period of training for both muscle and bone adaptation.

Training influences on bone adaptation

In general there has been a significant lag between scientific advance and change in the training methods used in the equine world in general and in the horse-racing industry in particular. No doubt some of the biologic mechanisms controlling adaptation of bone to its functional environment could and should be applied to the conditioning of equine athletes. It is also probable that the empirical traditional methods of training do incorporate some scientific principles as a consequence of many years of experience. However, given the highly competitive nature of the equine industry, it is difficult to identify training methods that relate to high and low incidences of injury. Recently a number of epidemiological studies have been performed to identify both the relationships between specific types of training and incidence of bone fractures. The response of the bony skeleton to different quantified training regimens has also been monitored using the minimally invasive techniques of blood markers for assessing bone formation and bone resorption.

Monitoring of skeletal responses to training

The ability to make an objective study on the monitoring of adaptive changes in the skeleton to training requires two components. First, the ability to define and quantify the training input and second, to measure the effect on the bones of the skeleton directly or indirectly. Even in the laboratory these are difficult to achieve; in field studies direct measurements such as radiography, scintigraphy and DEXA/CT scanning are not practical. Therefore, indirect assessments of bone modeling and remodeling are being developed. Blood markers have been used both in controlled studies and in commercial training facilities. In studies using controlled exercise regimens it is possible to relate these to changes in marker levels and to evaluate factors such as seasonal, age and gender-related effects.

Markers of bone adaptation

In a controlled exercise study over 1 year in 2-year-old Thoroughbreds, the effects of the exercise on two biochemical markers of bone formation were determined. These markers were the carboxy-terminal propeptide of type I collagen and the bone-specific alkaline phosphatase. In addition, one potential marker of bone resorption, the pyridinoline cross-linked telopeptide domain of type I collagen, was also monitored. In both the low and high intensity exercised groups there was a significant reduction in marker levels over the year. This is expected as a normal age-related change. However, it was encouraging that the pattern of reduction differed between groups in a way that indicated an increase in bone turnover in the high intensity trained group.[18] These results are encouraging, as they indicate the potential to develop a non-invasive method of monitoring the effects of training on bone.

Direct monitoring of skeletal adaptation

Radiographic techniques

Radiography can be used to visualize some direct responses of the skeleton to increased or decreased mechanical demands. Changes in the architecture and radiographic density of bones can be used to monitor the competence of the skeleton. Standardized positioning and the use of a calibration step wedge allows standardization of exposure by optical digitization, which may then allow a determination of relative bone density in relation to responses to applied training or conditioning regimens. Radiologic methods have been used to assess functional adaptation to exercise in the equine skeleton and a radiographic index has been used to assess the changes in shape of the third metacarpal bone in response to training. Studies have been performed to define the limitations and level of accuracy of this technique that indicated acceptable accuracy providing alignment of the limb, cassette and X-ray machine is accurate. These findings suggest that the radiographic index can be used to measure MC3 bone shape using relatively simple and widely available technology.[64]

Peripheral quantitative computed tomography (pqCT)

Improvements to radiographic methods can be obtained by the use of pqCT. A two-dimensional image showing bone mineral density distributions may be generated and quantitative information on cortical cross-sectional area and second moment of area can be provided (see Fig. 7.9). Thus the effects of training could be monitored in relation to specific regimens. The disadvantage of this technique at present is that, as in MRI, the machine is fragile and the horse has to be anesthetized. Also the aperture of the machine is limited and thus only small peripheral limb segments can be assessed. For experimental studies and in young horses, this technique can provide considerable useful data on the response of specific distal limb bones to imposed exercise.

Dual energy X-ray absorptiometry (DEXA)

This system can be used to determine bone mineral content of the skeleton and regions of the skeleton. These scanners are normally used in assessment of bone density in relation to metabolic bone disease, particularly postmenopausal osteoporosis. The disadvantage in relation to monitoring of equine skeletal responses to training is the need to anesthetize the horse together with the limited area that can be scanned. In humans it is possible to relate individual scan data to population values and provide a fracture risk score. This may be an interesting concept in relation to monitoring of the equine skeleton but is not yet possible.

Nuclear scintigraphy

By attaching an isotope to a bone-seeking bisphosphonate, areas of active bone modeling or remodeling can be labeled. By imaging with a gamma camera these active sites can be located in the living skeleton at specific points in time. Although used predominantly for diagnostic purposes, this technique could identify site-specific skeletal responses to exercise or mechanical loading.

There is a need for an effective non-invasive method to monitor both bone quality and skeletal integrity during development and in both athletic training and competition. Some handheld methods have been tried. Potentially the use of ultrasound in terms of measuring speed of sound through bone and broad-band attenuation can give information on both modulus and structural integrity. The systems are available commercially for human use and also recently for use in the horse. A combination of this type of monitoring and associated adjustment of training schedules could prevent the overt occurrence of conditions such as ‘bucked shins’.

Training strategies to condition the skeleton of the equine athlete

Age-related changes in the skeleton

In a study on fatigue strength, Nunamaker et al measured surface bone strains on the third metacarpal bone of young and old North American Thoroughbred horses to determine the mechanisms involved in fatigue failure of bone leading to fracture.[65] They found greater levels of strain (deformation) at the gallop in the young horses with almost a 40% reduction in strain in the older horses. The significance of this is that the fatigue failure point of a bone depends upon both the magnitude of the deformation and the number of loading cycles to the failure point. Thus if the strain magnitude is reduced there can be a greater number of cycles of deformation prior to failure. In addition, since bone is a dynamic tissue that responds to mechanical deformation, the bone architecture as a structure can be modeled to reduce the bone strain at high loads.

These authors suggest that changes in shape of the third metacarpal bone during growth and maturity may represent a mechanism to reduce strain and mitigate fatigue failure. The high incidence of fatigue failure as seen in 'bucked shins' in young horses subjected to exercise that induces high strains over short periods of time would support this hypothesis. Interestingly, Nunamaker et al also investigated breed differences in the incidence of 'bucked shins', hypothesizing that there might be a breed difference in the material properties of the bone matrix leading to a difference in the fatigue failure patterns.[66] They determined fatigue properties in the bone material of the third metacarpal bone in Thoroughbred and Standardbred horses. No significant differences were found in the mechanical properties of the bone. This may suggest that other factors such as the training methods and type of loading affect the incidence between these two breeds. Perhaps this is indicative that imposed mechanical events, even within a breed of horse, can influence the incidence of such conditions. An understanding of the pathobiology and material properties of bone could be used to determine the appropriate age and exercise regimen to minimize such injuries.

Exercise during development

Most of the training and conditioning of equine athletes occurs after skeletal maturity. In some cases, such as training of race horses, the period of training is relatively short and the ongoing training is also limited to short periods. The training methods are largely empirical based on a traditional approach rather than advances in the science underlying training.

Recently a number of studies have been investigating the concept of introducing conditioning for athletic performance during the period of postnatal growth and development. This approach imposed the distribution of mechanical loads associated with the athletic activity at a time when modeling processes are active in forming the functionally related aspects of skeletal structure. Thus optimization of primary bone development can be attained in relation to the loading patterns that will be experienced during athletic activity. There is some evidence that bone strain can be reduced with gait transition, decreasing by 42% at the trot/canter transition.[62] Thus in activities where gait changes are suppressed as a component of the particular athletic activity, for example in dressage and in racing trotters and pacers, the high strains at high speeds may predispose to microdamage when introduced in the adult. Whereas if these patterns of gait are introduced gradually during the growth and modeling phase of skeletal development, then appropriate skeletal architecture can be attained with lower risk of damage. This, combined with the incremental increases in training load during development, will also increase skeletal mass and may reduce the strain magnitudes that would occur if training is introduced after skeletal development, and thus minimize injuries.

Changes in foot balance in foals have also been shown to induce strain changes of up to 40% reduction in medial metacarpal compressive strains and 100% increase in lateral compressive strains. However, these were found to return to normal distributions after a period of time.[67] As discussed previously, bone adapts to increased strain and changed strain distribution, so a return to normal strain at a local site may reflect an adaptation resulting from changes in mass and distribution of bone. In this study changes in bone mass or architecture as a consequence of the changed loading were not reported. This adaptation to abnormal loading during growth may result in an abnormal architecture of the bone with possible implications for other skeletal components such as joints in later life. Therefore, attention to exercise type, intensity and foot balance during growth and development should optimize the skeleton for athletic activity in the adult. The concept may also apply to other skeletal tissues in which the process of growth can be modified by early conditioning.

Human athletes are frequently identified as children and both train and compete during growth and maturation. In addition, human athletes tend to undertake high volumes of training. The equine athlete, particularly the race horse, is given relatively low volumes of training and spends considerable time in the stable.

Conclusion

Horses as equine athletes must be conditioned and trained to optimize the whole animal for the particular type of athletic activity. An extremely high proportion of all injuries in the equine athlete in general and in the race horse in particular are associated with the musculoskeletal system. Within musculoskeletal injuries, fractures and bone-related pathology

account for a great proportion. Bone both as a tissue and structure is acutely responsive to mechanical loading and thus can be conditioned to withstand the applied loads. In order to maximize performance and minimize injury it is important to appreciate the pathobiology of functional adaptation of bone. This together with appropriate monitoring can enable owners, trainers and veterinarians to apply the science underlying functional adaptation to the training of specific equine athletes, thus improving equine welfare.

CHAPTER 8

Tendon and ligament physiology

Roger K.W. Smith and Allen E. Goodship

Introduction

Role and definition of tendons and ligaments

The distinction between tendons and ligaments has been largely an anatomic one – tendons join muscle to bone whereas ligaments join bone to bone. Although this division is generally true, topographic, biomechanic, ultrastructural and matrix compositional investigations have revealed a merging of these two structures in a continuum from 'pure' tendon to 'pure' ligament.

In connecting muscle to bone, tendons have been considered rather inert structures that are involved in the movement of joints. However, while this 'positional' function is still an important one, certain tendons in cursorial animals have developed another role in acting as springs to store energy for efficient locomotion. This is particularly true in the horse, where the tendinous structures on the palmar aspect of the metacarpal region – the superficial digital flexor tendon (SDFT) and the musculus interosseous medius tendon (suspensory ligament; SL), in particular, and the deep digital flexor tendon (DDFT) – act to support the hyperextended metacarpophalangeal joint during weight bearing (Fig. 8.1), releasing energy when the limb is protracted (Fig. 8.2). Hence, at fast gaits, the horse effectively bounces up and down on springs, similar to a child's pogo stick. As further modifications to this role, the digital flexor tendons have accessory 'ligaments', which attach the tendon directly to bone to provide a direct bone-to-bone tendinous connection when under full weight bearing.

It would be expected, and indeed found, that these tendons would have mechanical characteristics for this function as a spring, while tendons with a more 'traditional' positional role (e.g. human digital flexor tendons and the common digital extensor tendon (CDET) of the horse) would require stiffer characteristics. Up to a two-fold difference in structural stiffness has been found between equine digital flexor and extensor tendons.[1]

Periarticular ligaments, while having similar composition to tendons, are anatomically more complex, with multiple bundles of fascicles that frequently spiral and are taut and relaxed at different joint positions, depending on the fascicle bundle. In addition to their role in providing support for the joint, they also provide proprioceptive information. The

Fig. 8.1
Galloping horse, showing the hyperextended metacarpophalangeal joint under weight bearing.

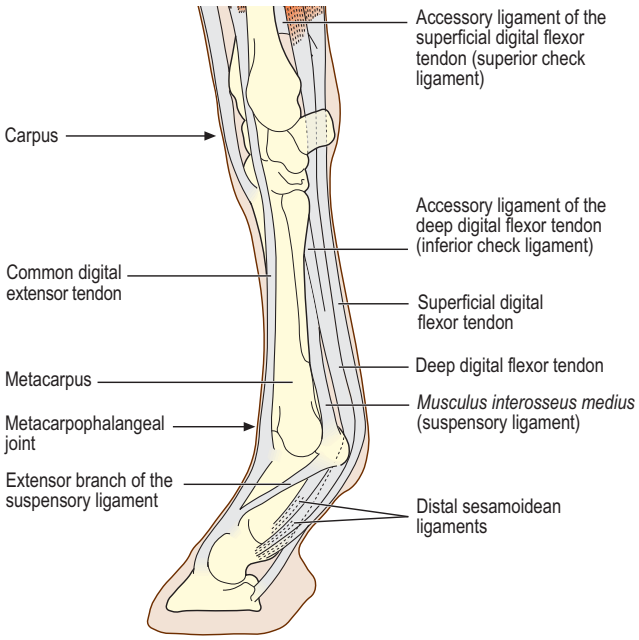

Fig. 8.2
Topographical anatomy of the distal limb of the horse (adapted from Adam's *Lameness in horses*, 3rd edn, reproduced with permission).

fibrous joint capsule is usually closely associated with these periarticular ligaments and functions in a similar way. Consequently, fibrous joint capsule is also an 'honorary' ligament.

Incidence of injury

Strain-induced injury of the tendons and ligaments is the most common orthopedic injury in athletic animals, be they equine or human. Recent epidemiologic surveys of race horse injuries sustained at UK race tracks between 1996 and 1998 showed that of all limb injuries (82% of all incidents), almost one-half (46%) were due to flexor tendon and/or SL injuries.[2] As observed clinically, this study confirmed that these injuries were much more common in older horses racing over jumps (steeplechasers or hurdlers) than in younger race horses racing on the flat. Furthermore, the data from these flat races correlated well with previous data published from studies in the USA (0.760 per 1000 starts in 1992).[3] However, this epidemiologic data, being obtained from only those injuries occurring during racing, represents only the tip of the iceberg. More recent studies investigating the incidence of superficial digital flexor tendinitis in horses during training showed that almost one-half (43%) of horses had evidence of tendon pathology, and that this incidence increased with age.[4] These data correlate well with similar ultrasonographic studies evaluating Achilles tendon damage in professional human athletes.[5] Other data recorded for training and racing injuries in flat race horses in Japan showed not only a rising incidence from 6.39% for 2-year-olds to 17.43% in 5-year-olds, but also, more worryingly, a rising overall incidence from 1990 to 2000 (Oikawa & Kasashima, personal communication). The reason for this is unclear but, interestingly, the incidence of Achilles tendinopathy in man has doubled in incidence in Europe in the last 10 years, believed to be associated with greater levels of exercise and increased longevity.[6–8]

The incidence in non-race-horses and for other strain-induced injuries of other tendons and ligaments have not been reported, although all horses involved in athleticism appear to be highly susceptible to tendon and ligament injuries. An interesting exception is ponies, which rarely suffer from superficial digital flexor tendinopathy, although they do have a relatively high incidence of desmitis of the accessory ligament of the DDFT.

Pathogenesis of tendon injury

Tendons and ligaments can be injured in one of two ways – overstrain or percutaneous penetration/laceration. The latter will not be considered further in this chapter. Overstrain injuries are believed to occur by one of two mechanisms. They can result from a sudden overloading of the structure, which overwhelms its resistive strength. This type of injury is probably the mechanism for most ligament and some DDFT injuries in the horse. However, for the most common strain-induced injuries in the horse, involving the palmar soft tissue structures of the metacarpal region, the clinical injury is believed to be preceded by a phase of degeneration. The evidence for this preceding degeneration is based on four observations:

1. The identification of 'asymptomatic' lesions, both grossly and microscopically, in post-mortem studies of normal horses.[9,10] Care, however, should be made in distinguishing gross central discolorations in otherwise normal tendons, which are more likely to represent early clinical injury than the preceding degeneration as compositional analyses reveal some opposite changes to that seen induced by exercise (see below) and many of these lesions can be identified ultrasonographically (Fig. 8.3).
2. Many, if not all, clinical strain-induced tendinopathies are bilateral with one limb more severely affected than the other. Careful ultrasonographic examination will reveal changes in the contralateral limb in many cases. In those seemingly unilateral cases, blood-flow studies have demonstrated increases in the 'normal' contralateral tendon, which would suggest that it is not totally unaffected.[11]
3. Epidemiologic studies have demonstrated close associations between age and exercise, and tendon injury.[2,4]
4. Following on from these epidemiologic observations, experimental investigations have demonstrated evidence of degeneration associated with a synergistic action of both age and exercise (see below).[12,13]

Thus, degeneration is usually the first phase of tendinopathy. This can be likened to 'molecular inflammation',[14] which does not provoke a repair process, as after clinical injury, but

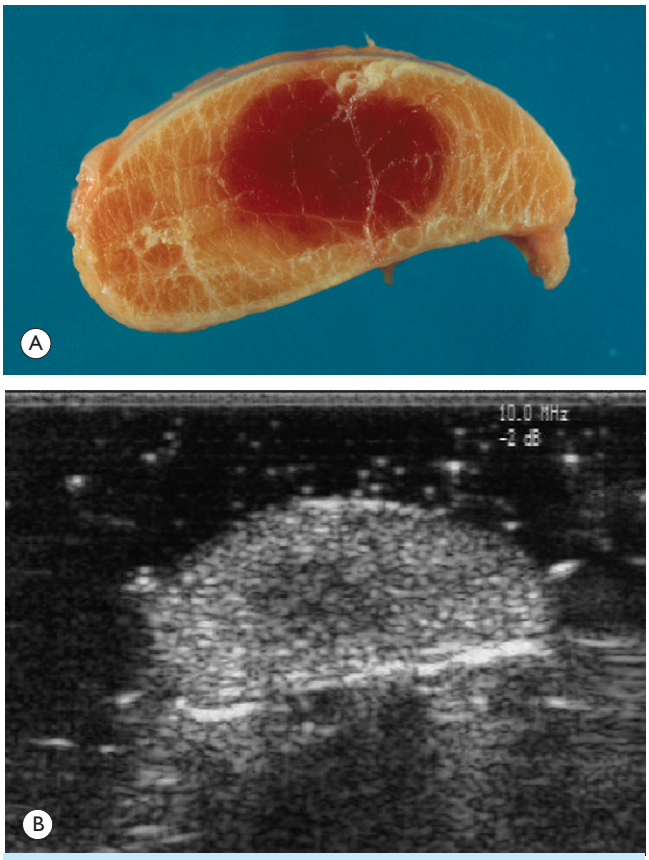

Fig. 8.3
(A) Central discolored region of 'asymptomatic' superficial digital flexor tendon (SDFT) – these 'lesions' are probably more representative of subtle clinical injury than the degenerative stage of tendinitis because they can be visualized ultrasonographically in a water bath as core lesions characteristic of clinical injury (B).

rather progressively weakens the tendon. Any change in the structural properties of the tendon does not have to be great as the tendon is already operating close to its tolerance limit. Clinical injury occurs when the highest stresses encountered by the tendon overwhelm its structural integrity, resulting in irreversible damage. Once this occurs, the damage created induces a repair process characterized by inflammation followed by fibroplasia (scar tissue formation).

This process allows the incorporation of risk factors that have been identified for tendinitis. These risk factors act to increase the peak loads on the SDFT, thereby increasing the risk of structural disruption. One of the most important factors is the speed of the horse. The faster the horse is going, the greater the risk of tendinitis.[2] Thus, hard going is associated with tendinitis as it increases the speed of the horse and also increases the peak impact loading.[2] Slower surfaces (including soft going) tend to be protective. Other factors, such as the weight the horse is carrying, fatigue, and the shoeing, can all influence peak tendon loads in this way. Low heels was thought to be protective of tendinitis as this conformation tends to increase the load in the DDFT, a secondary supporter of the metacarpophalangeal joint, thereby reducing the support necessary from the SDFT and SL. However, as the highest loading in the DDFT is towards the end of the weight-bearing phase, this may not have an influence on the initial high level loading of the SDFT at the onset of weight bearing.

Once the peak load on the tendon overcomes its structural strength, there is physical disruption to the tendon matrix. This varies in degree from fibrillar slippage, with breakage of cross-linking elements, to fibrillar rupture and, in some cases, complete separation of tendon tissue. This damage initiates a reparative sequence of events not dissimilar to that in other soft tissues, such as skin, which is characterized by phases of inflammation, followed by fibroplasia (see Tendon injury and repair, p. 143), which results in the replacement of normal tendon tissue with scar. With the formation of abundant scar tissue, the healed tendon becomes strong but it is functionally inferior to normal tendon. As a structure, healed tendon is stiffer than normal tendon, which compromises the tendon function and predisposes to reinjury, often at sites adjacent to the original injury.[15]

Structure of tendon

Biology of the muscle/tendon/bone unit

The musculature in the limb of the horse is proximally positioned to minimize the weight of the distal limb. This enables the horse to achieve efficient high speed locomotion through increased stride length and reduced energetics of limb protraction. This means that the tendons associated with these muscles have to be long to traverse the joints on which they act and, consequently, the digital flexor tendons, for example, are some 45 cm in length.

The horse's distal limb has reduced the number of phalanges to a single digit (with vestigial digits, the splint bones, either side of the third metacarpus) which has simplified the tendon and ligament anatomy (see Fig. 8.2). The distal fore and hindlimb therefore has an arrangement of three palmarly positioned structures – SDFT and DDFT with their associated accessory ligaments, and the SL – which serve to support the hyperextended metacarpo/metatarsophalangeal joint, and two or three dorsally positioned digital extensor tendons, which function only to extend the distal limb during protraction. Hence the loads experienced by these tendon groups are very different – the extensor tendons experience only low loads while the palmar tissues are subjected to high loads of weight bearing (7–10 kN on the SDFT).[16]

The horse has further adapted the basic muscle–tendon–bone unit in order to withstand the high weight-bearing loads and for its palmar soft tissue structures to act as an elastic unit for energy storage and efficient locomotion. Thus, the superficial digital flexor muscle has a much larger amount of connective tissue within it and has an accessory ligament (accessory ligament of the SDFT; proximal, or superior, check ligament) that 'bypasses' the muscle belly to insert on the distal radius. These two adaptations allow the musculo-

tendinous unit to withstand greater loads than would be possible by the muscle itself. The SL has taken this adaptation even further. It was originally derived from a muscle and still contains a variable amount of muscle within its mid and proximal regions. It could therefore be classified as a structure in which the tendon component has replaced the muscular tissue. However, its cellular morphology more closely resembles a ligament and, in the absence of a significant muscle belly, is usually classified as a ligament.

The muscle belly of the SDFT is not redundant, however, although its proposed role is different from the classical function of flexing the limb. Recent data have suggested that this muscle serves to fix the origin of the tendon. In vitro maximal contraction of the muscle has demonstrated a maximum of only 2 mm of muscle shortening.[17] It is hypothesized that the muscle acts to dampen the high-frequency damaging peak loads when the foot is placed on the ground at high speeds. Thus, loading of the SDFT can be considered an essentially passive process where energy is stored by the elastic properties of the tendon and returned when the limb flexes.

As a further adaptation to the long tendon length and the hyperextended metacarpo-/metatarso/phalangeal joint, the digital flexor tendons are contained within synovial sheaths in regions where they pass over high motion joints (the carpal sheath proximally and the digital sheath distally). While these structures protect the tendons from shear damage, they limit the ability of the tendons to heal, both because they are bathed in a synovial environment but also because the thick surrounding layer (paratenon) of extrasynovial tendon is absent within the confines of a tendon sheath. The paratenon is believed to be important in supplying fibroblasts capable of repairing tendon after injury.

Tendon receives its nutrients from three potential sources – intratendinous blood supply emanating from the musculotendinous junction and its osseous insertion, from blood vessels entering the tendon via mesotenon attachments within tendon sheaths or the paratenon, and from the synovial fluid within the tendon sheath. The relevant importance of these components depends on the tendon and tendon site. For the metacarpal region of the SDFT, studies have suggested that the intratendinous supply is the most important,[18] as necrosis was only achieved by ligation of the blood vessels within the tendon whereas stripping the paratenon had no effect.

The blood flow in the SDFT has been recorded between 1 and 2 mL/min/100 g,[10,11,19] which is of similar magnitude to that within resting skeletal muscle. Blood flow has been shown to increase two-fold with exercise,[11] although this can be delayed in horses that have not been trained. Injury caused an even greater increase in blood flow (> 300%), which has been recorded in both limbs of a horse with clinically unilateral tendinitis, further confirming the bilateral nature of the disease.

Tendon as a connective tissue

Although seemingly homogeneous on initial gross inspection, tendon is, in fact, composed of a complex arrangement of extracellular proteins in which are embedded cells, blood vessels, lymphatics, and nerves.

Tendon cells

Little is known about the cells that populate equine tendon. Although they are collectively known as tenocytes, they are unlikely to be a uniform population of cells because they differ considerably in nuclear morphology on light microscopy and when grown in culture. Previous descriptions have described three types[10] although a fourth type is evident within the endotenon tissue (Fig. 8.4; Table 8.1), and in other species, the synovial cells lining the outside of the tendon are differentiated from those within the tendon.[20]

The function of these cell types is not known but their location, morphology and presence in young or adult tendon propose functions which are reflected in the type classification (Table 8.1). The actual synthetic activity of these different types is unknown because there are currently no markers for identifying each type, nor methods for selectively recovering them from tendon tissue. Tenocytes have been often likened to fibroblasts and, while they have many

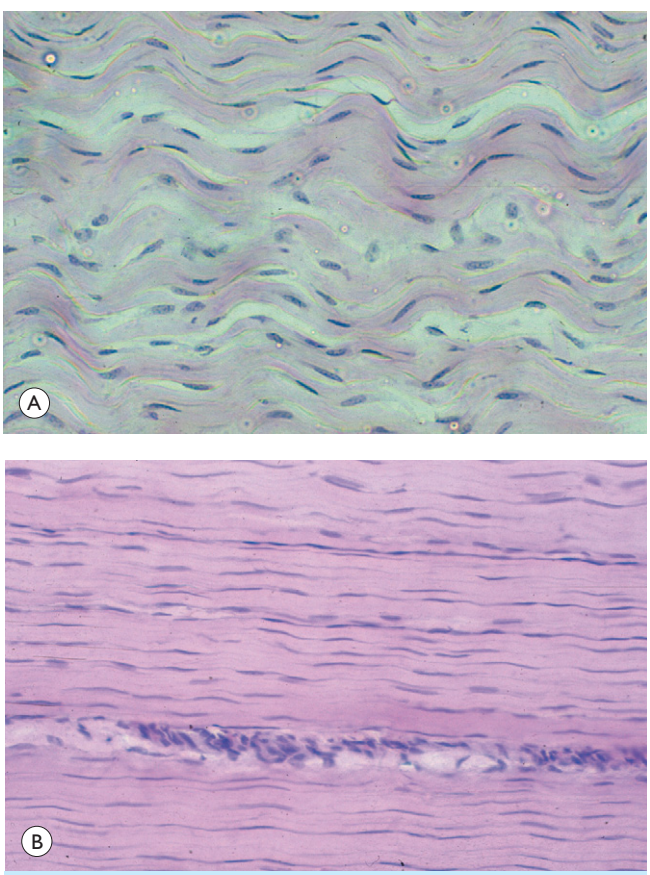

Fig. 8.4
H&E histologic sections showing the different morphologies of tenocyte nuclei in young (A) and mature (B) equine tendon. Note the large numbers of cell nuclei within the endotendon in the mature tendon.

Table 8.1 Types of cells within tendon and ligament based on nuclear morphology and location.

Cell classification	Type	Nuclear morphology	Location
I	'Resting'	Spindle-shaped nuclei lying between collagen fibers	Within the tensional region of all adult tendons
II	'Active'	Cigar-shaped nuclei lying between collagen fibers	Within young tendon and both young and adult ligaments
III	'Chondrocytic'	Round nuclei	In compressed regions of tendons and areas of chondroid metaplasia
IV	'Precursor'	Round nuclei with prominent nucleoli	Endotendon

similarities, it is unlikely that all these tenocyte types are identical to the fibroblasts seen in the skin or scar tissue. Recent studies have shown that fibroblasts recovered from different tissues behave differently in terms of the amount of certain proteins they synthesize (Smith & Heingard, unpublished data).

Work performed on laboratory animal[21] and equine (Ralphs, personal communication) tendons has shown that tenocytes have a large number of cytoplasmic extensions, which connect to neighboring cells via gap junctions. This provides a synctium that could provide an efficient system for mechanotransduction, similar to that occurring between osteocytes in bone.

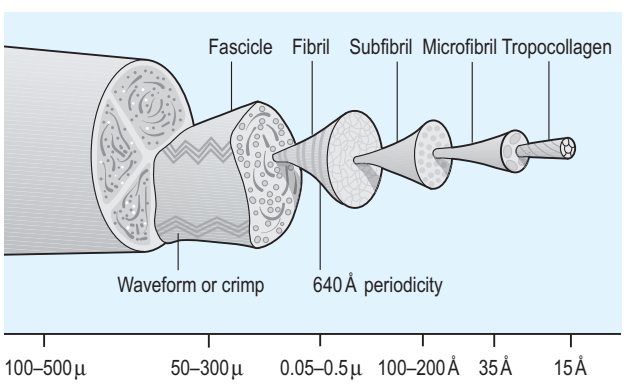

Fig. 8.5
Hierarchic arrangement of collagen in tendon (courtesy of the Veterinary Clinics of North America: Equine Practice, reproduced with permission).

Tendon matrix

As the cellular component of tendon is small, the functional properties of tendon rely on the extracellular matrix. This is determined, in turn, by both the composition and, equally importantly, the arrangement of these proteins within the matrix. It is constructed from a series of increasingly sized subunits into a hierarchic arrangement (Fig. 8.5).

Morphology

Crimp

'Crimp' refers to the characteristic waveform seen in longitudinal tendon histologic sections (Fig. 8.6). Originally suspected to be a preparation artifact, it is now known to be a real feature of tendon fascicles that is responsible for the 'toe' region of the stress–strain curve for tendon where tendon elongates with only a low level of applied stress

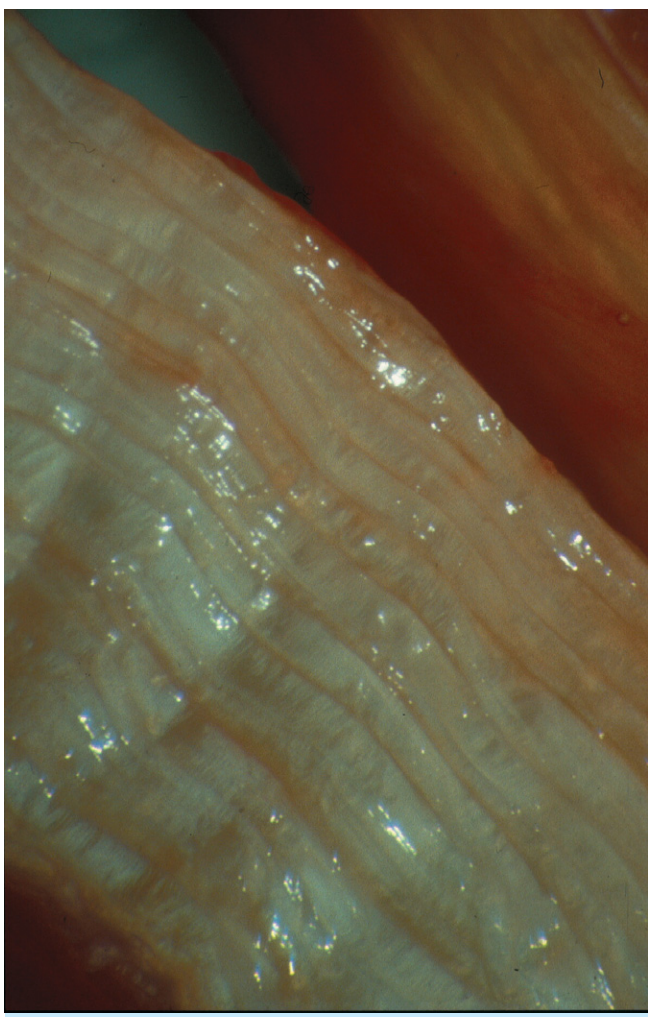

Fig. 8.6
'Crimp' pattern seen in the fascicles of the accessory ligament of the deep digital flexor tendon.

(Fig. 8.7). It is thus eliminated within the first 2% of tendon elongation and hence is unlikely to be present when the tendon receives normal weight-bearing load when standing. However, the 'toe' region has important implications for the overall strain capabilities of the tendon. Crimp can be described by its angle and length and these change as the animal ages (see p. 140).

Ultrastructural morphology

Collagen fibrils, the basic 'building block' of tendon, appear as banded filament on transmission electron microscopy of longitudinal sections of tendon. Transverse sections show the collagen fibrils as electron dense circular structures of varying sizes. The distribution of collagen fibril diameters can be determined from these sections, as well as assessment of the mass average diameter, which takes into account the relative proportion of the area taken up by different-sized fibrils.

Investigations on the development of tendon in laboratory animals have shown that collagen fibrils aggregate, resulting in thicker collagen fibrils. Recent work has proposed a regulatory mechanism for this process where only unipolar (N–C terminals) collagen fibrils can fuse resulting in a bipolar fiber (C–C terminals).[22,23] Thus, as the tissue matures, the proportion of unipolar fibrils becomes depleted, limiting the final size of the collagen fibril.

Whereas this process might also occur in the early development of equine tendon, the picture is much more complicated after birth. The adult SDFT has a bimodal distribution of fibrils with large numbers of small fibrils and lower numbers of large-diameter fibrils[24] (Fig. 8.8). Furthermore, there are differences between tendons, with the DDFT having fewer small-diameter and greater numbers of large-diameter fibrils.[25]

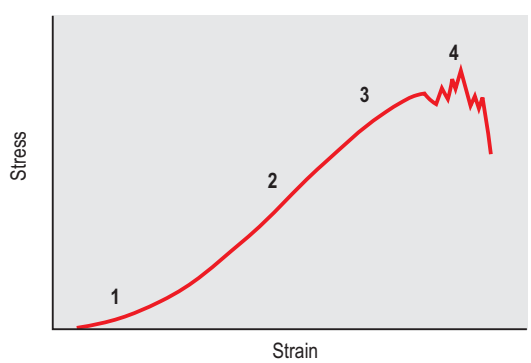

Fig. 8.7
Stress–strain curve for tendon. Zone 1 refers to the toe region, thought to be associated with the elimination of crimp; zone 2 to the linear phase from which the elastic modulus is calculated; zone 3 to the yield point after which irreversible damage occurs; and zone 4 to where individual tendon fibers rupture leading to complete failure (courtesy of the Veterinary Clinics of North America: Equine Practice, reproduced with permission).

Molecular composition

Tendon is predominantly composed of water, which makes-up approximately two-thirds of the weight of the tissue. The presence of this water is fundamental to maintaining the elasticity of the tissue because dehydration results in an increase in stiffness and tendons containing less water tend to be stiffer (Birch, personal communication). Although unsubstantiated at present, movement of water through compartments within the tendon might result in 'streaming potentials', which could provide a mechanism for mechanotransduction, whereby mechanical forces on the tendon influence the metabolic activity of the tenocytes.

The remaining third of the content of tendon (the dry weight) is predominantly composed of type I collagen. This protein is a major component of all connective tissues. Each type I collagen molecule is constructed within the endoplasmic reticulum of the cell from two α1 (I) chains and one α2 (I) chain, which forms a triple helix with non-helical N and C terminal extensions (propeptides) and is known as a procollagen molecule. These individual collagen molecules are assembled by cleavage of their propeptides at the N and C terminal ends by specific N- and C- proteinases, either after secretion into the immediate pericellular environment or intracellularly (Kadlar, personal communication). This results in a tropocollagen molecule that is 285 nm long and 1.4 nm wide. These molecules are then assembled into collagen fibrils in a highly organized fashion, each collagen molecule overlapping its neighbor by a quarter length (the 'quarter stagger' arrangement that is responsible for giving the banded pattern seen in electron microscopy), so that five collagen molecules make up a subunit of the collagen fibril. Although collagen molecules will spontaneously self-assemble, other proteins are likely to play a role in orchestrating this assembly (see below).

The fibrils are stabilized by the formation of covalent cross-links between lysine/hydroxylysine residues in adjacent fibrils, catalyzed by the enzyme lysyl oxidase. The collagen fibrils are in turn assembled in a longitudinally oriented pattern into increasingly larger subunits, which ultimately form the collagen fibers seen under light microscopy. These collagen fibers are further associated into tendon fascicles, which can be identified on the cut surface of a tendon (Fig. 8.9).

Non-collagenous components

While 80% of the dry weight of tendon is composed of collagen, the remaining 20% (5–6% of the wet weight of the tendon) is comprised of a wide variety of non-collagenous proteins. Although these are only a small component of the tissue, recent work has suggested they are vital for the organization and function of the tissue.[26]

During growth of the digital flexor tendons, one of the most abundant proteins is cartilage oligomeric matrix protein (COMP). This protein consists of five 'arms', joined at their N termini and with globular C termini (Fig. 8.10). There are only low levels of this protein in tendon at birth but it accumulates during growth within the digital flexor tendons with

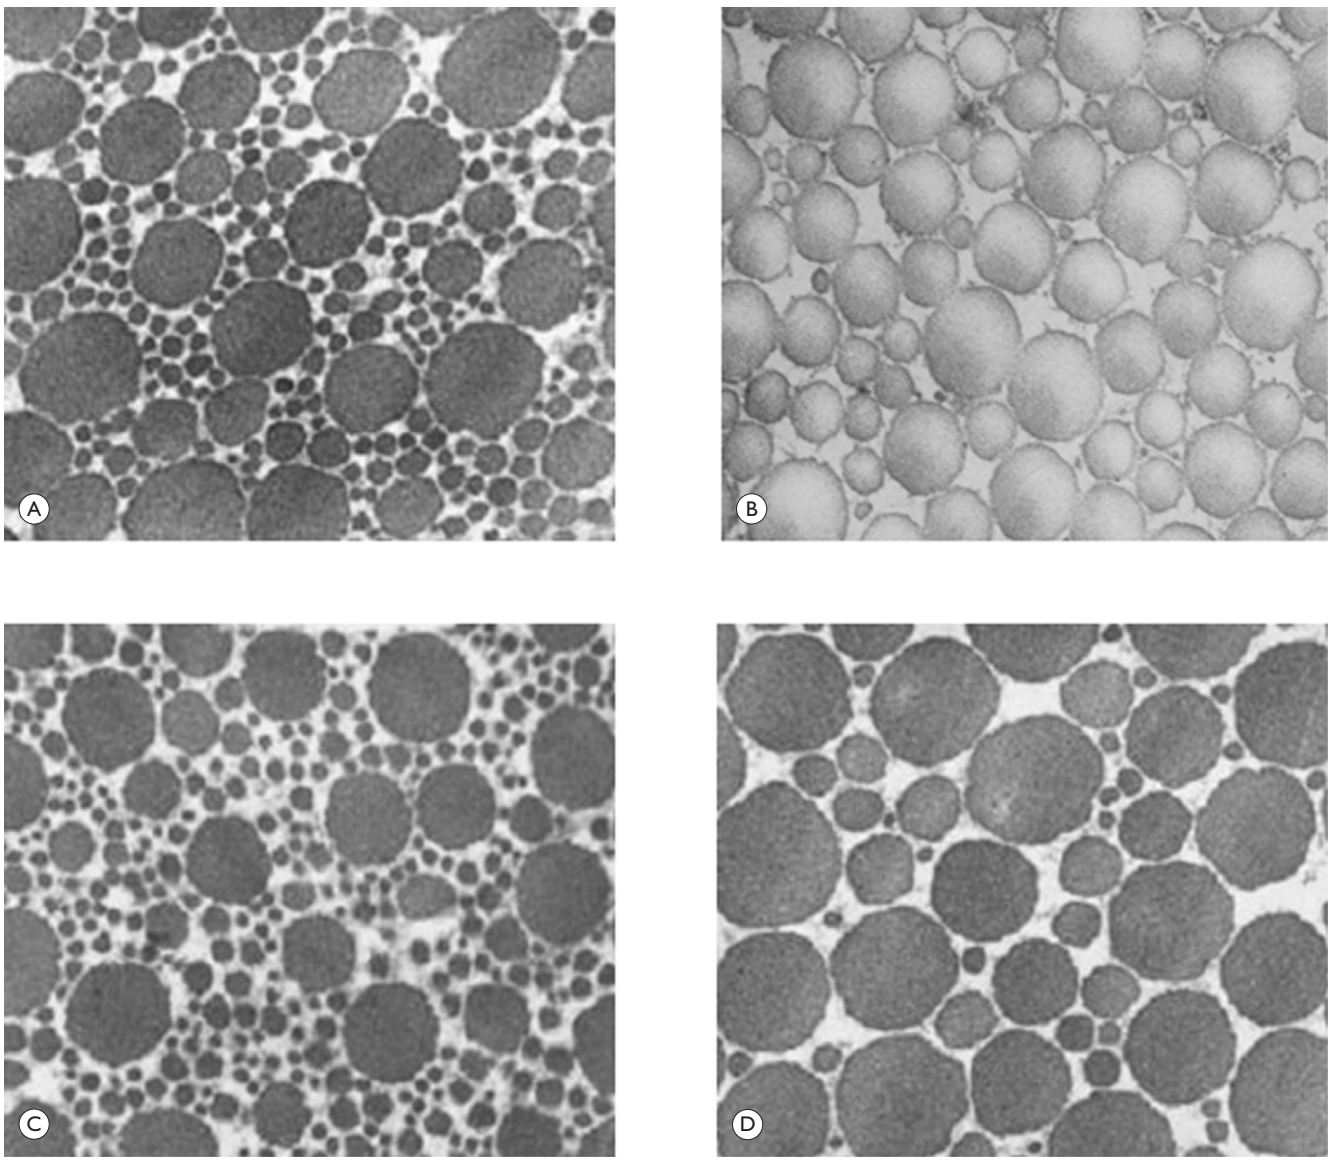

Fig. 8.8
Collagen fibril morphology in (A) the superficial digital flexor tendon, (B) the deep digital flexor tendon, (C) the suspensory ligament, and (D) the common digital extensor tendon. Note the similarities of the primary supporters of the metacarpophalangeal joint (superficial digital flexor tendon), and the positional tendon (common digital extensor tendon) with the deep digital flexor tendon.

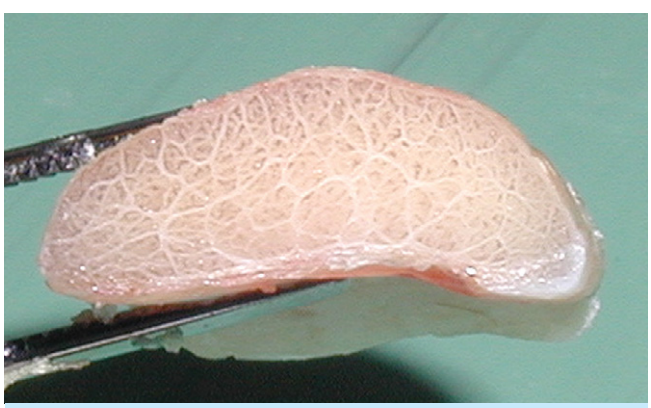

Fig. 8.9
The cut surface of the superficial digital flexor tendon (SDFT), showing the fascicular arrangement.

the highest levels achieved in the tensional region of the SDFT at skeletal maturity in the horse (at approximately 2 years of age) of approximately 10 mg/g wet weight.[27] This equates to approximately 30 mg/g dry weight or approximately 1% of the wet weight. After the period of growth, however, levels of COMP in the tensional, but not the compressed, region of the SDFT fall (see p. 145).

The function of COMP has not been completely determined but it is known to bind fibrillar collagens (including type I) via a zinc-dependent mechanism.[28] This interaction with collagen occurs via the globular C terminal domains at four equally spaced sites along the collagen molecule.[29] The size of the arms is such that it cannot interact with more than one site on one collagen molecule but instead can order five collagen molecules for assembly into a collagen fibril during

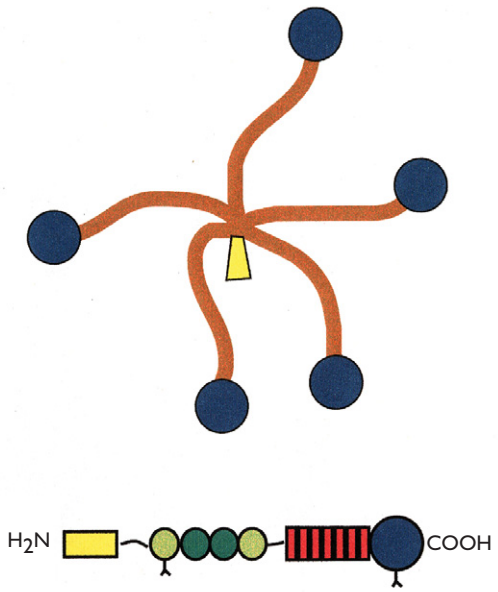

Fig. 8.10
A cartilage oligomeric matrix protein (COMP) molecule (courtesy of Dr K Rosenberg and *Comparative Biochemistry and Physiology*, reproduced with permission).

the earliest stages of collagen fibril formation. As it does not bind to formed collagen fibrils, COMP is displaced from the fibril. This makes its role as a structural protein within the formed tendon matrix a difficult one to rationalize. However, recent studies have shown that COMP can accelerate collagen fibrillogenesis in vitro and it is possible that this protein acts more as an 'organizational' molecule rather than in a structural role (Heinegård, personal communication). This would be supported by observations that the highest levels are present during the growth of the tendon when matrix is being synthesized and that levels fall after skeletal maturity when there is little change in the structural properties of the tendon. While possibly not important for the structural integrity of the matrix once it has formed, it is potentially critically important in the formation of soft tissue collagenous matrices that are designed to withstand loads, as it is present only in tendon, ligament, cartilage, intervertebral disk, and meniscus. Indeed, initial data relating mechanical properties of SDFT at skeletal maturity to COMP levels demonstrate a significant positive relationship.[26] Thus, the hypothesis is advanced that the more COMP synthesized during growth, the stronger the resulting tendon. In further support of this function, a functional 'knock-out' of the protein caused by a naturally occurring mutation in the COMP gene shows a tendon phenotype.[30]

Proteoglycans

Proteoglycans consist of a central protein core with O-linked glycosaminoglycan side-chains. They can be divided into two classes – the large proteoglycans (such as aggrecan, the large proteoglycan of cartilage, and the soft tissue equivalent, versican) and the small proteoglycans (such as decorin, biglycan, fibromodulin, lumican, and mimican) all of which are present in equine tendon. The large proteoglycans have numerous highly sulfated glycosaminoglycan side-chains, which hold water and therefore are present where the tendon has to resist compression. The small proteoglycans are closely associated with the collagen fibrils and are believed to regulate collagen fibril diameters. 'Knock-out' of the decorin gene in mice resulted in large, irregular-sized collagen fibrils believed to be caused by unregulated lateral fusion and this was associated with weak and fragile skin.[31] Fibromodulin knock-out mice showed paradoxically smaller collagen fibrils but also a compensatory increase in another small proteoglycan, lumican, which binds to the collagen molecule at the same site to fibromodulin,[32] demonstrating that many of these small proteoglycans can 'cross-function'. However, tensile testing of the mice's tail tendons showed a significant reduction in tensile strength in the adult fibromodulin null mice,[33] consistent with the hypothesis that although another small proteoglycan can do the same job, it does so less well.

Other proteins

There is a wide variety of other proteins in tendon whose functions are only partially elucidated. There is a variety of minor collagens, including type III, predominantly surrounding the fascicles within the endotendon tissue, and type VI, especially in the digital flexor tendons, which also appears to be regulated by mechanical load. Thrombospondin 4, tenescin-C, fibronectin, hyaluronic acid, and small amounts of elastin are also present but their contribution to the function of equine tendon is unclear.

Tendon-specific differences in structure and composition

Considerable debate still surrounds the simple question as to whether all tendons are constructed from the same material and/or have the same basic material properties. Our data would suggest that neither the composition nor the material properties are the same for all tendons, with differences reflecting the functional requirements. Thus, along the length of the digital flexor tendons in all animals weight bearing on a hyperextended metacarpophalangeal joint, where compressive forces are applied to the tendons as they change direction around the palmar aspect of the metacarpophalangeal joint, there is an accumulation of those matrix proteins most suited to resisting that compression. Thus, the tendon has a fibrocartilage-like composition in this region.[34,35]

Between tendons, there are differences in hydration, collagen content and some of the non-collagenous proteins. Thus, when comparing the digital flexor tendons, which are weight-bearing tendons, with the digital extensor tendons, which are positional tendons, the flexor tendons have higher hydration and lower collagen content, which is reflected in differences in

stiffness. Probably the most dramatic difference is seen in the COMP content during growth.[36] Both tendons have similarly low levels at birth but there is a dramatic rise in COMP levels in the superficial digital flexor tendon to 10 times levels at birth, while levels in the common digital extensor tendon do not alter. This probably reflects the different functional requirements between these weight-bearing and positional tendons. Interestingly, similar differences in COMP levels and other minor matrix components, such as type VI collagen, are observed between weight-bearing (e.g. Achilles tendon) and positional (e.g. anterior tibial tendon) tendons in man (Smith & Heinegård, personal communication).

Functional characteristics of tendon

Tendon and ligaments transmit forces to move the equine skeleton, or for support of the distal limb in the case of the digital flexor tendons, or, as ligaments, to maintain joint integrity. At heel strike, the loads rise the quickest in the soft tissue structures primarily supporting the metacarpophalangeal joint – the SDFT and the SL. High-frequency transients are also a feature of the early phase of weight bearing in these tendons. The load in the deep digital flexor tendon is slower to rise, which may help to explain why the SDFT and SL are the most prone to injury.

Load/deformation characteristics

The biomechanical properties of a tendon can be defined in vitro by its structural (as an organ) or material (as a tissue) properties. To establish these data, tendons can be recovered from cadavers and pulled to failure in a material testing machine. Anchoring of the tendon ends is problematical as final rupture often occurs at the tendon–clamp interface, which can result in artificially low values. Furthermore, data varies depending on a number of factors including rate of loading. Thus, comparisons between data sets performed in different ways should be made with caution.

In vitro loading experiments generate a load–deformation curve from which the structural properties of ultimate tensile strength (kN) and stiffness (N/mm) can be derived (see Fig. 8.7). There are four regions to the curve:

1. The 'toe' region, where there is non-linear stretch to the tendon. This is associated with the elimination of the crimp pattern of the collagen fibrils.
2. Linear deformation – it is this area of the curve from which the stiffness is determined (load divided by deformation for the linear portion of the curve). The mechanism for this elongation is not known but arises from elongation of the collagen fibrils and/or sliding of fibrils relative to one another. Recent work has suggested that interfibrillar (and even interfascicular) deformation is much greater than intrafibrillar/intrafascicular deformation, suggesting that tenocytes survive in a 'strain-protected' environment where they experience considerably lower deformation than that recorded for the whole structure.[37]
3. Yield region – irreversible lengthening of the tendon occurs at these deformations, possibly arising from covalent cross-link rupture and slippage of collagen fibrils.
4. Rupture, where the stress–strain curve falls quickly to zero as the collagen fibrils sequentially rupture.

Knowing the cross-sectional area of the tendon and its length, the stress (force per unit area) can be plotted against strain (change in length over original length), from which the material properties of ultimate tensile stress (N/mm^2) and Young's modulus of elasticity (E; MPa) can be calculated. As both the cross-sectional area and original length are assumed to be constant, the stress–strain curve has a similar shape to the load–deformation.

Ultimate tensile strength and stress

The ultimate tensile strength for the equine SDFT (rupturing at the midmetacarpal region) in the horse is approximately 12 kN or 1.2 tonnes. The approximate ultimate tensile stress is 100 MPa for the equine SDFT, which agrees well with previously documented figures for other species (45–125 MPa).[38,39]

Ultimate tensile strain

Equine flexor tendons can extend 10–12% of their length, and values of up to 20% have been reported[10] before the tendon ruptures. However, the ultimate tensile strain reflects only the final strain before rupture and includes that yield portion of the stress–strain curve that represents irreversible damage to the tendon tissue. In addition, the ultimate tensile strain may not be constant along the length of the SDFT in vitro.[40] Recent work has demonstrated that the normal strains in the digital flexor tendons in vivo (in ponies) are in the region of 2–4% at the walk and 4–6% at the trot.[41] Riemersma and colleagues[41] also noted that different results were obtained in vivo to in vitro, thereby indicating caution in the interpretation of in vitro measurements. Other studies have shown that, in the galloping Thoroughbred, strain changes between heel-strike and maximum weight bearing can reach 16% in the SDFT.[42] Such strains – far greater than usually expected in tendons from most other species – may reflect the importance of the digital flexor tendon as an elastic energy store where maximum deformation stores the most energy.

Cyclical loading and preconditioning effects

The biomechanical parameters mentioned above can only act as guides to the mechanical properties of tendons as tendon is a viscoelastic tissue.[39] Its time-dependent and history-dependent properties indicate a more complex structure than a simple elastic substance.

Hysteresis

The property known as hysteresis is demonstrated by the difference in the stress–strain relationship when the tendon is loaded compared to when it is unloaded (Fig. 8.11). The area between these two curves represents the energy lost during the loading cycle. This is usually about 5% in equine tendons. Much of this energy is lost as heat and is responsible for the rise in temperature within the tendon core associated with repeated loading (as in an exercising horse).[43] These temperatures can rise to as high as 46°C, which is potentially damaging to either tendon matrix or tenocytes. However, tenocytes recovered from the center of equine SDFT remain viable when subjected to rises in temperature of this magnitude, whereas those recovered from the periphery of the tendon do not.[44] This property is also present in fetal tenocytes, which suggests that the tendon has an inherent genetic adaptation to this physical process.

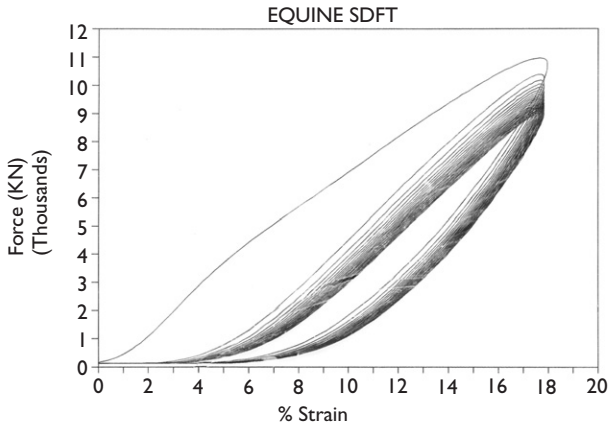

Fig. 8.11
The effect of repeated loading and unloading of tendon. The loading and unloading curves are different resulting in a loss of energy (hysteresis). Repeated loading shifts the curve to the right (conditioning).

Conditioning

The viscoelastic properties of tendon are demonstrated by movement of the stress–strain curve to the left or right (Fig. 8.11). Loading rate has only a minimal effect on tendon biomechanics; a rapid loading rate will move the curve slightly to the left, indicating a stiffer tendon.[45] Repeated loading, in contrast, results in shifting of the curve to the right (i.e. the tendon becomes less stiff), a process known as conditioning. This change is recoverable but significant resting time is necessary.[45] This property, however, has been demonstrated in vitro and may not reflect the normal behavior in vivo.

Contribution of tendon mechanics to the energetics of locomotion

With tendon loading under weight bearing being essentially a passive process, energy is stored in the extension of the tendon. As the energy stored in the tendon is represented by the area under the stress–strain curve, for this system to operate with maximum efficiency, the tendon must stretch as much as possible. As this tendon will rupture with in vitro testing at between 12 and 20%, the SDFT in vivo strain levels of up to 16% at the gallop[42] demonstrate that the high efficiency comes at a cost – there is little tolerance in the system and the tendon is prone to overstrain injury. Consequently, any small deterioration in the mechanical properties would have a significant effect on the risk of tendon injury.

The tendon returns energy with an efficiency of approximately 93%,[46] which provides considerable energy-saving for the horse. Predicted efficiencies of locomotion in the horse at different gaits calculated from the energy expenditure required for limb and trunk movement and the movement of the horse, and the energy production by the muscles (which have an efficiency of approximately 30%) shows an efficiency of greater than 100% at the gallop. This discrepancy is due to the energy-storage capacities of the locomotor soft tissues, in particular the SDFT and SL. Thus, these structures are critical to the optimum efficiency of equine locomotion.

Age and exercise effects on tendon pathophysiology

With preceding tendon degeneration proposed as an important factor in the initiation of equine superficial digital flexor tendinopathy, investigations have concentrated on changes occurring with the tendon matrix associated with aging and exercise. The importance of these factors on tendon physiology has been supported by epidemiologic studies in both horses (superficial digital flexor tendinopathy)[2,4] and man (Achilles tendinopathy).[6–8]

A combination of in vivo and post-mortem studies on 'normal' horses, both domesticated (trained) and ferral (untrained), and analyses of tendons from a number of experimental exercise studies has shone new light into the influence of both exercise and aging on equine tendon. These studies have investigated mechanical, morphological (ultrasonographic and histologic), ultrastructural, compositional, and metabolic changes in association with aging and exercise in equine tendon. The effects of these two factors have been found to be different between immature (growing) and mature (adult) tendon. The age at which equine digital flexor tendon matures is estimated at approximately 2 years of age from these studies.

Mature (adult) tendon

Mechanical changes

There is a large variation in mechanical properties between individuals – more than two-fold for ultimate tensile strength[10] so that alterations in both structural and material

properties are difficult to determine. In vitro testing from a large number of horses has demonstrated a decrease in ultimate tensile stress with age although this was not significant.[47] In further support of this hypothesis, human studies in vivo have demonstrated a decrease in stiffness in the Achilles tendon with age.[48] As this was an in vivo study, no ultimate tensile strength measurements are possible, although reduced stiffness is often associated with reduced strength in collagenous soft tissues.

The effect of exercise on the mechanical properties of tendon and ligament are variable, although much of this variation may be due to different ages and species used.

Morphological changes

The crimp pattern of equine SDFT was found to reduce in both angle and length with age.[49,50] Furthermore, the imposition of exercise resulted in an accelerated loss of this crimp in a heterogeneous manner – the central region of the tendon was disproportionately affected.[51] This may help to explain the occurrence of central 'core' lesions seen clinically as the central fascicles, having less crimp, straighten first and are therefore loaded preferentially, becoming the first ones to rupture.[49]

Other studies have assessed the change in fascicle pattern with aging and training.[52] Here, a significant reduction in the number of fascicles with a thickening of the interfascicular (endotenon) tissue was found associated with aging. This correlates well with the location of TGF-β in maturity (see 'Metabolic changes' below) and is consistent with this part of the tendon being the most labile portion of the tendon.

The effect of exercise on the cross-sectional area of tendon has shown inconsistent results. Ultrasonographic and gross cross-sectional measurements during experimental treadmill exercise in young adult horses failed to show any significant change with exercise over and above that caused by growth in digital flexor tendons.[53] In contrast, the common digital extensor tendon did show a significant increase with exercise, confirming similar findings in exercise studies on mini-pigs.[54] Another study, following cross-sectional area changes with the onset of training showed a significant increase.[55] However, two of the seven horses followed developed evidence of clinical tendon injury and so it is difficult to relate such increases in cross-sectional area to either adaptation or injury.

Ultrastructural changes

Collagen fibril diameters, calculated using transmission electron microscopy, in the adult SDFT in horses show a biphasic distribution, with a large number of small (40 nm) fibrils and a low number, but broader range, of large fibrils, while very old tendons have a more unimodal distribution characteristic of fetal and newborn tendon.[24] The bimodal distribution was unaffected by a short-term (4.5 months) experimental treadmill exercise program in ~2-year-old horses but there was a shift to smaller diameter collagen fibrils in the longer term study (18 months) where the horses were over 3 years of age[56] (Fig. 8.12). This effect was believed to be due to the disruption of large fibrils rather than the formation of new ones as the collagen content and 'age' (as determined by non-enzymatic glycation) were unaltered.

Compositional changes

Collagen content varies little with age and exercise but the non-collagenous component of tendon is much more labile.

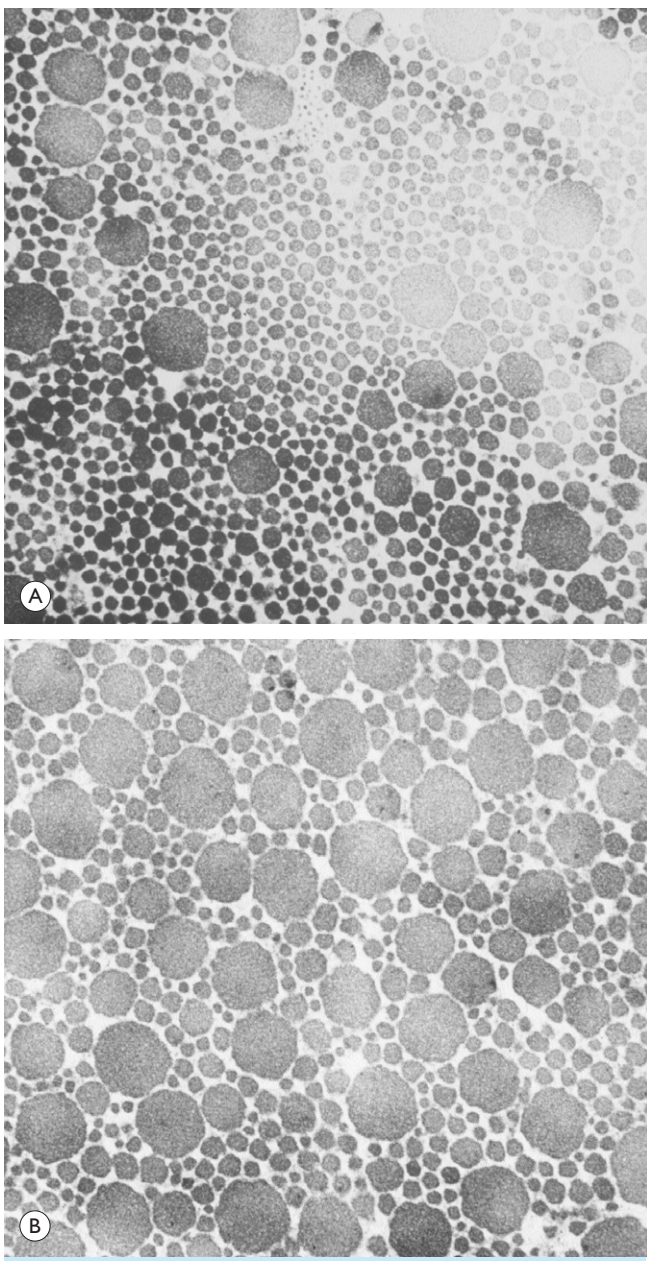

Fig. 8.12
Transmission electron microscopy of superficial digital flexor tendon in 3-year-old Thoroughbreds after 18 months of treadmill exercise (A), compared with controls that received only walking exercise (B). Exercise has induced a greater number of small-diameter fibrils (courtesy of the *Equine Veterinary Journal*, reproduced with permission).

Analysis of tendons from a wide range of ages, together with those from experimental exercise studies has shown a decrease in glycosaminoglycan (GAG) levels with age and exercise, where both act synergistically.[57] This is in contrast to the central discolored regions seen as an occasional coincidental finding at post-mortem, which contain increased GAG levels suggestive of scar tissue formation[58] (see Fig. 8.3). GAGs are part of proteoglycan molecules but vary in amount between different proteoglycan species. Thus, the small proteoglycans of tensile tendon contain only one or two side-chains of GAGs while the large proteoglycans, more characteristic of areas of tendon under compression (e.g. where the digital flexor tendons change direction at the level of the metacarpophalangeal joints contain large numbers of GAG side-chains. Thus, changes in GAG levels within tendon probably reflect more changes in the large, rather than small, proteoglycan species.

Another non-collagenous protein, COMP, which is abundant within the digital flexor tendons of horses, shows marked changes with age and exercise. Levels are low at birth but rapidly increase with tendon growth during the first 2 years of life. Once maturity is reached, which is at approximately 2 years in tendon, levels rapidly decline but only within the tensile (metacarpal) regions of the digital flexor tendons.[27] The superimposition of exercise at this time results in a significant increase in the loss of COMP from this area of the tendon.[12] In contrast, levels of COMP within the low loaded tendons, such as the common digital extensor tendon are also low at birth but do not alter significantly with growth and aging[36] although exercise did alter levels in immature tendon (see below).

Metabolic changes

Recent studies investigating the distribution of the growth factor, TGF-β, a potent anabolic growth factor and stimulus for COMP synthesis *in vitro* has demonstrated reduction in the presence of the three isoforms of TGF-β after skeletal maturity, although TGF-β1, believed to be most associated with scar tissue formation in wound healing, remains prominent within the interfascicular (endotenon) tissue where age-associated thickening occurs.[59]

These findings have resulted in the hypothesis that the tensile region of the digital flexor tendons of the horse lose their ability to adapt to exercise after skeletal maturity and both age and exercise provoke degeneration in the tendon matrix, characterized by a loss in non-collagenous proteins. In support of this hypothesis, analysis of matrix gene expression in bovine digital flexor tendons has shown prominent matrix gene expression at birth and during growth but a complete absence of gene expression in the tensile (but not compressed) regions.[60] Interestingly, COMP levels are also maintained in the compressed regions of equine digital flexor tendons and this area is frequently spared clinical injury. The mechanism for this failure of tenocytes to produce tendon matrix in the adult is unclear, but might involve either an absence of appropriate growth factor stimulus or cellular senescence. Certainly, investigations into the synthetic response by equine tenocytes to mechanical load (biaxial stretch) and growth factors (TGF-β) in vitro have demonstrated little response to mechanical load alone.[13] TGF-β has a major effect on protein synthesis and, when combined with mechanical load, is synergistic. However, tenocytes recovered from aged flexor tendons do demonstrate a small, but significant, reduced response to load and TGF-β suggesting that the failure of an adaptive response in adult tendon is potentially due to a combination of the absence of growth factors and, to a small degree, cellular 'senescence'. Interestingly, this age effect is not apparent in tenocytes recovered from digital extensor tendons.

Mechanisms of strain-induced degeneration

The close association between age and exercise suggests that number of loading cycles is important. It is logical to presume that the highest loading rates are likely to be the most damaging, so the amount of time spent at the fastest gaits (canter and gallop) where strains can reach 16% with an initial strain rate of up to 200%/s are likely to be the most contributory for degeneration. To combat these deleterious effects of exercise, it has been proposed that the muscle of the SDFT primarily acts to fix the origin of the tendon and dampen the potentially harmful high frequency vibrations.[17]

The actual mechanism for the degeneration of the tendon is currently unknown although there are several possibilities. These mechanisms can be either physical or metabolic processes. The physical energy imparted to the tendon under weight-bearing load can produce direct damage to the matrix by disrupting cross-links or actual matrix proteins. An indirect physical effect of weight bearing is via the energy lost through hysteresis. This results in a temperature rise within the center of the tendon.[61] While the tenocytes in the superficial digital flexor tendon have been shown to be resistant to these temperature rises,[44] this temperature could still be damaging to matrix proteins. Loading cycles can induce cellular activity with potentially the release of proteolytic enzymes.[62] Furthermore, cleaved matrix proteins, generated either from direct physical forces or from enzymatic cleavage, can also provoke further matrix degradation.[63] Further work is necessary to elucidate the mechanisms of soft tissue degeneration so that preventative strategies can be developed.

Immature (growing) tendon

Although there appeared to be a failure in adaptive response to exercise in mature digital flexor tendon in the studies outlined above, is this also the case in immature tendon? Two recent studies have addressed this question – the first involving three different exercise regimes (box rest, box rest with enforced exercise (training), and pasture exercise) in Warmblood foals from 6 weeks to 5 months of age[64] and an increasing amount of treadmill exercise in Thoroughbred foals from 6 weeks to 15 months of age.[65]

Mechanical changes

In the Warmblood study, foals kept at pasture had significantly stronger tendons structurally at 5 months of age than the other two groups largely due to the development of a larger cross-sectional area (see below) as the ultimate tensile stress at rupture (material property) was not different between groups. By 11 months of age, after all three groups had received a 6-month period of low-level exercise, the differences between groups were largely no longer present.

Morphological changes

The recent study by Kasashima and colleagues[64] has documented a significant increase in the rate of increase in cross-sectional area of the superficial digital flexor tendon with treadmill exercise administered for only a small period each day in addition to pasture exercise. Interestingly, the variation in tendon cross-sectional area between limbs increased in both exercise and control groups towards the end of the study. In the study on Warmblood foals, the cross-sectional area was significantly larger at 5 months of age in the foals kept on pasture in comparison to those maintained on box rest or box rest with small bouts of enforced intense exercise. These differences were no longer significant at 11 months after all three groups had received a similar level of low-level exercise for 6 months.

Ultrastructural changes

Fetal and newborn equine SDFT has a uniform fibril size of moderate diameter (i.e. not universally small).[24,66] During growth, a bimodal distribution of fibril sizes, with the largest number of small (~40 nm) diameter fibrils and lower numbers of large fibrils (> 200 nm in diameter) becomes apparent within the first year of life.[66] These small fibrils may represent either new collagen fibrils waiting to be incorporated into larger fibrils, different collagen (type III has universally smaller fibril diameters than type I) or the disruption of larger diameter fibrils. This change in fibril diameter distribution appears to be influenced by loading and exercise, as different exercise regimes given to foals altered the time at which the small fibrils appeared.[66] Pasture exercise resulted in the most rapid appearance, with a predominance of small fibrils present by 5 months of age. Foals maintained in a box had a delayed onset of this 'adult' phenotype.

In comparison, treadmill exercise given to foals from 6 weeks to 15 months of age failed to alter the fibril diameter distribution between controls and exercised foals (Kasashima, personal communication) although these foals also had access to pasture exercise, which may have been sufficient to induce the bimodal distribution of fibrils.

Compositional changes

COMP levels have been found to be exquisitely sensitive to loading in vivo early in life. COMP failed to accumulate in the digital flexor tendons of an 11-week-old foal that had been non-weight-bearing on one limb for 6 weeks. This effect was not marked if the period of non-weight-bearing occurred after COMP had accumulated within the digital flexor tendons.[27]

In 5-month-old foals given pasture exercise, box rest, or box rest with enforced exercise (training) from 7 days of age demonstrated changes in molecular composition with respect to exercise.[66] Both COMP and PSGAG levels were lowest in the training group, suggesting that this exercise regimen was detrimental to tendon development. After normalizing the exercise across all groups for a further 6 months, there was only limited ability for the tendons to recover, although there were changes associated with growth, in particular increases in hyaluronic acid and COMP. Thus, early exercise is potentially the most important determinant of tendon development.

In contrast, in the exercise study performed by Kasashima and colleagues,[64] COMP levels were not altered in the SDFT although significant rises were induced in the CDET. This further supports earlier work in miniature swine by Woo and colleagues[54] who demonstrated a significant change in tissue properties for digital extensor tendons and ligaments but not digital flexor tendons. It may be that the load 'history' over the 15 months of exercise was not sufficiently different between the two groups to induce a significant change in the digital flexor tendons.

Metabolic changes

TGF-β isoform expression was found both within and between fascicles in young tendon, mainly pericellular in location.[59] Interestingly, PCR analysis of TGF-β gene expression showed no growth factor expression after birth, except when the tendon was injured, suggesting that the tendon TGF-β stores are fixed and limited at birth.

These investigations suggest that tendon is able to respond to exercise during growth. However, this response appears to be dependent on the exercise regimes. In the study using Warmblood foals,[64] pasture (constant) exercise appeared to produce a better quality tendon than that resulting from either box rest (limited, low level, exercise) or enforced exercise with box rest (limited, but high level, exercise). Some, but not complete, recovery appeared to be possible between 5 and 11 months when the animals were allowed low-level free exercise. This study also confirmed that the 'window of opportunity' for tendon adaptation appeared to be early in the life of the animal.

The minimal changes induced by additional, albeit small, amount of treadmill exercise suggested that the natural exercise level at pasture may be optimal for tendon development. Certainly, the gamboling activities of foals at pasture would appear to be ideally suited for high strain rate controlled loading of the digital flexor tendons (Fig. 8.13). It may be that both time and intensity 'windows of opportunity' exist above or past which further augmentation of tendon properties can not be achieved.

Fig. 8.13
Gamboling activity of foals at pasture may be ideally suited to the development of tendons (courtesy of Dr Yoshinori Kasashima, Japan Racing Association).

Tendon injury and repair

Gross damage and mechanical failure

With the advent of clinical injury, the extent of the damage to the matrix varies from disruption of fibrillar cross-links (covalent and electrostatic), to individual fiber ruptures and ultimately failure of the entire tendon. This damage can be focal or generalized and one of the more common manifestations of superficial digital flexor tendinitis is a centrally located region of injury (so-called 'core' lesion seen ultrasonographically; Fig 8.14), usually with the most severe level being just below the midmetacarpal region but also extending throughout most of the length of the metacarpal extrasynovial tendon. Regions of the SDFT enclosed within a tendon sheath (carpal sheath proximally; digital sheath distally) are usually much less severely affected, although this can be relatively more common when the metacarpal region has been previously injured.

Desmitis of the accessory ligament of the DDFT can occur as an isolated injury or in conjunction with superficial digital flexor tendinitis. Its pathogenesis is therefore more related to the SDFT than the DDFT to which it attaches. While ponies rarely suffer strain-induced tendinopathy, they do have a relatively high incidence of desmitis of the accessory ligament of the DDFT.

The SL can fail at any site along its length, although certain areas are more common in horses used in different disciplines. Thus, race horses tend to suffer lesions of the body (and branches) of the SL, while sports horses more frequently have pathology centered within the proximal or branch regions of the ligament.

In contrast to the SDFT and SL, the deep digital flexor tendon (DDFT) is most frequently injured within the digital sheath. It is not known whether these injuries have a preceding phase of tendon degeneration but many are potentially due to single loading cycles which induce overstrain damage. Consequently, bilateral pathology is rarer. Two manifestations are seen clinically. The first arises within the substance of the tendon (although it may extend to the borders of the tendon), which is similar to other clinical manifestations of tendinitis. The second arises at the medial or lateral borders of the tendon, usually in the region of the metacarpo/metatarsophalangeal joint, with no, or limited, involvement of the internal substance of the tendon. These tendon 'tears' are thought to arise from 'bursting' pressures within the tendon when the metacarpo/metatarsophalangeal joint is overextended.

Other tendons can suffer from strain-induced injury, although much less commonly than that affecting the palmar soft tissue structures of the metacarpus. Ligament injuries tend to occur when the joint they span is loaded inappropriately to result in a degree of subluxation.

Repair processes in tendon

Once the tendon suffers clinical injury with disruption of the tendon matrix, there is intratendinous hemorrhage initially, usually followed rapidly by a pronounced inflammatory reaction. This inflammatory reaction results in an increase in blood flow, the development of edema, infiltration of neutrophils, macrophages and monocytes, and the release of proteolytic enzymes. While this is the earliest stage of repair, designed to remove damaged tendon tissue, the response is usually excessive, causing further damage to the tendon. This inflammatory phase is usually short lived but, within a few days, the reparative phase of repair begins. This results in a pronounced angiogenic response and the synthesis of scar tissue. This tissue has a different composition to tendon, having a higher ratio of collagen types III/I (~50% cf. 10% for normal tendon; Birch, personal communication), higher levels of glycosaminoglycans and much lower levels of COMP.[27]

The reparative phase of tendon healing merges with the remodeling phase when there is a gradual, but incomplete transformation of collagen type III to I as the scar tissue matures.[67] The new collagen fibrils become thicker and cross-linked. Even mature scar tissue tends to be less stiff as a material than tendon, but because large amounts are formed, the scarred tendon often becomes stiffer as a structure than the original tendon.[15]

Diagnosis

Diagnosis of tendon injury is usually based on history (frequently a preceding bout of intense exercise) and the development of the signs of inflammation (pain, heat, swelling and lameness) over the affected structure (Fig. 8.14). Lameness may not always be present and tends to be related to the degree of inflammation rather than the degree of damage. In many cases, however, the onset of clinical tendinitis is associated with severe lameness.

The posture of the limb may be altered depending on the structure damaged and the severity of the injury. In the

case of severe superficial digital flexor tendinitis, resting metacarpophalangeal joint angle may be normal because of the action of the other supporters of this joint (SL and DDFT). However, when loading on the limb increases (e.g. when the contralateral limb is raised), the affected limb shows greater than normal overextension of the metacarpophalangeal joint. Severe damage to the SL will have greater effect on metacarpophalangeal joint extension.

For more subtle cases, careful palpation of the tendons in the limb should be made both with the limb weight bearing and

Fig. 8.14
(A) Clinical, (B) ultrasonographic, and (C) post-mortem appearance of the 'core' lesion – a common manifestation of superficial digital flexor tendinitis (SDFT).

raised. Careful attention should be made to pain response, subtle enlargement and consistency of the structure (soft after recent injury; firm after healing). The horse must be relaxed so that muscle activity does not tense the tendons and make them appear artificially firm. Careful visual assessment of 'bowing' of the palmar contour of the metacarpal region can help to identify subtle superficial digital flexor tendinitis.

Clinical examination, however, may not detect the most subtle injuries and assessment of the severity is limited by clinical examination alone. As prognosis is most dependent on the severity of the initial injury, it is prudent to evaluate the damaged area ultrasonographically and this is best carried out 4–7 days after the onset of the injury as many lesions expand during the initial few days. Modern ultrasound machines with a 7.5–10 MHz linear transducer produce excellent quality images of the flexor tendons and SL (see Chapter 20). While the metacarpal region can be evaluated ultrasonographically without clipping the hair, it is recommended to prepare the limb by clipping and washing (with a surgical scrub and spirit) to give the best-quality images. The horse should be standing square and both transverse and longitudinal images obtained in a methodical fashion throughout the length of the region containing the injured tendon. For the metacarpal region, the area is divided up into seven levels or zones, each with characteristic anatomy. Alternatively, the distance between the transducer and the accessory carpal bone can be recorded. The palmar soft tissue structures of the metacarpus can be evaluated satisfactorily from the palmar aspect of the limb, except for the SL branches which should also be evaluated from the medial and lateral aspects of the limb. Both limbs should *always* be examined as many cases of strain-induced tendon injury have bilateral components but with one limb more severely affected than the other.

Acute tendon pathology is manifest ultrasonographically by enlargement, hypoechogenicity (focal, e.g. 'core' lesion; see Fig. 8.14, or generalized), reduced striated pattern in the longitudinal images, and changes in shape, margin, or position. Chronic tendinopathy is associated with variable enlargement and echogenicity (often heterogeneous), and a reduced irregular striated pattern indicative of fibrosis.

Markers of tendon injury

When a tendon is injured, proteins are released from the tendon into either a surrounding synovial fluid (for intrathecal injuries) and/or the blood (for extrathecal injuries). It is potentially possible to detect these released proteins in either tendon sheath synovial fluid or blood which could then be used as a molecular marker of tendon disease.

The development of a specific assay for a molecular marker of tendon injury relies on one of two different approaches. One alternative is to identify a protein which is specific for tendon tissue and released into the bloodstream following injury. Studies on the molecular composition of tendon using 2D gel electrophoresis (Smith & Heinegård, personal communication) have demonstrated that there are many similarities between the proteins present in cartilage and tendon and few, if any, specific for tendon tissue, making this approach less viable at present.

The second alternative is to identify a protein that is not specific to tendon but whose distribution is restricted and/or whose fragmentation with injury is specific for tendon injury. One such protein is COMP, which has a restricted distribution to tendon, ligament, cartilage, intervertebral disk, and meniscus. Furthermore, COMP is particularly abundant in young midmetacarpal SDFT, the area most prone to injury. After skeletal maturity, the natural decrease in COMP levels within the metacarpal region of the SDFT can be accelerated by exercise.[12] These findings suggest that it might be a useful indicator of tendon damage if, once it is released from the metacarpal region of the SDFT, it gains access to the bloodstream and can subsequently be assayed. COMP is not significantly absorbed by the peripheral lymph nodes (cf. proteoglycan fragments; Frazer et al, unpublished data) and COMP fragments are found in the serum in humans.[68] While studies in man have demonstrated that COMP has potential usefulness as a marker of joint disease,[69] assay of the total amount of COMP in serum showed no significant alterations in COMP levels with tendon disease,[68] although there were significant increases associated with the commencement of training (Smith & Bathe, unpublished data). This assay quantifies COMP using a polyclonal antiserum that recognizes a number of epitopes on the COMP molecule. There is a normal significant background level of COMP in the serum (1–2 μg/mL), possibly representing the normal turnover of COMP from all tissues containing the protein. Certainly there are considerably higher levels of total COMP in the serum of growing horses compared to adults,[68] when COMP is being accumulated in the tissues. In addition, damage to cartilage in joint disease also contributes to the 'pool' of COMP in the serum and is therefore responsible for a reduction in the sensitivity of the assay for tendon disease itself.

However, COMP levels in digital sheath synovial fluid in horses with intrasynovial tendon injury demonstrated significant rises. We know from previous studies that there is < 1/100 the level of COMP in the digital sheath capsule,[27] so that rises observed in the digital sheath synovial fluid (approximately four times normal levels) suggest that COMP is lost from the intrasynovial tendon rather than the digital sheath. The COMP released within the digital sheath synovial fluid is composed of fragments which have been identified on SDS–PAGE after partial purification with ion exchange chromatography. This fragmentation pattern is different from that described for human joint diseases,[69,70] although may not be in the horse. These fragments represent ideal candidates for markers of tendon disease. Assay of these fragments, not normally present, would potentially enable a very sensitive assay to be developed.

In addition to proteins released after injury being useful for the detection of tendon damage, the healing process can also potentially be monitored using markers of protein synthesis. While serological markers of collagen synthesis (e.g. propeptide of collagen type I; PICP) were thought to be relatively specific for bone remodeling, recent studies have demonstrated significant rises of PICP following tendon injury.[71] Further work is necessary to determine if this molecular marker will be useful for the monitoring of tendon repair.

Review of current treatment strategies

Over the years, many treatment modalities have been tried with most showing equivocal or even deleterious effects. From our knowledge of the phases of tendon healing, the following have at least a rationale for treating tendinitis.[72]

Acute (inflammatory) phase

Physical therapy (rest, application of cold, and compression with bandaging) is the most important aspect of early management where the goal is to minimize inflammation and limit the action of proteolytic enzymes that continue to destroy tendon tissue (see Chapter 25). Pharmacologic interventions include short-acting steroids within the first 24–48 h (later application can inhibit the second phase of fibroplasia) and the use of polysulfated glycosaminoglycans, which have been shown to inhibit prostaglandin E2 production in vitro.[73] The intralesional use of steroids should be avoided as this has been associated, at least with depot preparations, with intratendinous calcification. Surgical treatment at this stage includes percutaneous tendon splitting, which has been shown to accelerate the resolution of the 'core' lesion seen ultrasonographically.[74] This can be done with a scalpel or, less invasively, performed with needle puncture, when it can be combined with intratendinous polysulfated glycosaminoglycan therapy. Desmotomy of the accessory ligament of the SDFT, often performed concurrently with percutaneous tendon splitting early on in the disease process, is suggested to reduce peak strains on the SDFT by bringing the superficial digital flexor muscle into play.[75] However, although initial data suggested a beneficial effect,[76] this has not been confirmed in other studies and has been suggested to contribute to a higher incidence of suspensory desmitis after its use.[77]

Subacute (fibroblastic) phase

Early and progressive mobilization and regular ultrasonographic monitoring aims to improve the quality of the forming scar tissue – the goal of this phase. If the cross-sectional area of the healing tendon increases by more than 10%, the exercise level should be reduced. The quality of the longitudinal fiber pattern when the animal returns to full work has been linked with the overall prognosis.[78] In an attempt to improve the quality of the scar tissue, β-aminoproprionitrile fumarate (BAPTEN™; no longer marketed for the treatment of tendon injuries) has been injected intratendinously 30–90 days after injury.[78] This drug inhibits lysyl oxidase, the enzyme that cross-links collagen molecules. In preventing the formation of cross-links, it is believed that collagen fibers will form with better longitudinal alignment under the stimulus of controlled exercise. When the drug wears off, cross-linking occurs and the scar increases in strength. Clinical trials in the USA indicated a benefit in the more severe cases.

Other drugs, such as sodium hyaluronate, have been used both intratendinously and peritendinously but studies have shown equivocal results. Some benefit in reducing adhesion formation in intrasheath tendon injuries has been demonstrated experimentally.

Newer treatments aimed at regenerating rather than repairing tendon represent the best hope for the future. Anabolic growth factors, such as IGF-1,[79] recombinant equine growth hormone,[80] and TGF-β have been tried empirically or in a collagenase model of tendon injury, but not comprehensively evaluated in the clinical situation, making interpretation of the benefits of these agents difficult. An important factor in assessing these new treatments is that they do actually generate tendon-like tissue rather than just increasing the amount of scar tissue produced, which will still compromise the outcome. One of the most exciting new developments is the use of mesenchymal stem cells (recovered from bone marrow)[81,82] although much work is still necessary to determine their effectiveness.

Chronic (remodeling) phase

A controlled ascending exercise program with regular ultrasonographic examinations encourages the further optimization of the scar tissue. In addition, ultrasound can enable the detection of early signs of reinjury to minimize the risk of catastrophic reinjury. Other methods aimed at preventing reinjury include desmotomy of the accessory ligament of the SDFT (see 'Acute phase' treatments) and the use of boots capable of providing significant support to the metacarpophalangeal joint. Traditional bandages fail to provide sufficient support under weight-bearing load, while novel designed boots have been shown to do so and potentially may help to prevent reinjury[83] (Fig. 8.15).

Specific therapies

Some tendon and ligament injuries have specific therapies in addition to those outlined above. DDFT tears within the digital sheath and SL tears into the metacarpo/metatarsophalangeal joint are best treated by tenoscopic/arthroscopic debridement. The outcome of hindlimb, but not forelimb, proximal suspensory desmitis appears to be improved (from 13% to 43%) by the use of extracorporeal shock wave therapy.[84,85] For those cases of hindlimb proximal suspensory desmitis also failing to respond to shock wave therapy, surgical neurectomy of the lateral plantar nerve combined with transection of the fascia overlying the proximal suspensory ligament provides an additional rational management technique. Both these latter two treatments are consistent with the hypothesis that hindlimb proximal suspensory desmitis is an example of a compartmental syndrome, unlike the forelimb (which carries a considerably better prognosis with conservative management alone).

Current concepts in prevention of tendinitis in the equine athlete

Strategies for the prevention of equine tendinitis

With the limitation of our ability with current treatments to return a horse with tendinitis to full work without danger of reinjury, prevention of the injury has to be considered as the most appropriate strategy. From our understanding of tendon physiology described in the preceding sections, four broad approaches for prevention can be considered.

Maximize the quality of the tendon prior to skeletal maturity

There is a large variation in the strength of the SDFT in a population of horses. Some of this variation may be due to specific genes. Either breeding out, or identifying horses with, those genetic variants associated with a genetic susceptibility to tendinitis would potentially lower the incidence of tendon injury. However, while the concept is simple, its achievement is considerably more difficult.

Skeletal tissues are much more able to adapt to the loads placed on them when they are immature and growing. This is certainly true for bone and muscle and we believe it to also be the case in tendon. Thus, carefully tailored exercise regimes during growth (0–2 years of age) would potentially improve the 'quality' of the tendon and minimize the effects of degeneration induced by training and racing after skeletal maturity (approximately 2 years of age in the horse) (Fig. 8.16). These exercise regimes must be within the 'windows of opportunity' of the right time and the right level. Growing tendon is also more susceptible to injury so these 'conditioning' programs have to induce adaptation suitable for subsequent racing without causing injury. However, the optimal prop-erty of equine tendon still needs to be deter-mined. Probably the most important characteristic would be fatigue resist-ance and, for any exercise regime in immature animals to be effective, it must demonstrate a reduction of tendon injuries within the subsequent athletic careers. The answers to these questions are not known but studies

Fig. 8.15
(A, B) Dalmar support boot capable of being used in the exercising horse and able to provide significant support to the metacarpophalangeal joint, unlike traditional bandages. This may provide a method of minimizing reinjury after rehabilitation (courtesy of the *Equine Veterinary Journal*, reproduced with permission).

are underwayto assess the effects of early exercise on musculoskeletal development.

Reduce the degeneration after skeletal maturity

Studies are turning towards investigating the mechanisms of aging in soft tissues, which may give therapeutic options for intervening in the aging process. At present, the only advice that can be given in this area is to avoid training solely aimed at the tendon in the adult horse. This will serve only to advance the rate of degeneration, which has to be considered an inevitable consequence of athleticism. Some forms of exercise may be more provocative of degeneration than others, but, at present, these are not known. However, high loading (i.e. fast speeds) is likely to be the most damaging.

Reduce the risk factors for tendinitis

The initiation of clinical tendinitis is provoked by sudden peak forces that overcome the strength of the (degenerated) tendon. This can obviously occur at any time, including out at pasture, but it is obviously most likely when the horse is loading its tendon maximally. This occurs when the horse is running fastest (hence the best horses are potentially more prone to tendon injury). Ground surface (which affects the horse's speed), fatigue (e.g. after longer races or in unfit horses), jumping, shoeing, and weight are all examples of factors that can increase the peak loading on the tendon and hence are risk factors for tendon injury. Some of these are rectifiable but others are a consequence of racing and not easily altered.

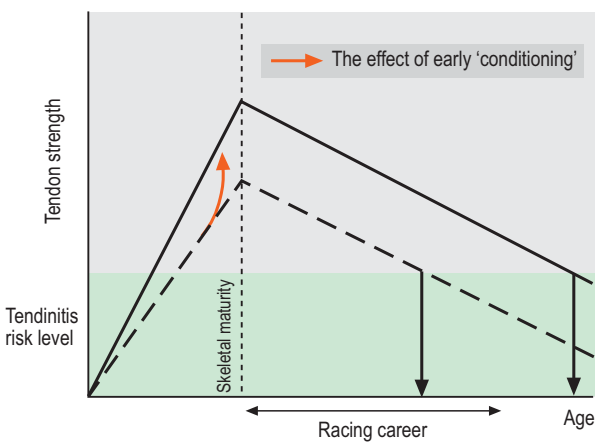

Fig. 8.16
Hypothetical response of tendons to the early introduction of exercise. The two lines refer to two different horses – one that develops poor-quality tendon during growth (dashed line) and one that develops good-quality tendon (solid line). Both accumulate damage within the tendon associated with postskeletal exercise and aging, which inevitably and progressively weakens the tendon. However, in the former, this weakening precedes the individual to clinical tendinitis within its racing career, whereas the latter is able to survive its racing career without suffering such injury. The imposition of 'appropriate' conditioning exercise during growth is hypothesized to improve the quality of the growing tendon, resulting in an individual more resistant to subsequent injury (courtesy of the *Journal of Comparative Biochemistry and Physiology*, reproduced with permission).

Early detection

This is not really a prevention strategy, as, by definition, a degree of tendon injury will already have occurred. However, if tendon injury can be detected very early, it is possible to prevent progression to more severe disease. Obviously, careful clinical inspection is vital in this area, but this is rather insensitive.

Ultrasonography has been the mainstay of tendon imaging and has advanced our knowledge and capabilities for management considerably. Ultrasonographic technology is still advancing and new machines have even better resolution. However, they are still relatively insensitive for predicting injury and the ideal time for a return to full work in the chronic stages. Furthermore, it is time-consuming and (frequently) requires the limbs to be clipped.

Future techniques in this area may rely on molecular markers of tendon injury. Fragments of proteins within the tendon, which are released with injury, can potentially be assayed for in the blood, which would give a practical test that would provide useful diagnostic, management, and prognostic information.

Recommendations for training of immature and mature animals

Pasture exercise early in life is essential for the development of digital flexor tendon that is likely to be most resistant to injury during adulthood. Additional imposed exercise may be able to augment this effect but the tendon is also more susceptible to injury at this age and so exercise levels have to be chosen with care. In addition, what about the other skeletal tissues? How do they respond to these exercise regimes? It would be pointless to develop a training regime beneficial for tendon but harmful to other tissues, such as bone and joints. However, different skeletal tissues mature at different times, thus potentially allowing different time 'windows of opportunity' for different tissues. We would suggest that tendon, ligament, and possibly cartilage are most responsive in the first year of life, while bone is more responsive at the yearling stage.

After skeletal maturity, training will have no effect on tendon adaptation and therefore training should be directed at muscular, respiratory, and cardiovascular fitness rather than the tendon.

CHAPTER 9

Joint physiology: responses to exercise and training

Alicia L. Bertone

Joint physiology and structure

The joint is an organ composed of synovium, articular cartilage and subchondral bone, with a local blood supply, innervation and fluid exchanges that function to maintain health and produce locomotion.[1] The joints are uniquely designed for rotary or hinge-like movement to permit limb and body movement. Joint tissues adapt to the magnitude and frequency of applied load which naturally occurs with exercise. Training (a forced exercise regimen) is designed to promote the adaptation of the joint structures and physiologic responses to permit high performance without joint compromise. The purpose of this chapter is to provide a comprehensive understanding of the consequences and complexities of physiologic and pathophysiologic changes that occur in the joint during training and exercise.

Basic anatomy and physiology

Tissues of the joint cavity have a specialized composition and three-dimensional anatomy which ultimately relate them to their specific biomechanical function. As such, the articular cartilage, whose ultimate function is to absorb and transfer loads, is a composite of collagen which provides tensile strength and highly charged proteoglycan subunits which provide compressive stiffness. In order to maintain cartilage composition and function, a slow but steady turnover of its components occurs, the rate of which is dependent on age, mechanical load and joint environment.[2–5] The building materials necessary for this turnover are provided through blood flow and exchanges from the synovial membrane and joint capsule, as well as through ultrafiltration and formation of synovial fluid, which provides the ultimate medium for these exchanges to occur.[6] The supply of nutrients to the avascular but metabolically active articular cartilage is provided by exchanges through the synovial microcirculation and transport in synovial fluid.

The synovial membrane is designed to provide a pathway for fluid exchanges, as well as a blood supply, and add to the composition of synovial fluid through hyaluronan synthesis. The synovial membrane is composed of an intima (also referred to as synovium), consisting of a luminal layer 1–5 cells deep, a capillary plexus which lies 6–11 μm beneath the intimal surface, a deeper network of lymph vessels and a subintima (or subsynovium) composed of adipose, areolar or fibrous tissue.[6] The intima is designed to favor exchanges between capillaries and the joint cavity: it lacks a basement membrane, intercellular gaps are present and intimal capillaries are fenestrated towards the joint cavity.[6] Furthermore, the synovial intima adopts a three-dimensional architecture which is dependent on its biomechanical environment. In areas of high biomechanical stress, the synovium is flat and rests on a fibrous, mechanically strong subintima. This is particularly true of synovium underlying tendons that cross over a joint, such as the extensor tendon overlying the metacarpophalangeal joint. In synovial recesses, the intima is thrown into a three-dimensional villous architecture. This network is more richly vascular and has been shown to be a preferential site of solute and macromolecule exchanges.[7] Hyaluronan synthesis is also greater in synovium from synovial villi.[8]

Intimal cells include synovial fibroblasts (or type B cells, approximately two thirds of cells) and bone marrow-derived mononuclear phagocytes (or type A cells, approximately one third of cells).[9] Light microscopy techniques are not a useful guide for assessing lineage, as subintimal macrophages are often elongated and intimal fibroblasts may take a rounded appearance.[9] These cells can be separated on the basis of cytochemical staining for uridine diphosphoglucose dehydrogenase, a marker for hyaluronan synthesis, and non-specific esterase, a macrophage marker.[10] These cells are also unique

as they are found in close association with specialized components of the intimal matrix, such as fibronectin, laminin, type IV collagen, type V collagen, entactin and sulfated glycosaminoglycans, which may serve to anchor the intimal cell layer to the underlying connective tissue.[11] The ability of the intima to maintain itself as a layer appears closely related to cell–matrix–cell interactions, through expression of adhesion molecules such as ICAM-1, VCAM-1, fibronectin, laminin and others and their integrin ligands are likely candidates.

With joint overuse and inflammation, the relative predominance of these cell types is altered, with subintimal macrophages forming 50–70% of cells in the intima. Integrin expression is also increased and the morphology of the cells is changed from small cells arranged parallel to the joint surface to a more superficial location arranged perpendicular to the joint cavity. These cells are also the dominant source of intimal vascular cell adhesion molecule (VCAM–1).[9] Expression of cell adhesion molecules by synovial intimal cells serves to direct leukocyte trafficking in disease. Most multinucleate cells within inflamed synovial intima carry macrophage lineage markers.[9] There is also evidence that synovial intimal cells could direct leukocyte trafficking in health and disease, through adhesion molecule expression.[9] Intimal fibroblasts proliferate in disease consistent with the synovial proliferation observed with chronic joint use and inflammation.[12]

Joint circulation

The synovial membrane functions to maintain articular homeostasis by providing a pathway for the exchange of nutrients and metabolic byproducts between blood and synovial tissues, including articular cartilage.[13,14] Optimal oxygen delivery to articular tissues serves to maintain normal synovial fluid composition,[15,16] chondrocyte metabolism and normal matrix composition and turnover.[17–19] The efficiency of exchange between the synovial membrane capillaries and joint cavity is dependent on capillary density, capillary depth and blood flow.[15,20]

Several tissues in the joint are provided with a rich vascular supply that responds to exercise and pathologic states. These include the joint capsule, synovial membrane, intra- and periarticular ligaments and subchondral bone. Articular cartilage is avascular. The articular blood supply of most diarthrodial joints is formed by small branches of the epiphyseal arteries running at the junction of the periosteum and the synovial membrane, forming an arterial circle. Larger branches penetrate the bone, whereas smaller branches remain at the periphery of the articular cartilage, forming the perichondral circulation. Subchondral bone blood supply is provided by the epiphyseal arteries, which travel in the epiphysis parallel to the articular cartilage, sending perpendicular branches which end in capillary loops at the deep surface of the calcified cartilage. Before physeal closure, this epiphyseal circulation is distinct from the metaphyseal circulation. The synovial membrane vascular supply is composed of capillaries which are very sparse in areas of high mechanical stress. The angle of reflection of the synovial membrane is composed of a rich vascular plexus and synovial villi are incompletely penetrated by a central arteriole.

The richest capillary density in the synovial membrane is within 25 μm of the joint surface. Capillary density is greatest in areolar or adipose synovium and lowest in fibrous synovium. Similarly, blood flow to synovium is greater than in the fibrous joint capsule and joint motion greatly affects intra-articular pressure and synovial blood flow (see intra-articular pressure below).[21] In addition, villous synovial membrane is more vascular than fibrous and preferential exchanges of small molecules such as albumin, as well as hyaluronan production, occur in synovial villi.[7] Health of the synovial villi is important to maintain viscous synovial fluid rich in hyaluronan.[22]

Factors that can acutely affect synovial blood flow include intra-articular pressure (IAP), local temperature, joint motion, vasomotor tone and reflexes and local release of vasoactive mediators. Exercise is the greatest activator of joint circulation. Cardiac output is concomitantly increased, as is blood flow.[23,24] Large arteries supplying the joint have intravascular pressure approaching systemic arterial pressure; however, blood flow and pressure are controlled at the arteriole and capillary level of the synovial membrane. Capillary pressure in the synovial membrane is low and local joint blood perfusion is strongly influenced by IAP. If effusion resulting in increased IAP is present, significant tamponade of the synovial blood flow occurs.[21] Intra-articular pressures of > 30 mmHg have been measured in fetlock joints of sound horses with effusion.[25] A significant decrease in blood flow to the synovial membrane was measured after an increased IAP of 30 mmHg.[21] Intra-articular acidosis develops at IAP of < 45 mmHg.[26]

Even in normal joint motion, as during exercise, regional blood flow will be arrested in accordance with high pressure profiles that occur within the compressed and highly tensed joint compartments.[27] As the joint moves from full extension to maximal flexion, a pumping action occurs, creating a pulsatile increase in blood flow.

Chronic joint disease, as seen in many active sports horses, can significantly decrease blood flow to the synovial membrane as the increased joint capsule fibrosis results in a concomitant decrease in capillary density and joint capsule compliance. Loss of joint capsule compliance increases IAP associated with joint effusion and motion.

Potential consequences of decreased articular blood flow include chronic ischemia and resultant synovial fibrosis and hypertrophy, generation of lactate and synovial fluid acidosis, and production of inflammatory mediators. Chronically hypoxic joints are more affected by exercise than normal joints, producing further hypoxia. A decreased blood supply could decrease drug delivery to the joint and decrease clearance of metabolites from the joint.

Morphometric and morphologic analyses of synovial vessels provide an insight into the contribution of synovial blood flow in disease.[28] Equine vessel anatomy contains a central arteriole and a helical venule descent from the tip to the base of the villus. The anatomical result is an

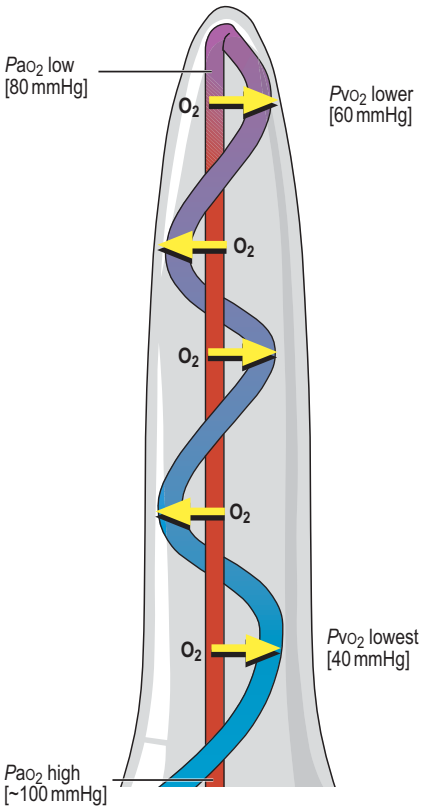

Fig. 9.1
Longitudinal section of an equine synovial villus. Note the central arteriole and helical venules that are anatomically appropriate for a countercurrent exchange mechanism and oxygen gradient from the arteriole to venules. The villus tip is susceptible to ischemia.

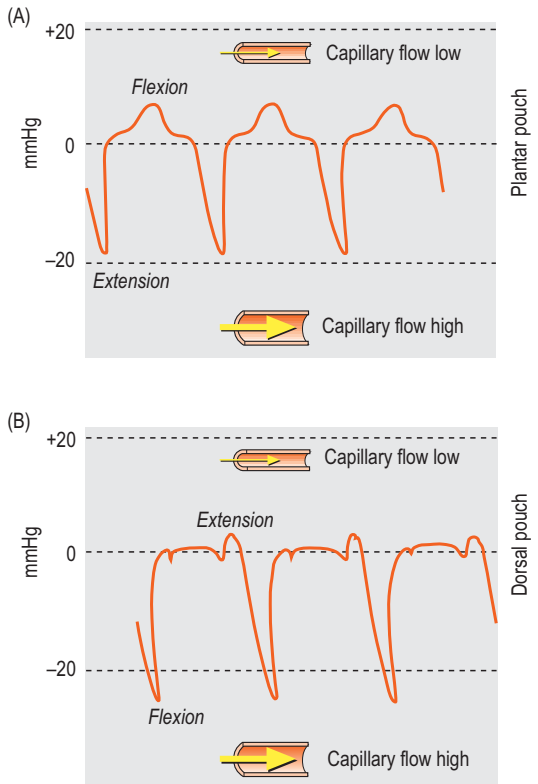

Fig. 9.2
Intra-articular pressure profiles of a normal exercising fetlock joint demonstrating the compartmentation and back-and-forth pulsatile blood flow in the capillaries of the synovial membrane. Capillary blood flow is higher during extension of the plantar pouch (A) and flexion of the dorsal pouch (lowest intra-articular pressure) (B) and lower during flexion of the plantar pouch (A) and extension of the dorsal pouch (highest intra-articular pressure) (B) .

arrangement that produces a countercurrent exchange system. These systems create ischemia at the tip of the susceptible villus[29] (Fig. 9.1). In normal synovial vessels, capillary flattening occurs with IAP greater than 25 mmHg.[28] In joint effusion and at phases of a normal stride, these IAP values are exceeded, resulting in decreased blood flow, decreased clearance and decreased lymph flow. These alterations are part of standard joint physiology in the horse in athletic training. In horses with chronic arthritis, decreased capillary density and increased intercapillary distance suggest altered trans-synovial fluid exchanges, as well as increased relative ischemia.

Data on joint physiology would suggest that in normal equine joints, an 'ebb and flow' of blood perfusion of synovial capillaries occurs from the back to the front of joints during exercise (Fig. 9.2). In joints with increased IAP (effusion) or decreased compliance (thickened stiff joint capsule), the reduction in blood flow will be even greater. The observation that synovial villi become blunted, shortened and clubbed with chronic joint overuse further supports the scientific evidence that the tips of the villi are most susceptible to hypoxia in the form of the typical ischemia reperfusion injury.[30] The fibrotic thickening of the villi may be stimulated by oxygen gradients created during tissue hypoxia.

Intra-articular pressure

Intra-articular pressure (IAP) is normally below atmospheric pressure in most joints at the 'angle of ease' and pressures between –2 to –12 mmHg have been reported. The 'angle of ease' is the most comfortable joint position and is typically a neutral position with the lowest IAP. Recordings of IAP in equine joints yielded similar subatmospheric values for the midcarpal and metacarpophalangeal joints.[25,28,31] Horses with healthy joints in active training will have 'tight' joints, i.e. no palpable effusion and a negative IAP. Maintenance of this negative pressure is thought to occur by joint motion, which enhances lymph flow from the interstitium, and by joint flexion which promotes fluid absorption by raising IAP.

The normal fluid balance is therefore maintained through two pumps in series, one that enhances fluid exchange to the interstitium and one that enhances lymph flow. Examination of pressure–volume curves in normal joints indicates that this relationship is sigmoid, with low articular compliance at normal subatmospheric pressures, an increased compliance at supra-atmospheric pressures up to 30 mmHg, and another increase in compliance at high IAP.[31] This relationship can be explained as a resistance to joint distension at IAP in the normal range, followed by accommodation of effusion at IAP up to 30 mmHg. This may prevent collapse of synovium capillaries and preserve joint blood flow. At IAP > 30 mmHg, the decreased compliance may counteract further effusion

and articular fluid accumulation. Rupture of the midcarpal joint capsule has been noted at IAP of > 80 mmHg in horses and this rupture was located in the palmar lateral pouch of the midcarpal joint, as has been observed clinically (Bertone, unpublished data, 1996).

The determinants of IAP include joint capsule compliance, joint angle, previous distension history, compliance of the joint capsule, muscle tension and joint load.[32,33] In addition, determination of pressure–volume relationships is also dependent on the type of infusate used for measurement.[31,34] Chronically inflamed joints have thickening and fibrosis of the joint capsule, resulting in decreased compliance. Joint flexion increases IAP. Slow distension–compression cycles result in progressive stress–relaxation of the joint capsule and a gradual increase in articular compliance. However, if rapid successive infusion–withdrawal cycles are performed, a progressive decrease in articular compliance can be measured. If the joint is distended with synovial fluid, an increased compliance is observed compared to infusion with saline, probably because of the lack of a fluid interface which increases surface tension and promotes joint collapse, confirming the importance of hyaluronan in joint lubrication during training and exercise.

The effect of joint history dependence on IAP and compliance explains the lack of correlation between the volume of effusion and pressure generated from the effusion. Long-term slowly accumulating joint effusion will have relatively low IAP compared to fast-developing effusions. In addition, pain due to effusion is caused by periarticular tension receptors; stress–relaxation may explain why rapidly forming effusions are more painful than slower forming ones.

Compartmentation of the joint is the functional separation of joint compartments at physiologic pressure and has been demonstrated in the rabbit stifle and the equine metacarpophalangeal joint.[27] During joint movement, synovial fluid flows from compartments of highest pressure to compartments of lowest pressure, producing an ebb and flow of synovial fluid over the articular cartilage. This process provides nutrients to the avascular cartilage, lubricates cartilage and keeps joint pressures from escalating excessively during joint movement. Movement of fluid through the synovium into the interstitium and lymphatics (termed conductance) is increased with exercise. Both a direct effect of increased IAP and a pumping action on the interstitium and lymphatics drive fluid resorption. Exercise increases this hydraulic conductance of fluid and improves clearance and turnover of joint fluid. This effect has been noted to continue for several hours after exercise. Normal exercise will not produce significant fluxes in IAP. These findings may be explained by the lower compliance of chronic diseased joints. In chronic joint effusion, pressures generated at rest but more remarkably at exercise are higher than capillary pressures, emphasizing the critical role of effusions on the generation of IAP.[35,36]

Synovial fluid dynamics

Understanding the pathophysiologic mechanisms behind synovial fluid turnover becomes important when one considers

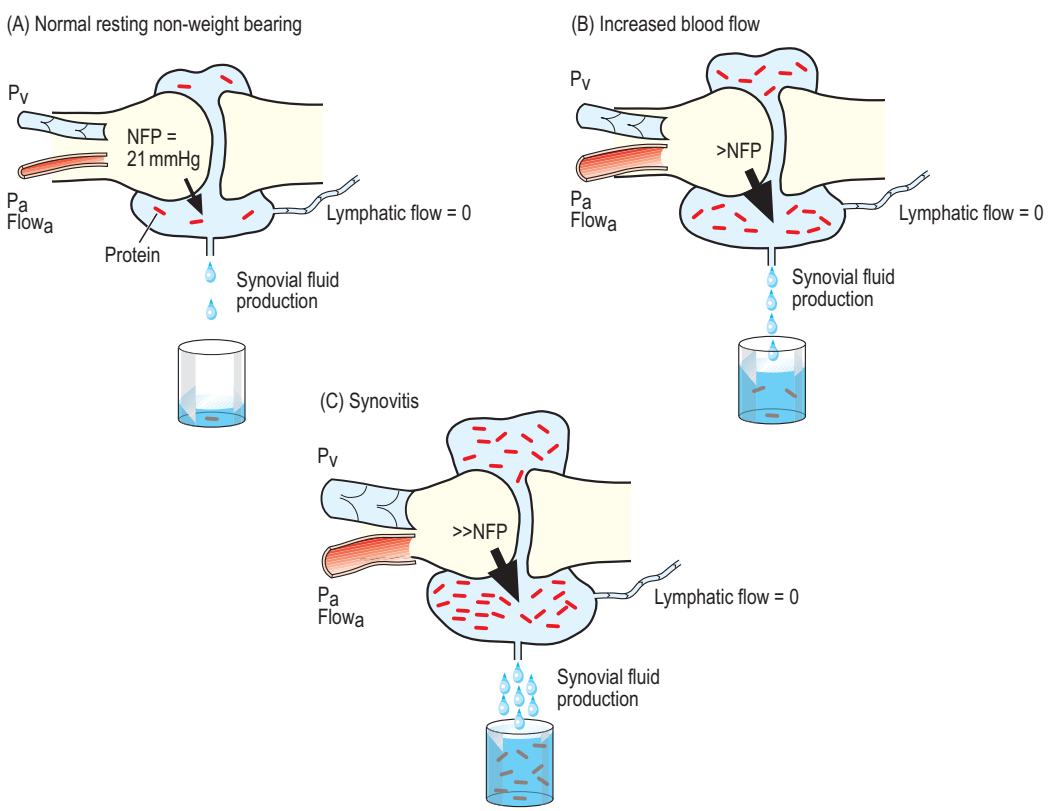

Fig. 9.3
Illustration of vascular and fluid forces in joints. (A) Normal joint at rest. (B) Normal joint during exercise with increased arterial blood flow. Arterial pressure and flow and trans-synovial flow are increased, but permeability is unchanged. (C) Abnormal joint with increased arterial blood flow such as occurs with synovitis. Arterial pressure (P_a) and flow ($Flow_a$) and trans-synovial flow are increased. Permeability, and therefore synovial fluid protein concentration, and interstitial edema are also increased. NFP = net filtration pressure, P_v = venous pressure.

the common concerns in actively training sports horses, including joint effusion, the potential clinical use of synovial fluid markers as indicators of exercise or disease state and progression[37,38] and the use of systemic or intra-articular medications in the treatment of joint disease (Fig. 9.3). The histology, ultrastructure and embryology of the synovium support the theory that the joint cavity is a third compartment of the interstitial space.[39] Interstitial and joint fluid is an ultrafiltrate of plasma to which hyaluronan is added. Fluid flow from the vascular space into the interstitium and joint space (third compartment space) and out into venules and lymphatics is tightly governed by Starling forces. Starling forces are a balance of arterial and venous pressures and colloid osmotic forces across the joint. The resultant fluid flow through the joint is modified by the permeability of the synovial membrane (osmotic reflection coefficient) and the vessel surface area available for fluid transport (filtration coefficient). Even in normal joints these forces are influenced by gravity (joint dependency), motion (exercise), and structure (joint compliance).[1,6,20,27,38,40,41] Horses are also somewhat unique in necessitating joint motion to maintain isogravimetric states of the joints (no fluid gain or loss). This is most notable in peripheral joints.[20] In normal stationary or standing equine limbs, lymphatic drainage from joints approximates zero until joint pressure exceeds 11 mmHg for the fetlock joint (transitional microvascular pressure). In standing animals without counterforces, such as motion or external bandages to increase lymph flow forces, gravitational pressures both increase arterial pressure to the joint and increase the venous and lymphatic pressure necessary for fluid to exit the joint. The result is the tissue edema and joint effusion known as 'stocking up', a physiologic imbalance of joint fluid flow leading to a positive isogravimetric state of the joint (gain of weight in the form of interstitial fluid).

Articular albumin and hyaluronan (synovial colloids) are molecules that play a role in oncotic pressures and drive joint fluid dynamics.[42] The half-life of the hyaluronan molecule in joints is relatively short (12–20 hours), suggesting that alteration in composition and molecular structure can quickly impact joint rheology. However, synovial fluid dynamics are dictated more by capillary permeability, IAP and protein concentration than hyaluronan concentration.[43]

Hyaluronan and joint lubrication

Hyaluronan is a non-sulfated glycosaminoglycan consisting of alternating units of D-glucuronic acid and N-acetyl-D-glucosamine. It exhibits polydispersity, but the average molecular weight is in the order of several million. In dilute solutions, each molecule behaves as a large coil but as the concentration of hyaluronan increases, entanglement of the coils occurs, eventually forming a uniform meshwork. Viscosity is non-linear and increases exponentially as the hyaluronan concentration increases, probably as a result of this three-dimensional framework.

The effect of hyaluronate on synovial fluid viscosity is proportional to chain length, protein concentration, pH, ionic composition and temperature. Viscosity decreases rapidly with increased shear rate, such as during sustained high motion in competitive events. Viscosity is variable between joints, being high in small joints. In a given joint, viscosity varies inversely with volume and joint effusion usually dilutes hyaluronan and viscosity. The hyaluronan molecule has been assigned a role in providing joint boundary lubrication while its viscoelastic and shear dependence properties have only been slowly accepted functions. It is apparent, however, that the nature and configuration of the molecule, and the existence of receptors to hyaluronan, provide some other insights as to the role of hyaluronan in vivo.

Hyaluronan solutions provide a barrier against water flow and may act as a barrier against rapid tissue weight changes. The meshwork may also act as a sieve to regulate transport of macromolecules and exclude macromolecules from space in the system.[44] In articular cartilage the hyaluronan-binding proteins, also referred to as hyaladherins, are aggrecan and link protein, which in combination with hyaluronan form the large proteoglycan aggregates of articular cartilage which provide the compressive stiffness necessary to accept loads such as occur in athletic events. Synovial fluid hyaluronan is also critically important to the mechanical properties ofthe joint cavity, enhancing the compliance of the joint capsule.[31]

Hyaluronan has also been shown to decrease joint pain with molecular weights of greater than 40 kDa. Hyaluronan of 860 kDa and 2300 kDa produced high-level and long-acting analgesia for 72 hours after injection. This effect was not related to binding to hyaluronan or bradykinin receptors.[45]

Joint pain

Joint pain is an important component of training any equine athlete as lameness is the greatest cause of morbidity in horses.[46] The physiology of joint pain primarily involves pain fibers found in the synovial membrane or subchondral bone. Joint pain can usually be attributed to joint inflammation, restrictive fibrosis and/or subchondral bone pain. Excessive joint strain during exercise can be in the form of a singular mishap or repetitive overstrain leading to joint inflammation. The joint is richly innervated with large myelinated afferent and efferent nerve endings and small unmyelinated C fibers. Sensory and motor innervation provide feedback that helps maintain joint stability, such that in the absence of these protective reflexes, severe arthropathy may develop if the joint is made unstable.[47] Activation of the peripheral nervous system can initiate the major features of acute inflammation, which include vasodilation, effusion and a lower threshold for pain.[48,49] The pain of arthritis is relayed by both C fibers and Aδ (delta) fibers. These fibers are activated by amines (serotonin, etc.) and neuropeptides (CGRP and substance P) that act synergistically to exert proinflammatory effects on the synovium. The presence of these neuropeptides has been documented in equine articular tissues.

Although acute inflammation is a necessary and appropriate response to initiate repair following tissue injury,

inadequate regulation of this response may lead to excessive tissue damage or chronic inflammation. A role of substance P in joint pain is supported by the clinical effectiveness of the substance P-depleting substance, capsaicin. Capsaicin (trans-8-methyl-N-vanillyl-6-nonenamide) is the pungent ingredient in hot paprika or chili peppers. It initially activates C fibers, resulting in substance P release and pain, but subsequently desensitizes or degenerates C fibers, suggesting a mechanism for pain alleviation with chronic use in articular inflammation.[50]

Non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used in the treatment of articular inflammation and in the control of joint pain in athletic horses in training. The role of prostaglandins in pain is indirect, as they act to sensitize C fibers to subsequent stimulation. NSAIDs inhibit prostaglandin synthase enzymes (also known as cyclo-oxygenase) and diminish the formation of PGE_1, PGE_2, PGF and PGI from arachidonic acid. Corticosteroids inhibit phospholipase A2, thus preventing the formation of arachidonate, a substrate for the cyclo-oxygenase and lipoxygenase pathways. At high doses, corticosteroids also inhibit IL-1 and TNF, which can also sensitize pain nociceptors. These mechanisms may explain the analgesic effects of NSAIDs and steroids.

The role of neuropeptides in joint disease is currently under investigation and there appear to be differences in the contribution of neuropeptides to disease process in acute versus chronic inflammatory arthritis. In acute arthritis, loss of sensory nerves may contribute to inflammation, as demonstrated by increased edema formation in denervated limbs.[50] Similar results have been reported in an IL-1 induced model of acute inflammation in the horse, where increased edema and decreased permeability to macromolecules were observed in denervated limbs.[51] The role of innervation in chronic arthritis is complex. Staining for CGRP and substance P was increased in the sciatic nerve, dorsal root ganglia and periarticular tissues, but synovium staining was decreased. It appears that the role of neuropeptides in acute or chronic inflammation may vary as the distribution of sensory nerves is altered with the inflammatory response.

The therapeutic implications of the participation of neuroendocrine mechanisms in arthritis are many. Intramuscularly administered gold or topically applied capsaicin are agents that selectively destroy C fibers, thus lowering substance P levels, and have been found clinically useful. Capsaicin initially causes release of substance P from nerve endings, explaining the burning sensation felt upon initial application. NSAIDs (PGH_2 or cyclo-oxygenase inhibitors) decrease prostanoid production and intra-articular corticosteroids which inhibit the arachidonic acid cascade are effective in the treatment of inflammation and pain in arthritis.[52] In addition, stimulation of primary afferent nociceptive fibers causes release of glutamate and substance P from central spinal pathways. This nociceptive input can be inhibited by stimulation of proprioceptive and tactile type I and II fibers. Stimulation of these fibers can be accomplished by high-frequency, low-intensity transcutaneous neural stimulation, frequently used in physiotherapy.

Cartilage adaptation to training and exercise

Adaptation of cartilage to exercise is well established in horses and results in cartilage able to handle greater biomechanical stress, particularly in anatomical sites receiving high loads.[53–69] Joint stress and osteoarthritis are correlated in people and are empirically correlated in the equine athlete as well.[70] Overuse results in wear and tear when the stress of exercise exceeds the capability of the cartilage to adapt and structural damage occurs. Virtually all elite equine athletes with an extended career will have some degree of osteoarthritis. Exercise both increases and accelerates the development of biochemical articular cartilage heterogeneity.[55,58,65] These changes reflect the biodistribution of loading[53] and loading-induced changes in synovial fluid.[62] Use of intra-articular steroid medication in exercising horses has been shown to reduce the biomechanical supportive properties of the equine articular cartilage.[67]

Some of the differences in biomechanical and biochemical properties of articular cartilage result from species disparities, the characteristics of a particular joint or as a function of location within a joint. Differences in similar anatomic site locations in joints as a function of the level of exercise (i.e. non-strenuous as compared to strenuous) demonstrate that the history of loading undergone by the joint alters these biomechanical material properties. Indentation studies on equine articular cartilage from exercised and non-exercised horses demonstrated clear differences in biomaterial properties of the cartilage which were site specific. Sites of higher loading had greater changes, indicating an exercise adaptation. This was most dramatic for cartilage permeability (fluid conductance) in which exercise promotes water (fluid) flow out of the cartilage on loading. Fluid extrusion from articular cartilage on high-impact loading is a known mechanism for cartilage lubrication.[41] These biomechanical adaptations of cartilage correspond in a site-specific manner to alterations in cartilage metabolism with exercise. Chondrocytes increase their production and quality of proteoglycan to increase the compressive stiffness of cartilage. It takes longer than 3 weeks of training for the increase in proteoglycan synthesis to result in a measurable increase in total proteoglycan content.[54]

There is no consensus on the influence of exercise (beneficial[71] or neutral[72]) on the healing of injured articular cartilage, although assimilation of the studies would suggest that exercise during healing is beneficial as long as the impact trauma is below the level of repair tissue destruction.

Bone adaptation to training and exercise

In young horses put in training, bone is exposed to new stresses. During training bone rapidly remodels to decrease

bone porosity and increase bone trabecular width and mineralizing surface, thereby enhancing the bone's ability to withstand stress.[73] Younger horse bone (2 year olds) is less stiff and therefore greater strains (bone movement) have been measured during high-speed exercise as compared to older horses. These high strains seen in these young horses may lead to high-strain, low-cycle fatigue of the bone and subsequent bone pain (dorsal metacarpal cortex, sesamoid bones, caudal metacarpal condyle).[74] Computed tomography and histology have confirmed the presence of microcracks at these high-strain bone sites. Bone strain is even greater in the lead limb (the left limb in North American racing) correlating with the most common location of ultimate fracture (dorsal cortical fracture and condylar fracture).[75]

Immature cortical bone of horses is normally resorbing primary osteons during training and has greater resorption cavities and incompletely filled secondary osteons than that of older horses. This bone structure is more susceptible to fatigue microdamage resulting from training because of higher bone porosity, fewer completed secondary osteons and a lower proportion of circumferentially oriented collagen fibers.[76] Indeed, in racing Quarter Horses put in training, the bone density significantly decreased early in training and then increased later in training. Race horses experienced fewer bone-related injuries when they had greater cortical mass in areas of known high bone stress at the commencement of training.[77]

The metacarpus changes shape during maturation[78] and training[79,80] to lower strains during high-speed exercise. As an example, the dorsal cortex thickens during training, by production of periosteal new bone. This natural response to these demands on the bone enables bone to handle stress without developing microfractures or complete bone failure (fractures). Experimental exercise conditions confirm marked modeling (not remodeling) of the bone, particularly subperiosteal bone formation at the midshaft of the third metacarpal bone. Horses that complete a full training program have greater bone mineral content despite a lighter body weight, further demonstrating the principle of Wolfe's Law, summarized as the principle that bone is deposited in areas of increased bone stress demands.[81] Bone mineral density increases with age and exercise is critical for normal bone development.[82]

In summary, in horses in training, high bone strain can induce cyclic fatigue of bone, resulting in microdamage and ultimate bone failure. The less bone present at the start of training (immaturity or lack of musculoskeletal conditioning), the greater this risk. Bone responds by modeling but microfracture damage may develop and cause pain. Many (> 80%) 2-year-old racing Thoroughbreds[83] and Quarter Horses[84] demonstrate bone pain and it is estimated that ~12% go on to develop stress fracture, usually within 6 months to 1 year of showing pain.[78] Horses trained on harder surfaces (dirt as compared to wood fiber)[85] and faster horses[83] are at greater risk of developing bone pain and microfracture. It is proposed that the greater incidence of bone fatigue failure in Thoroughbreds, as compared to Standardbreds, is due to gait differences and resultant bone stresses during training and racing, not to inherent differences in the mechanical properties of the bone.[86]

CHAPTER 10

Imaging of the musculoskeletal system in horses

Jean-Marie Denoix and Fabrice Audigié

Introduction

During recent decades, diagnostic imaging has considerably progressed in human and veterinary medicine. Horses have benefited from the tremendous technological progress made in different imaging modalities. Because of this improvement in our diagnostic capabilities, significant advances in equine medicine, and especially in the knowledge of musculoskeletal diseases, were made and many new clinical entities previously unknown were identified and documented.

In the 1980s, radiography was the only technique used by the equine practitioner. Now several imaging procedures are available, at least in referral centers. According to their use, indications and complexity, imaging techniques can be divided as basic procedures, easily used in practice (such as radiography and ultrasonography), topographical modalities giving information on the location of pathologic processes (such as thermography and nuclear scintigraphy), and advanced, more sophisticated cross-sectional and multiplanar techniques (such as computed tomography and magnetic resonance imaging).

Basic techniques

Radiography

Conventional radiography is the classic technique of diagnostic imaging. It provides high-definition image quality, especially when single emulsion film is used. This procedure is well known, simple to use, and allows examination of every part of the horse body and limbs. Radiographic

Fig. 10.1
Nineteen-month-old French Trotter colt. Dorsomedial–plantarolateral oblique projection of the left hock. Osteochondral fragmentation of the lateral trochlear ridge of the talus (arrowheads).

interpretation requires a good knowledge of anatomy, geometry of the radiographic projections,[1] and the different manifestations of tissue alterations. It features an excellent imaging representation of bones. Identification of bone injuries is based on changes in density (bone lysis or bone sclerosis) and bone architecture (sclerosis of the spongious bone and lysis of the compact or subchondral bone) as well as changes in shape and contour.[2]

Many osteoarticular conditions can be diagnosed with radiography.[3,4] This modality allows diagnosis and documentation of most of the osteochondral lesions, such as articular surface or periarticular osteochondral fragmentation (Fig. 10.1) and subchondral bone cysts (Fig. 10.2) in young and adult horses. Radiography is the first technique used for the diagnosis and documentation of complete fractures (Figs 10.3, 10.4) as well as fatigue fractures (Fig. 10.5). This technique is also essential for the diagnosis of degenerative joint disease (Fig. 10.6), based on the presence of lysis or sclerosis of the subchondral bone, periarticular osteophytes and, in some cases, thinning of the 'joint space', which represents the two opposite articular cartilage layers in synovial joints. Lysis of the compact bone (in short bones) or cortical bone associated with sclerosis of the adjacent cancellous bone is

Dorsolateral–plantaromedial oblique projection on the left hock. Degenerative joint disease of the distal intertarsal joint with severe suchondral bone lysis of the central and third tarsal bones. Note the sclerosis of the spongious bone of Tc and T3.

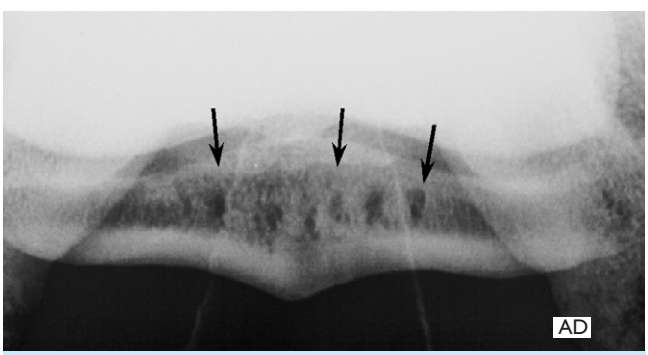

Fig. 10.7
Sixteen-year-old Selle-Français gelding.
Proximopalmar–distodorsal oblique (sky-line) projection of the distal sesamoid (navicular) bone. Severe lysis of the compact bone of the distal sesamoid bone flexor surface and sclerosis of the cancellous bone between the enlarged distal synovial fossa (arrows).

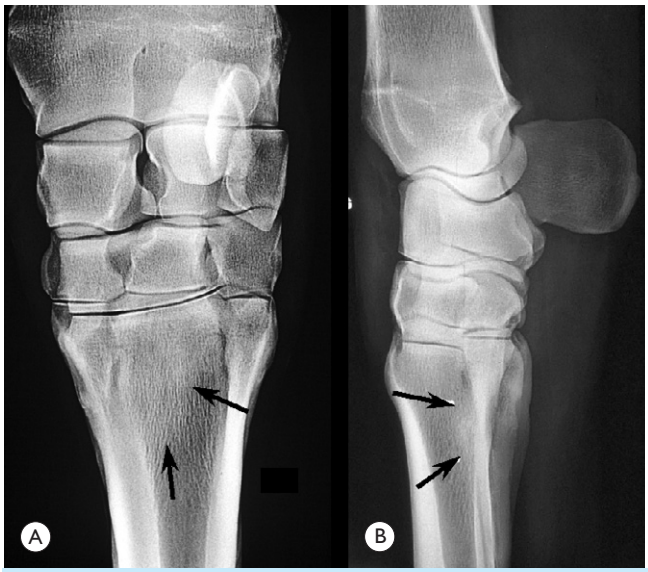
always indicative of advanced bone remodeling in pathologic processes (Fig. 10.7). In conjunction with ultrasonography, radiography is also very useful for the detection of enthesopathies, providing information on the insertion surface of ligaments and tendons (Fig. 10.8). As this technique does not have any regional limitation (depending on the power of the machine), many neck, back, and pelvic problems can be diagnosed with radiography. Cervical lesions including malformation, malalignment (Fig. 10.9), stenosis of the vertebral canal (Fig. 10.10), osteochondral fragmentation of the articular processes, fractures, and degenerative intervertebral disk lesions are easily assessed with portable machines, especially in young horses. In the thoracic spine, the diagnosis of kissing spines in the midthoracic region (Fig. 10.11) and in the withers (Fig. 10.12) can also be achieved with portable machines. Conversely, lesions involving the articular processes (Fig. 10.13) and vertebral bodies (Fig. 10.14) can be diagnosed only with non-portable powerful machines, which are only available in equine referral hospitals. In our patients, osteoarthrosis of the synovial joints between the articular processes of the lumbar and thoracic spine is a significant condition responsible for poor performance in sport and race horses.

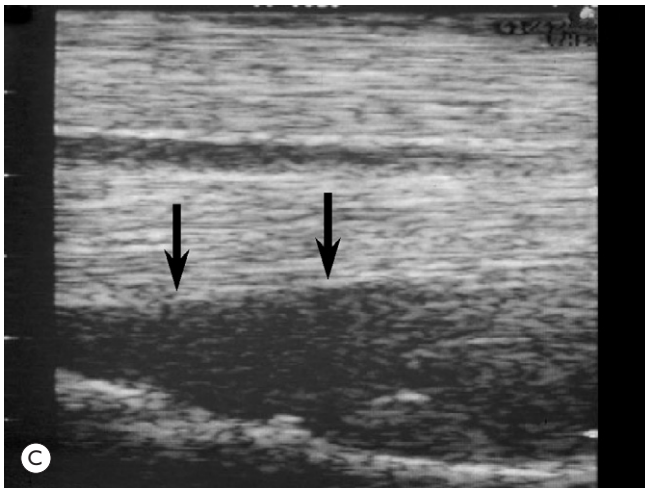
Besides the anatomopathologic information, radiography allows a functional evaluation through the assessment of joint angulation and congruency. Stress radiographs can be performed to assess joint stability, and to identify localized reduction of the cartilage thickness. Contrast radiography is an invasive technique whose indications have been reduced since the use of ultrasonography.[5]

Contrary to other techniques, such as magnetic resonance imaging (MRI) or computed tomography, most of the joints can be examined with radiography, including the proximal joints and intervertebral joints. As radiography is the older imaging technique used in diagnostic imaging, its limitations are well known. They include:

- evaluation of complex anatomic regions, because of the superimposition of multiple soft tissue and bony structures
- lack of identification of contour, size and shape changes when the structure evaluated is not profiled by the X-ray beam
- failure to identify changes in radiopacity for moderate changes in mineral content
- the lack of differentiation of soft tissues that present a similar density
- the lack of information on cartilage architecture that does not permit detection of early lesions. Thinning of cartilage is recognized only late in the disease process. Moreover, imaging techniques such as MRI and scintigraphy have demonstrated the limitations of radiography in the identification of some bone injuries such as stress fractures, bone contusion, and bone edema.

With computed and digital radiography, differentiation of the soft tissues is improved.[6] Manipulation of the density and contrast parameters allows a better evaluation of the





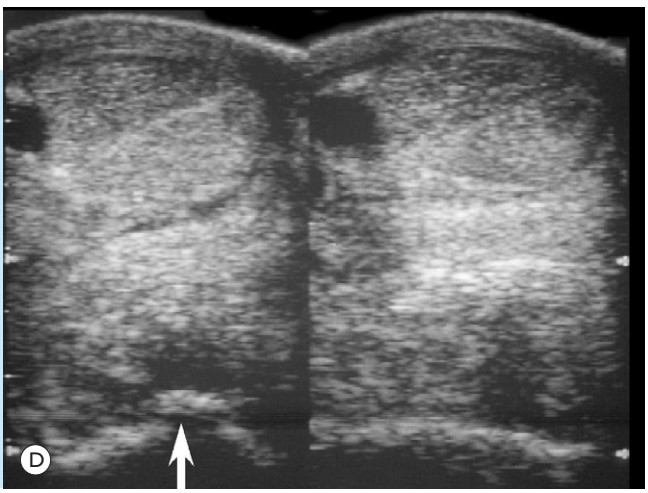


Fig. 10.8
Three-year-old French Trotter filly. Proximal third interosseous enthesopathy. (A) Dorsopalmar projection of the proximal metacarpus. Note the heterogeneous density of the proximal third metacarpal bone (arrows). (B) Lateromedial projection of the proximal metacarpus. Note the sclerosis of the spongious bone at the origin of the suspensory ligament (arrows). (C) Sagittal ultrasound scan of the proximal metacarpus. The suspensory ligament is enlarged and hypoechogenic (arrows) and its insertion surface is irregular. (D) Transverse ultrasound scans of the proximal metacarpus. The suspensory ligament is enlarged and hypoechogenic and an enthesophyte is imaged on the left scan (arrow).

Fig. 10.9
Eighteen-month-old Anglo-Arabian colt. Lateral projection of the cranial cervical spine. Malalignment of the third (C3) and fourth (C4) cervical vertebrae with hypoplasia of the ventral part of the vertebral head of C4 inducing a C3–C4 stenosis of the vertebral canal.

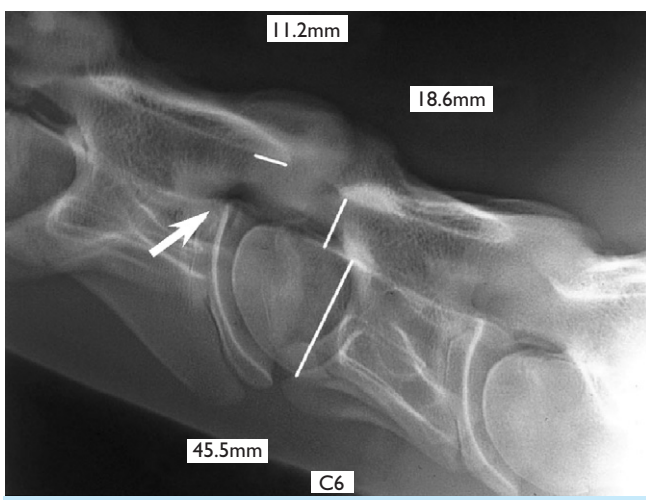

Fig. 10.10
Four-month-old Thoroughbred filly. Lateral projection of the caudal cervical spine. Stenosis of the vertebral canal of the sixth cervical vertebra (C6) and caudal lengthening of the vertebral arch of the fifth cervical vertebra compatible with static and dynamic spinal cord compression. There is also hypertrophy of the articular processes between C5 and C6, a ski-jump deformation of the vertebral fossa of C5 (arrow) as well as a malalignment between C6 and C7.

different anatomical components of the area examined. Small structures such as joint spaces can be enlarged and direct measures (such as thickness, angulation) can be easily done (see Fig. 10.10). Both duplication of the images and communication are considerably improved for dissemination of the diagnostic information.

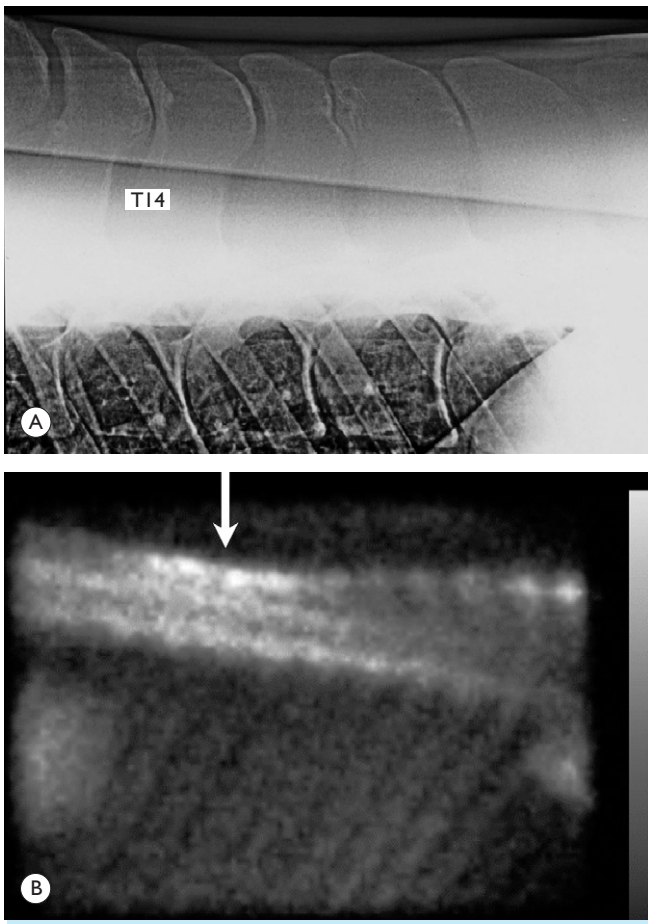

Fig. 10.11
Ten-year-old Grand Prix show jumper, Selle-Français male. Kissing spines in the thoracic vertebral column. (A) Lateral radiographic projection on the standing horse showing contact and bone remodeling between the spinous processes from T12 to T17 (cranial to the left). Periarticular bone proliferation (arrows) between the first (L1) and second (L2) lumbar vertebrae indicative of osteoarthrosis of the synovial joints between the caudal and cranial articular processes. (B) Transverse ultrasound scan of the back of the same patient at the junction between L1 and L2 (L1–L2) showing that the periarticular osteophyte (arrows) is mainly located on the right side (right scan).

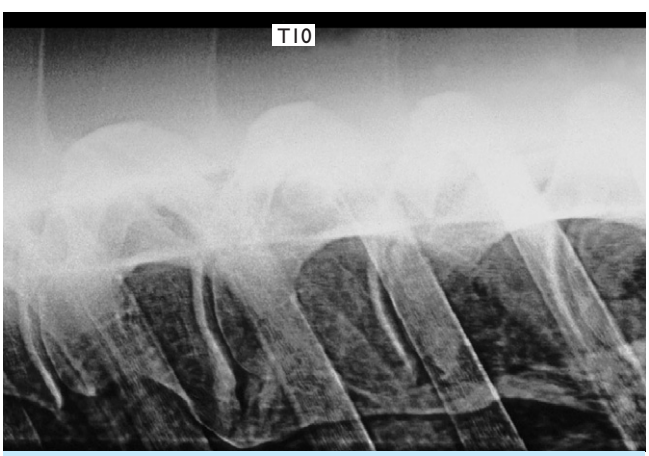

Fig. 10.14
Fourteen-year-old Grand Prix show jumper, Hanoverian male. Lateral projection of the thoracic vertebral column showing an extensive ventral spondylosis between the ninth and twelfth thoracic vertebrae (T10 = tenth thoracic vertebra).

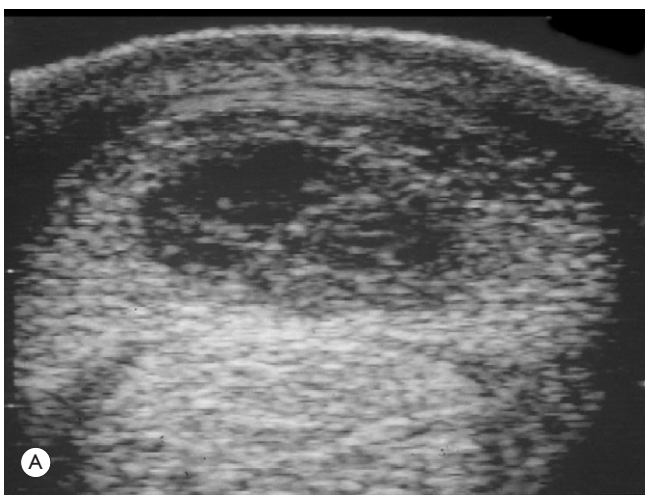
Despite the development of new imaging modalities, radiography remains essential in the management of sport and race horses. Extensive evaluation of the four limbs, back and neck can be made easily with this technique, allowing the detection of clinical, subclinical or silent bone or osteoarticular lesions. This information is useful in the management of high level athletic horses as treatment can be anticipated and preventive measures can be instituted with an adequate shoeing program and adaptation of the physical exercise program.

Ultrasonography

The use of ultrasonography for diagnosis and management of disease in athletic horses began in the 1980s with the assessment of tendon injuries and heart problems. It was considerably extended during the 1990s in the field of exercise physiology, internal medicine, and in the diagnosis of lameness with the application of ultrasonography in the diagnosis of joint injuries.[5]

Providing imaging of soft tissues, and being easy to use, ultrasonography represents an excellent complementary technique to radiography in equine practice. On multiple joints it allows a good representation of ligaments, capsule, synovial membrane and fluid, articular cartilage and subchondral bone. Identification of tendon, ligament and capsule lesions is based on modification of size (thickening and more rarely thinning) and shape as well as modification of echogenicity and architecture (alteration of the fiber pattern).

One of the main applications of ultrasonography in athletic horses is the diagnosis and follow-up of tendon injuries in the metacarpal and metatarsal areas[7–9] as well as in the pastern region.[10,11] The diagnosis of recent lesions is based on the presence of thickening and hypoechogenic areas with altered fiber pattern (Fig. 10.15). These changes are indicative of edema, hemorrhage and rupture of tendon fibers. In old and completely healed lesions, the tendon remains thickened (Fig. 10.16). Although it recovers an echogenicity close to normal, the fiber pattern remains altered, with shorter linear fibers than in uninjured parts of the tendon (Fig. 10.17A). Realization of oblique cross-sections highlights the contrast between the normal parts of the tendon and the scar tissue which remains echogenic because of the non-uniform alignment of its fibers (Fig. 10.17B). Thanks to its real-time capability, ultrasonography is useful for evaluation of dynamic events such as flexor tendon behavior during mobilization of the fetlock.[12] The diagnosis and documentation of enthesopathies has been considerably improved since the combined use of radiography and ultrasonography (see Fig. 10.8). In these conditions, abnormal findings are present in the tendon itself and on the bone insertion surface (the enthesis) where remodeling, lysis and enthesophytes can be seen.



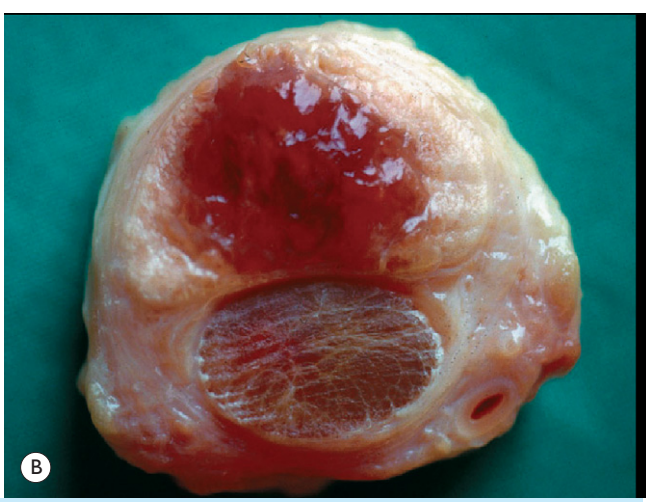


Fig. 10.15
(A) Seven-year-old three-day event Selle-Français gelding. Transverse ultrasound scan of the metacarpal area. Acute hypoechogenic core lesion of the superficial digital flexor tendon. (B) Transverse section of an anatomopathologic specimen showing a typical recent core lesion of the superficial digital flexor tendon.

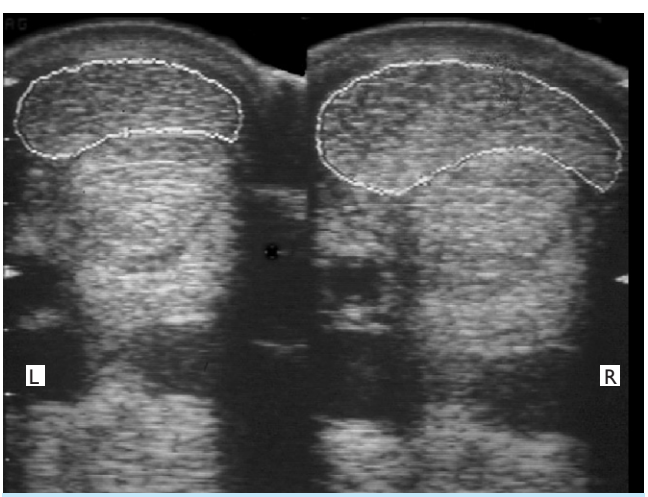

Fig. 10.16
Eight-year-old Grand Prix show jumper, Hanoverian male. Transverse sections of the left (left image) and right (right image) metacarpal areas. Old lesion of the right superficial digital flexor tendon. Note the thickening of the right tendon compared to the left one.

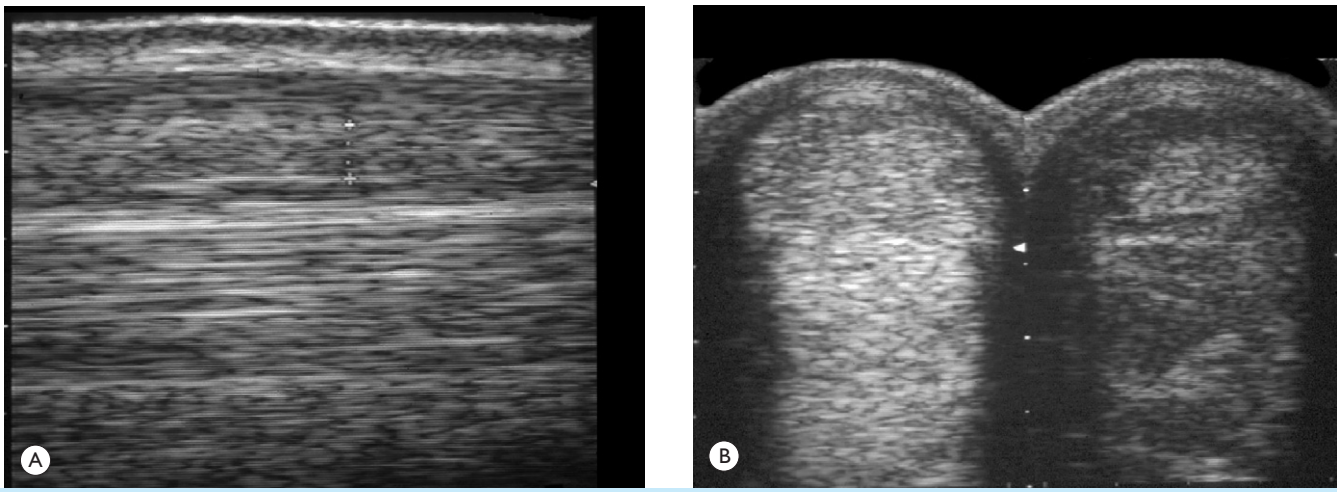

Fig. 10.17
Eight-year-old three-day event Thoroughbred gelding. Old core lesion of the superficial digital flexor tendon. (A) Longitudinal section showing central scar tissue with shorter linear pattern than in the rest of the tendon. (B) Transverse sections. The left scan is made with the ultrasound beam perpendicular to the tendon; the scar tissue and normal tendon present small difference in echogenicity and architecture. On the right scan, the ultrasound beam is oblique and only the scar tissue is echogenic because of the lack of uniform orientation of its fibers. This technique allows better tissue differentiation within the tendon.

Ultrasonography is a well-tolerated technique allowing non-invasive imaging of most of the soft tissues in joints including ligaments.[5,13–15] Complete ligament rupture can easily be diagnosed with this technique (Fig. 10.18A).[16] In

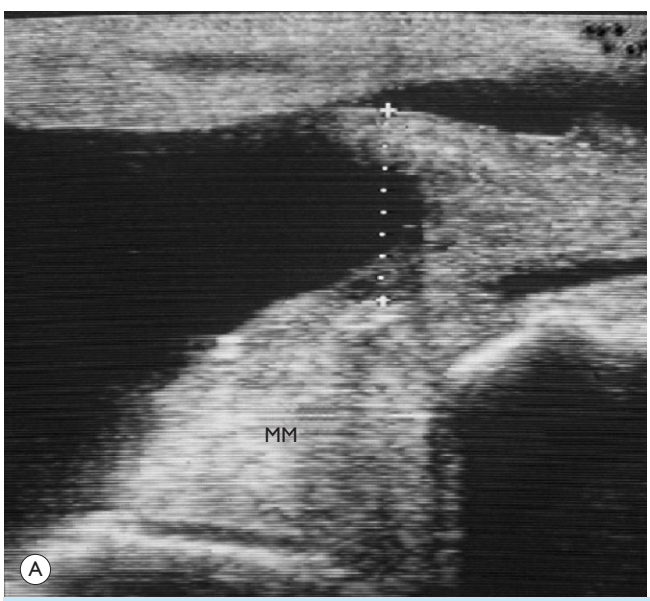

Fig. 10.18
Two-year-old Selle-Français colt that was recently kicked by another horse on the left stifle. (A) Longitudinal ultrasound scan at the medial aspect of the stifle (proximal to the left). Complete intrasynovial rupture (crosses) of the medial collateral ligament of the femorotibial joint. (B) Caudocranial radiographic projections of the same stifle. The lower view was performed after the ultrasound scanning, the limb being gently abducted to demonstrate joint instability. MM, medial meniscus.

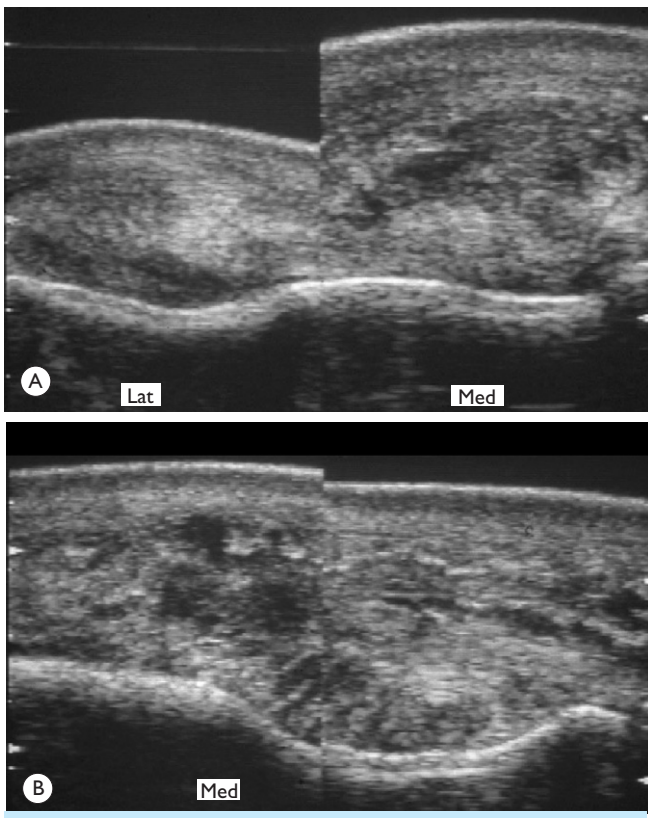

Fig. 10.19
Four-year-old French Trotter filly. Severe chronic desmopathy of the medial collateral ligament of the right hind fetlock. (A) Transverse section of the normal lateral (left) and injured medial (right) collateral ligaments of the affected fetlock. (B) Longitudinal section of the injured medial collateral ligament (proximal to the left). The superficial layer of the ligament is tremendously thickened with a very heterogeneous echogenicity and loss of fiber pattern.

Fig. 10.20
Six-year-old Selle-Français female. Sagittal section of the dorsal aspect of the fetlock (proximal to the left). Mild synovial fluid distension of the dorsal recess of the metacarpophalangeal joint allowing a nice representation of the proximodorsal synovial fold and metacarpal articular cartilage of the fetlock joint.

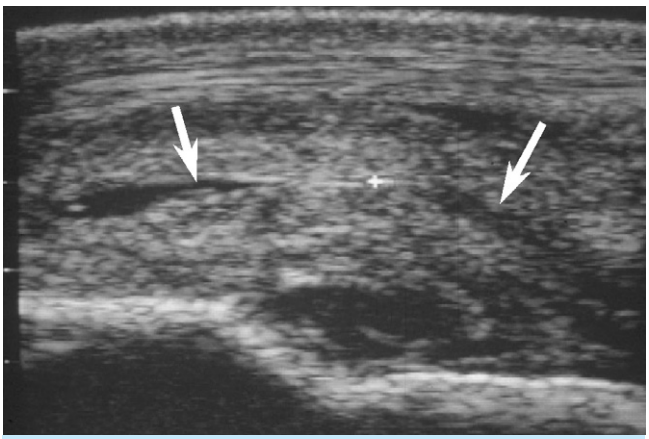

Fig. 10.21
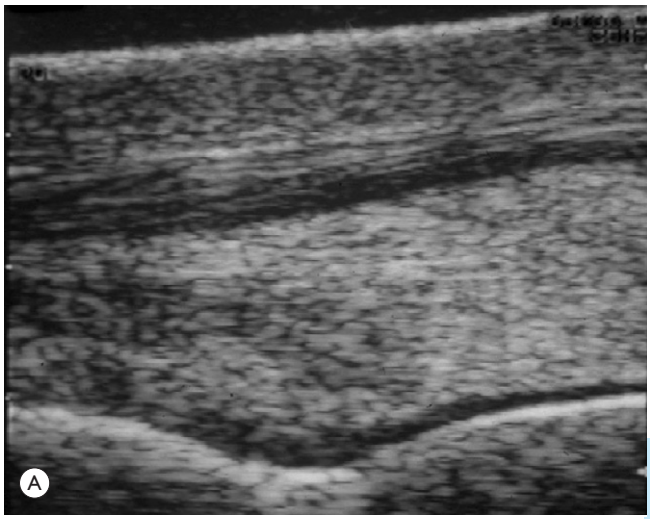
Four-year-old French Trotter male. Sagittal section of the dorsal aspect of the fetlock (proximal to the left). Severe chronic proliferative synovitis of the proximodorsal synovial fold (arrows) of the fetlock joint.

this particular condition, joint instability can be demonstrated with both ultrasonography and radiography (Fig. 10.18B). Acute as well as chronic desmopathies are common in race and sport horses and were often underdiagnosed when diagnostic imaging was limited to radiography. Now with ultrasonography these lesions can be identified (Fig. 10.19) and their healing can be documented.

Many other joint conditions have benefited from the more generalized use of ultrasonography. Synovial fluid distension, often associated to acute or chronic synovitis, can easily be identified with this technique and the presence of fluid highlights the other structures of the joint such as the articular cartilage and synovial plica or villi (Fig. 10.20). Chronic proliferative synovitis at the dorsal aspect of the fetlock no longer requires contrast radiography to be diagnosed, as ultrasonography is much more informative on the architecture of the lesion (Fig. 10.21) and is non-invasive.[5] Capsule lesions also are common, especially in race horses, and again underestimated if imaging is limited to radiography. Their ultrasonographic diagnosis is based on the same criteria used for tendon lesion and enthesopathies (Fig. 10.22). Ultrasonography has also demonstrated the frequent occurrence of meniscal injuries in sport and race horses.[5] These lesions can be found alone or concomitantly with other femorotibial lesions such as subchondral bone cysts, collateral desmopathies or cruciate desmopathies. With reference to the normal appearance of uninjured menisci (Fig. 10.23) several types of lesion can be seen, such as tears (Fig. 10.24), deformation (Fig. 10.25), collapse, prolapse, dystrophic mineralization, and bone metaplasia.[5]

Articular margins, cartilage, and subchondral bone lesions can be shown with ultrasonography, which represents a very valuable complementary technique to radiography for a more complete assessment of joint injuries.[5,13] This technique is very sensitive to any periarticular bone remodeling and osteophyte formation (see Fig. 10.13). Articular cartilage can only be examined when the joint surface is exposed to the ultrasound beam (Table 10.1; Fig. 10.26). Ultrasonography provides



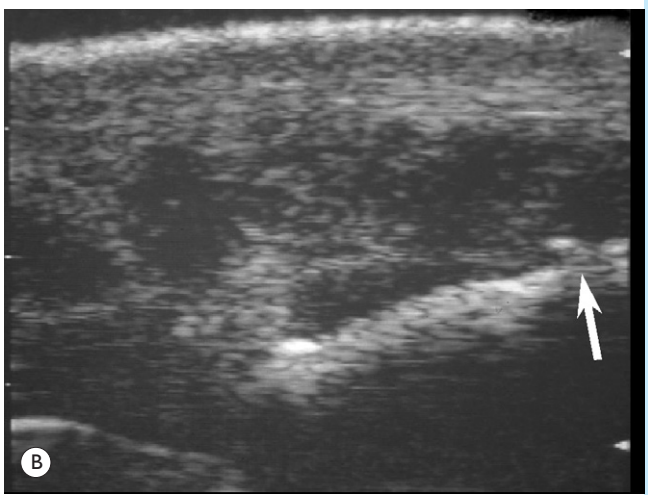


Fig. 10.22
Four-year-old French Trotter male. Sagittal section of the dorsal aspect of the fetlock (proximal to the left). Capsulitis of the fetlock joint. (A) Sagittal section dorsal to the metacarpal condyle. The capsule has a normal appearance. (B) Sagittal section dorsal to the metacarpophalangeal joint space and proximal aspect of the proximal phalanx. The capsule is thickened and hypoechogenic with alteration of its fiber pattern; a small enthesophyte can be seen on the dorsal aspect of the proximal phalanx (arrow). (C) Transverse section at the level of the enthesophyte (arrow) on the dorsal aspect of the proximal phalanx, showing thickening and hypoechogenicity of the capsule. P1, proximal phalanx.

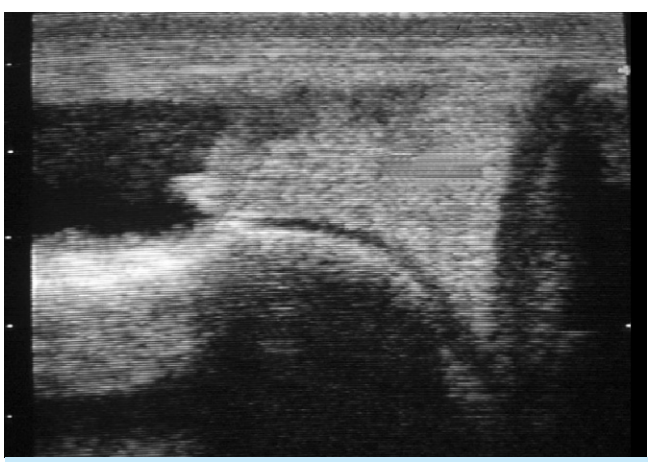

Fig. 10.23
Five-year-old French Trotter male. Reference transverse ultrasonographic image of the medial meniscus obtained from a longitudinal scan performed at the medial aspect of the stifle (proximal to the left). The meniscus presents a triangular echogenic appearance between the medial femoral (left) and tibial (right) condyles.

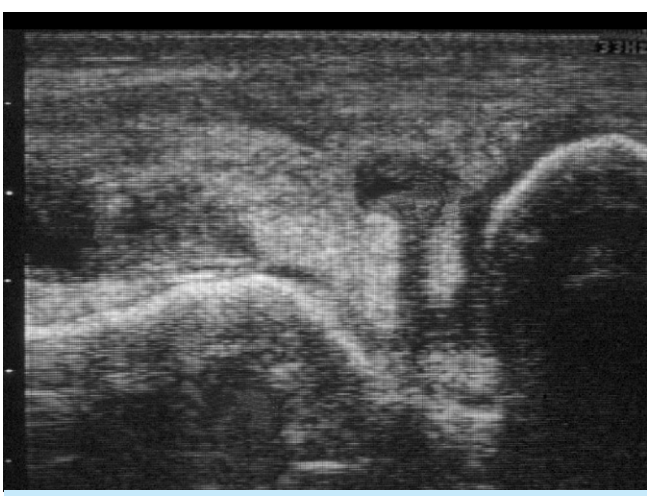

Fig. 10.24
Eight-month-old French Trotter filly. Longitudinal ultrasonographic scan performed at the medial aspect of the stifle (proximal to the left). Severe acute tears of the medial meniscus demonstrated as hypoechoic horizontal and vertical lines dividing the meniscus into three parts.

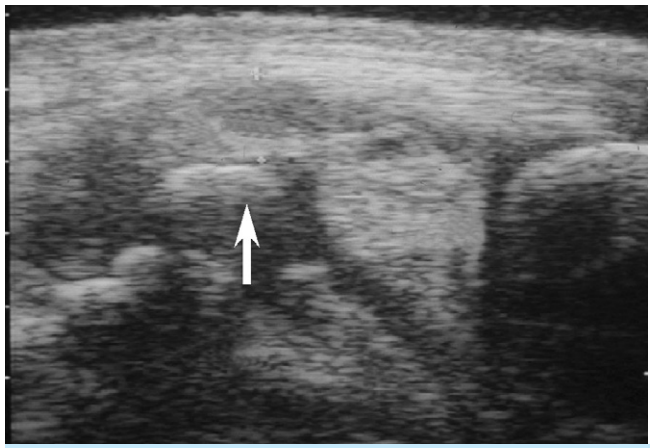

Fig. 10.25
Ten-year-old show jumper, Selle-Français female. Longitudinal ultrasonographic scan performed at the medial aspect of the stifle (proximal to the left). Severe periarticular remodeling of the medial femoral condyle. Compare to the shape of the condyle in Fig. 10.23.

Fig. 10.26
Ten-year-old Thoroughbred gelding used in flat racing. Reference parasagittal ultrasound image of the medial femoral condyle, made on the flexed stifle (proximal to the left). The hypoechogenic articular cartilage separates the articular capsule and the regular hyperechogenic subchondral bone surface.

diagnostic information on the cartilage surface (fibrillation, defect), the deep limit with the subchondral bone (defect of ossification, subchondral osteolysis), and the structure of the cartilage in surfaces where it is thick enough (e.g. femoral trochlea and condyles). With high-definition probes, the cartilage thickness can be measured, and complete, as well as partial, defects can be documented. A cartilage lesion must be considered if ultrasonographic examination reveals the presence of periarticular osteophytes, joint distension with synovitis or echogenic spots in the synovial fluid.

Table 10.1 Ultrasonographic access to articular surfaces in horses

Joints	Weight bearing	Flexion	Main limitations
Fetlock joint	Dorsal aspect of the metacarpal condyle	Distal aspect of the metacarpal condyle	• Proximal surface of proximal phalanx • Articular surface of the proximal sesamoid bones • Plantar aspect of the metacarpal/tarsal condyle
Antebrachiocarpal joint	Articular margins	Most of the distal surface of the radius	Proximal surface of the proximal row of the carpus
Middle carpal joint	Articular margins	Most of the proximal surface of C3	Distal surface of the proximal row of the carpus
Shoulder	Articular margins and peripheral part of the humeral head	Flexion and adduction: lateral part of the humeral head	Distal surface of the scapula Medial part of the humeral head
Tarsocrural joint	Dorsal aspect of the trochear ridges of the talus	Plantar aspect of the trochear ridges of the talus	Distal surface of the tibia
Femoropatellar joint	Trochear ridges of the femur	No more	Articular surface of the patella
Femorotibial joint	Articular margins and abaxial surfaces of the femur and tibia	Femoral condyles	Tibial condyles

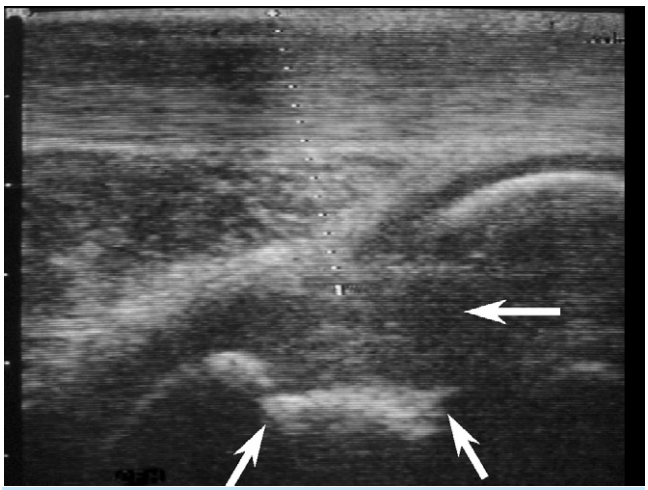

Fig. 10.27
Two-year-old Thoroughbred colt. Parasagittal ultrasound scan showing a large subchondral cyst (arrows) of the medial femoral condyle. The dotted line was drawn to measure the depth of the lesion.

The normal subchondral bone surface is imaged as a regular hyperechogenic line.[5,17] This line is interrupted by subchondral bone cysts, which are imaged as subchondral bone depressions (Fig. 10.27). Sensitivity of utrasonography to detect subchondral bone defects is high, and is often superior to radiography. This technique is also very sensitive to subchondral bone lysis (Fig. 10.28). In the proximal regions of the limbs, the diagnosis of bone fracture is easier with ultrasonography than with radiography, especially in field practice. Transrectal examination of the medial aspect of the acetabulum allows diagnosis of acetabular fracture (Fig. 10.29) on the standing horse avoiding the need for a radiographic examination in dorsal recumbency under general anesthesia, which presents a risk for the patient.

Ultrasonography brought new significant knowledge in the causes of lameness and poor performance in horses involving the foot, back and pelvis.[18,19] In the foot, the diagnosis of suprasesamoidean deep digital flexor tendinopathy, as well as distal enthesopathy of this tendon on the flexor surface of the distal phalanx, can be acheived with adequate probes and technique (Fig. 10.30).[15,18] Distal impar sesamoidean desmopathy and enthesopathy can also be diagnosed with a distal approach of the foot through the frog (Figs 10.31, 10.32). Routine

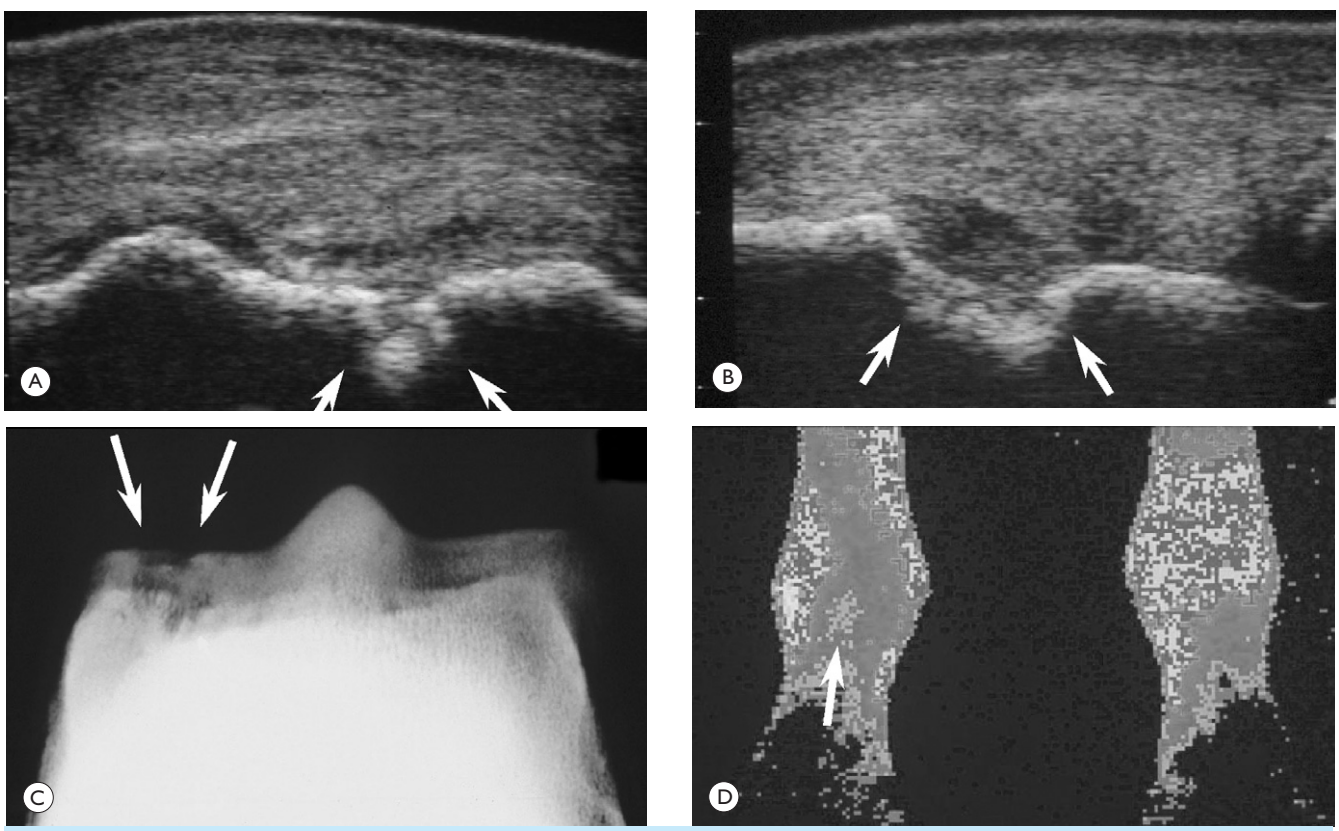

Fig. 10.28
Five-year-old French Trotter gelding. Subchondral osteolysis of the medial metacarpal condyle of the right fetlock. (A) Transverse ultrasound scan of the metacarpal condyle showing a focal subchondral osteolysis of the medial condyle (arrows). (B) Parasagittal ultrasound scan of the medial metacarpal condyle confirming the subchondral osteolysis (arrows). (C) Subsequent proximodistal radiographic projection of the flexed fetlock demonstrating the severe subchondral osteolysis of the medial metacarpal condyle (arrows). (D) Thermographic image demonstrating a colder area over the medial metacarpal condyle of the right fetlock.

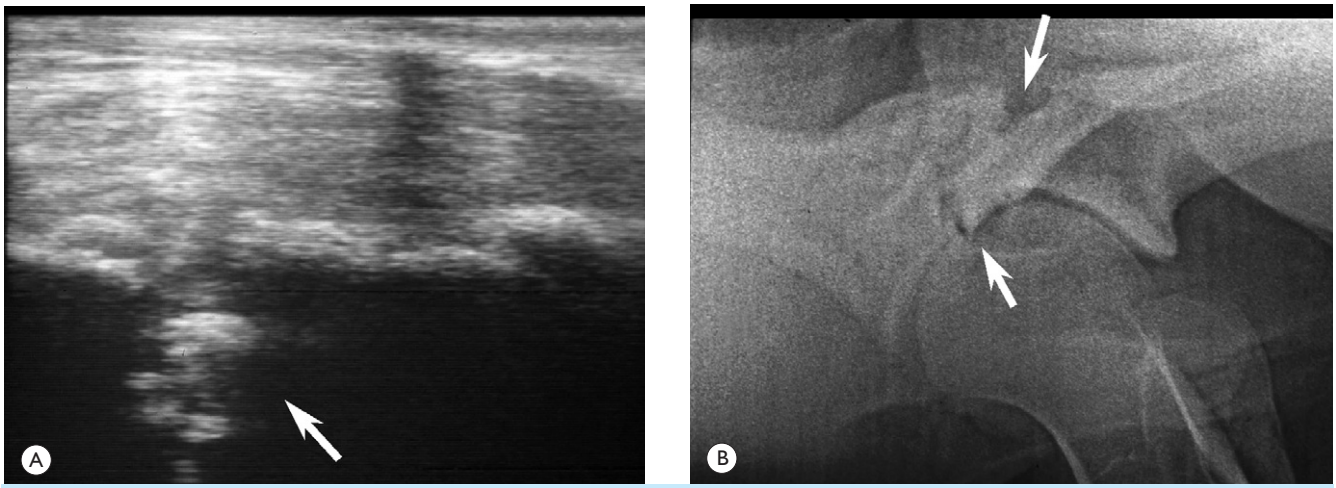

Fig. 10.29
Two-year-old French Trotter filly. (A) Transrectal ultrasound scan of the medial aspect of the acetabulum showing an echogenic fracture line (arrow) interrupting the bone surface of the coxal bone. (B) Subsequent radiographic examination of the hip area on the standing patient demonstrating the acetabular fracture and moderate displacement of the bone fragments (arrows).

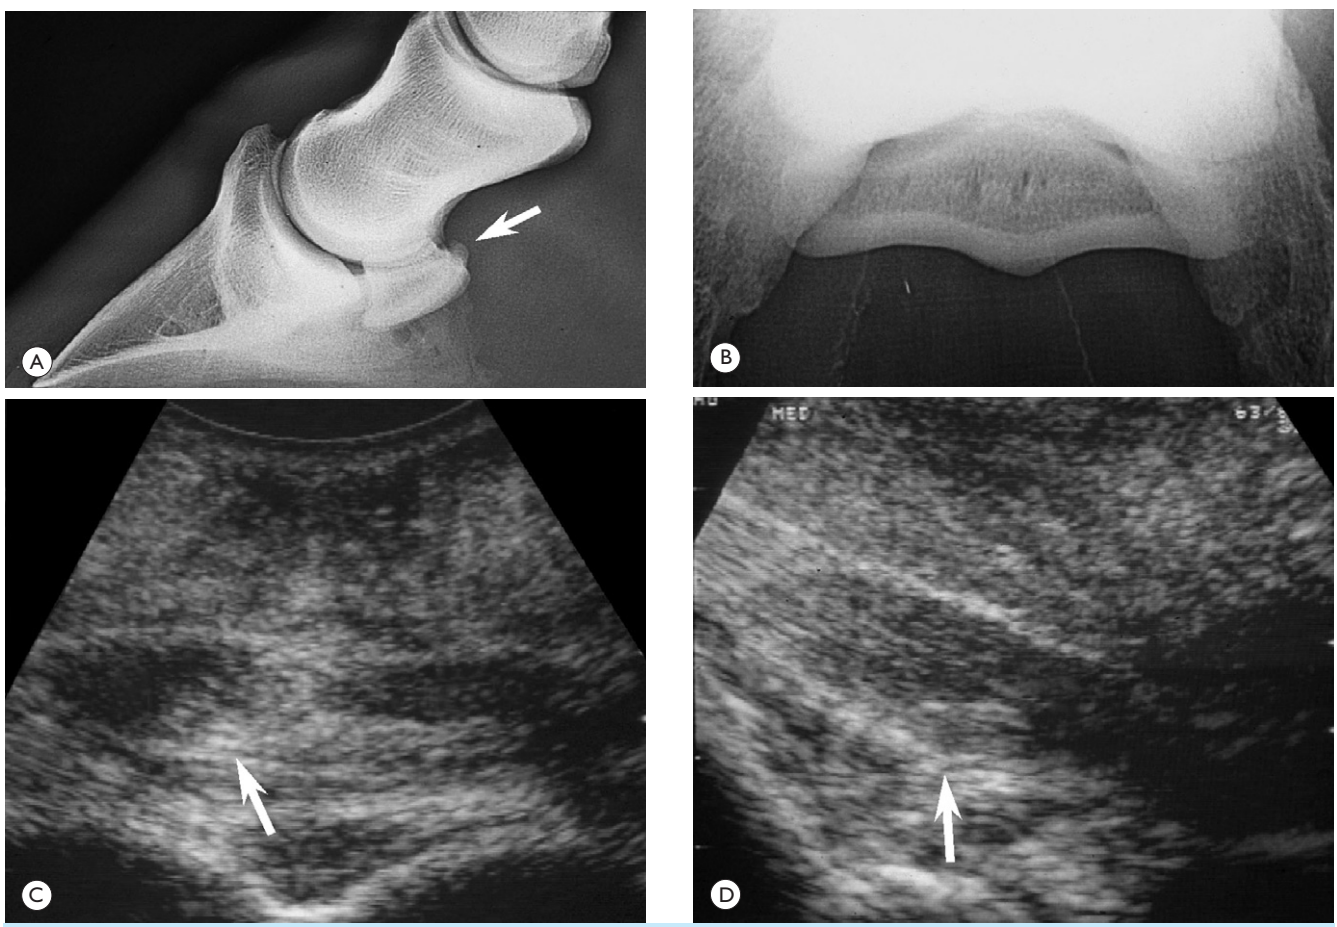

Fig. 10.30
Ten-year-old show jumper, Selle-Français stallion. Suprasesamoidean tendinopathy of the deep digital flexor tendon (DDFT). (A) Lateromedial radiographic projection of the affected foot showing remodeling of the proximal border of the distal sesamoid bone (arrow). (B) Proximopalmar–distodorsal radiographic projection of the distal sesamoid bone showing a normal flexor surface. (C) Transverse ultrasound scan of the DDFT using a proximopalmar approach of the navicular apparatus, the probe being placed at the most distal aspect of the pastern. The medial part of the DDFT (on the left) is thickened (compare to the lateral part, on the right) and presents deep abnormal echogenic material indicative of dystrophic mineralization (arrow). (D) Medial parasagittal ultrasound scan of the DDFT using a proximopalmar approach of the navicular apparatus. The medial part of the DDFT is thickened (its two borders are convex) and presents deep abnormal echogenic material indicative of dystrophic mineralization (arrow).

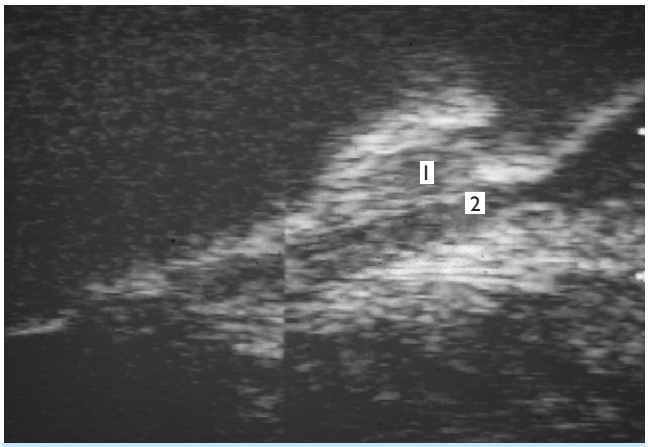

Fig. 10.31
Four-year-old French Trotter gelding. Reference ultrasound scan of the distal aspect of the navicular apparatus imaged through the frog. The distal impar sesamoidean ligament (1) is more echogenic than the deep digital flexor tendon (2).

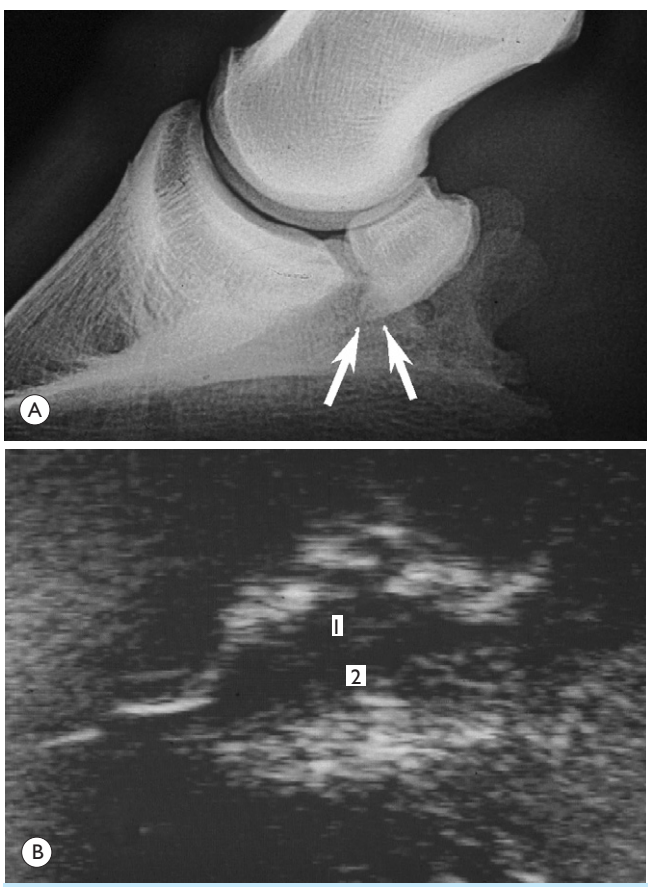

Fig. 10.32
Eleven-year-old show jumper, Selle-Français gelding. Desmopathy and enthesopathy of the distal impar sesamoidean ligament (DISL). (A) Lateromedial radiographic projection of the affected foot showing remodeling and osteolysis of the distal border of the distal sesamoid bone (arrows). (B) Ultrasound scan of the distal aspect of the navicular apparatus imaged through the frog. The DISL (1) is completely anechogenic and severe bone remodeling is present at its proximal and distal attachments (2).

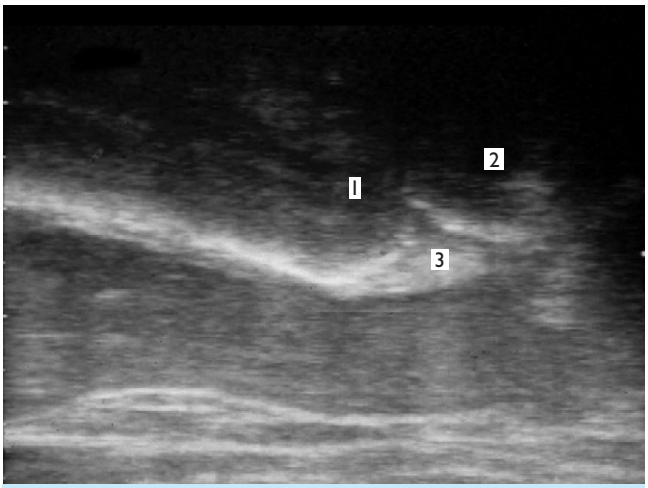

Fig. 10.33
Six-year-old French Trotter gelding. Reference transrectal ultrasound scan of the ventral aspect of the sacroiliac joint. The articular margins of the sacrum (1) and ilium (2) are smooth and regular and the ventral sacroiliac ligament is echogenic (3).

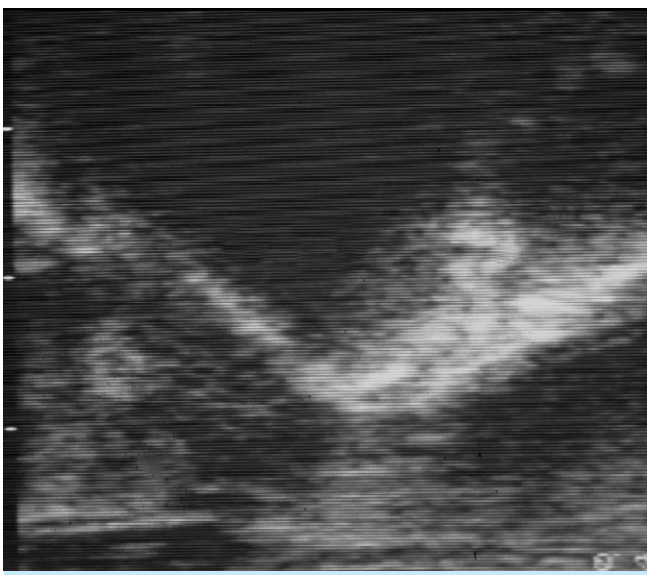

Fig. 10.34
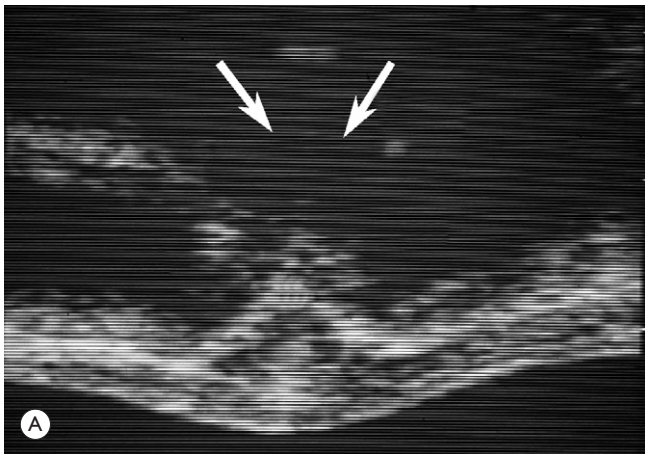
Six-year-old Selle-Français stallion. Transrectal ultrasound scan of the ventral aspect of the sacroiliac joint. There is marked remodeling and elevation of the articular margins of the joint indicative of sacroiliac degenerative disease.

transrectal ultrasonographic examination of the lumbosacroiliac area provides valuable diagnostic information on the causes of hind limb gait irregularities and poor performance in athletic horses.[19] Sacroiliac degenerative lesions can be demonstrated (Figs 10.33, 10.34). Lumbosacral disk degenerative lesions have been diagnosed in clinical cases and documented in horses subsequently examined post-mortem (Fig. 10.35).[18] Other abnormal findings observed in athletic horses include lumbosacral ankylosis, disk dystrophic mineralization, bone lesion involving the vertebral fossa of the last lumbar vertebra and lumbosacral subluxation (Fig. 10.36).



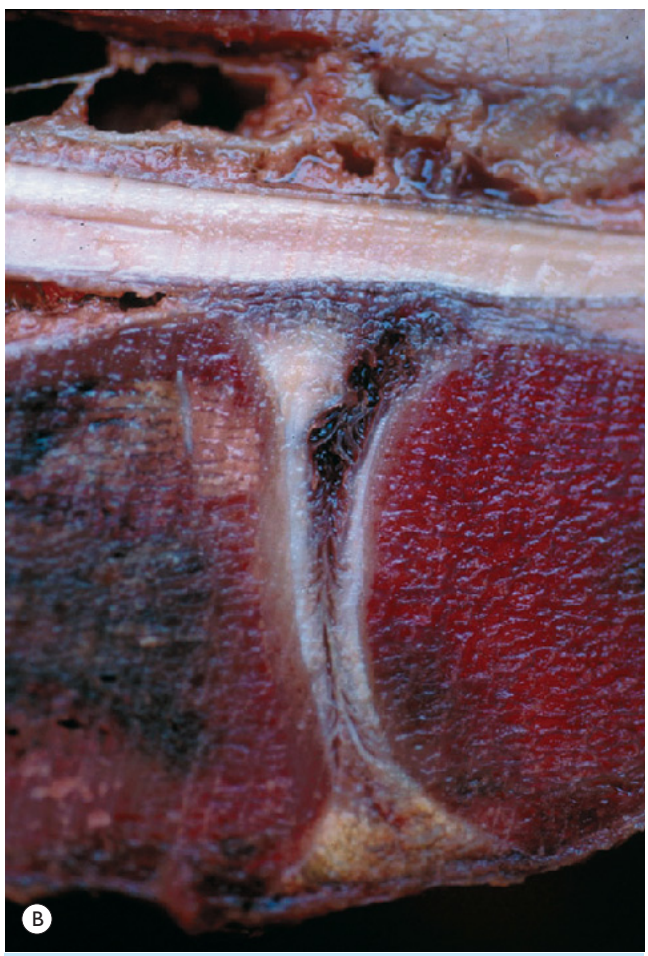


Fig. 10.35
Six-year-old French Trotter female. Severe lumbosacral intervertebral disk degeneration. (A) In vivo median transrectal ultrasound scan of the ventral aspect of the lumbosacral joint. Only the ventral part of the disk is echogenic; the dorsal part is completely anechogenic (arrows). (B) Post-mortem frozen specimen of the same intervertebral disk imaged on a median section. There is disruption of the disk fibers with fluid accumulation in the dorsal part of the disk.

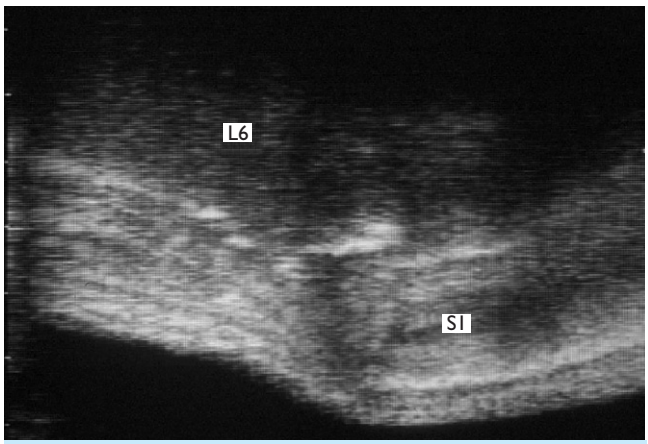

Fig. 10.36
Three-year-old French Trotter female. Lumbosacral subluxation (spondylolisthesis). There is ventral displacement of the sacrum (S1, on the right) relative to the sixth lumbar vertebra (L6, on the left).

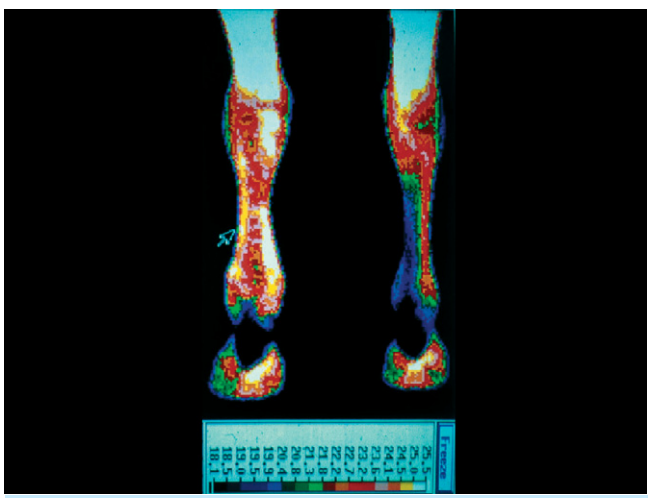

Fig. 10.37
Palmar aspect of the forelimbs of a 7-year-old French Trotter female with an acute episode of suspensory desmitis on the left limb. The palmar aspect of the left metacarpal area is approximately 4°C warmer than the right one.

Ultrasonography requires considerable knowledge of soft tissue anatomy[15,17] as well as a precise and rigorous technique. As there are many breed and individual variations in the size of anatomical structures, each specific element must be compared with the equivalent one on the opposite limb or with the more cranial and caudal ones in the neck and back. If a lesion is suspected it must be demonstrated on longitudinal and transverse sections, and the findings must be different from the equivalent unaffected structure when the same approach is made.

The acoustic impedance of bone and air is responsible for the main limitations of ultrasonography. Because of that, the deep internal architecture of bones and lungs cannot be imaged and the access to abdominal viscera is incomplete. Regarding the musculoskeletal system, ultrasonography is limited for a complete representation of the internal structures of the foot, the medial aspect of the shoulder, the cruciate ligaments within the intercondylar fossa of the femur, the

interosseus sacroiliac ligament and the interosseus ligaments of the carpus and tarsus. Limitations of ultrasonography in the evaluation of the articular cartilage include: the limited access to articular surfaces in congruent and low mobile joints (see Table 10.1); the lack of precise information on architectural changes and the need for high-definition probes for evaluation of thin articular cartilage such as in the distal part of the metacarpal condyle.

Today, for the assessment of equine musculoskeletal diseases, ultrasonography must be used in conjunction with radiography on most of the clinical cases requiring an imaging evaluation. With the constant technological improvement of ultrasound imaging equipment, the use of this modality will be applied to new anatomic areas with new approaches. Therefore, this technique will continue to advance the progress in equine veterinary diagnosis and science and will expand its use for the management of athletic horses.

Topographical techniques

Two techniques, thermography and nuclear scintigraphy, can be used in conjunction with the clinical examination in an attempt to identify the location of pathological processes.

Thermography

Using infrared cameras, complete thermal imaging of the horse body or a focused evaluation of a precise area is easy to perform.[20] In all cases, image acquisition must be done under standardized conditions. As interpretation is mainly based on the comparison of symmetrical areas, the horse limbs must be placed symmetrically, without lateral or medial rotation. During image acquisition of the axial regions, the horse must stand square while the camera is strictly placed in the median plane.

Much emphasis has been placed on the detection of acute inflammatory processes (Figs 10.37, 10.38) and this procedure seems useful in the detection of early changes in the flexor tendons in horses in training or competition.[20] In

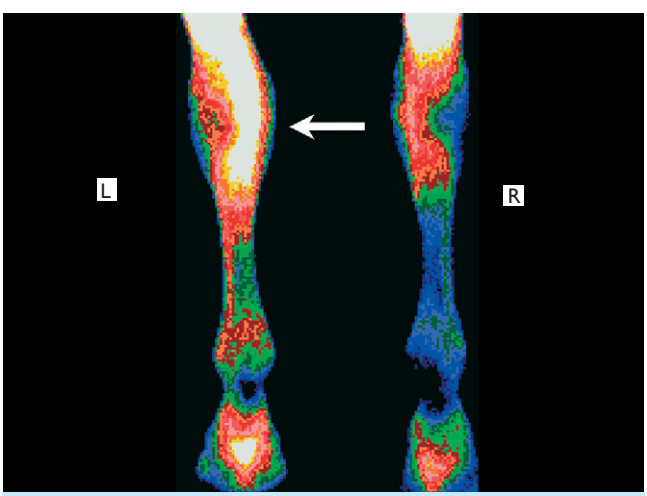

Fig. 10.38
Palmar aspect of the forelimbs of an 8-year-old show jumper, Selle-Français male with a recent left front limb lameness and a mild swelling at the palmaromedial aspect of the carpus. This area presents an increased skin temperature compared to the opposite (arrow). Utrasonographic examination showed that the horse had a rupture of the flexor retinaculum.

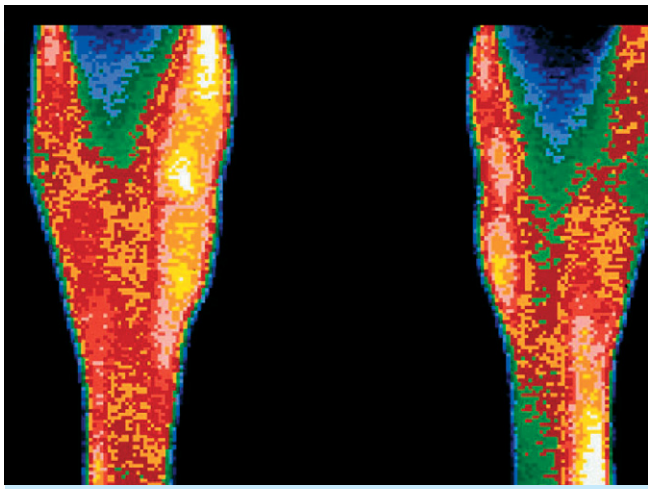

Fig. 10.39
Plantar aspect of the hind limbs of a 14-year-old Grand Prix show jumper, Selle-Français gelding with a chronic proximal enthesopathy of the left suspensory ligament. The plantaromedial aspect of the left hock and proximal metatarsal area is mildly warmer than the opposite ones (same horse as Fig. 10.47).

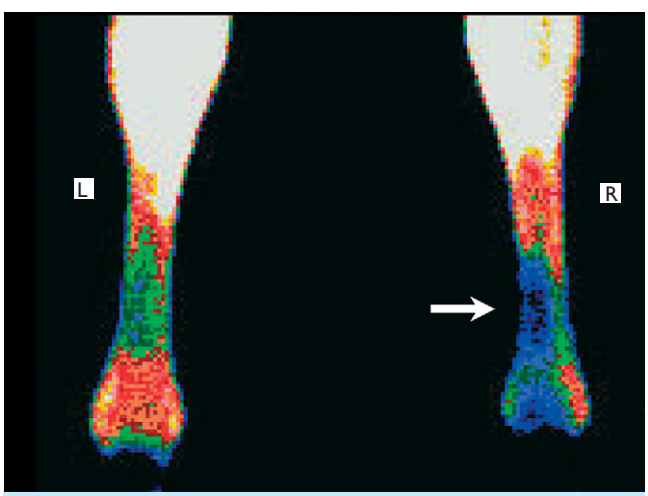

Fig. 10.40
Palmar aspect of the forelimbs of a 6-year-old steeplechaser Thoroughbred gelding who presented a severe right superficial digital flexor tendinitis 12 months before this image was made. The skin temperature of the right tendon region is colder than the opposite one (arrow) indicating a good tolerance of the exercise level of activity during the reconditioning program.

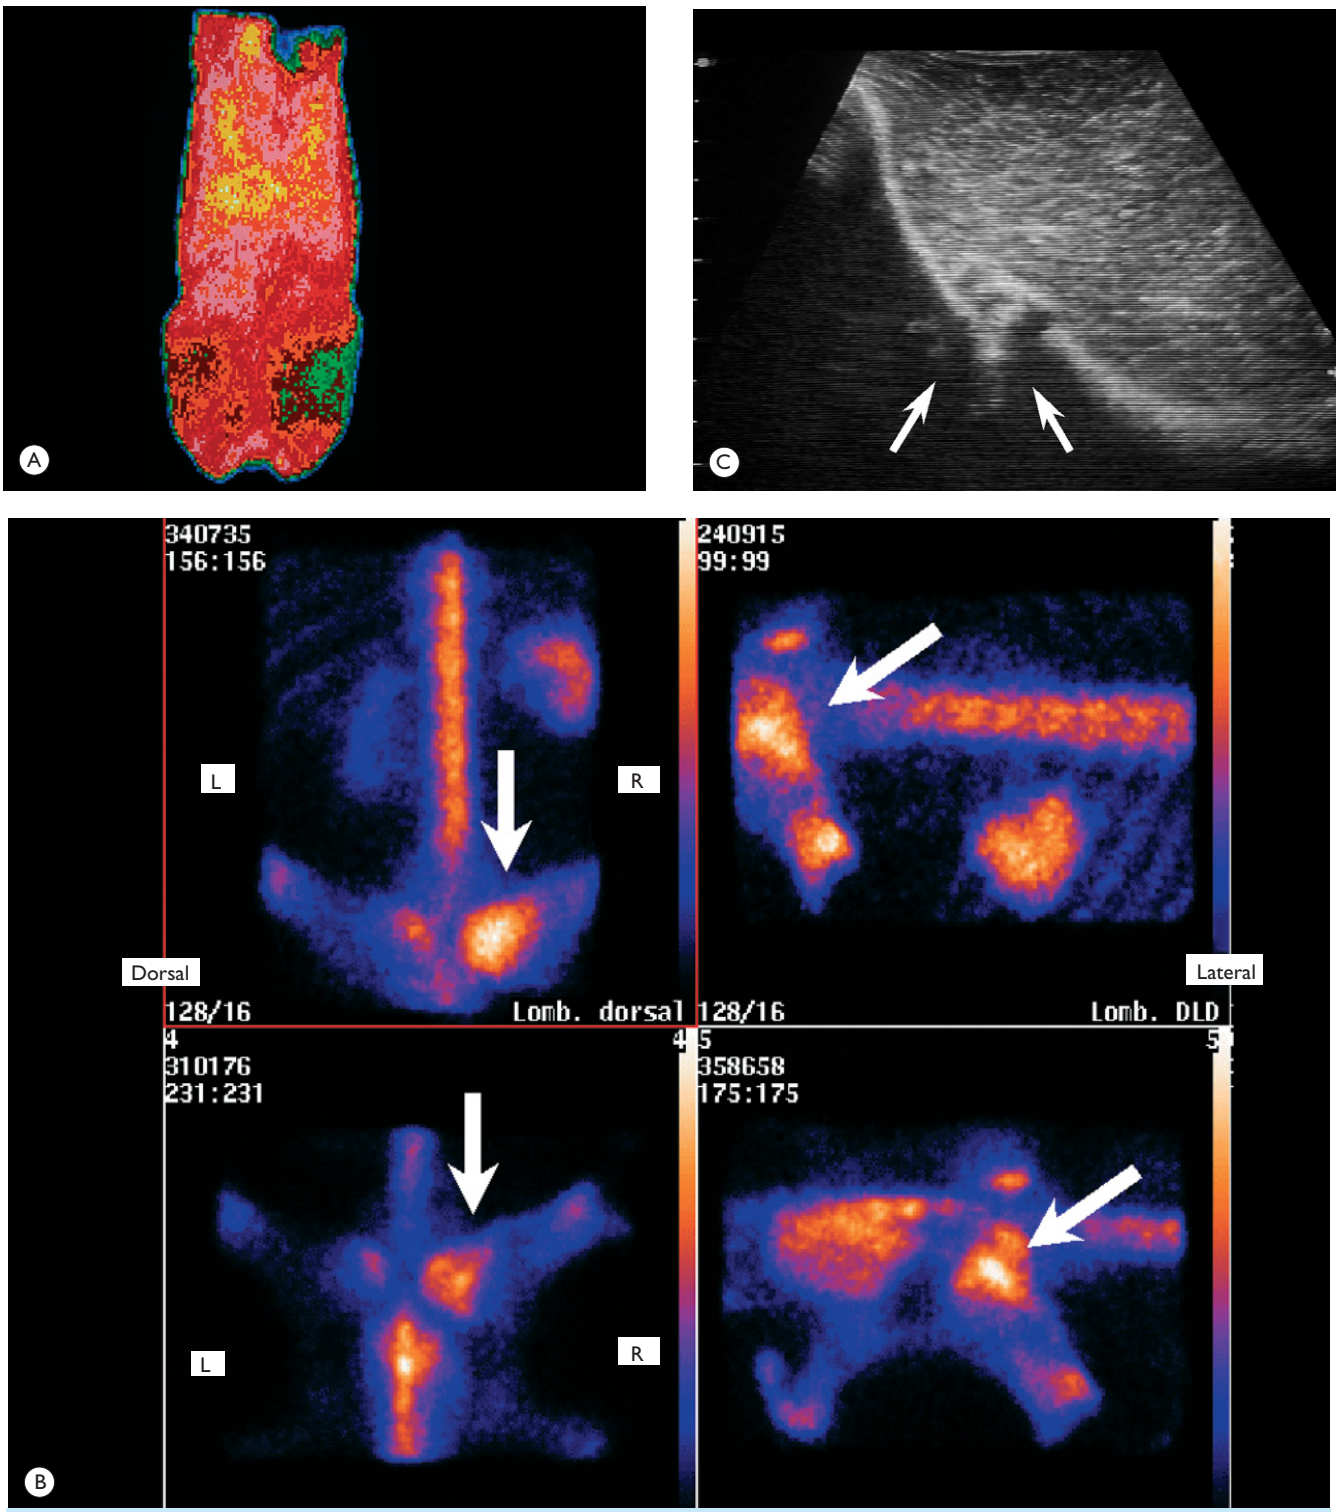

Fig. 10.41
Imaging documentation of a 6-year-old Thoroughbred gelding who presented an acute and severe lameness of the right hind limb during a flat race 10 days before the examination. (A) Dorsal aspect of the back and pelvis showing a cold area over the right side of the croup. (B) Bone phase scintigraphic image of the dorsal aspect of the pelvis. Increased radioisotope uptake is observed over the right ilial wing close to the sacroiliac joint (arrows). (C) Transverse ultrasound scan of the right side of the croup showing a sagittal fatigue fracture (arrows) with callus formation of the ilial wing. The cold cutaneous area observed on the thermogram (A) can be related to sympathetic reflex in the affected region as well as disuse of the painful structures.

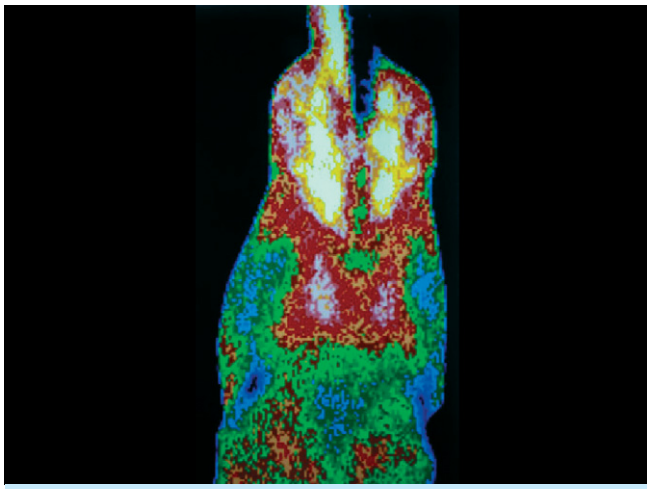

Fig. 10.42
Thermogram of the dorsal aspect of the back and neck of a 10-year-old show jumper, Selle-Français female with severe osteoarthrosis in the caudal cervical spine. A symmetric hot area can be seen in the withers receiving the ultimate endings of the dorsal rami of the caudal cervical spinal nerves.

chronic processes, the diagnostic value of thermography is more limited (Fig. 10.39), and in many cases, cold spots can be seen over the injured areas (see Fig. 10.28D). Thermography is useful for follow-up of horses returning to training after suffering tendinopathies (Fig. 10.40). Alteration of the skin temperature may also be induced by nerve reflex (Fig. 10.41) or nerve irritation or injury (Fig. 10.42).

Thermography is completely non-invasive and easy to use. Thermograms are real-time images, easy to read and understand by horse owners. This method is useful for documentation of a lesion and presents a pedagogical point-of-interest to support the discussion of the pathophysiology of a disease process.

The diagnostic value of this method has been actively promoted in the veterinary market during the last 10 years. Nevertheless, thermography presents some limitations, including the lack of sensitivity to deep lesions and chronic processes, and a lack of specificity because of interference, with many artifacts. Therefore, interpretation of the images must be done carefully to avoid false-negative and false-positive diagnoses.

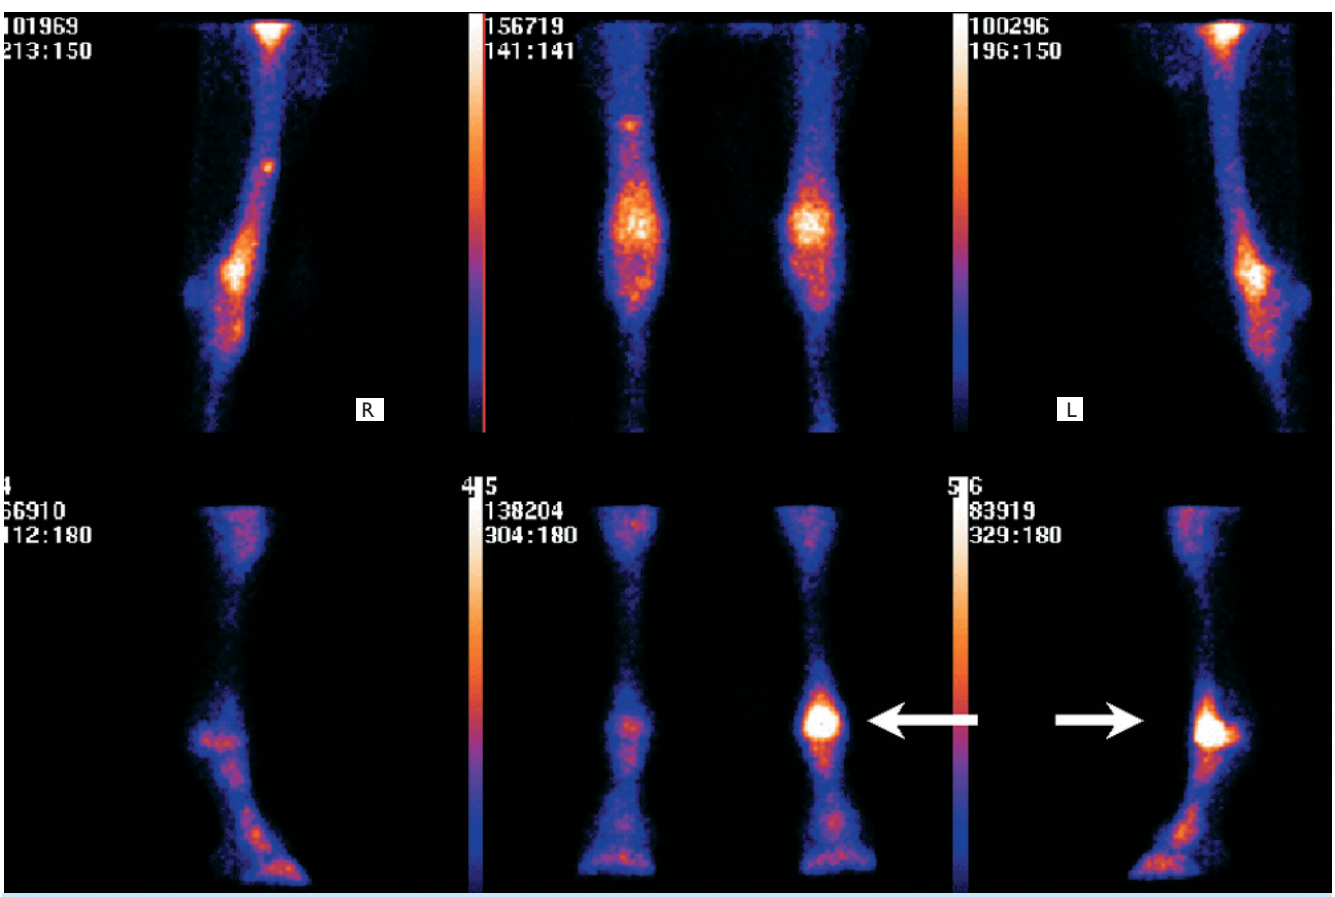

Fig. 10.43
Five-year-old French Trotter male presenting a chronic right front limb lameness at low and high speeds, improved after analgesia of the proximal suspensory ligament. There is intense radioisotope uptake in the metacarpal condyle of the left front fetlock (arrow), which was interpreted as a secondary compensating change induced by functional overload.

Nuclear scintigraphy

Bone scintigraphy is based on the detection of the fixation of polyphosphonate molecules labeled with technetium on bone sites undergoing active remodeling.[21] The bone tracer binds on the hydroxyapatite crystals of newly forming bone. The detection of bone radiation activity is made using a gamma camera.

Scintigraphy is indicated in many clinical situations, the two most common indications being a complete whole-body scan ('locomotor check-up') in horses presented because of poor performance without obvious lameness, and investigation of a specific lameness that is difficult to diagnose. Other common indications include detection of mutiple sites of pain, identification of back and pelvis osteoarticular injuries, investigation of non-blockable lameness and examination of hind limb (or front limb) lamenesses in dangerous horses.

After injection of the radiolabeled phosphonate, complete osteoarticular scintigraphic examination consists of three phases.[22,23] The vascular phase occurs immediately after injection. Because of this, the camera must be placed against the most clinically interesting region before performing the injection. The second phase is the soft tissue phase and images must be made within 10 to 15 min after injection. Soft tissue phase scintigraphy provides information regarding injuries such as tendinitis,[23] synovitis, or bursitis.[24] The bone phase examination, the third phase, is usually performed 3 h after injection.

The technique of image acquisition and interpretation has been described in several papers[21,23] and only specific comments are made in this chapter. Physical exercise before injection of the marker is highly recommended to increase distribution of the marker in the distal and middle parts of the limbs as well as in the regions presenting lesions or compensating stresses. Longeing for 15 min is effective for sport horses.[25,26] In race horses, and especially in Trotters, exercise on the track is preferable because it reproduces the biomechanical conditions responsible for the athletic problems of the patient.

Interpretation of the scintigraphic images is based mainly on the detection of radiopharmaceutical uptake ('hot spots'). The distribution and intensity of bone uptake is dependent on the individual horse, age, conformation,[26] locomotion as well as the discipline in which the horse is used.[27] Therefore, it is critical to compare carefully the radioisotope uptake pattern of homologous limbs and symmetric areas of the same patient to appreciate the significance of each site. To do that, it is important to get absolutely symmetric images during image acquisition (same frame, same 3D orientation, same distance). Positioning of the horse, of the limb (or back), and placement of the camera must therefore be standardized.

The amount of radiation detected by the camera is dependent on morphologic parameters (bone size), physiologic parameters (bone remodeling), and the thickness of overlying soft tissues. The amount of radioisotope uptake of a particular location depends on the blood distribution (bone perfusion) of the radiopharmaceutical and on the degree of bone remodeling of this site. Therefore, scintigraphy provides physiopathologic information. Bone remodeling increases

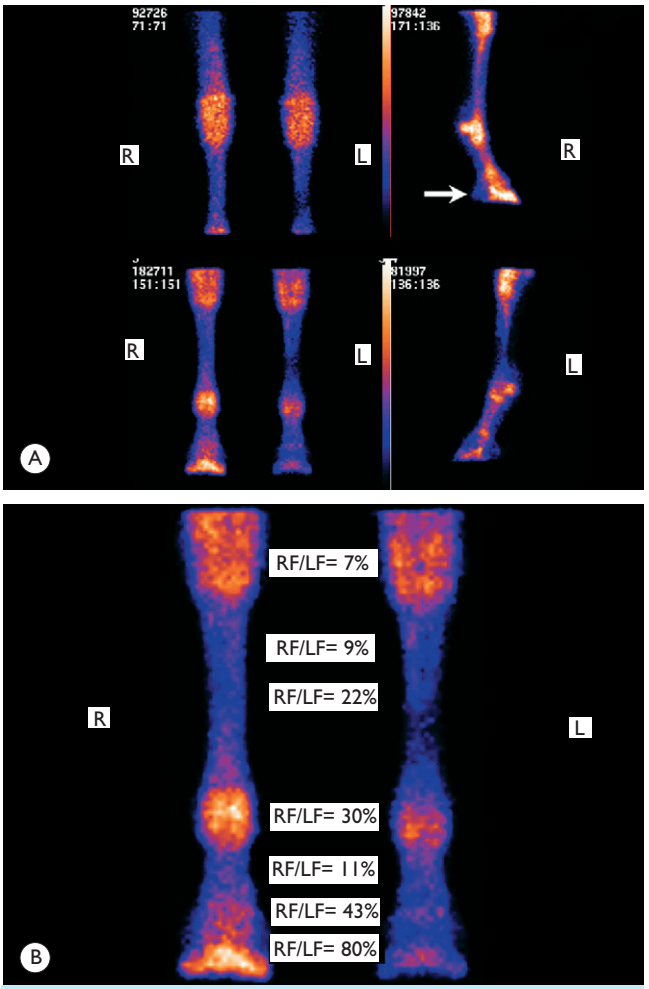

Fig. 10.44
Five-year-old Trackener male used for dressage presenting a right front limb lameness with clinical, radiographic, ultrasonographic and MRI findings (same horse as Fig. 10.50) of podotrochlear syndrome (navicular disease). (A) There is increased radioisotope uptake in the navicular area of the right limb (arrow), but all the more proximal regions are more active than their left equivalent regions. (B) Quantification allows determination that the ratio of relative activities of right versus left regions is higher in the foot than in the more proximal regions.

under physiologic conditions (exercise level, increased biomechanical stresses) and pathologic conditions such as active bone lesions. Presence of a painful area in a limb induces higher stresses on the opposite limb. Because of that, higher radioisoptope activity can be detected in the sound limb (Fig. 10.43) compared with the lame limb (compensation on the opposite limb). When an inflammatory process is responsible for the lameness (Fig. 10.44) the increased blood supply delivers more radiopharmaceutical to this limb (increased perfusion in the same limb).[27] These physiopathologic factors must be considered in the interpretation of the scintigraphic scans to avoid misdiagnosis. Identification of these factors and interpretation of the uptake distribution underline the need for a precise clinical examination, which must be done before and after the scanning procedure.

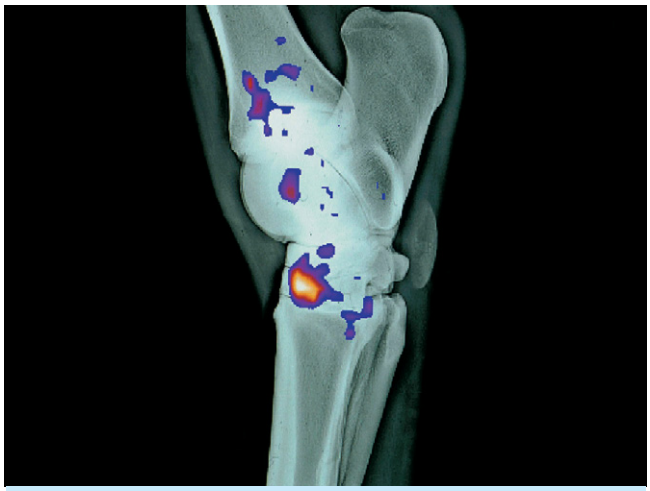

Fig. 10.45
Four-year-old French Trotter female. Scintigraphic image of the right hock superimposed on a lateromedial radiographic projection. Increased radioisotope uptake is present in the third tarsal bone (T3). There were no radiographic abnormalities found on a complete study. This observation was indicative of bone stress of T3.

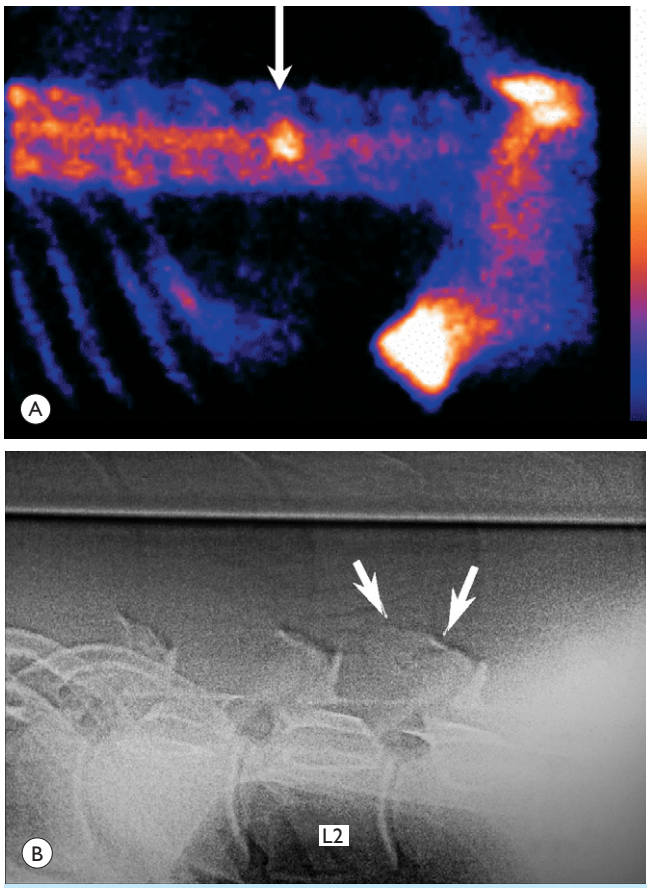

Fig. 10.46
Ten-year-old Grand Prix show jumper, Selle-Français stallion presenting an active osteoarthrosis of a synovial intervertebral joint and articular processes in the lumbar area. (A) Oblique scintigraphic image of the lumbar area. Intense radioisotope uptake is observed in the articular processes of the intervertebral joint between the second (L2) and third (L3) lumbar vertebra (arrow). (B) Radiographic image of the lumbar area of the same horse. An extensive periarticular bony proliferation can be seen over the articular processes of the L2–L3 joint space (arrows).

Identification of lesions is based on increased radioisoptope uptake due to the more intense remodeling taking place in bone injuries such as fractures, stress fractures,[28,29] enthesopathies[30] or osteophyte production. This interpretation can be done subjectively or objectively using software designed for quantification of the radiation activity (e.g. Hermes, from Nuclear Diagnostics, Gravesend, UK).[26] Correct interpretation of the scintigrams requires precise anatomic and topographic landmarks of the region examined, especially for deep structures.[31] Besides, not every region of increased uptake is necessarily correlated to pain (false-positive information). Conversely, it is likely that some chronically painful areas, such as in the back, do not show significant uptake because of attenuation by overlying muscle (false-negative information).

Although skeletal muscle damage has been diagnosed with scintigraphy,[32] this technique is especially useful for identification of bone trauma (contusion, stress, microfractures) without or with discrete radiographic manifestation.[29] These lesions can be seen in the cuboidal bones of the carpus and tarsus (Fig. 10.45) as well as in epiphyses such as the distal metacarpal or metatarsal condyles and distal radial condyle. In race horses, this procedure is also very useful for the detection of cortical bone stress fracture such as in the third metacarpal and metatarsal bones, tibia, radius and humerus. In the pelvis, complete fracture may be difficult to diagnose without scintigraphy (see Fig. 10.41). Some subchondral bone cysts can present very intense radiosotope uptake, especially in the medial femoral condyle, proximal radius and distal epiphysis of the proximal phalanx.

Scintigraphy is also indicated for the detection of osteoarthrosis in low-motion joints (distal tarsus, proximal interphalangeal joint, back) where the involvement of the subchondral bone is often essential (Fig. 10.46). In the distal tarsus, when several joints (tarsometatarsal, distal intertarsal, proximal intertarsal joints) present concomitantly abnormal radiographic findings, scintigraphy allows determination of which site is undergoing the most active remodeling process. In the thoracolumbar spine, scintigraphy is useful in establishing the clinical significance of abnormal radiographic findings involving the spinous processes (see Fig. 10.11), the articular processes (Fig. 10.46) or the vertebral bodies (spondylosis). Many recent or chronic enthesopathies demonstrate an increased radioisotope uptake in the bone insertion surface. This has been observed in the proximal and distal insertions of the suspensory ligament (third interosseus muscle) in both the front and hind limbs (Fig. 10.47) as well as in the insertion surface of collateral ligaments in several joints.

Quantification of the radiation activity (Fig. 10.48) provides objective data on the remodeling intensity during the follow-up of specific lesions. It allows evaluation of the efficacy

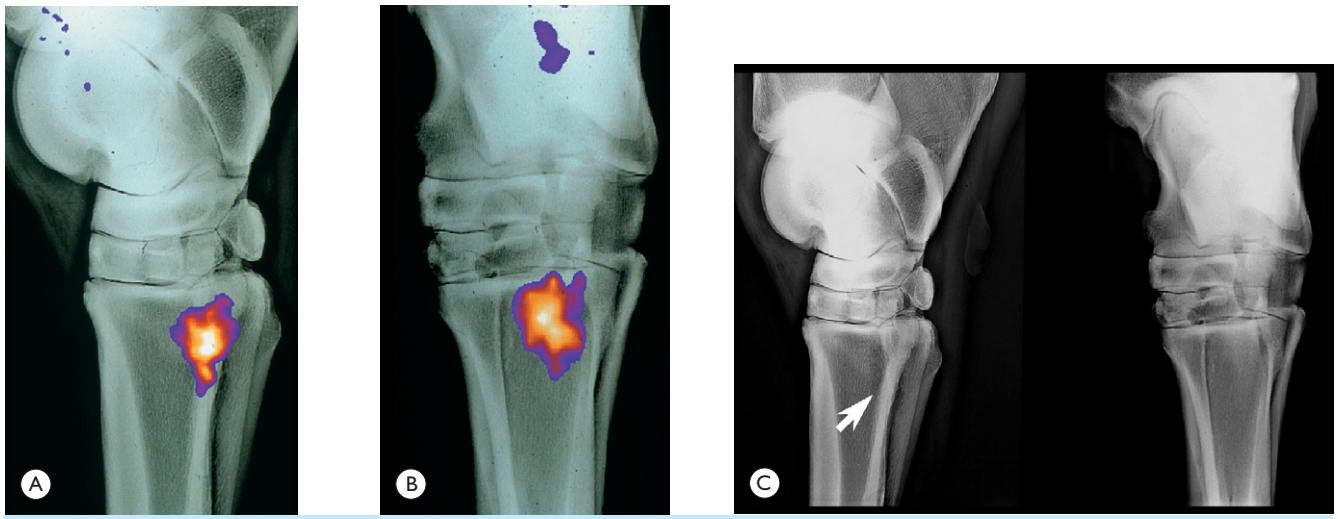

Fig. 10.47
Fourteen-year-old Grand Prix show jumper Selle-Français gelding with a chronic left hind limb lameness (same horse as Fig. 10.39). Superimposition of the radiographic and scintigraphic images of the left hock. (A) Lateromedial radiographic projection and lateral scintigram. (B) Dorsoplantar radiographic projection and plantar scintigram. (C) Lateromedial and dorsoplantar radiographic projections demonstrating mild thickening of the plantar cortex of the proximal third metatarsal bone. Based on these findings, the result of ultrasonographic examination and local analgesia, a diagnosis of chronic proximal enthesopathy of the left suspensory ligament was established.

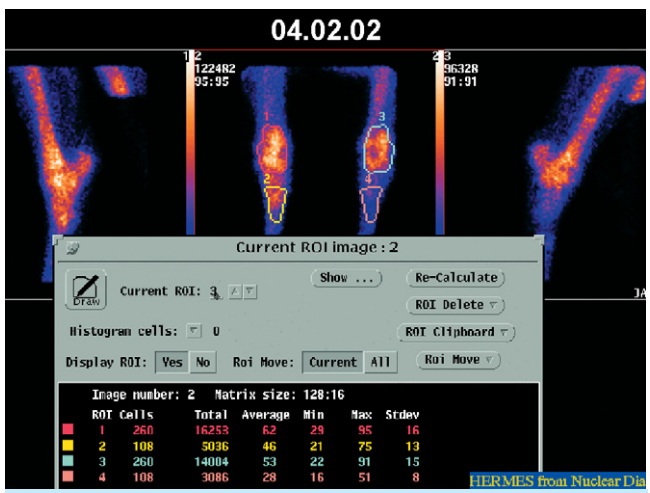

Fig. 10.48
Nine-year-old Grand Prix show jumper, Selle-Français stallion presenting a bilateral proximal enthesopathy of the suspensory ligament in the hind limbs. Scintigram of the plantar aspect of both hocks. Marked increased radioisotope uptake is present in the right proximal metatarsus and mild uptake is seen on the left proximal metatarsus. Uptake quantification was used to monitor the response to treatment and to manage the horse's level of physical activity.

of treatments and to provide recommendations regarding the physical exercise level of activity of the affected horse.

Scintigraphy presents specific advantages compared to other imaging techniques. It permits a complete screening of the whole body of the horse and detection of lesions that cannot be identified by other methods. There is no regional limitation with this technique, except the access to the medial aspect of the limbs and deep structures such as the pelvic symphysis.

Apart from its cost, the main limitation of bone scintigraphy is the low sensitivity to soft-tissue injuries, although incidental radioisotope uptake may be observed in damaged tendons or skeletal muscles. It is likely that the uptake of deep vertebral lesions such as spondylosis and vertebral osteoarthrosis between the articular processes is attenuated by the thick dorsal epiaxial muscles of the horse. Besides, this procedure seems to have a quite poor sensitivity to old or chronic osteoarticular problems such as periarticular osteochondral fragmentation. It must be also recognized than some 'silent' lesions could be painful and have a clinical significance. Therefore, scintigraphy does not replace a good clinical examination, which remains essential for interpretation of the scintigrams. The conclusions of the clinical and scintigraphic examinations must be assessed using diagnostic analgesia techniques. Besides, the definitive diagnosis of the lesion and determination of its severity requires the use of other imaging techniques such as radiography, ultrasonography as well as CT and MRI when indicated and available.

Advanced techniques

Computed tomography

Because of the limited access of the horse body in machines designed for human patients, computed tomography (CT scanning) has the same anatomic limitations as MRI.

In a specific region of interest, the image is produced after quantification by a series of detectors of an X-ray beam passing through a slice of the examined anatomical area.[33–35] The different anatomic tissues, presenting specific X-ray

absorption, are imaged on sequential slices of the scanned region. The ability of the technique to detect slight difference in X-ray absorption within tissues[36] and manipulation of the CT gray-scale provides a much better differentiation of soft tissues than with conventional radiography. CT images can be selectively displayed to highlight either bone structures or soft tissues by adjusting window width and level as necessary (bone or soft tissue display windows).

Because of the cross-sectional characteristics of this imaging modality, superimposition or overlapping of different tissues do not occur and this allows a real isolation ('dissection') of the lesion directly exposed without covering layers, and therefore permits detection of small lesions inside a volume. Digital assembling of adjacent tomographic images allows reconstruction of new images in different anatomical planes as well as 3D representation of bone and joint surfaces.[35]

CT provides an exceptional imaging representation of bone and joints. With this technique, detection of radiographically occult fractures in the distal phalanx[37,38] or in fourth metacarpal bone[35] has been achieved. CT presents an extreme ability to detect variations of bone density,[34,38,39] such as sclerosis and lysis of the subchondral bone,[40] as well as cancellous bone. The sensitivity of CT to subchondral bone cysts[34,35] and bone stress (fatigue fractures) is now well established. Moreover, this technique can provide an excellent spatial representation of fractures.[41] Bone shape and contour are precisely imaged allowing diagnosis of enthesophytes and periosteal proliferative lesions.[35]

CT may also provide useful information on soft tissues, especially in the foot where lesions involving the deep digital flexor tendon such as abnormal shape, dystrophic mineralization and enthesophytes can be identified. Because of the capabilities of ultrasonography and MRI, the use of CT for examination of soft tissues elsewhere than in the foot is questionable. In humans, 3D CT angiography with volume-rendering technique is now used for evaluation of intracerebral aneurysms.[42] In the future, it is likely that this technique will allow evaluation of blood vessels in the foot, such as in laminitic horses.

Magnetic resonance imaging

MRI represents the gold standard technique in human orthopedics, sport medicine and neurology.[28,43–46] This technique is based on the analysis of magnetic properties of the tissues, All tissues are imaged on the MRI scans. It provides excellent anatomic information on cross-sections in different planes. As a cross-sectional imaging modality, every isolated slice can be imaged separately, thereby allowing identification of small lesions, avoiding superimposition and hiding of deep layers by superficial tissues.

In most applications of MRI, horses are examined using devices designed for human patients.[35,36,47,48] With open machines,[47] more areas can potentially be examined than with tunnel machines and the positioning of the horse is more flexible. High-magnetic-field machines (e.g. 1.5 T field machine) provide better definition and quicker image acquisition than low-field equipment (e.g. 0.2 to 0.5 T fields), without significantly affecting a difference in diagnostic capabilities. With the use of human machines adapted to equine patients, the procedure requires general anesthesia of the horse and is time consuming. The cost and maintenance of the facility is expensive and, above all, examination is currently limited to the distal and intermediate parts of the limbs (from the foot to the carpus/tarsus) as well as to the head and cranial part of the neck in adult horses. Equipment that may image distal limbs while the horse is standing is currently

Fig. 10.49
Eight-year-old dressage Selle-Français gelding presenting a chronic bilateral front limb lameness for 3 years. Sagittal T1-weighted MRI scan of the left foot showing a focal area with high signal in the palmar compact bone of the distal sesamoid (navicular) bone (arrow). The horse also had clinical, radiographic, and ultrasonographic findings of podotrochlear syndrome (navicular disease).

Fig. 10.50
Five-year-old Trackener male used for dressage presenting clinical, scintigraphic (same horse as Fig. 10.44), radiographic, ultrasonographic and MRI findings of podotrochlear syndrome (navicular disease). Transverse T1-weighted MRI scan of the right foot. There is a focal area with high signal in the palmar compact bone of the distal sesamoid (navicular) bone (arrow).

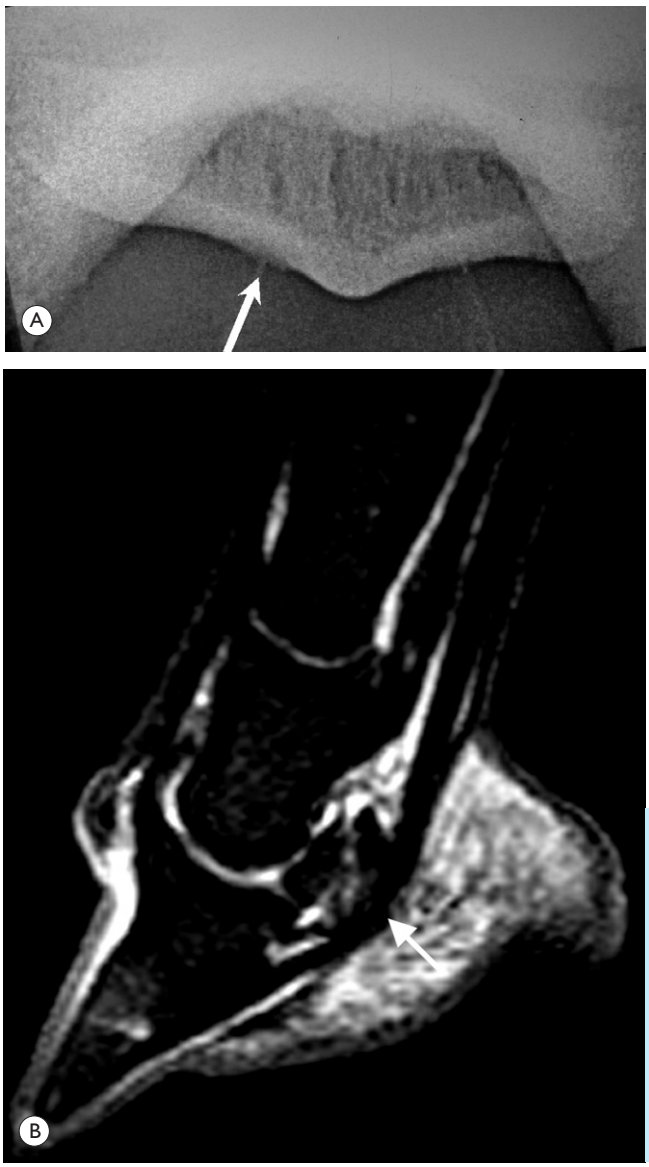

Fig. 10.51
Eight-year-old show jumper Selle-Français gelding presenting a chronic left front limb lameness. (A) Proximopalmar–distodorsal (skyline) projection of the distal sesamoid (navicular) bone (DSB). A discrete irregularity can be seen on the flexor surface of the DSB (arrow). (B) Sagittal T2-weighted MRI scan demonstrating an increased signal in the cancellous as well as palmar compact bone of the DSB (arrow). (C) Lateral parasagittal T2-weighted MRI scan demonstrating an increased signal in the cancellous as well as palmar compact bone of the DSB (arrow). These MRI findings are indicative of bone contusion in the palmar part of the DSB.

under development[49] and will probably allow MRI to be more available for horses in the future.

Images can be acquired in sagittal, transverse and frontal planes using different sequences. The most commonly used imaging sequences are T1-weighted spin echo and T2-weighted turbo spin echo. Inversion–recovery sequences designed to suppress the fat signal, therefore enhancing the fluid signal, are used for bone imaging. It is especially useful for evaluation of the subchondral bone.[50] Mixed T2-/T1-weighted 3D gradient echo sequences providing enhancement of fluid are particularly indicated for identification of articular cartilage lesion (arthrographic effect).

MRI is particularly sensitive for identification of bone lesions (Figs 10.49–10.52).[45] With T2-weighted and fat saturation sequences the high fluid signal can clearly be identified in contrast with the low signal in compact bone and fat (Figs 10.51, 10.52). This signal is produced by bone edema, inflammation, necrosis, fibrosis, and bone contusion (or bruise) with marrow edema and trabecular damage.[45] MRI is also very sensitive to changes in bone density, allowing diagnosis of sclerosis and osteolysis, as well as subchondral bone cysts, fracture lines, fatigue fractures and bone stress.[50] As for every cross-sectional imaging technique, MRI provides detailed information on alteration of bone surfaces for detection of periarticular osteophytes (Fig. 10.53) as well as enthesophytes at insertion sites.

In the diagnosis of joint diseases,[51] MRI has been demonstrated to provide information about the integrity and pathologic status of the articular cartilage in equine cadaver limbs[15,52] as well as in patients.[35,47,48] It is the only imaging technique that permits detection of early and limited cartilage degeneration.[53–55] MRI contrast arthrography with gadolinium diluted with sterile saline injected into the synovial cavity of joints has been used to improve visualization of articular cartilage. Dedicated sequences (for instance mixed T2-/T1-weighted 3D gradient echo sequence) are now available for direct and non-invasive imaging of this structure. MRI provides unique morphologic and biochemical

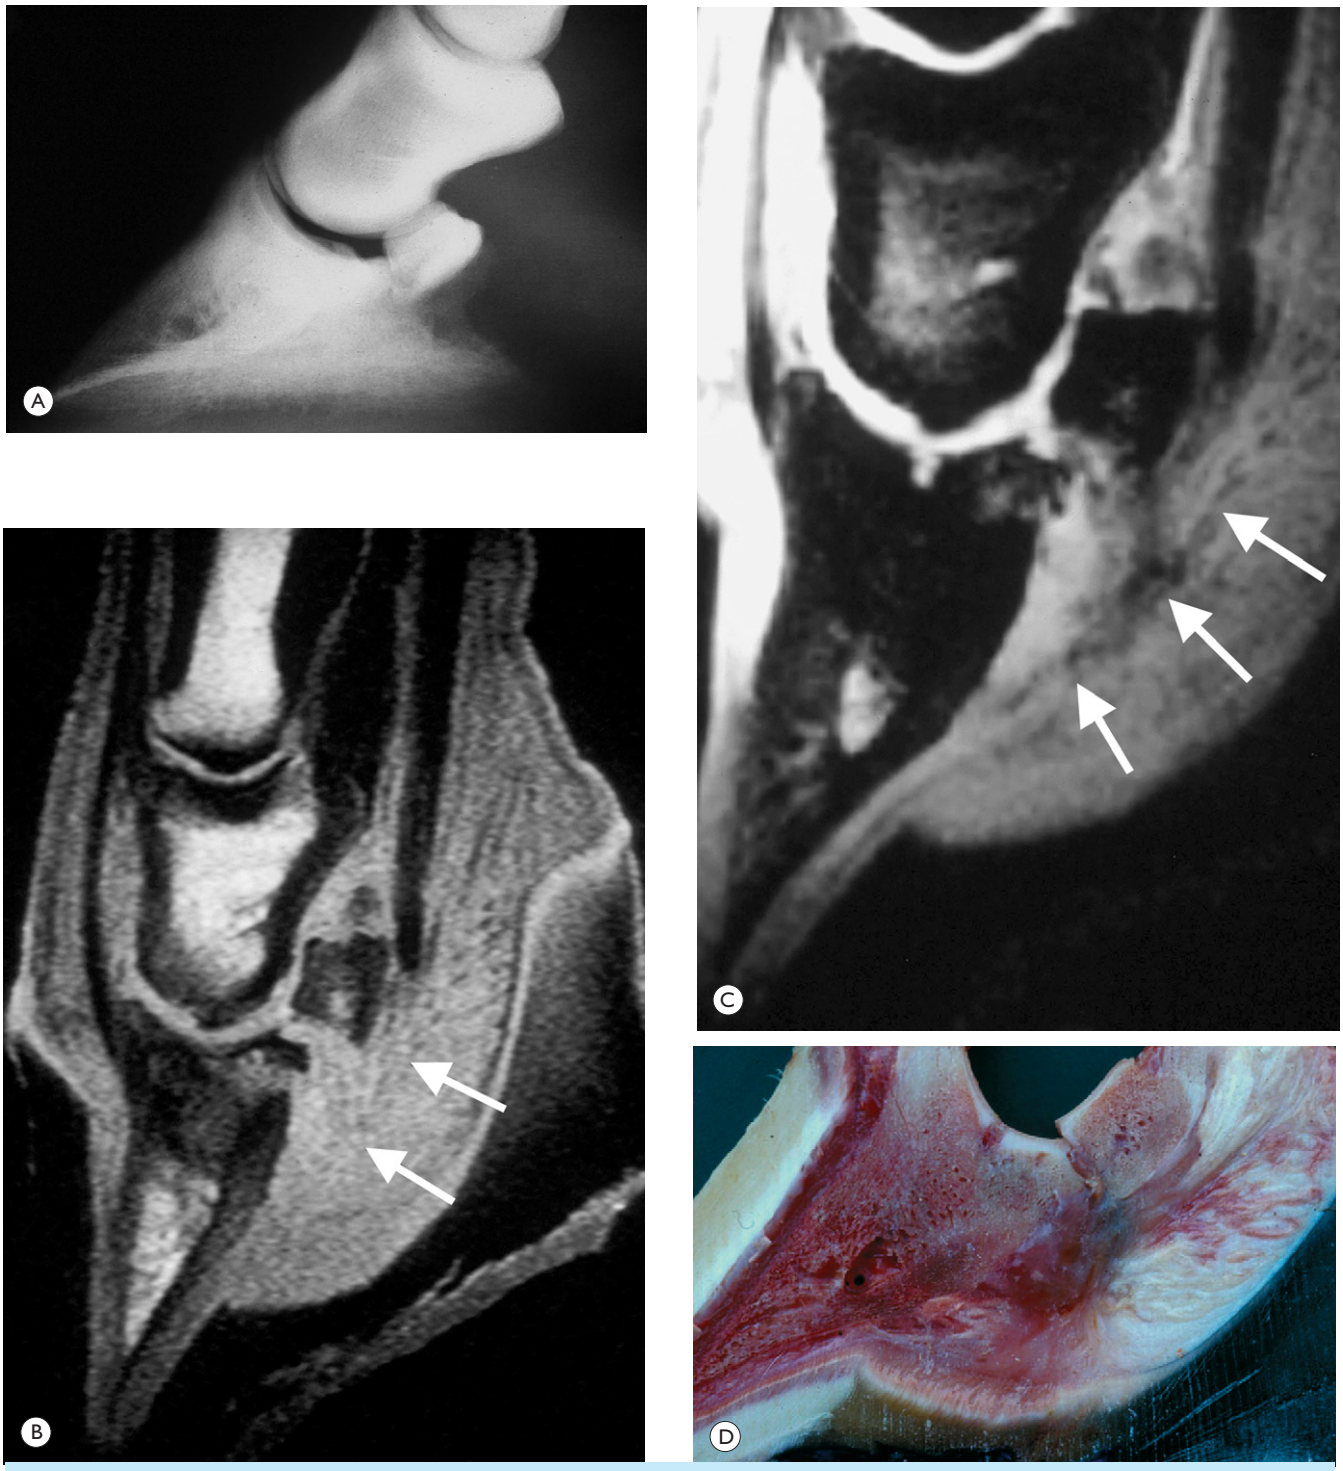

Fig. 10.52
Radiographic and ex vivo MRI examination of the foot of a 5-year-old Selle-Français male who had a deep puncture wound over the frog area of the left foot. (A) Lateromedial radiographic projection showing an osteolysis of the distal part of the distal sesamoid (navicular) bone (DSB) and sclerosis of the distal phalanx and rest of the DSB. (B) Sagittal T1-weighted MRI scan of the same foot showing abnormal hyposignal in the body of the DSB and distal phalanx compatible with bone sclerosis. Bone lysis is present at the distal aspect of the middle phalanx, DSB, and in the subchondral bone of the distal phalanx. The distal part of the deep digital flexor tendon (DDFT) is thickened and presents an abnormally intense signal (arrows). (C) Sagittal T2-weighted MRI scan of the same foot showing abnormal loss of signal in the distal phalanx, DSB and distal middle phalanx. Intense signal indicative of edema is present in the subchondral bone of both the middle and distal phalanx, as well as in the distal impar sesamoidean ligament (DISL) and DDFT. (D) Post-mortem specimen showing the subchondral bone lysis of the distal phalanx and the extensive scar tissue formation within the DISL and DDFT. The horse had septic arthritis of the DIP joint involving the DISL and a septic DDF tendinitis.

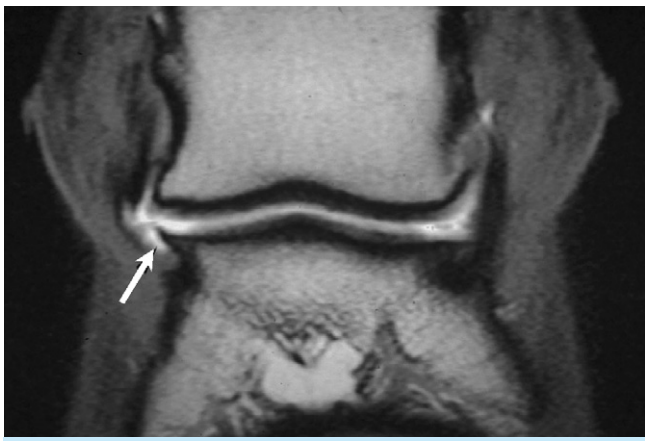

Fig. 10.53
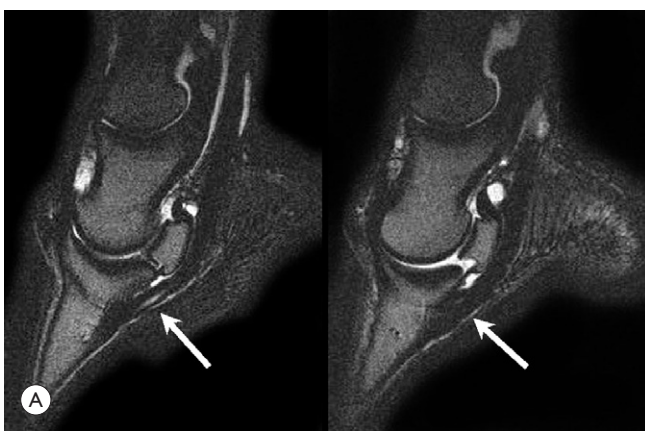
Frontal T1-weighted MRI scan of the distal interphalangeal joint performed ex vivo on an isolated limb. A periarticular osteophyte (arrow) involving the medial margin of the distal phalanx can be seen in a site difficult to investigate with radiography and ultrasonography.



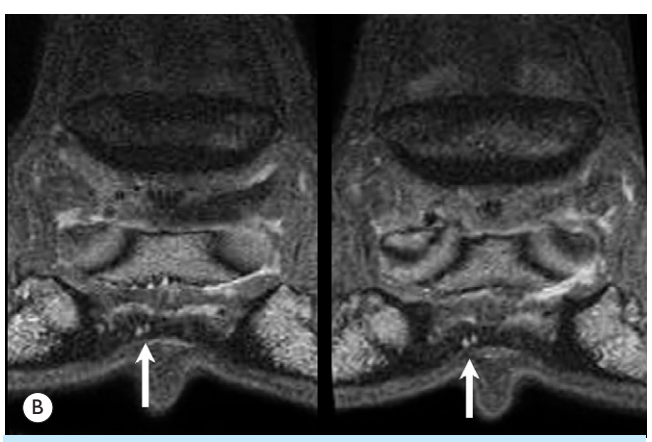


Fig. 10.54
MRI scans of the left foot of a 13-year-old Grand Prix show jumper, Selle-Français gelding with a chronic bilateral front limb lameness. (A) Sagittal and parasagittal T2-weighted MRI scans demonstrating a longitudinal hyposignal lesion (arrow) in the terminal part of the DDFT (left). The right image shows that the most distal part of the DDFT is thickened with an heterogeneous signal (arrow). These findings are indicative of distal DDF tendinitis. (B) Frontal mixed T2-/T1-weighted 3D gradient echo sequence scans of the same foot confirming the heterogenous signal of the distal part of the DDFT.

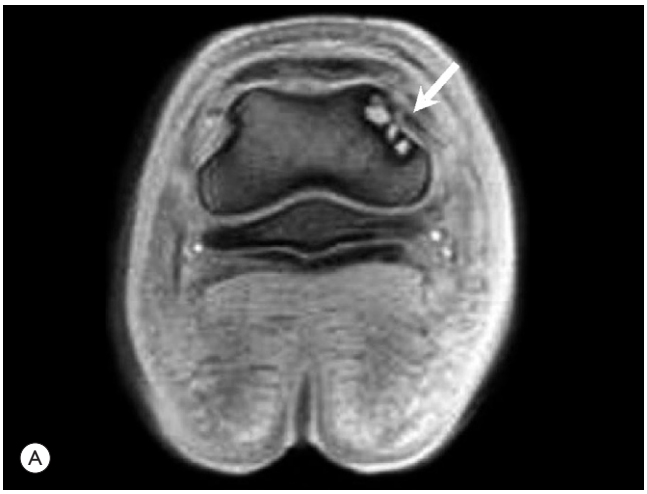

Fig. 10.55
Eight-year-old dressage, Selle-Français gelding presenting a chronic bilateral front limb lameness for 3 years. Transverse (A) and parasagittal (B) T1-weighted MRI scan of the right foot showing severe alteration of bone signal at the proximal attachment of the lateral collateral ligament. A diagnosis of chronic proximal collateral enthesopathy of the distal interphalangeal joint was made.

information on the articular cartilage. Its ability to acquire images in any plane considerably increases its sensitivity. MRI is also very sensitive to subchondral bone alterations such as contusion, bone stress, and sclerosis. With the use of fat suppression sequences, which eliminate the high fat signal within bone marrow, subchondral bone edema, an important feature of articular injuries, is better visualized.[50]

MRI is also very appropriate for the diagnosis of acute as well as chronic tendon (see Figs 10.52, 10.54) and ligament injuries providing an increased signal intensity on both T1- and T2-weighted sequences.[36,52,56] The capacity of the technique to detect edema as well as granulation or scar tissue and to document the lesion in three planes represents the main advantages of MRI compared to ultrasonography or CT scanning. Because of the sensitivity of MRI for bone, as well as tendon and ligament injuries, this technique has a high diagnostic value for enthesopathies, involving collateral ligaments (Figs 10.55, 10.56) tendons, or the interosseus

Fig. 10.56
Four-year-old Selle-Français female presenting a chronic left front limb lameness for 6 months. Parasagittal T1-weighted sequence (left), transverse inversion–recovery sequence (bottom) and frontal inversion–recovery sequence (right) MRI scans of the left foot showing an enthesophyte (arrow, left) and severe alteration of bone signal (arrow, right) at the distal attachment of the lateral collateral ligament. A diagnosis of chronic distal collateral enthesopathy of the distal interphalangeal joint was made.

Fig. 10.57
Five-year-old Trackener male used for dressage presenting clinical, scintigraphic, radiographic, ultrasonographic and MRI findings of podotrochlear syndrome (navicular disease) in the right front limb (same horse as Figs 10.44 and 10.50). Sagittal and transverse T2-weighted sequence images showing an extensive fluid distension of the podotrochlear bursa. Intrasynovial analgesia of this bursa using 1.5 mL of local anesthetic solution resolved the lameness.

muscle. Moreover, fluid distension involving the synovial cavities (tendon sheaths, bursae, or joint cavities) is easily imaged especially in T2-weighted and mixed T2-/T1-weighted 3D gradient echo sequences (Fig. 10.57). Because of its cross-sectional characteristics, in axial regions, MRI can reveal the asymmetric appearance of structures

Fig. 10.58
Transverse T1-weighted MRI scan of the neck of a 6-month-old foal presenting a wobbler syndrome. There is marked asymmetry of the articular processes between the fifth and sixth cervical vertebrae. The hypertrophic articular processes present a loss of signal compatible with bone sclerosis. On the same side, there is marked dorsolateral stenosis of the vertebral canal inducing compression of the cervical spinal cord.

within the head or vertebrae that are difficult to demonstrate with radiography (Fig. 10.58).

This technique is indicated when the site of the lesion(s) is clearly identified and other imaging procedures do not provide a conclusive diagnosis. Unfortunately, as mentioned above, MRI is limited to anatomic regions that can be placed into the machine.

Providing specific information on both soft tissues and bone components, MRI is the most informative diagnostic imaging procedure available for all areas that are accessible with the device. In metacarpal (tarsal) areas and pastern, with the progressive improvement of ultrasound machines, ultrasonography challenges MRI for the diagnosis of tendon lesions (except insertion sites). Knowing the sensitivity of MRI to detect small bone, cartilaginous, tendon, and ligament lesions, we need to adapt our interpretation and, again, reconsider the clinical examination to establish the real clinical significance of any abnormal finding.

Conclusion

Diagnostic imaging of musculoskeletal conditions is a permanently evolving field; several imaging modalities are

now available for equine patients and therefore a rational utilization of each of them is essential. The use of different techniques for a better analysis of the same lesion increases the knowledge of the advantages and limitations of each of them and underlines the need for combining several procedures to reach a better diagnosis.

As radiography and ultrasonography present complementary advantages, they should be used in conjunction as basic imaging modalities in most clinical situations in field practice. With this combination, a re-evaluation of several 'well known' dogmatic pathologic entities and identification of many new clinical entities have already been made.

Apart from the diagnostic aspect, another development of imaging techniques is interventional imaging. Ultrasonography has now been incorporated in the treatment of several musculoskeletal conditions through ultrasonographic guided injections of synovial joints in the cervical and thoracolumbar spine or intrasynovial injections in joints, tendon sheaths, or bursae.

Unfortunately, at present, advanced technologies such as CT and MRI are available only in a limited number of equine referral centers. Nevertheless, they have already provided new data, allowing a better appraisal of the indications and limitations of radiography and ultrasonography. In the coming years, further technological progress in each modality will continue to provide better image quality. Development of 3D representation of lesions will improve in MRI, CT scanning, and ultrasonography. Communication between referral centers and equine practitioners will also be easier with computed or digital images. With this evolution, a better diagnosis and management of our patients will be possible, but we will have to avoid performing only an 'instrumental medicine', where images are manipulated and patients forgotten. In the teaching of new generations of practitioners, we have to keep an emphasis on the clinical examination, to make young colleagues think about the horse, not only discuss the images.

In the near future, another important aspect of diagnostic imaging in horses will be the need to establish the most adequate imaging protocols for specific clinical problems. In practice, the objective is to reach the diagnosis with the most appropriate technique(s), considering the ratio of information to cost as well as the impact of more information on the potential subsequent management of the condition. In the mean time, comparative or combined imaging for better documentation of musculoskeletal conditions is required to increase knowledge of pathologic processes and to establish the most effective diagnostic protocols.

Acknowledgments

Clinical research in comparative imaging in horses is supported by the Haras Nationaux and the regional council of Basse-Normandy (France). Many thanks to J Tapprest for the realization of the MRI scans presented in this chapter and to D Didierlaurent for the preparation of the scintigrams.

CHAPTER 11

Arthroscopic examination and surgery

John P. Walmsley

Introduction

Since the 1980s arthroscopy has become an important tool for the diagnosis and treatment of orthopedic disorders of many synovial spaces in the horse. It has several advantages: it is minimally invasive and, as a technique, has a low morbidity when compared to arthrotomy; it provides detailed information on arthroscopically accessible intrasynovial structures that cannot be obtained by radiography, ultrasonography or magnetic resonance imaging; it permits direct treatment of many injuries to these structures and concurrent removal of degradatory inflammatory enzymes by lavage. The main disadvantages are the necessity for general anesthesia, the expense of the equipment required for the procedure and the difficulty of the technique.

Indications

While there are many obvious and specific indications for arthroscopic surgery in the horse, there are several general points that may help decide if the procedure is indicated.

- The clinical investigation should have confirmed that the joint is the cause of lameness.
- The advantages to the patient of performing the procedure must outweigh the disadvantages.
- Where radiography and ultrasonography show no abnormalities and conservative treatment has failed, arthroscopy may be indicated as a diagnostic and potentially therapeutic option.
- Radiographic or ultrasonographic findings indicate that arthroscopy is the most appropriate course of action.
- Despite absence of radiographic or ultrasonographic findings, the joint injury is clinically so severe that arthroscopy is indicated as a primary course of action.

General points

Arthroscopic surgery should always be performed under strict aseptic conditions. Good-quality equipment is essential. A poor image or inadequate instrumentation can significantly compromise the surgery. Details of arthroscopic equipment are beyond the scope of this chapter but can be found in other texts.[1] The narrative in this chapter is based on the use of a 4 mm diameter telescope with a 25° lens angle. The surgeon should have a good anatomical knowledge and the necessary hand–eye co-ordination demanded by arthroscopy, best achieved by cadaver practice, before embarking on the clinical case. Fatigue affects the quality of surgery so it is important to ensure that the horse is positioned to enable the surgeon to operate comfortably.

Portals should be placed precisely to ensure that the surgical goals can be achieved as effectively as possible. Unless distension of the joint affects the landmarks, such as in the carpus, distension with sterile polyionic fluid prior to making the first incision is preferable. The skin incision should be wider than the incision into the joint capsule in order to reduce the possibility of subcutaneous extravasation of fluid during the surgery. The incision into the joint capsule for the introduction of the arthroscope sleeve and the conical obturator is made with a no. 11 scalpel blade. Because of the risk of damaging the articular cartilage, sharp trocars should never be used for this. The arthroscopic sleeve and obturator

are usually positioned at the site where the examination of the joint will begin before replacing the obturator with the telescope and attaching the light cable, camera and fluid system. When using an arthroscope it is very important to maintain the camera in the vertical plane so that the orientation of the image on the monitor is always the same as that in the joint. Oblique lenses widen the range of the telescope and increase triangulation.

The placement of the instrument portal is best determined by simulating the positioning of the instruments with a hypodermic needle. For ease of triangulation the instrument portal should be as far as possible both from the lesion to be operated and from the arthroscopic portal.

The treatment of lesions within the joint depends on the type of lesion. Bone fragments may require separation from the parent bone with an osteotome or dissection off their soft tissue attachments with a sharp instrument such as a meniscal knife or an O'Connor punch. It is wise never to free the fragment completely before removal in order to avoid it floating free into the joint. Ferris Smith rongeurs are ideal for removing fragments and several cup sizes are necessary ranging from 2 × 10 mm to 6 × 12 mm. When removing large fragments through the joint capsule, widening of the incision by sharp dissection may be necessary as the fragment is withdrawn. The debridement of soft tissue lesions such as infected synovial villi or torn ligamentous tissue can effectively be performed using a motorized synovial resector or a scissor-action punch instrument. Rongeurs tend to tear rather than cut soft tissue.

The correct treatment of articular cartilage lesions is still controversial: full-thickness defects should be curetted to healthy subchondral bone and micropicking of denuded bone is recommended by some.[2] Partial-thickness defects should be trimmed superficially, leaving intact tissue in situ but ensuring that all loose cartilage is removed. The use of radiofrequency instrumentation for debridement of soft tissue and articular cartilage lesions may have a place in equine arthroscopy but is still under evaluation.

Complications of arthroscopic surgery include infection, subcutaneous extravasation of fluid and instrument breakage. The most serious, postoperative infection, is rare but potentially catastrophic and emphasizes the importance of strict aseptic technique. Subcutaneous extravasation of fluid during surgery can hamper an arthroscopy by compressing the intra-articular space. Several technical points will help to avoid this: the skin incision should be large enough to allow excess fluid to escape through the skin incision rather than into the subcutaneous space; it should be kept in line with the incision into the joint capsule by avoiding too much flexion or extension of the joint once the portal has been made; and the flow of fluid should be maintained at the minimum necessary. A magnet for retrieval of a broken instrument should always be available. Old instruments and fine scalpel blades are the most susceptible to breakage. Scalpel blades can also be lost when creating portals for joints that are well covered with muscle, such as the shoulder joint or suprapatellar pouch of the femoropatellar joint. Using handles that are wider than the scalpel helps to prevent the hilt of the blade catching on tissue as the blade is withdrawn.

Synovial sepsis is an important indication for endoscopy of all the synovial spaces included below.

The carpus

Middle carpal joint

Positioning

Most surgeons prefer the horse in dorsal recumbency for easier access to both sides of the joint, but the surgery can be performed with the horse in lateral recumbency, preferably with the affected leg up. Active flexion and extension of the limb should be possible during surgery. The carpus should be flexed at 90°. The surgeon operates from the dorsal side and the arthroscopy equipment tower is placed behind the limb.

Arthroscopic approach

The standard arthroscope portal for the middle carpal (MC) joint lies on its dorsal surface in the center of the depression between the common digital extensor (CDE) tendon, the extensor carpi radialis (ECR) tendon and the middle and distal rows of carpal bones. The skin incision is made prior to distending the joint since the landmarks are more recognizable at this stage. The examination of the joint commences at the medial side of the joint. The instrument portal lies medial to the ECR tendon midway between the radial carpal (RC) and the third carpal (3C) bones. This is checked visually with a hypodermic needle to ensure that the portal is appropriately placed. The instrument and arthroscope portals can be exchanged if the lesion is on the lateral side of the joint.

Normal anatomy[3]

Viewing medially, the RC bone will be seen in the lower field and the 3C and second carpal (2C) bones in the upper field (Fig. 11.1). There is a synovial plica extending from the dorsomedial aspect of the RC bone medially and distally into the joint capsule. The dorsal surface of the RC bone can be examined followed by the palmar aspect of the joint, which contains a fossa in the palmar aspect of the 3C bone. The medial palmar intercarpal ligament (MPICL) lies within this

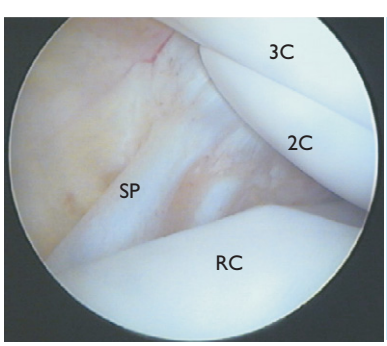

Fig. 11.1

fossa and is a complex structure attached to the RC and 3C bones.[4] Increasing flexion of the joint improves the view of this structure. Examination of the dorsal aspect of the 3C bone is facilitated by extending the joint. The arthroscope can now be withdrawn to examine the prominent axial border of the RC bone, the intermediate carpal bone, the intermediate facet of the 3C bone and the axial part of the fourth carpal (4C) bone. Moving laterally, the ulnar carpal (UC) bone and 4C bone can be inspected (Fig. 11.2) and by rotating the arthroscope, the lateral palmar intercarpal ligament is seen lying between the 4C and the UC bones.

Antebrachiocarpal joint

Positioning

The general principles of positioning for the MC joint apply to the antebrachiocarpal (ABC) joint with the exception that the joint should be flexed at approximately 130°.

Arthroscopic approach

The incision for the arthroscope portal is made before distending the joint; both portals lie in the same relation to the ECR and CDE tendons and the center of the depression between the middle row of carpal bones and the radius. Inspection of the joint commences medially as for the MC joint. There is less room to maneuver within the ABC joint.

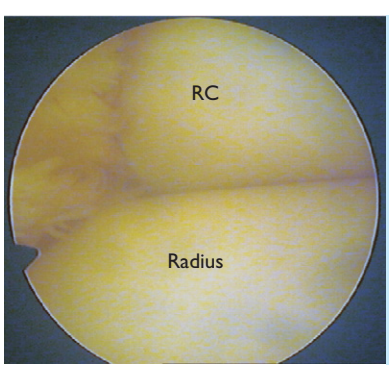

Fig. 11.3
Arthroscopic view of the medial aspect of the right antebrachiocarpal joint. RC, radial carpal bone.

Normal anatomy

The medial aspect of the distal radius and proximal RC bone is examined first (Fig. 11.3). The synovial villi can inhibit the visibility of the dorsal border of the radius but this can be counteracted by fluid distension and extension of the joint. As the arthroscope is withdrawn the junction between the IC and RC bones is seen opposite the midsagittal ridge of the radius. Moving laterally, the joint space becomes narrower and it can more easily be inspected with the arthroscope in the medial portal. In young horses the groove at the junction of the styloid process and the radius will be seen on the articular surface of the radius (Fig. 11.4). Looking distally and laterally, the axial part of the UC is visible.

Indications for arthroscopy of the carpus, specific techniques and results

Osteochondral chip fractures

These are most frequently seen in young race horses and are rare in competition and general riding horses. The reported order of incidence of the specific site of these injuries in the MC joint is the dorsodistal RC bone (Fig. 11.5), the dorsodistal IC bone and the dorsoproximal 3C bone.[5] In the ABC joint the reported order of incidence is the dorsoproximal IC bone, the dorsoproximal RC bone, the dorsodistal lateral radius and the dorsodistal medial radius.[5]

The arthroscope portal is best placed on the side of the joint away from the lesion. In both joints RC fragments are viewed from the lateral portal and IC fragments from the

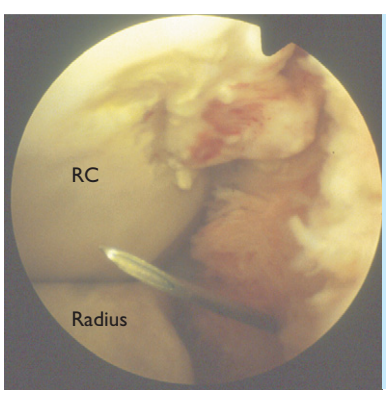

Fig. 11.5

RC, radial carpal bone.

medial portal. 3C fragments can be difficult to operate because they often lie under the ECR tendon and some extend beyond the attachment of the joint capsule. Decreasing the carpal flexion improves access to these lesions. In general some osteochondral chip fragments in the carpus may require loosening with an elevator but most can be removed directly with Ferris Smith rongeurs. Fragments with attachments to the joint capsule should be carefully dissected free before removal. Soft diseased bone in the fracture bed is curetted and the healthy articular cartilage on its borders is curetted to create a clean edge to the lesion.

The success rate of arthroscopic surgery for horses with osteochondral chip fractures in the carpus has been reported as 68% of horses returning to racing at their preinjury level.[5] The degree of articular damage was related to a worse prognosis. Another report on results of treatment in Standardbred horses showed similar findings, but the incidence of fracture sites was different. The most common sites were the dorsodistal RC bone and the dorsoproximal 3C bone in approximately equal numbers and very few ABC joint lesions were seen.[6]

Internal fixation of third carpal bone slab fractures

Frontal plane slab fractures of the 3C bone occur, in descending order of frequency, on the radial facet, on both the radial and intermediate facets and on the intermediate facet of the bone.[7] They can be repaired by internal fixation using arthroscopic and radiographic control.[8] Best results are obtained in the acute case. Comminuted or very thin slab fractures may be treated by fragment removal. For radial facet fractures the lateral arthroscope portal is used. The fracture is assessed arthroscopically, debrided and reduced. Reduction is assisted by flexion of the limb. Spinal needles (19 gauge, 9 cm) are inserted along the articular surface of the 3C bone at each edge of the fracture. An additional spinal needle is placed along the articular surface at the center of the fracture and a finer gauge needle is inserted into the carpometacarpal joint in the same plane as the center of the fracture. A needle that will mark the position of the screw is inserted and a radiograph is taken to confirm that this needle placement is correct (Fig. 11.6).

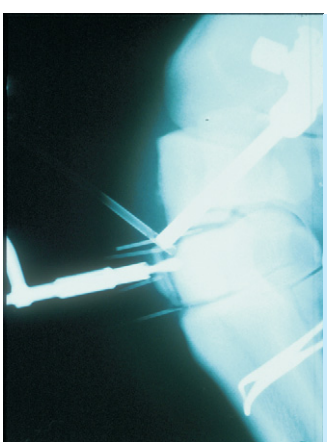

Fig. 11.6
Radiograph of slab fracture of the third carpal bone undergoing arthroscopically assisted internal fixation and demonstrating needle placement.

A stab incision is made at the site of the needle that marks the screw position and a 4.5 mm glide hole is drilled using the remaining needles as a guide for the drill angle. A further X-ray to check drill placement is taken. The 4.5 mm drill hole should be 14 mm to allow for the countersink instrument. Following placement of the 3.2 mm drill sleeve in the glide hole and drilling of the 3.2 mm pilot hole, the drill hole is countersunk, measured and tapped. An appropriate length 4.5 mm cortical ASIF (Association for the Study of Internal Fixation) cortical screw is inserted and the fracture line is examined arthroscopically to assess fracture reduction while the screw is tightened. Fractures across both the radial and intermediate facets usually require two screws. For small fracture fragments 3.5 mm cortical ASIF screws may be used.

The success of this surgery depends on many factors, including the quality of the reduction, the presence of degenerative joint disease, the age and gender of the horse and the duration of the injury.[9]

Chronic arthropathy and carpal lameness without radiographic signs

Arthroscopic investigation of horses with chronic carpal arthropathy can be useful to determine the extent of joint disease, lavage inflammatory debris from the joint and debride lesions where appropriate. In some cases this may at least temporarily extend the horse's working life and should improve prognostic accuracy. Arthroscopy is indicated for carpal lameness without radiographic signs that has not responded to conservative treatment.[10] In the young race horse tearing of the MPICL will sometimes be encountered and can be debrided using a punch or motorized resector.[11]

The fetlock

Dorsal fetlock

Positioning

Most surgeons prefer to operate the dorsal fetlock with the horse in dorsal recumbency and the fetlock extended. Operating from the dorsal aspect of the limb with the arthroscope monitor caudal to the limb allows easier interchange of portals and instrument manipulation. Extension of the joint relieves the pressure of the extensor tendon, which is especially important in the hind limb. Suspending hind limbs by the heel improves extension. Some surgeons prefer to position the horse in lateral recumbency.

Arthroscopic approach

Following distension there will be an outpouching of the joint either side of the extensor tendon. For surgeries involving the distal part of the joint, the arthroscope portal is made proximal to the center of either outpouching. If the portal is placed

too distally it is difficult to advance the arthroscope across the sagittal ridge. If the site of interest is in the proximal joint, the portal should be made at the center of the outpouching. The obturator and arthroscope sleeve should be passed across the joint before commencing the examination. The instrument portal is sited on the contralateral side of the joint.

Normal anatomy

If the arthroscope portal is lateral, the medial proximodorsal aspect of the first phalanx (P1) will be seen first. The synovial fronds of the joint capsule lie dorsal and the articular cartilage of the third metacarpal/metatarsal (MC3/MT3) condyles lie palmar/plantar in the field of view. Moving axially over the sagittal ridge, a similar view of lateral P1 is obtained. If the arthroscope is directed proximally the synovial pads proximodorsal in the joint both laterally and medially are examined.

Palmar/plantar fetlock

Positioning

There are advantages in positioning the horse either in dorsal or lateral recumbency for palmar/plantar fetlock arthroscopy and the choice depends on the surgery to be performed and the surgeon's preference. Dorsal recumbency is more satisfactory if both fetlocks require surgery or if there are both medial and lateral lesions in the affected joint. Where possible, the author prefers lateral recumbency. A tourniquet is necessary if the horse is in lateral recumbency, but it should not prevent the arthroscope being positioned parallel to the limb (Fig. 11.7). The limb must be supported so that it can readily be flexed and extended during surgery.

Arthroscopic approach

For most surgeries the arthroscope portal is placed in the most proximal outpouching of the palmar/plantar joint capsule and the obturator and arthroscope sleeve are passed to the distal, contralateral aspect of the joint. The site of the instrument portal will depend on the lesion involved.

Normal anatomy

The first view will be of the proximal sesamoid bone and the condyle of MC3/MT3 in the distal contralateral aspect of the joint. Looking distally, the palmar/plantar edge of P1 is usually screened by synovial villi, but can be seen when the joint is flexed. Proximally the apex of the proximal sesamoid is inspected before withdrawing the arthroscope to view the intersesamoidean ligament and the sagittal ridge of MC3/MT3, and finally the ipsilateral proximal sesamoid bone and MC3/MT3 condyle.

Fig. 11.7
Arthroscope and instrument portals for arthroscopic removal of palmar/plantar P1 osteochondral fragments. Note that the arthroscope and the camera are parallel to the limb.

Indications for arthroscopy of the fetlock, specific techniques and results

Osteochondral chip fractures in the dorsal joint

These occur in both racing and non-racing horses and sometimes they are incidental findings. They arise from the dorsal aspect of P1 in both fore- and hindlimbs and are more frequent in the medial aspect of the joint[12,13] (Fig. 11.8). The arthroscope portal is made on the dorsal aspect of the joint contralateral to the fragment and the instrument portal is ipsilateral. A careful examination of the joint is made to evaluate concurrent joint disease and to ensure that no fragments are hidden in the synovial villi. Wear lines and erosions of the articular cartilage in the condyle of MC3/MT3 are often associated with any osteochondral fragmentation in the fetlock[13] (Fig. 11.9). Most fragments are attached and should be dissected free, carefully avoiding complete separation to prevent them falling into the dependent part of the joint where they can be more difficult to retrieve. Small Ferris Smith rongeurs are suitable for grasping and removing the fragments. The site of the lesion on P1 requires debridement and usually consists of thickened irregular fibrous tissue covering softened bone.

In two studies of 336 and 461 horses respectively, return to use was reported in approximately 85% of horses following arthroscopic removal of fetlock fragments.[12,13] In one report 82% of horses achieved their original performance level,[12] while in the other this figure was 69% and the success rate declined by 10% if other fetlock lesions were present.

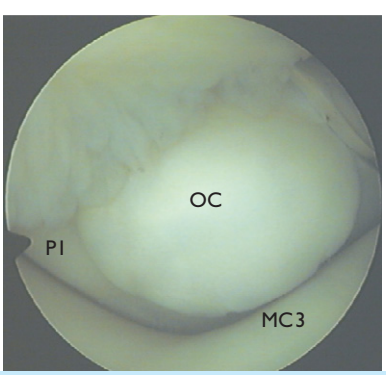

Fig. 11.8
Arthroscopic view of the dorsomedial aspect of the right fore fetlock showing an osteochondral fragment attached to the dorsoproximal aspect of the first phalanx. P1, first phalanx; MC3, medial distal condyle of the third metacarpal bone; OC, osteochondral fragment.

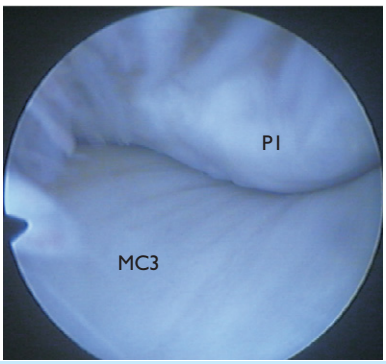

Fig. 11.9
Arthroscopic view of the dorsomedial aspect of the right fore fetlock showing wear lines on the articular cartilage of the distal third metacarpal bone (MC3). These fragments were associated with the presence of osteochondral fragmentation on the dorsal sagittal ridge. P1, first phalanx.

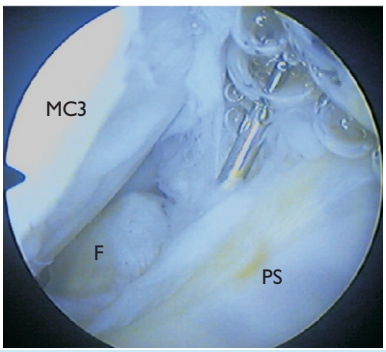

Fig. 11.10
Arthroscopic view of the palmaromedial distal aspect of the left fore fetlock showing a type I palmar P1 osteochondral fragment revealed by probing. MC3, medial distal condyle of the third metacarpal bone; F, fragment; PS, proximal sesamoid bone.

Osteochondritis dissecans lesions on the dorsal sagittal ridge of MC3/MT3

The approach for these lesions is similar to the approach for dorsal P1 fragments, with minor modifications. Triangulation is improved if the portals are made slightly further abaxially and distally to the standard portals.

Fibrotic proliferation of the synovial pad in the dorsoproximal aspect of the joint

This condition is also termed proliferative synovitis or villonodular synovitis. It is thought to be associated with chronic trauma in the metacarpophalangeal joint and is often associated with other traumatic lesions in the joint.[14] Partial or complete arthroscopic excision of one or both pads is accomplished using sharp dissection with a meniscal knife or a cutting instrument such as an O'Connor punch. An extra instrument portal sometimes facilitates the dissection. Debridement of underlying diseased bone is often necessary. A study of 63 horses with this condition reported that 43/50 horses treated arthroscopically and one out of eight horses treated medically returned to their previous level of racing.[14]

Type I palmar/plantar P1 osteochondral fragments[15]

These lesions occur in fore- and hindlimbs both medially and laterally but are more frequently seen in the medial aspect of hindlimbs.[16] They can be bilateral and can also be an incidental finding. This is one of the more difficult arthroscopic procedures.

The author prefers to place the horse in lateral recumbency with the lesion uppermost and approach this with both portals on the same side as the fragment (see Fig. 11.7). The arthroscope and camera must lie flush with the limb to permit a clear view of the distal ipsilateral part of the joint where the fragment often lies hidden by the synovial villi (Fig. 11.10). The instrument portal must be made distal enough for the instrument to pass distal to the MC3/MT3 condyle, giving direct access to the fragment. The fragment will often require extensive dissection from its attachments and this is more safely performed with a meniscal knife than a scalpel blade, which can easily be broken. A motorized synovial resector is useful for clearing away excessive synovial tissue. Dissection of the fragment with a radiofrequency probe is also effective but care should be taken to avoid charring tissue. Horses with fragments in both fetlocks or fragments in both medial and lateral aspects of the same joint are more easily operated in dorsal recumbency.

In a report on a series of 119 cases treated arthroscopically, 63% of 87 race horses and 100% of nine non-race horses returned to preoperative performance levels.[16] Concurrent joint disease worsened the prognosis.

Small articular basilar sesamoidean fracture fragments

These can be removed surgically using the same technique as for palmar/plantar P1 fragments. Dissection of the fragments off the attachments of the distal sesamoidean ligament is necessary and the prognosis for return to use is reasonable.[17]

Apical sesamoidean fracture fragments

Surgical removal is generally considered to be the most appropriate treatment for apical fractures involving up to one-third of the proximal sesamoid bone.[18] Arthroscopic removal is a relatively difficult procedure but does appear to have advantages over arthrotomy.[19] The author prefers an ipsilateral approach with the horse in lateral recumbency so that the lesion is uppermost, but some surgeons prefer to operate with the horse in dorsal recumbency and the arthroscope portal on the contralateral side of the joint to the lesion. When operating with the arthroscope ipsilaterally the arthroscopic portal must be as proximal as possible so that the whole apex of the bone is clearly visible (Fig. 11.11). The instrument portal is made in line with the fracture. The fragment is first dissected off the intersesamoidean ligament

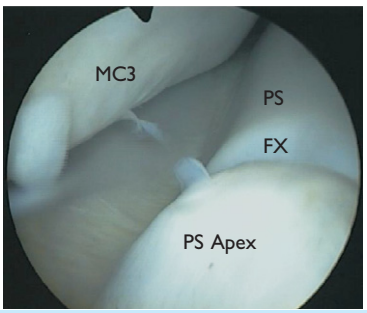

Fig. 11.11
Arthroscopic view of a fracture of the apex of the right fore lateral proximal sesamoid bone. PS, proximal sesamoid bone; MC3, median sagittal ridge of the distal third metacarpal bone; PS Apex, apex of proximal sesamoid bone; FX, fracture line in proximal sesamoid bone.

using a downcurved osteotome. A serrated meniscal knife is suitable for completion of the dissection of the fragment off the suspensory ligament (Fig. 11.12). The use of electrocautery for this dissection has also been reported.[20] Removal is completed with Ferris Smith rongeurs and may require enlargement of the portal for large fragments.

There are few reports of surgical excision of apical sesamoid fractures in a large number of horses. A retrospective study of 43 Standardbred race horses with apical sesamoid fractures showed a good prognosis following surgical removal, but the technique was not defined. Prognosis was not affected by the dimensions of the fracture nor by the degree of suspensory ligament damage.[21]

Articular abaxial sesamoidean fracture fragments

The approach for these lesions is similar to the approach for apical fracture fragments.[22] Sharp dissection of the fragment off the suspensory ligament can be performed entirely with a meniscal knife or similar instrument. Favorable results for return to racing were reported in a series of 47 horses. Non-race horses, horses with smaller fragments and horses with fragments that involved only the abaxial aspects of the bone had a better prognosis.[22]

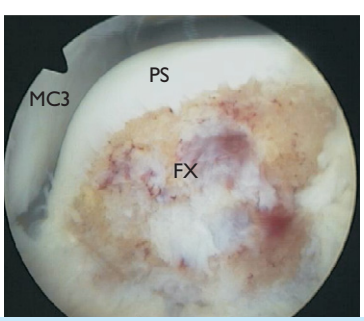

Fig. 11.12
Postoperative view of the apical sesamoid fracture in Fig. 11.11. MC3, median sagittal ridge of the distal third metacarpal bone; PS, proximal sesamoid bone; FX, fracture line in proximal sesamoid bone following removal of the apical fragment.

Chronic fetlock arthropathy and sepsis

Arthroscopy of the dorsal and palmar/plantar fetlock can be of value for joint disease that fails to respond to conservative treatment. Sepsis should be approached with appropriate medical therapy and through-and-through lavage can be achieved using dorsal and palmar/plantar portals.

The hock

Positioning

Most surgeons prefer to position the horse in dorsal recumbency and whether the arthroscopy is performed with the surgeon standing cranial to the limb and facing caudally or standing caudal to the limb and facing cranially is a matter of personal preference. The joint is placed in partial flexion in such a way that it can be flexed or extended during the surgery.

Dorsal tarsocrural joint

Arthroscopic approach

Once the saphenous vein has been identified, the standard arthroscopic portal is placed in the medial pouch of the tarsocrural joint just axial to the saphenous vein. Great care should be taken to avoid lacerating the vein. If the hock joint is sufficiently flexed the obturator and arthroscope sleeve can be advanced under the extensor tendons to the lateral reflection of the joint before inserting the arthroscope to commence the examination. Adjustments to this routine may be necessary for certain lesions.

Normal anatomy

The lateral reflection of the joint is first examined. Rotating the arthroscope proximally will bring the lateral malleolus into view. The lateral trochlear ridge (LTR) can be examined by withdrawing and rotating the arthroscope. As

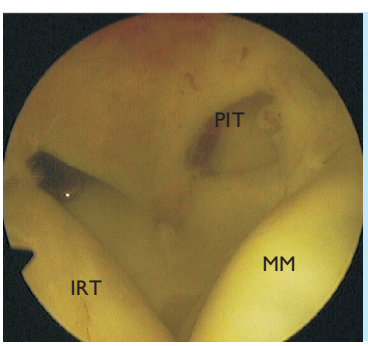

Fig. 11.13
Arthroscopic view of the mid tarsocrural joint showing the pouch over the proximal intertarsal joint (PIT), the intermediate ridge of the tibia (IRT) and the medial malleolus (MM).

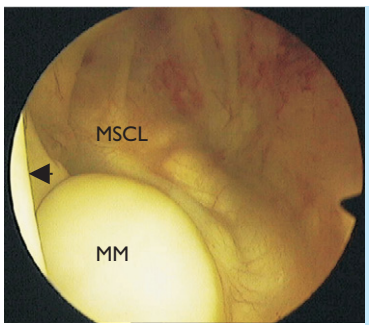

Fig. 11.14 Arthroscopic view of tarsocrural joint showing the medial malleolus (MM), the medial short collateral ligament (MSCL) and the edge of the medial trochlear ridge of the talus (arrow).

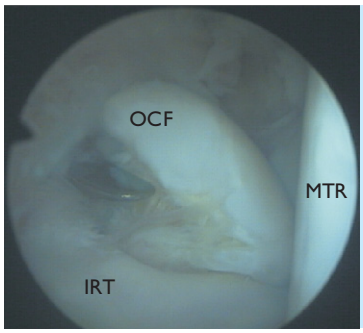

Fig. 11.15 Arthroscopic view of an OCD lesion on the intermediate ridge of the left tibia (IRT) being loosened with an elevator. OCF, osteochondral fragment; MTR, medial trochlear ridge of the talus.

the arthroscope is withdrawn further the intermediate ridge of the tibia, the axial aspect of the LTR and the proximal intertarsal joint come into view (Fig. 11.13) and finally the medial trochlear ridge (MTR), the medial malleolus and the medial short collateral ligament are visible when the arthroscope is withdrawn into the medial aspect of the joint (Fig. 11.14).

Plantar tarsocrural joint

Arthroscopic approach

The plantar aspect of the joint can be approached from the center of either the medial or the lateral outpouching of the joint.[23] With the joint flexed in a right angle the arthroscope sleeve and obturator can be passed across the joint before inserting the arthroscope.

Normal anatomy

From the plantaromedial portal the lateral malleolus is viewed by looking dorsally in the lateral reflection of the joint. With the arthroscope in the midjoint region the distal intermediate ridge of the tibia, the MTR and the LTR will lie dorsally and the synovial sheath of the deep digital flexor tendon will lie plantarly in the field of view. Withdrawing the arthroscope medially allows inspection of the MTR and the medial reflection of the joint but the medial malleolus is not visible. From the plantarolateral portal the same midjoint structures can be inspected and when examining the lateral reflection of the joint from the lateral side, the talocalcaneal ligament and the lateral malleolus are visible. Examination of the joint is facilitated by flexion and extension as required.

Indications for arthroscopy of the hock, specific techniques and results

Osteochondrosis dissecans (OCD)

The intermediate ridge of the tibia (IRT) in the dorsal tarsocrural joint is the most frequent site for OCD lesions in the hock.[24] Lesions are also encountered on the LTR, the medial malleolus and occasionally on the MTR.[24] OCD lesions in the hock may be an incidental radiographic finding and the decision to treat them surgically depends on there being evidence that they are causing clinical signs. When operating IRT lesions the instrument portal should be relatively dorsal in the lateral pouch and before making the incision the exact position of the portal can be confirmed using a 9 cm spinal needle to ensure that the whole lesion is accessible through the portal. Fragments often require loosening with an osteotome (Fig. 11.15) before being grasped with Ferris Smith rongeurs for removal. They should not be completely freed since they can be difficult to grasp when loose in the joint. The instrument portal may need to be enlarged for large fragments so it is preferable to remove smaller fragments first while joint distension is maintained. The lesion site is curetted smooth and all debris flushed from the joint at the end of surgery.

LTR lesions are more difficult to treat arthroscopically. Some surgeons prefer to place both the arthroscopic and instrument portals ipsilaterally since the distal part of the LTR is difficult to view from the medial position because of the extensor tendon. However, increasing joint flexion improves the view from the medial portal and this approach gives better triangulation. Medial malleolus lesions are best treated with both portals ipsilateral.

A 76.5% success rate for return to normal function has been reported for arthroscopic treatment of OCD lesions in the hock.[24] The size of IRT lesions did not affect outcome but accompanying degenerative joint disease worsened the prognosis. Resolution of synovial effusion was seen in approximately 80% of horses but was worse for medial malleolus and LTR lesions.

Intra-articular fractures

Some fractures in the hock that involve intra-articular fragmentation can be treated by arthroscopic removal of the fragments and debridement of the fracture bed. Care should be taken to ensure that the fractures do not extend into major supporting bones since there is a high chance of disintegration of the bone during anesthetic recovery. The approach depends on the site of the lesion but the standard portals are often appropriate. Some smaller lateral malleolus fractures can be removed arthroscopically. A dissecting instrument such as a meniscal knife is needed to resect the fractured fragment from its attachments.

Chronic arthropathy unresponsive to conservative treatment

Arthroscopic evaluation of the dorsal and plantar aspects of the tarsocrural joint can be useful diagnostically,

prognostically and for debridement of intra-articular lesions. Appropriate debridement of lesions and lavage of debris from the joint should improve the horse's comfort. Lesions in the short lateral collateral ligament will sometimes be evident arthroscopically and can also be debrided.

Septic joint disease

This indication is common to all the synovial spaces described in this section but it is especially common in the tarsocrural joint as a sequel to hock trauma. It requires aggressive treatment. Arthroscopic treatment often involves both dorsal and plantar pouches of the joint for investigation of the injury and for through-and-through lavage. Osteomyelitic lesions can develop particularly on the trochlear ridges and should be debrided by curettage to healthy tissue.

The stifle

Femoropatellar joint

Positioning

Most surgeons prefer operating this joint with the horse in dorsal recumbency. The limb must be in extension in order to allow the arthroscopic sleeve to pass easily under the patella into the suprapatellar pouch (Fig. 11.16). If the limb is positioned vertically the arthroscope can be held with the surgeon's arm passing caudally around the limb, which some find more comfortable, and this marginally increases the space beneath the joint capsule in the distal joint. The monitor is placed cranially and the surgeon faces forwards. The joint can also be operated with the limb extended more caudally so that the surgeon works with both hands on the cranial side of the limb.

Arthroscopic approach

For most procedures the arthroscopic portal is sited between the lateral and middle patellar ligaments midway between the patella and the tibial crest. In many horses a small blood vessel traverses just proximal to this site when the limb is vertical. Unless the joint is pathologically distended, at least 60 mL of fluid will be required for sufficient distension to lift the patella off the intertrochlear groove and permit the arthroscope sleeve and obturator to be passed into the suprapatellar pouch. If this is difficult, it may be facilitated by further distension of the joint.

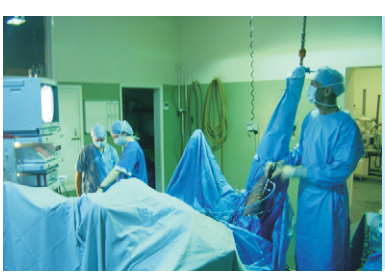

Fig. 11.16
Positioning for arthroscopy of the femoropatellar joint with the leg extended vertically.

Normal anatomy

The examination commences in the suprapatellar pouch where loose debris will accumulate. As the arthroscope is withdrawn, the base of the patella and proximal intertrochlear groove of the femur come into view. The articular surface of the patella and intertrochlear groove can be examined as the arthroscope is steadily withdrawn from beneath the patella. Once clear of the patella, its apex can be inspected followed by both medial and lateral trochlear ridges (MTR and LTR) to their most distal points where the plicae covering their communications with the medial and lateral femorotibial (MFT and LFT) joints are present in most horses.

Indications for arthroscopy of the femoropatellar joint, specific techniques and results

Osteochondrosis dissecans

In the femoropatellar joint (FP), OCD is most frequently encountered on the LTR (Fig. 11.17) and also occurs, though less commonly, on the patella, the intertrochlear groove (ITG) and MTR.[25] Both limbs are often affected. Before making the instrument portal a spinal needle is used to check that all the lesions can be reached at the correct angle, since a wrongly positioned portal may make it impossible to treat some of the

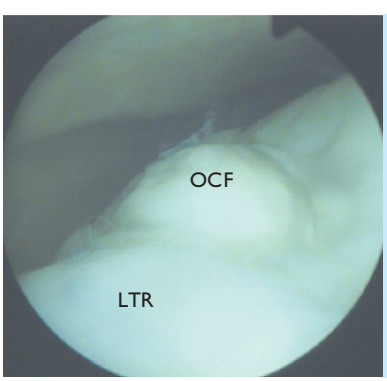

Fig. 11.17
OCD lesion containing attached osteochondral fragments on the lateral trochlear ridge of the right femur (LTR). OCF, osteochondral fragments.

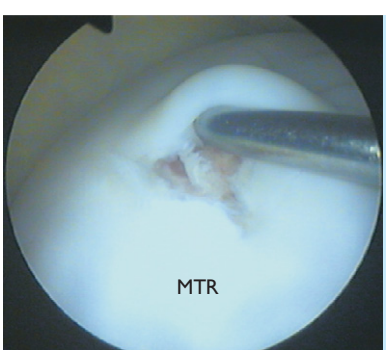

Fig. 11.18
OCD lesion on the medial trochlear ridge (MTR) of the left femur of a yearling Thoroughbred gelding. Probing has revealed poorly attached soft articular cartilage.

lesions. Most lesions can be reached from a lateral portal but an extra portal can be used if necessary. Osteochondral fragments may need partial loosening with an osteotome before removal with Ferris Smith rongeurs and following removal, the remainder of the lesion should be curetted to healthy subchondral bone. This can be achieved with both spoon and loop curettes, rongeurs and motorized equipment. Some lesions, particularly in foals and yearlings, appear as soft articular cartilage but when probed this peels off its attachment (Fig. 11.18). In older horses there may be associated degenerative change in the articular cartilage. Loose fibrillated cartilage can be trimmed with a synovial resector or a coblation wand. Many patellar, ITG and MTR lesions can be reached from the lateral instrument portal but if not, a more appropriate position is used.

The removal of debris and osteochondral fragments from the suprapatellar pouch is an inevitable part of arthroscopic surgery of OCD lesions in the FP joint. Long Ferris Smith rongeurs (shaft length 20 cm) are very useful for removing fragments and a long, wide-bore egress cannula in conjunction with high fluid flow rates and suction will effectively remove loose debris. Retrieval of fragments through a portal proximal to the patella into the suprapatellar pouch is also possible in the absence of long instruments, but it is difficult to maintain this portal because of the distance from the skin to the joint capsule. An alternative portal that is easier to manage can be made laterally between the proximal patella and the proximal edge of the LTR.

Occasionally very large fragments will be encountered and very large rongeurs are needed to remove them. Fixing the fragment with a spinal needle passed transcutaneously facilitates grasping it with the rongeurs. The instrument portal may need to be enlarged considerably when the fragment is extricated.

In one report 64% of 161 horses treated by arthroscopic surgery returned to athletic use.[25] Best results were seen in older horses and those with mild lesions. From a series of 57 horses operated at the author's practice, 83% returned to athletic use and the presence of associated degenerative change on the articular cartilage did not affect the prognosis (JP Walmsley and TJ Phillips, unpublished data, 2002).

Fractures of the patella

Fractures of the patella that can be treated by arthroscopic excision of the fracture fragment include medial sagittal, basilar and some apical fractures. These fractures can be evaluated from the standard arthroscopic portal, though some basilar fractures may be better assessed from a portal developed medially or laterally just proximal to the base of the patella. Medial sagittal fractures (Fig. 11.19) require dissection off their attachments to the parapatellar fibrocartilage of the medial patellar ligament, which can be difficult and extensive. Meniscal knives are useful instruments for this procedure. The prognosis for medial sagittal fractures treated by excision arthroscopically is reasonably good. In one case series of 12 horses 10 returned to full use.[26] Basilar fractures sometimes accompany other trauma in the joint. An appropriate instrument portal medial or lateral and proximal to the base of the patella will be necessary for removal of fragments. Some small fragments become embedded in the local soft tissue and may not cause lameness. Apical fracture fragments that can be removed arthroscopically are unusual but are approached as for fragmentation lesions.

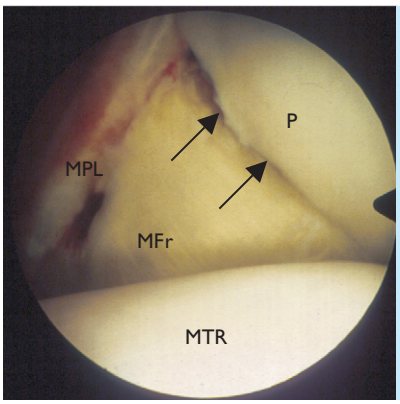

Fig. 11.19 Arthroscopic view of medial sagittal fracture of the left patella (P). MFr, medial fragment of the patella; MPL, medial patellar ligament; arrows, fracture line; MTR, medial trochlear ridge of the femur.

Fracture fragmentation of the trochlear ridges

These fragments are usually present as loose bodies that have fractured off a trochlear ridge in the FP joint. It can be difficult to ascertain the source of the fracture. Following examination of the joint to assess the injury, the fragments are located and removed with rongeurs. They will usually fall into the suprapatellar space but they may be attached to the joint capsule and difficult to find. Any remaining lesions in the joint are debrided appropriately. Depending on the effect of any concurrent injuries, there is a good chance of return to athletic use following treatment.[27,28]

Fragmentation of the patella

This condition is usually a sequel to medial patellar desmotomy and requires arthroscopic debridement when it causes lameness.[29] It may develop without causing lameness. The fragments usually lie in the synovium just distal to the apex of the patella and the synovial villi may not be immediately visible. The arthroscopic portal can be placed slightly more distal than the standard site and the instrument portal is placed on the lateral side of the joint since the diseased patellar tissue mostly lies on the lateral side of the apex. The fragments are removed with rongeurs and the patellar lesion is curetted to healthy bone. The prognosis is favorable.[29]

Femorotibial joints

Positioning

If all accessible parts of the FT joints are to be examined, placing the horse in dorsal recumbency is preferred with the tibia horizontal and a hock angle of 90°. It is important to be

able to flex and extend the limb during surgery. The cranial and caudal compartments of the joints can be arthroscoped with the horse in this position though some surgeons partially extend the joint when examining the caudal compartments.[30] The surgeon operates facing cranially with the monitor placed cranial on the opposite side of the horse.

Arthroscopic approach, cranial compartments

Three approaches to the cranial compartments of the FT joints have been described.

Cranial approach[31] The arthroscopic portal for the medial femorotibial joint (MFT) is made 2 cm proximal to the tibial crest between the middle and medial patellar ligaments. The joint can be distended with 50 mL of fluid using a spinal needle inserted medial to this site over the medial femoral condyle (MFC), which is a useful, easily palpable landmark. The instrument portal is at the site of the spinal needle, which if left in place can be manipulated to confirm that all the appropriate structures will be accessible through the portal. Its position can be readjusted if necessary. The lateral femorotibial joint (LFT) is approached from the MFT by first replacing the telescope with the conical obturator in the arthroscope sleeve and then passing it through the median septum and under the tendon of origin of the long digital extensor tendon (LDE) into the lateral aspect of the joint. This has to be done by feel and if positioning is correct the instrument should pass relatively easily across the LFT after the median septum has been penetrated. The LFT instrument portal lies about 6 cm lateral to the arthroscopic portal. Because of the distance between the joint capsule and the skin, the portal should be carefully sited with a spinal needle before making the incision. When creating portals in the FT joints, advancing the scalpel until it is visible within the joint facilitates the subsequent passage of instruments. Care must be taken not to catch the hilt of the scalpel in subcutaneous tissue so that it is pulled off the handle whilst being retrieved.

Lateral approach[32] Used mainly for surgical treatment of subchondral bone cysts in the MFC, this portal lies between the lateral patellar ligament and the tendon of origin of the LDE, 2 cm proximal to the tibial plateau. The arthroscopic obturator and sleeve are inserted parallel to the tibial plateau and passed through the LFT into the MFT. This is facilitated by palpating the MFC and aiming across the joint at it. The instrument portal is positioned over the lesion.

Approach from the FP joint This approach follows examination of the FP joint and the limb is maintained in extension (KJ Boening, personal communication, 1992). It is more easily performed with a longer arthroscope. The slit-like communication with the MFT is viewed and dissected open with arthroscopic scissors. A window is then created in the septum between the FP and FT joints. This approach provides a good view of the axial parts of the FT joints but poor access to their lateral and medial aspects.

Normal anatomy

From the cranial approach the surgeon's landmark is the medial intercondylar eminence of the tibia (MICET). The median septum occupies the axial field of view and partially covers the cranial cruciate ligament (CrCL), which can be palpated with the arthroscopic probe beneath its fascia. In the caudal aspect of the MFT the caudal cruciate ligament (CaCL) is seen extending from the roof of the intercondylar notch of the femur distally towards its caudal tibial insertion. Moving medially, the cranial aspect of the articular surface of the MFC can be viewed. The cranial pole of the medial meniscus (MM) lies between the MFC and the tibial plateau, and the cranial ligament of the medial meniscus (CrLMM) extends from the MM to the cranial border of the MICET (Fig. 11.20). When examining the LFT by the cranial approach, the popliteal tendon in the most lateral aspect of the LFT joint will be the first structure viewed. As the arthroscope is withdrawn it will slip out from underneath the LDE, which can then be followed proximally to its origin in the lateral femoral condyle (LFC). In the more axial part of the joint the lateral

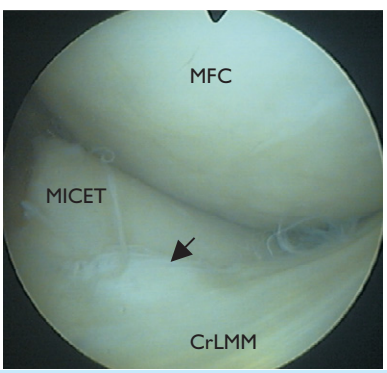

Fig. 11.20
Arthroscopic view of the right medial femoral condyle (MFC), the medial intercondylar eminence of the tibia (MICET) and the cranial ligament of the medial meniscus (CrLMM). There is fibrillation of the axial border of the ligament (arrow).

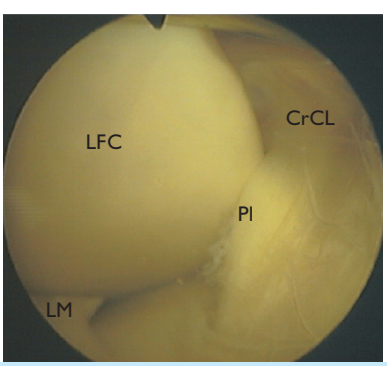

Fig. 11.21
Arthroscopic view of the right lateral femoral condyle (LFC), the cranial pole of the lateral meniscus and its cranial ligament (LM). The cranial cruciate ligament lies under the median septum in the right of the picture with the plica-like branch (PI) coursing towards the tibial plateau.

meniscus (LM) and its cranial ligament have a similar configuration to their medial counterparts. Axial to this the CrCL is almost completely covered by the median septum and a small plica-like branch of the ligament is present at about the level of the articulation of the LFC and tibial plateau (Fig. 11.21).

Arthroscopic approach to the caudal compartment of the medial femorotibial joint

The author prefers to position the stifle in flexion for this procedure, though some authors suggest positioning in partial flexion[30] and others in extension.[33] Distension of the caudal MFT is achieved through a 9 cm spinal needle placed just proximal and caudal to the caudal most palpable point of the medial tibial condyle. The arthroscopic portal is placed about 2 cm caudal to this and the sleeve and blunt obturator aimed towards the caudal articulation of the femur and tibia. The joint capsule lies approximately 3 cm deep to the skin. Sharp trocars should only be used for penetration of either caudal FT joint with great caution because of the risk of penetrating the popliteal artery, which lies between the two caudal compartments of the FT joints. The instrument portal is placed according to the position indicated by spinal needle guidance.

Normal anatomy

The relatively large sac of the caudal MFT is easily inspected. The caudal articular surface of the femur can be followed to its articulation with the medial meniscus on the tibial condyle. In the axial aspect of this articulation the caudal ligament of the medial meniscus can usually be seen and caudal to this the outline of the CaCL is detectable in most horses where it lies deep to the synovial membrane as it courses from its distal attachment to its femoral insertion proximomedially between the femoral condyles (Fig. 11.22).

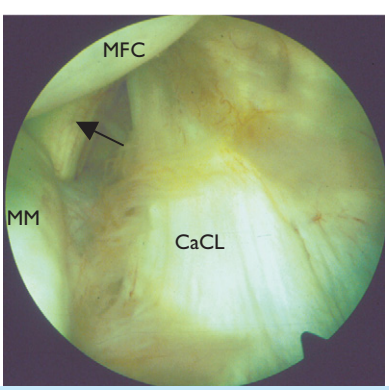

Fig. 11.22
Arthroscopic view of the left caudal compartment of the medial femorotibial joint, showing the caudal cruciate ligament (CaCL) under the synovial capsule and the caudal ligament of the medial meniscus (arrow). MFC, medial femoral condyle of the femur; MM, medial meniscus.

Arthroscopic approach to the caudal compartment of the lateral femorotibial joint

Arthroscopy of this joint is easier with the stifle partially flexed.[30,33,34] The joint is divided by the popliteal tendon. Distension is best achieved through a spinal needle inserted caudal to the lateral collateral ligament and just proximal to the level of the tibial plateau. The arthroscope portal for the joint proximal to the popliteal tendon is situated 2.5 cm proximal to the tibial plateau and 3 cm caudal to the collateral ligament. The distal part of the joint is entered through a portal which lies at the level of the tibial plateau and 1.5 cm caudal to the lateral collateral ligament. The common peroneal nerve lies approximately 7 cm caudal to the lateral collateral ligament, so all portals should be sited cranial to this. The instrument portal is placed according to the position indicated by spinal needle guidance.

Normal anatomy

Proximal to the popliteal tendon, apart from the tendon itself, the caudal part of the lateral femoral condyle is the main structure identified. Through the distal portal the LFC and caudal lateral meniscus are visible.

Indications for arthroscopy of the femorotibial joints, specific techniques and results

Stifle lameness unresponsive to conservative treatment

Diagnostic and therapeutic arthroscopy of the FT joints of horses whose lameness is alleviated by intra-articular analgesia and which does not respond to conservative treatment is one of the most frequent indications for arthroscopy of the FT joints (240 in a series of 403 stifle arthroscopies performed at the author's hospital).[35] Lesions most likely to be encountered are articular cartilage injuries, meniscal tears and cruciate ligament lesions. Multiple lesions are common which emphasizes the importance of a careful examination of the whole joint.

Articular cartilage lesions vary from severe, extensive, full-thickness lesions to mild fibrillation of the surface of the cartilage. Treatment involves debridement of loose material, but only full-thickness defects should be curetted to subchondral bone. Large areas of denuded bone may benefit from micropicking.[2] With careful management and in the absence of other injuries, the prognosis for primary articular cartilage lesions is reasonable. In one study six out of seven focal lesions returned to racing though five horses with larger lesions remained lame.[36] In the author's practice, 44 horses with cartilage lesions out of 61 followed up returned to full use but there was no differentiation between size of lesions in the study.

Meniscal and meniscal ligament tears are more common in the medial meniscus.[37] Loose tissue should be resected

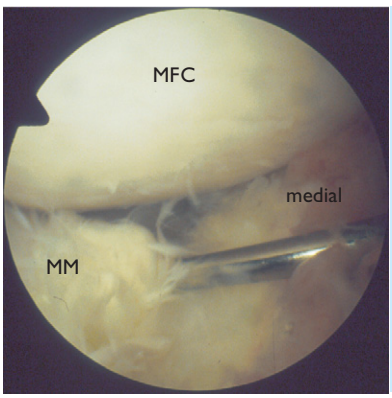

Fig. 11.23 Arthroscopic view of a torn right medial meniscus (MM) with associated articular cartilage lesions on the medial femoral condyle (MFC).

wherever possible although in more severe lesions some of the damaged tissue will be inaccessible beneath the femoral condyle. The prognosis is statistically related to severity of injury and it is worse if there are concurrent cartilage lesions[37] (Fig. 11.23). Of 80 horses which were diagnosed with meniscal tears by arthroscopy at the author's hospital, 33 out of 70 horses followed up returned to full use.[37]

Cruciate ligament injuries are more difficult to assess because of the covering of synovium and median septum. This can be removed with a synovial resector to improve the visualization of the ligament but care should be taken to avoid hemorrhage. Light debridement of loose tissue is all that can be achieved with mild to moderate lesions and over 50% can be expected to return to use. Severe lesions, which are sometimes accompanied by avulsion fractures, require more drastic debridement and have a poorer prognosis.

Subchondral bone cysts and osseous cyst-like lesions

Subchondral bone cysts (SBC) in the distal MFC and more rarely in the proximal tibia can be treated surgically. Surgical treatment is generally considered to be indicated for articular lesions and those that have not responded to conservative treatment.[38–40] Small articular defects on the MFC can be worsened by aggressive debridement. The use of the lateral arthroscopic portal permits better triangulation with the standard instrument portal, which is sited over the lesion, but the cranial arthroscope portal can also be used. The articular defect may be quite small (Fig. 11.24) but a probe can easily be pushed through into the subchondral lesion if the cyst communicates with the joint. All the contents of the cyst should be removed. Hooked curettes can be useful for curetting the sides of the lesion. Postoperatively intralesional treatment with corticosteroids has been advocated to suppress inflammatory mediators which are thought to contribute to the development of the cyst.[41] Forage of the subchondral bone can provoke worsening of the lesion[38] and one study showed that a cancellous bone graft in the lesion did not improve the outcome.[42] Over 70% success has been reported in young horses[38,40] but the author has noted that worse results might be expected in horses over 3 years old though this has not been analyzed statistically.

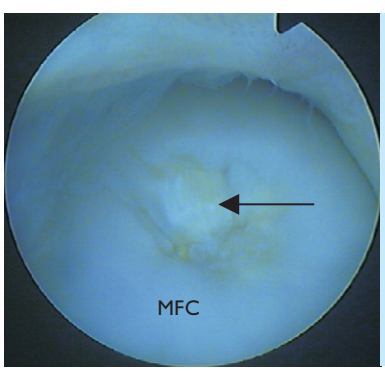

Fig. 11.24 Arthroscopic view of articular cartilage lesion (arrow) associated with a subchondral bone cyst in the medial femoral condyle (MFC).

Most tibial SBCs can be approached from the cranial arthroscopic and instrument portals though some may lie beneath the cranial meniscal ligament and if very abaxial, may not be accessible.[43] Osseous cyst-like lesions in the caudal femoral condyles may be candidates for surgery if there is no response to conservative treatment; they are approached through the standard portals, the proximal lateral one being the more appropriate for LFC lesions.[33]

Fracture fragmentation of the femoral condyles

Small fracture fragments may occur in any compartment of the FT joints. They frequently accompany other joint injuries and a thorough examination of the whole joint is indicated. Fragments may require dissection from their soft tissue attachments. The prognosis depends on the extent of damage in the whole joint.

Fracture of the intercondylar eminence of the tibia

These fractures are not always associated with CrCL injuries and each should be assessed objectively. Some fragments can be removed by dissection off the fracture bed,[44] while internal fixation under arthroscopic control may be more appropriate if removal involves extensive soft tissue dissection.[45] Occasionally long-standing fractures will have healed by fibrous union and may be better left in situ. As for all traumatic FT injuries, other joint lesions are often present and a careful evaluation of the whole joint is essential. It is often the associated injuries that determine the prognosis.

Distal interphalangeal joint

Positioning

With the horse in dorsal recumbency and the foot fixed to a crossbar so that the distal interphalangeal (DIP) joint is in extension, good access to the dorsal aspect of the joint is obtained for both arthroscopic and instrument portals. By flexing the joint, this position is also appropriate for arthroscopy of the palmar/plantar aspect of the joint. If the

horse is placed in lateral recumbency it is more difficult to enter the joint from the lower side, but some surgeons prefer this approach as the lateral pouch is larger.

Arthroscopic approach

Dorsal joint Both the arthroscope and instrument portals for the dorsal aspect of the DIP joint are situated 2 cm abaxial to the midline and approximately 2 cm proximal to the coronary band.[46]

Palmar/plantar joint This is entered medially or laterally just proximal to the collateral cartilage, palmar/plantar to the second phalanx and dorsal to the deep digital flexor tendon.[47] The lateral pouch is larger.[47]

Normal anatomy

Dorsal joint The extensor process of the third phalanx lies in the immediate field of view, though it is often partially covered with synovium. The most proximal dorsal surface of the articular cartilage of the second phalanx can be inspected and proximal to this is the dorsal, proximal reflection of the joint.

Palmar/plantar joint The palmaro/plantaroproximal articular surface of the second phalanx and proximal border of the navicular bone are readily seen and distension of the joint increases the area of observable articular cartilage (Fig. 11.25). Underlying the joint capsule the collateral sesamoidean ligament of the navicular bone can be viewed inserting on the proximal border of the navicular bone.

Indications for arthroscopy of the distal interphalangeal joint, specific techniques and results

Fracture fragmentation of the extensor process of the third phalanx and the distal second phalanx

Smaller fracture fragments are readily removed arthroscopically using the standard portals. It may be necessary to clear away synovium that sometimes obscures the fracture with a motorized synovial resector before loosening the fragment with an elevator and removing it with small rongeurs (Fig. 11.26). Larger fragments can be split with an osteotome or burred down to a manageable size with a motorized arthroburr; the latter is usually easier and less traumatic. Arthroscopy can also be used to assist internal fixation of very large fragments. The prognosis is generally good if there is minimal concurrent degenerative joint disease. In a series of 16 horses with fracture fragments of the extensor process treated by arthroscopic excision, 14 horses became sound.[46]

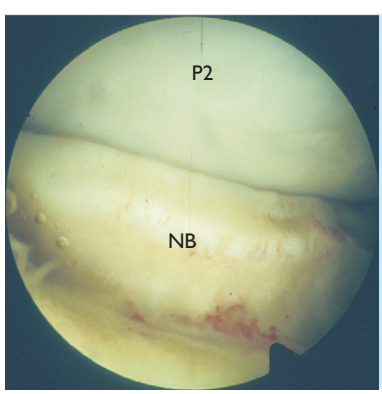

Fig. 11.25 Arthroscopic view of the palmar aspect of the left distal interphalangeal joint showing the proximal border of the navicular bone (NB) and the palmar articular surface of the second phalanx (P2).

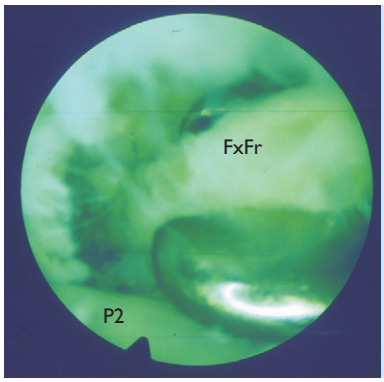

Fig. 11.26 Arthroscopic view of removal of a type IV fracture of the third phalanx with Ferris Smith rongeurs. FxFr, fracture fragment; P2, second phalanx.

Articular fracture fragments off the distal dorsal articular border of the second phalanx can sometimes be accessed and removed arthroscopically using a standard arthroscope portal and an instrument portal located over the fragment.[48] Some dissection is required to free the fragment.

Assessment of joint disease

Arthroscopic evaluation and debridement of degenerative joint disease can be of value.[49] From a series of 36 horses treated arthroscopically for chronic DIP joint disease at the author's hospital, 18 horses were followed up and eight of these returned to work for 1 year or more, though the prognosis for long-term soundness was poor.

The shoulder

Positioning

The shoulder joint is most easily examined with the horse in lateral recumbency, having the affected leg uppermost and slightly adducted.

Arthroscopic approach

Two arthroscopic approaches have been described. The arthroscope portal for the cranial approach, which the author prefers, is sited between the cranial and caudal eminences of the greater tubercle of the humerus.[50] An 18 gauge, 9 cm spinal needle is used to distend the joint with 60 mL of fluid. The arthroscope sleeve with conical obturator is passed into the joint and then advanced caudally under the infraspinatus tendon in the lateral aspect of the joint before

inserting the arthroscope. The arthroscope portal for the caudal approach is sited 1 cm caudal to the infraspinatus tendon[51] just proximal to the level of the humeral head. In order to widen the joint space curved, blunt-tipped forceps are passed into the cranial portal so that the tip of the forceps can be placed in the glenoid notch and used to lever open the joint.[51]

The instrument portal site depends upon the lesion to be operated and is usually more caudal. It should be carefully sited using a spinal needle. Some lesions are difficult to reach and almost impossible if the portal is incorrectly positioned. The portal should be accurately incised into the joint to create a smooth path for instruments since the skin is several centimeters from the joint capsule and extracapsular extravasation of fluid is almost inevitable during surgery. Adduction and traction of the limb provide more space between the articular surfaces.

Normal anatomy

The lateral rim of the glenoid is visible for its full length. The humeral head and articular surface of the glenoid can be examined but the caudomedial surfaces are difficult to see without extra joint separation or a 70° arthroscope lens. The cranial rim of the glenoid is clearly visible and the glenoid notch lies medially and caudally to this. Synovial bands lie in the caudolateral and craniomedial joint capsule and there is a single synovial band medial to the glenoid notch. The glenohumeral ligament may be seen under the joint capsule just caudal to the glenoid notch.

Indications for arthroscopy of the shoulder, specific techniques and results

Osteochondrosis dissecans

Lesions may involve the glenoid cavity, the humeral head or both of these and vary from deep areas of severe erosion to articular fissures only detectable on probing (Fig. 11.27). Medial lesions can be difficult to operate and it is almost impossible to perform a complete debridement of large caudomedial lesions. A right-angled curette is useful. Because of the development of extracapsular fluid, surgery should be performed as efficiently as possible. Bertone et al[52] reported a return to full athletic function in five out of 11 horses with shoulder OCD following arthroscopic surgery and a similar success rate of 45% from 49 horses operated was reported by McIlwraith.[53]

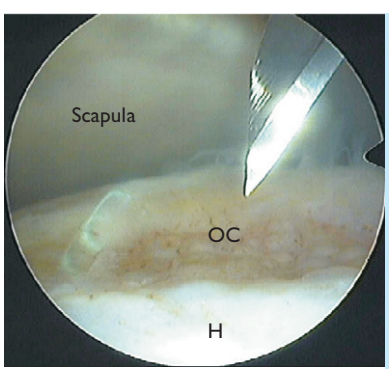

Fig. 11.27 Arthroscopic view of an OCD lesion (OC) on the lateral left humeral head (H). The scalpel is incising the instrument portal. The lateral margin of the scapula is in the top of the picture.

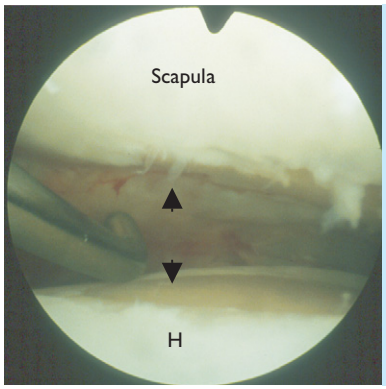

Fig. 11.28 Arthroscopic view of left midcranial shoulder showing full-thickness cartilage lesions (arrows) in the articular cartilage of the humeral head (H) and the scapula.

Articular cartilage lesions

Arthroscopy of the shoulder can be a worthwhile treatment for shoulder lameness, with or without abnormal radiographic signs, that has not responded to conservative treatment. Lesions include cartilage fissures, full-thickness cartilage defects, fibrillation of the cartilage surface, and humeral and glenoid subchondral cysts (Fig. 11.28). The lesions are debrided to healthy tissue and the joint lavaged. Twelve of 15 horses treated arthroscopically for these lesions returned to their previous use,[54] but in a series of 11 cases at the author's hospital only three out of eight followed up returned to full use. Scapulohumeral osteoarthritis in miniature horses has not responded well to arthroscopic treatment.[55]

The elbow

Positioning

Arthroscopy of the elbow is most easily performed with the horse in lateral recumbency. The affected leg is placed uppermost when operating from the lateral side and placed lowermost when operating the medial side. Flexion and extension of the joint should be possible during surgery.

Arthroscopic approach

For all approaches the joint can be distended with 100–200 mL of fluid using a 9 cm spinal needle inserted parallel to the joint surface caudal or cranial to the lateral collateral ligament.

Craniolateral approach The arthroscope portal is placed 2 cm proximal to the radial head and at the cranial border of the lateral condyle of the humerus.[56,57] The arthroscope

sleeve and conical obturator are passed to the medial side of the joint before inserting the arthroscope into the sleeve to commence the examination. The instrument portal is usually made slightly more cranial and medial to the arthroscope portal.

Proximocaudal approach When the joint is distended the synovial pouch in the olecranon fossa is palpable and a portal is created in the distal part of the outpouching.[56]

Caudomedial approach This is sited 2 cm distal to the radiohumeral articulation between the flexor carpi radialis and flexor carpi ulnaris muscles.[57] The instrument portal is placed caudal to and at the level of the joint articulation. The ulnar nerve lies caudal and the median nerve lies cranial to these muscles so these portals must be positioned accurately. This approach is a more hazardous access to the caudal joint than the proximocaudal approach but it allows a better view of the caudal, medial, humeral condyle.

Normal anatomy

Cranially both condyles of the humerus and the cranial proximal rim of the radius are visible. A synovial fossa usually divides the humeral condyles and there are synovial bands extending from the radius to the humerus in the midjoint region (Fig. 11.29). From the proximocaudal approach the lateral humeral condyle and part of the medial condyle can be seen together with the lateral aspect of the anconeus and caudal radius. The caudomedial approach provides a good view of the medial humeral condyle. The trochlear notch of the ulna can be followed caudad and more caudad still, in the caudoproximal sac, it is possible to see the medial epicondyle of the humerus, the deep digital flexor tendon and the cranial border of the ulna.[57]

Indications for arthroscopy of the elbow, specific techniques and results

In the author's hospital the main indication for arthroscopy of the elbow is sepsis. The craniolateral and proximocaudal portals can be used to obtain through-and-through lavage. Less commonly, the joint has been examined to evaluate chronic trauma, and potentially arthroscopy could be used for treatment of OCD lesions and subchondral bone cysts in the humerus if the lesions are accessible.

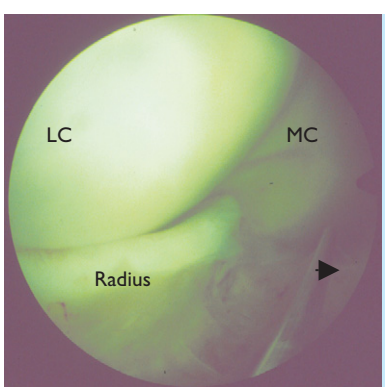

Fig. 11.29 Arthroscopic view of the right elbow from the craniolateral approach. The lateral (LC) and medial (MC) humeral condyles are visible and a probe is placed on the cranial synovial bands (arrow).

Endoscopy of the navicular bursa

Positioning

The horse is positioned in lateral recumbency with the affected leg uppermost and supported in the proximal metacarpal/metatarsal region. The foot is free so that it can be manipulated. A tourniquet is applied.

Endoscopic approach

The portal for the arthroscope is situated immediately proximal to the collateral cartilage on the abaxial border of the deep digital flexor tendon (DDFT) and axial to the palmar/plantar digital neurovascular bundle.[58,59] The author prefers to distend the bursa using a 9 cm spinal needle prior to introducing the arthroscope sleeve with the conical obturator. The sleeve and obturator are passed distally along the dorsal surface of the DDFT and into the bursa. If they are directed too dorsally or if the foot is overflexed the distal interphalangeal joint may be entered. When operating penetrating wounds the penetration track can usually be used as the instrument portal (Fig. 11.30). If not, an equivalent portal to the arthroscope portal on the contralateral side is used.

Normal anatomy

The impar ligament, most of the palmar/plantar surface of the navicular bone and opposing DDFT can be examined. Some flexion of the foot is required to examine the more distal part of the bursa. Abaxially the collateral ligament of the navicular bone is visible under the lining of the bursa. Because of the angle of entry into the bursa, the ipsilateral side is more difficult to examine.

Indications for endoscopy of the navicular bursa, specific techniques and results

Penetration of the navicular bursa

The penetration track can usually be used as the instrument portal for this procedure (Fig. 11.31). The lesions are debrided with hand tools and motorized equipment which is

Fig. 11.30 Endoscopy of the navicular bursa using the penetration in the frog as the instrument portal.

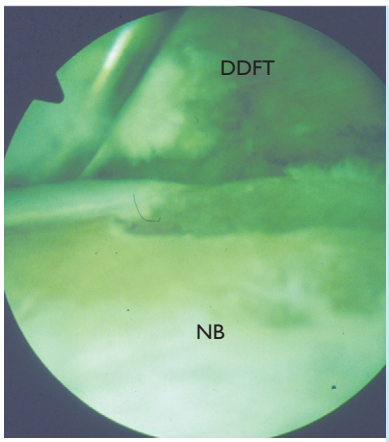

Fig. 11.31
Endoscopic view of the left fore navicular bursa which had sustained a penetrating wound 7 days previously. There is extensive cartilage loss on the navicular bone (NB) and a deep erosion in the bone. A probe has been passed into the bursa through the penetration in the deep digital flexor tendon (DDFT).

particularly useful for debriding the edges of the DDFT. In closed cases a contralateral portal to the arthroscope portal is used. An efficient lavage system is essential to achieve the pressure and quantity of fluid required for effective bursal lavage. Early reports on the use of bursoscopy for the treatment of navicular bursa penetrations show improved results compared with the open 'streetnail' procedure.[58,60]

Investigation for abnormalities in the navicular bursa

This has been postulated as a more sensitive method of identifying disease in the navicular bursa,[59] but at present there are no published reports on the value of the procedure.

Tenoscopy of the palmar/plantar digital sheath

Positioning

The digital sheath can be operated from its medial or its lateral side. The horse is placed in lateral recumbency with a tourniquet on the affected limb above the hock/carpus so that it does not obstruct the use of instruments parallel to the limb. The limb can be supported at the foot or above the fetlock.

Tenoscopic approach

Distension of the sheath can be effected with approximately 30 mL fluid either into the small outpouching of the digital sheath distal to the proximal digital annular ligament or into the sheath at the site of the arthroscope portal.[61] This lies between the proximal digital annular ligament and the annular ligament of the fetlock 1 cm distal to the base of the sesamoid bone and halfway between the ergot and the neurovascular bundle. An incision is made into the sheath and the arthroscope sleeve and a conical obturator passed obliquely into the sheath towards the contralateral side and lateral to the flexor tendons (Fig. 11.32). If the sleeve does not pass easily it should be redirected since the flexor tendons can readily be damaged by excessive pressure with the arthroscope sleeve and obturator. The digital sheath can also be entered proximally on the abaxial border of the superficial digital flexor tendon (SDFT).

Fig. 11.32
Tenoscopic annular ligament desmotomy using a meniscal knife.

Normal anatomy

Examination of the proximal part of the sheath can be hampered by the bulb of the heel obstructing manipulation of the arthroscope, but this can be partially alleviated by flexing the foot. On insertion of the arthroscope into the sleeve, its position will be either between the DDFT and SDFT, superficial to the SDFT or dorsal to the DDFT. Superficially an important landmark is the manica flexoria coursing around the DDFT. The attachment of the SDFT to the synovial capsule prevents examination of the contralateral surface palmar/plantar to the SDFT. The best access to the proximal reflection of the sheath is obtained by passing the arthroscope between the DDFT and the SDFT or dorsal to the DDFT. Directing the arthroscope into the distal sheath reveals the division of the SDFT overlying the DDFT. The straight sesamoidean ligament can be identified beneath the synovial lining dorsal to the DDFT. The branches of the SDFT can be followed to their insertion either side of the DDFT. The distal attachments of the digital sheath to the DDFT are visible by passing the arthroscope more distally.

Indications for tenoscopy of the palmar/plantar digital sheath, specific techniques and results

Annular ligament desmitis

This procedure can be performed using a proprietary slotted cannula and angle tip knife system (Smith and Nephew Dyonics Inc, Andover, Massachusetts)[62] but the author prefers to use a meniscal knife to cut the annular ligament under tenoscopic control (see Fig. 11.32). The arthroscope is passed proximally and superficially so that the manica flexoria is identified, confirming that the arthroscope lies between the SDFT and the annular ligament. An instrument portal is made proximal to the annular ligament and ipsilateral to the arthroscope following careful positioning with a hypodermic needle so that the portal can be viewed tenoscopically. The meniscal knife is passed through the portal to

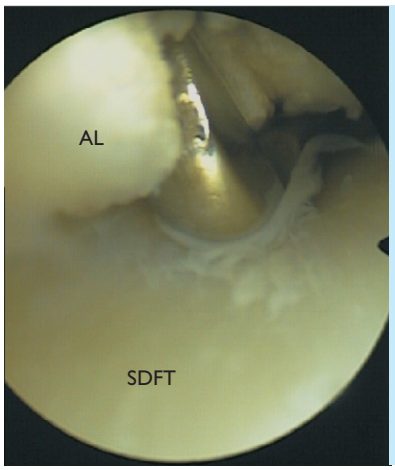

Fig. 11.33 Tenoscopic view of meniscal knife sectioning annular ligament (AL). SDFT, superficial digital flexor tendon.

the distal end of the annular ligament in order to cut the ligament by withdrawing the knife under tenoscopic control (Fig. 11.33). Confirmation that the distal end has been adequately released can be achieved by reversing the portals. Anecdotally there seems to be a better cosmetic result and very low incidence of incisional problems in comparison with open surgery. A comparison of the results of 56 desmotomies performed by open surgery and 45 desmotomies performed tenoscopically has been made at the author's hospital. Follow-up information was obtained on 32 and 28 horses respectively and of these, 63% treated by open surgery and 82% treated tenoscopically returned to work (Walmsley and Phillips, unpublished data, 2002).

Treatment of synovial masses, adhesions and manica flexoria injuries

These conditions often accompany annular ligament desmitis and have been named 'complex digital sheath tenosynovitis'[63] (Fig. 11.34). The lesions can be operated through the same portals used for annular ligament release. A motorized synovial resector may facilitate the resection of lesions and the debriding of the surface of the flexor tendons.[63] It is preferable to perform annular ligament desmotomy after debriding the lesions. Tenoscopic treatment for this condition has been reported for 25 horses, 75% of which returned to athletic use.[63]

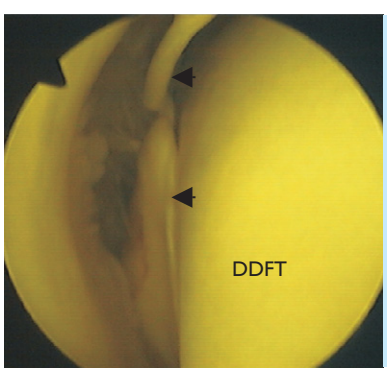

Fig. 11.34 Tenoscopic view of torn manica flexoria (arrows). DDFT, deep digital flexor tendon.

Tenoscopy of the carpal sheath

Positioning

For this procedure the horse can be positioned either in lateral recumbency, with the affected leg uppermost, or in dorsal recumbency. The carpus should be slightly flexed. A tourniquet is useful when using lateral recumbency.

Tenoscopic approach

The sheath is distended with 60–120 mL of fluid using an 18 gauge, 5 cm needle inserted at an angle of 60° distally between the ulnaris lateralis and lateral digital extensor tendons, 1.5 cm proximal to the distal radial physis.[64] The proximal arthroscope portal is sited 3 cm proximal to the radial physis and 2.5 cm caudal to the radius.[64] The distal portal can be made distal to the accessory carpal bone in the outpouching of the distended sheath.[65]

Normal anatomy[64–66]

Proximally the DDFT lies in the caudal aspect of the sheath and is joined by the radial head of the deep digital flexor muscle which courses from the cranioproximal aspect of the sheath. The accessory ligament (AL) of the SDFT, with its fibers running perpendicular to the radius, can be seen medial to the radius just caudal to the DDFT. The distal radial physis can be detected distal to the arthroscope portal and from here the DDFT can be followed medial to the accessory carpal bone to the distal end of the carpal sheath. The lateral border of the SDFT is found palmar to the DDFT and proximal to the antebrachiocarpal joint but the arthroscope cannot be passed medially between them because of an intertendinous ligament joining their medial borders.

Indications for tenoscopy of the carpal sheath, specific techniques and results

Osteochondroma of the distal radius

These lesions are viewed from a proximal portal. The osteochondroma can be separated with an osteotome and removed with large rongeurs.[67,68] The radius is then smoothed with a curette or burr and excessive fibrillation in the sheath removed with a synovial resector. Good results have been achieved in the few reported cases.[67,68]

Desmotomy of the accessory ligament of the superficial digital flexor tendon (AL-SDFT)

The use of this technique in experimental horses has been reported.[69] The arthroscopic portal lies 2–3 cm proximal to the distal radial physis in order to observe the proximal part of the

AL-SDFT underneath the radial head of the DDFT, and the limb is flexed to a right angle after distension of the sheath and insertion of the arthroscope. Using a meniscal knife, the ligament is sectioned under the DDFT as close as possible to its caudal edge where it joins the SDFT. The incision must be extended through the proximal end of the sheath in order to reach the proximal limit of the ligament and care must be taken to avoid the perforating vessel. Maintenance of sheath distension is important.

Other indications

These include tenosynovitis of the carpal sheath and any inflammatory condition of the sheath.

Tenoscopy of the tarsal sheath

Positioning

The horse can be placed in dorsal or lateral recumbency unless access to the lateral side of the proximal pouch is required.

Tenoscopic approach

Best access into both the proximal and the distal tarsal sheath is obtained through an arthroscopic portal sited on the medial aspect of sustentaculum tali (ST).[70] The incision is made through the retinaculum and the arthroscope sleeve and obturator are passed into the sheath proximally or laterally from this site since it is at the point where the DDFT changes direction within the sheath.[70] Portals into the proximal or distal pouches can be made at their most prominent points.

Normal anatomy[70]

The lateral deep digital flexor tendon (LDDFT) occupies the full length of the sheath. It is attached to the sheath by a mesotendon on its medial aspect. The proximal pouch is spacious. In the tarsal groove there is much less room but the arthroscope can still be directed either side of the LDDFT. The fibrocartilage covering the ST can be seen medial and dorsal to the LDDFT. In the distal pouch there is a clear demarcation between the fibrocartilaginous groove of the tarsal canal and the insertion of the accessory ligament of the DDFT. Dorsomedially there is a synovial fold attached to the LDDFT.

Indications for tenoscopy of the tarsal sheath, specific techniques and results

Sustentaculum tali injuries

Fractures or bony proliferations or other lesions of the medial border of the ST can be treated tenoscopically[70] (Fig. 11.35). Lesions extending beyond the medial plantar edge may require open surgery. In order to gain access to the lesion, the arthroscope portal described above can be used as an instrument portal and the arthroscope placed medially in the proximal pouch.

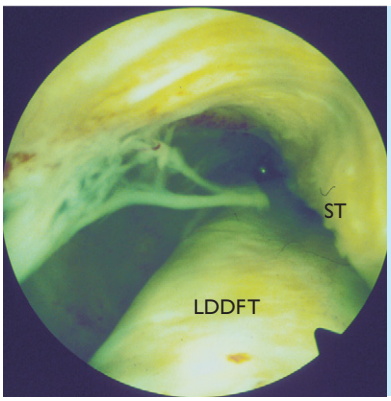

Fig. 11.35 Tenoscopic view of an infected right tarsal sheath from a proximal portal. LDDFT, lateral deep digital flexor tendon; ST, sustentaculum tali.

Chronic traumatic tenosynovitis, adhesions, nodular hypertrophic villi

Any chronic condition of the tarsal sheath that has not responded to conservative treatment may benefit from tenoscopy. Portal positions will depend on the lesions and radiographic and ultrasonographic preoperative assessment can be useful when determining the best portal sites.

Endoscopy of the intertubercular bursa of the humerus

Positioning

The horse should be placed in lateral recumbency with the affected leg uppermost. It is useful to be able to extend the limb cranially and abduct the limb during endoscopy.

Endoscopic approach

The bursa is distended with 100 mL of fluid through a 9 cm, 18 gauge spinal needle. The distal arthroscope portal is sited 2–3 cm proximal to the deltoid tuberosity on the dorsolateral aspect of the humerus.[71] The arthroscope sleeve and obturator are advanced proximomedially through the brachiocephalicus and caudal to the biceps brachii muscles into the bursa on the dorsal surface of the humerus. The proximal portal can be sited endoscopically using needle placement to position the portal, which is 2–3 cm proximal to the greater humeral tubercle and lateral to the biceps brachii tendon.[71] Either portal can be used as an instrument portal.

Normal anatomy

From the distal portal the distal medial and lateral aspects of the humeral tubercles and the intertubercular grooves can be

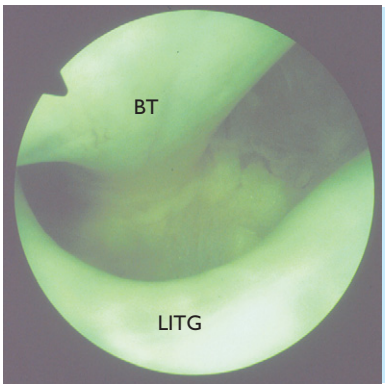

Fig. 11.36 Endoscopic view of left bicipital bursa from the distal portal. The lateral lobe of the tendon of the biceps brachii (BT) lies above the lateral intertubercular groove (LITG).

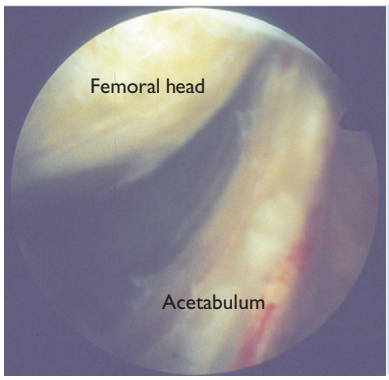

Fig. 11.37 Arthroscopic view of right coxofemoral joint. There is extensive cartilage loss on the femoral head and acetabulum.

seen caudal to the biceps brachii. The two diverging lobes of the biceps brachii lie in the intertubercular grooves. The proximal recess is viewed by passing the arthroscope proximally along the lateral aspect of the biceps brachii (Fig. 11.36). The proximal recess can also be examined from the proximal portal. The medial intertubercular groove is inaccessible to instruments from these portals.

Indications for endoscopy of the intertubercular bursa, specific techniques and results

Traumatic bursitis

In the author's experience sepsis of the bursa is the most frequent indication for endoscopy and this has also been reported,[72] but chronic aseptic bursitis is an occasional indication for endoscopy. Lesions involving the medial aspect of the bursa are difficult to access and may not be treatable endoscopically.

Joints seldom approached arthroscopically

Proximal interphalangeal joint

Arthroscopy of this joint is occasionally indicated for removal of bone fragments[73] or treatment of sepsis. There is very little room to maneuver in this joint. The horse can be placed in dorsal or lateral recumbency. Following distension of the joint, the arthroscopic portal is made medial or lateral to the extensor tendon at the distal edge of the distended joint capsule. The position of the instrument portal can be decided by needle placement over the lesion.

Coxofemoral joint

Arthroscopy can be useful diagnostically and therapeutically in horses with traumatic injuries, osteochondrosis and sepsis in the coxofemoral joint[74,75] (Fig. 11.37). For horses whose bodyweight is greater than 300 kg all instrumentation must be 25 cm long.[74]

With the horse in lateral recumbency the joint is distended and the arthroscope portal made over the notch between the cranial and caudal prominences of the greater trochanter of the femur. The arthroscope sleeve with its obturator is advanced along the femoral neck into the joint. The margins of the acetabulum and femurs can be examined but axial traction on the limb is necessary to view the central part of the joint and the round ligament. The medial joint is difficult to examine, particularly in adults. A 70° arthroscope improves the examination of the caudomedial and craniomedial aspects of the femoral head.[74] The instrument portal is made 4–6 cm cranial to the arthroscope portal and checked by needle placement.

Temporomandibular joint

This joint is divided into a smaller ventral compartment (discomandibular joint) and a larger dorsal compartment (discotemporal joint) by an intra-articular disc. Disorders of the joint include degenerative joint disease, tearing of the articular disc and sepsis.[76] Ultrasonography can be used to identify the joint space between the lateral eminences of the temporal bone and the mandibular condyle,[76] as well as identifying the overlying parotid salivary gland and facial vessels. When the joint has been distended with 5 mL of fluid, the discotemporal joint is entered caudodorsally at the center of the outpouching.[76,77] A standard 4 mm arthroscope can be used but there is very little room to maneuver it. The discomandibular joint is a smaller joint and can only be entered rostrolaterally.[76] The facial vessels lie close to the site of access. Only the lateral part of either joint can be examined.

CHAPTER 12

Biomechanics of locomotion in the athletic horse

Eric Barrey

Introduction

The horse is a superathlete which often suffers from injuries of its locomotor apparatus because of human management errors (nutrition, training, shoeing, breeding), bad environmental conditions (tracks, weather) and/or an unfavorable constitution (limb conformation, genetics). In stables specializing in gallop racing, about 53–68% of the wastage in race horses is due to lamenesses.[1,2] This economical disaster justifies the great effort now being put into equine locomotion research, including clinical applications and techniques for preventing lameness. Currently, economic constraints also favor the development of early performance evaluation in order to improve the training and selection of young horses.

This chapter presents a review on equine locomotion and the applications of gait analysis. Current knowledge concerning the equine locomotion variables in various sporting disciplines and the influence of training are discussed. Finally, a survey of the practical applications of equine gait analysis will be presented.

Locomotion analysis

The body of the horse is composed of a set of rigid segments articulated one to another. Consequently, the body of the horse follows exactly the same mechanical laws as a series of

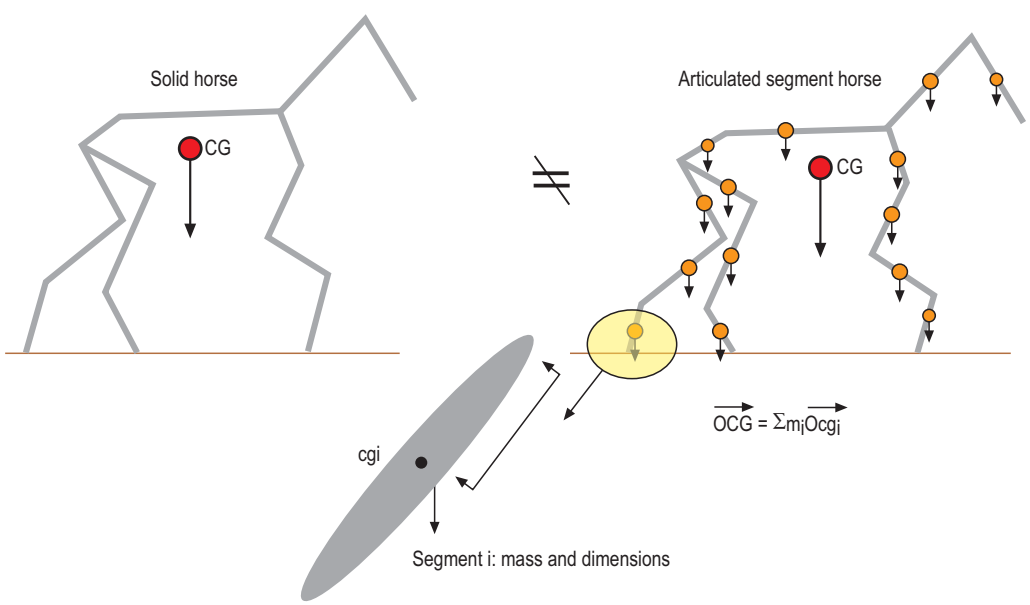

Fig. 12.1
A horse mechanical model composed of articulated body segments. It is very different from a mechanical model with only one solid segment. For each segment (i) of the body, the center of gravity (cg_i) and the moment of inertia can be calculated. The location of the general center of gravity (CG) of the horse can be calculated by considering the mass and the co-ordinates of each center of gravity segment. Reproduced from Barrey E. Methods, applications and limitations of gait analysis in horses. The Veterinary Journal 1999; 157:7–22.

Physical sensitivity	Visual

inanimate objects (Fig. 12.1). However, these laws need to be applied carefully because the mechanical equations which determine the motions of a set of articulated body segments are much more complicated than those that determine the motion of a single inanimate object like a bullet. There are two complementary methods for studying the body in motion: kinetics and kinematics (Box 12.1).

- *Kinetics or dynamics* studies the cause of the motion, which can be explained by the force applied to the body, its mass distribution and its dimensions. Kinetics is concerned with forces, energy and work which are also related to kinematic variables such as acceleration and velocity. Acceleration can be directly measured by specific sensors. However, acceleration is defined as an instantaneous change of velocity (i.e. the derivative of the velocity against time). Consequently, it can be deduced from velocity data obtained in kinematics by displacement measurements.
- *Kinematics* studies the changes in the position of the body segments in space during a specified time. The motions are described quantitatively by linear and angular variables which relate time, displacement, velocity and acceleration. No reference is made in kinematics to the cause of motion. The kinematic approach is more commonly employed, probably because it is easier to measure and visualize some displacements or velocities than to measure and imagine some forces, moments or accelerations applied to the body.

Kinematic analysis

The use of chronophotography was first developed by Muybridge and Marey for animal locomotion analysis. Currently new technology, using high-speed cameras (16 mm, 500 images/s), is used for example to film the locomotion of Standardbred horses from a camera car under track conditions.[3] Markers are used which are composed of small white spots or half spheres glued onto the skin over standard anatomical locations (Fig. 12.2A).[4,5] They are intended to indicate the approximate instantaneous center of rotation of the joint.[6,7] However, the skin displacements over the skeleton during locomotion generate some artifacts, especially in the proximal joints.[8,9]

The processing of the film for collecting the joint marker co-ordinates is undertaken using a computer. This is a relatively time-consuming task but many time and linear characteristics of the strides can be obtained for describing individual gait variations. With the improvement of the video camera sensors (CCD) many professional high-speed video cameras (100–2000 images/s) and home video cameras (PAL or NTSC Standard: 25–30 images/s or 50–60 frames/s) can be employed for locomotion analysis. The video signal can be treated by a video interface in order to digitize the images which are then analyzed by the appropriate software to collect semiautomatically or automatically the marker co-ordinates in space and time.[10] A more sophisticated motion analysis system uses active markers which consist of photodiodes (modified Cartesian Optoelectronic Dynamic Anthropometer; CODA-3). The advantage of this system is its good resolution (0.2–2.6 mm) in three dimensions, high recording frequency (300 Hz) and the automatic tracking possibilities of the active markers.[11] The main disadvantage is that the subject needs to be equipped with many photodiodes connected to wires.

Most equine locomotion studies show two-dimensional motion analysis but some systems with four or more video cameras make it possible to reconstruct the motion in three dimensions and to analyze the limb motions of both sides.[12,13] One limit of these sophisticated gait analysis systems is the restricted field of view. This is only about 5 meters which corresponds to several walking strides or one trotting stride. In order to analyze sporting exercise in a wider field (up to 30 m), a camera panning technique has been developed and used to study gait parameters in dressage and jumping horses.[10,14,15] This technique can be used for the kinematic analysis of athletic locomotion under real exercise conditions (Fig. 12.2B).

After filming, the operator needs to track manually, semiautomatically or automatically, the co-ordinates of the markers on each image of the film. In most of the systems, the tracking phase is a long task because there are many images to analyze and as the markers are not always easy to detect automatically, manual supervision is required. Nowadays, the use of specific algorithms such as direct linear transform (DLT) is an efficent way to automatically determine the trajectory of the markers. This makes it possible to use these systems for practical applications such as lameness quantification or athletic gait evaluation.

After collecting the co-ordinates of the markers, the linear and angular velocities can be obtained by computing the first derivative of the trajectories and angles with respect to time. If the filming image frequency is high, the second-order derivative of a trajectory or angular variation with respect to time, using appropriate smoothing and filtering techniques, provides linear and angular acceleration data. The advantage of kinematics methods is that you can obtain all the kinematic parameters (displacement, velocity, linear acceleration, angle of rotation, angular velocity and angular acceleration) of the identified segments. If the center of gravity and the moment of inertia of each segment can be determined by measuring their mass distribution and dimensions, it is possible to calculate the kinetic parameters (forces and kinetic moment), which determine the motion of each segment, from the kinematic data. Finally, the kinetic energy can be estimated for each segment and for the whole body in motion. Several methods have been described to estimate the location of center of gravity and the moment of inertia of each segment (Fig. 12.2C).[15–17]

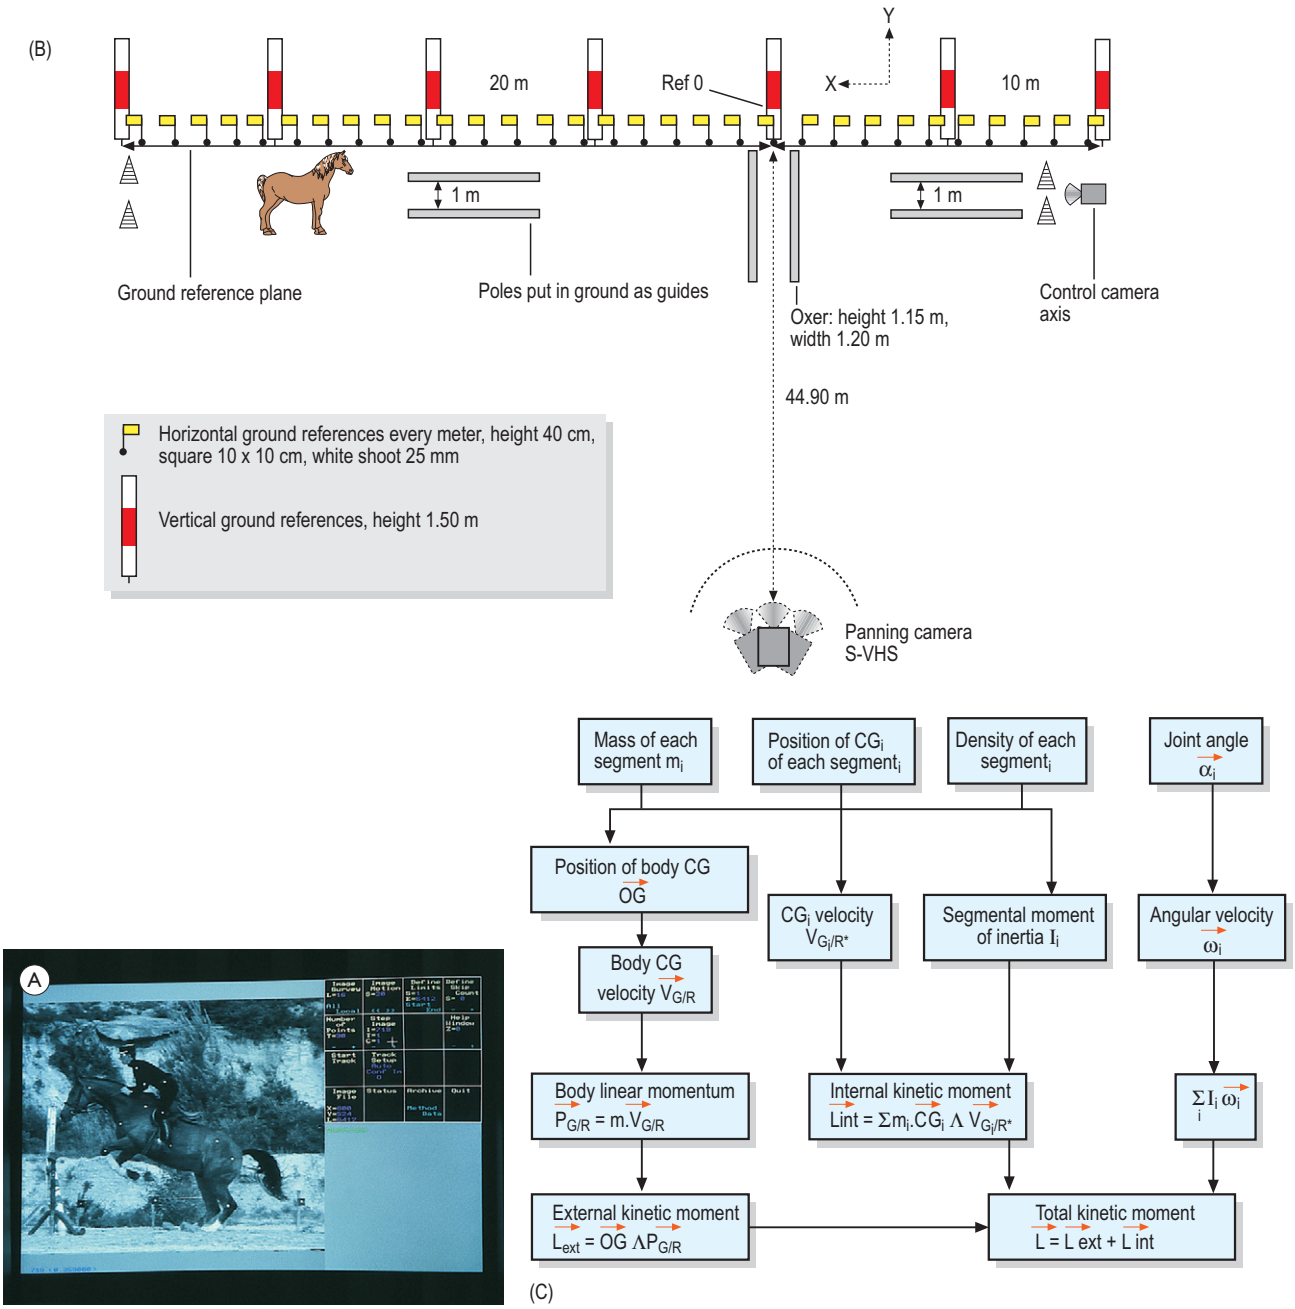

Fig. 12.2
Example of two-dimensional kinematic study of jumping horse. (A) One image extracted from the video film shows the horse and rider equipped with white anatomic markers. These markers are used to identify the location of each joint on each image. (B) Film recording procedure for a panning camera system to film and analyze the motion of a large field (30 m) as in jumping exercise. A set of ground reference planes was placed parallel and behind the horse trajectory. (C) Data analysis procedure to compute the center of gravity (CG) and total kinetic moment (L). After tracking the markers of each joint, the co-ordinates data were used to calculate the center of gravity (CG_i) of each segment, the velocity (Vg_i), the moment of inertia (I_i), the angles (α_i), the angular velocity (ω_i) and the external and internal kinetic moment. (Fig. 12.2B, C reproduced from Galloux and Barry[15] with permission.)

Kinetic analysis

Another approach to the study of the biomechanics of locomotion is to measure either the external forces applied to the body or the accelerations of the center of gravity of the body segments. Marey (1873) was the first author to use a pressure sensor attached to the ground surface of a horse shoe and accelerometers attached to the limbs to measure the hoof–ground contact durations at the various gaits.[18] All the sensors measured forces using pneumatic principles. The variations in pressure generated by the various transducers were recorded by tracing curves with a portable pneumotachograph.

Ground reaction forces

Modern sensor technology is much impoved and is capable of making accurate measurements over a large range of conditions. However, the measurement principles have remained identical. The external forces are measured using electronic force sensors which record the ground reaction forces when the hooves are in contact with the ground. The sensors can be installed either on the ground in a force plate device or in a shoe attached to the hoof. The force plates can provide the force amplitude and orientation (vector co-ordinates in three dimensions; Fig. 12.3), the co-ordinates of the point of application of the force and the moment value at this point.[19–23]

The accuracy of this type of device is usually good but the sensitive surface is rather small (about 0.5 m^2) and a visual control of the hoof trajectory is required.

In human biomechanics, the treadmill has been used to measure vertical ground reaction forces in standardized exercise conditions. In equine biomechanics, vertical ground reaction forces are measured for all four limbs simultaneously with the treadmill integrated force measuring system.[24] It is used for lameness evaluation in standardized conditions of speed, hardness of the ground and environment.[25]

In order to measure the ground reaction forces during various exercises, several authors have developed hoof force shoes including one or several force sensors (Fig. 12.4).[18,26–30]

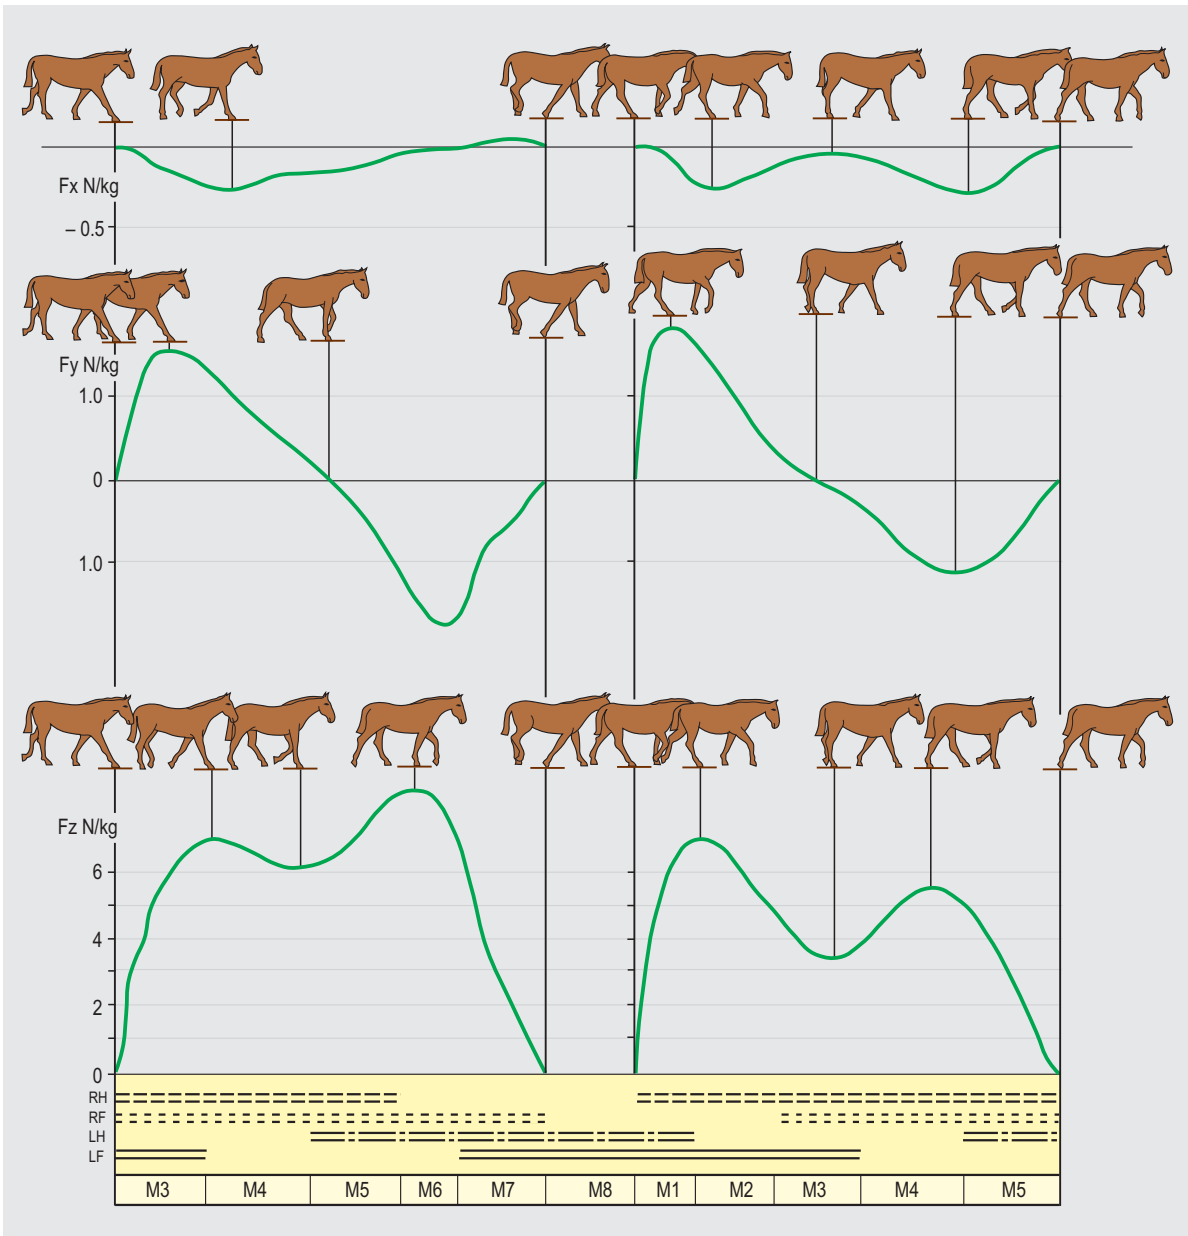

Fig. 12.3

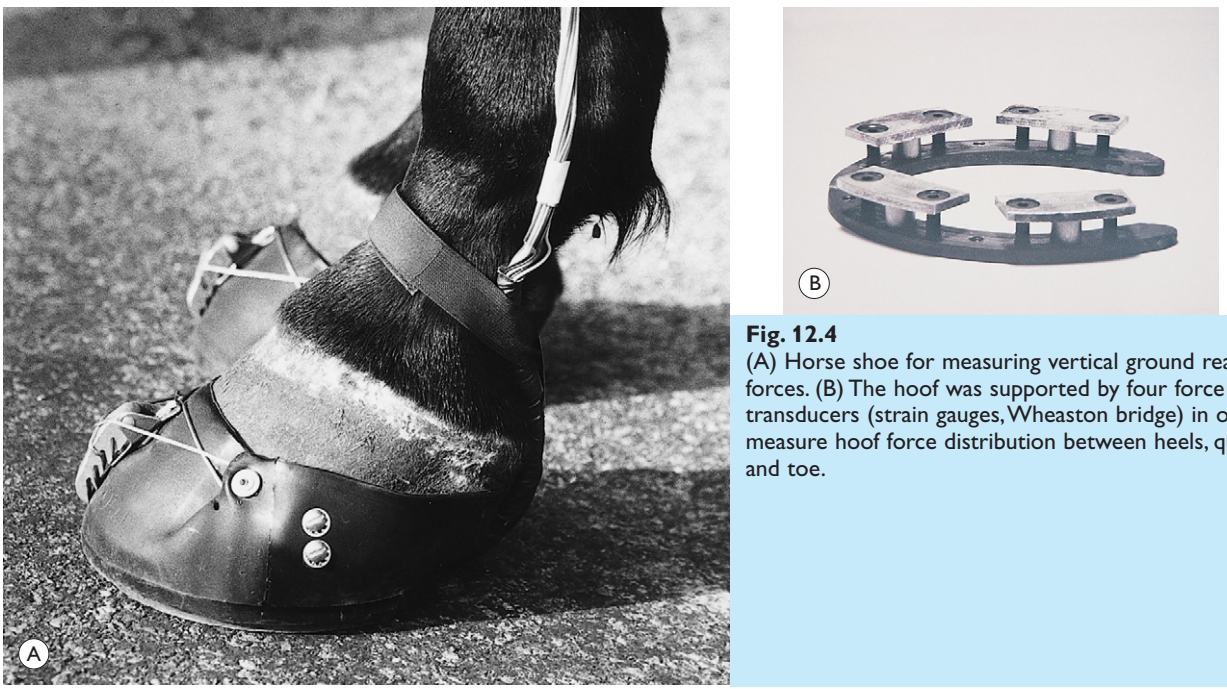

Fig. 12.4
(A) Horse shoe for measuring vertical ground reaction forces. (B) The hoof was supported by four force transducers (strain gauges, Wheaston bridge) in order to measure hoof force distribution between heels, quarters and toe.

Depending on their design, these devices can give between one and three components of the ground reaction forces and the point of application. They are generally less accurate than the force plate and their main disadvantage is the additional weight and thickness of the special shoe. Recently, another indirect ambulatory technique of ground reaction force evaluation was proposed using strain gauges glued onto the hoof wall. After the training of the appropriate artificial neural networks, the ground reaction forces can be estimated from the hoof wall deformations.[31]

Acceleration analysis

Acceleration analysis is a kinetic method which measures instantaneous change of velocity which is produced by applying a force on a solid during the same duration. Acceleration measurements are performed using small sensors (accelerometers) which should be firmly attached to the body segment under study. These sensors are made of a small suspended mass giving a signal which is proportional to the acceleration. A sudden change in velocity can give a high acceleration or deceleration (decrease of acceleration) even if the displacement is small. The acceleration vector is proportional to the resultant force applied to the body's center of gravity and its measurement provides a convenient way to study the kinetics of a body in motion.

In order to analyze horse locomotion, the accelerometer should be placed as near as possible to the body center of gravity. The caudal part of the sternum between the right and left pectoralis ascendens muscles at the level of the girth

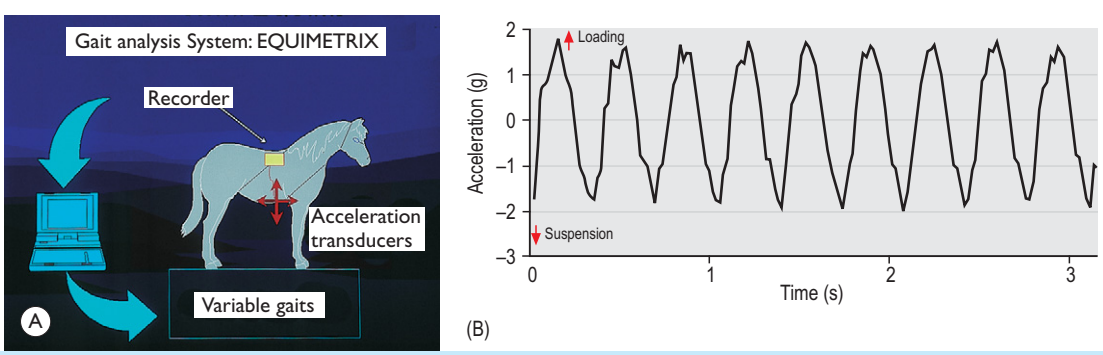

Fig. 12.5
Accelerometric Equimetrix gait analysis system. (A) Two- or three-dimensional accelerometers are fixed on the sternum by an elastic belt or the girth of the saddle. The accelerations are recorded continuously during the exercise. Then data analysis calculates gait characteristics such as stride frequency, vertical and longitudinal activity, regularity and other gait variables specific to the exercise. (B) Example of the vertical acceleration recorded at the trot. The peaks correspond to the maximum loading of the diagonal. The valleys correspond to the suspension phases.

provides a good compromise between transducer stability and closeness to the horse's center of gravity (about 65 cm dorsocaudally at the gallop). The acceleration signal is transmitted to a PC or recorded with a small data logger placed in the saddle pad (Fig. 12.5A). The first application of this gait analysis system (Equimetrix TM) was used for harnessed trotters evaluation.[32] The acceleration signal, such as dorsoventral acceleration of the trot (Fig. 12.5B), could be treated by signal analysis procedures in order to extract the dynamic and temporal stride variables. Calculating the double integral of the linear acceleration makes it possible to find kinematic variables (linear or angular displacement) such as the instantaneous displacement of the saddle in space.[33] Several examples of gait variables calculated from acceleration data will be presented in the following paragraphs.

Acceleration measurements could also be employed for analyzing the energy characteristics of shocks and vibrations which are transient in the hoof.[34–36] An accelerometer could be fixed on the hoof wall in order to measure the maximal deceleration of the hoof impact on the ground and the vibration frequency (Fig. 12.6). The influence of horse shoes and ground surface characteristics could be studied using this method.

The main advantage of using an accelerometric transducer is the simplicity of the measuring technique. It can easily be used under field conditions. The main limitation is that the measurements are given with respect to a set of body axes and consequently it is not easy to calculate the acceleration, velocity or displacement values with respect to a set of ground axes.

Fig. 12.6
Accelerometer fixed on the hoof to study the shocks and vibrations of the hoof after impact on the ground. The influence of the ground surface and the shoe on the shock damping was studied using this transducer.

Conditions of gait measurements: treadmill exercise versus ground exercise

Under laboratory conditions it is possible to study the locomotion of horses running on an experimental track or on a treadmill. The latter provides an excellent means of controlling the regularity of the gaits because the velocity and slope of the treadmill belt are entirely fixed by the operator. In order to analyze the gait of a horse without stress, some preexperimental exercise sessions are required to accustom it to this unusual exercise condition.[37] The horse adapts rapidly at the trot and stride measurements can be undertaken beginning at the third session. For the walk, many stride parameters are not stable even after the ninth training session. Within a session, a minimum of 5 min of walking or trotting is required to reach a steady state of locomotion.

Many fundamental locomotion studies have been performed on commercially available high-speed treadmills, since the development of the first installation of this type of machine at the Swedish University of Agricultural Science in Uppsala.[38] At the beginning of human treadmill use, it was suggested that locomotion on a treadmill would be exactly the same as on the ground.[39] This hypothesis did not take into account the fact that the human body is not a rigid body system but an articulated set of segments. In horses, it was

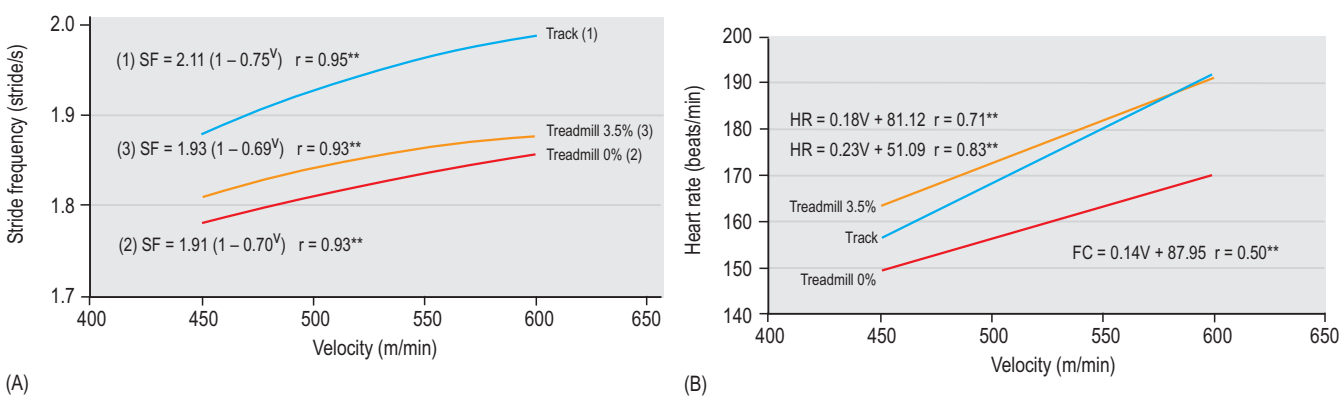

Fig. 12.7
Comparison of the stride frequency (A) and heart rate (B) of horses galloping on track, flat treadmill and 3.5% inclined treadmill. At the same velocity, the stride frequency is lower on the treadmill (i.e. stride length longer) than on the track. The heart rate response is the same on track and 3.5% inclined treadmill. (Reproduced from Barrey et al. Equine Athlete 1993; 6:14–19, with permission.)

demonstrated experimentally that the stride parameters are modified in flat and inclined exercise at trot and canter.[23] At the same speed, the stride frequency was lower on the treadmill and the stride length was longer than in overground conditions (Fig. 12.7A). The exercise on a flat treadmill generated a lower cardiac and blood lactate response than exercise on the track at the same velocities.[23,40] In Trotters tested under two training tracks and treadmill conditions, there were no significant differences in locomotor and physiological variables between tracks but the treadmill had the same influence as in saddle horses.[41] In order to reproduce approximately the same energetic exercise on a treadmill, it was found that a treadmill incline of 3.5% gives the same heart rate response as in overground conditions (Fig. 12.7B).

The mechanical reasons for these differences are still not entirely understood but some explanations have been suggested by the experimental and theoretical results. The treadmill belt is driven by the motor and it helps the horse's limbs to move backwards (Fig. 12.8). The speed of the treadmill belt fluctuates in relationship to the hoof impact on the belt.[31] The total kinetic energy of human runners filmed at the same speed on flat track and treadmill was calculated using the kinematic data (all the body segments taken into account). It was found that the total kinetic energy was reduced by a factor of 10 on the treadmill compared with on the track.[42] This difference was mainly explained by a reduction of the kinetic energy of each limb and arm segment, which moved with a lower amplitude around the total body center of gravity on the treadmill as compared with track conditions. However, these results cannot be extrapolated to the horse because the measurements and calculations do not relate to quadrupedal locomotion.

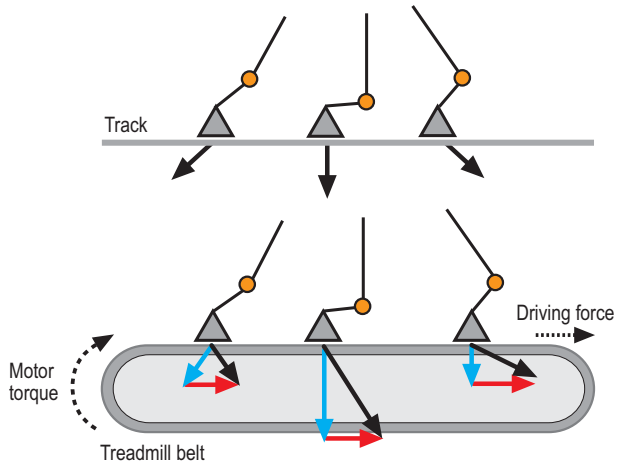

Fig. 12.8
Schematic diagram of hoof force differences in overground and treadmill locomotion. The additional force of the treadmill motor acts on the hoof which could explain the decrease of work and increase of stride length observed in treadmill exercise. (Reproduced from Barrey et al. Equine Athlete 1993; 6:14–19, with permission.)

At a slow trot, a 6% inclination of the treadmill tends to increase the stride duration and significantly increases the stance duration of the forelimbs and hindlimbs.[43] Kinematic analysis has confirmed that the hindlimbs generated higher propulsion work on the inclined, rather than flat, treadmill. The inclination of the treadmill did not change the stride length nor did it change the stance, swing and stride duration in a cantering Thoroughbred.[44]

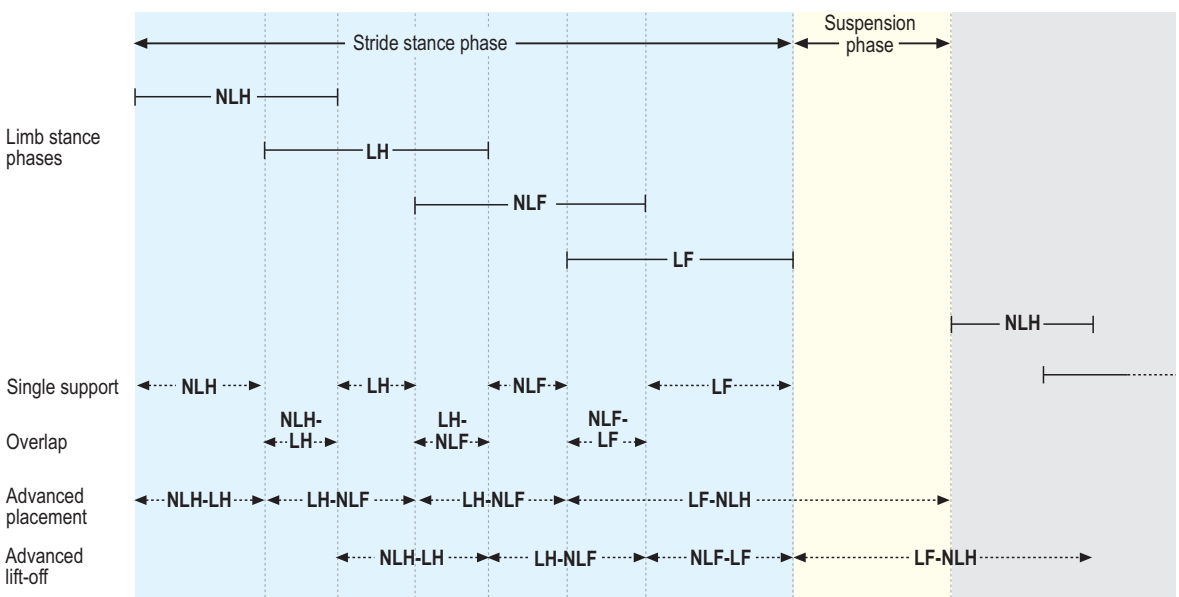

Fig. 12.9
Example of temporal stride variables at the gallop. Bars indicate the stance phase of the limbs. NLH, non-lead hindlimb; LH, lead hindlimb; NLF, non-lead forelimb; LF, lead forelimb. (Reproduced from Clayton[49] with permission.)

Response to exercise: velocity-related changes in gaits and stride characteristics

Gait terminology and definitions of stride characteristics

Gait variety and complexity have always created difficulties because of the need for adequate terminology to describe the locomotor phenomenon. Some efforts have been made to define a standard terminology for describing equine locomotion.[45–47] A *gait* can be defined as a complex and strictly coordinated rhythmic and automatic movement of the limbs and the entire body of the animal which results in the production of progressive movements. A two-, three- or four-beat gait corresponds to the number of hoof impacts that can be heard during a stride of trot, canter and gallop, respectively. The sounds are related to the footfall sequence of the gait but small asynchrony cannot be detected audibly. To describe the footfall sequence of each gait, it is useful to name the four limbs: right forelimb (RF), left forelimb (LF), right hindlimb (RH) and left hindlimb (LH). Many methods have been proposed to describe more precisely in time and space the limb movements: drawings, chronophotographies, stick bar (Fig. 12.9), phase and pie diagrams.[18,48–50]

The stride is defined as a full cycle of limb motion. Since the pattern is repeated, the beginning of the stride can be at any point in the pattern and the end of that stride at the same place in the beginning of the next pattern. A complete limb cycle includes a stance phase when the limb is in contact with the ground, a swing phase when the limb is not in contact with the ground and a suspension phase when none of the hooves is in contact with the ground. The stride duration is composed of the stride stance phase (total duration of ground contact) plus the suspension phase. It is also equal to the sum of the stance and swing phase duration of one limb. The stride frequency corresponds to the number of strides performed per unit of time. The stride frequency is equal to the inverse of stride duration and it is usually expressed in stride/s or in hertz (Hz).

During a unipodal stance phase, only one limb is in contact with the ground, as in the gallop. One forelimb and hindlimb can be synchronized in two different ways.

1. During a diagonal stance phase, for example at the trot, a hindlimb and the contralateral forelimb are in contact with the ground at the same time. The left diagonal is composed of the left forelimb and right hindlimb; the right diagonal is composed of the right forelimb and left hindlimb.
2. During a lateral stance phase, for example at the pace, the hindlimb and forelimb of the same side are in contact with the ground at the same time.

When the forelimbs and hindlimbs hit the ground non-synchronously during a lateral or diagonal stance phase, the time elapsed between the hindlimb and forelimb contact is called the advanced placement. It is positive if the hindlimb hits the ground first. Similarly, the advanced lift-off can be measured between the hooves lifting off.

The stride length corresponds to the distance between two successive hoof placements of the same limb. The over-reach or overtrack is defined as the distance between the hindlimb imprint and the ipsilateral forelimb imprint. It can be positive or negative if the imprint of the hindlimb is in front of the forelimb imprint (positive) or behind it (negative).

The number of lines defined by the successive hoof imprints on the ground defines the number of tracks. This qualitative information characterizes the transverse motion of the gait. If the horse locomotion is slow and straight, there should be two tracks because the forefeet are exactly in the same line as the ipsilateral hindfeet. In some dressage exercises, such as 'shoulder in', 'haunches in', 'quarters-in', 'quarters-out' or 'half pass', the horse can use two, three or four tracks. During the examination of a hindlimb lameness, three or four tracks can be observed and usually the lame hindlimb follows one of the median tracks. The fast trot of a harness trotter usually shows four tracks with the two hindlimbs most abaxial.

Variety of gaits

The main characteristics of the equine gaits are described in Table 12.1. Within each gait there exist continuous variations from slow speed with a collected gait to higher speed with an extended gait. Two types of gait can be distinguished by the symmetry of the limb movement sequence with respect to time and the median plane of the horse:

- *symmetric gaits*: walk, trot, toelt (paso) and pace
- *asymmetric gaits*: canter, transverse and rotary gallop.

Several methods have been proposed to classify the gaits acording to their temporal characteristics. The continuum of symmetric gaits was described by a diagram proposed by Hildebrand.[51] The stance duration of the hindlimb was plotted against the lateral advanced placement. On the *x* axis, the stance duration of the hindlimb indicates if the gait is walked (no suspension phase) or run (two suspension phases). On the *y* axis, the lateral advanced placement quantifies the asynchrony or the phase lag of the lateral forelimbs and hindlimbs. The two-beat gaits are up and down the diagram and the four-beat gaits are in the middle part of the diagram. Another diagram has been proposed for illustrating the diagonal gaits by plotting the hind stance phase duration against the diagonal advanced placement.[52]

Another method, based on a series of coupled oscillators, has been proposed to describe and simulate both symmetric and asymmetric gaits. This model also has the advantage of describing the gait transitions and unique gaits like 'aubin' and 'traquenard'. The model uses four coupled oscillators which simulate the cyclical patterns of the four limb

Table 12.1 Gait characteristics

Classification	Gait	Gait variations	Footfall sequence	Rhythm (beat/stride)	Type of symmetry	Speed (m/s)	Stride length (m)	Stride frequency (stride/s)	Limb stance phase (s or % stride)	Suspension phase (s or % stride)
Symmetric gaits	Walk	Collected, medium, extended	RH,RF,LH,LF	4	Right/left bipedal	1.2–1.8	1.5–1.9	0.8–1.1	65–75%	0
	Toelt = Paso		RH,RF,LH,LF	4	Right/left lateral	3.4–5.3	1.7–2.3	2.23–2.36	40–55%	0
	Trot	Piaffe, passage, collected, medium, extended, flying trot	RH-LF, Susp., LH-RF, Susp.	2	Right/left diagonal	2.8–14.2	1.8–5.9	0.9–2.52	26–53%	0–9%
	Pace		RH-RF, Susp., LH-LF, Susp.	2	Right/left lateral	9.1–16.0	4.5–6.3	1.8–2.4	0.130–0.138 s	0.081–0.094 s
Asymmetric gaits	Canter	Collected, medium, extended, disunited	Trail.H,Lead.H-Trail.F,Lead.F, Susp.	3	Asymmetry with a phase lag between limb pairs	2.9–9	1.9–4.6	1.6–2.0	0.28–0.30 s	0–0.013 s
	Gallop	Transverse, rotary	Transverse: Trail.H,Lead.H, Trail.F,Lead.F, Susp.	4	Asymmetry with a phase lag between limb pairs	9–20	4.5–7.2	2.27–2.92	0.085–0.09 s	0.063–0.114 s 16–28%

movements. By using five methods of coupling the oscillators, it was possible to generate all types of equine gaits. This type of functional model can be useful to understand the locomotor control which includes rhythmic pattern generators.

Symmetric gaits

Walk The walk is a four-beat gait with a large overlap time between stance phases of the limbs. This is the slowest equine gait but probably one of the more complex because of overlap and lag phase variability. During lameness examination, the variability of stride regularity and symmetry measured at the walk was higher than at the trot.[53] In dressage horses, the speed of the walk increases from the collected walk (1.37 m/s) to the extended walk (1.82 m/s) and simultaneously there is a small increase in stride frequency.[54] The change in speed was primarily the result of lengthening of the stride by increasing the overtracking distance. Even in horses trained for dressage, the regular four-beat rhythm of the footfall was observed in only one of the six horses measured.

Toelt Icelandic and Paso Fino exhibit a four-beat symmetric lateral gait (Fig. 12.6). This gait can be called 'toelt', 'paso', 'rack', 'fox-trot' or 'slow gait'. The toelt is comfortable for the rider because the amplitude of the dorsoventral displacement is lower than at the trot. The speed ranges between 1.7 and 2.3 m/s and the natural gait transition for toelter is walk–toelt–canter.

Trot The slow trot is a two-beat symmetric diagonal gait. Among the normal variations of the trot of saddle horses, the speed of the gait increases from collected to extended trot. Passage and piaffe are two dressage exercises derived from collected trot. However, their temporal variables are different as was shown in the dressage finals at the Olympic Games in Barcelona.[52] The stride duration is longer (i.e. slower stride frequency) for piaffe (1.08 s) and passage (1.09 s) than for collected trot (0.84 s). For most of the other temporal variables, collected trot and passage were very similar except for the suspension phase which was shorter in passage. A positive diagonal advanced placement measured at the collected trot was observed in the elite dressage horses.[52,55] This means that the hindlimb hits the ground about 20–30 ms before the diagonal forelimb.

In harness trotters, the trot is so extended that it can reach a maximum speed of 14.2 m/s with a maximum stride frequency of 2.52 strides/s and a maximum stride length of 5.92 m.[56] The diagonal sequence is usually affected and this particular gait is named the flying trot. It is a four-beat gait because there is an asynchrony of the impact and/or lift-off of the diagonal.[57] In most cases the hindlimb touches the ground first (a positive advanced placement). The dissociation at lift-off is greater than at impact.

Various trot irregularities can occur during a harness race and the horse can be disqualified by the gait judges: at the aubin, the forelimbs gallop and the hindlimbs trot while at the traquenard, the forelimbs trot and the hindlimbs gallop. A trotter is also disqualified if it breaks into a pace or gallop.

With increasing speed the stride length increases linearly but the interference between the hindlimb and the lateral forelimb becomes a limiting factor. A large over-reach of the hindlimbs can be performed only if the hindlimbs follow two lateral tracks (track abaxial to the forelimbs) during the swing phase.

Pace This lateral symmetric gait is used in harness racing mainly in North America and Australia. The maximum speed can be faster than at the flying trot. It is also a four-beat gait at high speeds with dissociation of lateral symmetry at impact and lift-off. The hindlimb hits the ground before the ipsilateral forelimb. This lateral advanced placement of the hindlimb is about 26–30 ms. In comparison with the flying trot there is less problem with limb interference because the lateral sequence avoids any contact between the ipsilateral limbs. Consequently, there are fewer co-ordination difficulties and it is easier for the horse to increase stride length. These differences may explain the faster speed records obtained by pacers (9.4–16.0 m/s) than by trotters (11.8–14.2 m/s).

Asymmetric gaits: canter and gallop

Canter and gallop refer to the same gait at increasing speed: the canter is a three-beat gait at slow speed and the gallop is a four-beat gait at a higher speed. At the canter, the diagonal stance phase is synchronized while at the gallop the footfalls of the diagonal limbs are dissociated. The first hindlimb hits the ground before the diagonal forelimb at the gallop. The gallop is the fastest equine gait and is used by racing horses such as Thoroughbreds and Quarter Horses.

These two gaits are composed of asymmetric movements of the hindlimbs and forelimbs. Because of this asymmetry, each limb is referred to differently: the lead limb is the last one of the limb pairs to leave the ground. The contralateral limb is called the non-lead limb or trailing limb. Consequently, there are two possible symmetric footfall sequences: right lead canter and left lead canter, and similarly, right lead gallop and left lead gallop. In free conditions the horse prefers to canter or gallop on the right lead to go into a right curve. If it is cantering on the right lead before going into a left curve, the horse will probably change the lead limb to maintain balance in the curve.

The lead change is the transition between right lead canter and the left lead canter footfall sequence. It is commonly accomplished by initially having the horse change the order of hindlimb placements and then the forelimb placements. However, in dressage the rider can elicit the canter lead change during the suspension phase. Racing horses change leads eight or more times per mile to avoid excessive muscular fatigue due to asymmetric work of the limbs and also to minimize the centrifugal forces as they accommodate to the curve.[58]

At the gallop, there are two types of footfall sequences called the transverse gallop and the rotary gallop. The transverse gallop is more frequently used by the horse than the rotary gallop but the latter may be used briefly under some circumstances, for example after a lead change or when muscular fatigue occurs during a racing gallop. A disunited canter occurs with the same footfall sequence as a rotary gallop except that the stance phase of the diagonal is synchronized. It can be observed for a few strides after a bad lead change in dressage or following a jump.

The jump is a unique gallop stride where the airborne phase is a long dissociation of the diagonal. The footfalls of the jump stride are: trail-H, lead-H at take-off and trail-F, lead-F at landing. At take-off, the hindlimb stance phase is more synchronized than in a normal gallop stride to provide a powerful push-off. The footfalls of the forelimbs at landing are not synchronized.[59] A lead change can take place during the airborne phase and in this case the change of forelimb placement order takes place before those of the hindlimbs. A disunited canter can be observed after the jump if the lead change of the hindlimbs does not occur immediately after the landing phase.

Gait transitions

To increase its velocity, the horse can switch gait from walk to trot and from trot to canter and then extend the canter to gallop. Each gait can also be extended by changing the spatial and temporal characteristics of the stride. From a dynamic point of view, a gait transition can be characterized by a gait change with non-stationary motions of the limbs. Periodicity and rhythm of the limb motions change suddenly. Gait transition is one of the most difficult basic exercises in dressage where specific co-ordination should be learned during training exercise.

There is little information about gait transitions in the scientific literature. The footfall sequence of various gait transitions has been described by Marey and Lenoble du Teil.[18,50] One kinematic study described four types of footfall sequences observed in dressage horses during the walk–trot transition.[60] One accelerometric study described the instantaneous changes of stride frequency and dorsoventral activity during all types of transitions recorded in competitions.[61]

From an energetic point of view, it appears that each equid has a preferred speed for the trot to gallop transition and this particular speed is related to an optimal metabolic cost of running.[62] However, another experiment demonstrated that the trot–gallop transition is triggered when the peak of ground reaction force reaches a critical level of about 1–1.25 times the bodyweight (Fig. 12.10).[63] Carrying additional weight reduced the speed of trot–gallop transition.

Velocity-related changes in stride characteristics

For increasing the speed at a particular gait, the amplitude of the steps becomes larger and the duration of the limb cycle is reduced in order to repeat the limb movements more frequently. Stride frequency (SF) and stride length (SL) are the two main components of gait speed. The mean speed (V) can be estimated by the product of stride frequency by stride length: $V = SF \times SL$. The velocity-related changes in stride parameters have been studied in many horse breeds and disciplines. Stride length increases linearly with the speed of the gait. Stride frequency increases non-linearly and more slowly.[5,64,65] For a quick increase of running velocity such as that occurring at the start

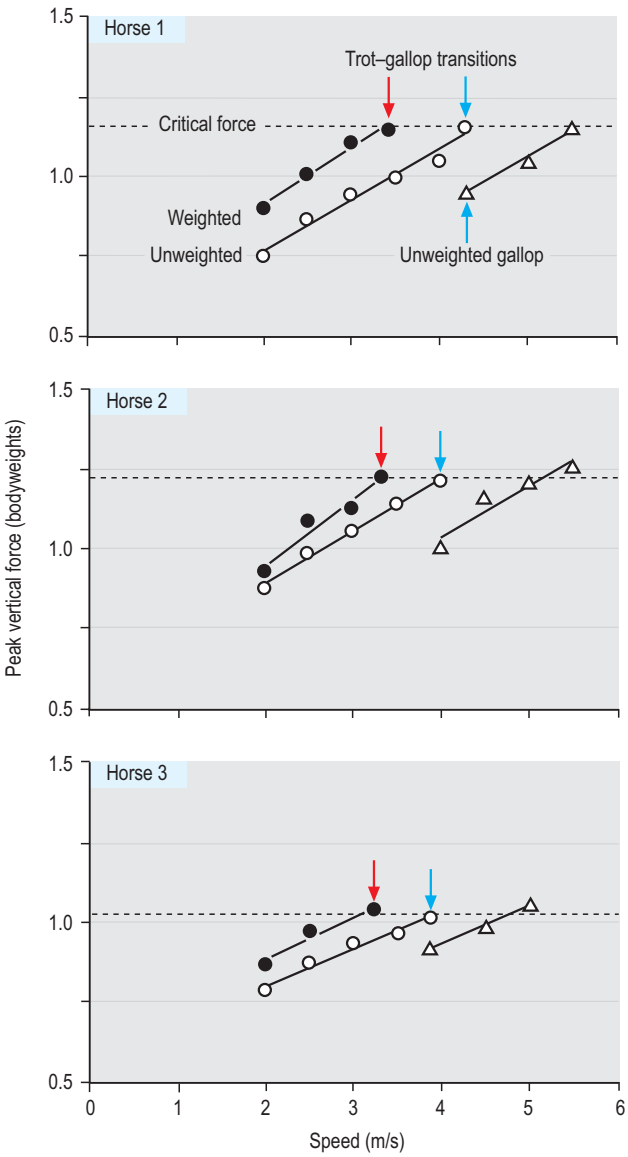

Fig. 12.10
Gait transition determinism. When the horses carried weights, they switched to a gallop at a lower speed but essentially the same critical level of forces as when they did not carry weights. By switching to a gallop, the peak ground reaction force was reduced by an average of 14%. The open circles and triangles denote unweighted trotting and galloping, respectively, and the closed circles denote weighted trotting. The plotted values are the average of the peak forces under each of the four limbs. The lines are linear least squares regressions. (Reproduced from Farley and Taylor[63] with permission.)

of a gallop race, stride frequency reaches its maximum value first to produce the acceleration, while the maximum stride length slowly reaches its maximum value.[66]

In Thoroughbred race horses, the fatigue effect on stride characteristics increases the overlap time between the lead hindlimb and the non-lead forelimb, the stride duration and the suspension phase duration.[67] The compliance of the track surface also can influence the stride parameters when the horse is trotting or galloping at high speed. At the gallop, stride duration tends to be reduced on a harder track surface.[38] There is a slight increase in stride duration on wood-fiber tracks in comparison with turf tracks at the same speed. When the rider stimulated the horse with a stick, a reduction in stride length and an increase in stride frequency corresponding to a reduction of the forelimb stance phase duration were observed. However, velocity was not significantly influenced.[68]

Most of the kinetic and temporal stride variables were influenced by the velocity of the gallop. Stride frequency, stride length and diagonal dissociation increased linearly with velocity. Velocity was mainly increased by the increase in stride length and secondly by stride frequency. Increase in stride length is mainly explained by the lengthening of the diagonal and airborne phases of the stride.[65] The overlap duration of the diagonal decreased linearly to about 50 ms as the galloping speed increases.[58,69] In order to increase gallop stride length, the movements of the hindlimbs and forelimbs are dissociated and length between the footfalls of the diagonal increases. The time elapsed between forelimb midstance phases and between hindlimb midstance phases is kept constant and independent from velocity.[65]

Respiratory coupling at trot, canter and gallop

Some relationships have been established between stride parameters and other physiological variables. At the canter and gallop, the respiratory and limb cycle are synchronized. Inspiration starts from the beginning of the suspension phase and ends at the beginning of the non-lead forelimb stance phase. Expiration then occurs during the stance phase of the non-lead and lead forelimbs (Fig. 12.11).[70] Expiration is facilitated by compression of the rib cage during weight bearing of the forelimbs. This functional coupling might be a limiting factor for ventilation at maximal exercise intensity. At the walk, trot and pace there is not a consistent coupling of locomotion and the respiratory cycle. At a trot, the ratio between locomotor and respiratory frequency ranged between 1 and 3 with respect to the speed, the duration of exercise and the breed.[71,72] The same type of low-level coupling was observed at a pace where the ratio between stride and respiratory frequency was 1–1.5.[73]

Muscle fiber characteristics and locomotion

The relationship between stride parameters and muscle fiber composition was studied in Standardbreds at high speed.[74] The stride length and frequency were extrapolated at a speed of V200 or V = 9 m/s. The stride length is positively correlated with the percentages of type I fiber (aerobic slow twitch) and type IIA (aero-anaerobic fast twitch) and negatively correlated with the percentages of fiber type IIB (anaerobic fast twitch). The stride frequency was positively correlated with only the percentage of type IIA fiber. However, in another study the opposite result was found: a negative correlation between the

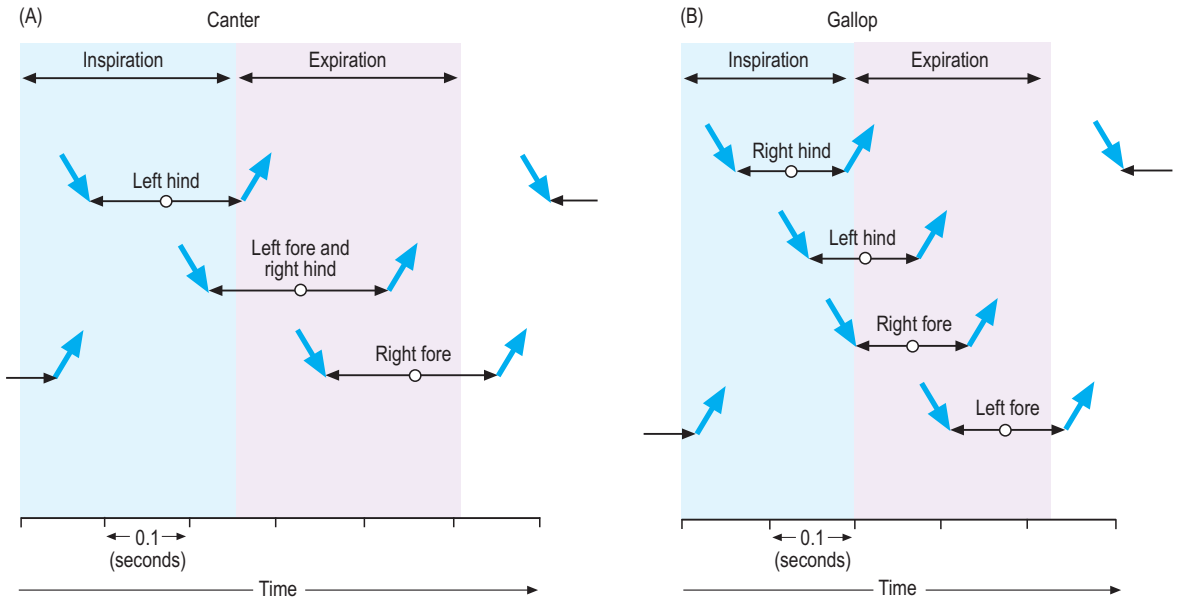

Fig. 12.11

The distances between arrowheads represent the periods of ground contact of the feet. (Reproduced from Attenburrow[70] with permission.)

stance duration of young Trotters and the percentage of type IIB fibers.[75] For race Trotters the force–velocity relationship for skeletal muscles implied in limb protraction and retraction might be an important limiting factor of maximal stride frequency.[58] In Andalusian horses, there is no significant correlation between the stance duration and the fiber type percentages. However, the diameter of fibers was negatively correlated with stance duration.[76] The propulsive force during the stance phase might be higher with larger fibers, especially of type I.

During a treadmill exercise test, blood lactate concentration and heart rate at high speed seem to be more correlated to stride length than to stride frequency.[74,77] This finding confirms that the high speed which elicited a cardiac and metabolic response is primarily explained by an increase in stride length. Furthermore, the velocity relating to change of stride frequency is not linear and consequently decreases the coefficient of correlation. In ponies tested on the track, stride frequency was more correlated to blood lactate concentration and heart rate than to stride length, which is more limited in this animal.[40]

Response to training: influence of age and training on locomotor variables

Gait development in foals and yearlings

Gait patterns are influenced by the age of the horse, but little is known about gait development. The relationship between conformation and stride variables in foals aged 6–8 months has been reported. Speed increases were achieved by longer stride length in heavier foals and higher stride frequency in taller foals.[5] The elbow, carpal and fetlock joint angle flexions were the most significant differences between the foals.[78] The stride and stance duration increased with age but the swing duration and pro-retraction angle were consistent. The joint angle patterns recorded at 4 and 26 months were nearly similar. The good correlations of some of the kinematic parameters measured in foals and adults make it possible to predict the gait quality of adult horses.[79]

Training effects

According to several studies, some of the gait characteristics can also be modified after a training period. However, little is known about the training effect, because few data from longitudinal studies are available. In one study, after 70 days of dressage and jumping training, the stance duration of the hindlimb decreased, its flexion increased and its maximal protraction occurred earlier. In addition, the protraction and retraction range of the forelimb decreased and the stride duration was unchanged. After the same period, the horses which had been left in pasture showed other locomotion modifications. They had a longer swing and stride duration and the range of the forelimb movement was larger.[80]

In race horses, the training influence has been investigated in Standardbreds and Thoroughbreds. After 3 years of training, the following changes in the trotting strides were observed: the stride length, the stride duration and swing phase increased.[57] Another study on Standardbreds trained on a treadmill did not show any change in temporal or linear stride variables after 5 months of training. In gallop racing, a stride duration and stride length increase was found.[67] After 8 weeks of a high-intensity training regime on a treadmill,

Table 12.2 Changes in trot variables with the stage of training in dressage horses

	4 years	5 years	6 years	7 years and older

the stance phase duration of the Thoroughbred gallop stride was reduced by 8–20%.[81]

Dressage horses should be trained to improve their coordination, their suppleness and their gait collection. Collection of the gait means that the forward movement becomes more upward movement and the stride frequency slows down. A group of dressage horses were tested from 4 to 7 years of age to determine the training-related changes in locomotion variables. The changes of the trot were more pronounced than the changes in the walk and gallop (Table 12.2). At the trot, the stride frequency decreases between 5 and 6 years old. During the same time walk and gallop stride frequency remains the same. At the trot dorsoventral displacement increases after the first year of training. The increase of dorsoventral activity with age corresponded to an increase of muscular power and an increase of the dorsoventral displacement with collected gaits. Stride regularity and symmetry increase in early training and then decrease after 6 years of age.

Applications of equine gait analysis

Gait tests for breeding

Early jumping evaluation

Free jumping tests are often used in the performance evaluation of 3-year-old horses. These tests are useful for selection of stallions and mares for breeding, and to select potential performance horses. Gallop, take-off, jump path and landing characteristics were measured during a free jumping test using the Equimetrix system. Heritabilities of these jump measurements were calculated in French saddle horses to determine the use of breeding criteria (Table 12.3). The heritabilities of jumping characteristics are moderate to high and can be used effectively in selection of bloodlines for breeding.

Table 12.3 Heritabilities (h^2 and standard errors) of the variables measured during a free jumping test in French saddle horses

Gait variables	h^2 (SE) for walk
Approach strides	
Stride frequency	0.32 (0.19)
Dorsoventral activity	0.50 (0.13)

Basic gait characteristics of young dressage horses

Gait and conformation test information is useful in making breeding plans and to more accurately identify young horses with good dressage potential. Gait characteristics may be measured early in a horse's saddle training. Walk and trot may be measured earlier in hand. Several studies were conducted in France and Germany to measure gait and conformation variables in 3-year-old horses presented in a performance test.[82,83] The relationships between these measurements and the judges' scores were analyzed. The locomotor profile of future dressage horses should have the following gait characteristics.

- *Walk*: large vertical limb displacement and propulsion activity, high regularity
- *Trot*: slow cadence, large vertical displacement, high regularity, large propulsion activity
- *Gallop*: three-beat gallop with high regularity, slow cadence and good propulsion activity

Horses having these basic gait characteristics obtain better scores in performance tests and they have better perfomance during the first year of dressage competition.

The 3-year-old German horses evaluated had gait characteristics more advantageously adapted for dressage competition. The results obtained in the best German horses tested could be considered as a reference standard for dressage breeding. Purebred Spanish horses should be considered as a reference standard for collected gaits used in farm work and classical dressage. Specific conformation and gait characteristics in German breeds may explain their higher level of success in dressage competition.[84] For dressage performance the trot characteristics and its variations are very important

Table 12.4 Comparison of the trot characteristics measured by the Equimetrix system in three groups of breeds used for dressage: German horses (Hannoverian, Westphalian, Oldenburger), purebred Spanish horses and French saddle horses

because they form the basis of passage and piaffe, movements which are performed at the upper levels of dressage competition. According to the FEI standards, the trot should be a two-beat gait with free, active and regular steps. Regularity and elasticity of the steps and engagement of the hindquarters are important qualities of the trot. The same cadence and rhythm should be maintained during trot variations. The trot characteristics of the German horses were consistent with the FEI standards: slow stride frequency, high regularity, large dorsoventral displacement and activity. Activity is considered good when the horse diplays elasticity and good propulsion (Table 12.4). Spanish horses have shorter stride length, higher stride frequency and lower dorsoventral displacement and activity than German horses. Spanish horses exhibited elevated movements (large flexion of carpus and tarsus) rather than extended movements of the limbs. It has been shown that purebred Spanish horses have larger elbow and carpus angular range than Dutch Warmblood horses.[85] Spanish and German groups have high propulsion and longitudinal activity which should be an advantage for collecting the trot to passage and piaffe. Spanish groups exhibited gaits with lower regularity than the German group but this could be explained by the lower training level of the Spanish horses at this age. Traditionally, purebred Spanish horses are broken in at the age of 4 years instead of 2–3 years for German horses.

The mean heritability of dressage performance was rather low ($h^2 = 0.04–0.27$) as reported by several authors because non-genetic effects like training have a large influence on outcome.[86–88] Consequently, early selection using gait tests could be more efficient than selection based on performance results. Moderate and high heritabilities have been found for trot and gallop variables such as stride length, stride frequency, dorsoventral displacement and propulsion variables (Table 12.5).[83] Some of the gait variables such as stride frequency, dorsoventral and longitudinal activity which have moderate to high heritability, could be used for improving gait collection ability by genetic selection. Most of the trot variables had a moderate to high heritability (mean heritability $h^2 = 0.24$). The trot characteristics are very important for dressage ability and should be used for early selection at 2 or 3 years old. Slow stride frequency, high dorsoventral activity and high propulsion vector and longitudinal activity are the trot characteristics required for performing in dressage. Gallop variables are highly heritable (mean heritability $h^2 = 0.43$) and could also be used for genetic selection. Slow stride frequency and high longitudinal activity are required. Walk heritabilities were rather low (mean heritability $h^2 = 0.15$) except for vertical activity, longitudinal propulsion and percentage of four-beat walk which were highly heritable. The low heritabilities could be explained because the walk is a complex gait which could be modified by many environmental factors.

Specific locomotion in racing and equestrian sports

Galloping race

Maximum gallop velocity is primarily determined by stride length. An increase in this component is obtained by decreasing the overlap duration of the lead hindlimb and non-lead forelimb stance phase.[58] The movements of the hindlimbs and forelimbs are dissociated and the length between the footfalls of the diagonal increases. Overlap time of the diagonal decreases linearly down to about 50 ms as galloping speed increases.[68,69] In poorly performing Thoroughbreds tested on an inclined treadmill (10% slope) at a maximum velocity of 12 m/s, stride length and velocity at maximum

heart rate were the variables most highly correlated to running speed.[89]

The racing career of a Thoroughbred is short and the number of racing opportunities is limited. To maximize an individual horse's potential for winning, it should be entered in races appropriate for its racing ability. To help make optimal decisions about entering horses in races, a profile may be developed for each horse while in early training. The profile should include indicators of the animal's speed, endurance, preferred track conditions and locomotor variables that help determine these characteristics. Locomotor variables of the racing gallop while at maximal speed can only be obtained on a race track because the temporal stride variables should be natural. On a high-speed treadmill maximal speed is limited to 14–15 m/s and the biomechanics of locomotion are modified by the driven belt.[23] However, the physiological variables such as respiratory variables are more accurately measured on an inclined treadmill at submaximal speed.[89]

A gallop test has been designed to determine the locomotor profile of Thoroughbreds. The gallop test is part of normal 'fast work' training, is easy to perform and provides locomotor variables to evaluate the racing capacity of Thoroughbreds in training. This test may be used for early evaluation of young horses as soon as they can gallop close to maximal speed on a race track. The results characterize the gallop and could assist the trainer in planning the training and racing program of the horse.

Several gait variables were related to race performance which was evaluated by the percentage of wins, placings and the logarithm of average earnings per start. The best performers had a higher stride frequency, stride regularity and diagonal dissociation. Stride length increase described most of the velocity increase but was negatively correlated with performance. Horses that appeared to be better adapted for short racing distances had higher stride frequency but longer ground contact duration which provided more time for propulsion. It has been found that suspension duration (= stride duration – ground contact duration) decreased at maximal velocities greater than 13–14 m/s.[69] A quick gallop acceleration at the start of the race is achieved intially by a high rate of stride frequency increase and then by stride lengthening.[66] During a race, a gallop acceleration is required at the finish to win. Consequently, horses that can increase their stride frequency to the highest value have a better chance to win. A locomotor test performed in harnessed Trotters on a track confirmed that the best race performances were obtained by horses that had the highest maximal stride frequency and a long stride length.[56]

These findings suggest that good race horses are able to trot or gallop at high speed using an optimal stride length and that they can accelerate by increasing their stride frequency in order to finish the race. The best performers reached high stride frequencies of 2.52 strides/s at trot and 2.81 strides/s at the gallop. However, stride length is negatively correlated with performance but stride frequency is positively correlated. Because of pendulum mechanics of the body, maximal stride frequency is dependent on the height of the horse (length of the limbs), weight distribution of the limbs (moment of inertia), elasticity of the limbs and rib cage (module of elasticity) and the percentage of fast-twitch muscle fibers (forces). Increased propulsive activity produced a much greater velocity. Dorsoventral loading of the limbs was increased at high speed probably because of the large effect of kinetic energy of the body. Dorsoventral displacement of the thorax decreased linearly with velocity and minimized the potential energy changes of the center of gravity which reduced the energy expenditure of locomotion. At the fastest speed, horses reached the 'wheel gallop' by lowering and keeping their center of gravity at the same height during the entire stride, even the suspension phase. The 'wheel gallop' is optimized to produce maximum energy for propulsive work in the longitudinal axis and avoid energy wastage for vertical oscillations of the body. Energy cost of the gallop increases as stride regularity decreases. This may make regularity of the stride one of the limiting factors which determine maximum galloping speed. Regularity was affected by the increase in speed as it has been found in harness Trotters and it is highly correlated with racing performance.[32]

Harness racing

In order to measure gait variables during training sessions on a race track, a mobile gait analysis system has been used in harness Trotters.[41,56] Good Trotters have a short stance phase duration with a longer stance phase in the hindlimbs than in the forelimbs.[90] A locomotor test performed in race Trotters on a track confirmed that the best race performances were obtained by Trotters that had the highest maximal stride frequency and a long stride length.[56] These findings suggest that good race Trotters are able to trot at high speed using an optimal stride length and that they can accelerate by increasing their stride frequency in order to finish the race.

Show jumping

During the 1988 Seoul Olympic Games, the kinematics of jumping over a high and wide obstacle (oxer) were analyzed in 29 horses and the relationship to the total penalty score was studied.[91] Fewer total penalties were associated with lower velocities during the jump strides, closer take-off hindlimb placements and closer landing forelimb placements. Another study on elite horses jumping a high vertical fence demonstrated that the push-off produced by the hindlimbs at take-off was associated with the mechanical energy required for clearing the fence.[92] The action of the forelimbs should be limited to positioning the horse's body into proper orientation with the jump before the final push-off of the hindlimbs. A more vertical component of the initial velocity was observed in the horses that successfully cleared a wide water jump (4.5 m).[93] The angle of the velocity (vector) relative to the horizontal was 15° in a successful jump compared to 12° in an unsuccessful jump and the vertical component of the velocity was about 0.5 m/s greater in a successful rather than an unsuccessful jump. This initial velocity was

generated by the impulse of the hindlimbs and determined the ballistic flight characteristics of the body.

These kinematic findings agree with another study which showed that poor jumpers had a lower acceleration peak of the hindlimb at take-off than good jumpers.[94] Poor jumpers brake too much with the forelimbs at take-off impulse and the hindlimbs produce an acceleration which is too weak for clearing the fence. This force is one of the main factors affecting a successful jump because it determines the ballistic flight of the center of gravity and also the characteristics of the body rotation over the obstacle during the airborne phase. The moment of inertia and its influence on body rotation were also studied in a group of jumping horses but no consistent relationship with the level of performance was found.[94] More penalties were recorded for horses that cantered at a low stride frequency (lower or equal to 1.76 stride/s) and suddenly reduced their stride frequency at take-off.

Dressage

In dressage the horse should easily execute complex exercises, gait variations and gait transitions while maintaining its equilibrium and suppleness. This discipline requires a high level of locomotor control of the horse by the rider which is achieved progressively through exercise and collecting the gaits. A horse's ability for collection is one of the main limiting factors for dressage because it is impossible to execute the more complex exercises correctly without having attained good basic collection of the gaits. The collected gaits have been extensively described in kinematic studies.[54,55,95,96]

The trot Among the normal variations of the trot in saddle horses, the speed of the gait and the stride length increase from collected, to medium and to extended trot. A slow stride frequency, including a long swing phase, is required for good trot quality. The time elapsing between hindlimb contact and diagonal forelimb contact defines the diagonal advanced placement and should be positive and high at the trot. The horse should place its hindlimbs as far as possible under itself. A large amplitude of vertical displacement of the body during collected trot is desired in the dressage horse. Vertical displacement of the trot is obtained through the storage of elastic strain energy in the fetlock, hock, stifle and pelvis. For extending the trot, having an inclined scapula (a steeper angle to the scapula) and the amplitude of the elbow joint appeared as important factors. The horses judged to have a good trot should have a large degree of flexion in the elbow and carpal joints at the beginning of the swing phase of the stride. A positive diagonal advanced placement measured at the collected trot was observed in elite dressage horses.[52,97] In these elite horses the hindlimb contacts the ground about 20–30 ms before the diagonal forelimb. This advanced foot placement could be a means for the hindlimbs to push off earlier during the stance phase.

The degree of collection at the trot could also be measured by the acceleration components of the body. Horses equipped with the Equimetrix system in a dressage test were recorded at all trot variations and passage. With increasing collection at the trot, the vertical component of acceleration increased.[83] At the same time, the forward component of acceleration decreased. This indicates that propulsion power in dressage horses is used to increase vertical displacement instead of longitudinal displacement.

The passage and piaffe Passage and piaffe are two dressage exercises derived from the collected trot but the kinetics of each are quite different. Differences in the temporal variables were demonstrated in kinetic analyses of the dressage finalists at the Olympic Games in Barcelona.[52] Stride duration is longer (i.e. stride frequency is slower) for piaffe (1.08 s) and passage (1.09 s) than for the collected trot (0.84 s). For most of the other temporal variables, collected trot and passage were very similar except for the suspension phase, which was shorter in passage.

Specific kinetics of passage and piaffe were analyzed on experienced horses using the Equimetrix system. Mean dorsoventral and longitudinal acceleration vectors were measured during the exercise. At the passage, the mean acceleration vector shows that the largest component of propulsion is dorsoventral instead of longitudinal as it is in the extended or working trot. The high collection of passage transforms forward propulsion into upward propulsion. The greatest propulsive activity in passage is from the forelimbs, while the hindlimbs provide for braking.

At the piaffe, the amplitude of dorsoventral acceleration during the stance phase is lower than at the passage because the amplitude of dorsoventral displacement is reduced. Hindlimbs have greater braking activity to avoid forward movement of the body. The forelimbs have moderate dorsoventral propulsion. The same type of results was observed in a horse at the piaffe with a force plate.[98] However, at the passage the longitudinal ground reaction force of the hindlimbs was higher than in the forelimbs.

The canter At slow speed the canter is a three-beat gait. At the canter, the diagonal stance phase is synchronized while at the gallop the footfalls of the diagonal are dissociated. The speed of the canter increases from the collected, to working, medium and extended canter by increasing stride length. While stride length increases, stride frequency remains nearly constant.[95] Stride length increase is due to increase of diagonal step length and distance covered during suspension.

Relationships between the total dressage competition score and canter characteristics in Olympic dressage horses revealed that the best horses were able to extend their canter strides by increasing their stride length without changing their stride frequency.[99] For three-day event horses at the Olympic games, extended canter stride length and velocity were positively associated with points awarded by judges. However, non-finishers of the event had higher extended canter stride lengths and velocities in the dressage phase than finishers.[100]

The lead change is the transition between the footfall sequence of two different canter leads. Normally the hindlimb sequence changes first, then the front limb sequence. In dressage the rider can elicit the canter lead change during the suspension phase. In a bad lead change, the change in forelimb placements occurs before the change of the hindlimbs, resulting in a disunited canter, which may be observed for

several strides. The canter during the two and one tempi lead change is slow (3.35–3.95 m/s) with a short stride length (2.08–2.44 m) and a stride frequency of 1.62 strides/s.[101] Two tempi changes result in a change in the canter lead every other stride and one tempi change results in canter lead changes on every stride.

During the canter pirouette, the canter footfall sequence is altered. The cadence is reduced from 1.58 stride/s at the collected canter to 1.13 stride/s.[96] The diagonal support is entirely dissociated and there is no suspension phase.

The walk In dressage horses, the speed of the walk increases from the collected walk (1.37 m/s) to the extended walk (1.82 m/s) and simultaneously there is a little increase in stride frequency.[54] The speed change was mainly the result of the stride lengthening by increasing the overtracking distance. Even in horses trained for dressage, the regular four-beat rhythm of the footfall was observed only in one of the six horses evaluated. The stride regularity could be assessed by dorsoventral acceleration recording. Extended walk has a more regular pattern than collected walk where the footfall sequence is slightly disturbed by the actions of the rider. Elite dressage horses usually have a very regular acceleration pattern at the walk. This is a sign of a high level of co-ordination and stability in the rhythm of footfall sequence.

Gait transitions A study of transitions from trot to walk showed a positive correlation between a higher level of training and a 'clean' transition without a short intermediate step.[60] The combination of gait analysis by accelerometric measurement and wavelet analysis allowed quantification of some of the temporal and kinetic characteristics of gait transitions.[61] Transition duration, dorsoventral activity and frequency were specific to each transition. Training improved smoothness of braking deceleration and frequency changes with a longer transition duration.

The transition duration increased significantly with training for trot–walk, canter–halt and canter–trot transitions. The lengthening of the transition duration allowed a slow decrease of stride frequency (canter–trot transition) and a smooth decrease of vertical activity (canter–halt and trot–halt transition). The rider adapted his technique to locomotion and training level of the horse. By lengthening transition duration, experienced horses could perform a smooth deceleration. In contrast, young horses could not adequately prepare their gait transition and suddenly brake their forward motion, which produced a high peak of deceleration. The amplitude of frequency change during the gait transition decreased with training for all transitions, especially for canter–halt and trot–walk transition.

Three-day eventing

The analysis of the gallop stride characteristics of three-day event horses during the steeplechase of the Seoul Olympic Games revealed optimal values for successful performance. The optimal stride length should range between 1.85 and 2.05 m while the optimal velocity should range between 13 and 14.3 m/s.[102]

Biomechanics of the hoof and lameness prevention in the athletic horse

Effects of the track

The kinetics of hoof impact is an interesting subject for lameness prevention because a relationship between repeated exposure to shock and the onset of chronic injuries has been established in human medicine[103] and in animal models.[104,105] The shoes and the track surface can be designed in order to minimize hoof shock intensity, especially for race and showjumping horses which undergo very large hoof decelerations at high speeds and landing, respectively. Hoof shock and vibration acceleration measurements after the moment of impact on the ground were used for testing the influence of the track surface on shock and vibration intensity of hoof impact at the trot.[34] The shock of deceleration can reach 707 m/s^2 on asphalt and 31 m/s^2 on sawdust mixed with sand. The subsequent transient vibrations have frequencies between 592 Hz and 41 Hz, respectively. The stiffness of the track surface directly influences these mechanical parameters and should be controlled to minimize vibration damage. In horses, as in human athletes, damping hoof impact with viscoelastic shoes and a soft track surface is useful to prevent overuse injuries of the distal joints.

Improvements in race track designs and surfaces for race horses exemplify the application of research for the betterment of horses and the racing industry. The limb kinematic studies on Standardbreds trotting on various types of race tracks (length, curves) made it possible to propose some recommendations regarding the ideal geometry for race tracks (Fig. 12.12).[106,107] The most important factor affecting comfort is the total length of the track, which determines the curve length and the horses' inclination to avoid any load disequilibrium between the lateral and medial sides of the limbs.

Effects of shoeing

Many shoeing techniques are available but any assumption concerning their effects on hoof biomechanics should be verified experimentally by locomotion analysis studies. The limb kinematics of six sound horses was studied at trot in hand to determine the effect of long toes and acute hoof angles.[108] In this study, no lengthening of the trotting strides was observed after reducing the hoof angle about 10° from the normal value. However, this hoof angle change resulted in toe-first impact and prolonged breakover, both of which are potentially disadvantageous for athletic performance and may predispose the horse to injury. In another study, the effect of an acute angulation of the hind hooves showed some changes in the limb co-ordination which could be interesting for reducing limb interference. The hind hoof breakover can be prolonged and the lift-off of the hindlimbs delayed, which could prevent interference with the ipsilateral forelimb.

Hoof shock and vibration acceleration measurements after the moment of impact on the ground were used to investigate the damping capacity of various hoof pads and shoes.[35] Compared to the reference steel shoe, shock

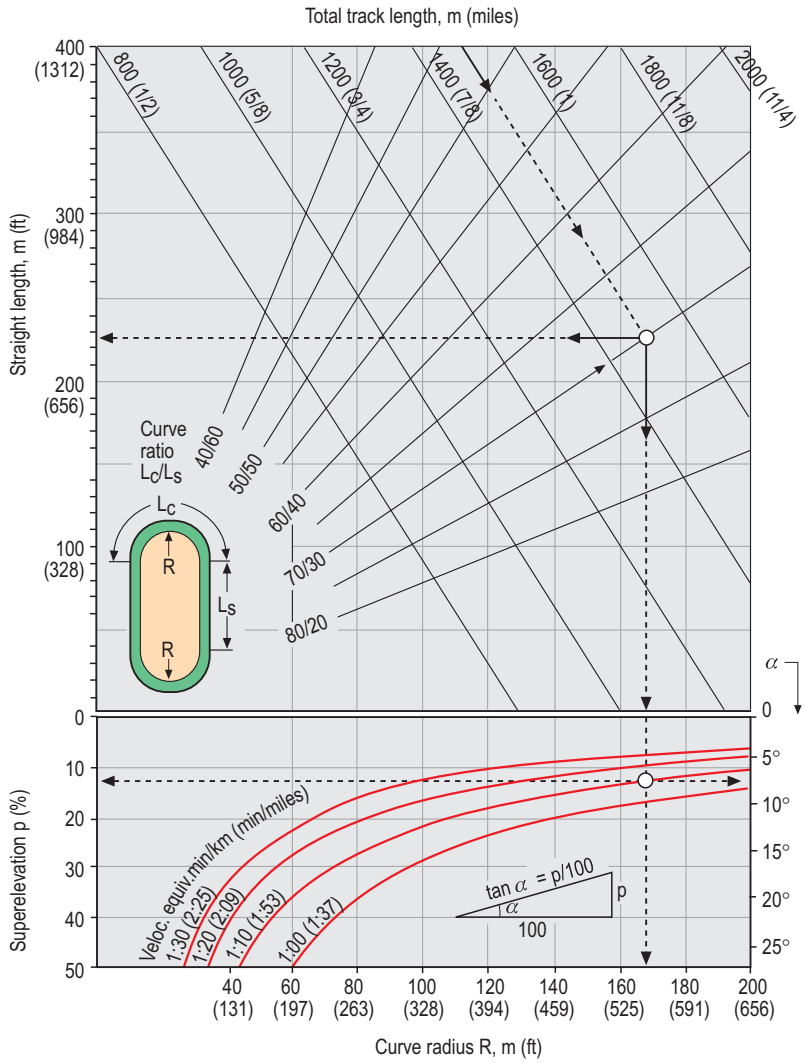

Fig. 12.12
Relationship between the geometric characteristics of a track with semicircular curves. Given a track length of 1500 m and a curve ratio (ratio of curve length to straight length) of 70/30, the length of each straight is read as 225 m and the curve radius as 167 m. For a velocity equivalent of 1:10 min/km the superelevation of the curve is read off on the scale as approximately 12.5% or 7°. (Reproduced from Fredricson et al.[106] with permission.)

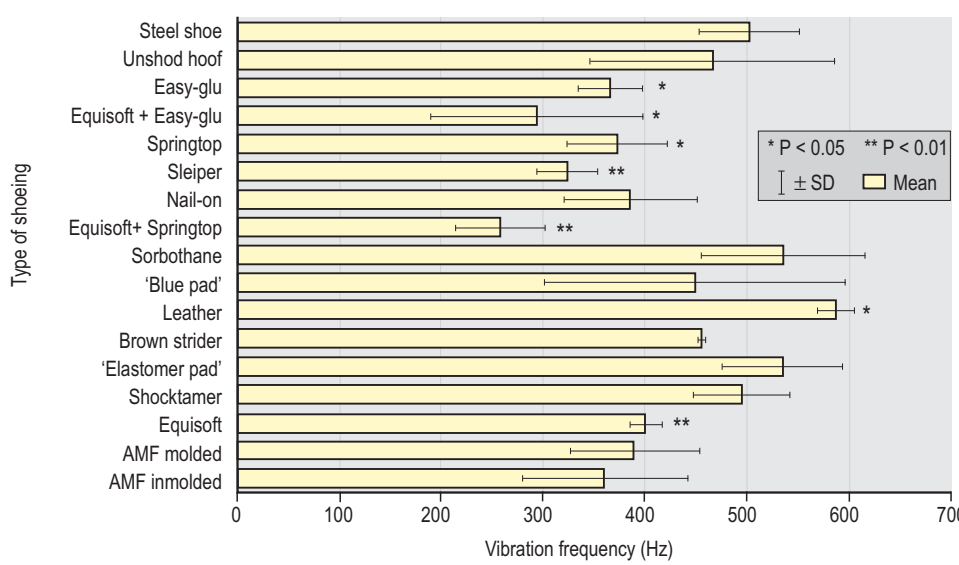

Fig. 12.13
Comparison of the hoof vibration recorded by an accelerometer at the trot on an asphalt road with different types of shoeing (shoe and pads). Better damping of the hoof vibrations after impact was observed with light shoes and soft pads. (Reproduced from Benoit et al.[35] with permission.)

reduction was higher for light shoes made of a polymer and/or aluminum alloy which had lower stiffness values and density than steel (Fig. 12.13). The use of viscoelastic pads contributed to shock reduction and attenuated the high-frequency vibrations up to 75%.

Damping hoof impact with viscoelastic shoes and a soft track surface is useful to prevent orthopedic overuse injuries of the distal joints. The shock damping potential of the track surface is higher than that of the shoes but when the track surface is too hard, the use of damping shoes is highly recommended for horses.

CHAPTER 13

Kinematics of lameness

Joanne Kramer and Kevin G. Keegan

Introduction

Lameness is a frequent problem in the horse and the ability to detect lameness by observing movement is a skill that must be acquired by the equine clinician. With practice and experience equine clinicians develop this skill by recognizing how certain patterns of movement of the body and limbs correlate with lameness. However, there is no set of universally accepted rules about what to observe or how important different movements are in correctly evaluating lameness. We are all trained somewhat differently to identify lameness and this contributes to diversity in the developed skills of lameness recognition between equine clinicians.

It is not difficult to correctly detect and identify the affected limb in a lameness of moderate to severe intensity. There is little disagreement among equine clinicians and the diversity in our training poses little difficulty in these cases. However, when examining horses with intermittent lameness, lameness of mild intensity, or shifting-limb lameness, the diversity in our lameness training results in confusion, disagreement and, ultimately, disparate diagnosis. Even between skilled equine clinicians, interindividual agreement in recognition of mild to moderate lameness and the designation of the correct lame limb have been shown to be poor.[1] The success of treatments for various lameness conditions has traditionally been based on subjective evaluations, imprecise lameness scores computed by few individuals or broad classifications of recovery such as return to function. These evaluative techniques are all potentially influenced by numerous factors unrelated to lameness severity. A more objective methodology to detect and quantify lameness would make lameness evaluations more scientific and thus more reliable.

Kinematic gait analysis is an objective measurement of body movement. The movement is captured with video or cine cameras and a quantitative analysis of that movement is performed. Kinematic gait analysis can be used to detect and quantify lameness without the bias inherent in subjective evaluation. In its simplest form it allows the examiner to record history and compare movement at different points in time. Small differences in movement between separate examinations become apparent with simultaneous, side-by-side comparison of the different time periods. Also, most kinematic gait analysis techniques utilize cameras with high spatial resolution (< 1 mm), high frame rates (> 60 frames per second) and some form of computer-aided data collection and analysis. The high frame rates of the cameras plus the ability to review the motion at slower than normal speed improves the temporal resolution of the examiner. Increased temporal and spatial resolution enables one to detect small changes in stride parameters caused by lameness that would not normally be seen by simple observation alone.

Kinematic gait analysis technique is also conducive to evaluating numerous strides contiguously, a quality that is lacking in more traditional stationary force plate analysis of limb weight bearing. This enables a more accurate evaluation of lameness when there is significant stride-to-stride variance, a common finding in horses with bilateral lameness or lameness of mild severity (Keegan, unpublished data). Multiple measurements of multiple parameters can be made at the same time. Parameter relationships can be studied; for

example, how head or pelvic movement varies with footfall sequence. Changing relationships among multiple kinematic parameters may correlate significantly with lameness.

More importantly, kinematic gait analysis is fundamentally practical because it is intuitive. When equine clinicians evaluate lameness in the field they evaluate movement. We see movement (a kinematic measurement) directly. Force (a kinetic measurement) must be transduced for human perception. Therefore, what we learn about movement and how it changes with lameness can be easily described, taught and learned. Kinematic evaluation closely resembles the techniques used by equine clinicians and thus can be used to improve their understanding and clinical detection of lameness.

Although movement compensation occurs with lameness during many gaits, the ideal gait for kinematic evaluation is the trot. The trot is a symmetrical gait with simultaneous contralateral forelimb and hindlimb placement in each half-cycle of the full stride. Vertical movement of the body is sinusoidal with equivalent amplitudes in each half-cycle. One of the most characteristic features of lameness is its tendency to upset the simple periodicity of normal movement. This perturbation of movement is most easily appreciated at the trot against the normal background of symmetrical vertical movement. In addition, the total vertical movement of the trunk's center of gravity, and thus the resulting forces placed on the limbs during weight bearing, is greater during the trot than at a walk or canter.[2–4] Lameness exacerbated by weight bearing, which includes the majority of lameness in the horse, would therefore be more expressed at the trot than at a walk or canter. In this chapter the kinematic changes referred to as representative of lameness are those primarily observed and measured at the trot.

Methodology

The basic methodology of kinematic gait analysis requires that the horse be 'filmed' while moving. To facilitate calculations of kinematic parameters, the horse is 'marked', usually with light-reflective spheres, over specific body parts such as easily recognizable bony landmarks or joint centers (Fig. 13.1). Each camera used during filming generates two-dimensional images of the positions of the body markers. Multiple cameras set up with different fields of view generate multiple, two-dimensional images of the positions for each marker (Fig. 13.1). These images are then transformed into a sequence of three-dimensional positions for each marker. Data generation rate is high. For example, using cameras that capture at 120 frames per second, a horse marked with 20 light-reflective spheres, filmed for 30 seconds, will generate 216 000 ($120 \times 20 \times 30 \times 3$[$x$, y, z position]) pieces of data that precisely describe the horse's movement over that time period. From these data many different measurements relevant to the horse's movement (joint angle, maximum vertical head position, stride length, etc.) can be calculated.

Most kinematic systems, because of the need for processing and computation of large volumes of data, are computer assisted. Also, standard systems require the horse to move within the camera's limited fields of view. Therefore, most kinematic analysis is performed with the horse moving on a treadmill. This has an advantage of providing for the capture of multiple, consecutive strides of the horse traveling at a precisely controlled velocity. Controlling velocity of movement is necessary since many kinematic parameters are known to be velocity dependent.

Kinematic parameters of importance for the detection of lameness

It is not the purpose of this chapter to give a past synopsis of movement parameters thought to correlate with lameness. Much of what has been described in textbooks is subjective expert opinion. However, until recently much of this expert opinion was either inadequately described or misleading. One only has to try to define and then reconcile the term 'hip hike', a frequent descriptor of hindlimb lameness in horses,[5,6] with pelvic 'sinking' or excessive rotation towards the side of lameness that is described in other reports.[7,8] Some clinicians evaluate the 'head bob' as greater upward movement of the head during the stance phase of the lame limb[6] and others evaluate it as less downward movement during the stance phase of the lame limb.[9] Some evaluate

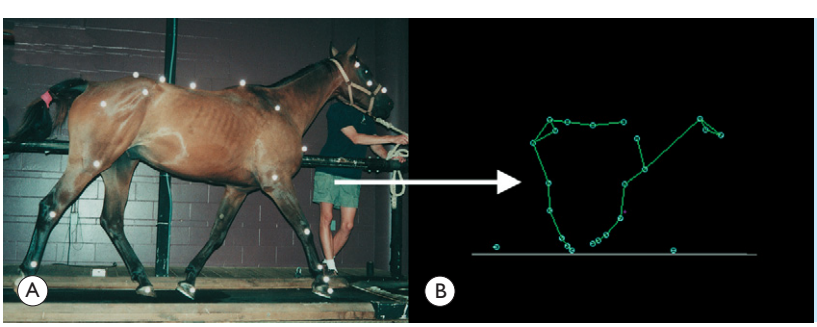

Fig. 13.1

(B) Data from multiple cameras are combined, resulting in the three-dimensional location of each marker in each video frame. Three-dimensional positional data for each marker are available for calculation of different kinematic parameters.

stride length and detect lameness when the length of stride seems to be short.[10] The shape of the hoof flight arc is said to be representative of lameness.[10] Joint angle excursions, during both the stance and swing phase of the stride, have been purported to be accurate indicators of lameness.[8,9,11] Recent objective evaluations have indicated that many of these parameters are either incorrect or, at best, insensitive.[12–14]

In this chapter we emphasize the parameters that are clearly significant and sensitive as indicators of lameness and that are easily seen by the unaided human eye. This necessitates a thorough description of the pattern of head movement for forelimb lameness and of pelvic movement for hindlimb lameness. All of the information necessary to detect lameness and identify it to the correct limb can be found in evaluation of the head and pelvic movement. For completeness, short descriptions of other kinematic parameters that have objectively been shown to correlate with lameness are described. We leave it to the reader to decide whether these other parameters are useful in detecting lameness in a standard clinical lameness examination.

Kinematic parameters used to detect and differentiate forelimb lameness

Vertical head movement

When the horse is trotting its head moves up and down twice during one complete stride. The head reaches a local maximum vertical position just before hoof contact of one forelimb and a local minimum vertical position near midstance of the same forelimb. Second local maximum and local minimum vertical positions are reached just before foot contact and at midstance of the other forelimb. In the sound horse the total vertical head excursion during the right and left forelimb stance phases is approximately equal so the local maximums and minimums are approximately the same heights relative to the ground.

Thus, the head moves up and down in a sinusoidal, temporally symmetrical pattern, with amplitude equivalent cycles corresponding to each half of the full stride cycle (Fig. 13.2). The familiar 'head nod', as an indicator of forelimb lameness in horses, is a disruption of this symmetrical movement. In most weight-bearing lameness conditions the downward head movement during weight bearing of the painful limb is reduced compared to that in the sound limb (Fig. 13.3). With increasing severity of lameness there is more reduction in the downward movement of the head (Fig. 13.4). With severe lameness there may be no downward movement of the head during the stance phase of the lame limb and with very severe lameness the head may actually move upward during the stance phase of the lame limb.

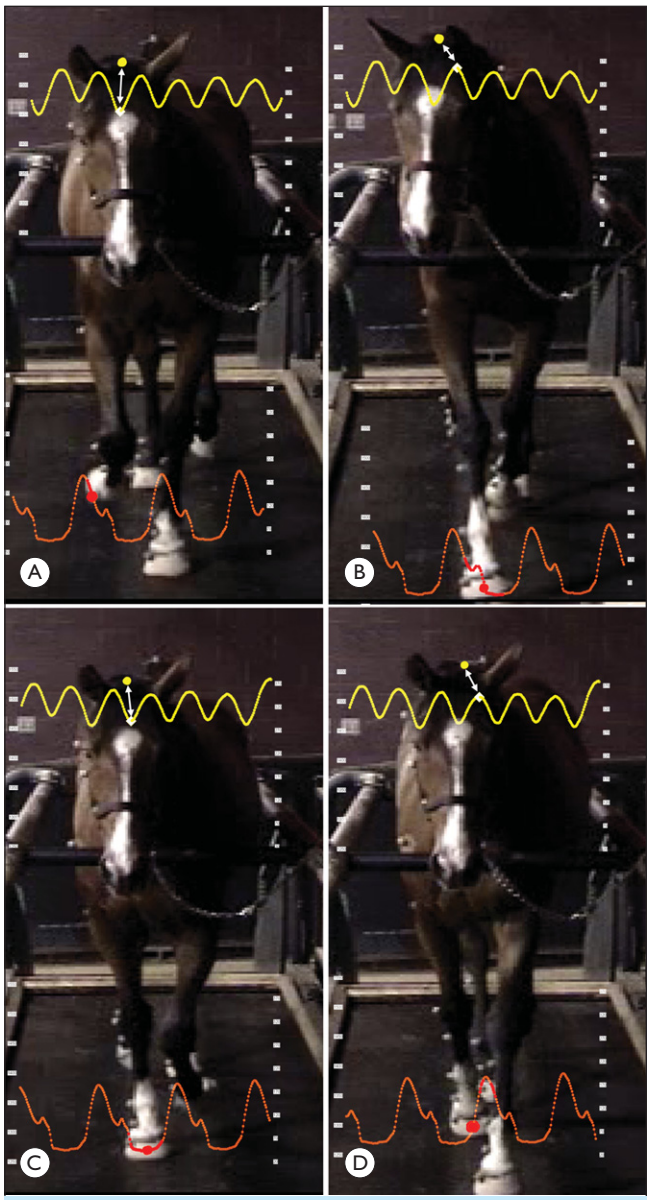

Fig. 13.2
Video frames and graphs depicting vertical head and right forelimb foot movement in a sound trotting horse. (A) First vertical minimum at midstance of the left forelimb. Right forelimb is at midswing. (B) First vertical maximum just after lift-off of the left forelimb foot and just before impact of the right forelimb foot. (C) Second vertical minimum at midstance of the right forelimb. Left forelimb is at midswing. (D) Second vertical maximum just after lift-off of the right forelimb foot and just before impact of the left forelimb foot. Curves at the top of each video frame (yellow) are the vertical head position. Arrows indicate points on the curve corresponding to video frame shown. Curves at the bottom of each video frame (orange) are the vertical position of the right forelimb foot. Orange circles on curve indicate the points corresponding to the video frame shown. Head and right forelimb foot heights are not in same scale. Approximately three full strides are indicated by the curves.

For purposes of categorization we have labeled lameness manifest by less downward movement of the head in the

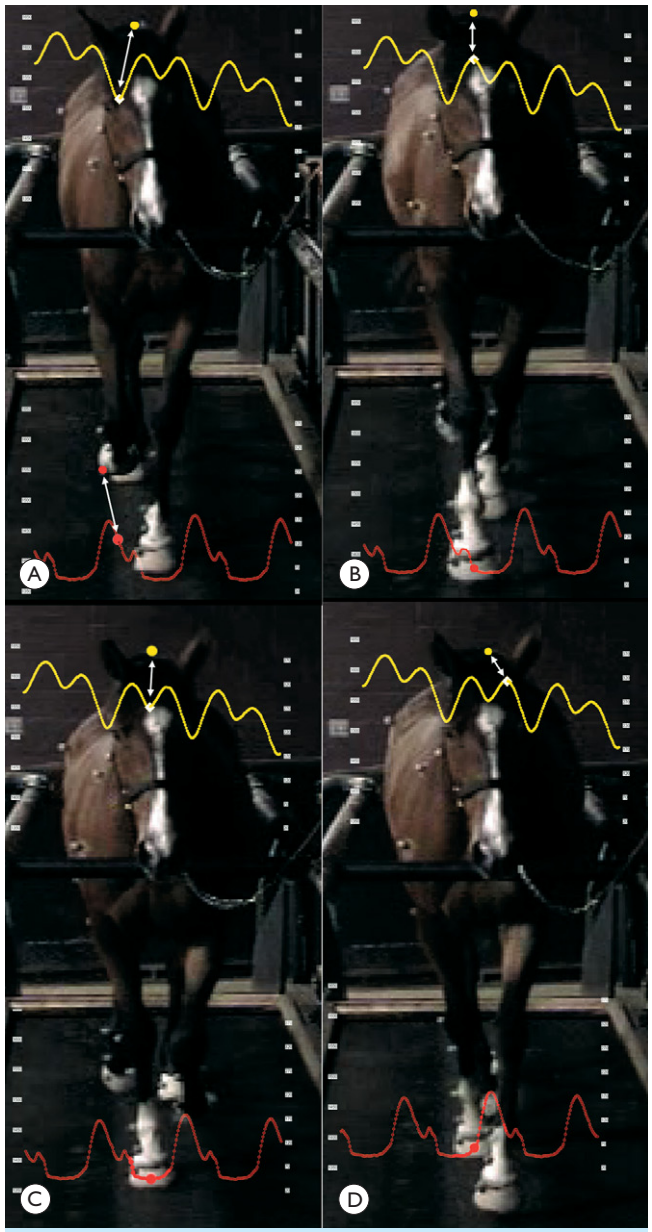

Fig. 13.3
Video frames and graphs depicting vertical head and right forelimb foot movement in a trotting horse with a unilateral (right) type-1 induced forelimb lameness. (A) First vertical minimum is lowest at midstance of the left forelimb. Right forelimb is at midswing. (B) First vertical maximum just after lift-off of the left forelimb foot and just before impact of the right forelimb foot. (C) Second vertical minimum at midstance of the right forelimb. Left forelimb is at midswing. There is less downward movement of the head compared to the minimum in left forelimb stance. (D) Second vertical maximum just after lift-off of the right forelimb foot and just before impact of the left forelimb foot. Curves at the top of each video frame (yellow) are the vertical head position. Arrows indicate points on the curve corresponding to video frame shown. Curves at the bottom of each video frame (orange) are the vertical position of the right forelimb foot. Orange circles on curve indicate the points corresponding to the video frame shown. Head and right forelimb foot heights are not in same scale. Approximately three full strides are indicated by the curves.

stance phase of the lame limb as type-1 lameness. Frequently in horses with type-1 lameness there is also less upward movement of the head at the end of the stance phase of the lame limb (Fig. 13.4). The majority of horses with weight-bearing lameness exhibit type-1 lameness. Sometimes during a clinical examination it is easier to appreciate the greater downward movement of the head during the stance phase of the normal or least lame forelimb. 'Down on sound' is an aphorism frequently used to describe this phenomenon.

Occasionally horses with forelimb lameness will have greater upward movement of the head at the end and shortly following the stance phase of the lame forelimb (Fig. 13.5). We have labeled lameness with this variant of head movement as type-2 lameness. Type-2 lameness is much less common than type 1. Horses with pain occurring during the breakover portion of stance may more likely exhibit type-2 lameness, although this has not been confirmed objectively. Also, display of type-2 lameness may be more idiosyncratic, possibly related to an individual's pain tolerance or threshold. It seems also that there is a higher incidence of type-2 lameness with lameness of increasing severity.

In the authors' opinion vertical head position is the most applicable and accurate movement parameter for use in clinical examination of forelimb lameness. It can be evaluated equally from the front or side of the horse. It is frequently exacerbated and made more apparent at the beginning (when the horse is accelerating) and end (when the horse is decelerating) of a short trot and when lunging the horse in short circles. However, conditions sometimes arise that make evaluation using this parameter more difficult. The asymmetrical nature of the vertical head movement in some mild lameness conditions may not occur at every stride. As the intermittent nature of the lameness increases, the need to evaluate increasing numbers of strides becomes more important and the ability to detect overall asymmetric head movement becomes more difficult. In addition, extraneous head movement, especially in the curious or excitable horse in an unfamiliar environment, may obscure small perturbations in vertical head movement. It is especially important not to jump to conclusions after a few strides and instead try to determine the overall predominant head movement pattern before committing oneself to a final decision. Algorithms to remove extraneous vertical head movement have been described and can be used in objective analysis of kinematic data to increase accuracy in detection of lameness.[15]

Temporal parameters (stance phase, swing phase and breakover durations)

Stance phase begins at hoof impact and ends after breakover, when the toe is lifted from the ground to start the swing phase of the stride. It is instinctive to suppose that stance-phase duration should be less in a lame compared to a sound limb and that it should decrease as lameness

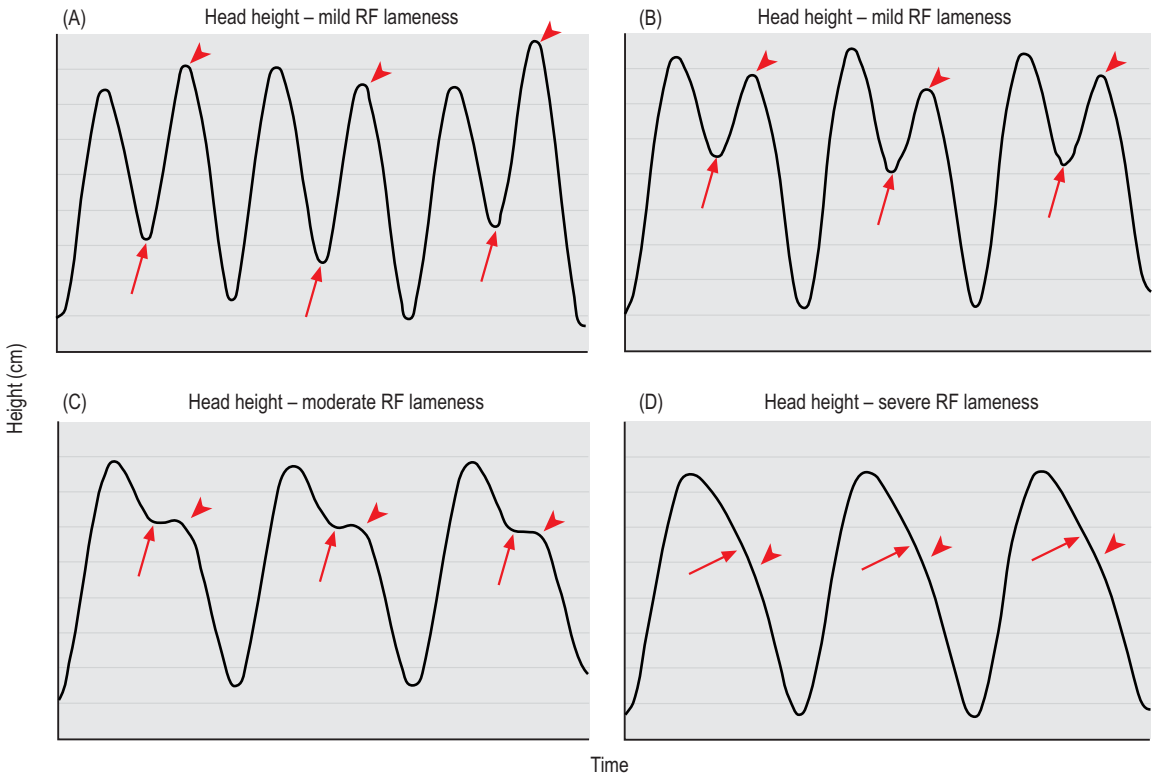

Fig. 13.4
Vertical head movement asymmetry with increasing severity of forelimb lameness. (A–C) Amount of downward movement during the stance phase of the lame limb becomes less and less, until (D) minimum vertical position during stance phase of lame limb disappears. Arrows indicate approximate time of lame (right) forelimb midstance. Arrowheads indicate corresponding decreasing elevation of the head after the stance phase of the lame (right) forelimb.

worsens. After all, a horse with a non-weight-bearing lameness spends no time on the affected leg. However, except for horses with severe lameness, the opposite occurs. In horses with mild to moderate lameness, stance-phase duration is increased compared to the contralateral sound limb.[9] Consequently, stance-phase duration decreases after alleviation of lameness, such as after a regional nerve or joint block.[13] This correlation between stance-phase duration and severity of lameness, however, is true only if the horse is constrained to move at the same forward velocity before and after treatment. Ensuring the same velocity before and after treatment is not easy without special equipment and therefore is not reliable enough for practical purposes of subjective lameness observation.

Stance-phase duration increases in horses with mild to moderate lameness as a direct consequence of the horse attempting to lessen peak loads on the affected limb.[16] When a horse is trotting at a particular velocity a resultant force is applied to the affected limbs. Some force is relieved from the affected forelimb by shifting of weight to the contralateral hindlimb, but the amount is small and inconsequential in horses with mild to moderate lameness.[17,18] Therefore, the only way available to the horse to reduce peak load on the affected limb (and therefore ostensibly to reduce pain) is to spread the total load over a longer period of time.

Despite being a good indicator of lameness, it is doubtful that subjective measurement of stance-phase duration would be of much use to the equine practitioner in the field. In a horse trotting at about 4 m/s the stance duration is less than 1 second and the increase in stance duration with moderate lameness is less than 20 ms.[13] Changes in duration of such small magnitude cannot be appreciated by simple observation.

As a direct consequence of an increase in stance-phase duration in mild to moderate lameness, there is an equivalent decrease in the swing-phase duration.[12] This may be more readily apparent during direct observation of a trained eye than the increased stance-phase duration. The decreased swing-phase duration may cause the observer to think that there is a decrease in the length of the stride or in the swing-phase height of the foot, two parameters commonly associated with lameness. It has also been shown that with unilateral forelimb lameness there is a shortened suspension-phase duration (the time during the stride when no feet are in contact with the ground) after the stance phase of the lame limb.[19] This asymmetry in suspension-phase duration is generally not present with hindlimb lameness.[19]

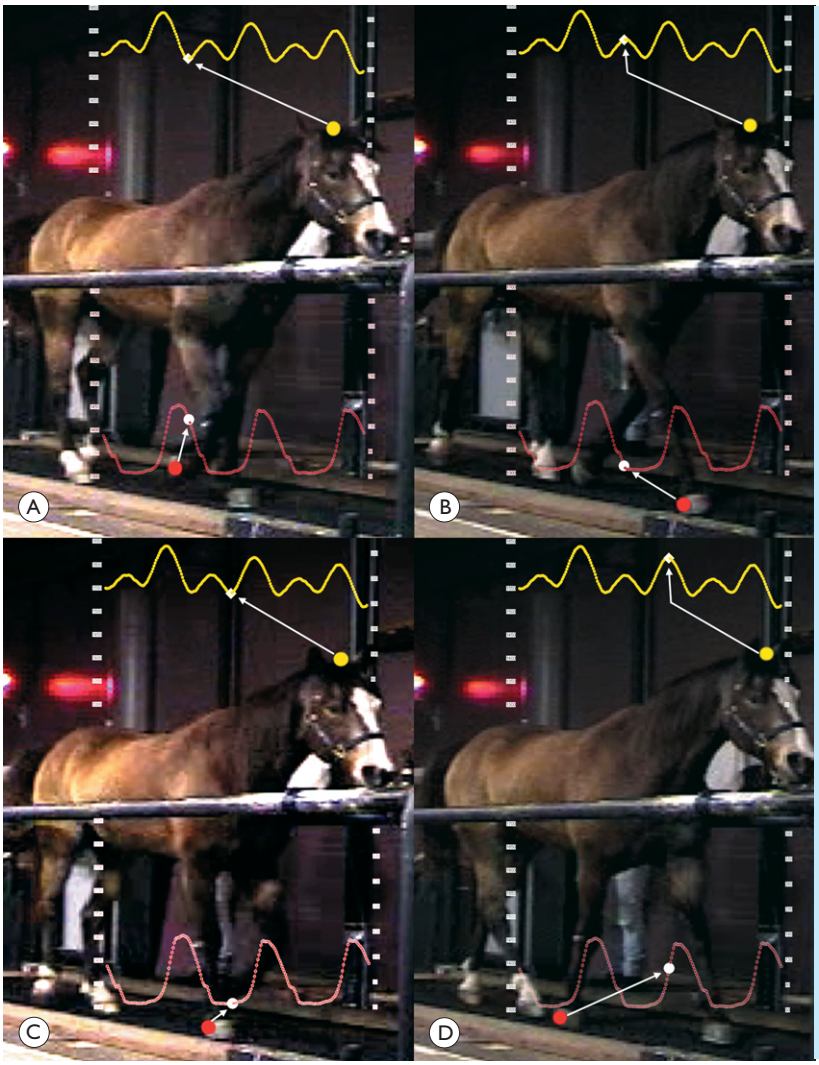

Fig. 13.5
Video frames and graphs depicting vertical head and right forelimb foot movement in a trotting horse with a unilateral (right) induced type-2 forelimb lameness. (A) First vertical minimum at midstance of the left forelimb. Right forelimb is at midswing. (B) First vertical maximum just after lift-off of the left forelimb foot and just before impact of the right forelimb foot. (C) Second vertical minimum at midstance of the right forelimb. Left forelimb is at midswing. (D) Second vertical maximum just after lift-off of the right forelimb foot and just before impact of the left forelimb foot. Head vertical position is at the highest point in the stride. Curves at the top of each video frame (yellow) are the vertical head position. Arrows indicate points on the curve corresponding to video frame shown. Curves at the bottom of each video frame (orange) are the vertical position of the right forelimb foot. Arrows indicate points on curve corresponding to the video frame shown. Head and right forelimb foot heights are not in same scale. Approximately three full strides are indicated by the curves.

An important limitation to remember when using these parameters is the changing velocity of the horse between sessions of a lameness examination. All temporal gait parameters are velocity dependent. When lame, the horse will naturally attempt to travel at a slower velocity. After a successful nerve or joint block and alleviation of the pain the horse will then naturally be more comfortable at a higher velocity. The handler may inadvertently increase forward velocity between evaluation sessions or the horse may move faster because of pain alleviation. An increase in velocity after alleviation of pain may be noticeable as an increased willingness of the horse to move, an inexact but subjective supporting piece of evidence indicating lameness improvement that is generally appreciated by the examiner.

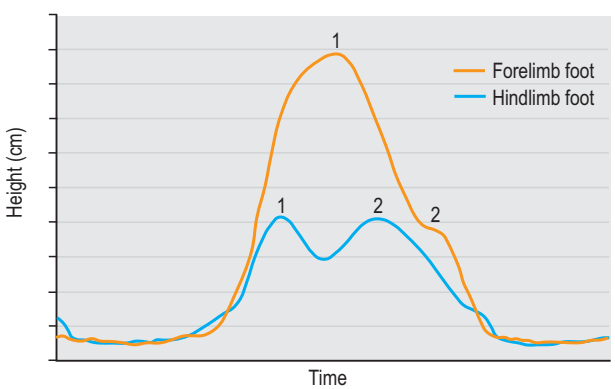

Fig. 13.6
Typical foot-flight pattern in the forelimb and hindlimb. Forelimb foot-flight pattern has a predominant peak (1) just before midswing and sometimes a small peak (2) at the end of the swing phase of the stride. Hindlimb foot-flight pattern has two prominent peaks, (1) the first within the first half and (2) the second in the last half of the swing phase of the stride.

Hoof movement in the swing phase of the stride (foot-flight pattern, swing-phase height, limb protraction and retraction)

Hoof flight pattern in the forelimb[20] is different from that in the hindlimb (Fig. 13.6). In the forelimb, maximum hoof height occurs before midswing and then gradually lowers as the foot moves toward impact, sometimes having a second, smaller peak at the end of the swing phase of the stride. In the hindlimb, maximum hoof height frequently also occurs before midswing, but it is followed by a lowering of the foot at midswing and a second prominent peak in the second half that may be almost as high as the peak in the first half of the swing phase of the stride.

There is much confusion concerning the effect of lameness on hoof movement in the horse during the swing phase of the stride. In experimentally induced forelimb lameness, an absolute higher hoof flight arc is seen in the sound limb with no change in the lame forelimb.[12] In experimentally induced hindlimb lameness, an absolute lower hoof flight arc is seen in the lame hindlimb with no change in the sound hindlimb.[12] Both of these combinations give rise to the impression of lower hoof flight arc with lameness.

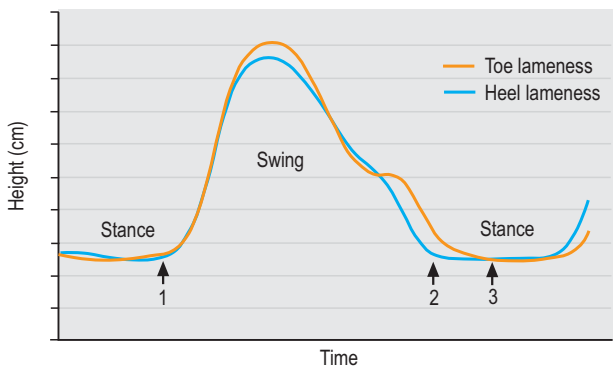

Fig. 13.7
Forelimb hoof-flight pattern after induction of toe and heel lameness. (1) Breakover is lined up in time to show the increased protraction with toe lameness. (2) Hoof impact after heel lameness. (3) Hoof impact after toe lameness.

Fig. 13.8
Fetlock extension at midstance (limb axis perpendicular to the ground). Dorsal angle decreases as fetlock extends.

However, there are over-riding biomechanical factors that make evaluation of this parameter problematic when observing horses for lameness. During lameness, the trunk height after push-off of the lame limb is reduced, causing a corresponding decrease in absolute limb and hoof height. However, in order to move the limb forward without ground interference the horse must increase flexion of the limb joints. This increased flexion results in higher relative foot height during the swing phase of the stride. Decreased hoof height resulting from decreased trunk height is partially canceled by the increased flexion of the limb joints. In the authors' opinion, absolute hoof height during the swing phase of the stride is not a reliable parameter for evaluating lameness in horses.

Lame forelimbs show a reduction in the extent of retraction at the end of the stance phase of the stride.[12] The extent of protraction is diminished only with severe lameness.[21] Some lameness conditions, specifically lameness of the toe of the foot, have even been shown to increase protraction of the lame forelimb (Fig. 13.7).[9] One only has to consider the typical gait of a horse with severe toe pain from laminitis, which is mostly protraction and little retraction, to understand this.

Joint angle changes

Fetlock extension at midstance, when the limb is perpendicular to the ground, is a very sensitive indicator of the amount of ground reaction force on the limb in both forelimbs and hindlimbs (Fig. 13.8).[22,23,39] When compared to the sound limb in a unilateral lameness condition, the fetlock is relatively less extended in the lame limb.[12] In a lameness of moderate severity this difference can be up to 5° in the sagittal plane at the fast trot.[13] With lameness, maximum coffin joint flexion within the first half of the stance phase of the stride is also reduced.[12] Although these changes are consistent and can be measured by sophisticated kinematic or goniometric techniques it is questionable whether they can be reliably detected by direct visual observation.

Kinematic parameters used to detect and differentiate hindlimb lameness

Vertical pelvic movement

Analysis of pelvic movement is frequently used in the identification of hindlimb lameness and varying descriptions of how to do this have been published.[24–27] The

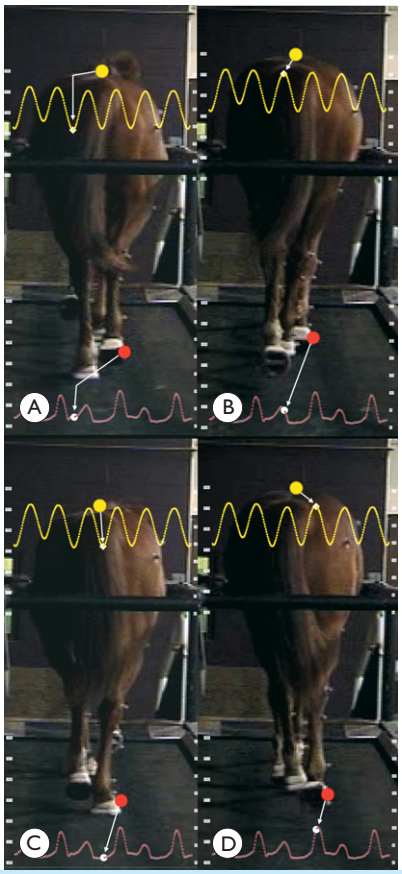

Fig. 13.9
Video frames and graphs depicting vertical pelvic and right hindlimb foot movement in a sound trotting horse. (A) First vertical minimum at midstance of the left hindlimb. Right hindlimb is at midswing. (B) First vertical maximum just after lift-off of the left hindlimb foot and just before impact of the right hindlimb foot. (C) Second vertical minimum at midstance of the right hindlimb. Left hindlimb is at midswing. (D) Second vertical maximum just after lift-off of the right hindlimb foot and just before impact of the left hindlimb foot. Curves at the top of each video frame (yellow) are the vertical pelvic position. Arrows indicate points on the curve corresponding to video frame shown. (B) First vertical maximum just after lift-off of the left hindlimb foot and just before impact of the right hindlimb foot. (C) Second vertical minimum at midstance of the right hindlimb. Left hindlimb is at midswing. There is less downward movement of the pelvis compared to vertical minimum at left hindlimb stance. (D) Second vertical maximum just after lift-off of the right hindlimb foot and just before impact of the left hindlimb foot. Curves at the top of each video frame (yellow) are the vertical pelvic position. Arrows indicate points on the curve corresponding to video frame shown. Curves at the bottom of each video frame (orange) are the vertical position of the right hindlimb foot. Arrows indicate points on the curve corresponding to the video frame shown. Pelvic and right hindlimb foot heights are not in same scale. Approximately three full strides are indicated by the curves.

pattern of vertical movement of the pelvis is similar to that of the head seen in trotting horses.[7] Vertical pelvic movement has a sinusoidal pattern with two cycles occurring during one complete stride. The first minimum height is reached during the middle of one of the limb's stance phase and the first maximum height at the end of this stance phase. A second symmetrical oscillation occurs during the stance phase of the contralateral limb (Fig. 13.9). Although extraneous vertical movement of the pelvis (unassociated with normal inertial changes due to mechanics of movement) does occur, its contribution to total vertical movement of the pelvis is much less than that seen in the head.[7] However, as in the forelimb, algorithms can be applied to eliminate extraneous pelvic movement and evaluate only movement due to the biphasic vertical excursion.

Unilateral hindlimb lameness changes the symmetry of pelvic movement.[7,25,28,29] During lameness the entire pelvis exhibits less lowering during the stance phase and less lifting at the end and following the stance phase of the lame limb (Fig. 13.10). Using the classification scheme described above, this describes a typical type-1 lameness. These changes are proportional to the degree of lameness. Severe hindlimb

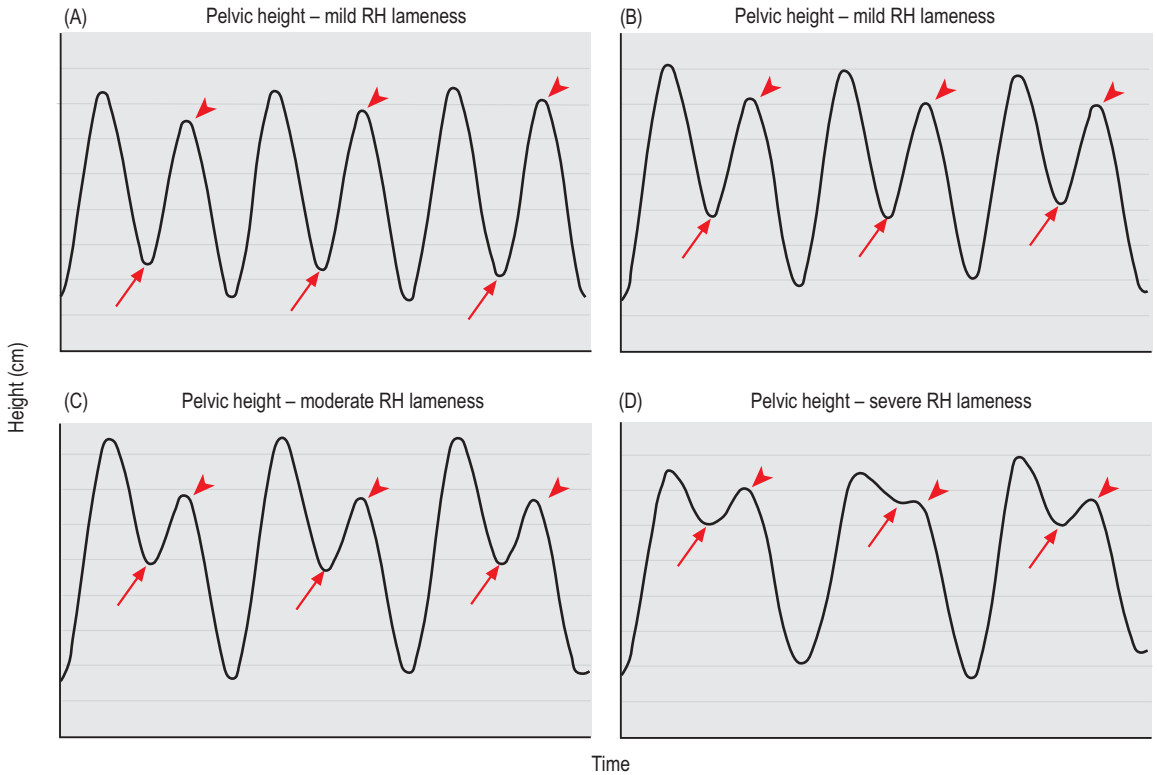

Fig. 13.11
Vertical pelvic movement asymmetry with increasing severity of hindlimb lameness. (A–C) Amount of downward movement during the stance phase of the lame limb becomes less and less, until (D) minimum vertical position during stance phase of lame limb almost disappears. Arrows indicate approximate time of lame (right) hindlimb midstance. Arrowheads indicate corresponding decreasing elevation of the pelvis after the stance phase of the lame (right) hindlimb.

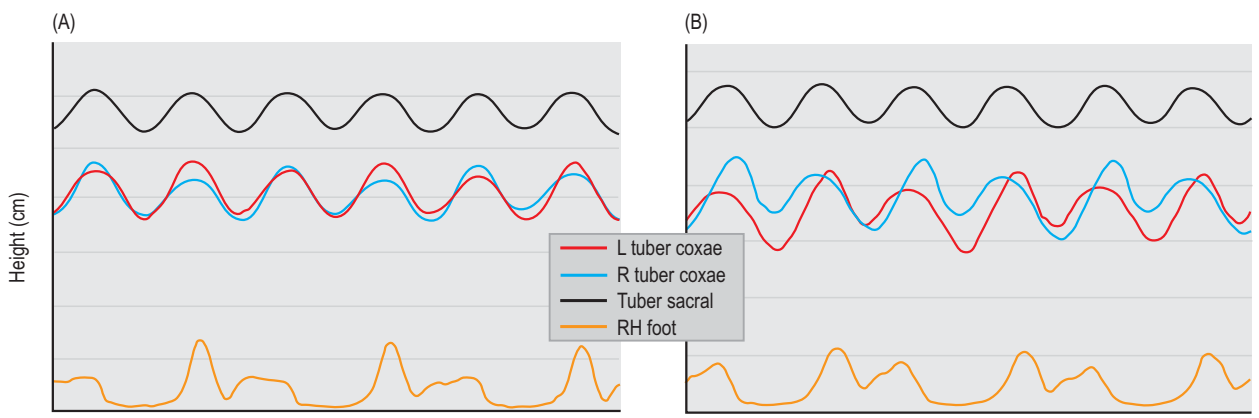

Fig. 13.12
Vertical tuber coxae movement in two sound horses. Tuber sacral movement is symmetric. (A) In horse 1, tuber coxae vertical movement is only slightly asymmetric, indicating little pelvic rotation. (B) In horse 2, tuber coxae vertical movement is very asymmetric, indicating greater pelvic rotation.

lameness may change the degree of symmetry to the extent that there is very little downward movement of the pelvis during the stance phase of the lame limb (Fig. 13.11). It is instructive to note that, in contrast to what is occasionally seen with head movement in forelimb lameness, increased pelvic movement at the end of the stance phase of the lame limb (a type-2 lameness) has not been described.

Tuber coxae movement

Vertical movement of the tuber coxae is normally slightly asymmetric in time. The vertical movement of the tuber coxae has the same basic pattern as the entire pelvis, but the two oscillations are not completely symmetric. The first minimum height is reached during the middle of one limb's

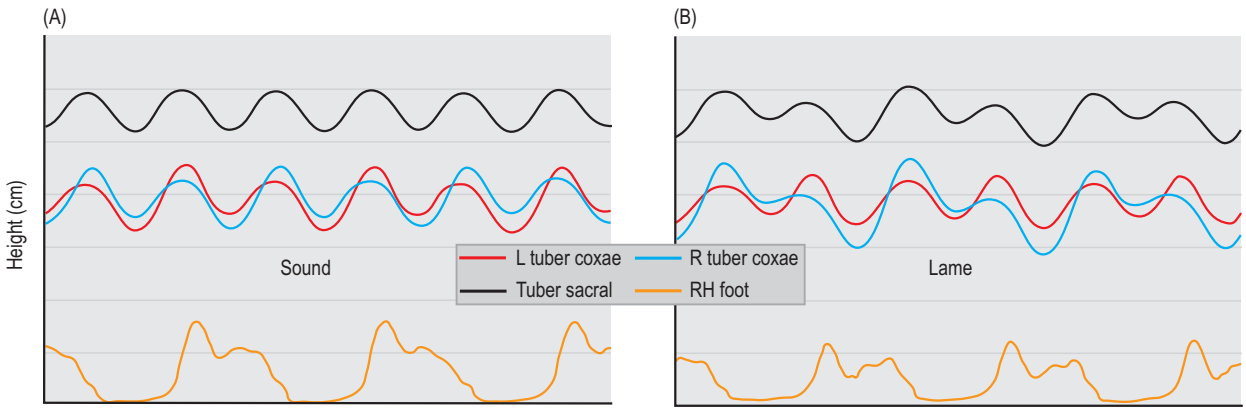

Fig. 13.13
Vertical tuber coxae movement in a (A) sound horse and in (B) the same horse after induction of a right hindlimb lameness. Note the increased vertical movement asymmetry in the right tuber coxae after induction of lameness. Note also the development of asymmetry of vertical tuber sacral movement after induction of lameness.

stance phase and first maximum height is reached at the end of this stance phase. The second oscillation occurs during and shortly following the stance phase of the contralateral hindlimb. However, the vertical movement of the tuber coxae is greater during and shortly after the stance phase of the contralateral hindlimb than that of the ipsilateral hindlimb. The tuber coxae reaches its lowest height at midstance and its maximum height just following the stance phase of the contralateral limb (Fig. 13.12). The asymmetrical movement of the tuber coxae has been attributed to rotational movements of the pelvis around the longitudinal axis of the vertebral column.[7,28] If the pelvis did not rotate the pattern of vertical movements of both tuber coxae would be identical to each other and to the entire pelvis.

The degree of tuber coxae vertical movement asymmetry seen normally in the sound horse is exaggerated in the lame horse (Fig. 13.13). In lame horses the tuber coxae of the lame limb has less downward movement during and less upward movement at the end and shortly following the stance phase of the lame limb. During the stance phase of the sound limb the contralateral tuber coxae has more downward movement during and more upward movement at the end and shortly following the stance phase of the sound limb. This increased upward movement after the stance phase of the sound limb may be what is referred to as 'hip hike'.

Clinically, tuber coxae movement has been described to be useful in the diagnosis of hindlimb lameness.[25] Because of pelvic rotation, total vertical movement of the tuber coxae is greater than total vertical pelvic movement and thus may be easier to observe. Total vertical movement of the tuber coxae is greater on the side of hindlimb lameness. This asymmetry in the amplitudes of left and right vertical tuber coxae movements has been measured and used to diagnose hindlimb lameness in horses.[7,8,14,25] One explanation for the exaggerated tuber coxae movement on the lame side has been

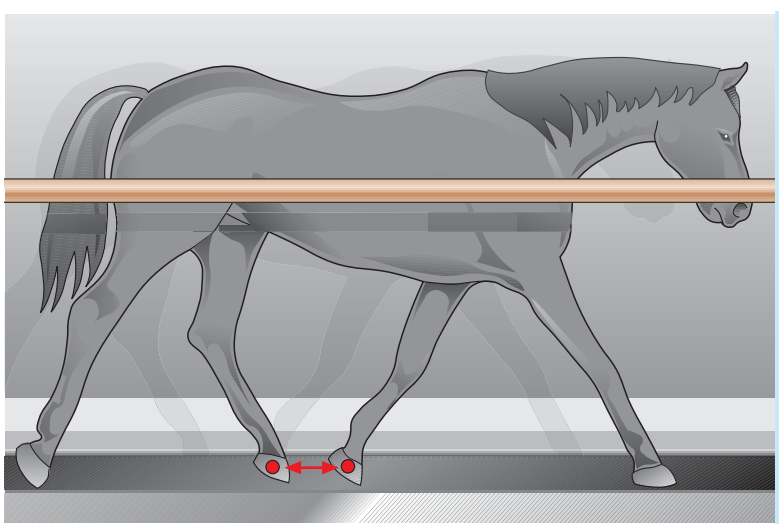

Fig. 13.14
Evaluation of hindlimb protraction at the trot by observing the distance between ipsilateral fore- and hindlimb feet.

offered by Buchner et al.[7] In a right hindlimb lameness the right tuber coxae during right stance has mainly vertical movements. These excursions are enlarged during left stance by rotational movements in the spine. Exaggerated back rotation during the stance of the lame limb may reduce lifting effort during lame limb stance phase.

Although total vertical tuber coxae movement may be observed more easily than total pelvic vertical movement, observing only total vertical tuber coxae movement in some cases may be misleading. Individual horses have varying amounts of vertical tuber coxae movement asymmetry, likely due to different rotational flexibilities of the pelvis and vertebral columns. In some horses tuber coxae movement is primarily due to vertical movement of the trunk and is equally symmetrical as total pelvic vertical movement. In other horses with more significant pelvic rotational movement there is greater vertical tuber coxae movement asymmetry (see Fig. 13.12). Mild asymmetries between right and left tuber coxae vertical movement have been identified in clinically sound horses,[8,28] suggesting that the degree of acceptable asymmetry has not yet been determined. Horses with pre-existing pelvic shape asymmetry unassociated with lameness may also have fairly dramatic vertical tuber coxae movement.

Hindlimb protraction

Decreased hindlimb protraction is a useful indicator of hindlimb lameness. With hindlimb lameness of the tarsus and foot, reduced protraction of the lame hindlimb has been measured.[12,14,30] This change may be a method of decreasing load on the hindlimb by placing it further away from the center of gravity.[12] The decreased protraction of the hindlimb is an easy gait parameter to evaluate at the trot and walk because of the reference point provided by the simultaneous backward movement of the ipsilateral forelimb. The space between the maximally retracted forelimb and the maximally protracted hindlimb on one side of the body can be easily compared to that on the other side during the next half of the stride (Fig. 13.14).

The difference between forelimb and hindlimb protraction and retraction accommodation with lameness can be most easily explained by differences in the timing of load on the limb. In the forelimb the load is greatest during the second half of the stance phase when the limb is more directly under the center of gravity of the trunk. In the hindlimb the highest load occurs in the first half of stance phase. The horse attempts to restrict the forward motion of the hindlimb so that hoof impact is farther from the trunk's center of gravity.

Joint angle changes

Changes in the maximum flexion and extension of various joint angles have been measured in the sound and affected limbs of horses with unilateral hindlimb lameness.[8,12,14,30,31] In general the flexion and extension patterns of the distal joints seem to be primarily affected by ground reaction forces or differences in the loading of the limbs.[32] Several researchers have documented significant decrease in fetlock joint extension of the lame hindlimb.[12,14] Comparing the relative extension of the right and left fetlock joint during stance has also been described in visual descriptions of lameness.[24,33] Changes in the pattern of fetlock and coffin joint movement mimic closely the pattern of changes in vertical ground reaction forces.

Tarsal flexion increases during the swing phase of the lame limb after sole-induced lameness (Fig. 13.15).[12] The increase is attributed to an effort by the horse to avoid dragging the toe after push-off in the lame limb, resulting in lower trunk height. If the trunk is not raised to the normal degree after push-off of the lame limb then increased flexion of the joints during swing may be necessary to avoid dragging the toe during the swing phase of the lame leg. However, in a study of induced distal tarsal lameness, fetlock flexion

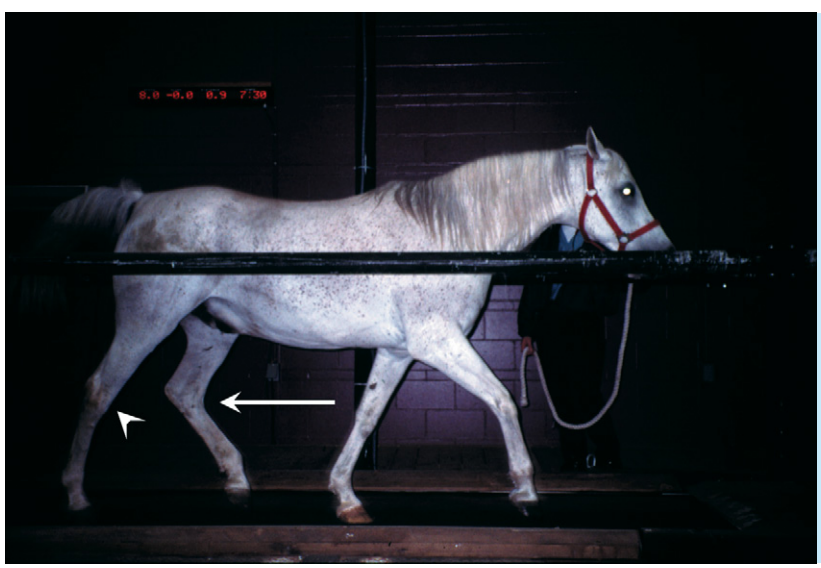

Fig. 13.15
Maximum tarsal flexion during the swing phase of the stride (arrow). Maximum tarsal extension at the end of stance (arrowhead).

increased but tarsal angle during the swing phase of the affected limb was unchanged.[14]

Decreased flexion of all limb joints during the swing phase of the lame hindlimb resulting in an increase in tuber coxae height during the swing phase of the stride has been described, but to the authors' knowledge this has not been measured directly. All present data suggest that, in weight-bearing lameness, flexion of the proximal joints is increased or unchanged.

By contrast, the tarsal joint during stance tends to flex more (extend less) during lameness of the hindlimb.[12,14] Tarsal angle during stance is influenced by ground reaction force, as in the fetlock, but being a proximal joint it is also under heavy influence of large proximal limb muscle groups. With pain during weight bearing in a lame limb, the large proximal muscle groups act to provide gentler and less sudden braking of the limb at the onset of weight bearing. In a study of induced distal tarsal lameness that resulted in the development of mild to moderate lameness, mean hock flexion during the stance phase of the stride was 3° greater after lameness induction than before.[14] This small degree of change is probably not apparent to the naked eye.

Changes in hindlimb abduction/adduction

Changes in hindlimb abduction and adduction have been reported in subjective, observational descriptions of lameness evaluation.[34,35] The most common description is that of tarsal adduction or medial swinging of the hindlimb during protraction and a lateral hoof wall landing pattern, which is reported to be specific for lameness involving the distal tarsal joints.[34,35] To the authors' knowledge, this parameter has not been measured directly and the same hindlimb movement pattern is seen in lameness emanating from other foci within the hindlimb.

Foot-flight pattern

As described previously, the foot-flight pattern of the hindlimb in horses has two peaks, with a depression or lowering occurring about midswing. Maximum height and pattern of hoof flight may be affected by lameness. In one study, maximum hoof height during the swing phase of the stride was lower after sole pressure-induced lameness.[7] A lower hoof flight arc has also been described in a single case report of distal tarsal degenerative joint disease.[30] A decrease in the height of the hoof-flight arc with hindlimb lameness may be due to an overall decrease in trunk height after push-off of the lame limb. In one study of induced distal tarsal arthritis, hoof height during swing increased in the lame limb.[14] As in the forelimb, hoof-flight arc is likely to be simultaneously affected by decreased trunk elevation and increased proximal limb joint flexion. Determination of lameness based upon hoof height or pattern alone is not reliable.

Interlimb co-ordination

In most trotting horses the forelimb and contralateral hindlimb contact the ground surface simultaneously.[34,36] At high forward trunk velocities or during elite performance, slight dissociation between the normal co-ordination of limb pairs may occur.[34,37] Dissociation of simultaneous forelimb and hindlimb impact in one forelimb–hindlimb pair may be a sign of lameness. In cases of moderate to marked hindlimb lameness the forelimb contacts the ground surface before the lame hindlimb.[36,38]

Kinematic parameters associated with bilateral lameness

Many musculoskeletal problems in horses present as bilateral lameness, two common examples being navicular disease and distal tarsal degenerative joint disease. The evaluation of bilateral lameness is complicated by two factors. Symmetry of movement between the right and left sides of the body is maintained to some extent with bilateral lameness.[31,38] Often the magnitude of pain and dysfunction in one limb is only slightly more or less intense than in the similarly affected other side. Careful observation is necessary to detect the small differences in symmetry of movement between the affected sides. A second factor complicating the detection of bilateral lameness is the propensity for the lameness to shift sides during the lameness examination. In some cases of bilateral lameness local, regional or joint anesthesia may be used to temporarily reduce lameness on one side. Frequently, after local anesthesia of one limb, the lameness will become more unilateral, simplifying lameness detection. In other cases the source of lameness may not be amenable to local anesthesia or the effects of local anesthetics may actually interfere with the detection of mild changes in lameness.[40,41]

The characteristic stride described for a horse with a bilateral lameness is a short, 'stiff' and 'shuffling gait'.[26,42] Attempts to objectively measure these changes in stride parameters during bilateral lameness have been made and described.[31,35] In one study utilizing a bilateral hoof-induced lameness model, horses exhibited some characteristic gait compensations. Total stride duration was reduced, relative stance duration was increased and a diagonal advanced placement (placing forelimbs earlier than hindlimbs) was initiated.[36]

Without pre-existing control data from a horse with bilateral lameness of equivalent severity between the right and left sides, diagnosis of lameness based upon kinematic parameters would be challenging. Kinematic detection of such cases requires analysis of multiple stride sequences to evaluate the limb-shifting nature of the lameness and precise detection of subtle asymmetries between left and right sides. A database of kinematic evaluation of normal sound horses

to establish accepted asymmetry measurements for relative comparison would also be needed.

Kinematic parameters in compensatory lameness

Horses with true hindlimb lameness will frequently appear to have false, ipsilateral forelimb lameness (Fig. 13.16).[43] The hindlimb lameness causes a compensatory asymmetric vertical movement of the head, with the head moving down less when the ipsilateral forelimb is in stance. Sometimes rather mild hindlimb lameness will cause a more apparent severe but false forelimb lameness on the ipsilateral side. Conversely, sometimes horses with true forelimb lameness will appear to have false, contralateral hindlimb lameness (Fig. 13.17). The forelimb lameness causes a compensatory asymmetric vertical movement of the pelvis. The pelvis will move down less when the contralateral hindlimb is in stance phase. The biomechanical compensation mimicking hindlimb lameness only occurs when the forelimb lameness is moderate to severe. Therefore, it is a good rule of thumb,

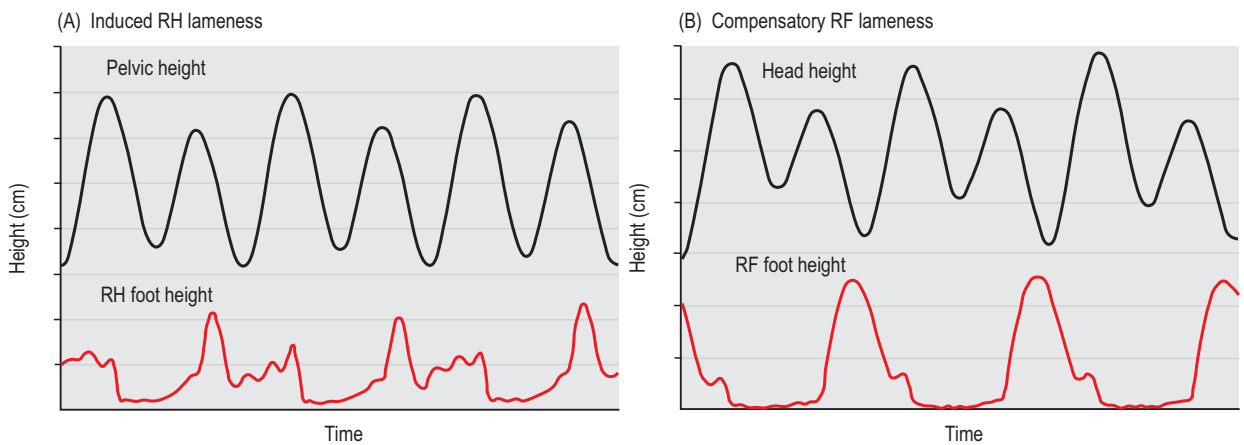

Fig. 13.16
(A) Mild induced right hindlimb lameness causing a (B) moderate to severe compensatory right forelimb lameness. Notice less downward movement of the pelvis during the stance phase of the right hindlimb in (A) and less downward movement of the head during the stance phase of the right forelimb in (B).

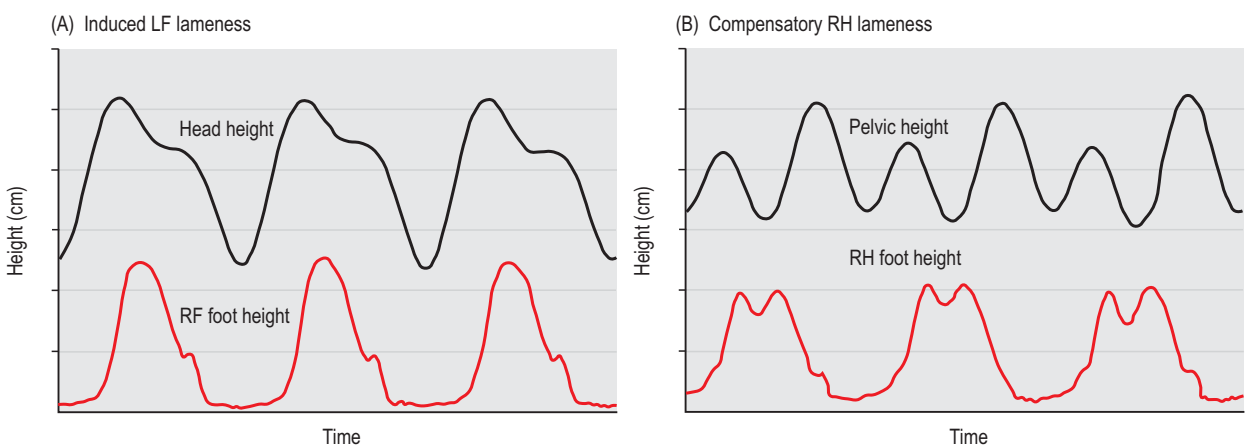

Fig. 13.17
(A) Severe induced left forelimb lameness causing a (B) mild compensatory right hindlimb lameness. Notice less downward movement of the head during the swing phase of the right forelimb (stance phase of the left forelimb) in (A) and slightly less downward movement of the pelvis during the stance phase of the right hindlimb in (B).

when presented with what appears to be an ipsilateral forelimb and hindlimb lameness, to assume first that the hindlimb lameness is primary and when presented with what appears to be a contralateral forelimb and hindlimb lameness, to assume that the forelimb lameness is primary. This rule of thumb has sometimes been termed 'the rule of sides'.

Future directions for kinematic analysis of lameness in horses

Advances in camera and computer technology are resulting in more clinically useful kinematic evaluation techniques. Kinematic analysis has identified objective and specific changes in movement indicative of lameness. This knowledge is improving our understanding and therefore teaching of normal and abnormal locomotion. As our knowledge and ability to detect gait compensations increase further, the possibilities for earlier and more accurate detection of lameness increase.

Future directions in the kinematic analysis of gait for the detection of lameness should concentrate on isolating parameters useful in localizing the site of lameness within an affected limb. Preliminary evidence indicates this may be possible with the aid of advanced signal and data processing techniques. As additional investigative endeavors and further study of known lameness conditions continue, automatic classification of lameness to the affected limb, and possibly to the specific site within the affected limb, could be achieved. Development of new kinematic measurement techniques that free the horse from the treadmill should also be pursued. Acceleration of the head, pelvis and feet can be measured with small sensors[44,45] and the signals transmitted wirelessly to receivers attached to laptop or handheld computers. Acceleration can then be integrated to positional measurements and the analysis techniques already developed from standard video-based kinematic analysis could be utilized.[46] Such a system could be used by equine practitioners in a field setting.

Combining measurement of ground reaction forces with kinematic gait analysis allows calculation of joint torque and internal tendon forces through inverse dynamic analysis.[47,48] The parameters are affected by lameness[49] and knowledge of how these parameters change with lameness will be helpful in developing models for the detection of equine lameness. However, further development of ground reaction force measurement techniques will be required for them to be really useful for the detection of mild to moderate lameness condition in horses. Trotting the horse over stationary force plates does not control stride variability. Collection of multiple, contiguous strides will lessen trial variance when evaluating lameness conditions with significant stride-to-stride variation. Force-measuring treadmills[50] and shoes[51–54] have been designed and described, but the techniques are either in their infancy or have not been widely adopted. Further development of these kinetic techniques for simultaneous use with kinematic gait analysis should be pursued.[55]

CHAPTER 14

Diagnosis of lameness

Andris J. Kaneps

Introduction

The evaluation of lameness includes the following steps:

- history
- visual examination at rest
- in motion examination
- manipulations
- localization
- diagnostic imaging.

A horse without gait abnormalities should move in a balanced manner with all limb movements in equilibrium. If lameness is present, it is the examiner's task to identify the gait abnormality, its location and the likely causes and to recommend appropriate treatment. Evaluation of lameness requires an ability to visualize gait abnormalities, skill in applying techniques that localize the abnormality to a specific site, and obtaining and interpreting appropriate images of the site. These findings must be consolidated to determine a diagnosis.

Experience in observing and interpreting the equine gait is a hard-fought and ongoing process. The science of gait evaluations (see Chapters 12 and 13) may help us understand how and why a horse moves in a particular fashion, but visual examination by a trained and experienced examiner remains the basis for most lameness examinations.

History

A complete anamnesis of a horse presented for evaluation of gait abnormality helps to narrow the list of differential diagnoses, determines the effect of previous treatment or shoeing protocols and may help to narrow the focus of the examination. The signalment of the horse (age, sex, breed and use of the horse) should be clearly elucidated. The list of potential diagnoses will be different for a 2-year-old Warmblood horse in early training as opposed to a 2-year-old Thoroughbred that has started three races.

Specific questions to ask during the history

When did you (or your trainer) first notice a lameness problem and how long has it been present?

Acute onset of lameness may indicate abnormalities such as severe subsolar bruising or osteochondral fracture. Prolonged, insidious onset of lameness may be due to wear-and-tear disorders such as navicular syndrome or bone spavin.

Describe what you noticed initially

Owners and trainers may make an incorrect interpretation of the initial signs of subtle lameness, but their interpretations may still be very useful. For example, a short and choppy forelimb gait associated with heel pain is often described by clients as 'sore in the shoulders' because of the shuffling gait. Also, advanced riders may notice subtle abnormalities in their horse's gait that may be extremely difficult to observe during the lameness examination. An example would be reluctance of a dressage horse to enter a round frame while being ridden.

When is the lameness most obvious?

Lameness that is first evident when the horse comes out of the stall or early in an exercise period (when the horse is 'cold') may be associated with synovitis or arthritis. Lameness that decreases in severity as the horse warms up during exercise is also often associated with arthritis. Lameness that becomes more pronounced with longer periods of exercise may be indicative of tendon or ligament inflammation. The lameness may be more evident on different types of surfaces. Deep footing may make soft tissue injuries more apparent, while very firm footing will cause greater concussion and may exacerbate lameness due to arthritis.

Have you noticed any swelling or thickenings?

Some effusions and soft tissue swellings may be transient. Joint effusion with carpal osteochondral fracture often is pronounced near the time of occurrence and then gradually subsides. Soft tissue swelling due to tendinitis is often observable for prolonged periods of time.

Has the horse undergone any treatment for this condition?

For example, has the horse had rest, medication, change in level of use or shoeing modifications?

When was your horse last shod?

Changes in hoof angle and paring of a thin sole may be a cause of transient lameness. Excessive wear of the hoof or shoes soon after a farrier visit may be indicative of a more severe gait abnormality.

Any previous history of lameness?

Is this a new condition or a continuation of a previous injury?

Visual examination at rest

Before observing the horse in motion, a careful appraisal of the horse's conformation and close visualization of its stance and limbs should be made. Start by evaluating the horse from a distance to allow appreciation of its stance, general conformation, areas of swelling or atrophy and attitude. Evaluate wear patterns of the hoof or shoes. Closer inspection should always involve palpation of each limb in its entirety. Subtle effusion of the carpal joints and medial femorotibial joints may only be noticed with palpation. Swollen regions should be palpated to evaluate tissue temperature and the degree of sensitivity to deep palpation. A swelling that is sensitive to touch and is warmer than surrounding areas is likely undergoing active inflammation. A cold, insensitive swelling may be a lesion that has healed and is no longer actively inflamed.

The digital pulses should always be palpated at the level of the proximal sesamoid bones or in the pastern region of each distal limb. Elevated pulses are associated with injury or inflammation in the distal limb and may help localize the lesion to medial or lateral aspects of the limb.

Tendons and ligaments should be palpated with the limb in both weight-bearing and flexed positions. Tendon sheath effusions are best evaluated with the limb bearing weight. When the limb is flexed the tendons and ligaments on the palmar or plantar surface are more easily defined and separated. Deep palpation of the mid- to proximal suspensory ligament often elicits some discomfort in the normal horse. Compare contralateral limbs if there is a concern regarding palpation sensitivity.[1]

In motion examination

Examination of the lame horse in motion is necessary to characterize the nature and intensity of the gait abnormality. The lameness should be graded using a consistent scale (Table 14.1).[2] Conducting the in motion examination in controlled surroundings will add consistency to the findings. The ideal location in which to examine a horse for lameness is a flat, firm surface where the horse may by jogged for 30–40 meters without encountering obstructions or distractions.[3] An asphalt surface has the advantage of allowing the examiner to both visualize and listen to the horse's footfalls. The sound of the lame limb impacting the surface will be diminished when compared to the unaffected contralateral limb. A common finding with subtle gait abnormalities is the unaffected limb of a pair impacting the surface louder than the affected limb.

A safe place to work the horse in a circle, preferably on a lunge line, should be available (Fig. 14.1). The surface should be firm, but safe enough to permit circles from 10 to 20 meters in diameter without risk of the horse slipping.

Table 14.1 Lameness grading scale

Grade	**Lameness grading scale** (after AAEP scale[2])
0	Lameness is not observed
1	Intermittent or inconsistent lameness at the trot that is difficult to discern under any circumstance
2	Lameness is difficult to observe at a walk or trot in a straight line, but is consistently apparent under special circumstances such as with manipulation, lunging or riding
3	Lameness is consistently observed at the trot under all conditions
4	Lameness is obvious with marked asymmetry of gait at the trot without manipulation
5	Minimal or no weight bearing on the affected limb, horse is reluctant to move

Fig. 14.1 Evaluating lameness on the lunge line may be used to exacerbate mild gait abnormalities and to determine how a horse performs during transitions of gait.

Horses with subtle gait abnormalities may need to be observed while being worked in normal tack. In select circumstances an examiner with sufficient experience may find it useful to work or ride the horse. This is particularly useful in harness race horses that only demonstrate their gait abnormalities at speed.

Watch the horse initially at a walk to evaluate footfall patterns and to familiarize the horse with the environment in which the examination will take place. Each foot should normally land heel first, then toe with the lateral and medial aspects of the hoof landing nearly equally in time.[4] Deviations from normal footfall may indicate dynamic imbalance of the limb that could be due to abnormalities of conformation, hoof shape, shoeing or pain. The swinging phase of the limb in a correctly conformed horse should be a straight track without any tendency to swinging in or out. Toe-in or toe-out conformations predispose the horse to swinging out ('paddling') or swinging in ('winging in'), respectively.[3]

The trot is the most useful gait to evaluate lameness because it is a symmetrical, two-beat gait where diagonal limb pairs are simultaneously in the stance phase. The horse should be trotted at a comfortable, unhurried speed with the head allowed to move freely up and down. The horse should be trotted directly away and returned directly toward the examiner. Subtle imbalances in gait may easily be missed if the examiner is not directly aligned with the center of the long axis of the horse (the vertebral column). The examiner should also observe the horse from the side as it trots by for characteristics of stride length and to determine if there is any toe dragging. Viewing the horse from the side at the trot may provide better evaluation of rear limb lameness.[5]

Lameness is evident to the observer as an asymmetry of the gait. Forelimb lameness is usually evident as a head bob: the head rises immediately prior to and during weight bearing of the lame limb. Conversely, the head drops as the sound limb contacts the ground and bears weight.[6] Stride length may also be altered by gait abnormalities. A shortened anterior phase to the stride (shuffling gait) may be associated with heel pain as the horse is reluctant to extend the affected limb and bear full weight on the heel.[3] This type of change in the stride may also occur due to pain during the swing phase of the gait, such as may be encountered with bicipital bursitis/tendinitis of the forelimb. Subtle forelimb lameness may only be evident as an unequal shift in weight with the unaffected limb bearing more weight than the lame limb. Such subtle weight shifts are best observed with the horse trotting directly toward the examiner.

Rear limb gait abnormalities may be evident as elevation of the hip (hip hike, gluteal rise), dropping of the hip (hip drop, gluteal drop), toe dragging and decreased stride length.[3] These responses to rear limb lameness are mechanisms the horse uses to avoid discomfort during various portions of the stride and are due to the nature of the abnormality. Elevation of the hip occurs when the horse shifts weight away from the lame limb during the weight-bearing phase of the stride. Dropping of the hip occurs if pain is most acute during the posterior phase of the weight-bearing portion of the stride. Often this movement is associated with abnormalities of the caudal/plantar aspect of the rear limb such as suspensory desmitis, flexor tendinitis, desmitis of the distal suspensory apparatus and injury to the semimembranosus/semitendinosus muscle group. Dragging of the toe is associated with reluctance to raise the limb during the swing phase of the stride and usually suggests upper rear limb joint lameness such as bone spavin and abnormalities of the stifle or coxofemoral joints.

Stashak describes 'gluteal rise and use' as characteristics observed from the rear of the horse at the trot. Gluteal rise is observed during the swing phase of the stride and use is observed during weight bearing.[3] Three characteristics of rear limb lameness in relationship to the gluteals were described.

1. Depressed gluteal rise and use is associated with upper rear limb (usually hip region) lameness.
2. Symmetric gluteal rise, but decreased gluteal use, is seen in subtle rear limb lameness and is non-localizing.
3. Rapid increased gluteal rise with decreased gluteal use is found in horses with marked discomfort during weight bearing and is often associated with a noticeable head bob.[3]

During the trot the pelvis normally rocks symmetrically from left to right in the sound horse when observed from the rear. In a study of induced right distal tarsal lameness, the right limb had greater vertical displacement of the tuber coxae than did the left (unaffected) limb, but the difference was not significant.[5] However, the ratio of left to right tuber coxae vertical displacement decreased 20% with the induction of distal tarsal lameness.[5] The change in ratio was evidence that tuber coxae asymmetric movement is a sensitive indicator of rear limb lameness at the trot.[5] A practical application of these findings is that when a rear limb lameness is observed at the trot from the rear of the horse, the tuber coxae of the lame limb usually has greater up-and-down motion compared to the tuber coxae of the sound limb.

Severe rear limb lameness (≥ grade 3) is often associated with a head bob. At the trot the rear limb and the contralateral forelimb are simultaneously in the same stride phase (working as a diagonal pair). If lameness of the rear limb is severe enough, as the affected limb contacts the ground the horse will shift weight forward (off the lame rear limb) using its neck, resulting in an observable head drop as the contralateral forelimb enters the weight-bearing phase of the stride. Kinematic analysis has found a measurable head bob with even mild rear limb lameness.[7] The examiner needs to be

aware of this process as moderate to severe rear limb lameness may be confused with a lameness of the ipsilateral forelimb.[3,7]

When the examiner has difficulty in determining which limb is lame, it may be easier to determine which limb is sound. At times it is simpler to visualize and/or hear which limb is bearing more weight (the sound limb). Manipulative tests should be used when lameness is subtle.

Manipulative tests and techniques

Manipulations that enhance or localize lameness include:

- work on the lunge line
- hoof tester application
- flexion tests
- riding or working with tack
- rectal palpation.

Lunge line

Most sport horses may be safely worked in a circle on a lunge line. Working the horse in a 10–20 meter diameter circle will put additional weight and stress on the innermost limbs and the medial aspect of the outermost limbs (see Fig. 14.1). The additional stress on the limbs helps the examiner identify subtle lamenesses and in some cases will help localize the region of soreness to a portion of the limb. A round pen of appropriate size may be similarly used.

Use of hoof testers

Hoof testers are squeezed on the sole and hoof capsule to determine if there are any sensitive areas present. Hoof tester pressure on normal hoof or sole does not result in a significant withdrawal response. If a sensitive area is found the hoof tester pressure should be repeated to verify the finding, then pressure should be maintained for 20–30 seconds and the horse should be trotted off to determine if pressure on the sensitive area causes an exacerbation of the lameness. Significant sensitive areas should be closely evaluated by paring out the foot.

While using the hoof testers the foot should also be evaluated for balance, general condition of the hoof and sole and the degree of wear of shoes and hoof walls. Abnormalities such as dished hoof, long toe, low heels, sheared heels, contracted heels, hoof cracks, thrush, flaky sole, hard sole, sole bruising and white line disease should be noted. Percuss the hoof wall with the hoof tester or a hammer. Hollow-sounding areas may correspond to a deep abscess or hoof wall separation. Areas of pain on concussion may be indicative of a tightly clinched nail or a nail that has penetrated the sensitive laminae and is causing a local abscess.

Flexion tests

Flexion tests are used to apply stress or pressure on an anatomic region of the limb for a set period of time. Following the flexion period the horse is trotted off and observed for the effects of the test on gait. Recalling the baseline level of lameness during both trotting on the lead rope and on the lunge line (if appropriate) is crucial to objectively evaluating the results of both flexion tests and diagnostic local anesthesia. The amount and duration of pressure applied may affect the outcome of flexion tests.[8] Consistency of application is also a key to correct interpretation of flexion tests. The flexion test, particularly of the distal limb, should not be overinterpreted. More than 60 of 100 horses determined to be sound prior to application of manipulative tests had some degree of lameness evident after distal limb flexion.[9]

Each flexion test should be completed in anatomic pairs (for example, distal flexions of both forelimbs) with the sound limb flexed first. Tests should progress from the distal to proximal aspect of the limbs. Moderate and equal pressure should be applied for each flexion test. Consistency is improved by having the same individual perform all of the tests during an examination. One study found a 12% coefficient of variation between multiple distal forelimb flexion tests applied by one clinician and a 20% coefficient of variation between different clinicians.[10]

Flexion tests used for lameness evaluation are described in Table 14.2. Results of flexion tests may be recorded as:

- *negative:* no change in lameness
- *slight positive:* slight exacerbation of lameness following flexion that is noticed during only a portion of the trotting course
- *moderate positive:* lameness is exacerbated while the horse is trotting away from the examiner, but not on the return
- *severe positive:* marked exacerbation of lameness during the outbound and return portions of the trotting course.

Other tests

Other aids to localizing lameness include rectal palpation of the pelvis for upper rear limb lameness, manipulations of the back (see Chapter 21) and working the horse in its given discipline with full tack. Working horses in circumstances that are similar to those when lameness is noticed by the owner or trainer is especially important for evaluation of subtle lamenesses or those that only occur under special circumstances.

Localization with diagnostic local anesthesia

Diagnostic local anesthesia ('nerve block') is performed to localize lameness. Important considerations are:

Table 14.2 Manipulative tests for lameness evaluation

Sequence of flexion tests	Technique	Duration of test
Forelimb		
Distal limb	Stand to the front or side of the horse with the carpus relaxed. Grasp the toe with one hand, using the other hand placed on the palmar aspect of the distal metacarpus as a fulcrum (Fig. 14.2A). Alternatively, stand in front of the horse and grasp the toe with both hands, placing the dorsal aspect of the fetlock on your knees and flexing the distal joints (Fig. 14.2B). Distal limb flexion stresses the metacarpophalangeal, proximal interphalangeal and distal interphalangeal joints and the navicular region	60 seconds
Carpus	Stand to the side of the horse and grasp the distal dorsal aspect of the metacarpus with one hand. Flex the carpus maximally. A full range of motion is evident when the palmar metacarpus contacts the caudal aspect of the antebrachium. The metacarpus may be adducted and abducted during flexion to provide more stress to the medial and lateral aspects of the joints	60 seconds
Metacarpus	Direct pressure on the flexor tendons or suspensory ligament	30 seconds
Proximal forelimb	The shoulder and elbow are difficult to isolate. The bicipital bursa of the shoulder may be evaluated by applying direct pressure over the bicipital tendon at the point of the shoulder or by retracting the upper forelimb caudally to its full extent. The upper limb should be abducted and adducted to stress the medial and lateral support structures of the joints	30–60 seconds
Rear limb		
Distal rear limb	Techniques are similar to that used in the forelimb. Flexion is performed with the tarsus and stifle relaxed. See Fig. 14.3A and B for two techniques	60 seconds
Full rear limb	Also referred to as the spavin test, this flexion test stresses all of the rear limb joints to some degree because of their connection via the reciprocal apparatus. However, the tarsus and stifle joints are stressed more than others. The rear limb is grasped with both hands around the distal metatarsus and the full limb is flexed maximally	90 seconds
Stifle	This joint is stressed during application of the full limb flexion. The cruciate ligaments may be stressed by abruptly forcing the tibial crest caudally using a hand on the tibial crest while the horse is fully weight bearing on the limb. The medial collateral ligament of the stifle may be stressed by picking up the limb, grasping the mid-metatarsus and placing the examiner's shoulder over the lateral aspect of the stifle. Abruptly abduct the distal limb, using the examiner's shoulder as the fulcrum	15–30 seconds
Coxofemoral joint	With the limb not bearing weight and nearly extended, 'stir' the limb in an arc. An alternative method is to adduct the limb. For example, to stress the right coxofemoral joint, stand on the horse's left, pick up the right rear limb while maintaining limb extension and pulling the distal limb to the horse's left side (Fig. 14.4)	30 seconds

Fig. 14.2
(A) Distal forelimb flexion using one hand as the fulcrum on the palmar aspect of the fetlock and one hand pulling on the toe of the hoof. (B) Distal forelimb flexion with the dorsal aspect of the fetlock resting on the operator's knees and both hands used to pull on the toe. Excessive force during this manipulation may lead to false-positive results.

Fig. 14.3
(A) Distal rear limb flexion with the limb nearly extended and one hand on the plantar aspect of the fetlock acting as the fulcrum and the other hand flexing at the toe of the hoof. (B) An alternative method of applying a distal rear limb flexion test by tucking the tuber calcis under the operator's inside arm pit and using both hands to flex the toe.

Fig. 14.4
Manipulative test of the coxofemoral joint by adduction of the rear limb. An assistant can initially pick up the limb and hand it to the operator.

1. understanding the anatomy to provide accurate placement of the anesthetic
2. being aware of different options for administering anesthetic to a site as clinical situations may dictate one technique over another
3. maintaining strict asepsis when penetrating synovial spaces.

Mepivacaine HCl 2% is the preferred local anesthetic for regional and joint anesthesia in horses. Compared to lidocaine (lignocaine), it is less irritating to tissues and has a comparable onset, yet a longer duration of action.[11,12] Local anesthetics cause blockade of sodium channels that results in inhibition of nerve conduction.[13] The effectiveness of local anesthesia depends on local tissue pH (local anesthetics are much less effective in acid pH), accuracy of deposition and the size of nerves being blocked (small, unmyelinated fibers are more sensitive than large, myelinated fibers).[13] The toxic dose is approximately 13 mg/kg (~6 mg/lb). Overdose of local anesthetics may result in heart block, bradycardia and convulsions.[14] Toxicity is usually only a concern in smaller animals. Onset of action for regional nerve blocks is 10–25 minutes with smaller diameter nerves desensitized earlier than larger nerves. Onset of intra-articular analgesia is 5–10 minutes with a gradual increase in analgesia over that time. Check the effects of the local anesthetic in most joints at 20 min-utes and in complex joints, such as the stifle, in 30 minutes. Mepivacaine inhibits nerve sensation for 90–180 minutes.[13]

Strict aseptic techniques should always be followed when injecting joints or synovial structures. A fresh bottle of local anesthetic should always be used. The site to be injected may be clipped, but in a study of various methods of preparing the site of intra-articular injections, clipping of the site was not found to improve results of skin surface bacteriological cultures.[15] A 7–10 minute scrub with povidone-iodine or chlorhexidine should be made of the injection site. Immediately prior to injection the site should be carefully wiped with 70% isopropyl alcohol. The operator should wear sterile surgical gloves. Adequate assistance should be available for restraining the horse. The most painful portion of the injection is needle penetration of the skin and joint capsule. Confident, quick insertion of the needle in the correct anatomic site minimizes discomfort for the horse. A skin bleb of local anesthetic may be helpful in making the joint

Table 14.3 Forelimb diagnostic local anesthesia

Sequence of diagnostic local anesthesia	Anatomic site of injection	Region desensitized	Needle size and anesthetic volume	Onset of action
Palmar digital nerves (PDN)	Palmar aspect of pastern, immediately proximal to the collateral cartilages	Palmar heel, entire sole	25–22 g × 1 inch 0.5–0.7 × 16 mm 1.5–2 mL/nerve	10–15 minutes
Dorsal branch of PDN	Same as above, redirect needle dorsally approximately 1 inch (25 mm)	All structures within the hoof	As above	As above
Abaxial sesamoid (palmar nerves)	Abaxial aspect of proximal sesamoid bones (may use either dorsal branch or abaxial sesamoid block)	All structures within the hoof and most of structures from midpastern distal	25–22 g × 1 inch 0.5–0.7 × 16 mm 2–2.5 mL/nerve	As above
Low four-point (palmar nerves and palmar metacarpal nerves)	At the level of the distal aspect of MCII and MCIV (splint bones). Palmar nerves are injected subcutaneously between the suspensory branch and the deep digital flexor tendon immediately proximal to the digital sheath. Palmar metacarpal nerves are injected subcutaneously immediately dorsal and distal to the splint buttons	Fetlock joint and all distal structures	22 g × 1 inch 0.7 × 25 mm 4–5 mL per palmar nerve, 3 mL per palmar metacarpal nerve	15 minutes
High four-point (palmar nerves and palmar metacarpal nerves)	At the most proximal aspect of the metacarpus that a palpable groove between the deep digital flexor tendon and suspensory ligament is palpable. The palmar nerves are injected in this groove. The palmar metacarpal nerves are injected by redirecting the needle to the axial surface of MCII and MCIV	All structures distal to the point of injection. Inadvertent injection of the carpometacarpal joint may occur[18]	22 g × 1 inch 0.7 × 25 mm 4–5 mL per palmar nerve, 3 mL per palmar metacarpal nerve	15 minutes
Base of the accessory carpal bone	The lateral and medial palmar metacarpal and lateral palmar nerves lie together at a site between the flexor retinaculum and the carpal sheath at a point midway between the head of MCIV and the base of the accessory carpal bone and immediately distal to the accessoriometacarpal ligament. The medial palmar nerve is injected as previously described[19]	All structures distal to the point of injection including the origin of the suspensory ligament. Inadvertent injection within the carpal canal may occur[18]	22 g × 1 inch 0.7 × 25 mm 3–4 mL at base of accessory carpal bone, 3 mL at medial palmar nerve	15 minutes
Suspensory ligament origin	The needle is inserted directly into the origin of the suspensory ligament. A large needle is used to reduce the chance of breakage. (High four-point, base of accessory carpal and suspensory origin blocks may be interchanged depending on operator preference)	The entire suspensory ligament and structures distal to the injection point. Inadvertent injection within the carpometacarpal joint may occur[18]	18 g × 1–1.5 inch 1.2 × 25–40 mm 4–6 mL	First check in 10 minutes, then again after 20 minutes
Median/ulnar/ musculocutaneous	The median nerve is injected on the caudomedial aspect of the radius immediately distal to the pectoral muscle mass. The needle is partially removed and redirected subcutaneously to a point just cranial to the cephalic vein for the musculocutaneous nerve. The ulnar nerve is injected 25 mm deep to the skin at a point 6–8 cm proximal to the accessory carpal bone between the flexor carpi ulnaris and ulnaris lateralis muscles	The entire limb distal to points of injection including the carpus, suspensory origin	22–20 g × 1.5 inch 0.7–0.9 × 40 mm 6–8 mL at median nerve, 4–6 mL at musculocutaneous nerve, 4–6 mL at the ulnar nerve	20–30 minutes

injection less uncomfortable to the horse, particularly when a larger gauge needle must be used.[16]

The sequence of diagnostic local anesthesia begins with the most distal nerves being injected first and gradually working proximally until the lameness has been localized. Regional anesthesia usually results in less effective analgesia of intra-articular soreness than direct intra-articular anesthesia. If the lameness has been improved noticeably, but not completely,

Table 14.4 Rear limb diagnostic anesthesia

Sequence of diagnostic local anesthesia	Anatomic site of injection	Region desensitized	Needle size and anesthetic volume	Onset of action
Palmar digital nerves (PDN)	Plantar aspect of pastern, immediately proximal to the collateral cartilages	Plantar heel, entire sole	25–22 g × 1 inch 0.5–0.7 × 16 mm 1.5–2 mL/nerve	10–15 minutes
Dorsal branch of PDN	Same as above, redirect needle dorsally approximately 1 inch (25 mm)	All structures within the hoof	As above	As above
Abaxial sesamoid (plantar nerves)	Abaxial aspect of proximal sesamoid bones (may use either dorsal branch or abaxial sesamoid block)	All structures within the hoof and most of structures from midpastern distal	25–22 g × 1 inch 0.5–0.7 × 16 mm 2–2.5 mL/nerve	As above
Low six-point (plantar, plantar metatarsal and dorsal metatarsal nerves)	At the level of the distal aspect of MTII and MTIV (splint bones). Plantar nerves are injected subcutaneously between the suspensory branch and the deep digital flexor tendon immediately proximal to the digital sheath. Plantar metatarsal nerves are injected subcutaneously immediately dorsal and distal to the splint buttons. Dorsal metatarsal nerves are injected immediately lateral and medial to the common extensor tendon	Fetlock joint and all distal structures	22 g × 1 inch 0.7 × 25 mm 4–5 mL per plantar nerve, 3 mL per plantar metatarsal nerve, 3 mL per dorsal metatarsal nerve	15 minutes
High six-point (plantar, plantar metatarsal and dorsal metatarsal nerves)	At the most proximal aspect of the metatarsus a palpable groove between the deep digital flexor tendon and suspensory ligament is palpable. The plantar nerves are injected in this groove. The plantar metatarsal nerves are injected by redirecting the needle to the axial surface of MTII and MTIV. Dorsal metatarsal nerves are injected immediately lateral and medial to the long digital extensor tendon	All structures distal to the point of injection. Inadvertent injection within the tarsometatarsal joint may occur[20]	22 g × 1 inch 0.7 × 25 mm 4–5 mL per plantar nerve, 3 mL per plantar metatarsal nerve, 3 mL per dorsal metatarsal nerve	15 minutes
Suspensory ligament origin	The needle is inserted directly into the origin of the suspensory ligament. A large needle is used to reduce the chance of breakage. (High six-point, and suspensory origin blocks may be interchanged depending on operator preference)	The entire suspensory ligament and structures distal to the injection point. Inadvertent injection within the tarsometatarsal joint may occur[20]	18 g × 1–1.5 inch 1.2 × 25–40 mm 4–6 mL	First check in 10 minutes, then again after 20 minutes
Tibial/peroneal	The tibial nerve is injected subcutaneously on the medial aspect of the limb approximately 6–8 cm proximal to the tuber calcis and immediately deep to the calcaneal tendon. The peroneal nerves are injected on the lateral aspect of the tibia with the needle inserted between the muscle bellies of the lateral and long digital extensor muscles. Injections are made 25 mm deep to the skin (deep peroneal n.) and subcutaneously (superficial peroneal n.)	The entire limb distal to points of injection including the tarsus, suspensory origin	20 g × 1.5 inch 0.9 × 40 mm 6–8 mL at tibial nerve, 4 mL at each peroneal nerve	20–30 minutes

following regional nerve anesthesia, intra-articular anesthesia of the suspect joint should be conducted. Regional nerve blocks are described for the forelimb (Table 14.3) and rear limb (Table 14.4). Distribution of the peripheral nerves is represented for the forelimb (Fig. 14.5) and rear limb (Fig. 14.6).

Intra-articular anesthesia

Navicular bursa

Strict asepsis must be adhered to at this site because of its close proximity to the ground and the attendant

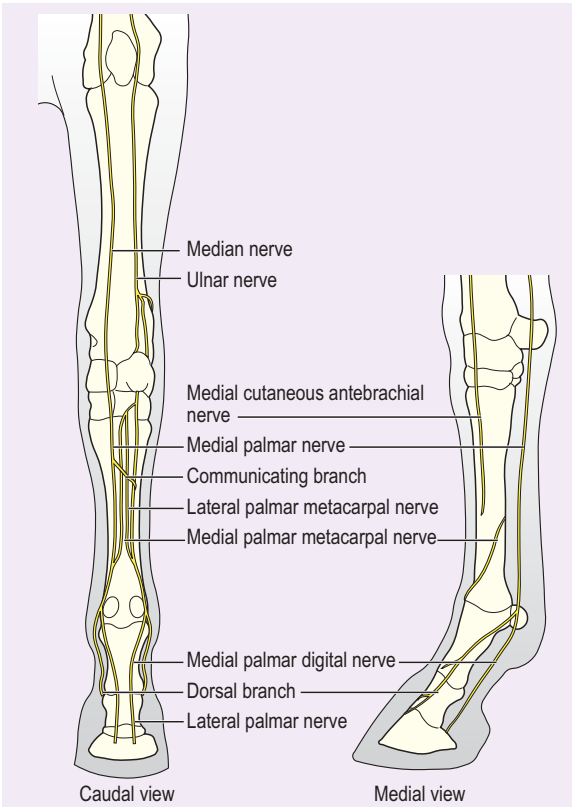

Fig. 14.5
Peripheral nerve distribution of the forelimb. Modified from Schmotzer & Timm,[16] with permission.

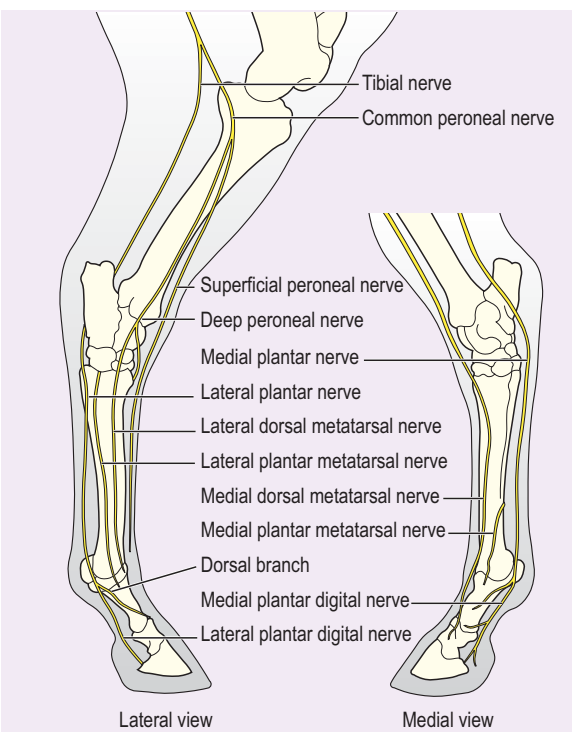

Fig. 14.6
Peripheral nerve distribution of the rear limb. Modified from Schmotzer & Timm,[16] with permission.

contaminants. A subcutaneous bleb of local anesthetic should be placed on the palmar aspect of the distal pastern in the midsagittal cleft immediately proximal to the heel bulbs. An 18 gauge, 3 inch (1.2 × 90 mm) spinal needle is advanced parallel to the bearing surface of the hoof until it contacts the flexor surface of the navicular bone. The needle should be aimed at a point 1 cm distal to the coronary band and midway between its most dorsal and palmar extent.[21] Correct placement of the needle should be confirmed with radiography or fluoroscopy before 3–5 mL of local anesthetic is injected.[22]

Comparing the results of navicular bursa, distal interphalangeal joint and palmar digital nerve local anesthesia may aid localization of distal limb lameness.[22] However, mepivacaine has been found to diffuse widely following injection in the distal equine limb, potentially confounding efforts to specifically localize the site of lameness.[25]

Distal interphalangeal joint

The distal interphalangeal (DIP) joint has a large dorsal pouch that is easily entered with a needle.[23] The joint may also be approached immediately cranial to the collateral cartilage.

Anesthetic injected in the DIP joint will desensitize other nearby structures. The proximal suspensory ligament of the navicular bone, distal extent of the palmar digital nerves, navicular bursa and impar ligaments are directly adjacent to palmar aspects of the DIP joint.[24] Thirty minutes after mepivacaine was injected in the DIP, local anesthetic concentrations sufficient to result in analgesia were found in the navicular bursa synovial fluid (10 of 10 horses) and in the medullary cavity of the navicular bone (six of 10 horse).[25] Mepivacaine diffused from the distal interphalangeal joint into the navicular bursa and vice versa in 25 of 25 joints evaluated.[25] Ten minutes following distal interphalangeal joint anesthesia lameness induced by tightening a set screw on the sole was resolved.[17]

Dorsal approach This injection is best made with the horse fully weight bearing using a 20–18 gauge, 1½ inch (0.9–1.2 × 40 mm) needle. The needle is inserted 1.5–2 cm proximal to the coronary band and a similar distance lateral or medial to the extensor process of the distal phalanx and directed toward the extensor process.[16] A skin bleb may be made at this site to facilitate needle placement. Alternatively, the needle may be directed perpendicular to the dorsal cortex of the second phalanx and 'walked' distally until the joint is entered. The needle usually penetrates the skin approximately 1 inch (25 mm) before entering the joint. Four to 6 mL of anesthetic is injected.

Hemorrhage often occurs from the coronary corium when the needle is withdrawn. Counterpressure and a light bandage will control any bleeding and help protect the region from contamination until the needle puncture seals.

Lateral approaches Two dorsolateral approaches have been described with the needle inserted either cranial[26] or proximal[23] to the collateral cartilage. The most cranial extent of the collateral cartilages is palpated and the needle is

inserted at that point approximately 1–1.5 cm proximal to the coronary band with the horse fully weight bearing. The needle is first inserted parallel to the bearing surface of the hoof, then immediately angled 30° distally and 30° toward the midline.

Needle placement proximal to the collateral cartilage may be performed with the horse non-weight bearing. The needle is inserted just proximal to the collateral cartilage midway between the dorsal and palmar aspect of the second phalanx and is directed along the palmar surface of the second phalanx by aiming at the center of the frog.[23]

Proximal interphalangeal joint

A dorsolateral or palmar approach may be used to enter the proximal interphalangeal (PIP) joint. The dorsal approach is made with the horse weight bearing. A large palmar pouch of the PIP joint is readily entered with the limb non-weight bearing and with the distal joints flexed.[27]

Dorsal approach The horse should be weight bearing for this approach. A 20 gauge, 1½ inch (0.9 × 40 mm) needle is directed through the skin approximately 1–1.5 cm distal to the distal eminence of the first phalanx and under the extensor tendon. Orient the needle parallel with the dorsal joint surface. Inject 4–5 mL of local anesthetic.[16]

Palmar approach The limb should be picked up and held with the distal joints in moderate flexion. The palmar pouch of the PIP joint is bounded by the palmar first phalanx, the palmarodistal eminence of the first phalanx and the insertion of the lateral branch of the superficial digital flexor tendon. When the pastern is moderately flexed these structures form a 'V' on the palmar first phalanx. Retract the palmar digital neurovascular bundle that lies directly over the needle insertion site in a palmar direction, using the operator's thumb. The needle is placed through the skin dorsal to the neurovascular bundle within the region of the distal 25% of the first phalanx and directed distally and toward the midline. Joint fluid is commonly aspirated.[27]

Metacarpophalangeal/metatarsophalangeal joint

The fetlock joint is commonly injected for diagnostic and therapeutic reasons. Three approaches may be used: dorsal, palmar/plantar pouch and palmar/plantar approach through the collateral sesamoidean ligament. The collateral sesamoidean ligament approach is best used if arthrocentesis is an objective because synovial fluid free of blood contamination is more readily obtained.[28] Administration of local anesthesia is most easily performed using the palmar/plantar pouch approach.

Palmar/plantar pouch The approach is made with the horse weight bearing. The palmar/plantar pouch is bounded by the third metacarpus/metatarsus dorsally, distally by the apex of the sesamoid bone, and palmar/plantar by the suspensory ligament. A 20 gauge, 1½ inch (0.9 × 40 mm) needle is inserted through the skin in the center of this site and directed distally and toward the midline. Synovial fluid commonly will drip from the needle if effusion is present, but aspiration with a syringe often results in plugging of the needle with synovial tissue. Four to 6 mL of local anesthetic is injected.[16]

Dorsal approach This approach should only be used if effusion is present because of the possibility of abrading joint cartilage with the needle. The horse should be weight bearing. The needle is placed from the lateral side into the proximal aspect of the dorsal joint capsule and directed toward the midline and under the extensor tendon. Care should be taken not to abrade the sagittal ridge.[16]

Collateral ligament approach The limb should be held up with the fetlock joint flexed. This procedure is facilitated by having an assistant hold the limb. The lateral palmar aspect of the distal metacarpal/metatarsal condyle and the dorsal surface of the proximal sesamoid bone are palpated. The collateral sesamoidean ligament may be rarely palpated. The neurovascular bundle over the abaxial surface of the sesamoid bone does not interfere with this approach because it is displaced palmar when the joint is flexed. The needle is inserted in the palpable space between the third metacarpus/metatarsus and the proximal sesamoid bone. Entry into the joint is easily determined because the needle may be inserted up to its hub.[28]

Carpal joints

The radiocarpal joint is always separate from the middle carpal and carpometacarpal joints, which always communicate.[29] Complete intra-articular anesthesia of the carpus necessitates injecting local anesthetic into the radiocarpal and middle carpal joints. The joints are traditionally injected with the limb flexed, but may also be injected with the horse weight bearing on the limb.

Dorsal approach The limb is flexed and the joint spaces of the middle and radial carpal joints are easily palpated medial or lateral to the extensor carpi radialis tendon.[16] A 20 gauge, 1–1½ inch (0.9 × 25–40 mm) needle is most often inserted medial to the extensor carpi radialis tendon. If the needle is inserted lateral to the extensor carpi radialis tendon care must be taken to avoid the common digital extensor tendon and its sheath. The most common difficulty encountered when inserting the needle is penetrating into articular cartilage. To avoid this, visualize the plane of the carpal articular surfaces distal to the intended needle insertion site. Direct the needle parallel to the joint surfaces on insertion. Inject 10 mL of local anesthetic per joint.

Caudolateral approach The carpal joints may also be injected with the horse weight bearing on the limb. By inducing slight carpal flexion, the joint spaces may be identified by palpation of the lateral aspect of the carpus. The radiocarpal joint is approached immediately cranial to the accessory carpal bone at roughly 50% of its proximal–distal length. The middle carpal joint is approached immediately cranial to the distal aspect of the accessory carpal bone.[30]

Cubital (elbow) joint

The cubital joint is injected on the lateral aspect of the limb just cranial to the lateral collateral ligament.[31] The joint

space may be palpated in most horses by identifying the humeral condyle and tracing its margin. The procedure may be done with the horse standing or by having an assistant elevate the forelimb slightly to open the joint space dorsally.[31] An 18–20 gauge, 1½ inch (0.9–1.2 × 40 mm) needle is inserted perpendicular to the limb and 15–20 mL of local anesthetic is injected. An alternative approach is to insert the needle on the cranial aspect of the olecranon at a point approximately 3 cm distal to its most proximal extent. The needle is directed distally and axially.[3]

Scapulohumeral (shoulder) joint

Craniolateral approach This is the most common approach used to inject the scapulohumeral joint. Identify the cranial and caudal parts of the greater tubercle on the craniolateral aspect (point) of the shoulder. An intradermal bleb of anesthetic will facilitate insertion of the spinal needle. An 18 gauge, 3½ inch (1.2 × 90 mm) spinal needle with a stylet is inserted in the notch between the cranial and caudal parts of the greater tubercle and directed slightly distally and toward the opposite tarsus (roughly a 30–40° angle to the long axis of the horse). The needle is inserted 2–3 inches (50–75 mm) to reach the joint. Synovial fluid is rarely aspirated to confirm the needle is within the joint. Injection of 10–20 mL of anesthetic with minimal resistance initially, followed by increased resistance as the joint fills, confirms that the needle is correctly positioned.[31] Excessive diffusion of local anesthetic into the surrounding tissues may cause temporary anesthesia of the suprascapular nerve. While this nerve is desensitized, the horse will lack use of the infraspinatus and supraspinatus muscles, which results in abaxial displacement of the shoulder during weight bearing. This may be avoided by injecting the minimum volume of anesthetic necessary to effect joint desensitization and by minimizing multiple needle punctures of the joint capsule.[3,31]

Lateral approach A skin bleb of anesthetic may be placed immediately caudal to the infraspinatus tendon at the level of the proximal humerus. The needle is inserted immediately caudal to the infraspinatus tendon, roughly perpendicular to the long axis of the horse and directed slightly distally. The needle is inserted 1.5–2 inches (40–50 mm) to enter the joint. Synovial fluid is more commonly obtained with this approach.[3]

Bicipital bursa The bicipital bursa lies between the bicipital tendon and the dorsoproximal aspect of the humerus. The bursa is injected using an 18 gauge, 1½ inch (1.2 × 40 mm) needle entering perpendicular to the skin at a point proximal to the deltoid tuberosity and distal to the proximal humeral tuberosity.[31] Ten to 15 mL of local anesthetic is injected.

Tarsal joints

It is commonly accepted that the tarsocrural (tibiotarsal) and proximal intertarsal (PIT) joints always communicate. Communication between the distal intertarsal (DIT) and tarsometatarsal (TMT) joints is reported to occur 8–38% of the time.[20,32,33] For accurate diagnosis or complete treatment of the distal tarsal joints, separate injections must be made in the DIT and TMT joints.

Use of 22 gauge (0.7 mm) needles with metal hubs facilitates injections of the distal tarsal joints, particularly when medications are being administered. The small needle size makes placement within the joint easier and the syringe is more securely seated in a metal than a plastic hub needle. The more secure syringe attachment decreases the inadvertent leakage of costly medications.

Tarsocrural (tibiotarsal) and proximal intertarsal joints These joints are approached on the dorsomedial aspect of the proximal tarsus. An 18–20 gauge, 1½ inch (0.9–1.2 × 40 mm) needle is inserted either lateral or medial to the medial saphenous vein at a point 1–3 cm distal to the medial malleolus.[16] Eight to 10 mL of local anesthetic is injected. If joint effusion is present, the needle may be inserted in the plantarolateral pouch of the tarsocrural joint.

Tarsometatarsal joint The TMT joint may be injected from a plantarolateral or medial approach. The plantarolateral approach is the easiest method because the landmarks are readily palpated and the needle can usually be inserted securely into the joint. The site for plantarolateral injection is directly proximal to the head of the lateral splint bone (metatarsal IV). The plantar edge of the splint and the indentation at its head is identified. A 22–20 gauge, 1 inch (0.7–0.9 × 25 mm) needle is directed toward the opposite forelimb and distally at approximately 10–15°.[32] When correctly placed, the needle is inserted nearly to its hub and 3–4 mL of local anesthetic is injected.

No landmarks are palpable when injecting the TMT from the medial approach. The needle is inserted perpendicular to the medial surface of the tarsus approximately 1 cm distal to the DIT joint (see below). A 22 gauge (0.7 mm) needle should be used and the joint is found by probing with the needle until it enters the joint.

Distal intertarsal joint The DIT joint is injected by placing a 22 gauge, 1 inch (0.7 × 25 mm) needle in a small space between the fused first and second tarsal bones, and the third and central tarsal bones. The space is immediately distal to the cunean tendon on the medial aspect of the tarsus. Firm digital pressure is necessary to identify the space. The needle is inserted perpendicular to the medial tarsal surface and some probing is often necessary to fall into the joint space.[33] If the needle does not enter the joint easily, inject 1–2 mL of local anesthetic subcutaneously. This will make repeated needle insertions more comfortable for the horse. Probing for the joint space often causes a burr to form on the needle tip, necessitating changing of the needle. Formation of a burr will be obvious because of the increased friction and rough feel of the needle during continued probing. Inject 3–4 mL of local anesthetic.

Stifle joints

The stifle includes three large-volume joints: the femoropatellar, lateral femorotibial and medial femorotibial. The

femoropatellar and medial femorotibial joints communicate in 60–80% of horses.[34,35] The lateral and medial femorotibial joints do not communicate under normal circumstances.[34] Each joint should be separately injected to ensure complete analgesia of the stifle.[35]

Femoropatellar joint Insert an 18 gauge, 3½ inch (1.2 × 90 mm) spinal needle at the cranial aspect of the stifle between the middle and medial or middle and lateral patellar ligaments at a point approximately 2 cm proximal to the tibial crest with the limb fully weight bearing. Direct the needle slightly proximal to a depth of approximately 2–3 inches (50–75 mm). Synovial fluid is rarely aspirated using this approach, but entry into the joint is assumed when there is minimal resistance during injection of 30–50 mL of local anesthetic.

An alternative approach may be used to enter the lateral proximal pouch of the femoropatellar joint. With the limb fully weight bearing, an 18 gauge, 1½ inch (1.2 × 40 mm) needle is placed immediately caudal to the proximal aspect of the lateral trochlear ridge and the lateral patellar ligament. The needle is directed lateral to medial and somewhat distal. The insertion point is approximately 5 cm proximal to the lateral tibial condyle. This approach avoids abrasion of articular cartilage with the needle and facilitates aspiration of synovial fluid.[36]

Lateral and medial femorotibial joints For needle placement in the lateral femorotibial joint have the limb fully weight bearing and identify the space between the proximal tibia and the distal trochlear ridge of the femur between the lateral patellar ligament and the lateral collateral ligament. The space is a small triangle of soft tissue that you may indent on digital palpation. An 18–20 gauge, 1½ inch (0.9–1.2 × 40 mm) needle is inserted perpendicular to the skin and may be placed nearly to its hub.[31] Inject 15–20 mL of local anesthetic. The approach is similar for the medial femorotibial joint with the needle being placed between the medial patellar and medial collateral ligaments.

Coxofemoral joint

Accurately injecting local anesthetic into the coxofemoral joint is not easily accomplished. The landmarks may be difficult to palpate in heavily muscled horses and the joint is very distant to the insertion point of the needle.

The horse should be standing squarely in stocks and a bleb of local anesthetic in the skin should be placed at the needle insertion point. The paired eminences of the major trochanter of the femur lie on a line approximately two-thirds of the distance from the tuber coxae to the tuber ischium. The proximal aspect of the cranial part of the greater trochanter lies approximately 5 cm distal to the proximal extent of the caudal part. A 16 gauge, 5–8 inch (1.5 mm × 15–20 cm) needle is inserted immediately proximal to the cranial part of the greater trochanter. The needle is directed in nearly a horizontal plane, slightly cranial and distal, toward the coxofemoral joint. The joint capsule is thick and may require vigorous pressure on the needle to penetrate. A volume of 20–40 mL of local anesthetic is injected.[31]

Imaging

When the lameness has been localized with manipulations and/or diagnostic local anesthesia, the region should have appropriate images obtained to allow a diagnosis of the lameness. Most often, this would involve radiography or ultrasonography but occasionally nuclear scintigraphy, computed tomography, magnetic resonance imaging or thermography may be used.

CHAPTER 15

Diseases of the foot

Andris J. Kaneps and Tracy A. Turner

A thorough examination and assessment of the equine foot forms an essential part of both the physical and lameness evaluation. Because foot problems are the most common cause of lameness in horses, the examiner must have an accurate knowledge of foot anatomy and must be willing to take a 'hands-on' approach to fully identify any problems the horse might be experiencing.

There are numerous causes of pain in the foot of the horse. These can be divided arbitrarily into: (1) conditions of the hoof wall and horn-producing tissues; (2) conditions of the distal phalanx; and (3) conditions of the podotrochlear region:

1. Hoof problems include: hoof-wall defects, such as cracks that involve the sensitive tissue; laminitis (systemic); laminar tearing (local, due to hoof imbalance); separation or inflammation of the sensitive laminae from the insensitive laminae; abscess formation; contusions of the hoof causing bruising or corn formation; neoplasia; and pododermatitis (thrush or canker).
2. Distal phalanx problems include: fractures of the coffin bone (types I–VII), deep digital flexor insertional tenopathy, pedal osteitis (generalized or localized inflammation of the bone), disruption of the insertions of the collateral ligaments, cyst-like lesion formation, and remodeling disease.
3. Conditions of the podotrochlear region have been reported to include: distal interphalangeal synovitis/capsulitis, deep digital flexor tendonitis, desmitis of the impar (distal navicular ligament) or collateral sesamoidean ligaments, navicular osteitis or osteopathy, and vascular disease of the navicular arteries, and navicular fractures.

The common denominator of all these conditions is that they are characterized by pain that can be localized to the hoof.

Anatomy

- The hoof capsule is comprised of tubular and intertubular keratin arranged as a laminated composite material.
- Ninety per cent of the energy input is dissipated by the hoof capsule and its associated structures.
- The lamellae of the inner layer of the hoof capsule provide a large surface area (13.75 sq ft; 1.28 sq meters) to suspend the coffin bone.

The hoof capsule is an amazing design that not only provides strength but also supports the horse's skeletal column. Keratin is the main structural protein of the epidermis in the animal kingdom and is present in skin, hair, nail, claw, wool, horn, feather, and scale, as well as hoof. The keratins can be loosely grouped into the 'soft' keratins of skin and the 'hard' keratins of horn, hair, etc. In the horse, the tubular hoof of the wall is composed of hard keratin and is rich in disulfide bonds, and so has great physical strength. The frog and the white zone are rich in sulfhydryl groups but poor in disulfide bonds, and therefore have lower physical strength but greater elasticity. The strength, hardness, and insolubility of keratin are due to disulfide bonds between and within the molecules. The sulfur-containing amino acids methionine and cysteine are incorporated into the keratinocytes in the final stages of its maturation and hence these amino acids (or their sulfur-containing precursors) are a necessary part of the diet.

New hoof is made continuously because there is continual loss of hoof wall from the ground surface. Continual regeneration of the hoof wall occurs at the coronary band where germinal cells (epidermal basal cells) produce populations of daughter cells (keratinocytes or keratin-producing cells), which mature and keratinize, continually adding to the hoof wall. It takes these cells anywhere from 6 to 12 months to reach the ground surface.

Two types of horn are produced from the coronary band. Tubular horn arises from cells surrounding papillae (finger-like projections from the coronary band) and become organized into thin, elongated, cylinders or tubules. In cross-section the keratinocytes of individual hoof wall tubules are arranged around a central hollow medulla in nonpigmented concentric layers. Each hair-like tubule is continuous, from its origin at the coronary band all the way to the ground surface (a distance of 5–15 cm, depending on the breed). The keratinocytes generated between the papillae mature into intertubular hoof, thus forming a keratin matrix in which tubules are embedded. The intertubular horn is formed at right angles to the tubular horn and bestows on the hoof wall the unique property of a mechanically stable, multidirectional, fiber-reinforced composite. Interestingly, hoof wall is stiffer and stronger at right angles to the direction of the tubules, a finding that is at odds with the usual assumption that the ground reaction force is transmitted proximally up the hoof wall parallel to the tubules. The hoof wall appears to be reinforced by the tubules but it is the intertubular material that accounts for most of its mechanical strength stiffness and fracture toughness. The tubules are three times more likely to fracture than intertubular horn. Thus hoof wall is considered to have an anatomical design that confers strength in all directions. During normal locomotion the hoof wall only experiences one-tenth of the compressive force required to cause its structural failure.

The fully keratinized cells of the tubular and intertubular hoof, cemented firmly to each other, form a continuum; the tough yet flexible stratum medium of the hoof wall. When mature, these cells, which are firmly cemented together, form a tough protective barrier preventing the passage of water and water-soluble substances inwards and the loss of body fluids, imparted by the highly vascular dermis, outwards. In addition to acting as a permeability barrier, the hoof wall ultimately is responsible for supporting the entire weight of the horse.

The tubules of the equine hoof wall are not arranged randomly. The tubules of the hoof wall are arranged in four distinct zones based on the density of tubules in the intertubular horn. The zone of highest tubule density is the outermost layer and the density declines stepwise towards the internal lamellar layer. As the force of impact with the ground (the ground reaction force) is transmitted proximally up the wall, the tubule density gradient across the wall appears to be a mechanism for smooth energy transfer, from the rigid (high tubule density) outer wall to the more plastic (low tubule density) inner wall, and ultimately to the coffin bone (third phalanx). The gradient in tubule density mirrors the gradient in water content across the hoof wall and together these factors represent an optimum design for equine hoof-wall durability. The zones confer on the hoof wall the design properties of a laminated composite; the interface between zones absorbs energy and prevents the propagation of cracks towards sensitive inner structures. In addition, the fact that the hoof wall is stronger in one direction ensures that cracks, when they occur, propagate from the bearing surface upwards and parallel with the tubules (that is, they propagate along the weakest plane). They do not extend to the innermost layers of the hoof wall because in this region the relatively high water content confers high crack resistance (the hoof wall is more pliable). The hoof wall also has a powerful dampening function on vibrations generated when the hoof wall makes contact with the ground during locomotion. It is able to reduce both the frequency and maximal amplitude of the vibrations. In fact, by the time the shock-wave of impact with the ground reaches the coffin bone, around 90% of the energy has been dissipated.

The corium is the region of the foot that nourishes the hoof-wall cells. There are several distinct zones, the coronary corium, lamellar corium, solar corium, and frog corium. The coronary corium fills the coronary groove and blends distally with the lamellar corium. Its inner surface is attached to the extensor tendon and the cartilages of the coffin bone by the subcutaneous tissue of the coronary cushion. Collectively the coronary corium and the germinal epidermal cells that produce the hoof wall are known as the coronary band. A feature of the coronary corium is the large numbers of hair-like papillae projecting from its surface. Each tapering papilla fits into one of the holes on the surface of the epidermal coronary groove and in life, is responsible for nurturing an individual hoof wall tubule.

The innermost layer of the hoof wall and bars is named the stratum lamellatum after the 550–600 primary epidermal lamellae that project from its surface in parallel rows. Examination of the hoof capsule, with its contents removed, shows that the lamellae of the dorsal hoof wall are shaped like long, thin, rectangles approximately 7 mm wide and 50 mm long. One edge of the rectangle is incorporated into the tough, heavily keratinized hoof wall proper and the opposite end faces the outer surface of the coffin bone. The proximal end is curved and forms the curved shoulder of the coronary groove. The distal end merges with the sole and becomes part of the white zone visible at the ground surface of the hoof (white line).

In common with all epidermal structures, the lamellae of the inner hoof wall are avascular and depend on capillaries in the microcirculation of the adjacent corium for nutrition. The lamellar corium covers the coffin bone. The primary function of the lamellar hoof is to suspend the coffin bone within the hoof capsule. It reserves its proliferative potential for the healing of injuries.

Because the role of the lamellae is suspension of the distal phalanx, an anatomical specialization increasing the surface area for the attachment of the multitude of collagenous fibers arising from the outer surface of the coffin bone would be expected. The secondary epidermal lamellae are just such a specialization. These folds form an extra 150–200 secondary lamellae along the length of each of the 550–600 primary lamellae.

The tips of the lamellae (both primary and secondary) all orientate towards the distal phalanx, thus indicating the lines of tension to which the lamellar suspensory apparatus is subjected. The surface area of the equine inner hoof wall has been calculated to average 13.75 square feet (1.28 square meters). This means that the lamellae (contained inside the hoof capsule) have a surface area roughly equal to two-thirds the size of a standard door. This large surface area for suspension of the coffin bone and the great compliance of the interdigitating

lamellar architecture helps reduce stress and ensures even energy transfer during peak loading of the equine foot. In life, this hoof wall/coffin bone interface is amazingly strong and can be separated only under the direst circumstances.

Examination of the distal limb

Six steps should be taken in the evaluation of foot pain:

1. history
2. subjective evaluation of the hoof
3. objective assessment of hoof balance
4. assessment of pain
5. the response to diagnostic analgesia
6. imaging of the foot.

History

Any examination begins by obtaining a history.[1] More information than age, breed, and sex is necessary. Obviously, the questions that should be answered would apply to any lameness examination, but some will have greater significance when dealing with foot problems.

The examiner must know what the presenting problem is and how long it has been apparent. It is an excellent idea to ask what the owner/trainer suspects is wrong. The examiner then can address these concerns while ascertaining the problem. The history-taker then needs to ask about the pattern of lameness (intermittent or constant) and, if the lameness is intermittent, under what conditions it is likely be seen, i.e. at the beginning of exercise or after hard work.

An appreciation of the breed and the use of the horse will also provide information relative to the incidence of certain foot problems. Thoroughbred and Quarter Horse racehorses have a relatively high incidence of foot bruising, pedal osteitis, distal phalanx fractures, heel bulb damage from overreaching, quarter cracks, nail problems, underrun and sheared heels. Standardbred racehorses have similar foot problems but also have a much higher incidence of quarter cracks. Racing combines extraordinary speed with surfaces that are more conducive to speed than to cushion, thus creating tremendous force on the hoof. Quarter Horses, Thoroughbreds, Standardbreds and the Warmblood breeds have the highest incidence of navicular problems, whereas Arabians and ponies have the least issue with the navicular bone. Horses that participate in agility sports such as roping, cutting, reining, barrel racing, and polo have frequent problems with pulled shoes and associated hoof wall loss. Distal phalangeal fractures occur but with less frequency than in racing. Palmar foot pain syndrome is a frequent diagnosis in this group as well. Horses used over fences, such as showjumpers and eventers, suffer frequently from foot bruising, pulled shoes and hoof-wall loss, quarter cracks, and palmar foot pain syndrome. Gaited horses such as Morgans, American Saddlebreds, Tennessee Walking Horses, Arabians, and Hackneys (horses and ponies) are often purposely shod with longer hooves, heavier shoes and pads, which alters the biomechanics of the hoof capsule for animation and frequently results in problems with hoof-wall breakage, hoof cracks, and thrush. Sand cracks (coronary quarter cracks) occur more often in Saddlebreds and Tennessee Walking Horses than any other breed.

Laminitis is seen frequently in older horses of all breeds, Morgans, ponies of all breeds, and heavily campaigned overweight show horses. Horses that are turned out to pasture for extended periods of time frequently show hoof-wall loss, superficial hoof cracks, and subsolar infections. The larger draft breeds (Clydesdales, Percherons, Belgians) that work in harness often injure the coronet and associated tissues by stepping on their feet. There is reportedly a high incidence of canker in these draft breeds.

It is helpful to determine when the horse was last shod or trimmed; to evaluate the shoeing you must know when it was performed. Often, a normal healthy hoof will grow over the shoe when it is due for a reset. The hoof also does not necessarily grow uniform, so the way the horse was shod by the farrier might not be what you see as an examiner weeks later. Foot problems that arise within a few days of shoeing can indicate sole pressure, a poorly placed or overclinched nail(s), or excessive trimming. Find out whether the farrier encountered any recent problems or has had to deal with ongoing shoeing problems. This might include horses that are difficult to shoe because of behavioral problems, thin walls, continual evidence of bruising, or thrush.

It is important to ascertain the environment in which the horse lives, trains, and competes. The environment plays a major role in the quality of the horn of the hoof and, as such, serves as the catalyst of many foot problems. The time of year and the surface can dramatically change the feet as well as the shoes. For instance, a horse training on a stone dust track will show very rapid wear of the shoes, the groove or fullering might be completely gone in less than 2 weeks; whereas, the shoes of a horse training on a deep, soft sand track might show very little evidence of wear in as many as 6 to 8 weeks. Foot bruising, pedal osteitis, and distal phalanx fractures are much more likely on hard 'fast' surfaces than on grass or deeper surfaces. Horses that are subjected to wet grass in the morning and hot, dry conditions later in the day often develop weak hoof walls and lose shoes easily. Adverse environmental factors can negatively influence the outcome of some foot problems. When horses move from one environment to another the feet often become a problem. This has been a particular problem of horses moving in the USA from the Midwest (soft, moist surfaces) to the Rocky Mountain region (hard, dry surfaces). The horse's foot is simply too slow to adapt to a change in stress. We have occasionally seen the same problem in horses coming from Europe. The hoof appears to need acclimatizing to the new environment.

Look at the current type of shoe being used, as well as the type of shoe used in the past. Is it steel or aluminum? The answer might be as simple as the horse appears to perform best with one particular type of shoe and poorly with another. However, the farrier might also have recognized a problem and begun to make adjustments. On the other hand,

the shoe could simply be a trainer's preference without a good reason for using it. Enquire why any special shoe or addition to a shoe (calk, grabs, extensions, or bars) was used. Bar shoes, for example, are often useful in treating various foot problems but can be essentially useless for some horses trying to race, in other instances, bar shoes might be a fad (e.g. all the dressage horses in a barn wearing egg-bar shoes). Is the bar shoe fitted appropriately? First and foremost it must be remembered that a shoe has no magical properties and how the shoe is applied is more important than the type of shoe, i.e. 'the application is more important than the appliance'. Some horses simply do not get sufficient traction on some surfaces or travel as well in certain types of shoes. Prior knowledge of a shoeing history as it affects an individual horse is useful information. It should suggest to the examiner that an alternative should be sought or that an individual horse should be trained at speed to see if he or she can 'handle' the surface with the type of shoe that is employed.

Information regarding previous foot problems must be obtained. The horse might have experienced a foot abscess 3 or 4 weeks earlier, or 'foundered' 1–2 years earlier, all of which would suggest to the examiner that the same problem might have resurfaced. Obtaining reasonable detail on the previous treatments is essential when examining an ongoing problem for the first time. This will help to prevent the use of a similar but previously unsuccessful treatment.

Subjective evaluation of the hoof

Like any physical examination, this involves more than simply measuring a few parameters and determining where on the scale of normality they fall; it should be a systematic evaluation of the hoof capsule and the structures within that tell the examiner about the general health of the hoof, the stresses that have been placed on it and how the hoof has responded to these stresses. The hoof is a dynamic structure that grows continuously and therefore has the ability to deform continuously to stresses that are applied to it.

The examination begins simply by looking at the hoof, preferably from sufficient distance to compare all four feet at once.[1] The size, shape, toe length, heel length, hoof pastern axis, and position of each foot relative to each limb and to each other are assessed. This is the best time to evaluate the horse's 'balance', i.e. the differences in each of the horse's legs and how the horse stands on the hoof.[2] One could consider this a conformational analysis but in fact the examiner is simply evaluating the position of the hoof on the end of the limb. This analysis must be evaluated from three directions: the front (dorsal), the side (lateral), and the back (palmar/plantar).[3] From the front, the hoof needs to be assessed for symmetry and alignment. Is the hoof centered under the cannon bone or is it offset? If the hoof is offset then the stresses on the hoof will change. Does the hoof rotate on the leg (toe-in or toe-out)? If it does rotate, what is the origin of the rotation, knee, fetlock, pastern, or hoof? This will determine where the torque is occurring in the hoof. Does the ground surface of the hoof appear symmetrical? If not, this indicates stresses on the hoof. Most commonly, one sees the medial hoof wall more upright. Is the coronary band straight and parallel to the ground surface? If not, this indicates a stress on the wall below the coronet.

The next factor to observe is the hoof alignment. This is viewed form the dorsal and lateral aspect.[2] The average horse (60%) will have a hoof angle between 50 and 55°. The alignment of the pastern and dorsal hoof wall is referred to as the hoof axis. Ideally, when the horse is standing square; the

Fig. 15.1
Underrun heels. Note how the bearing surface of the hoof and the caudal extent of the shoe is well cranial of the optimal position. Less heel stress would occur in this foot if the hoof were trimmed to bring the bars caudally and the shoe was set with its caudal aspect in line with the bulbs of the heel.

Fig. 15.2
Bilateral club-footed confirmation due to flexural contracture of the deep digital flexor tendon.

cannon bone, pastern, and hoof should line up straight as seen from the front. From the side, the pastern and hoof should be straight with the angle created by the dorsal hoof wall the same angle as the pastern and the angle of the heels within 5° of the angle of the toe.[4] Horses that have a low hoof angle compared to the pastern have a broken-back hoof axis (Fig. 15.1). This hoof conformation is also called 'long toe and low heel'. On the other hand, horses with a steep hoof angle and sloping pastern have a broken-forward axis. This hoof conformation is also called 'club foot' or 'clubby' (Fig. 15.2). Unfortunately, horses do not normally stand with their cannon bones perpendicular to the ground, so evaluation of hoof alignment must be done with the horse standing comfortably.

The next area to evaluate is hoof shape and level. Generally, the front hoof should be round or circular in shape, whereas the rear hoof is more triangular or pear-shaped. Front and rear hooves should be shaped like inverted cones. Both hooves should be evaluated for differences in length and width. Hooves of equal width and length tend to look circular but as hoof capsule length increases the width of the hoof wall in the quarters becomes more upright and the stresses on the hoof will naturally be different. There are two aspects to hoof levelness. First, is the ground-bearing surface flat? This determines how evenly the hoof wall will bear weight. Second, is the ground-bearing surface perpendicular to the upper limb? This determines how the leg is loaded during weight bearing. These factors are the basis for determining medial to lateral hoof orientation.

The final observation is to evaluate the heel support. This is done by evaluating the location of the ground-bearing surface of the heels relative to the remaining hoof capsule, relative to the pastern and relative to the fetlock and cannon bone. Does the ground-bearing surface provide sufficient support to the palmar (plantar) aspect of the digit? Are the heels of the hoof centered under the cannon bone (from the palmar/plantar aspect) or are they offset. This can be important in determining how the horse loads the heels, whether they are landing simultaneous or whether one heel might strike before the other. These observations are helpful for understanding how the hoof capsule has grown and remodeled to adapt to the forces on it.

Watching the horse at a walk will enhance these previous observations. Observing the foot in motion should determine the manner the horse lands and breaks over, as well as the path of the foot during the flight phase of the stride. Toe-first landing or excessively heel-first landing indicates either compensation for pain or dorsopalmar hoof imbalance. Similarly, medial or excessively lateral heel-quarter-first landing suggest either compensation for limb conformation or pain leading to mediolateral hoof imbalance. The flight of the foot during the stride is correlated with rotational deviation of the limb and imbalance of the foot. The horse that wings-in or 'dishes' is either toed-out or breaking over the inside toe. Conversely, the horse that paddles or wings-out is either toed-in or breaking over the outside toe.

Once the above observations have been made the examiner needs to make a closer evaluation of the hoof. This evaluation needs to be performed first with the horse in weight-bearing position and then with the foot in non-weight-bearing position.

This begins by palpating the pastern to determine if there is any obvious heat, pain, or swelling. More subtly, the examiner needs to palpate the bones and tendinous structures. Generally, the flexor tendons are not as wide as the pastern bones and there is a finger's-width difference medially and laterally. Follow the tendons down the leg until they disappear at the heel bulb.

Next palpate the digital arteries, vein, and nerve. It is normal to feel a digital pulse but not a bounding pulse, which is abnormal and an indicator of foot inflammation. The strength of the pulse can be compared to other limbs if one is in doubt. A symmetrical abnormal pulse indicates generalized inflammation, whereas an asymmetric pulse indicates the inflammatory process on the side of the stronger pulse. In addition, the skin should to be carefully palpated for the presence of neurectomy scars.

Palpation is then continued to the coronet (hairline/hoof capsule junction). Normally one should appreciate a 'spongy' feel to this area and abnormalities such as swelling, discharge, focal pain or heat, or absence of tissue (loss of sponginess or a 'trough') should be examined more closely. The examiner should feel that the hairline forms a smooth edge with the hoof capsule. Any area where the hoof capsule is prominent indicates an area of stress. Prominent edges of the coronary band indicate proximal movement of the hoof capsule ('jamming') into the hairline. In many breeds, particularly in the gaited breeds that carry longer lengths of hoof, this seems to be normal. As the edge becomes more prominent the examiner can be sure that the vertical distance from the hairline to the extensor process of the third phalanx is increasing (measurement that is made from a lateral radiograph).

From the coronet the examiner moves to the collateral cartilages where they are palpated and manipulated. The palmar and proximal edges should be easily defined. The thickness, density, and pliability of the cartilages need to be assessed. Palpation of this area will not only determine if there is any pain but also can give an impression of the flexibility of the hoof. For instance, a very stiff inflexible collateral cartilage is associated with a narrow, upright hoof. On the other hand, flimsy cartilages are commonly seen in the hoof with collapsed heels and a narrow, convex frog.

The entire hoof wall must be examined for the presence of cracks, fissures, bulges, growth abnormalities, focal heat, wall loss, or breakage. A high percentage of quarter and heel cracks begin as small, very fine fissures at the coronet. They might extend less than 1 cm distally and are easily missed if this area is not examined carefully. These small fissures are a definite cause of foot pain and usually associated with deeper injury to the coronet and/or lamina below.

The exit of all shoeing nails from the hoof capsule needs to be evaluated. The higher the exit point the more likely the nail is impinging on sensitive tissue. This is an excellent time to use the hammer and gently percuss the hoof wall to determine if wall defects, hollow sounds, or painful areas are present.

From this point it is natural to begin manipulating the foot in the non-weight-bearing position.[1] Begin by cleaning the bottom of the hoof and lightly paring away any debris that

obscures visualization of the frog, sulci of the frog, sole, and white line if the horse is unshod. Once the foot is clean, examine it in its entirety. The frog should be examined for size, shape, and consistency, and to determine whether it is securely attached to the underlying tissue and its sulci (collateral and central). The examiner needs to determine how much of the structure could actually bear weight and how much represents loose tissue. The frog should be resilient and rubbery, rather than hard and flaky, and the caudal two-thirds should be nearly level with the ground surface of the hoof wall. The frog should not be recessed deep into the sulci of the foot and nor should the frog be convex at its apex. The receded frog is often associated with upright narrow feet, whereas the convex frog is associated with weak and underrun heels. I have long thought that this conformation is associated with a poorly constructed digital cushion and therefore a poor hoof support mechanism but this has yet be proven.

The medial and lateral bars of the foot usually require light paring with a hoof knife to appreciate problems such as bar cracks. Do not pare the bars away totally as this weakens the foot. The entire sole of the foot should be carefully examined for fissures, punctures, consistency, discoloration (bruising), and the degree of concavity. The shape of the sole should be concave. A flat sole might signify either poor hoof conformation (a weak hoof) or distal coffin bone displacement. A convex (dropped) sole indicates a displaced coffin bone (Fig. 15.3). The consistency (relative degree of stiffness) of the sole is determined using digital pressure as well as hoof testers. At this point it is necessary to evaluate the texture of the sole. By grasping the quarters with your fingers, the thumbs can be used to gently press on the sole. A sole that moves under this pressure is thin and there is little space between the coffin bone and the outside environment. On the other hand, if the sole does not move then the examiner knows there is at least some thickness and depth to the sole. True sole depth can be determined via radiography.

The white line (the junction between the sole and inner hoof capsule) is examined to determine its width and character. The white line is usually wider at the toe and gradually thins as it approaches the heels. It is best visualized following either light paring with the hoof knife or light rasping of the superficial portion of the sole margin. It is used as a landmark by farriers to demarcate the insensitive hoof from the sensitive hoof for the purpose of driving horseshoe nails. Everything superficial to the white line is insensitive, everything more central is considered sensitive. Widening of this area represents stress and separation of the laminar hoof wall from coronary hoof wall. The deeper the separation goes the more severe the injury. This separation can be seen anywhere on the solar surface and indicates a bending force on the wall that is pulling the wall away from the coffin bone. Most frequently this separation is seen at the toe and is referred to as 'seedy toe' because it looks like small seeds could fit between the spaces created by the separation.

Examine the bulbs of the heels to determine their relative position to one another. The strength of this tissue is assessed manually by attempting to distract the two bulbs from one another in a vertical direction. Digitally explore the heel bulbs for the presence of swelling, heat, pain, or separation at the coronet. The central sulcus of the frog needs to be examined and probed to determine its depth. Normally this should be a shallow depression of no more than a centimeter. If the sulcus goes deeper it can be due to either very serious thrush or loss of structural support in heel bulbs (the heel bulbs can be distracted in opposite vertical directions).

Lightly support the limb at the metacarpus (metatarsus) and allow the foot to drop naturally. Position your line of

Fig. 15.3
Dropped sole due to distal phalanx displacement. The sole should normally be concave.

Fig. 15.4
Solar surface of a foot prior to trimming. Lines have been drawn across the widest portion of the foot and sagittally. From this perspective the foot is in quite good balance. The dorsal and palmar portions of the foot are nearly equal. The half to the viewers right (lateral) is slightly larger than the half to the left (medial).

vision so as to appreciate foot balance and levelness of the walls (see above). Examine the entire ground surface of the foot to determine the divisions of the hoof (toe, quarters, and heels) and their proportions (Fig. 15.4). Imagine a line drawn through the axial center of the limb, which transects the ground surface of the foot, and then determine the relative proportion of medial and lateral foot to this imaginary line. For example, a given foot may demonstrate a unilateral medial heel contraction in combination with a flared lateral quarter and toe (diagonal imbalance).

Examine the foot systematically with hoof testers. Begin with the bar, move to the heel, to the quarter, and then to the toe and back toward the opposite heel. Space the sites where the hoof testers are applied at approximately 2.5-cm (1 inch) intervals. Be sure to apply hoof tester pressure at each exit point of the shoeing nails. Next, place the testers in each of the collateral sulci and across the hoof to the opposite hoof wall (progressively move the hoof tester along the hoof wall caudal to cranial to check for alterations in the pain response), then place the testers in the central sulcus to the hoof wall at the toe, and then across the heels. Finally, using the hammer gently rap the structures on the bearing surface of the sole and frog.

Repeat the palpation of the cartilages of the distal phalanx and the coronet. Bringing the limb forward and flexing the toe facilitate palpation in the region of the extensor process of the distal phalanx region and the associated distal interphalangeal joint. The thumbs can then be pressed over this area to feel for joint distension, heat, or pain. The foot also should be rotated (twisted) medial and lateral around the vertical axis of the pastern. A normal range of motion allows for 10–15° of rotation each way. Injury to the joint capsule or collateral ligaments, or chronic navicular pain, tends to reduce this motion. Likewise, distal limb flexion should reveal 30–45° of excursion. Again, injury to the joint capsule, collateral ligaments or chronic navicular pain tends to reduce this motion.

If the horse is shod, the exam should include the following additions.[1] First, determine the security of the shoe to the foot by gently rapping the shoe at 2.5-cm (1-inch) intervals with a shoeing hammer. Note the shoe type as well as the presence or absence of additions such as toe grabs, block heels, trailers, and so forth. Carefully determine if abnormal shoe wear exists. Position the hoof testers to include the hoof wall at the exit point of each nail. Record your findings because it is easy to forget subtle discoveries that may ultimately determine how the horse should be treated or shod. Remember that hoof testers are essential but certainly not foolproof. The response the examiner gets from hoof testers depends on many factors, such as the hardness of the wall, depth of the hoof, thickness of the hoof, and the stoicism of the horse.

Objective assessment of hoof balance

As part of the overall evaluation of the horse an objective assessment of hoof balance is important. The horse's weight is determined with a weight tape or scale and then 11 measurements are made of each foot:[4]

- Seven measurements are made of the hoof length with a tape measure: medial and lateral heel lengths, medial and lateral quarter lengths, dorsomedial and dorsolateral toe lengths, and sagittal toe length. These measurements are recorded on a graph to illustrate the general shape of the foot.
- The frog's length and width are measured at their longest and widest points.
- The hoof circumference immediately below the coronary band is measured.
- The hoof angle (using a hoof gauge) is also measured.

From these measurements, two additional measurements can be calculated: the frog ratio (frog width divided by length) and the body size to hoof area (horse's weight (pounds) × 12.56/square of the hoof wall circumference (inches)).

A dorsopalmar (plantar; D65PDO) and a lateromedial radiograph of the hoof can also be used to determine valuable information about hoof balance. The horse must be standing with the metacarpus (tarsus) perpendicular to the ground, which can most easily be determined by either the use of a level placed against the cannon bone or the use of a weighted string to align the leg. The radiographic beam should be horizontal and centered on the hoof. Resting the horse's foot on a block to raise the hoof off the ground facilitates these exposures (the opposite limb should be similarly elevated). A wire or radiopaque paste placed sagittally (midline) along the toe from the coronary band to the ground, a thumb tack in the apex of the frog and thumb tacks in the most caudal point of the ground contact of each heel emphasize these areas on the radiographs, making their identification much easier.

After plotting the hoof wall lengths on a graph, one should have a curve that reflects the shape of the hoof. For a hoof of average hoof angle (48–55°), flattening of the plotted curve indicates that the heels are underrun. A flat curve would also be expected for very upright hooves (≥ 60°). Generally speaking, the three measurements at the toe should be equal. The measurements at the quarter are usually 1–2 cm shorter than the toe (for the average hoof). The heel length should generally be about one-third of the toe length.

Another factor to evaluate is the size (weight) of the horse versus its foot size. Guidelines have been made relative to toe hoof length. The average toe length is a function of the horse's weight. The average pleasure horse weighing 360–400 kg (800–900 pounds) should have 7.6 cm (3 inches) of hoof length at the toe. A horse weighing 430–480 kg (950–1050 pounds) should have 8.25 cm (3.25 inches) of hoof length, and horses weighing 520–570 kg (1150–1250 pounds) should have 8.9 cm (3.5 inches) in length. Another rule of thumb that has been suggested is to add or subtract 3.3 mm (⅛ inch) of length for every 90 kg (200 pounds) using a 470 kg (1000-pound) horse carrying 8.25 cm (3.25 inches) of length. Obviously these are guidelines only. A measure that has been an excellent aid to assessment is comparing the horse's weight to the coronary band circumference using the formula of the horse's weight × 12.56 and divided by the square of the coronary

circumference to determine the weight to hoof size ratio. A ratio of 5.5 kg/cm^2 (78 lb/in^2) is seen in 99.5% of horses; horses weighing more are too heavy for their hoof size. The measurements of the frog length and width are used to determine if the hoof is contracted. Normally the frog width should be two-thirds its length. Furthermore, ideally the frog length would be two-thirds of the solar length (heel bulbs to toe).

Examination of the lateral and dorsopalmar (plantar) radiographs provides excellent pictorial evidence of imbalance. The lateral radiograph should be evaluated for P2 and P3 alignment, which may reveal the presence of a broken-hoof axis. In addition, the alignment between P3 and the hoof wall should be assessed. If the hoof wall and dorsal surface of P3 are not parallel the functional hoof angle can be determined by measuring the angle of the dorsal surface of P3 with the ground. Usually the slope of the heels can be seen on the radiograph and can also be used to determine whether the heels are underrun.

The D65P–PDO radiographic projection should be assessed for joint alignment, medial and lateral hoof wall lengths, and foot symmetry. Joint alignment is determined by examining the symmetry of the joint space. Misalignment is present if one side of the joint is narrower. This phenomenon can also be caused by poor positioning of the limb, in which case all three of the lower leg joints (fetlock, pastern, and coffin) will be affected. The hoof wall length can be measured directly from the film. The symmetry of weight bearing can be predicted in a similar manner.

Assessment of pain

The next step in developing a logical approach to the evaluation of the hoof is an accurate assessment of pain and careful evaluation of hoof structure that may predispose to or cause the pain.[5] First, examine the horse in motion; watch the foot strike for each foot. Determine if the foot lands flat, heel or toe first, medial or lateral quarter first. The landing position of the individual foot relative to the vertical axis of the respective limb should be noted. Evaluate the path the individual foot takes from foot breakover to strike. The character of motion may be a clue as to where on the foot or the limb the problem exists. Always include this examination at the walk because it is the one gait that is sufficiently slow to permit the determination of fine movement error. Repeat the same process when reviewing the horse from the left and right side. The horse is then trotted (or paced) and visualized in the same manner. Circling the horse will often exacerbate foot problems.

Four diagnostic tests should be performed: hoof tester examination, distal limb flexion, hoof extension wedge test, and palmar hoof wedge test.[5] A positive response to any of these tests is important but a negative response is equivocal and does not rule out any problem. Hoof tester examination should be performed as previously described. A positive response should be repeatable, and in the distal sesamoid region the pain response should be uniform over those areas and must be evaluated in relation to examination of the remaining foot. That is, a positive response in the heels and quarters of the sole would also be expected to cause a positive response across the distal sesamoid region in the same area of the foot. Percussion utilizing a small hammer can also provide important information regarding pain in the hoof wall or sole.

The distal limb flexion test can exacerbate lameness if any of the three distal joints of the leg are affected by synovitis or osteoarthritis. A positive response could also be expected by any condition that causes induration of the tissues of the foot. This has been shown to be positive in over 95% of horses with foot pain.[5]

The hoof extension test is performed by elevating the toe with a block, holding the opposite limb, and trotting the horse away after 60 seconds. The palmar hoof wedge test is performed by placing the block under the palmar two-thirds of the frog and forcing the horse to stand on that foot. The test can be further modified so that the wedge can be placed under either heel to determine if the pressure there causes exacerbation of the lameness.

These tests simply allow the examiner to evaluate the horse's response to a particular stress. None has been shown to be pathognomonic for any particular cause of lameness.

Diagnostic analgesia

Regional analgesia will provide the evidence to localize the region of pain. The performance of regional analgesia needs to be performed in a logical manner. Intra-articular injections anesthetize joint regions; whereas regional analgesia desensitizes skin segments.[6] Intra-articular injection is more accurate and does not interfere with regional analgesia. Regional anesthesia desensitizes local nerves that innervate areas of the limb. They provide indisputable evidence of the location of lameness. The most important point is to have some idea of what areas have been desensitized. See Chapter 14 for details on local and intra-articular diagnostic anesthesia.

Imaging of the foot

After localization of the lameness to the foot imaging will be necessary to determine what pathology is present. Radiographic examination of the hoof requires a minimum of five radiographic views of each foot.[7] The views consist of a dorso-60°-proximal to palmarodistal (D60PrPD) of the navicular bone, a dorso-45°-proximal to palmarodistal (D45PrPD) of the third phalanx, a lateral to medial projection, a horizontal dorsopalmar projection, and a palmaroproximal to palmarodistal navicular bone projection (see Chapter 10).

Furthermore, each of these views must be assessed for any significant changes in any of the bone surfaces. It is the authors' opinion that the radiographs should be assessed for change and what the change means from a pathologic sense. Most of the time, radiographs are examined for signs consistent with the tentative diagnosis. Once the basic films have been examined, it may be necessary to take additional oblique views to completely appreciate any pathologic change.

A new method of assessing navicular pathology is through the evaluation of the flexor surface of the navicular bone by contrast arthrography.[8] The distal interphalangeal (DIP) joint can be evaluated for cartilage defects or the communication of subchondral cysts with the joint. Defects or punctures into the hoof can also be examined using contrast radiography, which can give much better insight into the structures that may be involved.

Recently, it has become possible to examine the structures within the hoof sonographically.[9] The collateral ligaments of the DIP joint can be clearly outlined by ultrasonography, as can the deep flexor insertion on the third phalanx, the distal deep flexor tendon, the impar ligament, and the navicular bursa. To examine the podotrochlea, the superficial horn must be pared from the frog to expose soft, spongy frog tissue.

The metabolic activity of the foot can be evaluated through the use of nuclear scintigraphy. Scintigraphy involves the injection of a radioisotope, and its subsequent uptake into the extracellular fluid and bone. Assessment is based on the detection of radiation from the radioisotope. The technique provides information on relative vascularity and rate of tissue metabolism. This is particularly useful in studying bone pathology and can help differentiate sites of injury in the foot.

Thermography provides information regarding skin temperature.[10] This technique is 10 times more sensitive than the human hand in detecting heat. It can be an early detector of inflammation in the foot. It has also been shown to be useful in assessing the relative blood flow to the foot. This information is of particular interest when pre- and postexercise temperatures are determined. Exercise will normally cause a 0.5°C rise in skin temperature. Whenever the skin temperature does not rise to this degree, poor blood flow should be considered a factor in the disease being assessed.

Diseases of the hoof wall

Hoof wall defects

- Lameness associated with hoof wall defects is due to irritation of the sensitive lamellae due to exposure, local infection or shearing of the unstable hoof capsule.
- Treatment should clean and stabilize the defect to permit healing from the coronary band.
- Healing of defects may require 5–10 months.

Recognition

History and presenting complaint The horse is presented for evaluation of cracks, fissures or morphologic defects in the hoof wall. Lameness may or may not be a presenting complaint.

Physical examination Defects should always be examined to their depth and size. Depth can be usually determined by probing the defect. The examiner needs to determine if sensitive tissues are involved. If pain is elicited by probing the defect, then it involves sensitive tissue. A percussion hammer is useful to determine the size of defects that are not readily visible. Normal percussion of the hoof results in a crisp resonance, whereas hoof wall separated from its deeper structures has a dull resonance. Radiography is very useful in these cases in identifying gas under the hoof wall, which indicates either infection or undermined hoof wall.

Defects at or near the coronary band should have the hair clipped from the coronary band. The coronary band then should be examined for injuries, wounds, splits, or other defects that would account for the abnormal hoof growth.

Diagnostic confirmation Radiographs may be necessary to rule-out involvement of the distal phalanx or sensitive tissues of the foot.

Treatment and prognosis

Therapeutic aims The first objective and most important goal of treatment is to eliminate or correct the problem that caused the hoof defect. Adjunctive therapy will usually make it possible to return to work sooner. If the underlying problem is not corrected recurrence should be expected.

Initial treatment is done to either stabilize a defect or prevent its further extension in the hoof capsule. Debridement of the defect is necessary to remove contamination of the hoof capsule and deeper laminae. Long-term support or protection of the affected region must be made.

Therapy It must be remembered that the healing of these injuries is based on growth of new horn from the coronary band. These tissues do not heal side to side; therefore healing is slow, and may take 5 to 10 months. To prevent the defect from expanding the crack should be immobilized. This can be

Fig. 15.5
Hoof crack with floated heel. The hoof crack has been debrided and stabilized with hoof staples. The foot has been shod with an egg bar shoe. A quarter clip is placed immediately dorsal to the hoof crack and the affected heel has been trimmed short enough to prevent contact with the shoe ('floated heel').

accomplished by application of a bar shoe that relieves pressure on the affected wall. The bar may be a full bar or a diagonal bar. Also, if the crack is near the heel, weight bearing to the heel can be reduced by 'floating' the heel (Fig. 15.5). The affected heel is trimmed short enough to prevent contact with the shoe during weight bearing. The objective is to relieve pressure, which causes movement at the area of the defect. In addition, clips placed on either side of the defect will help prevent hoof expansion and, therefore, will immobilize the crack. To further immobilize the crack it can be sutured or wired. In some cases a small metal plate can be screwed into the wall over the crack.

If the hoof crack does not extend from the ground to the coronary band changes in the hoof wall may be made to prevent crack lengthening. 'Grooving' the hoof wall perpendicular to the defect has the effect of deflecting stress away from the crack. Cracks that originate from the weight-bearing surface should be grooved at the most proximal aspect of the crack. Cracks that originate from the coronary band should be 'grooved' at their distal aspect and in the shape of a 'V'. 'Grooving' will only work if the crack does not extend into sensitive tissues, it is not cosmetic. Bonding or acrylic repair of a crack is a cosmetic and very successful method used to obliterate the crack.

Because of their horizontal orientation hoof clefts do not lengthen as do cracks. However, clefts are much more likely to involve sensitive layers and cause lameness. The horn around the cleft should be removed to the depth of the cleft. Sufficient horn should be removed so there is no undermined horn. In many cases, this may require a partial resection of the hoof wall from the cleft to the weight-bearing surface; a rotary burr (dremel tool) does an excellent job. After sufficient hoof wall is debrided, the underlying tissue should be inspected carefully.

Treatment of crumbling hoof may require wide debridement of hoof wall. As for a cleft, all undermined hoof wall should be removed. It should be removed until intact hoof wall is present around the edge of the debrided area. Again, the deep tissues must be carefully examined for necrotic tissue or contaminated debris.

Long-term support or protection of the defect is necessary to return the horse to use as soon as possible. This usually requires some type of repair to restore the integrity of the hoof wall. First, the area must be free of hemorrhage or sepsis. Controlling hemorrhage requires packing the bleeding area with gauze and wrapping the foot. Approximately 1 week is required to dry the hemorrhagic area and allow new horny growth over the area. Application of a 1% tincture of iodine to the horn in and around the defect will usually dry the area without desiccating it. If sepsis has occurred, or a foreign body has penetrated the hoof wall, it is necessary to soak the foot in a saturated solution of magnesium sulfate-tamed iodine solution to eliminate the infection. It may be necessary to soak the foot for 7 to 10 days before the septic area is healed. An alternative to soaking is to pack the affected area with a magnesium sulfate paste (ichthammol or povidone–iodine ointment mixed with magnesium sulfate). This treatment is followed by application of tincture of iodine solution. A helpful hint to determine if infection is still present is to examine the area 24 h after application of iodine. The presence of moisture or exudate in or around the defect is indicative of continued active infection. Soaking should continue until the infection is resolved.

The hoof wall can be repaired after the defect has been adequately debrided and the hemorrhage/sepsis has been controlled. The hoof should be properly trimmed and balanced. In most cases, a bar shoe with clips should be applied. The hoof should be dry. Application of either acetone or alcohol to the outer layers of the horn is an excellent method to remove debris and dry the hoof. To aid retention of the repair material, the hoof wall around the defect should be beveled inward (undermined) for 6 mm ($\frac{1}{4}$ inch) using a rotary hand burr. Some defects can be reinforced by wire laced across the gap. This not only helps immobilize the area but also adds substrate to which the repair material can bond. If the defect is not sutured, holes should be drilled from the normal hoof into the undermined area to allow penetration of repair material. The holes should be 0.5 to 1 cm apart.

There are numerous agents that are available for repair, including fiberglass, rubber, thin metal sheets, leather, and acrylic/epoxy materials. The acrylic/epoxies are the most popular materials. Modern hoof epoxies have biomechanical properties similar to normal hoof capsule, reducing the complications of hard, inflexible materials such as hoof capsule contraction. The material is mixed and applied to the defect and surrounding hoof wall. When sufficient time has elapsed to allow hardening of the material, excess acrylic is rasped away resulting in a cosmetic repair.

Two types of adhesives are used for hoof repair: acrylics and polyurethanes. Applied properly, these acrylics and urethanes have the texture, strength, and flexibility of natural hoof wall, allowing the farrier to rasp and nail to and through the bonded material, and then allowing the bonded material to 'grow down' with the hoof. Using available hoof repair composites, we can address capsular maladies such as hoof-wall cracks, avulsions, underrun heels, and thin walls. In effect, rather than having simple cosmetic repair materials, we now have materials suited for structural bonding and repair. Applied properly, the composite material alone generally provides great structural support; when combined with a reinforcing cloth, such as a fiberglass or Spectra cloth, the overall strength of the material can be increased by as much as five-fold. Subsequently, horses with hoof conditions that would have required lay-up before the advent of these new products are actively racing and competing today.

Successful application of these composite materials depends on numerous things, but manufacturers and farriers agree that the most important concern is proper hoof preparation. The farrier must thoroughly debride the hoof wall where the composite will be applied and follow this with a solvent rinse, ensuring that the hoof wall is clean, dry, and smooth. Any loose, flaky hoof wall, any moisture or oil weakens – and sometimes prevents – the bond. Indeed, improper application can result in greater disaster than a simple failed bond. Using these materials to seal moist and infected areas provides an environment conducive for bacterial and fungal proliferation, which undermines the hoof and destroys more hoof tissue.

Undoubtedly, these materials have proven themselves to be highly effective tools in the hands of the skilled farrier. However,

it is important to recognize that there is no acrylic magic wand, no composite panacea. In all cases, exercise of these animals should be minimized. Once a shoe is applied and the defect protected, work can resume. When large amounts of hoof wall have been lost, it may be necessary to complete the repair process before the horse is exercised. On occasions the entire hoof may need to be rebuilt before a shoe can even be applied.

The horse should be re-examined at 4- to 8-week intervals. The shoe will need to be reset and in many cases the repair repeated until the hoof wall grows out. If the animal is active and competitive the constant trauma may cause the repair to loosen. If the repair material loosens it should be removed and the repair repeated. Under no circumstances should new acrylic be applied over old acrylic. This can trap bacteria and cause an abscess to form.

Prognosis The prognosis for healing of hoof wall defects is usually good to excellent. Given proper hoof care, adequate time, and proper follow-up care, the defect will heal. Large defects that have resulted from an inflammatory cause may have a tendency to recur because of damage to the laminae and loss of bonding between the hoof wall layers. However, if the hoof is kept shod and protected, further problems can be avoided.

Etiology and pathophysiology

Etiology There are numerous causes of defects in the hoof. Careful examination of the hoof can often identify the probable cause, which must be eliminated before therapy will be effective. The first consideration is moisture; either excessive dryness or excessive moisture can result in defects. Dryness usually results in a brittle hoof that tends to crack when stressed. If the hoof is unprotected, large portions of hoof wall may break away at the weight-bearing edge. Conversely, excessive moisture can cause the hoof wall to crumble. This is probably due to a combination of a decay process caused by micro-organisms, a disruption of the normal horn tubules by the moisture, and stress on the hoof wall. This problem is usually characterized by hoof-wall crumbling, which starts at the weight-bearing surface. Examination of the wall reveals a hoof wall that is soft in nature at the area of crumbling. The hoof wall can easily be dislodged for several millimeters around the defect. The wall that is affected has little normal architecture and crumbles into a fine powder when pressure is applied.

The next consideration for evaluating the cause of defects is hoof conformation, balance, or improper shoe application. These problems can cause overloading of a portion of hoof wall and result in disruption of the integrity of horn. Defects resulting from speed work or work on uneven surfaces are also due to similar abnormal stresses.

Infection or foreign bodies in the hoof may also result in defects. Clefts and crumbling are the most common results of these factors. Clefts may result from either a separation of horn from the coronary band, as occurs with 'gravel', or from splitting of the hoof wall as a result of the inflammation associated with infection. Inflammation caused by infection disrupts the normal architecture of the hoof sufficiently to cause the wall to break or crumble under normal stress and usage.

Prevention

Prevention of hoof wall defects is best accomplished by regular farrier attention and early recognition and response to changes in hoof moisture (too dry, too wet). Hooves that are exposed to excessively moist conditions may benefit from application of sealing agents. Hooves that are extremely dry may be moisturized by simply allowing the paddock stock tank to overflow. The resulting muddy area will moisturize the hooves of horses that come to the water to drink. Horses that are in regular work and have a regular bath do not usually suffer from dry, cracked hooves. In fact, excessive hoof moisture remains a considerable problem in these horses.

Lacerations to the hoof and coronary band

- First aid should control hemorrhage and prevent further contamination.
- Damage to the corium may result in hoof wall defects.
- Deep wounds may affect synovial structures.
- Wounds that involve the hoof capsule will heal slowly by second intention.

Lacerations to the hoof causing loss of germinal tissue and either partial or complete avulsions of the hoof wall are not common injuries to the horse. When these injuries do occur, however, their management can be perplexing for the veterinarian.

Recognition

History and presenting complaint Horses with hoof-wall lacerations are presented for distal limb injury that usually includes considerable hemorrhage and may include varying degrees of lameness. The horse may have been caught in wire or kicked through a solid partition.

Physical examination Complete examination of the wound is necessary to determine the extent of the injury. Although the foot has as great a capacity for healing as any other tissue, the prognosis for return to full function is dependent on the severity of tissue destruction and the tissues involved. In most cases, adequate collateral circulation develops following injury. Because ischemia will impair healing and predispose the wound to infection, permanent loss of blood supply necessitates surgical removal of the ischemic portions of the wound.

Complete denervation of the foot by extensive damage to the digital nerve trunks may result in neurogenic degeneration and sloughing of the foot. Ironically, transection of the nerve, where damage has not been extensive, may aid recovery by reducing chronic pain associated with the injury.

Injuries that involve the corium of the foot should be inspected carefully. The corium is modified vascular tissue similar to the dermis, and is responsible for nutrition to the horny layers of the hoof. Damage to these structures often results in permanent defects in the coronary band and hoof. Injuries that cause avulsion or necrosis of corium will cause changes in horn production around the hoof. Many times one

must wait for the regrowth of the hoof to assess these changes and how they may affect the horse.

Deep wounds that extend to the middle or distal phalanges cause additional complications. Hoof avulsions may involve all or part of the wing of the distal phalanx. In these cases, it is usually easiest to simply remove the fractured portion of the bone. However, wounds that damage the periosteum or collateral ligaments surrounding these bones may cause permanent lameness as a result of excessive calcification of soft tissues or joint instability. Associated soft tissue injuries such as these will not be apparent on initial radiographic examination and can only be anticipated after close examination of the wound. Once soft tissue support is damaged the veterinarian may have to wait 3 to 4 months to evaluate the final consequences of this type of deep injury.

Although wounds that enter a joint may appear to have a poor prognosis, they can respond quite well if appropriate therapy is initiated immediately. Small wounds into a joint may not be readily apparent, the only sign being synovial fluid leaking into the wound. Occasionally, serum is mistaken for joint fluid or vice versa.

Other criteria that must be considered when evaluating these wounds are the horse's age, value, and function. Immature horses tend to heal more readily, and growth may help resolve some deformities. Wounds of the foot usually heal over an extended period, resulting in increased expense and residual lameness due to the injury; permanent deformity is a distinct possibility.

Special examination If any doubt exists as to whether a joint has been entered, saline is injected under pressure into the joint and the wound examined for the leakage of fluid. Another method of testing for joint involvement is to perform an arthrogram and see if leakage of contrast media from the joint is evident on a radiograph. Radiographs of the affected region should be obtained to determine if skeletal injury accompanies the hoof laceration.

Treatment and prognosis

Therapeutic aims The principal goals of surgery are to optimize conditions for wound healing and to achieve the most favorable cosmetic and functional result. The horse's hoof is not amenable to suturing and therefore wounds must heal by second intention.

Therapy Therapy consists of surgical debridement and wound apposition. The foot should be prepared for aseptic surgery. In addition, the hoof wall, sole, and frog should be trimmed, pared, and rasped to remove any contamination that may be in cracks or crevices. The hair from the fetlock distally should be clipped to allow surgical preparation of the entire foot and pastern area with an antiseptic soap. Exposed tissues should be cleansed and irrigated with a physiologic saline solution. Harsh antiseptics or irritating cleansers should not be used on exposed tissues because these chemicals may cause further damage. After thorough cleansing, the wound should be covered with a sterile, nonadherent dressing and the entire foot bandaged. The outer layer of the bandage should be impervious to water.

Surgery may be performed on either a standing or an anesthetized patient. Standing surgery should be performed with sedation and local anesthesia. However, this should be reserved for the most tractable of horses. It will also often require one person to hold the leg or to tie the leg up for surgery to be performed. General anesthesia provides optimal conditions to establish and maintain aseptic techniques, as well as optimizing the surgeon's ability to inspect the wound.

The goal of surgery is to optimize conditions for wound healing that will result in the most favorable cosmetic and functional result. The horse's hoof is not amenable to suturing and therefore wounds must heal by second intention. The most important factor in the management of these wounds is adequate debridement. Necrotic or severely damaged tissues and all foreign materials provide media for bacterial growth and impede wound healing. However, vital tissues such as nerves, arteries, and tendons should be salvaged, if possible. Complete wound excision is the simplest, most effective means of debridement. If this is not feasible, simple debridement of obviously devitalized tissue and foreign material combined with wound irrigation should be performed. Pulsating lavage is the most effective type of irrigation system.

If a synovial structure is opened or if it is suspected that a synovial cavity has been entered, the structure should be lavaged with copious amounts of physiologic saline solution so that the lavage flows out through the wound. The foot is a highly vascular structure and hemostasis is difficult. Hemostasis by ligation and electrocautery are usually not adequate. A temporary pressure bandage is usually necessary and will stop bleeding if left in place for 12 h. The initial bandage applied after surgical debridement should be moistened with sterile saline or an antimicrobial dressing over the wound and covered with an outer waterproof bandage.

Wounds of the hoof generally heal slowly, due in part to the high incidence of contamination. Subsequent wound infection can be minimized by proper cleaning, appropriate bandaging, and ensuring that enough help is available when changing the dressing (this usually requires two people). Contraction of hoof wounds is also minimal because of the inelasticity of the epithelial tissues and the fact that they are all attached to bone or rigid connective tissue. Thus, healing is the result of epithelialization and regeneration of connective tissue. All portions of corium can migrate and cover a healthy bed of granulation tissue. This process will be slow and may take 3 to 5 months.

Immobilization and protection of the wound are important considerations in the maintenance of the tissue environment achieved at surgery. A short limb cast that encases the hoof is usually the most effective method. The cast will not only immobilize the tissues and protect them from excess motion but will also serve as protection for the hoof from moisture and fecal contamination. On a long-term basis, a cast can be a much less expensive method of immobilization than daily bandage changes.

Ten to 14 days is the minimum duration suggested for cast immobilization. The cast should be maintained as long as necessary to provide a good initial healing (4 to 6 weeks if necessary). The cast needs to be monitored daily. If lameness, excessive heat, or odors develop, it should be removed.

After cast removal, bar shoes with clips can be effective in immobilizing the hoof. The glue-on shoe is also effective at immobilizing the hoof. This can also be used with less severe wounds of the foot when combined with aseptic dressings and water-impervious bandaging.

Antibiotics are indicated during the acute phase of wound healing and are indicated with traumatic wounds, when deep structures are involved, or when there has been severe tissue damage and loss. However, antibiotics should not be used in lieu of adequate surgical debridement, or without appropriate bacterial cultures and antibiotic sensitivity testing. Often the contamination in these cases involves multiple organisms, so the debrided deep tissues should be used for the culture.

Pain relief may be necessary postoperatively, particularly for 48 to 72 h. Nonsteroidal anti-inflammatory drugs (NSAIDs) are recommended to reduce inflammation and to minimize the effects of unequal weight bearing on the unaffected limbs. Pain relief may also be provided by soaking the hoof in warm or hot water. This aids the wound healing by reducing surface contamination and stimulating reflex hyperemia with increased blood flow. If a wound is immersed in water, the water must be clean to prevent contaminants from contacting the wound through the water bath. Wounds involving the joints, tendon sheaths, or bursae are not soaked until healing is adequate to prevent secondary contamination.

As healing progresses, the hoof should be trimmed to remove excess horn. The hoof should have excess wall removed, the sole should be pared of scales, and the horn surrounding the wound should be kept even with the wound until complete keratinization of the wound has occurred.

The horse should not be allowed free exercise until keratinization is complete. Follow-up examination at 2- to 4-week intervals is usually adequate. Once keratinization is complete, corrective shoeing, acrylic remodeling, or simply cessation of bandaging is in order. Corrective shoeing and/or acrylic remodeling are often necessary for complete soundness. This will have to continue until the hoof completely grows out. Usually this takes about 8 to 12 months.

Prognosis The prognosis for these injuries is generally good for soundness. However, a prognosis should be withheld until after adequate inspection of the wound has been made. The prognosis should be based on the duration of injury, the structures involved, the temperament of the horse, how adequately debridement can be achieved, and the structural integrity of the hoof after debridement

Sepsis within the hoof: subsolar abscess, laminar abscess, septic navicular bursitis

- Sepsis within the hoof is a primary differential diagnosis for non-weight-bearing lameness.
- Treatment must successfully approach, open, and drain the site of sepsis.
- Deep puncture wounds must be aggressively treated with parenteral and local antibiotics. Surgical debridement may be necessary.

Sepsis within the hoof capsule may be due to defects in the sole or hoof capsule, penetrating wounds. The treatment and prognosis for successful outcome depend on the location and duration of the abscess and response to initial therapy.

Recognition

History and presenting complaint Lameness of acute onset that becomes more pronounced over several days is the primary presenting complaint for horses with sepsis within the hoof. Sole abscessation occurs more frequently when the weather changes from dry to wet conditions. The sole and white line become softer and more prone to penetration of contaminants. Penetrating wounds may cause abscessation at any site within the hoof.

Of particular concern are nails or other foreign bodies that penetrate in the caudal one-third of the foot. Contaminants that penetrate the caudal portion of the foot are readily sealed in by the elastic frog and digital cushion. Close proximity of the navicular bursa, distal interphalangeal joint, and tendon sheath make deep abscesses in the site difficult to drain and treat, with a high risk for extension of infection into these synovial spaces.

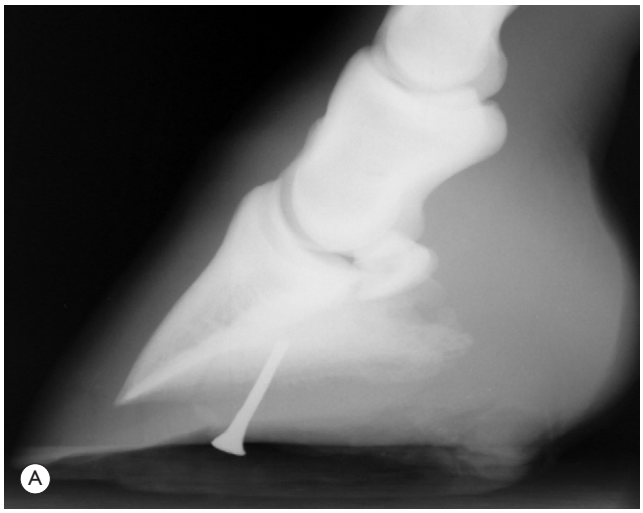
Physical examination Lameness will vary from mild (grade 2 of 5) to non-weight-bearing (grade 5 of 5). The horse will often point with the affected foot and that distal limb will usually have a pronounced digital pulse. Application of hoof testers to the affected sole usually results in a very painful response directly over the abscess site. Examination of the sole may reveal a tract, site of foreign body penetration, soft and painful spot overlying the abscess or any combination of the above. If a foreign body is found, it should be left in place, if possible, until radiographs can be taken of the foot.

Special examination Radiographs are warranted in nonresponsive cases of hoof sepsis to help identify sites of gas or fluid accumulation in the hoof or beneath the sole and to rule-out osteomyelitis or other causes of severe lameness of the distal limb. Imaging is not required for the great majority of feet suffering from routine sole abscessation.

If a foreign body is still within the foot, radiographs can be used to determine the depth of penetration and the most likely anatomical structures affected (Fig. 15.6). If a tract is suspected to be due to a foreign body that has been removed a contrast study of the foot will often provide similar information regarding location and depth of penetration.

If the foreign body penetrated the caudal one-third of the foot it is imperative to determine if synovial structures have been invaded. Arthrocentesis of the distal interphalangeal joint, navicular bursa and the distal aspect of the digital sheath may need to be done. Samples should be obtained for fluid analysis, cytology, and bacterial culture. These procedures are often accomplished most easily with the horse under general anesthesia.

Diagnostic confirmation The diagnosis is confirmed when the sole abscess is drained. Other differential diagnoses include deep penetrating wound to the foot, distal limb fracture, severe bruising of the sole, deep bruising of the sole that has become septic, laminar necrosis secondary to laminitis, keratoma, septic arthritis, and osteomyelitis.



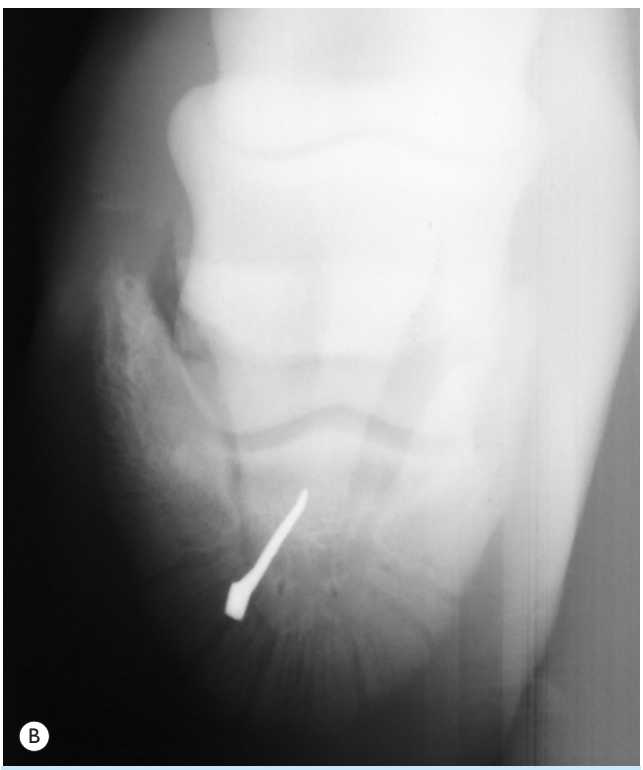


Fig. 15.6
Penetrating foreign body. (A) Lateral radiographic projection of the distal limb with a nail penetrating the sole. (B) The orthogonal view (D65Pr–PaDO) reveals that the nail has penetrated the sole overlying the distal phalanx. The position of this nail makes it unlikely that a synovial structure was penetrated.

Treatment and prognosis

Therapeutic aims Simple abscesses should be opened to allow drainage and access of antiseptic solutions. Parenteral antibiotics are not usually necessary for simple abscesses. Horses with deep penetrating wounds of the foot should be treated with broad-spectrum antibiotics, have lavage of the affected synovial spaces performed, and may require exploration and debridement of the wound tract.

Therapy The sole of the affected foot should be carefully pared to reveal clean, uniform sole. A combination of hoof tester and finger pressure may be use to localize the likely site of the abscess. If the horse is shod, the shoe must often be removed to afford evaluation of the sole margins and the white line – the most common sites for sole abscess. Tracts should be pared and followed in the painful region until the abscess is relieved or until on further paring the solar corium is revealed by a slight pink hue. A specialized hoof knife with a tightly curved tip, or a bone curette may be useful for following tracts through the sole. Most sole abscesses consist of a gray-colored, malodorous liquid that flows freely when the abscess cavity is breached during paring (Fig. 15.7). Excessive paring may result in hemorrhage from the solar corium. The size of the sole opening used to drain the abscess and permit local treatment is quite small. Excessively large defects used to drain an abscess require prolonged healing time and protection with a sole pad.

If the abscess cannot be drained on the initial visit, verify tetanus status and poultice or soak the foot. Poulticing and soaking are done to soften the foot and draw out the abscess.

Fig. 15.7
A sole abscess that has been successfully localized and opened for drainage. The characteristic gray color of the abscess material is evident.

Soaking is done by placing the foot in warm water with diluted povidone–iodine and a handful of Epsom's salts for 10 to 20 min once or twice daily. Other agents for poulticing the foot include Ichthammol and an ointment consisting of magnesium sulfate, methyl salycilate, and menthol (Magnapaste, The Butler Company, Columbus, OH). Another method of providing prolonged soaking of the foot is by using the bran mash poultice. Place a strong plastic bag that fits over the foot, add one handful of bran, a small handful of Epsom's salts. Add sufficient water to soak the bran and add povidone–iodine (approximately 1 part to 10 parts other constituents). Fit the bag with mixture over the foot and secure with gauze, elastic tape and duct tape. This poultice is changed every 24 h.

If the abscess was easily drained, apply a povidone–iodine-soaked gauze to the pared defect and protect the sole with a commercial protective boot or a bandage. Change the bandage daily for the first few days, then as needed to protect the foot. After the abscess is dry – as soon as 4–5 days or as long as 2 weeks – a shoe with a leather pad should be applied to protect the pared area. Systemic antibiotics are not administered in uncomplicated sole abscess cases. In all cases of hoof sepsis, tetanus status should be determined. If the horse has not been vaccinated within the previous 6-month period, reimmunization is indicated.

Deep sole abscesses that cannot be drained through the sole result in prolonged lameness and often break out at the coronary band of the hoof capsule or over the bulbs of the heels. If the abscess cannot be accessed from the sole or white line, radiographs may help localize the site. Radiographs will also determine if the distal phalanx has suffered osteomyelitis or osteitis due to the prolonged inflammation and infection. Rarely extensive, prolonged sole abscesses must be treated with localized, partial hoof or sole resection, and/or curettage of the distal phalanx.

More extensive treatment must be done in the case of a deep penetrating wound to the caudal one-third of the foot. At the first indication of a deep wound in this crucial location, the horse should be administered broad-spectrum parenteral antibiotics such as penicillin and gentamicin, or ceftiofur and gentamicin. Enhanced coverage for anaerobic organisms may be obtained by adding oral metronidazole to either protocol.

Because of the poor prognosis for horses that develop sepsis of the deep structures within the caudal aspect of the hoof, vigorous therapy is imperative. If the radiographic study confirms deep penetration in this critical zone the horse should be placed under general anesthesia to allow sampling and treating of the most at-risk structures: navicular bursa, distal interphalangeal joint, and the distal digital sheath.

If lameness is severe at presentation and a tract in the caudal foot is recognized surgical debridement is necessary ('street nail' procedure). This procedure requires cleansing and soaking of the foot in antiseptic solution, and progressive debridement of tissue along the foreign body tract. This usually requires cutting a 2-cm square hole through the frog and digital cushion. If the tract penetrates the deep digital flexor tendon, the debridement continues through the tendon to permit examination and debridement of the flexor surface of the navicular bone. Arthroscopic examination of the flexor surface of the navicular bone is feasible and may be appropriate (see Chapter 11).[11]

Following debridement, the foot must have sterile bandage changes to prevent contamination. This process is facilitated by applying a hospital plate shoe to the foot.

Prognosis Prognosis is usually excellent for return to complete soundness within 2 weeks for uncomplicated sole abscesses.

Deep penetrating wounds to the foot have a guarded to poor prognosis. Using the street nail procedure 32% of affected horses returned to soundness.[12] Using the arthroscopic approach 75% of treated horses returned to their intended use.[11]

Laminitis

- Bounding digital pulses, marked lameness, and postural efforts to shift weight from the affected feet characterize the signs of laminitis.
- Inciting causes include metabolic derangements, severe illness, and excessive weight bearing.
- Treatment must remove the inciting cause, reduce inflammation, maintain blood flow, and prevent distal phalanx displacement.
- Trimming using radiographic control is necessary to return the hoof to function.
- Overall prognosis for soundness in most cases is favorable.

Laminitis is defined as inflammation of the pedal laminae, which provide the support between the hoof wall and distal phalanx. Numerous causes of the disease have been defined but the leading cause remains gastrointestinal disturbances. Although the condition primarily affects the foot, the disease is actually a systemic disease, which causes disturbances in most body systems. The disease can be arbitrarily divided into four phases: developmental, acute, chronic, and postchronic.

Recognition

History and presenting complaint Horses presented with clinical signs of laminitis are always in the acute, chronic or postchronic phases of the disorder. Signs of acute laminitis include: 'bounding' digital pulses, warm feet, and 'camped in front' stance. This characteristic stance is an effort by the horse to shift weight bearing to the (usually) unaffected rear limbs. The severity of lameness relates to the severity of damage to the laminae. Pain and inflammation from ischemia to the secondary laminae is the direct cause of acute pain in laminitis. Horses with chronic laminitis are presented for misshapen hooves, seedy toe, chronic, recurring hoof abscessation, and chronic lameness.

The practitioner must be aware of potential inciting causes of laminitis. When a horse is exposed to a situation that may cause laminitis preventive measures must be taken to minimize the adverse effects. The period of time between exposure to a situation that may cause laminitis and the onset of clinical signs is called the developmental or subclinical phase. Factors that may induce laminitis should be identified in the history and include:

grain overload, colic, illness associated with endotoxemia, retained placenta, exhaustion and metabolic derangements, exposure to black walnut shavings, excessive ingestion of lush pasture grasses (grass founder), excessive concussion (road founder), Cushing's syndrome, excessive weight bearing on a limb, and excessive ingestion of cold water.[13–17]

Physical examination Horses with acute laminitis generally show varying levels of foot pain, often characterized by treading in place or a shifting limb lameness.[13,14] When severe pain is present in the forelimbs a characteristic 'walking-on-egg shells' gait is evident as the horse shifts weight to the rear limbs. Most commonly, both forelimbs are affected. All limbs may be affected in extraordinary cases. Unilateral limb involvement is usually found in the contralateral limb of horses that have non-weight-bearing lameness due to fracture or infection.[16] Digital pulses are generally increased and may be bounding in severe laminitis. Hoof tester sensitivity at the toe near the apex of the frog is usually marked. When rotation or distal displacement of the distal phalanx has occurred the sole will lose its normal concavity and a depression may be palpated at the coronary band. Imminent exposure of the distal phalanx or separation of the hoof capsule from the foot may be first recognized with serum weeping from the sole or coronary band, respectively.

Horses with chronic laminitis may have remodeling of the tip and dorsal border of the distal phalanx, solar margin fractures, and distal phalanx rotation evident on radiographic examination. Inadequate trimming may leave a dished hoof with long toes and severely underrun heels. Chronic abscessation of the hoof and coronary band associated with a wide and weakened white line is also commonly found in chronic laminitis cases.

The Obel grade classifications record the severity of gait abnormalities in horses with laminitis:[18]

- Obel grade 1: the horse exhibits constant shifting of its weight from leg to leg. The horse's gait is stiff and stilted at the trot but not the walk.
- Obel grade 2: lameness is characterized by a stiff and stilted gait at the walk and trot. The horse is reluctant to rest full weight on a leg but a leg can still be lifted off the ground readily.
- Obel grade 3: has the horse reluctant to move. Lifting a limb off the ground is very difficult. Permanent morphologic change occurs within 12 h of the onset of Obel grade 3 lameness.
- Obel grade 4: is so severe that the horse refuses to move unless forced and spends most its time recumbent.

Diagnostic confirmation Diagnosis is based on physical signs and radiographic examination. The dorsal hoof wall and dorsal distal phalanx in the normal horse should be parallel and the space should measure < 19 mm or < 30% of the length of the distal phalanx measured from its tip to its articular surface at the navicular bone (Fig. 15.8).[19] Rotation is the most common displacement and is caused by disruption of dorsal laminar attachments and the pull of the deep digital flexor tendon (DDFT). Radiographic evaluation of distal phalanx displacement may help determine a prognosis. Prognosis is good for horses with rotation < 5.5°, but poor for rotation > 11.5°.[20] Horses with distal displacement ('sinking') have a poor prognosis. Another study contradicted the aforementioned report and found no correlation between radiographically measured distal phalanx displacement and prognosis for resolution of laminitis.[14]

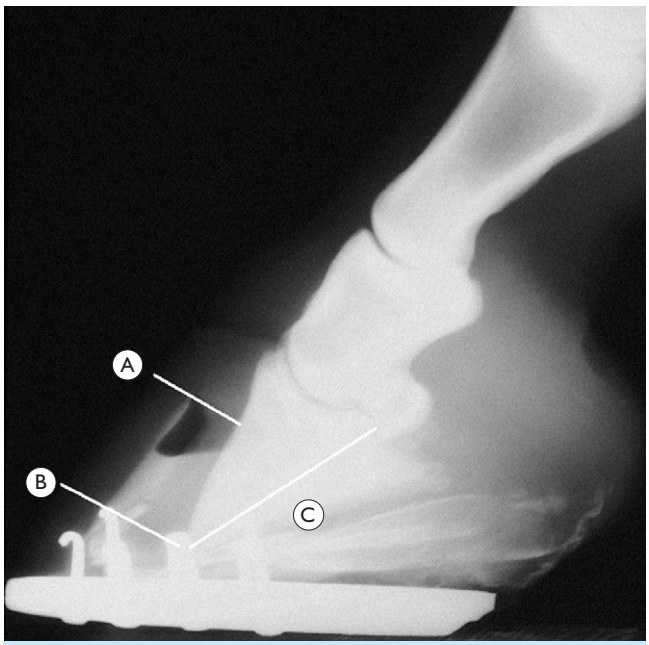

Fig. 15.8
Radiographic measurement of distal phalanx displacement. This lateral radiographic projection of the distal phalanx has been marked to demonstrate two methods for measuring distal phalanx displacement. Measured distances: A, 24 mm; B, 30 mm; C, 54 mm. Normally, A and B should measure less than or equal to 19 mm and be equal values, indicative of parallelism of the dorsal distal phalanx with the dorsal hoof capsule. A and B should also be less than 30% of the measurement taken from the tip of the distal phalanx to the articulation with navicular bone (C). In this case C/A = 44% and C/B = 55%. These values are indicative of severe distal phalanx displacement. A gas and fluid pocket indicative of lamellar necrosis is also found in the dorsal laminae.

Venograms of the distal limb have been advocated to help determine prognosis.[21] The prognosis for successful treatment is enhanced when the vasculature of the coronary corium and dorsal laminae are visible during venography.

Differential diagnoses include deep abscess, distal phalanx or navicular bone fracture, septic tenosynovitis, or deep bruising. Most of these conditions commonly occur in a single limb, but laminitis most commonly occurs bilaterally except when caused by excessive weight bearing.

Treatment and prognosis

Therapeutic aims The treatment objectives for laminitis include eliminating the inciting cause, decreasing inflammation, maintaining or re-establishing blood flow to the laminae, and preventing displacement of the distal phalanx.

Treatment during the developmental phase is done to prevent the onset of clinically apparent laminitis or to reduce the potential adverse effects of exposure to inciting causes of

laminitis. Under all circumstances the first aim of therapy is to treat and remove any potential inciting cause of laminitis.

The aims of treatment during the chronic phases of laminitis include stabilizing the distal phalanx to reduce further displacement and providing an environment where the distal phalanx, laminae and hoof capsule may re-establish a firm, stable bond. When all other significant hoof issues have been resolved, gradually returning distal phalanx to normal orientation with the ground surface is the ultimate goal.

Therapy Treatment during the developmental and acute phases of laminitis includes elimination of the inciting cause, increasing the blood flow to the laminae, antithrombotic therapy, and distal phalanx support. In the developmental phase, successful treatment should prevent the laminar damage that results in distal phalanx displacement and the untoward sequellae, while treatment in the acute phase should reduce the adverse effects and extent of the damage.

In horses that have been exposed to the inciting causes of laminitis it is prudent to exclude all grains and concentrates from the diet until the outcome is evident. Cathartics are administered in grain or pasture overload. Mineral oil or water with Epsom's salts (up to 1 kg per 4 L water) may be administered via nasogastric intubation. Gastric lavage may be performed within 2 to 6 h of overeating. Intravenous fluid and electrolyte therapy should be instituted in exhausted horses. Fractures and severe lameness should be treated to permit weight bearing in the affected limb as soon as possible.

If a severe illness, abdominal surgery, or other condition that may cause endotoxin release is present the horse should be administered hyperimmune serum and flunixin meglumine at the anti-endotoxic dose (2.5 mg/kg i.v., q 6 h).[22]

NSAIDs such as phenylbutazone (4.4–8.8 mg/kg/day), flunixin meglumine (1 mg/kg/day) or ketoprofen (2.2 mg/kg/day) should be administered in all cases of laminitis. Phenylbutazone is most commonly used, yet ketoprofen may have a slightly better effect in select cases. NSAIDs reduce prostaglandin and thromboxane production through inhibition of cyclo-oxygenase, decreasing inflammation associated with ischemia and thereby decreasing pain and promoting blood flow through small peripheral vessels by inhibiting platelet aggregation and thrombosis.

Dimethyl sulfoxide (DMSO) may be used to prevent reperfusion injury of the laminae. It acts as a free-radical scavenger and non-specific anti-inflammatory agent.[23] DMSO is administered at 0.25–1.0 g/kg i.v. in saline or 5% dextrose solution at a concentration less than 20%. In acute laminitis treatment with DMSO is usually continued for 3 days.

Blood flow to the laminae may be enhanced with peripheral vasodilators.[24] Acepromazine maleate is an α-adrenergic antagonist and is administered at 0.03–0.06 mg/kg i.m. either q 6 h or q 8 h for 3 to 5 days, or until the horse improves. This drug is readily available in all practices and should be used at the first indication of laminitis. Isoxsuprine HCl is a β- and α-adrenergic antagonist that is administered at 1.2 mg/kg p.o. q 12 h for indefinite periods. There is some controversy regarding systemic availability of this drug via the oral route and treatment effects should not be expected for days or weeks.[25]

Small vessel blood flow may also be enhanced by administering antithrombotic or anticoagulant medications. Aspirin is very effective at inhibiting platelet aggregation and may be administered at 10–20 mg/kg p.o. every other day.[14] Heparin may be administered at a dosage of 40–80 units/kg SQ q 12 h.[26]

The distal phalanx must be supported in the developmental phase to prevent displacement and in the acute phase to also prevent or limit distal phalanx displacement. Initially simple gauze rolls taped over the frogs may be helpful. Lily Pads® (Kentucky Blacksmith Supply, KY), fitted over the heel bulbs and frogs and secured with tape, may be a longer-term solution. Full sole support may be custom fitted using Scotchcast Custom Support Foam fiberglass cast padding tape (3M Orthopedic Products, St Paul, MN), dental impression material, or common foam building insulation. These pads can be frequently reset to provide the most comfort in cases with rapidly changing sole contours. Deep sand footing is a simple method to maintain good sole contact and soft bedding.

Excessive tension of the DDFT is one of the factors responsible for distal phalanx rotation and can be reduced through several methods. Special horse shoes have been developed to help reduce DDFT tension and to support the foot. The Ultimate Wedge shoe (Kentucky Blacksmith Supply, KY) raises the heel 20°, significantly reducing DDFT stress.[27] The Ovnicek shoe (Equine Digital Support System, Columbia Falls, MT) has several components that results in custom foot support and can be configured with a high heel wedge and styrofoam-like sole padding.

A surgical alternative for reducing DDFT tension also exists. Tenotomy of the DDFT at midcannon bone or at the level of the heel bulbs has been used as a salvage method for nonresponsive cases of laminitis with severe rotation and in some cases for treatment of peracute distal phalanx displacement.[28] Tenotomy at the midcannon level is a practical technique that may be performed under local anesthesia through a small stab incision. The limb is bandaged and the foot is supported with sole pads. An extended heel shoe or a shoe with a marked wedge pad is necessary to prevent subluxation of the distal interphalangeal joint. Response to tenotomy has been variable. In the successful case, the DDFT eventually heals, but scarring and adhesions may limit athletic use of the horse.

Chronic laminitis presents a variety of treatment challenges. Displacement of the distal phalanx usually occurs by rotation in the sagittal plane but may also involve complete distal phalanx displacement ('sinking'). The damaged lamellae also predispose the hoof to abscessation at both the sole and the coronary band (Fig. 15.9). The displaced distal phalanx is predisposed to solar margin fractures, especially near the toe. In the most serious cases, complete slough of the hoof may occur or the distal phalanx may penetrate the sole. Management of these conditions requires long-term treatment with NSAIDs and repeated shoeing and trimming. Follow-up treatment should always involve the veterinarian, farrier, and horse owner. Decisions regarding continued support of the sole, easing of breakover, and correct trimming of heel and toe should be made using radiographs of the affected feet taken at intervals during recuperation.

Fig. 15.9
Arrowheads identify dark tracts at the sole margin and the white line. This hoof has suffered from chronic laminitis. These tracts must be pared out at each trimming.

In most cases of mild laminitis, gradual reshaping of the hoof capsule must be performed over several months to return the distal phalanx to the proper relationship with the ground surface and the hoof. This generally requires removing excess heel and excess toe. Trimming should result in gradual changes only and should be controlled by measurements and relationships made from lateral radiographs of the distal phalanx (Fig. 15.10). In some cases more radical trimming changes may be indicated. The four-point trimming protocol as described by Ovnicek may help reduce DDFT tendon strain and the strain on the distal limb during breakover. By providing more surface area of contact with the ground surface the method may also reduce overall foot pain.

Prognosis Most mild cases of laminitis respond to treatment in several days to weeks. Those that linger, have marked displacement of the distal phalanx, display increasing levels of severe pain or suddenly 'walk out of their feet' may be candidates for euthanasia. The owner's strong desire for resolution of this devastating condition 'at all costs' because the horse is a 'best friend' must not override rational analysis of the horse's condition and humane aspects of continuing treatment. In most cases the horse should be euthanized when pain is unmanageable and the horse shows signs of anorexia, cachexia, or severe decubital ulcers. Most cases with distal phalanx penetration of the sole, sloughing of the hoof capsule, and recurrent deep abscessation of the sole or laminae should be euthanized. There are always exceptions,

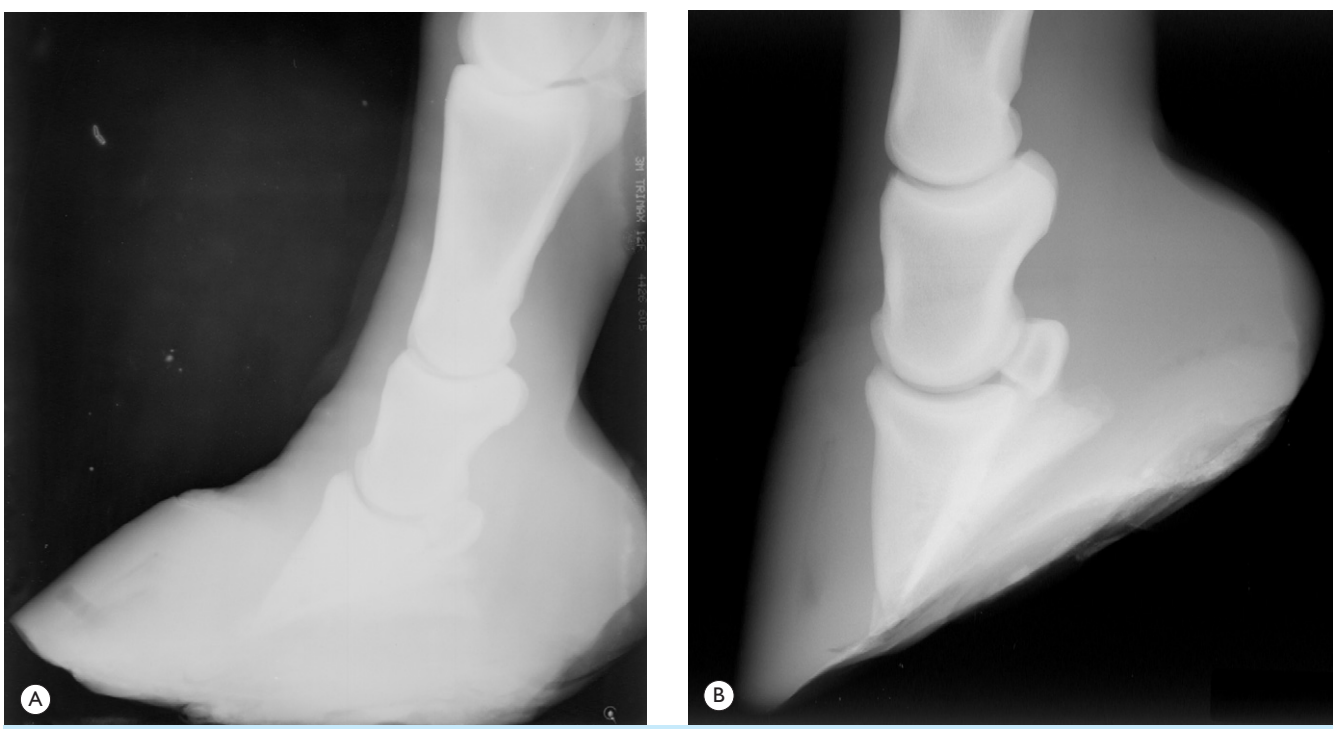

Fig. 15.10
Radiographs as an aid for trimming of chronic laminitis. (A) Lateral radiographic view of a hoof with chronic laminitis characterized by rotational distal phalanx displacement and dishing of the dorsal hoof capsule. Using this film, the farrier was able to determine the position of the distal phalanx and trim the hoof appropriately. (B) Lateral radiographic view of the foot after trimming. Following evaluation of this film even more toe was trimmed away.

and quality of life for the horse should be a primary, although at times arbitrary and qualitative, concern.

Prognosis for resolution of laminitis is usually fair to good for horses with minimal distal phalanx displacement. Prognosis is good for horses with rotation < 5.5°, but poor for rotation > 11.5°.[20] Horses with marked displacement nearly always suffer more chronic hoof problems that may limit soundness. Horses with sinking displacement have a poor prognosis for survival, as do horses that slough the entire hoof or have penetration of the sole by the distal phalanx.

Prognostic indicators for laminitis were reported in a study from the UK.[29] Of 216 horses with laminitis: 162 (77%) became sound as athletes, 7 (3%) did not become completely sound, but survived and 42 (20%) horses were euthanized or died due to laminitis. The remaining five horses were euthanized and not treated. The most significant prognostic indicator was quantification of distal phalanx displacement from radiographs. Less significant prognostic indicators were the severity of lameness, distal phalanx rotation angles, the presence of dropped sole, and the number of feet affected.[29]

Etiology and pathophysiology

Etiology The following conditions are associated with laminitis: excessive grain or lush pasture ingestion; endotoxemia associated with infectious diseases such as diarrhea, septicemia, or retained placenta; excessive metabolic stress associated with dehydration or overexertion; excessive weight bearing on a limb opposite one with a fracture or severe lameness; and management factors such as bedding with black walnut shavings, excessive obesity, and underconditioned horses worked excessively.

Pathophysiology There is general agreement that laminitis is associated with circulatory disturbances at the level of the lamellae, but the specific nature of the changes continues to be under investigation.[13,14,24,30–34] Current research suggests that there is a period of lamellar vasodilatation during the developmental phase of laminitis.[24,30,31] In experimental laminitis vasodilatation within the hoof was found from 12 to 32 h after carbohydrate overload.[30] The increased local blood flow may result in exposure of the lamellae to enzymes such as metalloproteinase-2 and metalloproteinase-9 (MMP-2 and MMP-9).[32] These enzymes are normally required to temporarily break the lamellar attachments as the keratinized hoof capsule grows and 'slides' along the dermal lamellae. In the normal hoof inhibitor enzymes are present to control MMP activity, whereas the laminitic hoof lacks these inhibitors. Vasodilatation of the vessels in the lamellae carries the activated MMP enzymes to their site of action, the cytokines and free radicals associated with reperfusion then act on the lamellae and cause their destruction. Hoof tissues from experimental horses with acute and chronic carbohydrate-induced laminitis have high expression of endothelin-1 (ET-1).[34] The presence of ET-1 causes marked vasoconstriction, which leads to ischemia of the lamellar tissues. This potential cycle of vasodilatation, followed by vasoconstriction and the attendant breakdown of lamellar attachments, necrosis, and inflammation constitutes the vicious cycle that leads to pain, distal phalanx displacement, and the other physical signs of laminitis.

Prevention

Minimizing changes in diet, particularly changes in the amount of grain fed and controlling access to lush, new pasture grasses, will decrease the incidence of laminitis. Recognize that horses that have had a previous bout of laminitis are predisposed to having the problem again. When inciting causes of laminitis are present preventive treatment should be instituted.

Diseases of the distal phalanx

Distal phalanx fractures

Distal phalangeal fractures can be classified into one of seven types (Fig. 15.11).[35–37] Type I is a non-articular fracture of the wing of the third phalanx. Type II fractures are articular wing fractures (Fig. 15.12). Type III fractures are sagittal and divide the bone nearly into equal halves. Type IV fractures comprise all extensor process fractures (Fig. 15.12). Comminuted and irregular distal phalanx fractures are type V. Fractures of the solar margin are type VI. Palmar process fractures are considered type VII (Fig. 15.13).[36]

Recognition

History and presenting complaint Acute onset of grade 3–5 of 5 lameness is the primary presenting complaint for frac-

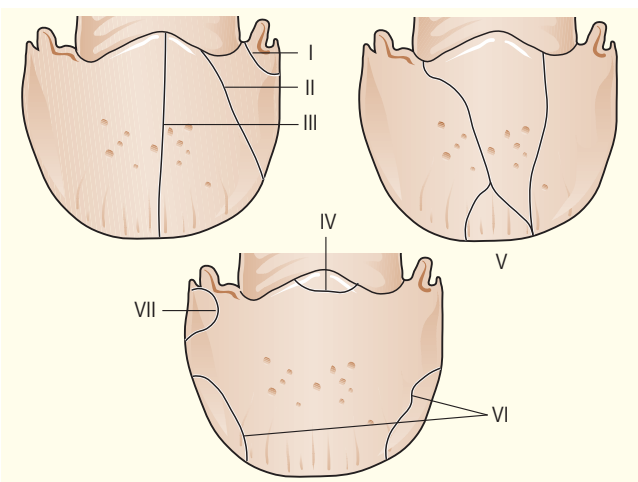

Fig. 15.11
Diagrammatic representation of distal phalanx fractures. Type I: non-articular fracture of the wing; type II: non-sagittal fracture that enters the distal interphalangeal joint; type III: midsagittal, articular fracture from the extensor process to the solar margin; type IV: extensor process fracture; type V: comminuted or irregular fractures; type VI: fractures of the solar margin; type VII: non-articular fractures of the palmar process.

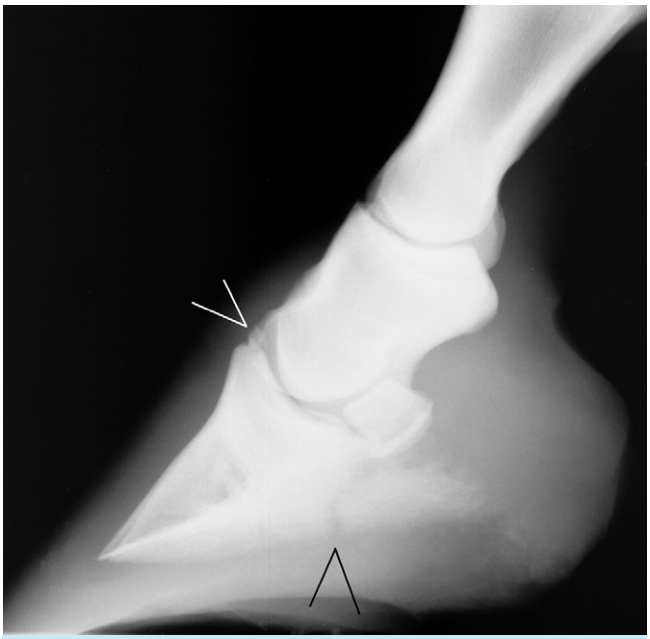

Fig. 15.12
Lateromedial radiographic view of the distal phalanx. Type II (black arrowhead) and type IV (white arrowhead) distal phalanx fractures are evident.

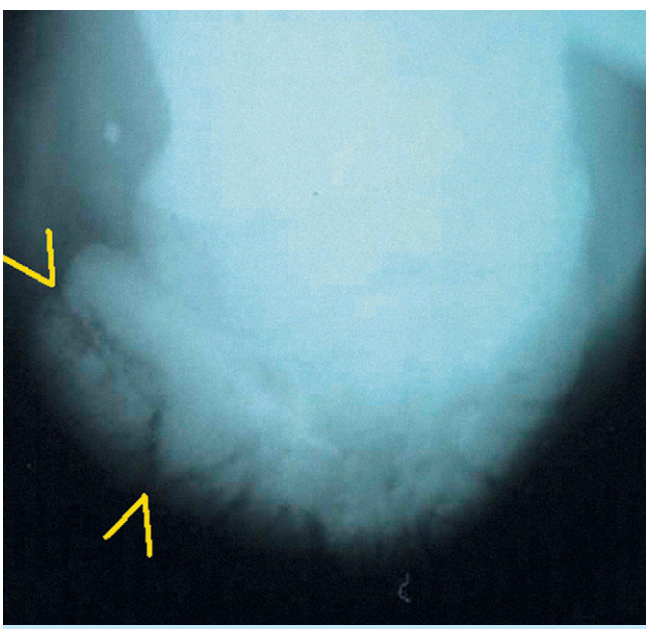

Fig. 15.13

tures of the distal phalanx. Often the inciting event is not seen but kicking in the stall or a miss-step followed by acute lameness may be reported. Young foals with distal phalanx palmar process fractures may be presented for evaluation of club-footed conformation that is accompanied by mild, short-term lameness.[38–40]

Physical examination Lameness is usually accompanied by an increased digital pulse. Extensor process fractures are often accompanied by swelling over the coronary band. Hoof tester examination usually reveals marked pain over the entire hoof but especially over the fracture. Hoof percussion reveals sensitivity around the entire hoof but especially over the fracture. These two techniques can usually aid the practitioner in lining up for radiography in order to center the X-ray beam on the fracture.

Diagnostic confirmation Radiographs are necessary to confirm the diagnosis. Usually at least four to five views should be made in order to examine the entire bone from several angles. The fracture may not be visible until lysis occurs along the fracture line, often for 10–14 days.[35] Nuclear scintigraphy and computed tomography are additional imaging methods to help recognize distal phalanx fractures.

Treatment and prognosis

Therapeutic aims Sufficient stability and reduced activity must be provided for the affected foot to permit healing of the fracture.

Therapy Fracture types I, II, III, and V are treated by therapeutic shoeing. A full bar shoe with quarter clips, full rim shoe, or certain glue-on shoes will immobilize the hoof capsule and effectively turn the hoof into a cast. Foals with any type of distal phalanx fracture should not be treated with a restrictive shoe because of the secondary complications that accompany hoof contracture. Foals under 1 year of age with these fractures usually respond favorably to stall or paddock confinement alone.[39,40]

Fracture types II, III, and IV may be repaired with lag screw fixation. This can be difficult because the fracture line cannot be visualized during surgery, therefore radiographic control during surgery is essential for a successful outcome. Also, the bone in the wings of the distal phalanx is porous and does not hold screws well.

Type IV fractures are best treated by surgical intervention. Small fragments are easily removed via arthroscopy. Larger fragments should be stabilized using lag screw fixation but can be removed completely via an arthrotomy. Neurectomy of the palmar digital nerve may be necessary to resolve chronic low-grade pain. Neurectomy is most effective for wing fractures but may reduce pain in all the fractures. It should not be performed if a palmar digital nerve block fails to substantially improve the lameness.

Prognosis The prognosis for soundness of fracture types I and II is fair to good.[35] Fracture types III and IV have a guarded to fair prognosis due to the likelihood of distal interphalangeal arthritis. The prognosis for type V fractures due to trauma is good, yet prognosis for this type of fracture secondary to osteomyelitis is guarded. Type VI fractures have an excellent prognosis. In adults complete healing of distal phalanx fractures may require 9 to 12 months. All fractures in foals less than 1 year of age have a very good to excellent prognosis for soundness.[39,40]

Etiology and pathophysiology

Etiology These fractures are usually caused by trauma. Pathological fractures of the distal phalanx may occur secondary to osteomyelitis. Improper shoeing, hard surfaces, stone bruises, infectious conditions, and nutritional deficiencies are all considered to be contributing factors.

Diseases of the podotrochlea

Navicular bone fractures

Navicular bone fractures are uncommon and can be classified into one of four types. These are simple sagittal fractures, comminuted fractures, avulsion fracture of the navicular suspensory ligament, and avulsion fractures of the impar ligament.

Recognition

History and presenting complaint History, presenting complaint and physical signs for avulsion fractures of the navicular bone are the same as for other causes of palmar foot pain (see below). Complete navicular fractures will present with acute onset of severe lameness that may decrease somewhat over time.[41]

Physical examination These fractures have pain referable to the navicular bone. They are usually acute and exhibit a grade III–V of V lameness. In most cases the horse is unwilling to place the heel of the affected foot on the ground. Marked pain over the navicular area is noted with hoof testers. Distal limb flexion markedly exacerbates the lameness.

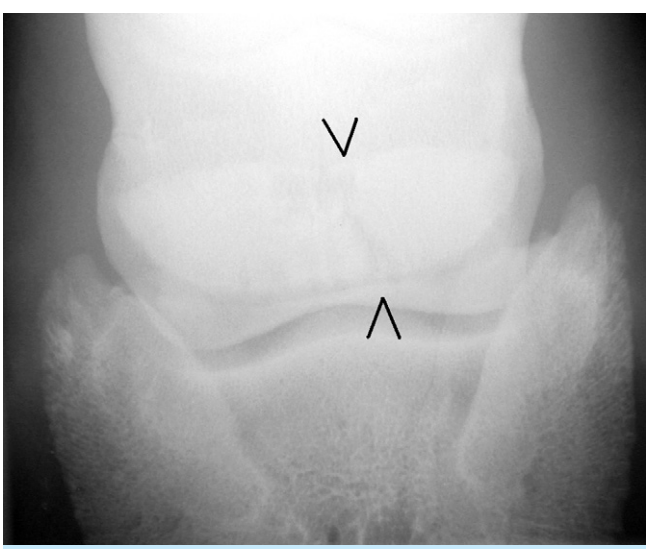

Fig. 15.14
Navicular bone fracture. The lucent line between the arrowheads is the fracture line.

Diagnostic confirmation Conformation of navicular fracture is made by localizing the foot pain to the heel region and radiographic evidence of fracture (Fig. 15.14). Recognize that occasionally the navicular bone will develop with two (bipartite) or three (tripartite) ossification centers. If these centers do not bridge with mineralized bone, the navicular bone may appear to be fractured. Localization of pain to the heel region using diagnostic local anesthesia should rule-out separate ossification centers.

Treatment and prognosis

Therapeutic aims Conventional therapy for navicular fractures is similar to that used for distal phalanx fractures. An alternative technique reduces DDFT and heel strain and is followed by a gradual exercise program to limit adhesions.

Therapy Navicular bone fractures are treated conservatively. Surgical exposure of the site and internal fixation of the fracture is exceedingly difficult. Therapy traditionally entails variable periods of rest with corrective trimming and shoeing to immobilize the hoof. Palmar digital neurectomy often is required after the fracture heals to increase soundness. However, the results of this type of therapy have been poor. The poor results are thought to be due in part to adhesion formation between the navicular bone and the deep flexor tendon.

An alternative technique may be used that reduces heel strain and returns the horse to controlled exercise sooner than conventional therapy.[42] Following the diagnosis of a navicular bone fracture, the affected hoof should be trimmed to its normal hoof pastern axis. The hoof is then shod with a flat shoe and four 3° wedge pads so as to elevate the heels 12°. The objective is to prevent the navicular bone from having weight-bearing contact with the second phalanx and to decrease the strain on the deep flexor tendon. Proper elevation of the hoof can be confirmed through the use of a lateral radiograph.

The horse should be stall rested for the first 60 days, then short periods of handwalking (15 min daily) can begin. The shoe is reset every 4 weeks. At each reset the hoof is trimmed and the horse is reshod with 3° less elevation. At the end of 4 months, when the horse is shod normally, an assessment of the degree of soundness is made. Podotrochlear bursography can be utilized at the end of the 4-month period to assess the degree of adhesion formation. Four cases have been treated utilizing this method. Three horses had simple sagittal fractures of the navicular bone involving the forelimb and one had a comminuted fracture of a rear limb navicular bone. Upon initial presentation these horses were grade 3–5 of 5 lame. Typically, the fracture was noted radiographically as a clearly demarcated fracture with well-defined margins. The fracture line became less well defined within 30 days. This was presumably due to bone resorption. Mineralization around the fracture in each of these cases occurred but complete radiographic healing of the fracture did not occur in any case. However, the horse's lameness resolved after the 4-month treatment period. Two horses returned to competition, one as a gaited horse and the other is a multipurpose Arabian show horse. The other two horses are not lame and are being ridden.[42]

Complete navicular bone fractures often heal with a fibrous, rather than an osseous, union.[41] Avulsion fractures of the proximal or distal border of the navicular bone usually respond to treatment for palmar foot pain.

Prognosis The prognosis for navicular fracture caused by trauma is guarded prognosis due to likelihood of secondary arthritis. Pathologic fractures due to infection have a grave prognosis.

Etiology and pathophysiology

Etiology The etiology of navicular fractures is always traumatic but can be predisposed by either infection or chronic demineralization from navicular disease. Repetitive trauma that predisposes the foot to palmar heel pain may lead to avulsion fractures of the proximal or distal border of the navicular bone. The navicular bone may have more than one center of ossification, resulting in either a bipartite or tripartite bone.

Palmar foot pain

- Manipulative tests and diagnostic anesthesia often do not specifically identify the site of palmar heel pain.
- Shoeing goals for palmar heel pain: correcting hoof imbalance, easing breakover, and providing concussion protection.
- There are more than 15 specific causes of palmar heel pain.
- Prognosis improves with diagnosis and treatment within 1 year of onset.

Lamenesses in this region account for more than one-third of all chronic lameness in the horse.[2] It must be understood that a palmar digital nerve block simply localizes the source of the pain the horse senses to the back of the foot. It is important to identify as specifically as one can the pathological and clinical findings. This in turn will help the clinician make their best assessment of the problem, and recommend the most specific treatment.

Recognition

History and presenting complaint Horses are presented for mild to moderate unilateral or bilateral forelimb lameness that is usually exacerbated in a circle. Quarter Horses, Thoroughbreds, Warmbloods, other Western stock-type horses and other breeds that compete over fences are predisposed to palmar heel pain. Subtle heel pain may be presented as a horse that no longer extends the forelimbs during the trot, resulting in a short, choppy or shuffling gait. Affected horses may stumble due to their preference to land toe first.

Physical examination The examination should closely follow the guidelines presented earlier in this chapter. No diagnostic test is pathognomonic for navicular or palmar foot pain.[43] Distal limb flexion has been suggested by Turner to be of importance in the differentiation of navicular disease. In that study, 87.5% of the horses responded to this test.[43] When grouped according to diagnostic analgesia response, the navicular region pain (NRP) group that blocked to a palmar digital, distal interphalangeal and podotrochlear bursa analgesic injection was positive to distal limb flexion in 88% of the cases. The palmar foot pain (PFP) group that did not respond equally to the three injections were positive to distal limb flexion in 87% of horses. This indicates that the test is good for exacerbating pain in the palmar hoof but does not help in specific differentiation of the cause.

The frog wedge test is thought to exert pressure directly on the navicular bone similar to hoof testers but is thought to be more accurate because the horse's weight exerts the pressure rather than man-made pressure. The study found that 75% of the horses responded to this test.[43] But 76% were from the NRP group and 74% from PFP group again indicating no difference.

The toe wedge test was positive in 56%. This is higher than that reported by Wright.[44] However, the test was of no help in differentiating the source of pain; 55% were positive in the NRP group and 58% were positive in the PFP group.

Hoof tester examination over the frog is considered by some clinicians as the definitive test for navicular pain. However, hoof tester examination was found not only to be less sensitive than other manipulative tests for navicular pain but that other types of palmar foot pain were more likely to respond to the hoof tester examination over the frog than horses with navicular pain.[43,44]

The first step in the treatment of palmar hoof pain is accurate assessment of the pain and careful evaluation of hoof structure that may predispose to or cause the pain. The examination of the foot has been previously described in this chapter.

Typically, all causes of lameness in the palmar foot will be improved by at least 90% after perineural anesthesia of the palmar digital nerves. Anesthesia of the distal interphalangeal (DIP) joint or the podotrochlear bursa are additional procedures that provide information about palmar hoof pain. In a study reported by Dyson and Kidd[45] 95% of the horses examined using DIP and bursa anesthesia gave significant new information about the pain the horse exhibited. The pain relief by anesthesia of any of these three regions has been shown to overlap. Further, recent identification of neuroreceptors for the navicular bone and podotrochlear region have indicated how these other diagnostic techniques may help differentiate these clinical conditions. The DIP joint and podotrochlear bursa do not communicate, and yet the response to local anesthesia injected into these synovial cavities is similar.[46] Both cavities have in common the navicular bone, the impar ligament, and the collateral sesamoidean ligament (proximal suspensory ligament of the navicular bone). The neuroreceptors for the navicular bone are in these two ligaments and they can be anesthetized from either synovial cavity.[47] Furthermore, Bowker et al. have shown that the palmar digital nerve is in very close proximity to the medial and lateral limits of the bursa and that the nerve may be anesthetized at this level whenever the bursa is injected.[48]

Special examination Podotrochlear (navicular) bursa contrast arthrography is a new method of assessing navicular pathology.[8] This technique allows evaluation of the cartilage of the flexor surface of the navicular bone. In several

cases we have been able to conclusively prove the presence of adhesions between the navicular bone and bursa.

Use of the podotrochlear bursa contrast study has provided new information regarding the flexor cartilage, the presence of adhesions between the deep flexor tendon and navicular bone, and possible tendon damage. Adhesions between the deep flexor tendon and navicular bone were seen as space-occupying lesions in the dye column across the flexor surface of the bone. In each of the cases in which this was noted the horse had navicular pain. Tendon damage was noted when the dye filled small defects in the tendon. This finding was found only in that group of horses with palmar foot pain. Flexor cartilage damage was evident by the loss of cartilage on the flexor surface. This finding was noted equally in horses with navicular pain and the group with other causes of palmar foot pain. This suggests that flexor cartilage erosion is probably of little consequence, or at least highly variable in causing navicular bone pain.

Diagnostic confirmation Radiographic examination is the imaging method most often used to assess osseous changes in the distal sesamoid bone. These changes with the exception of fractures are usually not pathognomonic but do provide insight into damage that has occurred to the foot (see Chapter 10).

Scintigraphy provides information on relative vascularity and rate of tissue metabolism. This is particularly useful in studying bone pathology and can help differentiate sites of injury in the foot. High-detail scintigraphy of the foot obtained using a skyline view can localize inflammation specifically to the navicular bone or to other structures in the palmar heel region.

Thermography has been shown to be useful in assessing the relative blood flow to regions within the foot.[10] This information is of particular interest when pre- and postexercise temperatures are determined. Exercise will normally cause a 0.5°C rise in skin temperature. Whenever the skin temperature does not rise, poor blood flow should be considered a factor in the disease being assessed.

It is clear that the diagnosis of navicular disease and palmar heel pain is facilitated by noting the response to diagnostic anesthesia. However, as discussed earlier in this chapter, none of the diagnostic anesthesia procedures employed results in specific desensitization of a single anatomic site. The diagnostician must use physical findings, response to diagnostic anesthesia, and imaging to determine the specific diagnosis.

Treatment and prognosis

Therapeutic aims Palmar heel pain is treated primarily by correcting hoof balance abnormalities, easing breakover and providing more concussion protection to the foot. Anti-inflammatory medications and peripheral vasodilating agents can also be utilized, but often play a secondary roll to corrective shoeing in the treatment of this type of lameness.

Therapy Treatment must be tailored specifically to the hoof characteristics and use of the horse. Corrective shoeing, anti-inflammatory medication, and peripheral vasodilating agents are all part of treatment protocols for palmar foot pain.

The most successful approach to shoeing is that based on individual case needs rather than a standard formula. The following principles should be followed:

1. Correct any pre-existing problems of the hoof, such as underrun heels, contracted heels, sheared heels, mismatched hoof angles, broken hoof/pastern axis.
2. Use all weight-bearing structures of the foot.
3. Allow for hoof expansion.
4. Decrease the work of moving the foot.

Shoeing is most effective when correction is made within the first 10 months of lameness, up to 96% success. This is in contrast to when shoeing changes are not made until after 1 year of lameness, where only 56% of the cases have been treated successfully.[49] The importance of a balanced foot in the treatment of equine lameness is well recognized. However, the assessment and choice of options for correction of an imbalanced foot can be quite subjective. Balance is defined as the harmonious adjustment of parts. For the hoof, balance has been defined as the equal distribution of weight, over the foot. This must be more precisely defined as equal medial to lateral distribution of weight, because more weight is normally placed on the caudal half of the foot. Caudal to cranial imbalance has been defined as deviation in the hoof alignment or as problems with heel support.

Six hoof balance abnormalities have been described: broken hoof axis, underrun heels, contracted heels, shear heels, mismatched hoof angles, and small feet. A broken hoof axis exists when the slopes of the pastern and hoof are not the same. This condition is further defined as broken-back, when the hoof angle is lower than the pastern angle, and as broken-forward when the hoof angle is steeper than the pastern angle. Underrun heels have been defined as angle of the heels of 5° less than the toe angle. Contracted heels were defined as frog width less than 67% of the frog length. Sheared heels have been defined as a disparity between the medial and lateral heel lengths of 0.5 cm or more. Small feet (small feet to body size) was defined as a weight to hoof area ratio of greater than 78 pounds per square inch. Quantification of hoof balance has been previously described in this chapter.

One of the most difficult parameters to assess is the hoof's ability to expand. Expansion of the foot is necessary for optimal concussion protection. Protection from concussion also depends on an elastic frog/digital cushion and pliable collateral cartilages.[50] Applied clinical studies have shown that the frog size influences hoof expansion. A frog in contact with the shoe or ground surface provides more hoof expansion than a frog that has no contact.[51] Identification of a narrow, recessed frog should alert the clinician that steps need to be taken to promote hoof expansion. These may vary from simply ensuring proper heel support to encouraging hoof expansion through the use of swedged or slipper heels on the shoes.

As previously discussed, shoeing parameters must be individualized for each horse. However, in most horses with

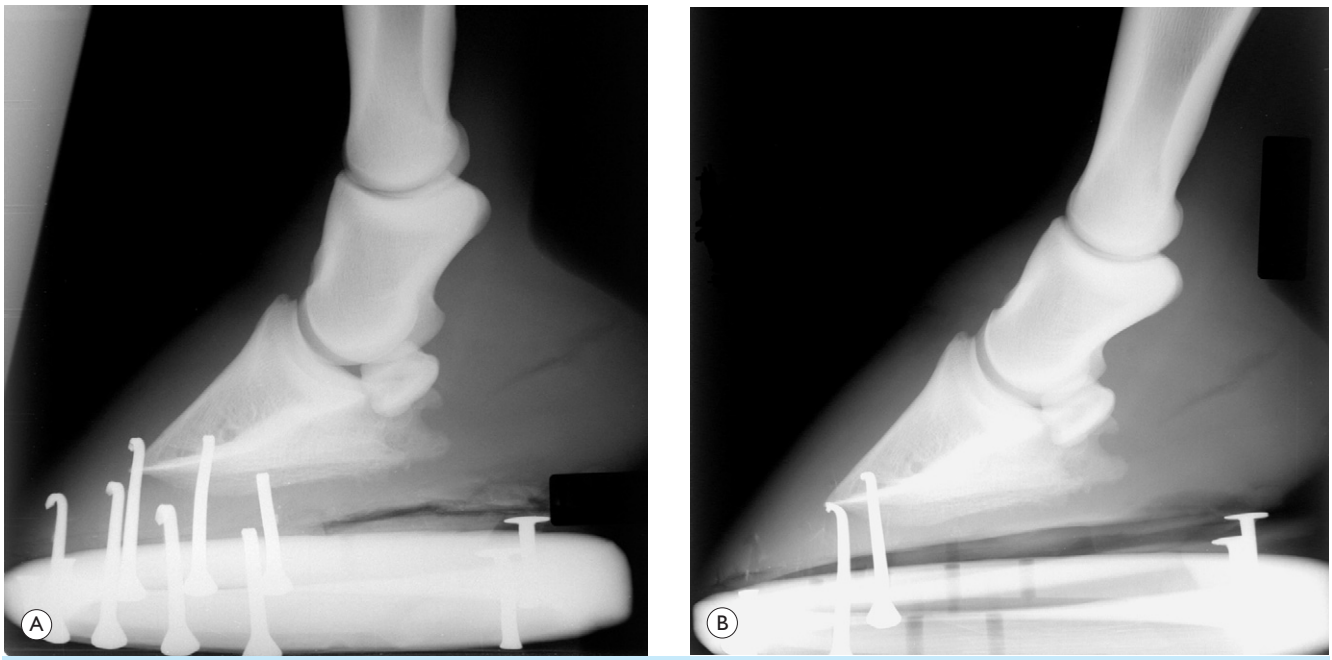

Fig. 15.15
Lateromedial radiographic projections of the distal limb. (A) Marked broken-back hoof pastern axis prior to shoe reset and trimming. This conformation results in excessive strain on the palmar aspect of the foot. (B) Improved hoof–pastern axis following trimming and placement of a larger heel wedge pad.

Fig. 15.16
Palmar view of a foot shod with an egg bar shoe. The sole is filled with resilient polyurethane packing material that provides further concussion protection and distributes weight over a larger surface area.

heel pain the following changes are made in most instances. Trim and balance the feet to eliminate hoof/pastern axis abnormalities, and underrun heels. Lateromedial radiographs may be used to determine hoof/pastern axis and to assess improvement of the axis following shoeing (Fig. 15.15). Shoe to raise the heels 2–3°, ease the breakover by rolling the toe, and provide heel support for horses with underrun heels. Decrease concussion to the foot by providing more surface area of contact (wide-web) or padding. Horses with contracted heels may benefit from shoes that encourage heel expansion during weight bearing, such as swedged heel shoes (outside rim of shoe at the heels is slightly lower than the inside rim: during weight bearing the hoof is encouraged to 'slide out'), or shoes that are not nailed caudal to the quarters. These practices will decrease stress on the DDFT and pressure of the DDFT over the navicular bone. Effective shoe types include wide-web aluminum shoes (more concussion protection than steel, less weight on distal limb), egg bar shoes (provide heel support), and 'Sneakers' (the widest-web available, with a polyurethane contact surface that provides the best concussion protection). Egg bar shoes may be filled in with resilient sole packing material to increase the surface area of weight bearing and provide further concussion protection (Fig. 15.16).

Inflammation is reduced by systemic administration of phenylbutazone (4.4–6.6 mg/kg daily) for 30 days. The DIP joint may also be medicated with triamcinolone (6 mg) and hyaluronic acid (HA; 20–40 mg). The intra-articular medication will treat coffin joint arthrosis directly, and also diffuse to navicular structures. Treatment with HA or PSGAGs is usually continued by intramuscular or intravenous routes.

Isoxsuprine HCl has also been used to treat navicular disease. It is a peripheral vasodilating agent that has been shown to improve lameness of horses with navicular syndrome.[52] The drug also may have anti-inflammatory and rheological properties that contribute to its efficacy. Treatment is continued initially for 6 weeks, if no effect is noted, discontinue its use. If a beneficial response is found treatment

may continue at once daily dosing. The drug is administered orally at 0.6–1.2 mg/kg q 12 h.

Two surgical options for treatment of navicular syndrome and palmar heel pain exist: navicular suspensory desmotomy and neurectomy. Desmotomy is indicated in horses not responding to medication and shoeing over a minimum of 20 to 30 weeks. The desmotomy procedure involves transecting the ligaments near their origin on the distal abaxial aspect of the proximal phalanx at the level of the proximal interphalangeal joint. Results may be due to reduced mechanical loading of the navicular bone associated with a slight shift in its position relative to the DDFT. There are virtually no adverse sequelae to the procedure. Horses are hand walked for 4 weeks after surgery and a gradual improvement starts in about 6 to 8 weeks. Seventy-six percent of horses treated with this technique were sound 6 months following surgery, with 43% sound at 36 months. Horses that were lame less than 10 months at the time of surgery were more likely to be sound than horses that were lame longer than 18 months.[53]

Neurectomy is the last option for treatment. Expect complications in 30% of the horses following neurectomy including incomplete denervation, regrowth of nerves, neuroma formation, unrecognized injury/abscess at desensitized heels.[54] In a follow-up study of neurectomy, 74% of horses were sound 1 year after surgery with 63% sound 2 years after the procedure.[54]

Prognosis Shoeing alone is a very effective method to treat heel pain and navicular syndrome. When correction is made within the first 10 months of lameness, up to 96% of horses are successfully treated. This is in contrast to when shoeing changes are not made until after 1 year of lameness, where only 56% of the cases have been successfully treated.[49] Addition of medications such as phenylbutazone and isoxsuprine improve the opportunity for soundness of horses with palmar foot pain.

Etiology and pathophysiology

Etiology There are numerous causes of pain in the palmar aspect of the foot of the horse. These causes can be divided arbitrarily into conditions of the hoof wall and horn-producing tissues, conditions of the third phalanx, and conditions of the podotrochlear region. Hoof problems would include hoof wall defects, such as cracks or clefts that involve the sensitive tissue; any laminar tearing, separation or inflammation; contusions of the hoof causing bruising or corn formation; abscess formation; and pododermatitis (thrush or canker). Third phalanx lamenesses blocked out by a palmar digital anesthesia would include wing fractures, marginal fractures, solar fractures, or deep digital flexor insertional tenopathy. Conditions of the podotroclear region have been reported to include distal interphalangeal synovitis, deep digital flexor tendonitis, desmitis of the impar (distal navicular ligament) or collateral sesamoidean ligaments, navicular osteitis or osteopathy, and vascular disease. The common denominator of all these conditions is that they are characterized by pain that can be localized to the palmar aspect of the hoof.

Pathophysiology Local vascular disturbances and biomechanical stresses constitute the two major hypotheses for the pathogenesis of navicular syndrome. Colles believed that thrombosis of arterioles supplying the navicular bone and consequent ischemia led to degeneration of the bone, increased size of the so-called 'vascular channels' of the distal border and the pain.[55] Agents that promoted blood flow to the distal limb such as heparin and warfarin were used successfully to treat navicular lameness based on this hypothesis, but this hypothesis has never been proven.

A unifying hypothesis for the cause of navicular disease which is based on pathologic findings has been promoted by Pool et al.[56] Changes associated with navicular syndrome are thought to be similar to degenerative joint disease found elsewhere in the horse. Repeated excessive biomechanical stresses on the flexor surface of the navicular bone result in fibrocartilage degeneration. Decreased shock absorption by the cartilage results in subchondral bone sclerosis. Defects in the cartilage may fill with granulation tissue, which can lead to adhesions between the navicular bone and DDFT. Inflammation associated with these degenerative changes causes excessive bone resorption, especially around synovial tissue attachments and may result in the increased synovial fossae of the distal border and medullary cysts seen on radiographic examinations.

Predisposing factors for lameness of the palmar heel region include faulty conformation such as long toe/ underrun heel, long sloping pastern, and small foot for large body mass. Horses used for jumping, or which are used frequently on hard footing, are also predisposed to this lameness.

Miscellaneous diseases of the distal limb

Underrun heels

Underrun heels have been defined as occurring when the angle at the heels is 5° less than the toe angle. Underrun heels are the most commonly encountered hoof abnormality (see Fig. 15.1). If left uncorrected, underrun heels can cause alterations in hoof-wall growth that can be very difficult to correct and it can predispose to lameness problems that range from bruised heels to navicular syndrome. In dealing with underrun heels it is important to assess several factors. The first is palmar hoof support. This is most easily assessed by radiography and observing where the heel ground contact is relative to the widest part of the hoof and relative to the navicular bone. It is generally accepted that at least half of the weight-bearing area of the foot should be palmar to the widest part of the foot. If this is not the case, the second assessment is of the orientation of the horn tubules in the heel region. With long-term hoof imbalance these tubules grow more horizontally. The proper position of the heels can be determined by either drawing a bisecting line through the metacarpus to the ground or by measuring the appropriate position on the radiograph. Where these lines contact the ground is the point where the heels should be. From a practical point, the heel–ground contact should be even with the base of the frog. Shoeing to achieve adequate heel support

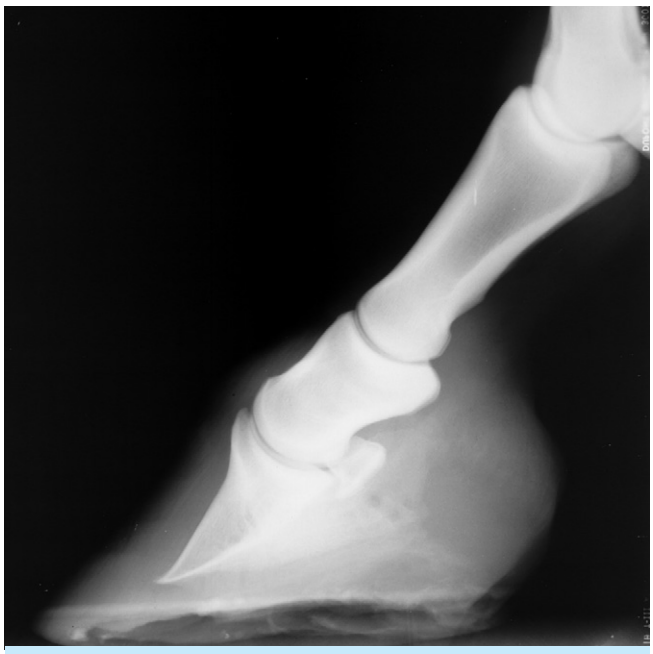

Fig. 15.17
Lateromedial radiographic projection of the distal limb with broken forward hoof pastern axis. This axis deviation is likely caused by flexural contraction of the deep digital flexor tendon.

can frequently restore the foot health. In some cases, however, it requires rebuilding the heels with acrylics or urethanes and altering the stresses on the coronary band to get the heel growth to improve. Some cases if uncorrected for too long, simply cannot be corrected.

Upright hoof

The upright or 'club' hoof is another frequently encountered problem. Most veterinarians consider this to be a problem when the hoof angle exceeds 60° (see Fig. 15.2). However, a more important consideration is the hoof–pastern axis. This axis should form a straight line when the horse is standing square. When the pastern angle is less than the hoof angle, this causes a 'broken forward' hoof axis (Fig. 15.17). The problem with this conformation is that in order to correct it, the hoof angle must be decreased. However, if the difference is more than 5° the deep flexor tendon will not allow further correction.

This can lead to several problems, such as hoof capsule separation, toe bruising, and coffin joint inflammation. A number of correction possibilities exists. In horses less than 2 years of age, extensions are placed on the toe either by shoeing or the application of acrylics or urethanes. This will cause stretching of the deep flexor tendon and muscle and slowly allow the hoof to assume a normal conformation. A problem with this method is that the stretching can actually lead to tendon injury and in some cases cause the problem to become worse.

A unique approach that has merit especially in acute cases is the use of heel wedges and rest. Raising the heel reduces deep flexor tendon stress and rest will allow the flexor muscle and tendon to relax. Wedges are continued for approximately 2 weeks. The hoof may then be trimmed or shod in a normal position. If shoeing fails to correct the axis deviation correction of this problem can always be made by inferior check (accessory ligament of the DDFT) desmotomy. Transection of the check ligament permits elongation of the flexor tendon/muscle unit. Application of a corrective shoe or acrylic toe extension is usually performed at the time of surgery. Correction of the hoof abnormality is critical to the success of club-foot confirmation due to flexor tendon contracture.

Distal interphalangeal (coffin) joint arthrosis

Distal interphalangeal (DIP) joint arthrosis is a lameness referable to the distal limb and localized to the distal interphalangeal joint with no evident radiographic abnormalities. This lameness is commonly found in many performance horses, particularly racing Quarter Horses, polo ponies, and horses that compete over fences. Horses that respond to DIP joint anesthesia should be treated for inflammation of that joint. Treatment may include parenteral NSAID therapy but intra-articular therapy or specific joint therapy should be considered. Hyaluronan and corticosteroids are commonly injected within the DIP joint for treatment.

Occasionally, horses affected with DIP joint arthrosis also have a chronic broken forward hoof–pastern axis. Many of these cases appear to be mild flexural deformities. Because of the malarticulation of the second and distal phalanges, the joint may remain inflamed despite therapy. In these cases, inferior check desmotomy to allow correction of the broken forward axis has been a very useful method to correct the hoof–pastern axis.

Keratoma

Keratoma is a rare benign tumor produced by the keratin-producing cells of the coronary band. The tumor becomes a space-occupying mass that causes pressure necrosis of the soft tissues and distal phalanx resulting in lameness, and may cause drainage from the white line or coronary band. Differential diagnoses include distal phalanx fracture, deep sole abscess, 'gravel', or corn. The diagnosis is suggested by radiographs that show smooth, circumscribed lysis of the distal phalanx. Treatment is excision via an approach through the hoof wall or sole. The mass is reminiscent of an onion: it has many layers that must be peeled away.

Collateral cartilage: side bone, quittor

Side bone is normal mineralization of the collateral cartilages and occurs in most adult horses. Mineralization may be accelerated by local trauma and is more prevalent in draft horses. Lameness is rarely associated with side bone but excessive mineralization could interfere with expansion of the heels during weight bearing.

Quittor is infection and necrosis of the collateral cartilages, usually due to trauma. The horse has localized pain and swelling at the coronary band region of the heels and may have a draining tract. Treatment is excision of the affected cartilage.

Thrush

Thrush is a degenerative condition of the frog and sulci due to excessive moisture, poor hoof hygiene, or filthy stabling conditions. It is characterized by a dark gray or black discharge around the frog, and poor-quality frog tissue. *Fusobacterium necrophorum* is frequently isolated from thrush-affected feet. Treatment consists of paring away affected tissue, cleaning the environment and providing dry bedding, and application of astringents. Simple cases respond well to daily application of povidone–iodine but formalin, phenol, strong tincture iodine, and copper sulfate have also been used alone or in varying combinations. One simple caveat: do not use Kopertox®, a liquid over-the-counter preparation consisting of copper napthanate. The liquid results in a gummy, sealed sole that traps moisture within the foot and results in accumulation of stall debris to its sticky surface.

Canker

Canker is an uncommonly encountered chronic proliferation of the keratinized tissues of the sole and/or frog and is usually associated with poor foot hygiene (Fig. 15.18). Canker may initially appear similar to proliferative granulation tissue but the tissue usually becomes white in color, bleeds easily on manipulation, and has a bad odor. Purulent exudate is often admixed with the tissue. Lameness is usually present because the proliferative tissue is very sensitive. Differential diagnosis includes severe thrush, large 'corns', and extensive underrun sole abscess.

Treatment is difficult and involves debridement of the proliferative tissue, cleaning the foot surfaces and application of topical antibiotics and astringents. The proliferative tissue may be removed with electrocautery, laser, or with cryosurgery. Astringents such as 5% picric acid or 10% neutral buffered formalin solution may be applied to the tissue. Debridement of the tissue is gradually made manually or by applying a saturated solution of benzoyl peroxide dissolved in acetone daily until the excessive keratinized tissue is all debrided. Metronidazole tablets ground into a powder and applied to the tissues are effective at controlling the bacterial infection. Prognosis for successful treatment is always guarded.

Fig. 15.18
Palmar view of a foot with severe canker affecting the frog. The white tissue now comprising the frog is very friable and bleeds easily. The horse is lame because the tissue is very sensitive to pressure.

Corns

Corns are usually found in the front feet at the angle formed by the hoof wall and bars. Shoes left on too long or shoes that overlap the bars and frog too much and irritate these tissues are implicated in the formation of corns. Corns may be dry, moist or suppurating. The tissue often appears similar to proliferative granulation tissue, but is usually only found in a localized area at the heels. The tissue is usually quite sensitive to palpation.

Treatment is similar to that used for canker, but usually does not require extensive tissue debridement.

Sole bruise

Sole bruises occur when vessels in the solar corium are traumatized and bleed. The hemorrhage is trapped with the solar tissues and causes varying degrees of lameness. Bruises are evident as discoloration of the affected sole that is painful to hoof tester application. Occasionally bruises will become contaminated and develop into a subsolar abscess.

Poor-fitting shoes, thin soles, and riding on hard terrain all are potential factors that contribute to solar bruising. Initial treatment is administration of NSAIDs, poulticing of the foot and removal of any inciting cause. Poor fitting or loose shoes should be removed. When the initial discomfort resolves the shoe should be reset. A full pad should also be used for feet with extensive bruising.

CHAPTER 16

Distal limb: fetlock and pastern

Alicia L. Bertone

The fetlock joint is a rotary joint that can exhibit the greatest range of motion of any equine joint, ranging from 120° of extension to 120° of flexion, particularly during athletic events such as racing or jumping (Fig. 16.1). This high degree of activity makes this joint particularly susceptible to exercise-induced wear and indeed, the fetlocks are commonly associated with injury and signs of degenerative joint disease. The pastern joint, by contrast, is a low range of motion joint exhibiting ~30° range of motion in the normal horse (Fig. 16.2). The pastern is less frequently afflicted with injury or degenerative wear than the fetlock, although its location just above the hoof and at the termination of the suspensory apparatus makes it vulnerable to high-impact, traumatic injury. Degenerative joint disease (high ringbone) frequently follows pastern joint injury. The combination of high-impact loading during sport performance and the distal location of these joints puts them at higher risk for fractures and breakdown.

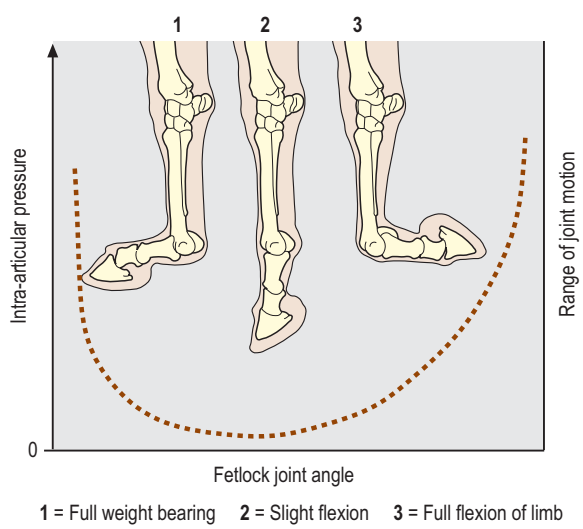

Fig. 16.1
The wide range of joint motion and intra-articular pressures associated with the fetlock joint.

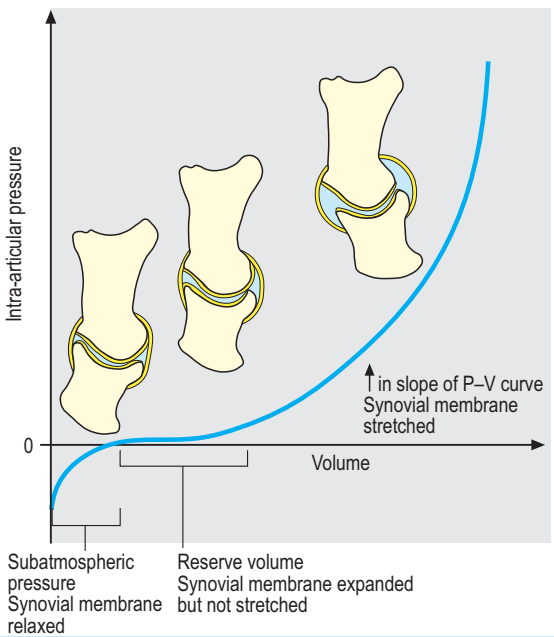

Fig. 16.2
The low range of joint motion and intra-articular pressures associated with the pastern joint.

Fractures of the fetlock joint

- Signs include acute lameness that often resolves in days, joint effusion and pain on flexion.
- Radiography confirms the diagnosis.
- Treatment is arthroscopic removal or internal fixation based on size and location of fragment.

Osteochondral (chip) fractures

Recognition

History and presenting complaint Most articular chip fractures of the fetlock are of the eminences of the proximal

Fig. 16.3
Dorsolateral to palmaromedial oblique radiograph of the fetlock joint demonstrating a typical dorsomedial eminence first phalanx osteochondral 'chip' fracture.

phalanx (P1) and are relatively common in the forelimb of the horse, particularly the sport horse (Fig. 16.3). In race horses, the left forelimb and medial eminence are affected more often. Other less frequently occurring fractures of the fetlock include fractures of the palmar/plantar eminences which, if articular and small, can be successfully removed arthroscopically with a good prognosis (~ 70%) for return to performance. These fractures, however, may be associated with subluxation of the fetlock joint and/or disruption of a palmar/plantar osteochondrosis lesion.[1–3] Careful evaluation of the joint is indicated to identify this more complex injury which can include injury to the collateral ligaments and distal sesmoidean ligaments.

Palmar/plantar fractures of the proximal phalanx are uncommon and should not be confused with osteochondral fragmentation of this site in young growing horses.[3] Developmental osteochondral fragmentation of the caudal eminences of the proximal phalanx occurs in ~5% of Standardbreds and Thoroughbreds without clinical signs in most horses. Clinical signs can occur as a high-performance lameness in which case fragments can be arthroscopically removed. True fractures of the caudal eminences of the proximal phalanx usually cause lameness and soreness to direct pressure over the eminence. Developmental osteochondral fragmentation in this location should not induce pain to pressure.

Physical examination Horses that sustain fetlock chip fractures develop clinical signs within hours after the injury. Clinical signs include fetlock joint effusion, pain on fetlock flexion and lameness at the trot. Soreness resolves within weeks with stall rest and anti-inflammatory medication. Chronic chip fractures are usually associated with generalized fetlock joint disease and may have capsular fibrosis, dorsal enlargement and reduced range of joint motion. Joint effusion, however, may or may not be present. Lameness may resolve with rest and return with athletic use.

Special examination In chronic fractures of unknown contribution to a lameness, direct intra-articular fetlock anesthesia may be indicated to localize the soreness to the intra-articular structures. Resolution of the lameness with a fetlock block would support arthroscopic exploration and fragment removal.

Diagnostic confirmation Diagnosis is confirmed with radiography, to include four views of the affected fetlock joint and the contralateral fetlock if surgery is to be considered. Osteochondral fragments are readily visible on the oblique radiographic views (see Fig. 16.3).

Nuclear scintigraphy can be used to distinguish fractures from incidental caudal eminence fragments.

Treatment and prognosis

Therapeutic aims Osteochondral fragments are removed, usually with arthroscopy, to decrease painful synovitis and to prevent further degenerative joint disease.

Therapy In horses with continued athletic expectations, acute fractures are preferably removed arthroscopically unless they are completely non-displaced. In non-displaced fractures a follow-up radiograph at 30 days is indicated as many of these fragments go on to displace and result in a non-union. In chronic chip fractures, other lesions commonly seen include proliferative synovitis of the dorsal metacarpal synovial pad (32% of which have chip fracture) and cartilage erosion of the metacarpal condyle.[4] Two to four months' rest is recommended before training is resumed depending on the degree of joint damage and cartilage debridement.

Fractures that continue to be a source of pain or are large enough to secure with a bone screw can be treated surgically. Injury to the collateral ligaments in conjunction with palmar/plantar fractures of the proximal phalanx should be supported by cast or support boot for 4–8 weeks to minimize joint laxity and osteoarthritis. Reconstruction of the ligament has been reported but is generally felt not to be necessary to regain use of the joint. Palmar/plantar eminence fracture healing is poor due to distraction by the distal sesmoidean ligament insertions and usually requires 4–6 months' rest.

Prognosis The prognosis for return to athletic performance, including elite performance, is ~80% with arthroscopic surgery to remove fragments. Concomitant injuries to the fetlock lower the prognosis.[5–8]

Etiology and pathogenesis

Etiology Concussion and overextension of the joint, exacerbated by fatigue, are factors in the production of these fractures and suspensory apparatus injury (Fig. 16.4). The overextension causes pinching of the dorsal eminences and dorsal metacarpal synovial pad.

Prevention

Incidence of fracture may be reduced by use of elastic bandages placed over the fetlock in a snug figure-of-eight configuration during hard workouts. The bandage absorbs some of the kinetic energy in the limb, thereby reducing the kinetic energy absorbed by the tissues supporting the fetlock.

Proximal sesamoid bone fractures

- Sesamoid fractures are most common in race horses.
- Apical fractures occur most commonly, followed by basilar and midbody fractures.
- Treatment is excision for fragments less than one-third the size of the entire bone and internal fixation for larger fractures.
- Prognosis may be affected by suspensory branch desmitis.

Fractures of the proximal sesamoid bones are a common fracture of the fetlock joint. Most are articular although non-articular (suspensory avulsion) fractures occur and can be distinguished by lack of joint effusion and firm swelling over the caudal aspect of the bone. Fetlock breakdown, including sesamoid fractures, is the most common fatal fracture in racing Thoroughbreds and Quarter Horses.[9] Sesamoid fractures are categorized as apical, abaxial (articular and

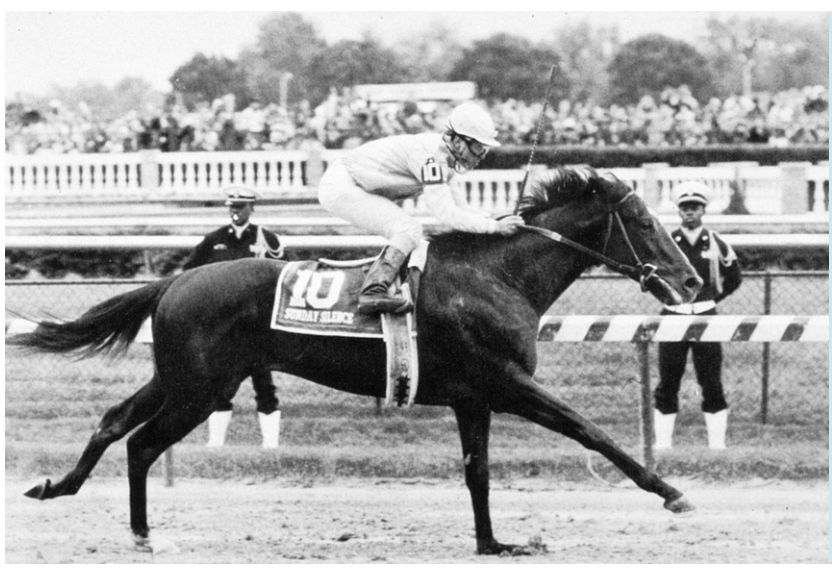

Fig. 16.4

Fig. 16.5
Oblique radiograph of a typical displaced apical sesamoid fracture. Recommended treatment is arthroscopic removal.

non-articular), midbody, basilar (articular and non-articular), sagittal and comminuted.[10]

Sesamoid fractures are most common (53.4%) in 2-year-old and then 3-year-old (23%) race horses. Apical sesamoid fractures are the most common, comprising over 88% of sesamoid fractures with an approximately equal distribution between the right and left limbs (Fig. 16.5). Apical fractures are frequently articular and singular, rarely comminuted and usually involve less than one-third of the bone.

Basilar fractures are more common in the Thoroughbred than the Standardbred, comprise 6% of sesamoid fractures in Standardbreds and represent an avulsion fracture associated with the distal sesamoidean ligaments. Basilar fractures are often comminuted into two pieces through a sagittal separation. These fractures can vary in size, from the smaller, triangular articular pieces to the larger fragments with a significant non-articular component.

Abaxial fractures appear to be more common in Thoroughbreds and Quarter Horses than in Standardbreds (3% of sesamoid fractures).[11,12] These can be difficult to diagnose and may require an additional tangential projection on the radiographic examination to identify their exact location or can be identified on the craniocaudal view.[13] Articular abaxial fractures will have joint effusion.

The midbody transverse fracture is seen most frequently in the Thoroughbred, older Standardbreds (mean age 6.5 years) and in young foals under 2 months of age. Most have a several millimeter gap and are distracted at the caudal surface. Fracture of both sesamoids usually results in complete loss of suspensory support and a 'dropped' fetlock (hyperextended during loading).[10]

Recognition

History and presenting complaint As with other fetlock fractures, horses become lame with joint effusion within hours of injury. Non-articular sesamoid fractures may not have joint effusion and swelling may be directly over the abaxial surface of the sesamoid.

Physical examination Clinical signs include lameness which is very pronounced in acute stages. Associated suspensory desmitis may confuse the diagnosis if radiographs are not taken. The horse evidences pain when pressure is applied to the affected bone. After 1–2 weeks' rest, lameness at the walk and trot may not be obvious but joint effusion persists.

Diagnostic confirmation Diagnosis is confirmed with radiography (see Fig. 16.5). Non-displaced fractures may be hard to see with plain radiography. The addition of the skyline projection of the abaxial surface of the sesamoid bone may help identify the exact location of fractures on the abaxial surface.[13] Suspicious but unconfirmed fractures should have a repeat radiograph taken after 2–4 weeks of stall rest or nuclear scintigraphy can be performed.

Treatment and prognosis

Therapeutic aims Most fractures should be surgically removed, usually arthroscopically, for the fastest return to athletic function and soundness. Large fractures may be best treated with internal fixation. Stall rest may be satisfactory for incomplete sesamoid bone fractures.

Therapy Preferred treatment for articular sesamoid fractures (apical, basilar or abaxial) of less than one-third of the bone is arthroscopic removal to provide the most rapid return to athletic use and least risk of degenerative joint disease and sesamoid reinjury. Stall rest (with or without soft cast or external coaptation) for 3–4 months may achieve fibrous or partial bony union, but management is prolonged, weakening of the bone is anticipated and continued soreness or refracture can occur due to failure of complete bony union.[12–17] Non-articular fractures can be removed, but conservative treatment is considered to produce similar outcomes and is generally recommended. Midbody transverse fractures affecting the middle third of the proximal sesamoid bones can be treated successfully with lag screw fixation or circumferential wiring to provide postoperative bone compression and immobilization.[13,18–21]

Fractures involving disruption of both sesamoid bones are a common cause of breakdown in speed horses.[9] Many of these horses are humanely euthanized due to compounding of the injury (disruption of the skin) or loss of vascular supply. Horses without an open injury and with immediate support to the limb with a support splint can be salvaged for breeding or retirement. The preferred management is appropriately timed surgical arthrodesis for the fastest return to comfort and to reduce the risk of contralateral laminitis from overloading[22] (see Fetlock luxation below). Fractures of the sesamoid can occur in conjunction with a condylar fracture of the metacarpus or metatarsus. This concomitant injury significantly reduces the prognosis for returning to sport athletics even with repair of the condylar fracture.[23] These sesamoid fractures are usually sagittal and axial from avulsion of the intersesmoidean ligament that occurs when the condylar fracture displaces. The fractures indicate significant soft tissue injury to the fetlock joint and degenerative joint disease is likely to develop.

Prognosis The prognosis for most simple sesamoid fractures ranges from fair to excellent. Eighty-eight percent of Standardbreds with apical fractures,[24] 71% of Thoroughbred or Quarter Horse race horses with abaxial fractures,[12] 50–60% of Thoroughbreds with basilar fractures[14,17] and 50–60% of Standardbreds with midbody fractures repaired by either lag screw fixation or circumferential wiring can return to racing.[18,19] Conservatively managed basilar or midbody fractures are most likely to develop significant degenerative joint disease and restricted range of joint motion. If both sesamoids are fractured, the prognosis is less favorable.

Etiology and pathogenesis

Etiology Sesamoid fractures are a result of excessive forces within the bone, generated by the tension of the suspensory apparatus during loading and occasionally contributed by direct concussion with the ground during fatigue–fetlock 'rundown'[11,13,14,23] (see Fig. 16.4). The forelimbs are most frequently affected in flat racing, whereas the hindlimbs are more frequently affected in Standardbreds. Displaced fractures are common due to the pull of the suspensory ligament proximally and the distal sesamoidean ligaments distally.

Severe blunt trauma to the sesamoid bone can cause highly comminuted fractures. The fetlock can contact the ground in an athletic event or at the time of a uniaxial sesamoid fracture. Fractures caused by 'running down' or interference are most likely to also contain a wound.

Pathophysiology Although the vascular pattern of sesamoid bones may be implicated in site selection of fractures as the orientation and distribution of vessels correspond to the configuration of apical fracture patterns,[25] the sesamoid fracture or the predisposition for sesamoid fracture has not been associated with the presence of sesamoiditis. Sesamoiditis describes a condition of sesamoid pain that demonstrates radiographic lucencies which parallel vascular channels seen radiographically.[25]

Prevention

Protective and support bandages for the fetlock can be worn during hard workouts to help prevent direct injury to the sesamoid and to reduce strain in the suspensory apparatus during loading. Appropriate training can result in strengthening and conditioning of the bone which is important to help prevent sesamoid fractures. Smooth racing surfaces may help prevent missteps.

Longitudinal fractures of the first phalanx

- Fractures may be complete or incomplete.
- Most fractures are treated with internal fixation.
- Some proximal incomplete fractures will heal with stall rest.

The first phalanx is prone to sagittal and, less commonly, frontal plane longitudinal fractures that occur during heavy exercise (Fig. 16.6). Almost all of these fractures are initiated at the articular surface of the fetlock joint and propagate distally.[26] Patterns of propagation for sagittal fractures include

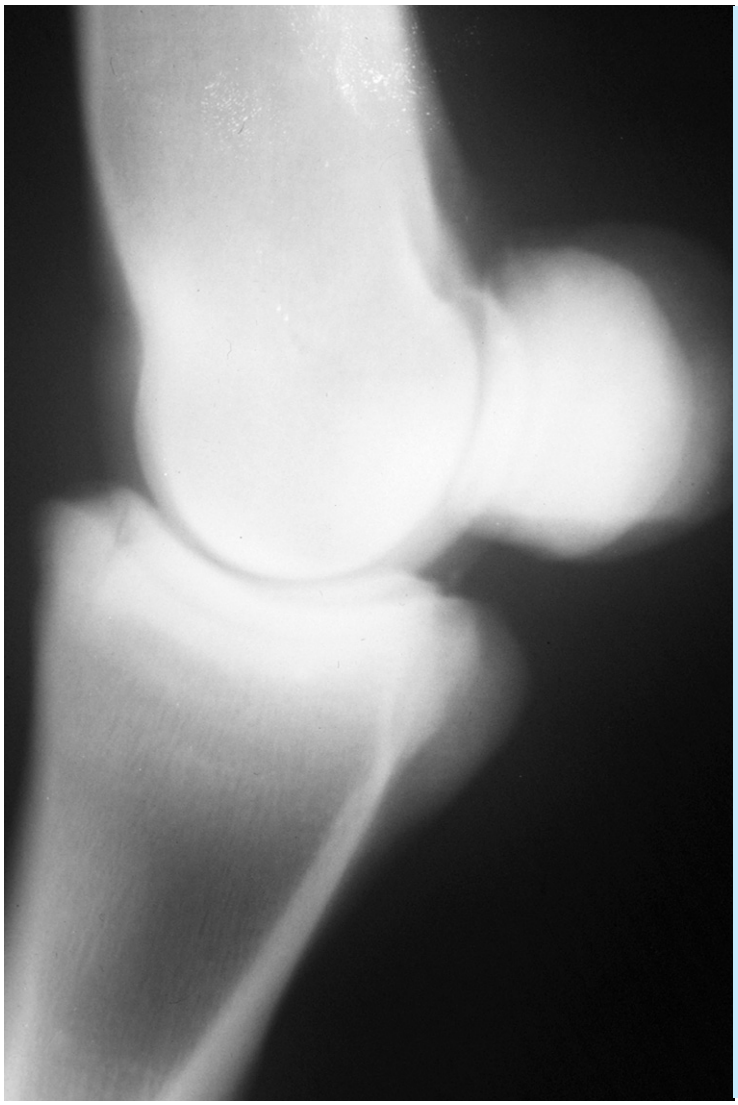

Fig. 16.6
Lateral radiograph of a typical frontal plane dorsal first phalanx fracture.

spiral fractures toward the pastern joint and/or lateral deviation toward the cortex (Fig. 16.7). If fractures extend into the pastern joint or exit the lateral cortex, they are considered complete. Many sagittal fractures are incomplete and propagate distally for varying distances, ranging from < 1 cm (short incomplete) to 5–6 cm (long incomplete) and ending just above the pastern joint.[27,28] Complete fractures can be displaced or non-displaced. Incomplete fractures are non-displaced or minimally displaced. A small proportion of sagittal fractures can also contain frontal plane fractures (Fig. 16.8). If this combination of fractures occurs it is highly predisposed to displacement (comminution) since the sagittal ridge of the metacarpus/tarsus acts as a pile driver upon loading, even with the limb in a cast or splint. Securely positioning the limb vertically on the toe minimizes this effect.

A portion of these fractures will also have a third fracture plane (transverse or coronal) which commonly results in complete instability and displacement of the fragments (comminution). Displaced, comminuted fractures are categorized by the presence or absence of an intact strut of bone from the proximal metacarpal/tarsophalangeal joint to the proximal interphalangeal joint. Prognosis for successful surgical reconstruction is greater if an intact strut of bone is present due to the longitudinal support to prevent collapse and providing a secure anchor for reconstruction of fragments.[26]

Frontal single plane longitudinal fractures can occur in the first phalanx, but are much less common than sagittal fractures (see Fig. 16.6). Clinical signs, treatment and outcome are as for sagittal fractures.[29] If a frontal plane fracture is identified on a lateral radiograph, an additional sagittal plane fracture should be suspected and ruled out.

Recognition

History and presenting complaint Most first phalanx fractures occur at racing speeds and therefore are closely associated with heavy workouts or competitive events. More severe fractures are associated with immediate lameness and rapid swelling (within minutes to hours).

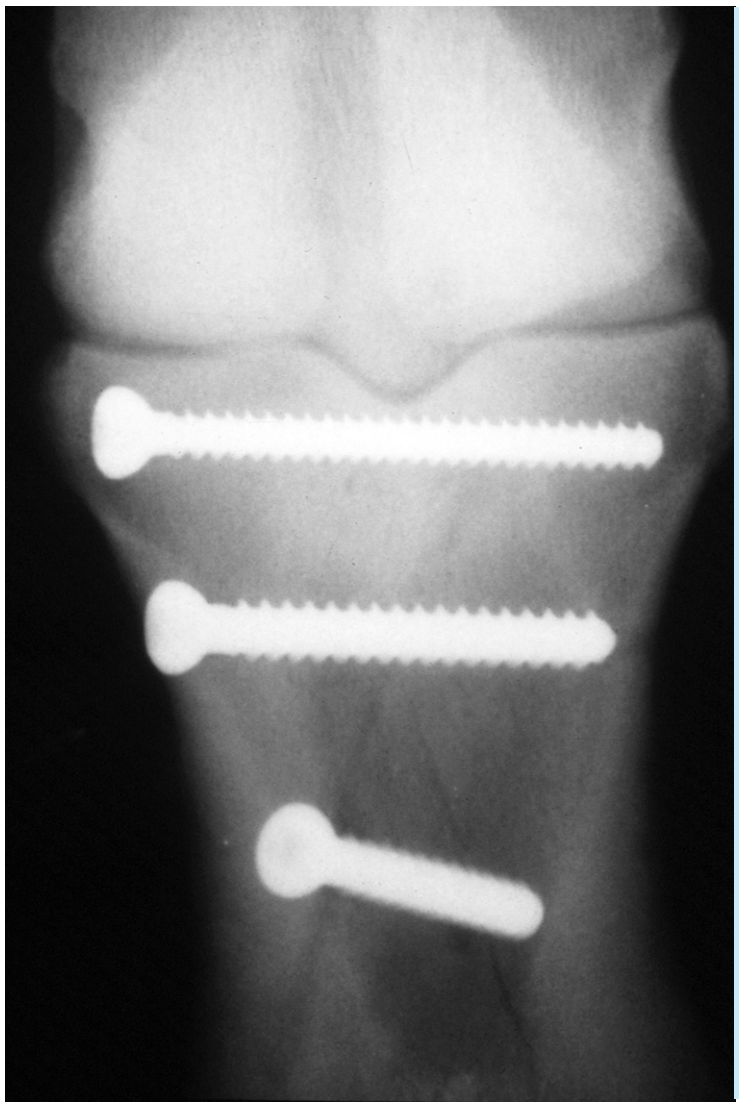

Fig. 16.7
Craniocaudal radiograph of a recently repaired typical complete sagittal first phalanx fracture. The fracture originates near the sagittal groove and exits the lateral cortex.

Physical examination Clinical signs of longitudinal fractures include lameness, which is immediate for all but the short incomplete fractures, fetlock joint effusion and pain on joint manipulation early after injury. Pain can be elicited by squeezing the P1 bone, particularly proximally. Lameness can resolve with stall rest within days to weeks with incomplete fractures, particularly short fractures, and local swelling may be imperceptible. Complete fractures usually result in a non-weight bearing lameness that persists and swelling in the pastern is present.

Special examination A first phalanx fracture should be suspected in any competitive horse, particularly a race horse, that is lame the day after the race and has fetlock joint effusion. The horse should not be jogged excessively or jogged following a nerve block to the distal limb as complete bone failure may occur.

Diagnostic confirmation The diagnosis can usually be confirmed with a complete series of radiographs. Most fractures are evident on the craniocaudal view (sagittal fractures) or lateral view (frontal plane fractures). Acute non-displaced first phalanx fractures can be undetectable by radiography. If a high degree of suspicion for a first phalanx fracture persists due to clinical signs and history, the radiographs should be repeated in 2–4 weeks or a nuclear scan performed. Horses with a confirmed fracture should remain on stall rest with appropriate coaptation for the fracture configuration until surgery, if elected.

Treatment and prognosis

Therapeutic aims The goals of therapy are to prevent worsening or displacement of an existing fracture with stall rest and coaptation and surgical treatment to provide immediate reduction and compression of the fracture. Internal fixation provides the most rapid healing and best joint alignment.

Therapy Most sagittal and frontal plane first phalanx fractures are best treated with surgical lag screw compression if the fracture length on radiograph is > 1 cm[26–29] (see Figs 16.7, 16.8). In non-displaced fractures, screws can be placed in lag fashion through small stab incisions. In displaced fractures an incision can improve exposure to ensure anatomic

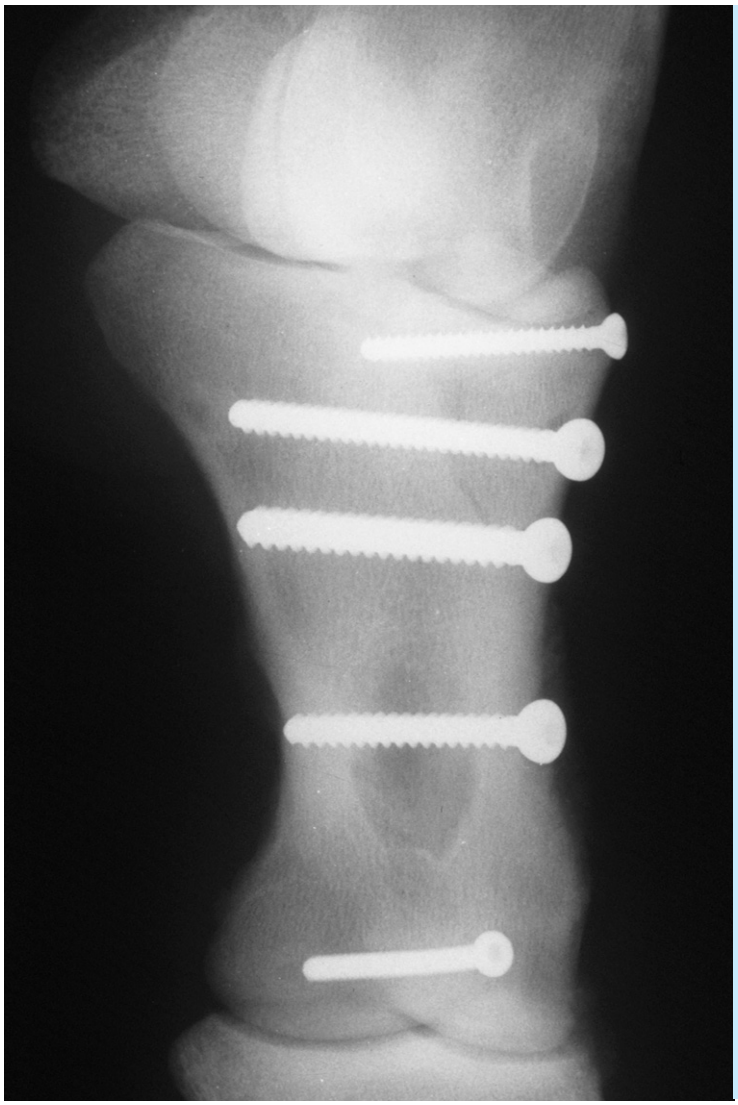

Fig. 16.8
Lag screw repair of a comminuted first phalanx fracture. Frontal and sagittal fracture planes required fixation in multiple planes. The fracture was complete into the pastern joint.

reduction prior to screw placement. Comminuted fractures that have lost an intact strut of bone support from the fetlock to the pastern joint are best treated ideally for several weeks with diverted loading through coaptative devices.[30] Positive profile transfixation pins in the metacarpus/tarsus supported with a cast or use of an external fixator apparatus have been successful in managing these fractures and can be used in the presence of open wounds.

Prognosis The prognosis for return to athletic use following repair is good to excellent (> 70%) for non-comminuted, incomplete, non-displaced fractures and complete fractures that exit the lateral cortex.[26–28] The prognosis following repair for complete fractures that enter the pastern joint is lower (49%).[27] The prognosis for complete fractures is also good if surgical repair effectively compresses the fracture with minimal displacement in the pastern joint. Repair of displaced complete fractures or comminuted fractures can achieve pasture soundness and breeding soundness, but athletic soundness is usually compromised.

Etiology and pathogenesis

Etiology Sagittal first phalanx fractures occur as the sagittal ridge of the metacarpal/tarsal condyle is loaded rapidly into the first phalanx during galloping (see Fig. 16.1). The shape of the bones and the rotation during movement create torsional forces within the bone, resulting in the classic spiraling fracture.

Pathophysiology Preceding bone pathology is not necessary for this fracture to occur and it is considered a high-speed casualty.

Proximal sesamoiditis

- Lameness localized to the fetlock and suspensory branches.
- Radiographically apparent widened vascular channels in the sesamoid confirms the diagnosis.
- Reduced exercise level and time for bone remodeling are necessary.

Fig. 16.9
Typical radiographic appearance of sesamoiditis with wide and prominent vascular channels.

Recognition

History and presenting complaint Sesamoiditis is a condition characterized by pain and associated lameness located to the proximal sesamoid bones and attachment of the suspensory branches.

Physical examination Pain, heat and inflammation are detected at the insertion of the suspensory ligament early in the disease, but usually marked lameness and limitations on performance occur without any clinically detectable signs.[31,32]

Lameness is usually obvious, particularly after exercise. Pain on pressure over the abaxial surface of the sesamoid bone and on fetlock flexion is typical. A distal metacarpal nerve block, but not an intra-articular fetlock block, will locate the lameness to the extra-articular structures of the fetlock. Additional diagnostic tests would include radiographs and ultrasound examination of the suspensory ligament.

Special examination Primary disease of the suspensory ligament or distal sesamoidean ligament can accompany the bone pain and should be evaluated with diagnostic ultrasound.

Radiographs can reveal a range of changes from accelerated early remodeling response in the bones (increased size and number of vascular channels) to marked proliferation of bone along the abaxial margin of the sesamoid and increased bone density of the sesamoid (Fig. 16.9). Some radiographic changes associated with chronic sesamoiditis are persistent and present in sound performing horses.

Nuclear scintigraphy usually demonstrates increased radiopharmaceutical uptake in the sesamoids of greater degree than bone remodeling associated with training and of lesser degree than sesamoid bone fracture.

Diagnostic confirmation The diagnosis is confirmed with a combination of radiographic changes indicated above, lameness that locates to the fetlock area and fetlock lameness that does not locate intra-articularly with a fetlock joint block. Ultrasound examination of the suspensory ligament is often normal.

Treatment and prognosis

Therapeutic aims The goal of therapy is to reduce bone pain so that a convalescent training program can be initiated to strengthen the bone. Bone remodeling will need to occur to permit the sesamoids to accommodate to the high-tensile strains of competitive sport without reinjury.

Therapy Initial therapy is stall rest, anti-inflammatory and pain medication to eliminate lameness. With a convalescent exercise program, bone remodeling can conclude, heal the injury and suspensory strength be regained.[31]

Treatment is palliative, including anti-inflammatory medications, physical and adjunctive therapy and supportive wraps in the acute phases. X-ray and γ-ray radiation, laser heat application, shock wave therapy and a balanced mineral diet are considered by some to be valuable in this condition. Rest from athletic activities is necessary until soundness is achieved. A convalescent exercise program would include lower levels of exercise that would stimulate bone strengthening, but not induce pain or bone damage. Typical pro-grams are prolonged, similar to suspensory ligament injuries (7–9 months). Pain can recur upon return to original levels of performance and may force retirement or a reduction in level of athletic competition.

Prognosis The specific prognosis is case dependent and can range from poor for severe cases with concomitant suspensory ligament injury to good for cases with mild lameness and minimal radiographic changes.

Etiology and pathogenesis

Etiology The etiology is considered to be excessive strain to the suspensory apparatus around the fetlock, including the sesamoid bones and the insertion of the suspensory ligament branches.

Pathophysiology The intraosseous blood supply to the sesamoid bone enters through a series of abaxial vascular channels that correspond to the enlarged channels seen

radiographically in sesamoiditis, indicating bone resorption. This may represent the initiation of the remodeling response to bone stress of training or may reflect an increase in blood flow due to inflammation and injury to the suspensory ligament, or both.[25] Sesamoid bone remodeling is a normal response to training and only if stresses exceed the capability to strengthen bone would microfracture and bone damage occur. Although radiographic vascular changes of bone remodeling were not associated with sesamoid fracture, the vascular structures course along known lines of fracture in adult racehorses. The sesamoid bones have an extensive sensory nerve supply that may explain bone pain associated with trabecular bone injury.[33]

Epidemiology

Sesamoiditis is observed frequently in racing horses and hunters and jumpers.[10]

Prevention

Appropriate training schedules to permit time for bone strengthening are helpful. A dietary cause has not been identified.

A separate condition of the axial border of the sesamoid bones, an osteomyelitis, has also been called sesamoiditis. Horses with axial sesamoid osteomyelitis are quite lame at the walk and radiographs reveal surface bone lysis at the attachment of the intersesamoidean ligament. The lesions and clinical signs suggest a septic condition in some animals but on histology infarction and necrosis predominate. Presumably an injury to the attachment of the intersesamoidean ligament and possibly seeding with bacteria from intra-articular injections may be associated with the condition. The prognosis for soundness with or without surgical debridement is poor.[34]

Rupture of the suspensory apparatus

- Injury unique to the race horse.
- Fractures of the sesamoid bones and/or suspensory ligament disruption occur.
- First aid splinting should be done to preserve soft tissues and the local blood supply.
- Surgery is done to stabilize the joint for salvage as a breeding animal.

Disruption of the suspensory apparatus is a common cause of acute breakdown in the racing Thoroughbred and frequently results in humane destruction of the animal.[9,22] Disruption can occur because of rupture of the suspensory ligament, fracture of both proximal sesamoid bones or avulsion of the distal sesamoidean ligaments. Due to the violent nature of these injuries, open fractures, fetlock joint luxation and loss of the vascular supply to the distal limb are associated complications. Successful treatment of these injuries requires immediate and appropriate emergency management of the horse, including sedation, possibly general anesthesia, ambulance service and limb stabilization. Commercial splints such as the Kimzey Leg Saver Splint (Kimzey Welding Works, Woodland, CA) have been designed for this purpose. Euthanasia may be chosen due to the extent of the injuries, risk of treatment failure, lack of sentimental or breeding value of the horse and cost of treatment.[22]

Recognition

History and presenting complaint These injuries occur during maximal exercise and are immediately recognized by distortion of the distal limb and the inability of the horse to bear weight without collapse of the distal limb.

Physical examination Immediate sedation or general anesthesia is recommended to gain control of the panicked horse for examination by palpation, radiography, ultrasound and Doppler ultrasound.

Special examination and diagnostic confirmation The diagnosis is confirmed by observation (the fetlock drops to the ground upon loading), palpation and radiograph. Ultrasound evaluation can locate the sites of suspensory ligament failure and, with Doppler, assesses blood flow to the distal limb. The vascular supply is best evaluated after the horse has been treated for shock and the limb has been stabilized to over-ride initial vasoconstriction. Radiographic examination most often reveals the proximal displacement of the intact sesamoid bone (rupture of the distal sesamoidean ligaments) or proximal displacement of the apical portions of the fractured sesamoid bones (sesamoid fracture).

Treatment and prognosis

Therapeutic aims The goal of treatment is to salvage the horse's life for breeding or as a retired pasture com-panion. Surgical fusion of the fetlock joint can be successful if limb blood supply is intact and infection can be prevented.

Therapy If treatment is chosen, a splint should be maintained for 4–5 days prior to the selection of the final treatment to permit recovery from the shock and trauma and to define the extent of skin necrosis and loss of vascular supply accompanying the injury. The arthrodesis procedure should be undertaken at the optimal time and evaluation of the soft tissue injury and permanent deficit and risk of infection must be ascertained to properly predict the outcome with surgery.[22] Surgical treatment options include fetlock ankylosis supported by use of an external fixator placed on the foot and metacarpus to fix the position of the joint during healing[35] or arthrodesis with implants and bone graft to achieve a pain-free stable fusion of the fetlock joint.[10,22] For implants, the soft tissues should be intact and the risk of infection minimal. Treatment by surgical means is preferable to relieve extended loading on the contralateral limb. In conservative management, supporting limb laminitis and erosion of the sesamoid bones by casts and splints is a significant cause of failure.

Prognosis The prognosis is grave for horses that also have open joint luxation, significant skin loss, loss of vascularity and open wounds. With the preselection and appropriate management of cases, the prognosis is good for pasture and breeding soundness. In one report, 60% of horses with fetlock arthrodesis fused the joint, survived and eventually had unrestricted activity.[22]

Etiology and pathogenesis

Etiology Fetlock disruption occurs during racing or maximal exercise as a traumatic event.
Pathophysiology Disruption of the suspensory apparatus is due to extreme overextension of the fetlock at high speeds and forces of loading. Pre-existing pathology of the bones or suspensory ligament is not a prerequisite for this injury to occur.

Epidemiology

Risk factors have been identified and include an abnormal finding in the suspensory ligament on pre-race inspection by a regulatory veterinarian[36] and racing with toe grabs.[37]

Prevention

Pulling horses with abnormal suspensory ligament findings from racing and maintenance of optimal track conditions will reduce the number of these catastrophic failures.

Fetlock luxation

Recognition

History and presenting complaint Luxation of the fetlock is usually in the frontal plane and occurs during a high-impact injury, such as slipping, running into an object or catching the hoof under a board or in a hole. A collateral ligament ruptures, resulting in an obvious varus or valgus deformity of the limb.[38] The dislocation of the joint may be temporary and often replaces spontaneously or is reduced by an attendant.
Physical examination After reduction, lameness may be minimal. Articular fractures of palmar/plantar eminence of the first phalanx may accompany the luxation[39] and can be avulsed several inches proximally. Medial to lateral laxity is present and the joint may be subluxated upon flexion. Swelling of the joint and torn soft tissues will locate over the injured side of the joint within hours. Persistent laxity can be palpated and presumably contributes to the chronic osteoarthritis that is often the sequela to this injury.[40]
Special examination Reluxation can occur at any moment if the joint is not stabilized until the swelling and pain begin to protect the joint, so it is critical to restrict the horse's activity.
Diagnostic confirmation The diagnosis is often made by the historical description of the limb deformity and manipulation of the fetlock. Radiographs should be taken to identify an avulsion fracture, intra-articular fractures or damage to the articular surface that has entered into the subchondral bone. Craniocaudal stress radiographs displacing the distal limb medially or laterally will identify more laxity to the fetlock joint than the contralateral joint, but is not necessary for a diagnosis (Fig. 16.10).

Treatment and prognosis

Therapeutic aims The goal of therapy is to reduce the luxation and stabilize the limb to prevent reluxation and decrease the risk of osteoarthritis.
Therapy Arthroscopic removal of articular fragments can be undertaken if the chances for athletic soundness are to be optimized. Reduction and immobilization for 4–6 weeks will result in fibrous restabilization of the joint and a good prognosis for light riding soundness. Surgical repair of the ligament is reported,[38,41] but is not universally accepted as an improvement over conservative coaptation. If osteoarthritis and permanent lameness occur as sequelae, a surgical arthrodesis can result in pasture soundness. In open fractures/luxations, external fixation may be necessary followed by bone grafting and stimulated joint fusion.
Prognosis Closed luxations without fracture that are quickly reduced can result in soundness, although competitive athletic soundness is less likely. Most luxations result in some degree of osteoarthritis and lameness with exercise. Luxations with associated injuries, such as an open joint, additional fractures or disrupted vascular supply, would carry a less favorable prognosis.

Etiology and pathogenesis

Etiology This injury is a sporadic, relatively random traumatic event.
Pathophysiology Lateral and medial luxation of the fetlock joint is a recognized syndrome, affects all ages and breeds of horses and usually occurs during high-speed falls or collisions. Pre-existing joint disease or collateral ligament disease is not associated with injury.

Traumatic synovitis and capsulitis

- Definitive diagnosis is via intra-articular anesthesia.
- Rule out osteochondral fractures.
- Treatment reduces joint inflammation to prevent deterioration of cartilage.

Traumatic synovitis/arthritis of the fetlock joint is one of the most common conditions in the equine athlete. The high range of rotary motion predisposes this joint to injury and wear.

Recognition

History and presenting complaint Most horses present with the onset of lameness of one limb initially which may be intermittent and worse after exercise. A specific injury may have been noted.
Physical examination Joint effusion, soreness to joint flexion and joint heat (detected by palpation or thermography) are the classic clinical signs.
Special examination Radiographs are normal until the condition becomes chronic and degenerative joint disease (osteoarthritis) develops. Arthrocentesis and fluid cytology are often not performed as the clinical signs are not severe enough to warrant them; however, intra-articular and systemic joint medication is commonly used. If training is continued with the use of aggressive medical therapy, a proportion of these horses will develop proliferative synovitis

Fig. 16.10
Stress radiograph demonstrating excessive joint laxity in the frontal plane, indicating rupture of the medial collateral ligament.

(see next section), chip fractures and articular cartilage damage (erosion and scoring). Intermittent hemarthrosis may be detected with primary traumatic synovitis but often indicates injury to subchondral bone, such as chip fracture or cartilage elevation.

Laboratory examination Synovial fluid analysis may be normal or reveal a mild increase in white blood cell count or protein concentration.

Diagnostic confirmation The diagnosis is definitive if the lameness resolves with an intra-articular fetlock joint block, radiographs are normal and a synovitis or hemarthrosis is present on synovial fluid analysis.

Treatment and prognosis

Therapeutic aims Most primary traumatic synovitis is mild, permitting continued training with medical management. Medical management is aimed at reducing joint pain and inflammation.

Therapy Early medical intervention and appropriate joint rest and physiotherapy are critical to prevent loss of glycosaminoglycan from articular cartilage and permanent joint wear. Early loss of articular cartilage proteoglycan is reversible with medication and joint rest. Systemic hyaluronan and polysulfated glycosaminoglycans may be used to reduce joint inflammation and assist with protection of articular cartilage. Topical dimethylsulfoxide (DMSO) and hyperosmotic agents under plastic and supportive wraps assist with removal of joint edema and fluid accumulation. Non-steroidal anti-inflammatory medication can reduce joint inflammation and should be used if close monitoring of the lameness is not critical. Long-term use of non-steroidal anti-inflammatory drugs would require continued evaluation of the patient.

Prognosis The prognosis for traumatic arthritis ranges from good for minor and first-time injuries to poor for severe or recurrent injuries. Early and less severe disease that is permitted joint rest to resolve the inflammation can often be

managed. Traumatic arthritis can be progressive or result in degenerative joint disease.

Etiology and pathogenesis

Etiology Traumatic arthritis usually begins as a strain to the joint during exercise that results in a joint bleed, pinching of the synovium and/or a cartilage erosion and secondary joint inflammation. Horses with high action and high-impact loading are the most susceptible.

Pathophysiology Joint inflammation (synovitis) induced by a traumatic injury results in immediate swelling of the synovium and possible joint hemorrhage. Capillary leakage introduces fluid and white blood cells into the area of injury and increases blood flow locally. These cells release inflammatory mediators, such as interleukins, eicosanoids and nitric oxide that perpetuate the inflammation until healing occurs. The result is joint effusion, synovial hemorrhage and edema, an increased joint fluid white blood cell count and protein content and activation of joint pain (see Chapter 9).

Epidemiology

Horses at risk for traumatic synovitis are in active training with maximal performances on a regular schedule. This includes all racing breeds (Thoroughbred, Standardbred, Quarter Horse, Warmbloods) and types of racing competition (flat racing, barrel racing, cross-country, steeple chase); dressage horses; Western performance horses; hunters; jumpers; three-day competition; and show horses.

Prevention

Regular exercise, appropriate warm-up, conservative competitive schedules and judicious use of joint medications, particularly steroids and non-steroidal anti-inflammatory drugs, will reduce the risk of joint trauma and prolong joint health.

Proliferative (villonodular) synovitis

- Result of chronic joint inflammation.
- Radiographically evident as supracondylar lysis.
- Treatment is surgical resection of proliferative tissue if medical therapy fails.

Proliferative synovitis is a clinical condition in which chronic traumatic synovitis and continued exercise result in a painful thickening of the synovium, particularly in areas of compression trauma.[8,42–46]

Recognition

History and presenting complaint Classic clinical presentation for chronic proliferative villonodular synovitis is joint effusion, decreased range of joint motion and soreness on joint flexion.

Physical examination Enlargement at the dorsal fetlock is often visible and disproportionately large for the amount of palmar effusion. The joints may appear and palpate normally, however.

Special examination Confirmation of enlargement of the pad is most easily obtained with dorsal metacarpophalangeal joint ultrasound. Normal dorsal fetlock pads measure < 4 mm dorsal to palmar in a plane perpendicular to the mass surface. A typical enlarged pad in clinical disease measured 11 mm.[8] Proliferative synovitis is often bilateral and therefore comparative measurements of one limb to another may not be helpful. Diagnosis can also be made with contrast arthrography and at arthroscopy (Fig. 16.11). Joints should be radiographed prior to surgery to identify presence and extent of bone erosion, mineralization in the masses, degenerative joint disease and concomitant proximal phalanx chip fractures. In a recent report of 63 horses, 93% of joints demonstrated a concavity at the distal dorsal metacarpus and 32% had a first phalanx chip fracture[8] but these findings are not conclusively diagnostic for an enlarged dorsal pad. In severe cases, these masses can become locally invasive of bone and joint capsule, continuing expansion beyond normal joint structures, similar to benign tumors.

Laboratory examination Synovial fluid analysis may be normal or indicative of mild to moderate synovitis.

Diagnostic confirmation The presence of clinical signs, pain located to the fetlock joint and a measurably enlarged synovial pad confirm the diagnosis. Radiographic changes are supportive, but not always present, particularly in early disease.

Treatment and prognosis

Therapeutic aims The goal of therapy is to reduce joint pain and inflammation and reduce the size of the dorsal synovial pad to prevent immediate recurrence on resuming exercise.

Therapy Upon identification of an enlarged dorsal fetlock proliferative mass, initial therapy would include joint rest, all forms of adjunctive joint synovitis therapy and consideration of a short-acting intra-articular steroid. Intra-articular steroids are potent suppressors of angiogenesis and fibrosis and will reduce active inflammation. Short-acting steroids, such as soluble dexamethasone and hydrocortisone, may minimize the long-term corticosteroid influence on chondrocyte metabolism. Arthroscopic surgical mechanical or laser removal of the enlarged masses is indicated if any associated fractures are identified, if pain persists or at planned lay-off periods.[47] Surgery should be undertaken before signs are associated with bone changes, articular cartilage damage or degenerative joint disease.

Prognosis Successful return to racing is reported in Thoroughbreds[8] and trotters[43] after surgical removal of the dorsal pad and intra-articular chip fractures. Proliferation of the pad can return despite surgical and medical management, but most horses are clinically improved with a longer performance career with surgical treatment.

Diffuse proliferative synovitis and capsulitis is also common in the fetlock joint and can be associated with chronic joint injection, joint damage and joint wear. Palpable

Fig. 16.11
Contrast arthrogram of the fetlock joint demonstrating a space-occupying soft tissue mass in the dorsal and palmar joint recesses typical of proliferative synovitis.

joint soft tissue thickening and loss of joint range of motion are classic clinical findings and are commonly noted in retired jumpers and race horses. Fibrosis of the joint capsule and loss of fine villous architecture are notable at arthroscopy. Diffuse synovectomy in these cases is probably of minimal benefit as restoration of normal villi is unlikely and loss of remaining villous architecture may be permanent. The loss of joint motion is permanent and may not be associated with lameness in retired horses.

Etiology and pathogenesis

Etiology This condition is most commonly seen in Thoroughbred race horses. High-impact joint use with extreme dorsiflexion causes direct mechanical trauma to the dorsal fetlock synovial pad between the metacarpal/tarsal condyle and the first phalanx.

Pathophysiology Proliferative synovitis is a clinical condition in which chronic traumatic synovitis and continued exercise result in a painful thickening of the synovium, particularly in areas of compression trauma.[8,42–46] The most common location in the horse for this condition is the dorsal fibrous pad of the metacarpophalangeal joint. This pad is normally present at the dorsal reflection of the metacarpophalangeal joint directly under the broad, flat extensor tendon and associated joint capsule.[8] At hyperextension and maximal flexion, this pad is compressed and can result in intrasynovial hemorrhage, granulation tissue formation, fibrosis and mineralization. Pigment in the pad is often hemosiderin, but melanin has also been noted.

Epidemiology

The condition is typically progressive as joint trauma is continued with use.

Prevention

Early treatment and adequate rest early in the disease process may arrest the development or progression of this condition.

Osteoarthritis of the fetlock (osselets)

Osteoarthritis is a chronic degenerative joint condition with the hallmark criteria of joint pain, articular cartilage degeneration, subchondral bone change, osteophyte production and loss of joint motion.[48] The fore fetlocks in athletic horses are probably the most commonly affected joint with this condition and therefore it is common bilaterally in geriatric horses, retired horses and exceptional athletes.

Recognition

History and presenting complaint Lameness is insidious in onset, often bilateral with one limb less and later affected.

Physical examination The gait is classically a stiff and shortened stride with an asymmetrical lameness. Lameness worsens on turns and after exercise. Joints are stiff, but may be minimally sore to forced flexion.

Laboratory examination Standard synovial fluid analysis is often normal.

Diagnostic confirmation The diagnosis is confirmed by the combination of clinical signs and radiographic evidence of osteophytes, subchondral bone sclerosis and narrowed joint space (Fig. 16.12). Extent of cartilage degeneration can only be assessed by direct visualization arthroscopically or by magnetic resonance imaging.

Treatment and prognosis

Therapeutic aims The goal of therapy is to relieve joint pain and improve joint use.

Therapy Treatment of osteoarthritis includes medical therapy and regular joint motion exercises, both passive and active. Surgical debridement of frayed cartilage and exposed bone as well as copious joint lavage have been described to alleviate pain in people, but are palliative only. Use of hyaluronan and glycosamine products systemically and intra-articularly is advised as needed. Intra-articular steroids can be used on a limited basis to provide comfort or short durations of athletic use. Non-steroidal anti-inflammatory medication, such as phenylbutazone, is commonly needed in these horses to permit their turnout or restricted athletic use. Chronic use of non-steroidal anti-inflammatory medication is common for osteoarthritis and can alleviate pain and permit activity. Chronic use can be associated with complications such as oral and gastrointestinal ulcers so it should be titrated to the lowest dose possible and used intermittently. Regular exercise on a limited basis is critical to maintain joint comfort and improve quality of life.

Many other adjunctive therapies, such as heat application, passive joint flexion, swimming, etc. have been anecdotally described as effective.

Prognosis The prognosis for resolution of osteoarthritis is poor because the cartilage degeneration is permanent. Disease-modifying drugs, such as interleukin-1 antagonists, are available for use in humans, but are costly and species specific.

Etiology and pathogenesis

Etiology Chronic joint 'wear and tear' associated with athletic careers is typical in the sport horse.

Fig. 16.12
Radiograph of a fetlock joint with osteoarthritis demonstrating osteophyte formation on the dorsal eminence of the first phalanx and proximal sesamoid bones and dorsomedial joint space narrowing.

Pathophysiology Healthy joints can develop osteoarthritis with time and use. A predisposition to earlier and more severe osteoarthritis may exist and be related to prior joint injury, conformation and use.

Epidemiology Osteoarthritis is seen more commonly in geriatric and career horses.

Prevention

Care of the joints during a horse's athletic career may help maintain joint health. Joint support wraps, judicious use of joint medications and immediate veterinary attention to joint injury are critical to containing the development and progression of osteoarthritis.

Fetlock annular ligament constriction

- Annular ligament constriction is usually secondary to chronic digital sheath synovitis or tendinitis.
- Treatment of the primary cause is often insufficient.
- Annular ligament resection may be done using arthroscopy.

The fetlock annular ligament is a ~3 cm wide fascial band spanning the abaxial ridges of the sesamoid bones and strategically located to support the superficial and deep flexor tendons as they course around the back of the fetlock joint. Synovia from the digital sheath reflects on the deep surface of the ligament. Damage to the flexor tendons can result in swelling and pressure within the sheath.

Recognition

History and presenting complaint The primary complaint is 'windpuffs' or swelling of the digital sheath. Lameness may or may not be evident initially.

Physical examination The clinical signs include pain, restricted range of fetlock motion and ischemia to the tissues within the fetlock canal (tunnel syndrome). Once present,

Fig. 16.13
Chronic low superficial digital flexor tendinitis with interference at the annular ligament.

lameness is persistent and worsens with exercise. Lameness is characterized by a decreased extension of the fetlock during weight bearing and a shortened caudal phase to the stride. In the most severe cases the horse will be reluctant to place the heel on the ground.

The pathognomonic clinical sign of fetlock annular ligament constriction is swelling of the palmar/plantar soft tissues of the distal limb around the fetlock and a characteristic observable proximal border of the annular ligament ('notching') caused by annular ligament constriction. Typically, there will be distension of the digital sheath of the superficial and deep flexor tendons proximal to the annular ligament and thickening of the superficial flexor tendon (tendinitis) (Fig. 16.13).

In Warmblood horses with fetlock annular ligament constriction, nine had thickening of the annular ligament and tenosynovitis, three were dominated by distension of the sheath, three had superficial digital flexor tendon injury and one had marked synovial sheath proliferation.[49] In race horses, superficial digital flexor tendinitis may be more commonly associated with fetlock annular ligament constriction.[50]

Special examination Regional diagnostic anesthesia usually results in improvement after a metacarpal block. Direct anesthesia of the digital sheath incompletely alleviates pain. Radiographic evaluation should be performed but is often normal unless infection is a cause. In 38 cases of annular ligament constriction, six horses had proximal sesamoid bone abnormality and 12 had bone enthesiophytes at the attachment of the annular ligament (insertion desmopathy).[51]

Laboratory examination Synovial fluid analysis of the sheath fluid and contrast radiography can be of value, but are usually limited in diagnostic value.

Diagnostic confirmation Diagnostic ultrasound confirms the diagnosis and permits the differentiation of structures involved, including thickening of the annual ligament (> 2 mm thick), tears of the deep flexor tendon, sheath adhesions and proliferative tenosynovitis.

Fig. 16.14
Open annular ligament transection revealing a chronic blunt end of the deep digital flexor tendon.

Treatment and prognosis

Therapeutic aims The goal of therapy is to reduce the constriction of the annular ligament by either decreasing sheath effusion or releasing the ligament or both.

Therapy Initial conservative treatment often includes an intrathecal injection of steroid to decrease sheath effusion. This is typically palliative and may further weaken or slow healing of injured tendinous structures. To relieve the constriction, the annular ligament is transected either percutaneously or endoscopically. Accessory ligament desmotomy of the superficial digital flexor tendon, tendon splitting, adhesiolysis and synovial resection to simultaneously treat tendinitis, tendon core lesions, adhesions and synovial proliferation, respectively, are indicated.[52–54] Limitations of open transection include incisional drainage and dehiscence, limited visibility as compared to tenoscopy, and greater soft tissue morbidity. Open transection may be necessary for tendon repair (Fig. 16.14).

Prognosis If the primary etiology is desmitis of the palmar or plantar annular ligament and is not accompanied by extensive changes in the tendon (bowed tendon), the prognosis is good (84% returned to performance).[55,56] The Standardbreds in which annular ligament desmotomy was performed in addition to other surgical procedures for tendinitis improved and were able to race.[50] In horses with synovial masses or adhesions that were resected endoscopically at the time of annular ligament resection, the prognosis for athletic soundness was 72%.[53]

Etiology and pathogenesis

Etiology Specific causes are usually trauma and/or infection (Fig. 16.15) and are associated with distal superficial digital flexor tendinitis (low bow) (see Fig. 16.14), fibrosis from wounds and tenosynovial adhesions and inflammation. The annular ligament may also be directly injured and thickened

(desmitis) with the same constricting result. The fetlock annular ligament constriction syndrome is reduction in pain-free movement of the fetlock due to the movement of the structures within the fetlock canal. The result is persistent lameness.

Pathophysiology Thickening of the ligament occurs through the process of fiber tearing and fibrosis.

Epidemiology

Desmitis of the fetlock annular ligament is diagnosed mainly in sport horses and less frequently in race horses and histologic changes suggest it is traumatic in origin.[55,57] Excessive use of the hindlimbs, such as in jumpers and cross-country competitors, puts horses at increased risk.

Prevention

Protection of fetlock support structures, such as with support wraps and heel extension shoes, particularly in the hindlimbs, may decrease risk of injury.

Pastern joint injuries

Intra-articular fractures

The pastern joint is uncommonly involved in articular fractures, in comparison to other joints. Articular chip fractures can occur from the proximal dorsal eminences of the second phalanx (P2) and the palmar/plantar intereminence of P2 (Fig. 16.16).

Recognition

History and presenting complaint These injuries are associated with acute onset of lameness and swelling at the pastern.

Physical examination Lameness located to the distal limb with regional nerve blocks and visible pastern swelling are often present.

Fig. 16.18
Surgical repair of a comminuted second phalanx fracture at 2 months postoperatively. Pastern arthrodesis and fracture fragment stabilization were performed simultaneously.

Diagnostic confirmation Source of the lameness can be confirmed with direct pastern joint block but this is often not necessary in acute cases. Fractures are confirmed on radiographs.

Treatment and prognosis

Therapeutic aims The goal of therapy is to eliminate or reduce the lameness due to the fracture. In many cases a pastern arthrodesis may ultimately be necessary for soundness.
Therapy The smaller articular fragments are retrievable surgically by direct arthrotomy (dorsally) or arthroscopy (palmar/plantar pouch). Unfortunately, degenerative joint disease is often a sequela because significant soft tissue injury is necessary to induce a fracture in such a stable joint. Disruption of the joint capsule frequently results in persistent thickening of the joint and chronic lameness due to osteoarthritis (high ringbone).

Immediate stabilization of the distal limb in splints or preferably casts is recommended to prevent collapse or displacement for comminuted fractures of the second phalanx (Fig. 16.17). Prognosis is dependent on the degree of displacement, particularly at the coffin joint. Surgical exposure of the coffin joint is not possible to aid in reduction, so prevention of distraction or displacement is strongly advised. Preferable treatment is surgical reduction, lag screw fixation and simultaneous plate arthrodesis of the pastern joint[58,59] (Fig. 16.18).

Caudal eminence traction fractures usually heal with a fibrous union. For athletic soundness, pastern arthrodesis is recommended either at the time of fracture or if soundness does not result with time. Reduction and direct lag screw fixation of the fragment is described, but osteoarthritis is often the sequela. Pastern arthrodesis is recommended (Fig. 16.19).
Prognosis With surgery, prognosis for pasture or breeding soundness is good to excellent (Fig. 16.20). Athletic soundness can be achieved with pastern arthrodesis if fractures did

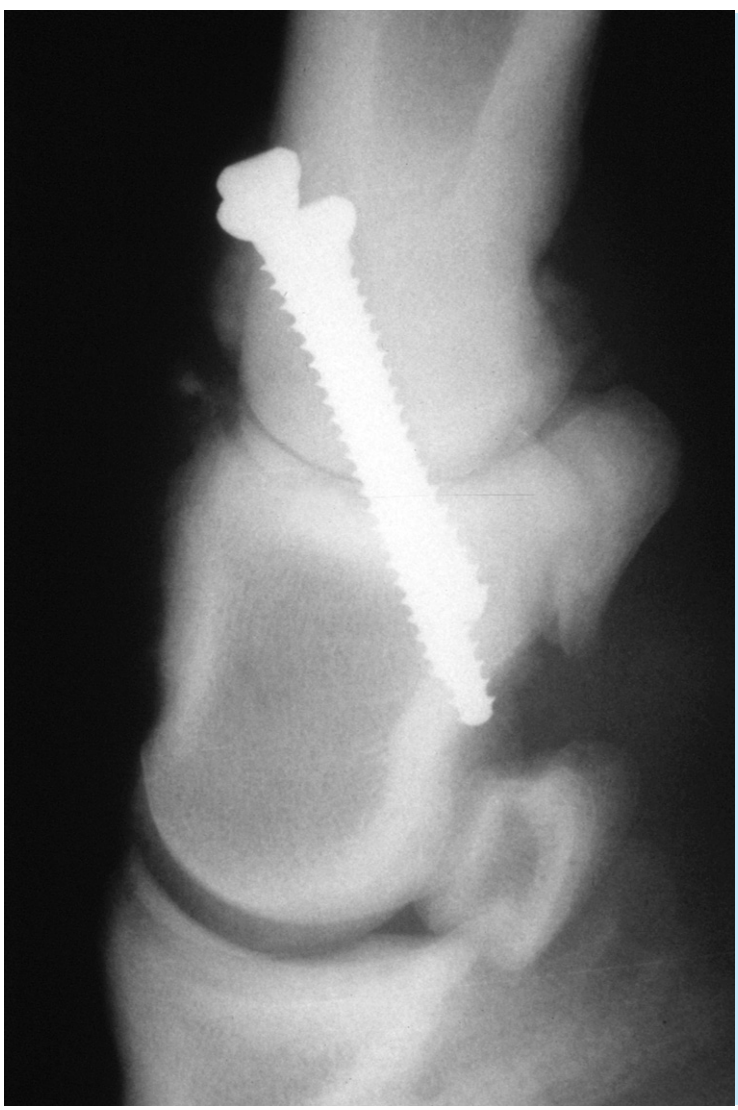

Fig. 16.19
Triple lag screw pastern arthrodesis as treatment for a caudal eminence fracture.

Fig. 16.20
Comminuted second phalanx surgical repair at 2 months postoperatively, demonstrating excellent healing and early use of the limb.

not enter the coffin joint. Prognosis for athletic soundness is guarded if the fracture entered the coffin joint. The prognosis for pasture or breeding soundness with conservative treatment is guarded to fair as horses remain lame for extended periods of time and healing is usually asymmetrical.

Etiology and pathogenesis

Etiology Fractures of the second phalanx can occur at exercise, typically when the horse is turning on a supporting limb.

Pathophysiology Pathophysiology is dependent on the type of second phalanx fracture. Larger caudal eminence fractures usually occur on the second phalanx, are often articular and can be biaxial. These fractures are distracted due to pull of the insertion of the collateral ligaments, flexor tendons and palmar annular ligaments.

Longitudinal and comminuted fractures of the second pastern bone are probably the most common fracture involving the pastern joint and can be catastrophic. Fractures of this short bone are high-energy injuries, usually from high-speed twists and turns with the foot planted. It is often reported that a loud 'pop' sound, like a gun going off, was heard and the horse was immediately non-weight bearing in the limb. Palpation can confirm the immediate pain, swelling and instability. Most P2 fractures are initiated at the pastern joint surface and spiral toward (incomplete) or into (complete) the distal interphalangeal joint (coffin joint). Fractures are often displaced and comminuted into five pieces in a classic pattern.[58]

Epidemiology

This injury may occur more commonly in Quarter Horses and jumpers, during slides, landings and turns.

Fig. 16.21
Pastern luxation with typical dorsal displacement.

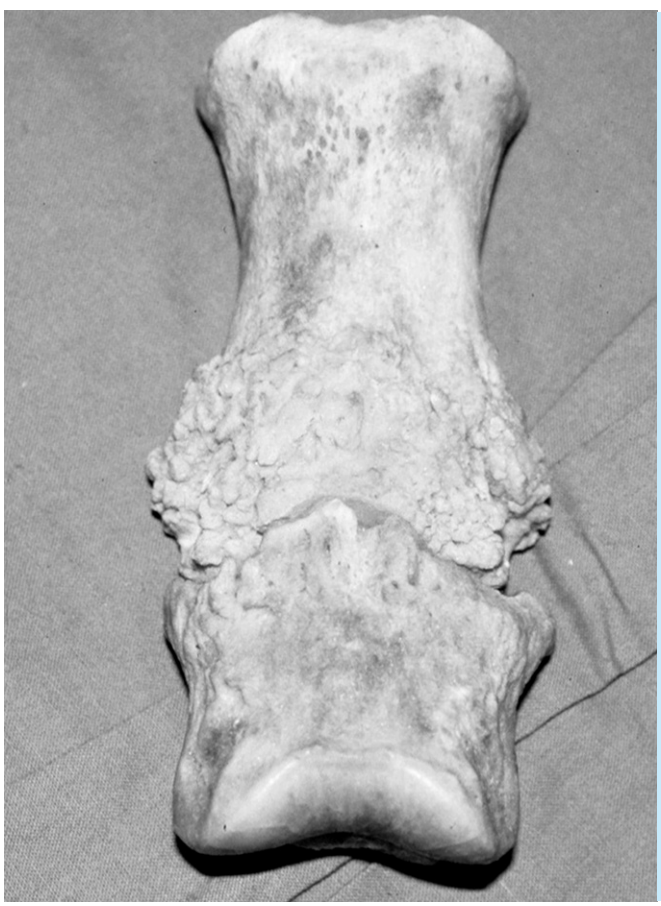

Fig. 16.22
Degenerative joint disease of the pastern joint demonstrating bony proliferation and joint destruction typical of ringbone.

Prevention

This injury is considered a sporadic and relatively random event that cannot be prevented.

Traumatic luxation/subluxation of the pastern joint

Traumatic luxation of the pastern joint usually occurs in front limbs with dorsal displacement of the first phalanx and is considered secondary to disruption of the insertion of the superficial digital flexor tendon and superficial distal sesamoidean ligament and palmar joint capsule[60] (Fig. 16.21). In the author's experience it is seen most commonly in event horses. This injury can appear similar to a fetlock breakdown injury in that the fetlock area drops upon weight bearing. However, closer observation reveals the distortion to the pastern with loading. The fetlock drops as the first phalanx moves dorsally. In complete luxations, similar complications can occur as with fetlock luxations. In subluxations, the pastern joint retains some stability although dorsal subluxation of the first phalanx is evident on palpation and radiograph.

Lameness depends on the degree of subluxation and disruption of the support structures of the pastern. Pastern arthrodesis is the treatment of choice as the outcome can be pasture and breeding soundness and possibly athletic soundness, depending on the extent of soft tissue injury to the flexor tendons. Use of strong implants and consideration of caudal joint wiring is recommended as the normal caudal support structures to the joint are disrupted. Repair should be approached in a similar manner to a fetlock luxation with loss of the caudal support structures.[22]

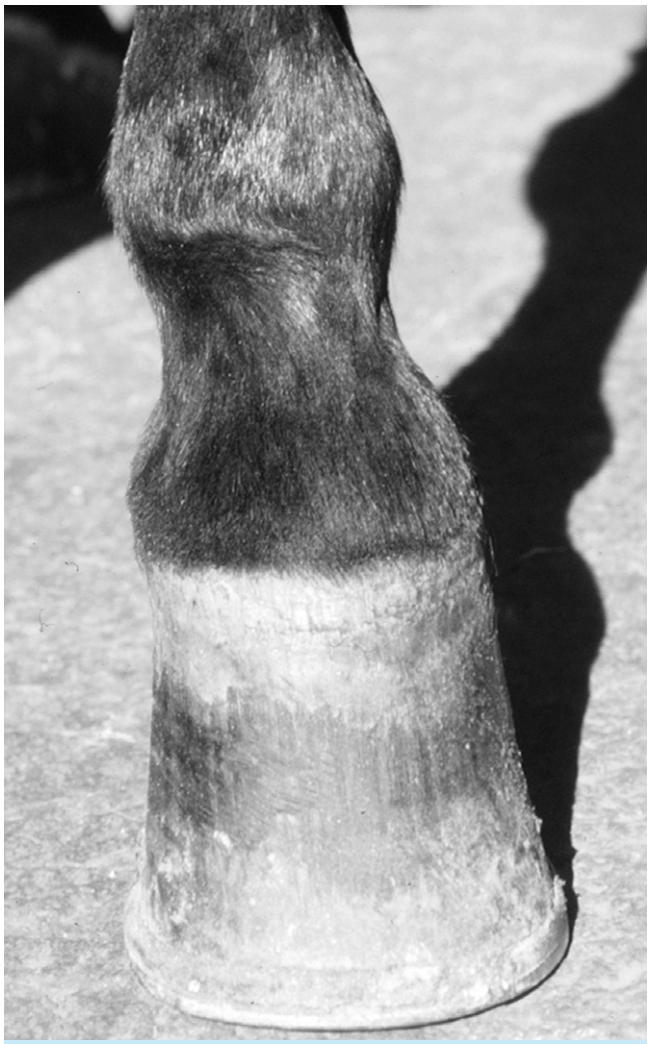

Fig. 16.23
Typical pastern joint appearance with high ringbone or pastern arthritis.

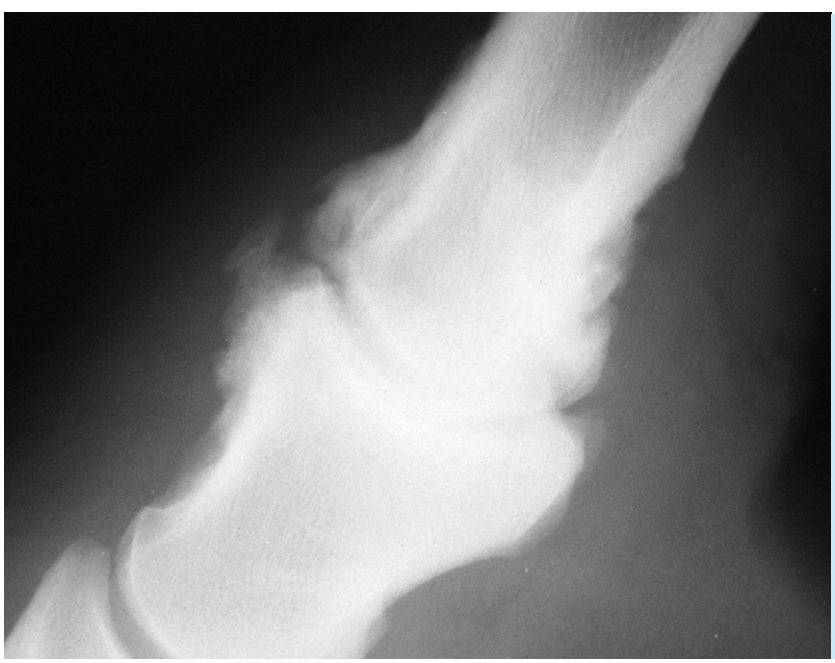

Fig. 16.24
Lateral radiograph of a pastern joint with arthritis demonstrating joint space narrowing and severe osteophytosis.

Pastern arthritis

Degenerative joint disease of the pastern joint is commonly called high ringbone or ringbone (Fig. 16.22).

Recognition

History and presenting complaint Horses are typically lame in one limb with a spontaneous onset. A traumatic etiology is often inferred. The lameness persists and pastern joint enlargement, although often overlooked, may be noted by the owner.

Physical examination Pastern arthritis has a classic outward appearance of an enlarged, thickened pastern joint (Fig. 16.23). Horses are lame often at the walk and are sore to flexion of the limb or joint.

Diagnostic confirmation The diagnosis is confirmed by radiography demonstrating osteophytes, narrowing of the joint space and subchondral bone sclerosis (Fig. 16.24).

Treatment and prognosis

Therapeutic aims The goal of therapy is to reduce pain and inflammation. To achieve athletic soundness, the joint must fuse.

Therapy Treatment with joint therapies is less successful in the pastern due to the greater degree of lameness, but non-steroidal anti-inflammatory medication improves movement and gait. Intra-articular steroids may improve comfort but often do not result in athletic soundness. Rest does not result in joint fusion. Resolution of lameness can be achieved with surgical pastern arthrodesis. Current procedures with plates and screws usually produce fusion within 6 months, even in older horses (Fig. 16.25). Assuming the pastern was the sole source of lameness, complete athletic soundness can be expected in > 80% of horses treated with surgical arthrodesis (Fig. 16.26). Current technique employs a combination of plates and screws for transarticular compression and stabilization.[61–64]

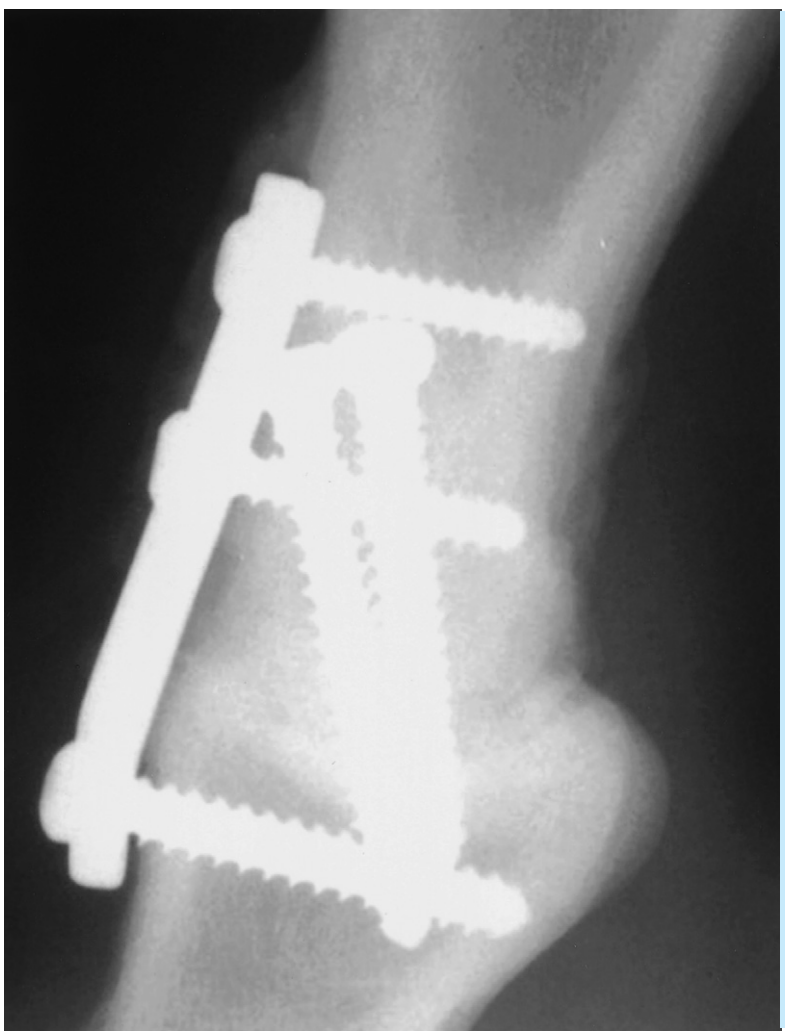

Fig. 16.25
Recommended surgical technique for pastern arthrodesis for adult horses is a single plate and two transarticular compression screws.

Fig. 16.26
Tennessee walking horse in full competition
2 years post-pastern arthrodesis of the right front. Pastern enlargement is minimal.

Fig. 16.27
Radiograph of pastern osteochondrosis demonstrating articular cysts and joint destruction.

Prognosis The prognosis is poor for soundness or fusion of the joint without surgical intervention. The pastern joint does not fuse on its own, even with extended time, in the author's experience.

Etiology and pathogenesis

Etiology Trauma and/or repetitive use are common inciting causes.
Pathophysiology Initial joint injury (fracture or sprain) results in joint inflammation and capsulitis. The process of persistent inflammation results in chronic joint destruction and degeneration.

Epidemiology

Although osteoarthritis of the pastern may not be as common as osteoarthritis of the fetlock, it is progressive and produces a greater degree of lameness in almost 100% of affected horses. Many horses with ringbone are lame at the walk and do not want to move around in pasture. Severe osteopenia of the affected limb and contralateral limb laminitis are complications of chronic ringbone.

Pastern osteochondrosis

Articular developmental orthopedic disease (osteochondrosis) occurs in the pastern joint.

Recognition

History and presenting complaint Lameness may be acute in onset and associated with heavy exercise or an incident, such as a fall, suggesting a traumatic etiology.

Fig. 16.28
Same horse as in Fig. 16.27 1 year after triple lag screw pastern arthrodesis, demonstrating complete bony fusion. The horse was sound for athletic use.

Physical examination Lameness and an enlarged pastern joint are the hallmark signs. Clinical signs occur most commonly in yearlings and become identical to osteoarthritis of the pastern (ringbone).

Diagnostic confirmation Radiographs demonstrate cysts on the articular surface and irregularity to the articular surface (Fig. 16.27). Osteophytes may not be present early on in the disease. The condition is often bilateral and contralateral radiographs are indicated before surgical treatment is considered.

Treatment and prognosis

Therapeutic aims The goal of therapy is to eliminate the lameness with joint fusion.

Therapy Preferable treatment is surgical arthrodesis[65] as has been described for pastern arthritis.

Prognosis In young horses, the possibility of full athletic soundness is excellent and fusion is relatively rapid (3–4 months) (Fig. 16.28). Left untreated, the joint will progress into osteoarthritis and lameness will persist.

Etiology and pathogenesis

Etiology Osteochondrosis is part of a developmental orthopedic disease complex.

Pathophysiology Endochondral ossification of articular cartilage is delayed or arrested, such that it forms abnormally. Articular cartilage flaps and cysts develop during growth, and joint pain and ultimately arthritis are a consequence.

Prevention

Although osteochondrosis has multifactorial risk factors, including high-energy diets, rapid growth and male gender, it is not possible to control the onset of clinical disease by controlling these factors. This is an active area of research.

CHAPTER 17

Metacarpus/metatarsus

Lance H. Bassage II

Dorsal metacarpal disease (the 'bucked shins' complex)

'Bucked shins' or dorsal metacarpal periostitis and dorsal cortical stress fractures of the third metacarpus (MC-III) are the two components of dorsal metacarpal disease (DMD). Over the last 2–3 decades, extensive investigation into the etiopathogenesis of the condition – including the role of the training regimen, track surface and shoeing techniques – has led to a far greater understanding of the syndrome of DMD and how to prevent it. However, despite these advances, 'bucked shins' and dorsal cortical stress fractures remain important problems in the racing industry.

- Common in young Thoroughbreds and Quarter Horses in early race training.
- Bilateral dorsal metacarpal swelling, heat and pain, with stiffness/soreness or 'choppy-gaited' lameness.
- Acute onset following a high-speed workout ('breeze') or first race.
- Treatment involves anti-inflammatory therapy, rest and controlled exercise, and modified training.
- Prevention involves modification of the training regimen.
- Prognosis is generally very good to excellent and recurrence is rare in skeletally mature horses.
- Horses that develop clinical 'bucked shins' are at risk for dorsal cortical stress fractures in the future.

Recognition

History and presenting complaint

Horses with 'bucked shins' present with an acute onset of bilateral soft tissue swelling, heat and sensitivity over the dorsal aspect of the metacarpus, with an associated lameness or 'stiffness' immediately after a high-speed workout ('breeze') or race. Very often this is the first race or first speed work for the horse at near-racing distances. In some horses there may be a more gradual onset of these signs, with a marked exacerbation following the first race or a longer 'breeze'. If training continues the lameness typically worsens considerably, as opposed to the horse 'warming out of it'. The signs of 'bucked shins' are generally so specific that most experienced trainers can make a reliable diagnosis.

Physical examination

Horses with 'bucked shins' exhibit variable degrees of soft tissue swelling, heat and sensitivity on palpation over the dorsal diaphyses of MC-III. When viewing the metacarpi from the lateral aspect there is often a distinct dorsal convexity. Firm digital pressure in this location will elicit a painful response. These signs are particularly pronounced in the acute stages, but after a period of rest and anti-inflammatory treatment there is generally considerable improvement. The exceptions are horses that have progressed to the chronic or 'recurrent' category and have developed a marked periosteal reaction along with chronic inflammation and associated soft tissue swelling. Less commonly, a more focal area of swelling may be present at some point along the dorsal diaphysis,[1]

which must be differentiated from a true stress fracture (see section below).

Lameness examination

Horses with acute 'bucked shins' typically exhibit a bilateral stiff or choppy forelimb gait at a trot (sometimes mimicking a foot or carpal lameness), but in those in which one metacarpus is more severely affected than the other, a distinct head nod may be evident. Lameness in these horses ranges from grade 1 to 3.[2] The most severely affected horses may acutely exhibit mild lameness at the walk. The severity of the lameness will vary greatly with the stage of the disease and the timing of the examination in relation to the last speed work.

Diagnostic confirmation

Diagnostic analgesia Diagnostic analgesia is generally not necessary to localize the source of pain in a horse with acute 'bucked shins'. High palmar analgesia (high palmar nerve block) with a dorsal ring block in the proximal metacarpus can be helpful in confirming the location of pain in those horses with subacute or chronic 'bucked shins'.

Nuclear scintigraphy Bone-phase (delayed-phase) nuclear scintigraphy classically reveals *diffuse* moderate-to-intense abnormal increased radiopharmaceutical uptake along the dorsal diaphyses of the affected MC-III[3] (Fig. 17.1).

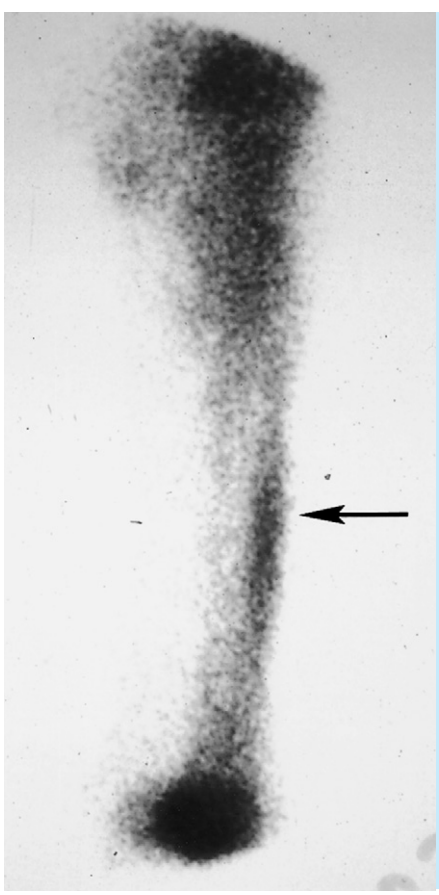

Fig. 17.1 Lateral bone-phase scintigraphic image of the right metacarpus of a 2-year-old Thoroughbred race horse with clinical 'bucked shins'. Notice the diffuse moderate-to-intense abnormal increased radiopharmaceutical uptake along the dorsal diaphysis of MC-III (arrow).

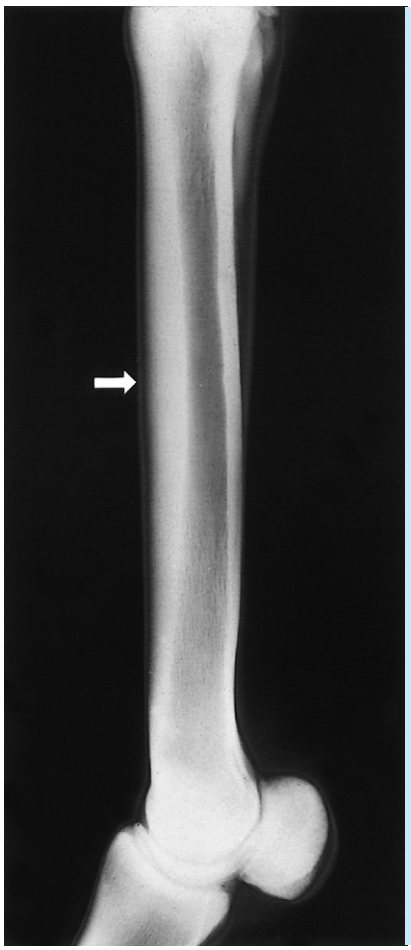

Fig. 17.2 Lateral radiograph of the left metacarpus of a 2-year-old Thoroughbred race horse with clinical 'bucked shins'. Notice the diffuse low-density periosteal proliferative reaction and subperiosteal osteolysis along the dorsal diaphysis of MC-III (arrow).

Radiography Radiographic findings vary with each case and the stage of disease. Radiographs in mildly affected horses or in the very early stages of the disease (subclinical) are often negative or equivocal for osseous abnormalities. In more severely affected horses diffuse subperiosteal osteolytic change in combination with smooth, low-density periosteal proliferative reaction is typically seen along the dorsal and dorsomedial diaphysis of MC-III (Fig. 17.2). High-detail radiographic or xeroradiographic films are superior for detecting the subtle abnormalities. Soft tissue swelling, when present, will also be evident radiographically in this location.

Thermography Thermography has recently been shown to be a valuable diagnostic aid for the detection of abnormalities in the metacarpi of racing Thoroughbreds, with up to 60% of 2 year olds in training exhibiting abnormal findings.[4]

Treatment and prognosis

Therapeutic aims

The goals of treatment for acute 'bucked shins' are two-fold: decrease or eliminate further excessive cyclic strains on MC-III and shift the balance from net bone resorption to net bone apposition, and reduce acute inflammation.

Therapy

Exercise restriction The degree of exercise restriction depends on several factors, of which the severity of clinical signs, in conjunction with radiographic and/or scintigraphic findings, is the most important.

Initially, all horses diagnosed with acute 'bucked shins' should be confined to a stall until soft tissue swelling and pain on palpation of the dorsum of MC-III have subsided. A program of controlled exercise can begin. In horses without extensive periosteal new bone formation or other severe radiographic changes, 2 weeks of stall rest with daily hand-walking (10–15 minutes once or twice a day) are initially recommended. Once horses are sound at a trot in-hand then formal training can commence, ideally employing a modified exercise protocol (see below).

Horses with moderate-to-marked periosteal reaction and/or subperiosteal osteolytic change, along with moderate-to-intense abnormal increased radiopharmaceutical uptake scintigraphically, require a more extended period of rest and controlled exercise. Generally, this encompasses 4 weeks of hand-walking, followed by 4–8 weeks of turnout exercise in a small paddock or 'shed row' exercise daily. The duration and extent of exercise restriction is modified based on the specifics of each case. Horses with chronic or recurrent 'bucked shins' (i.e. those that have had several acute episodes with or without an appropriate period of convalescence) should be allowed a total of 90–120 days' rest and in many instances they are simply turned out for the remainder of the season and training is resumed the following year.

Follow-up radiographic and scintigraphic examinations can help guide the recommendations for resumption of training in those cases where this is economically feasible.

Anti-inflammatory therapy Anti-inflammatory therapy should be initiated immediately in cases of acute 'bucked shins' and continue until signs of swelling and 'shin sensitivity' (pain) subside. Up to 30 minutes of cold hosing or icing, several times a day, along with bandaging, are generally effective. Anecdotally, application of a poultice or antiphlogistic dressing (e.g. Gel-o-cast®) for several days may also help decrease swelling.

The use of NSAIDs for their anti-inflammatory and analgesic effects in patients with inflammatory bone disorders is becoming increasingly controversial in light of the gathering body of evidence that these drugs, when used chronically at high doses, may impair bone healing in horses.[5] However, it is this author's opinion that a brief period (i.e. a few days) of NSAID treatment during the acute stage of 'bucked shins' is warranted in horses with moderate-to-severe signs. Phenylbutazone or flunixin meglumine at standard doses is generally effective. Long-term NSAID treatment is contraindicated, in this author's opinion, for the reasons noted above.

Modified training protocol The key to preventing 'bucked shins' is to stress the dorsal cortices of the developing metacarpi in such a way as to stimulate adaptation to the cyclic compressive loads under conditions that are similar to those experienced during a race, i.e. to train at racing speeds.[6] Traditional training strategies for flat-racing Thoroughbreds have employed a basic scheme of daily galloping exercise for extended distances (e.g. 1–2 miles) with speed work or 'breezes' at shorter distances (e.g. 2–6 furlongs) weekly to every third week. In immature (untrained) horses the timing (too infrequent) and distance (too long) of the high-speed work sets up a state of maladaptive remodeling in which bone resorption outpaces apposition and fibrous periosteal new bone predominates.[6] Eventually, this inferior bone develops microfractures and resulting inflammation, which manifests clinically as periostitis or 'bucked shins'.

To prevent or mitigate the potential for this vicious cycle, horses should be trained in such a way as to increase the frequency of high-strain cyclic compressive loading (high-speed exercise or 'breezes') and decrease the total distance at which they are galloped.[6] It is recommended that horses be worked at or near racing speed at least twice a week, initially at very short distances, for example 1 furlong. The distance of the speed work is increased gradually (e.g. adding 1 furlong every 1–2 weeks) and then as the horse is asked to go faster, the distance is reduced and the process repeated until the horse is conditioned to race. Throughout this process, daily galloping is limited,[6] for example to no more than 1 mile/day. Upon resumption of training, horses are continually monitored for signs of 'shin soreness', lameness or dorsal metacarpal swelling and exercise intensity should be modified accordingly.

Traditional or alternative therapies Over the course of time, seemingly endless 'traditional' therapies or essentially 'home remedies' have been promoted for treating 'bucked shins', as well as the many other inflammatory lesions and injuries of race horses. Many have gone by the wayside but a handful have persisted and remain in use today (see Table 17.1) and other 'alternative' therapies continue to arise on almost a daily basis. Unfortunately, many of these modalities have not undergone the necessary scientific scrutiny to enable rational conclusions regarding their efficacy. It is beyond the scope of this chapter to cover this subject in great detail but some of these therapies are summarized in Table 17.1.

Prognosis

The prognosis for the vast majority of horses with 'bucked shins' is generally very good if appropriate intervention is undertaken and adhered to. Recurrence is rare; however, a variable proportion of horses will experience repeated episodes or 'chronic' DMD. Horses not given adequate convalescence and those that have not had their training protocol modified (see above) are at high risk for recurrence. 'Bucked shins' is quite rare in older horses (> 4 years of age)[7] once the immature bone has remodeled and changed its inertial properties in response to the demands of high-speed exercise. However, horses that have experienced clinical 'bucked shins' as 2 or 3 year olds are in the high-risk group for dorsal cortical stress fractures (see section below).[8]

Table 17.1 Traditional and alternative therapies for metacarpal injuries

Modality	Technique	Rationale	Scientific support?	Comments
'Paints'	Topical application of a rubefacient liquid. (Numerous products and mixtures exist.)	Topical counterirritation to create hyperemia, which facilitates healing.	None for treating periostitis.	A reduction in soft tissue swelling is primarily attributable to the associated massage and bandaging.
'Blisters'	Topical application of a vesicant (agent causing cutaneous vesicles). As with 'paints', numerous products exist.	Potent counterirritation, creating deep hyperemia. Creates acute inflammation within chronically inflamed tissues to accelerate healing.	None for treating periostitis.	Any actual benefit is derived from the extended period of enforced rest, which traditionally accompanies 'blistering'.
'Pin firing'	Thermocautery: cutaneous application of a hot metallic rod or probe in multiple sites creating focal burns of varying depth.	A severe form of counterirritation.	None for treating periostitis.	As with 'blisters', the enforced rest is the primary benefit of 'pin firing'.
'Freeze firing'	Cryotherapy: cutaneous application of a liquid nitrogen-cooled metallic probe in multiple sites (similar to hot iron firing).	Method to create long-lasting local analgesia. Many practitioners consider this to be another method of creating counterirritation as well.	Scientific data support cryotherapy as having analgesic effects under certain circumstances. As with the above modalities, there is no evidence that counterirritation (if created) facilitates healing of periostitis.	Analgesia to the degree needed to mitigate that associated with 'bucked shins' is easily achieved using ice, cold water and NSAIDs. Analgesia to enable continued training is of questionable merit as the premature resumption of exercise is contraindicated.
Periosteal 'picking'	Percutaneous irritation of the periosteum in multiple sites using a hypodermic needle. (The periosteum is picked or scratched with the needle tip.)	A form of counterirritation involving direct periosteal trauma purported to accelerate healing of periosteal microfractures.	No specific studies on healing of metacarpal periostitis. In general, induced periosteal trauma does stimulate a proliferative response.	All reports on the efficacy of this treatment remain anecdotal. Further periosteal trauma is unnecessary in acute cases of 'bucked shins'.
Blood injection	Injection of an autogenous blood sample subcutaneously/ supraperiosteally in the dorsal metacarpus.	Another variation on counterirritation. Purported to accelerate healing.	None for treating periostitis.	All reports on the efficacy of this treatment remain anecdotal.
Extracorporeal shockwave therapy	Application of high-frequency shockwave energy along the dorsal metacarpus using a customized handpiece or probe.	A form of deep counterirritation purported to accelerate bone healing.	No *controlled* studies for treatment of periostitis in horses. Increasing anecdotal evidence suggests this modality *may* have a positive effect on bone healing.	Further 'stimulation' is unnecessary for the healing of acute periostitis. This modality may have merit for treating chronic DMD/stress fractures, but further investigation is needed.

Etiology and pathophysiology

The reader is referred to the chapter on stress-induced bone disease and maladaptive remodeling syndromes (Chapter 7) for a detailed discussion of this topic.

Epidemiology

Historically, DMD and, more specifically, 'bucked shins' have been and continue to be an extremely common problem in young flat-racing horses in early training. In the US, a prevalence of 65–70% in Thoroughbreds has been reported[12,13] and in Australia the prevalence has been estimated at 42–80%.[14–16] Similarly, estimates of 5–50% have been given for the prevalence in racing Quarter horses in the US.[17] DMD also affects racing Arabians. In contrast, the incidence of DMD is comparatively low in the UK, with an estimate of 17% in young Thoroughbreds in one large study.[10] This difference could be attributed to a number of variables, but differences in training surface (predominantly grass in the UK and predominantly dirt in the US) are regarded by many to be a primary factor.[9]

In stark contrast is the very low incidence of DMD in Standardbred race horses.[12] This has been attributed to differences in speed and gait between Standardbreds and Thoroughbreds, which result in different strains imposed on MC-III, and not to an inherent difference in bone material properties between the breeds.[18]

Prevention

The most effective way to prevent or decrease the incidence of 'bucked shins' is to modify the training scheme as outlined previously (see under Therapy). Essentially, this involves decreasing the daily distance worked at a gallop and increasing the frequency of short intervals of high-speed work or 'breezes'. The distance of the speed work is initially very short and is increased gradually.

Different training surfaces may also affect the incidence of 'bucked shins'. Training on wood chip-based surfaces or grass appears to be superior to the traditional dirt of most tracks in the US.[9,10] For example, in one 2-year study of Thoroughbred race horses, 55.8% of those trained on dirt experienced 'bucked shins' compared to only 26.1% of those trained on a wood chip-based surface.[9] This study did not rigidly control for differences in training methods, however.

Prevention also involves close monitoring of the horse for signs of impending shin problems. Along with physical examination for shin soreness, thermography and scintigraphy are useful imaging modalities for screening high-risk horses. In one study, pre-race detection using physical examination to screen horses for signs of DMD resulted in reduction in post-race diagnoses of lameness attributable to DMD, and more predictable race results, on Thoroughbred tracks in Australia.[11]

Dorsal cortical stress fractures of MC-III ('saucer fractures', metacarpal fatigue fractures)

- Fatigue fractures seen in racing Thoroughbreds, Quarter Horses and Arabians.
- Horses experiencing previous 'bucked shins' are at high risk.
- Short, oblique, intracortical fracture seen most commonly in the mid-diaphysis of the left MC-III (in Thoroughbreds in the US).
- Acute onset of moderate-to-severe lameness following high-speed work ('breeze') or a race.
- Fractures are often slow to heal and chronic or recurrent fractures are common if initially undiagnosed or mismanaged.
- Surgical treatment is preferred for the majority of fractures and involves osteostixis, screw fixation or a combination of the two.
- Prognosis is generally very good for return to racing.
- New or recurrent fractures develop on occasion.

Recognition

History and presenting complaint

Horses with an acute dorsal cortical stress fracture of MC-III typically exhibit a moderate-to-severe lameness immediately following high-speed work ('breeze') or a race. Less commonly, the lameness will not be evident until several hours after the horse has 'cooled out'. Acutely, these horses are too lame to continue training. There is almost invariably a focal area of soft tissue swelling, focal periosteal irregularity and sensitivity at the fracture site along the dorsal aspect of MC-III.

Some horses have a history of low-grade, chronic or intermittent lameness on the affected limb for several weeks prior to the acute onset of a more severe lameness once overt fracture has occurred. Another subset develops signs of acute fracture upon resumption of training after a brief period of lay-up (a few to several weeks) for an unrelated illness or injury.

Some horses may become sound enough to train or even race after extended rest, but continue to be plagued by recurrent lameness and poor performance. This is a common scenario for those with chronic stress fractures that have gone undiagnosed. Almost all horses with dorsal cortical stress fractures of MC-III will have a history of clinical 'bucked shins' in the 6–12 months preceding the fracture.[19]

Physical examination

For horses with acute fracture, physical examination will classically reveal a focal area of soft tissue swelling along the dorsum of the metacarpus at the site of the fracture, with a corresponding bony 'knot' or periosteal irregularity (hard swelling or exostosis) along the dorsal or dorsolateral diaphysis of MC-III. Firm digital pressure at the fracture site will consistently elicit a painful response. These signs are less dramatic in horses with chronic or subacute fractures. Horses with multiple fractures may have signs more suggestive of 'bucked shins' (i.e. diffuse pain and swelling along the diaphysis). Fractures are almost always unilateral in Thoroughbreds (in contrast to 'bucked shins') and involve predominantly the left forelimb in the US.[20–23] Bilateral fractures occur, but are rare.

Lameness examination Acutely, horses exhibit a moderate-to-severe lameness on the affected limb, which is typically grade 3–4.[2] Many are lame at a walk and all are profoundly lame at a trot. With a brief period of rest (a few days to a few weeks), horses generally walk comfortably but exhibit a mild-to-moderate lameness at a trot in-hand (grade 2–3). Horses with chronic fractures may exhibit only mild lameness at a trot in-hand. Firm pressure applied over the fracture site will exacerbate the lameness in most acute and subacute cases.

Diagnostic confirmation

Diagnostic analgesia Diagnostic analgesia is rarely necessary to localize the source of lameness in horses with acute and subacute dorsal cortical stress fracture of MC-III (owing to the specificity of clinical signs) and in fact, it is arguably contraindicated in these horses. Diagnostic analgesia *can* be useful for this purpose in horses with chronic fractures when clinical signs are less specific. High palmar analgesia (a 'high palmar block') will be positive.

Scintigraphy Bone-phase (delayed-phase) nuclear scintigraphy will reveal a *focal* (or multifocal in horses with multiple fractures) area of moderate-to-intense abnormal increased radiopharmaceutical uptake in the dorsal diaphysis of the affected MC-III in acute and subacute cases (Fig. 17.3). The intensity of radiopharmaceutical uptake will be less intense in chronic cases and will vary with the time course of the injury.[3]

Radiography The classic radiographic abnormality is a short, oblique intracortical (unicortical) fracture line in the dorsal or dorsolateral cortex of MC-III (Fig. 17.4). Most commonly the fractures are diaphyseal and are oriented dorsodistal to palmaroproximal at a 30–45° angle with the dorsal cortex. Most extend to the junction of the middle and palmar third of the dorsal cortical width and do not enter the medullary cavity. Occasionally, a complete fracture will extend proximodorsally out through the dorsal cortex (a true 'saucer fracture'). Metaphyseal fractures, those that begin and propagate in a dorsoproximal-to-palmarodistal direction, and those that enter the medullary cavity are less common.

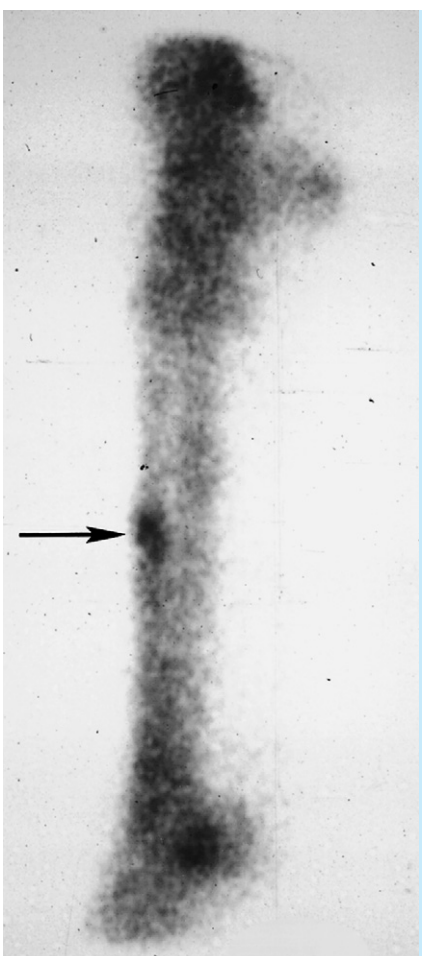

Fig. 17.3 Lateral bone-phase scintigraphic image of the left metacarpus of a 3-year-old Thoroughbred race horse with a dorsal cortical stress fracture of MC-III. Notice the focal area of moderately intense abnormal increased radiopharmaceutical uptake in the dorsal cortex (arrow).

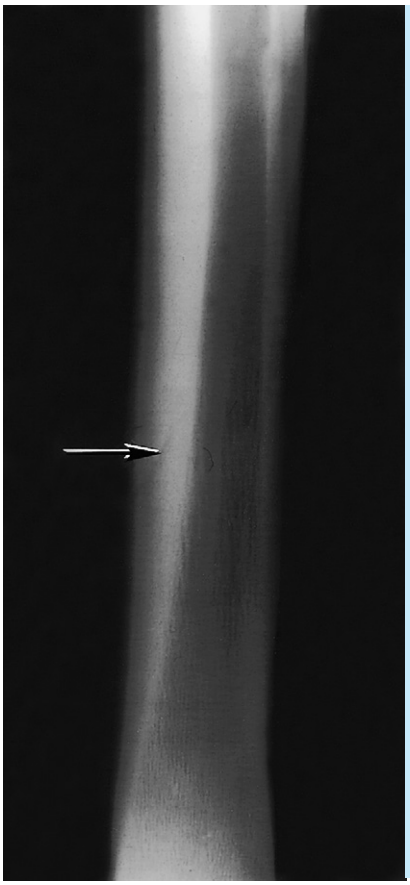

Fig. 17.4 Lateral radiograph of the left metacarpus of a 3-year-old Thoroughbred with a typical dorsal cortical stress fracture (arrow).

A full series of radiographs (four views: lateral, dorsopalmar, DMPLO and DLPMO) of the entire MC-III should be taken. Multiple fractures are sometimes present. In rare cases fracture lines may propagate or radiate away from the primary fracture site.[24] The majority of fractures are oriented in a frontal or near-frontal plane, but occasionally sagittally oriented fractures are seen.[25] Variable degrees of periosteal and endosteal callus may be present, as will soft tissue swelling and more diffuse osteolytic and proliferative periosteal reaction associated with previous 'bucked shins' in many horses.

Radiographs may be negative in acute cases. As with other stress fractures, high-detail radiographic films or xeroradiographs are advantageous for detecting subtle cortical abnormalities. When initial radiographs are negative or have equivocal findings, and clinical signs and/or scintigraphic findings are highly suggestive of stress fracture, follow-up radiographs should be taken in 7–10 days.

Treatment and prognosis

Therapeutic aims

The primary goal of treatment for dorsal cortical stress fractures of MC-III is to promote fracture healing and, although uncommon, minimize the potential for catastrophic fracture.

Therapy

Complete cessation of exercise (stall confinement) and anti-inflammatory treatment are the initial steps in the immediate postfracture period. A light padded bandage and local cold therapy (hosing/icing as previously described), along with NSAID treatment for a few days, are helpful to reduce soft tissue swelling and improve comfort in the acute phase.

Non-surgical management There is debate among clinicians regarding the merits of surgical and non-surgical management of dorsal cortical stress fractures of MC-III. These fractures are notorious for being slow to heal or for following an unpredictable course between horses.[12,19] Fractures in younger horses (2 and 3 year olds), those that enter the medullary cavity or that involve the metaphyseal regions are the most likely to heal expediently without surgical intervention. In general, this involves a period of 3–4 months of controlled exercise; however, it is not unusual for some fractures to require 4–6 months or longer for satisfactory healing.[26]

When non-surgical management is chosen, 4–6 weeks of stall confinement with daily hand-walking is recommended. This is followed by 6–8 weeks of controlled exercise in the form of small paddock turnout or very light jogging. Some form of controlled exercise is important to stimulate remodeling and fracture healing.[20,21] Complete cessation of exercise for a prolonged period (e.g. long-term stall confinement) favors the development of a chronic fracture (i.e. a delayed or non-union).

Follow-up radiographs should be taken every 4–6 weeks to assess healing before increasing the intensity of exercise or for determining whether surgical intervention is warranted (to overcome delayed healing). Follow-up scintigraphic scans can also help in making these decisions.[3] A radiographically visible fracture exhibiting low or diminishing scintigraphic activity would warrant strong consideration as a candidate for surgery.

Surgical management With the above exceptions, the majority of horses with acute dorsal cortical stress fractures of MC-III, and *all* horses with chronic fractures, are candidates for surgical intervention. Surgical treatment stimulates healing, thereby assuring a more rapid and predictable convalescence, and in the hands of an experienced surgeon carries a low rate of complications.

Surgery involves either osteostixis (fenestration), screw fixation (either positional or compression) or a combination of the two. One clear disadvantage of screw fixation over osteostixis alone is the need for a second surgical procedure to remove the screw. For any technique, the procedure can be performed with the horse under general anesthesia or standing under sedation and using local anesthesia (high palmar analgesia with a dorsal ring block). This author prefers sedation and local anesthesia unless the temperament of the horse is exceptionally fractious. There is a slight increase in risk for non-catastrophic complications (e.g. contamination/infection or drill bit or tap breakage if the horse moves unpredictably), but the risk of catastrophic fracture during recovery, although rare, and other potential anesthetic-related problems is eliminated and the overall length of the procedure is minimized.

The surgical approach is similar with any method, although if just a single screw is being placed some surgeons elect to perform this through a small stab incision. After routine aseptic preparation and draping, the fracture should be localized using radiopaque markers. (In many cases it is not possible to accurately identify the fracture simply through surgical exposure and periosteal elevation.) A row of stainless steel skin staples or hypodermic needles inserted perpendicular to the skin is placed along the dorsal metacarpus in the region of the fracture and a lateral (or slightly oblique if appropriate) radiograph is taken.

Osteostixis A 4–6 cm longitudinal incision is created between the digital extensor tendons, centered over the fracture, and extended through all tissues, including the periosteum, in a single cut. Self-retaining retractors (Gelpi, sharp Weitlaner) are used to maintain exposure and the periosteum is elevated. Four to six holes in a diamond pattern are then drilled across the fracture line perpendicular to the long axis of MC-III and entering the medullary cavity, using the preplaced markers as a guide. It is appropriate to monitor hole placement radiographically and therefore a radiograph should be taken after the first hole is drilled to ensure proper location. Successive holes are then drilled using the first hole as a reference point.

Drill bit preference varies with surgeon but 2.5–3.5 mm diameter bits are appropriate. Smaller bits (e.g. 2.0 mm) are more easily broken in the standing patient and larger holes may unnecessarily weaken the bone, as does an excessive number of holes.[27] Distance between holes should be kept at approximately 1.0 cm. A large number of holes placed close together can result in sequestrum formation or resorption of a core of bone or significantly weaken MC-III. Copious lavage during drilling, and frequent cleaning of the bit, are important to minimize the potential for the bit to break. After final radiographic confirmation of adequate hole placement the extensor tendons, subcutaneous fascia and skin are closed routinely in separate layers and a padded bandage is applied.

Horses are confined to a box stall for a total of 4–6 weeks following surgery. Skin sutures are removed 12–14 days postoperatively, at which time daily hand-walking exercise should commence. A bandage is maintained for 2–3 weeks after surgery. After this period of stall confinement and hand-walking, horses are allowed daily turnout exercise in a small paddock for 4 weeks. If at that point follow-up radiographs reveal good progression of healing, daily light jogging exercise can begin. Harder training should not commence until fractures have sufficiently healed radiographically. Drill holes may persist radiographically for many months (beyond the point of fracture healing), even while horses are training at speed. Based on studies in other species[28] and on clinical observation in horses,[21] it is assumed that these holes should no longer act as stress risers by that stage.

Osteostixis is believed to accelerate or promote healing by facilitating access of mesenchymal cells and other osteogenic medullary elements to the fracture line.[7,29] The 'cores' of new bone that form across the fracture line may act to stabilize the fracture and further promote healing.[30] Osteostixis may also

stimulate fracture healing through activation of the 'regional acceleratory phenomenon'.[31]

Screw fixation If osteostixis is to be employed along with screw placement, the surgical approach is identical to that described above. If a single screw is being used without osteostixis a smaller (~1.0 cm) 'stab' incision can be used. A 3.5 or 4.5 mm ASIF cortical screw is appropriate. Regardless of the technique, either compression ('lag screw') or positional ('neutral'), screws are placed in a unicortical manner. Transcortical screws that engage the palmar cortex are contraindicated and no longer recommended, as they are associated with a higher incidence of osteolysis around the implant and implant-associated pain,[12] as well as fracture and the risk of suspensory ligament damage during placement.[32]

Unicortical screws placed in lag fashion to create compression provide the greatest degree of stability, but the technique is challenging given the width of the fragment/cortex. Standard ASIF techniques are employed and great care is required to ensure adequate position and depth of the glide hole. Once the glide hole is created the pilot hole is drilled and tapped, the hole is countersunk and a screw of appropriate length is inserted. Screws should be placed as close to perpendicular to the fracture line as possible. For positional screw placement the technique is similar but a glide hole is not created. Osteostixis, if employed, is then performed as previously described and the incision is closed routinely (skin sutures may only be necessary for smaller stab incisions).

Bandaging and initial aftercare are similar to that described for osteostixis. Screw removal is usually performed between 2 and 3 months after surgery. Proponents of the combination of a positional screw and osteostixis feel that 2 months is generally adequate.[20] The decision for screw removal is based on adequate progression of healing on follow-up radiographs. Screws are removed with the horse standing and using sedation and local anesthesia. An additional period of controlled exercise is recommended before resuming training following screw removal. This period varies from 2 to 8 weeks.[20,33] Unicortical screws in the dorsal cortex of MC-III do not cause pain in all horses upon resumption of training and return to racing.[32] However, screw removal in the early postoperative phase (i.e. at the 2–3 month point) obviates the need to take the horse out of training if pain develops and it eliminates the screw being implicated as the cause for any number of unrelated problems in the future.

The benefits of interfragmentary screw compression ('lag screw' technique) in fracture healing are quite clear and well understood. The mechanisms by which a neutral or positional screw acts specifically to promote or accelerate healing of stress fractures of the dorsal cortex of MC-III remain incompletely understood. In a recent uncontrolled study,[20] dorsal cortical stress fractures of MC-III treated surgically by a combination of screw fixation using a positional (non-compression) screw and osteostixis were reported to heal faster (95% of fractures healed in 2 months) than fractures treated with osteostixis alone (3–4 months for radiographic healing).[21,23] Differences in postoperative exercise regimens between studies may have influenced the results, but interfragmentary stabilization and the 'regional acceleratory phenomenon' have been proposed as mechanisms by which screws facilitate fracture healing over osteostixis alone.[20]

Prognosis

The prognosis for horses to return to racing following healing of dorsal cortical stress fractures of MC-III is generally very good. Eighty-two to 89% of Thoroughbreds in the US returned to race at least once following osteostixis.[21–23] One report on the outcome following screw fixation and osteostixis in Thoroughbreds indicated that 94% raced at least once postoperatively.[20] The majority of horses in all studies returned to compete at their prefracture levels.

A small percentage of horses experience repeat fracture or new fractures upon resumption of training and racing, regardless of treatment modality.[20,21] Recurrent fractures presumably result from inadequate healing (i.e. delayed union) and this may occur up to a year or more following treatment and return to training. New fractures developing at the site of an osteostixis hole have been reported.[21] Development of new fractures may also be related to training methodology in these horses (see below). Catastrophic fracture upon resumption of training and racing, although uncommon, has also been reported in Thoroughbreds.[22]

Etiology and pathophysiology

Dorsal cortical stress fractures of MC-III are a classic example of fatigue fractures that result from failure of bone to adapt to accumulated high-strain cyclic loading.[34,35] The reader is referred to the chapter on stress-induced bone disease and maladaptive remodeling syndromes (Chapter 7) for a detailed discussion of this topic.

Epidemiology

See the previous section on 'bucked shins' for additional details of the epidemiology of DMD.

Almost all Thoroughbreds with dorsal cortical stress fractures of MC-III experience a previous episode of clinical 'bucked shins'[19] and the same observation has been made in Quarter horses.[1] It has been estimated from older studies that 10–15% of Thoroughbreds which develop 'bucked shins' will go on to experience a true stress fracture in 6–12 months.[12,19] Therefore, this subgroup of DMD cases in Thoroughbreds is slightly older than the 'bucked shins' group, typically 3–5 years of age, but even horses older than 5 occasionally present with this injury. In contrast, dorsal metacarpal stress fractures in Quarter horses are seen predominantly in 2 year olds.[1]

In Thoroughbreds, these fractures appear to be more common in males than females,[20–23] but whether this simply reflects a referral bias or a true physiologic difference between males and females remains incompletely understood.[21,36,37]

Fractures most commonly involve the left forelimb in Thoroughbreds in the US (72–91%).[20–22] This has been

attributed to increased strains on this limb as a result of the counterclockwise direction of racing in this country.

Prevention

The reader is referred to the discussion of DMD prevention under 'bucked shins' (previous section) for details on the role of training modification and altering training surfaces.

Prevention of stress fractures in horses with DMD also involves early detection of bone disease or the 'prefracture state'. In addition to a high index of suspicion that should be maintained for horses that have experienced an earlier episode of 'bucked shins', careful physical examination and the use of diagnostic imaging modalities such as nuclear scintigraphy and thermography to detect prefracture pathology should enable identification of horses at risk of impending fracture.

Condylar fractures (parasagittal or longitudinal fractures of the distal third metacarpus and metatarsus)

- Condylar fractures are high-speed injuries affecting race horses of all breeds.
- The lateral condyles in the forelimbs of young Thoroughbreds are most commonly affected.
- Condylar fractures are presented as an acute injury during or shortly after a race or workout.
- Horses are markedly lame and clinical signs are highly consistent with a fetlock injury.
- Surgical treatment involves interfragmentary screw compression.
- Some non-displaced fractures can be managed non-surgically with a favorable outcome.
- The prognosis for return to racing for most horses with non-displaced lateral condylar fractures is favorable.
- The prognosis for most horses with displaced lateral condylar fractures is guarded.
- Medial condylar fractures are associated with a significant risk for catastrophic fracture of the affected bone.
- Treatment of medial condylar fractures may necessitate supplemental internal fixation to mitigate catastrophic failure.
- The prognosis for future athletic soundness for most horses with medial condylar fractures is favorable if catastrophic fracture is avoided.

Condylar fractures are common high-speed injuries in race horses of all breeds.[38–43] However, they most commonly affect the lateral condyle of MC-III in Thoroughbreds[39,42,43] and are only rarely seen in non-race horses.

Fractures can involve the medial or lateral condyles. Lateral fractures are categorized as incomplete, complete/non-displaced or complete/displaced. Medial condylar fractures fall into three categories: 'short' (simple, sagittally oriented fractures involving only the distal metaphysis/diaphysis); 'spiral' (fractures that propagate proximally in a spiral configuration and remain a simple fracture); and 'Y fractures' (long sagittal fractures that abruptly change configuration or direction in the mid-diaphysis) (Fig. 17.5).

Recognition

History and presenting complaint

The classic presentation of a horse with a condylar fracture is an acute onset of moderate-to-severe lameness during or immediately after a race or high-speed work. In most cases the rider or driver is immediately aware that the horse has sustained an injury. In others, the horse successfully finishes the race or workout with lameness immediately obvious after pulling up (slowing down). Less commonly, the injury will not become apparent until several hours after the horse has 'cooled out' or even until the following day. Acutely, most horses exhibit lameness of varying degrees at a walk. Joint effusion and periarticular soft tissue swelling may also be noted.

The vast majority of horses are not able to continue training. On rare occasions a horse with a chronic fracture (generally short and incomplete) will be presented with a history of recurrent lameness and/or poor performance that is exacerbated with exercise. Some horses have a history of seemingly minor or low-grade 'soreness' on the affected limb or other concerns of an 'ankle problem', for several days or weeks prior to overt acute fracture (see discussion of pathophysiology below).

Physical examination

In the majority of horses with acute condylar fractures there is little difficulty identifying the location of the injury. Most horses have obvious heat and effusion of the involved fetlock joint and flexion will elicit a marked painful response. In horses with displaced lateral condylar fractures there is typically soft tissue swelling over the affected condyle and a noticeable deviation in the contour of the metaphysis. The same is true for horses with medial condylar fractures that have become displaced or have failed catastrophically in the diaphysis. (Open and/or unstable fractures in this category are common and are not a diagnostic challenge.)

Horses with chronic fractures (typically a non-displaced, short, lateral condylar fracture) tend to have less soft tissue swelling, but joint effusion and pain on lower limb ('fetlock') flexion persist, although the degree will vary from horse to horse.

Lameness examination

Radiographs should be taken *first* in all cases of suspected condylar fracture before proceeding with a formal lameness examination. Owing to the severity and relative specificity of the clinical signs, a full diagnostic lameness evaluation is generally unnecessary in these horses.

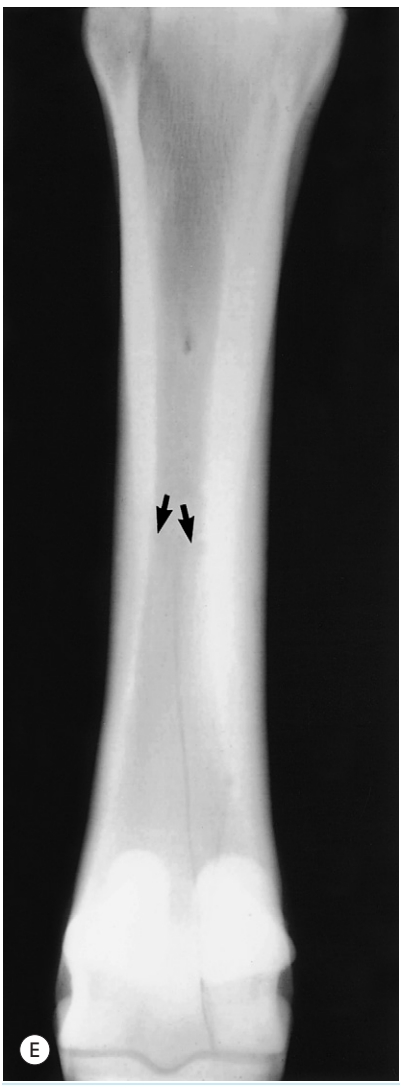

Fig. 17.5
Dorsal-palmar/plantar radiographs of the metacarpo/metatarsophalangeal joints and distal MC-III/MT-III of various horses depicting different configurations of condylar fracture. (A) Incomplete lateral condylar fracture. (B) Complete, non-displaced lateral condylar fracture. (C) Complete, displaced lateral condylar fracture. (D) Medial condylar fracture with spiral configuration. (E) Medial condylar fracture with mid-diaphyseal 'Y' configuration (arrow).

Fig. 17.6 (A) Routine dorsopalmar radiograph of the metacarpophalangeal joint of a horse with a complete, displaced condylar fracture of MC-III. (B) Flexed 125° dorsopalmar projection of the same joint revealing a comminuted fragment at the palmar aspect of the metacarpal condyle (arrow).

Acutely, the majority of horses with a condylar fracture exhibit mild-to-moderate lameness at a walk. Some exhibit limited weight bearing but generally after a few days of rest, bandaging and anti-inflammatory treatment, most will bear full weight and walk readily. In the early postfracture period these horses generally remain moderately to severely lame at a trot in-hand (grade 2–4 of 5). Horses with chronic, incomplete fractures typically exhibit mild-to-moderate lameness at a trot (grade 1–3 of 5). Lameness in horses with chronic displaced fractures is often quite severe as degenerative joint disease progresses.

Diagnostic confirmation

Diagnostic analgesia Diagnostic analgesia is rarely needed to localize the site of pain in horses with condylar fractures and is contraindicated in *all* horses with clinical signs typical of acute fracture given the risks for exacerbation of the injury (i.e. development of a complete or even catastrophic fracture). In the exceptional case of a horse with a chronic, incomplete or unicortical lateral condylar fracture[44] (a horse that has been able to continue some level of exercise or does not have a history of acute onset of marked lameness and joint effusion), a full lameness examination with diagnostic analgesia would be acceptable. In these horses a low palmar/plantar nerve block or intra-articular local anesthetic block of the fetlock joint will result in improvement of the lameness.

Scintigraphy Nuclear scintigraphy is rarely needed to assist in the diagnosis of condylar fracture. Nonetheless, condylar fractures are readily detected scintigraphically and occasionally are identified on scans of horses with acute lameness for which specific clinical signs are lacking or equivocal.

Scintigraphy is of greatest value in identifying chronic condylar fractures. Depending on the stage of disease (chronicity), these appear as focal areas of mild-to-intense abnormal increased radiopharmaceutical uptake in the distal metacarpus/metatarsus. Scintigraphic activity is often most intense in the palmar/plantar aspect of the condyle.

Radiography Four standard radiographic projections (lateral, dorsopalmar/plantar, DLPMO, DMPLO) of the involved fetlock are indicated for all cases of lateral condylar fracture. Ideally, these should include the full length of the metacarpus/metatarsus because on rare occasions fracture lines will extend proximally into the diaphysis. Radiographs of the full metacarpus/metatarsus are *mandatory* for all cases of medial condylar fracture given the propensity for these fractures to extend into the proximal diaphysis, and the concerns of mid-diaphyseal comminution and the associated potential for catastrophic fracture.[45]

A flexed dorsopalmar/plantar projection[46,47] is also recommended to evaluate the palmar/plantar aspect of the condyles for the presence of a comminuted fragment at the articular surface (Fig. 17.6). Similarly, the proximal sesamoid bones should be scrutinized for the presence of any associated fractures – in particular, axial fractures of the lateral proximal sesamoid, which are most commonly associated with displaced lateral condylar fractures[42,48] (Fig. 17.7). It is important to note the presence of any additional pathology such as dorsal P1 chip fractures (flexed lateral radiographs are beneficial here), so that these can be addressed at the time of surgery, or signs of degenerative joint disease so that their potential impact on the horse's prognosis can be appropriately considered.

Treatment and prognosis

Therapeutic aims

The goals in treating condylar fractures are to reduce healing time and minimize the potential for further degenerative changes in the affected joint. Optimal anatomic reconstruction of the articular surface and stabilization of the fracture

Fig. 17.7 Dorsopalmar radiograph of the metacarpophalangeal joint of a horse with a lateral condylar fracture and associated axial fracture of the lateral proximal sesamoid bone (arrow) (same case as in Fig. 17.6).

are the keys. When dealing with medial condylar fractures (and the rare lateral fracture that extends into the mid-diaphysis), prevention of a catastrophic fracture is also paramount.

Therapy

Emergency treatment Horses with acute condylar fractures should be confined strictly to a stall. The majority of non-displaced or incomplete lateral condylar fractures can be managed by coaptation with a firm, padded bandage pending definitive treatment (see below). Horses with displaced lateral condylar fractures are initially best managed by more rigid coaptation with the distal limb in a neutral or 'equinus' position (oriented such that the metacarpus/metatarsus and digit are in line). This can be accomplished with a dorsally applied splint and bandage that extends from the toe to just distal to the carpus or tarsus (such as a Kimzey splint®). This type of coaptation is important until the full extent of the injury can be assessed to rule out concurrent suspensory apparatus pathology and to prevent further fracture displacement and damage to the fetlock joint.

Horses with short medial condylar fractures should at least be managed with a rigid heavily padded bandage (such as a Robert-Jones bandage), with the addition of splints a prudent option. In horses with radiographically identifiable fracture lines in the mid-diaphysis, dorsally and laterally applied splints in the forelimb (extending to the elbow) or plantar and lateral splints in the hindlimb extending to the point of the hock are recommended. Rigid coaptation with a bandage and splints or application of a well-constructed full-limb cast should also be considered prior to transportation given the propensity for catastrophic failure.[42,45]

NSAIDs are administered as needed for analgesia.

Non-surgical management In certain cases of short, incomplete condylar fractures, particularly those in which economic considerations preclude surgery, non-surgical treatment can result in a good outcome.[39,42,49] The distal limb is kept in a bandage for 2–3 weeks to help minimize any soft tissue swelling and to provide some support. NSAIDs are administered only as needed to provide analgesia. Generally, the majority of horses in this category are quite comfortable within a few days to a week or so following the injury. Horses initially should have 1–2 months of strict stall rest, followed by another 1–2 months of stall confinement with daily hand-walking exercise. Follow-up radiographs are repeated 3 months from the time of fracture and if healing is progressing well, exercise in the form of small paddock turnout can begin. Under ideal circumstances, fractures heal in approximately 4 months.

The major disadvantage of non-surgical treatment is the tendency for fractures to exhibit delayed healing at the articular surface.[39,49,50] Resumption of training should not commence until fractures have completely healed and this may take up to 6 months or longer in some horses treated non-surgically. However, in a small percentage of horses a gap or defect in the subchondral bone may persist indefinitely well beyond the point at which the fracture has healed, which can complicate the decision on when to resume training.

Surgical treatment of lateral condylar fractures With the exceptions noted above, interfragmentary screw compression[33,51] is the treatment of choice for the majority of horses with lateral condylar fractures. Surgical treatment is imperative for all horses with displaced fractures, regardless of their intended future use. The severity of the degenerative joint disease that develops in horses with untreated displaced fractures, even within a few months, is crippling and horses that are not surgical candidates should be euthanized.

Surgery is performed with the horse in lateral recumbency under general anesthesia with the affected limb up. The limb is clipped and aseptically prepared from the foot to the carpus or tarsus and draped to allow access to the fetlock and distal metacarpus/metatarsus.

Non-displaced fractures are compressed and stabilized using 4.5 mm or 5.5 mm cortical screws placed in lag fashion through stab incisions. The most distal screw is inserted first and should be centered in the epicondylar fossa. Screw position should be monitored radiographically or fluoroscopically throughout the procedure. Countersinking is not necessary for this screw since the contour of the bone at this level accepts the head of the screw. Given the density of the trabecular bone in this location, it is not necessary for this screw to engage or exit the trans (medial) cortex to achieve adequate holding power and compression. This avoids having the tip of the screw impinging on or irritating the medial collateral ligament.

Subsequent screws are placed proximally at 1.5–2.0 cm intervals and in contrast to the most distal screw, these holes must be countersunk (Fig. 17.8). Care should be taken not to place a screw too close to the apex (proximal extent) of complete fractures since this may cause fragmentation when the screw is tightened. Arthroscopic exploration of the joint is optional (unless chip fractures or other lesions are present), but this does allow thorough evaluation, which may identify radiographically occult pathology.

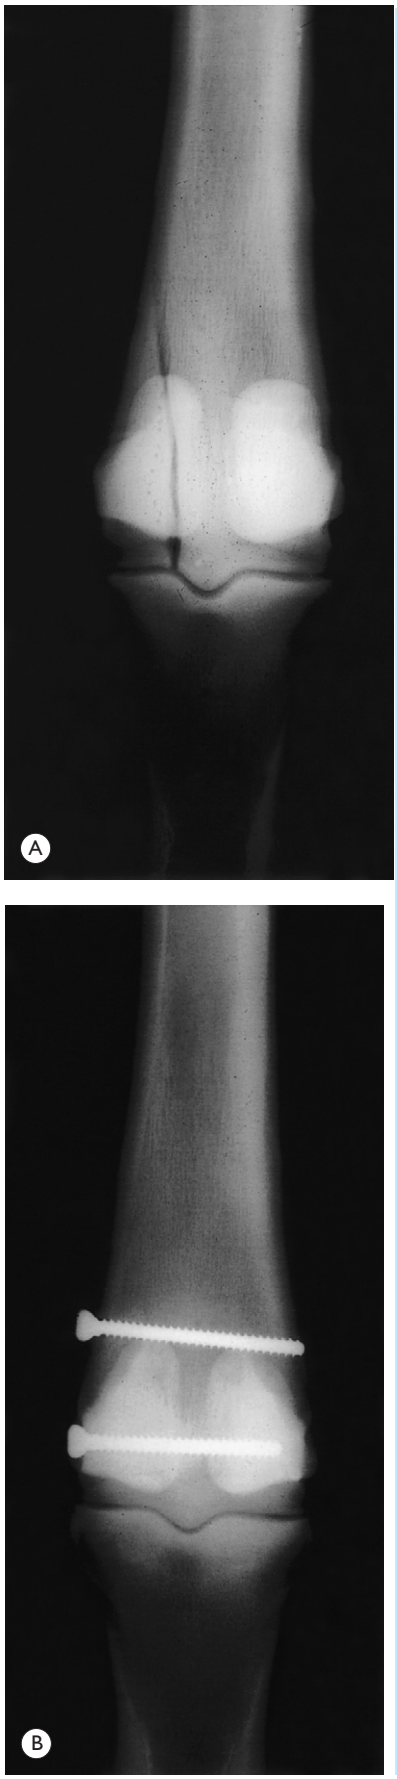

Fig. 17.8
(A) Preoperative dorsopalmar radiograph of the metacarpophalangeal joint of a horse with an incomplete lateral condylar fracture. (B) Postoperative radiograph following interfragmentary screw compression using 4.5 mm cortical screws in lag fashion.

Displaced lateral condylar fractures must be reduced prior to screw compression. Different techniques can be employed depending on individual preferences and the degree of displacement. If the fracture is not more than a few days old reduction can often be achieved under arthroscopic visualization while manipulating the limb and fragment. Alternatively, reduction can be monitored through a small incision near the apex of the fracture or through a small arthrotomy. Arthroscopy has the advantage of allowing thorough evaluation of the joint and some debridement of the fracture gap to facilitate reduction.

Fractures that are more chronic or any that require extensive debridement that cannot be accomplished arthroscopically must be reduced through a large dorsal arthrotomy. This incision is located over the fracture line and extends from the apex of the fracture to the distal insertion of the fetlock joint capsule on P1. Any blood clots, fibrin and bone fragments are cleaned from the fracture line and the fracture is then reduced.

Reduction is maintained with self-retaining bone reduction forceps. Alternatively, a 2 mm drill bit can be inserted through the fragment and into the parent bone to maintain reduction. Screws are inserted in a manner similar to that described for non-displaced fractures. Screw position and articular alignment are checked radiographically or fluoroscopically prior to closure and recovery from anesthesia. Failure to anatomically reconstruct the articular surface is an inexcusable technical error.

Stab incisions are closed with simple interrupted skin sutures using a 2-0 monofilament. Arthrotomies are closed in multiple layers, consisting of joint capsule/deep fascia, subcutaneous fascia and skin. A sterile dressing is applied to cover all incisions. Horses should be recovered from anesthesia in a half-limb fiberglass cast, although some surgeons do not customarily apply casts for horses with incomplete fractures. A customized compression boot (e.g. Farley boot®) is an alternative. Assistance during recovery in the form of head and tail ropes should be provided where feasible.

Casts or splints are removed within 24 hours of recovery and a firm, padded bandage is maintained for 2–3 weeks following surgery. NSAIDs are administered for a few days to provide analgesia and help decrease the inflammatory response in the joint. For the majority of horses antibiotics are limited to a single preoperative dose of an intravenous broad-spectrum antimicrobial or combination of antimicrobials. For horses undergoing an arthrotomy, antibiotic treatment is continued for 24–48 hours. Skin sutures are removed 10–14 days after surgery. Horses receive strict stall confinement for 1 month, followed by 1–2 months of stall rest with increasing daily hand-walking exercise. Follow-up radiographs are taken 2–3 months postoperatively and if healing is progressing satisfactorily, horses are allowed a minimum of 1–2 months of small paddock turnout before gradually resuming training.

Screw removal is not customarily recommended following repair of lateral condylar fractures. However, screw-associated pain in some horses upon resumption of high-speed exercise has historically been a concern. Subchondral

bone reaction ('subchondral stiffening') or collateral ligament irritation, associated with the most distal screw, have been proposed as possible causes.[52,53] Another possible explanation is simply pain and lameness associated with degenerative joint disease or from an unrelated injury, with the screw being implicated as the cause. In the author's experience, screw-associated pain is very rare. Surgeons that advocate screw removal generally do so between 3 and 4 months following surgery. Others remove screws only when there is strong reason to suspect them to be causing problems. In any situation, this can usually be accomplished with the horse standing under sedation and using local anesthesia. Screws are identified (using radiographs if necessary) and removed through stab incisions. An additional 2 months of rest and controlled exercise are recommended before resuming hard training.

Surgical treatment: medial condylar fractures 'Short' medial condylar fractures (sagittally oriented fractures that do not extend proximal to the distal diaphysis) are repaired in a manner similar to that described for non-displaced lateral condylar fractures.

Medial condylar fractures that extend proximally in a spiral configuration are approached through a long dorsal incision that splits the digital extensor tendons. The periosteum is elevated and the fracture line inspected for any signs of radiographically inapparent comminution or mid-diaphyseal divergence of fracture lines. The most distal screws are inserted through separate stab incisions (as above) and subsequent screws are inserted perpendicular to the fracture plane at 2.0–2.5 cm intervals through the long dorsal incision. Application of a dorsal or dorsolaterally positioned dynamic compression plate (DCP) is an alternative to help minimize the potential for catastrophic failure (see below).[54]

Care should be taken not to unnecessarily traumatize the splint bones, suspensory ligament or other soft tissues during drilling and tapping. Screw length and position should be monitored radiographically or fluoroscopically to ensure that they do not engage soft tissues or the splint bones. Similarly, screws that are placed through a fracture line can significantly weaken the bone and increase the risk for catastrophic fracture[51] and this should be avoided.

Long sagittally oriented fractures that exhibit mid-diaphyseal comminution or the so-called 'Y' configuration are at high risk for catastrophic failure, either preoperatively or in the early postoperative period. Fractures of this nature are almost exclusively seen in MT-III.[42,45] However, because of the potential adverse consequences, all medial condylar fractures should be regarded as having the possibility of catastrophic failure. These fractures should be treated with a combination of interfragmentary screw compression followed by application of a broad DCP that spans the length of MT-III.

Screws that compress the sagittal (distal) component are inserted through a combination of stab incisions (for the condylar screws) and through the long dorsal incision as previously described. Alternatively, plate screws inserted in lag fashion can be used to compress the fracture, although they will not be absolutely perpendicular to the fracture plane. A 4.5 mm, broad DCP of appropriate length is then applied along the dorsal or dorsolateral aspect of the bone, using 4.5 mm or 5.5 mm cortical screws and routine ASIF techniques. Again, care should be taken not to place a screw through a fracture line.

The dorsal incision is closed routinely in multiple layers and stab incisions are closed with skin sutures. Unless a pool recovery system is available, horses with medial condylar fractures that have not been plated should be recovered from anesthesia in a full-limb cast and recovery should be assisted. A cast is also prudent for cases in which plates have been applied but the risks of a full-limb cast, particularly in the hindlimbs, should be taken into consideration.

Postoperative care and exercise restriction are similar to that for lateral condylar fractures with a few exceptions. Hand-walking exercise does not begin until 2 months postoperatively in cases of spiral or long sagittal fracture. Antimicrobial treatment may be extended for an additional 24–48 hours in cases of plate application.

Horses that are intended to resume athletic careers must have plates and any independent screws placed in a dorsal-palmar/plantar direction removed prior to resumption of training. This is generally performed 3–4 months postoperatively under local anesthesia and is followed by an additional 2 months of convalescence.

Prognosis

The prognosis for horses with non-displaced lateral condylar fractures is generally very good. Results of retrospective studies indicate that 61–86% of Thoroughbreds with non-displaced fractures will race successfully following surgical treatment.[39,42,49,53,54] The prognosis for horses with displaced fractures is less favorable, with a reported range of 18–48% successfully returning to racing following surgical repair.[39,42,49,53,54] Fractures in the hindlimbs carry a more favorable prognosis, with 34% versus 76% of horses with complete fractures, and 79% versus 93% of horses with incomplete fractures of the front and hindlimbs, respectively, returning to racing in one study.[42]

Differences in prognosis between displaced and non-displaced fractures can be attributed to several factors, including a greater degree of articular and periarticular trauma associated with the original injury or with an open surgical approach, or technical errors during surgery for displaced fractures resulting in poor reduction and realignment of the articular surface.

The presence of a concurrent axial fracture of the proximal sesamoid (typically the lateral sesamoid) has also been shown to impart a poor prognosis for racing in Thoroughbreds with condylar fractures.[42]

Convalescent time (time from injury to first postoperative start) for horses with lateral condylar fractures generally ranges from 6 to 12 months, with an average of 8–9 months. This time is generally slightly shorter for non-displaced fractures and longer for horses with displaced fractures, but will vary considerably depending on the specifics of each case.

The propensity for catastrophic fractures to occur in horses with medial condylar fractures is now well recognized. The prevalence of this complication has been reported at 25–40% and can occur even up to several weeks following surgery if supplemental plate application is not utilized.[39,42,45] However, if catastrophic failure is not encountered, the prognosis for these horses to return to racing soundness is generally quite good following implant removal.[42,45,54] It should be noted that convalescent time for horses with medial condylar fractures tends to be longer than for those with fractures of the lateral condyles and has been attributed to a prolonged period of controlled exercise associated with implant removal.[42,54]

Etiology and pathophysiology

Etiology

There is increasing evidence to suggest that condylar fractures are another form of fatigue fracture in horses associated with repetitive trauma, or cyclic strain, incurred during high-speed exercise (see Pathophysiology below).

Pathophysiology

It is recognized that condylar fractures originate in the palmar/plantar articular surface of the condyles of distal MC-III/MT-III.[39,44,49,55] In race horses, the subchondral bone in the region of the condyles undergoes intense adaptive and maladaptive remodeling in response to the strains of high-speed exercise.[55–57] There is ample evidence, both grossly and histologically, of degenerative changes in the subchondral bone associated with lateral condylar fractures[58] (Fig. 17.9). These findings suggest that condylar fractures are another manifestation of a cyclic fatigue injury, rather than an acute fracture in otherwise normal bone.

A recent series of morphologic studies in Thoroughbred race horses has added further support to this theory. Riggs et al (1999)[59] demonstrated that as training progresses, high-speed strains stimulate subchondral sclerosis in the palmar/plantar aspect of the condyles of MC-III/MT-III. This results in the development of a steep density gradient between the subchondral bone of the condyles and the adjacent sagittal ridge. The investigators proposed that this density gradient results in stress concentration in this region of MC-III/MT-III (the 'condylar groove'), which is the location of the majority of condylar fractures. A related post-mortem study demonstrated that small fissures develop first in the zone of calcified cartilage in this area.[60] When sufficient pathologic forces are generated on the condyle, overt fracture may then occur. Because the trabecular bone in the distal metaphyses is organized into sagittally oriented plates[61] – an adaptation to resist the strong bending loads applied in the dorsal-palmar/plantar direction – these fractures propagate in a characteristic sagittal configuration and course axially or abaxially depending on the location of the fracture (i.e. medial or lateral condyle).[60]

It is reasonable to conclude that cyclic fatigue initiates the pathologic changes that predispose the bone to fracture. However, from a purely biomechanical standpoint, it has been proposed that overt fracture occurs in association with excessive dorsiflexion (hyperextension) of the fetlock joint and disruption of the normal synchronous rotation of P1 on MC-III/MT-III at the end of the weight-bearing phase of the stride.[62–66] Several recent post-mortem epidemiologic studies on racing Thoroughbreds in the US have implicated shoes with toe grabs and poor dorsopalmar hoof balance (specifically long toe/low heel or 'under-run' heel conformation) as *potential* risk factors.[67,68] Presumably, these shoe and hoof characteristics may biomechanically contribute to, or exacerbate, the abnormal forces that predispose to condylar fracture.

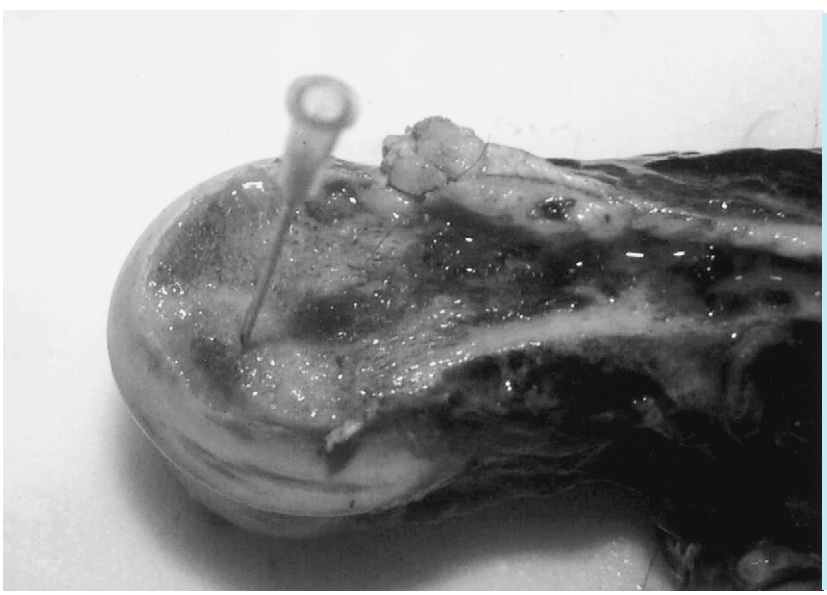

Fig. 17.9
Post-mortem photograph of the lateral condyle of MC-III from a horse with a complete, displaced lateral condylar fracture. Notice the well-demarcated degenerative lesion in the subchondral bone in the palmar aspect of the condyle (needle).

Epidemiology

Condylar fractures most commonly occur in young Thoroughbred race horses but they also occur in Standardbred, Quarter Horse and Arabian race horses.[39,42,43,49] In one study in racing Thoroughbreds in Britain, condylar fractures and sagittal fractures of the first phalanx were the two most common fractures occurring during racing or race training, each accounting for approximately 15% of all fractures.[41] In another study in the US, approximately 20% of Thoroughbreds euthanized for musculoskeletal injury on California racetracks had lateral condylar fractures of MC-III.[40]

In Thoroughbreds, condylar fractures occur more frequently in the forelimbs, and lateral fractures are much more common than medial.[39,42,43,49] However, in Standardbreds there is a more even distribution between fore and hindlimbs and there may be a more equal distribution between lateral and medial fractures.[42] This difference in fracture distribution between the two breeds can presumably be attributed to biomechanical differences between the gallop or pace/trot. Among Standardbreds, pacers may be more commonly affected than trotters.[42]

Prevention

While the vast majority of condylar fractures present as an acute injury there is increasing evidence that condylar fractures are fatigue fractures (see Etiology and pathophysiology above). In theory, early detection of pathologic changes in the subchondral bone of the distal metacarpus or metatarsus should enable intervention prior to fracture. At present, bone-phase nuclear scintigraphy offers the most sensitive means for detecting maladaptive remodeling processes in the clinical setting.[55–57] Horses with abnormal increased radiopharmaceutical uptake in the distal palmar or plantar subchondral bone of MC-III/MT-III should be regarded as being at increased risk for condylar fracture, and modifications in training intensity would be warranted. Common sense would also dictate that horses with clinical signs of a problem in the fetlock joint be thoroughly evaluated.

Proliferative periostitis of the small metacarpal/metatarsal bones/interosseous desmitis ('splints')

- Inflammatory lesions affecting primarily young athletic horses of all breeds and uses.
- Recognized as a focal area of firm, painful swelling along the shaft of the affected splint bone.
- Lesions on MC-II are most common, but all splint bones can be affected.
- Lameness is generally mild to moderate, with acute or insidious onset.
- Caused by exercise-associated strain and tearing of the interosseous ligament with associated periostitis.
- Others caused by external trauma and resulting primary periostitis.
- Majority respond to exercise restriction and anti-inflammatory therapy.
- Surgery reserved for chronic or recalcitrant cases.
- Prognosis is generally favorable.

'Splints' are inflammatory lesions resulting from repetitive strain during exercise, or from external trauma, that affect the small metacarpal/metatarsal bones or splint bones (MC-II/IV, MT-II/IV), and are seen in all varieties of athletic horses.

Recognition

History and presenting complaint

Horses with 'splints' typically are presented with a mild-to-moderate lameness having either an acute or insidious onset. Many horses can continue training, albeit with impaired performance, while others must be taken out of work. Lameness may also be intermittent and quickly improve with rest, but recurs upon resumption of exercise if the lesion has not been allowed adequate time to heal. Whether or not lameness improves, worsens or remains static *during* exercise is also highly variable, but in most horses lameness worsens as exercise progresses.

In addition to lameness, the other chief complaint or clinical sign is a variable degree of focal swelling at the site of the lesion. Astute trainers or owners may also recognize the lesion to be painful on palpation. There is a subset of young horses that develop 'splints' without overt lameness and in these cases the cosmetic blemish is the primary concern.

Physical examination

A 'splint' is recognized as a focal swelling along the shaft of the affected bone that is smooth and firm to hard on palpation. In some cases the swelling is located axially and the lesion can only be detected by palpation. Axially located 'splints' are most easily palpated with the limb held in flexion while running the fingers along the shaft of the splint.

There may be a single lesion or multiple lesions affecting the same bone but, overall, a single lesion is most common. Multiple lesions are most common on MC-II in young horses associated with early training. In this group, 'splints' are also commonly bilateral.

Horses exhibit variable degrees of pain on palpation of the 'splint'. Pain is most severe in the acute stages and does not always correlate well with the degree of swelling/exostosis. Chronic 'splints' or those that have healed clinically are not sensitive to palpation, but some horses react to firm skin pressure and this can give a false-positive response.

Open wounds or abrasions may be present over the lesion when the cause is external trauma.

Lameness examination

Lameness, when present, typically is mild to moderate (grade 1–3 of 5).[2] The majority of horses walk comfortably and only exhibit lameness during exercise. Acutely, most horses will exhibit lameness at a trot in-hand and the lameness tends to be exacerbated with the affected bone on the inside of a circle when working on a lunge line. Horses that are affected bilaterally may exhibit a 'choppy' or 'stiff' gait bilaterally and not a distinct 'head nod' or 'hip hike' per se. Firm digital pressure on the splint will often exacerbate the lameness.

Other horses are only affected when working at speed. Classic examples are the Standardbred race horse that is bearing in or out, or is 'on a line' or 'getting over on a shaft', or the performance horse that will not take or maintain the appropriate lead.

Diagnostic confirmation

Diagnostic analgesia High palmar/plantar analgesia (a 'high palmar/plantar block') will reduce lameness in horses with 'splints'. Selectively blocking just the medial or lateral nerves provides greater specificity. Local infiltration of anesthetic directly over the lesion is also an alternative method for localizing the site of pain. Local infiltration may be less effective if a substantial component of the pain is related to inflammation of the interosseous ligament and the anesthetic is deposited superficially (abaxially). The same is true if there is suspensory ligament impingement as a component of the lameness. In these horses a combination of successive blocks may be necessary to pinpoint the problem.

Scintigraphy As with other inflammatory bone disorders, nuclear scintigraphy is a very sensitive method for detecting increased bone remodeling at the site of a 'splint'. It should be noted that the majority of acute 'splints' can be diagnosed on physical examination. Nuclear scintigraphy, like diagnostic analgesia, has its strongest application in ruling in or out other potential causes for lameness, as well as monitoring healing in exceptional cases.

Focal abnormal increased radiopharmaceutical uptake will vary from mild to intense, depending on the stage of disease (Fig. 17.10). As with many other conditions, scintigraphy will often be positive when radiographs are negative or equivocal in the acute stages. Scintigraphic activity also tends to persist after the lesions have healed clinically and therefore, results of physical/lameness examination, diagnostic analgesia, radiographs and clinical experience are necessary to formulate a therapeutic plan.

Radiographs Radiographic abnormalities may not be evident with many acute 'splints', even in cases where considerable external swelling is present (see Pathophysiology below). For that reason, and because treatment for young horses in early athletic training is not necessarily modified based on radiographic findings, many clinicians do not recommend an initial set of radiographs in every case. However, radiographs are essential to rule out a fracture and to assess the nature and extent of any periosteal reaction – which is particularly important in horses with chronic or recalcitrant

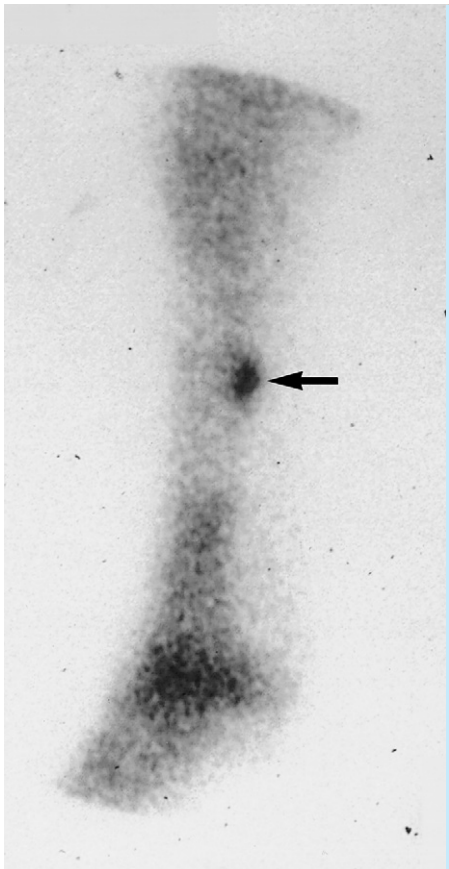

Fig. 17.10 Lateral bone-phase scintigraphic image of the left metacarpus of a horse with an active proliferative periostitis lesion ('splint'). Notice the focal area of moderately intense abnormal increased radiopharmaceutical uptake affecting MC-IV (arrow).

Fig. 17.11 Dorsomedial-to-palmarolateral oblique radiograph of the left metacarpus of a horse with a proliferative periostitis lesion ('splint') affecting MC-II. Notice the exuberant irregular periosteal reaction, which is typical of lesions resulting from external trauma.

'splints', cases where lameness is profound, those with a large swelling/exostosis and certainly any with a draining wound.

Four views (lateral, dorsopalmar/plantar, DMPLO, DLPMO) of the affected metacarpus/metatarsus are recommended, although most information is obtained on the appropriate oblique view that isolates the affected bone(s). Lesions that are the result of internal trauma (exercise-associated cyclic strain) most commonly have a variable degree of focal, smooth periosteal reaction along the shaft of the affected splint bone. In addition, there may be evidence of subtle osteolytic change along the axial aspect of the bone (the region of the interosseous ligament) as well as subtle or mild proliferative and lytic changes in the underlying cannon bone. Lesions resulting from external trauma are more likely to have an irregular and exuberant periosteal reaction (Fig. 17.11). It is important to note that superimposition of normal and periosteal new bone can result in misdiagnosis of a fracture in some cases if radiographs are not interpreted carefully.

Ultrasound A sonogram is important for evaluation of concurrent suspensory ligament pathology in cases with potential impingement on this structure by a large exostosis.

Thermography In the hands of an experienced operator, thermography can be useful in identifying active lesions.

Treatment and prognosis

Therapeutic aims

The goals of therapy for 'splints' are to reduce or eliminate the inciting cause, reduce inflammation, minimize the size of the exostosis and allow the lesion to become quiescent or 'set up' (see Pathophysiology below).

Therapy

Exercise restriction The extent of exercise restriction varies with each case and depends on the duration and severity of clinical signs and, to some extent, the use of the horse and stage of training.

Most horses should be confined to a stall with exercise limited to daily hand-walking until lameness and the majority of the focal pain have subsided. In most cases this will be a period of 2–6 weeks. However, this will also vary depending on response to treatment. Exercise intensity is increased gradually and, as above, the specific protocol will vary with each case.

Anti-inflammatory treatment As with exercise restriction the extent of anti-inflammatory treatment for 'splints' will vary with each case. The NSAIDs phenylbutazone or flunixin meglumine are administered systemically at standard doses for several days in most cases, or up to a few weeks in exceptional cases. As in other inflammatory disorders, long-term NSAID treatment is becoming more controversial due to its potentially negative impact on bone healing. Promoting metacarpal/metatarsal fusion (see Pathophysiology) is desirable but how NSAIDs affect this process is unclear. NSAIDs, along with corticosteroids (see below), may be of greatest importance in minimizing the development of an exuberant exostosis.

Local cold therapy, in the form of cold hosing or icing (bucket or ice boot) administered for 20–30 minutes several times daily for several days in the acute stages, is also beneficial to reduce soft tissue swelling and inflammation in the affected tissues.

Local injection of corticosteroids can also be highly beneficial, particularly with respect to decreasing the fibrous and osseous proliferative response. Local injection of corticosteroids is particularly efficacious for managing lameness associated with 'splints' in horses whose competition schedules will not allow an extended period of lay-up.

Corrective shoeing Corrective trimming and shoeing plays an important role in reducing or eliminating the tendency for interference when this form of external trauma is the cause of a 'splint'.

Boots and protective bandages In cases in which interference is the primary cause, 'shin boots' or other protective wraps or bandages are helpful to prevent further trauma.

Surgery The vast majority of 'splints' respond well to non-surgical management.[32,69] Refractory cases associated with chronic or recurrent lameness, cases with exuberant exostoses and suspected suspensory ligament impingement and those with osteitis associated with an open wound are appropriate candidates for surgery. Surgery is also occasionally undertaken to improve the cosmetic appearance of show horses.

Surgery involves either a partial ostectomy (osteotomy just proximal to the lesion with excision of the distal aspect of the splint bone) or surgical debridement of the exostosis with preservation of the bone. The option chosen depends on the nature and location of the lesion, the bone involved and in some cases the surgeon's preference. With the exception of MT-IV,[70] excision of more than the distal two-thirds to three-quarters of a splint bone will result in instability of the remaining proximal portion, which can lead to chronic lameness of various origins.[71] This is particularly true when dealing with MC-II. Therefore, when considering surgery for a large impinging exostosis affecting the proximal portion of a splint bone, debridement of the exostosis and preservation of the bone are appropriate.

Fortunately, 'splints' resulting from cyclic internal trauma (exercise-associated repetitive strain) that affect the proximal aspect of the bone rarely become chronic problems once allowed to 'set up' (formation of a stabilizing synostosis or fusion – see Pathophysiology), and surgical intervention is therefore not a consideration. 'Splints' of this nature that are most likely to result in chronic lameness generally affect the midshaft of the splint bone and in the author's opinion they are candidates for partial ostectomy.

Surgery is performed with the horse in lateral recumbency under general anesthesia. A tourniquet is helpful but not essential. The limb is clipped and aseptically prepared from midpastern to carpus/tarsus and draped to allow access to the full metacarpus/metatarsus. An incision is made directly over the splint bone and extends from a few centimeters proximal to the lesion to just distal to the distal aspect or 'button'. Sharp and blunt dissection is used to expose the portion of the bone to be excised. Care is taken to avoid trauma to the suspensory ligament and neurovascular structures in the

Fig. 17.12 Intraoperative DMPLO radiograph of the right metacarpus following ostectomy of the distal portion of MC-II (arrow) in a horse with a chronic proliferative periostitis lesion ('splint').

area (particularly when dealing with MT-IV). A 6–12 mm osteotome and mallet are used to transect the splint bone just proximal to the lesion, at a 30–45° angle with the long axis of the bone (Fig. 17.12). The distal portion is then excised, beginning distally and working proximally. Mayo scissors can be used to cut the heavy fibrous tissue attached to the most distal aspect and then an osteotome or chisel and mallet are used to undermine and separate the more proximal portion from the cannon bone. The periosteum is removed with the bone. Remaining bone fragments and fibrous tissue are carefully debrided and a bone rasp is used to smooth the remaining proximal stump and cannon bone where needed. Excessive rasping or other trauma to the cannon bone should be avoided. The surgical field is lavaged copiously to remove small bone fragments. Intraoperative radiographs are helpful to identify small fragments that may not be readily seen. A Penrose drain is not essential, but does help prevent seroma formation in some cases. The wound is closed routinely in multiple layers and a dressing containing rolled or folded sterile gauze pads is applied over the incision to provide increased direct pressure and help minimize swelling and seroma formation prior to application of a padded bandage.

The surgical approach for debridement of a large exostosis is similar, but with a shorter incision centered over the lesion. After reflecting the soft tissues an osteotome (or chisel) and mallet are used to carefully separate the proliferative periosteal bone from the surfaces of the underlying splint and cannon bones. The periosteal bone is usually softer and more irregular than the normal cortical bone and in most cases is easily identified. All overlying periosteum is removed with the exostosis, taking care not to unnecessarily traumatize bone that is left behind. Intraoperative radiographs may help identify foci of remaining periosteal new bone. Lavage, closure and bandaging are similar to that for ostectomy.

Postoperatively, horses are treated with an NSAID for 3–7 days. Broad-spectrum antibiotics are initiated preoperatively and continued for 24–48 hours postoperatively. If excessive soft tissue swelling or a seroma develops, antibiotic treatment is continued at the discretion of the surgeon. Sutures are removed in 12–14 days and a bandage is maintained on the limb for 3–4 weeks to help minimize swelling. Horses are confined to a stall for 6–8 weeks, with light hand-walking exercise beginning after suture removal. Exercise intensity gradually increases over the ensuing 6–8 weeks. Early resumption of harder exercise predisposes horses to inflammation at the site of the ostectomy and sets up the possibility of chronic problems postoperatively.

Traditional and alternative therapies Many of the numerous traditional therapeutic modalities mentioned in the section on 'bucked shins' continue to be used by some lay persons and veterinarians for treating 'splints'. As with 'bucked shins', the efficacy of these techniques for treating 'splints' has not been substantiated scientifically, but many clinicians remain strong advocates based on anecdotal evidence and personal experience. A detailed discussion of this topic is beyond the scope of this chapter. In addition to those modalities listed in Table 17.1, soft lasers, therapeutic ultrasound and magnet boots have been employed in the treatment of 'splints'.[69] The efficacy and scientific rationale of these treatments also remain controversial.

Prognosis

The prognosis for most horses with 'splints' is generally very good if appropriate intervention is undertaken and adhered to. This is particularly true for 'splints' that develop in young horses in early training. The majority of horses will recover and their athletic potential will not be impaired. Most chronic or recurrent problems develop in situations where the lesion initially goes undiagnosed or horses are not allowed an adequate time to heal and undergo fusion or synostosis (see Pathophysiology below).

'Splints' that develop in older horses, either from internal or external trauma, tend to take longer to heal and are more likely to fall into the chronic or recurrent category. Other exceptions are cases of chronic interference where repeated external trauma cannot be corrected or rare proliferative lesions that affect the very proximal aspect of the bone and contribute to problems with the carpometacarpal/tarsometatarsal joints.

The prognosis for athletic soundness following partial ostectomy is also generally fair to good if appropriate case selection, surgical technique and aftercare are adhered to.[72] Prognosis is guarded for horses undergoing proximal ostectomy, with or without supplemental stabilization of the remaining portion.[73] Recurrence of the exostosis following surgical debridement has been a recognized problem[69] and owners should be cautioned accordingly. Careful removal of the associated periosteum appears to minimize this complication.[74]

Etiology and pathophysiology

Etiology

'Splints' can be caused by internal or external trauma. Internal trauma is in the form of repetitive or cyclic strains incurred during exercise. External trauma is essentially blunt force or concussive trauma, resulting either from a kick or interference.

Pathophysiology

'Splints' caused by cyclic strains during exercise (internal trauma) are initiated by tearing and inflammation of the interosseous ligament and underlying periosteum of the cannon and splint bones. In immature horses the splint bones are mobile relative to the adjacent cannon bone. As such, during exercise, axial forces applied to the proximal aspect of the splint bones by the overlying carpal or tarsal bones result in strain and shearing of the interosseous ligament and periosteum. As exercise continues a focal desmitis and periostitis develop, which in turn results in the clinical signs of focal swelling and lameness. The swelling is initially a combination of soft tissue edema and fibrosis, and progresses to periosteal new bone or exostosis.

This type of 'splint' is most common in younger horses in early training and the small metacarpals, and in particular MC-II, are most frequently affected. The small metacarpal bones have larger articulations with the overlying carpal bones, and more extensive soft tissue attachments, than do the small metatarsal bones. Functionally, it is assumed that the small metacarpal bones play a more important role in stabilizing the carpus and experience greater stresses during exercise than the small metatarsals.

Eventually, a synostosis between the splint and cannon bones develops at the site of a 'splint' – termed 'metacarpal fusion'[75] – and it is hypothesized that this results in stabilization and resistance to further strain and shear.[75] 'Splints' at this stage are said to have 'set up' and no longer appear to cause clinical problems. Given that metacarpal fusion has an estimated prevalence of over 95%, with 78% of horses over 2 years old having two or more sites of fusion,[75] it is reasonable to assume that the process is not always associated with an inflammatory reaction severe enough to produce clinical signs of 'splints' and, in fact, may be a normal adaptive process as the skeleton matures.

Poor conformation is also implicated as a risk factor for the development of 'splints',[50] presumably by exacerbating the shearing forces applied on the splint bones and interosseous ligament. Specifically offset or 'bench knees' appear to favor development of splints of MC-II.[50,75] Carpal or tarsal valgus or varus deformities may also potentiate the development of 'splints'.

In contrast to the above, 'splints' caused by external trauma begin as a primary focal periostitis/osteitis of the affected splint bone, although a primary interosseous desmitis may also be initiated by the event.[50] Exercise can aggravate and perpetuate this inflammatory process and presumably a secondary interosseous desmitis and periostitis of the cannon bone may result. Base narrow, toe-out conformation, which may exacerbate the tendency for interference – specifically trauma to the contralateral MC-II – has been suggested as one risk factor.[69]

Regardless of the underlying cause, if the exostosis becomes exuberant and projects axially a secondary, focal suspensory desmitis may develop in some cases. However, in the author's experience, this condition is uncommon but is more likely with the marked exostosis that tends to develop following external trauma.

Epidemiology

'Splints' resulting from cyclic strains associated with exercise are common in young performance horses of many breeds and uses. As previously mentioned, MC-II is the bone most commonly affected in this group, followed by MT-II, but the lateral splint bones (MC-IV, MT-IV) can certainly also be affected. Lesions are very commonly bilateral and multiple 'splints' affecting a single bone are not unusual, particularly on MC-II.

'Splints' are very common problems in race horses of all breeds aged 2–4 years and, as with 'bucked shins', many trainers still consider them to be almost a 'rite of passage'. In performance horses other than race horses, 'splints' can develop at any age but are common in those aged 3–10 years (young adults). 'Splints' also develop in weanling and yearling horses that are not in formal training and in the author's experience, these are frequently fast-growing or overconditioned animals. Overnutrition has been cited as an associated risk factor by others.[69]

'Splints' resulting from external trauma can affect horses of any age and involve any of the splint bones. Obviously, those resulting from interference are most likely to occur during performance and affect MC-II. However, this type of splint is also frequently seen on MT-IV resulting from a kick or contact with natural or manmade objects.

Prevention

In theory, with training modifications it should be possible to prevent or minimize the incidence of 'splints' that develop in young horses in early training as a result of cyclic trauma that exceeds the physiologic limits of the tissues and their capacity to adapt to the imposed stresses. In reality, it is impossible at this stage to outline a specific training regimen that would be appropriate for each breed and use of athletic horse. Early detection using physical examination and diagnostic imaging techniques such as thermography and scintigraphy, to then enable timely intervention, is a more realistic goal. Correction of gait abnormalities that predispose to interference should minimize the incidence of traumatic 'splints' in the individual horse. In horses with a tendency for interference, long-term use of shin boots or other protective wraps is also an option.

Fractures of the small metacarpal/metatarsal bones (splint bone fractures)

- Splint bone fractures occur in all types of performance horses.
- Fractures of the distal third are the most common type.
- Fractures of the middle and proximal aspect result from trauma associated with interference.
- Fractures of the head may be caused by torsional forces or be avulsions.
- Distal fractures are treated by surgical excision.
- Middle and proximal fractures are treated by excision or internal fixation.
- The prognosis is generally favorable for all fracture types.
- Concurrent suspensory desmitis is the limiting factor with distal fractures.

Splint bone fractures can occur during exercise or randomly as a result of some form of external trauma. The following will deal exclusively with fractures that occur in athletic horses during performance. The most common in this category are fractures of the distal third. Others include fractures of the midshaft or proximal portion (head) resulting from interference, and oblique fractures of the head that may result from torsional forces or be avulsions associated with the extensive soft tissue attachments.

Recognition

History and presenting complaint

Acute lameness and swelling are the primary clinical signs of splint bone fractures.

Degree of lameness in horses with fractures of the distal portion is highly variable and may have an acute or more insidious onset. Most horses develop an acute lameness during or immediately after exercise. Lameness is generally mild to moderate. Many horses are able to resume exercise after a period of rest, but have lingering problems with low-grade lameness. Acutely, mild soft tissue swelling and sensitivity are usually present near the fracture site. Horses may have a history or clinical signs of suspensory desmitis. Some chronic distal fractures are incidental findings.

Lameness with fractures of the proximal portions of the splint bones is generally acute in onset, ranges from moderate to severe and generally persists despite rest. The majority of these horses are too lame to continue exercise. Soft tissue swelling ranges from mild to marked and abrasions or wounds may be present.

Physical examination

Horses with distal splint bone fractures generally have very mild to moderate local soft tissue inflammation. The degree varies with the chronicity of the injury. Fractures that are more than a week or two old may have minimal residual associated swelling. Distal splint fractures have a high incidence of associated suspensory desmitis and therefore suspensory enlargement, most commonly of the associated branch, may also be present. Focal pain is common on firm palpation of the fracture site. If the fracture is chronic, a callus can often be palpated, along with instability if the distal tip or 'button' is pressed axially.

Variable degrees of soft tissue swelling and pain on palpation of the fracture site are the hallmarks of fractures of the more proximal portions of the splint bones. Open wounds or abrasions may be present if the fracture is the result of interference.

Lameness examination

Lameness in horses with splint bone fractures ranges from very mild to relatively severe and depends in great part on the type of fracture and the chronicity.

Horses with acute fractures of the distal aspect generally exhibit mild-to-moderate lameness at a trot and in some cases exhibit mild lameness at a walk (grade 1–4). Horses with chronic distal fractures generally exhibit only mild lameness at a trot, but performance is impaired at high speeds. Lameness may be exacerbated on a circle. Lower limb ('fetlock') flexion may exacerbate the lameness, particularly if concurrent suspensory desmitis is present.

Horses with acute fractures of the middle and proximal portions of the splint bones generally exhibit severe lameness at a trot and many are markedly lame at a walk (grade 2–4 of 5). Lameness in chronic cases is highly variable. Lameness is exacerbated with the fractured bone on the inside of a circle in many horses. Carpal or tarsal flexion may be positive in horses with fractures affecting the head of the splint.

Diagnostic confirmation

Diagnostic analgesia Diagnostic analgesia is rarely needed to definitively localize the source of pain in horses with most acute splint fractures. Diagnostic analgesia becomes important in the work-up of horses with chronic fractures involving either the distal aspect or the head of the splint, in which soft tissue swelling and lameness have improved considerably. In horses with distal splint fractures, response to low palmar/plantar analgesia is variable. High palmar/plantar analgesia will consistently be positive in all cases of splint bone fracture, with the exception of those involving the articular aspect, in which the response is variable. In these cases, intra-articular analgesia of the carpometacarpal (via the middle carpal joint) or tarsometatarsal joint will be positive or result in substantial improvement.

Scintigraphy Nuclear scintigraphy is unnecessary for diagnosis of acute splint bone fractures. This modality is beneficial in the work-up of horses with chronic fractures when attempting to rule in or out other potential causes of lameness.

Radiography Radiographs are necessary to confirm the diagnosis. Four views (lateral, dorsopalmar/plantar, DMPLO and DLPMO) of the full metacarpus/metatarsus are required. In

cases of fractures involving the head of the bone (articular fractures) a full series of the associated carpus/tarsus is also warranted.

Ultrasonography A sonogram should be performed to evaluate the suspensory ligament in cases where concurrent desmitis is suspected.

Treatment and prognosis

Therapeutic aims

Therapy for distal fractures is directed at eliminating a source of chronic irritation/inflammation. Goals of therapy for fractures involving the midshaft include minimizing the convalescent time and mitigating the tendency for development of delayed or non-union and formation of exuberant callus/exostosis. Goals in treating proximal fractures include promoting primary bone healing, preservation of the stability of the proximal portion and minimizing the potential for degenerative joint disease.

Therapy

First aid Initial treatment for all splint bone fractures includes bandaging and anti-inflammatory therapy, as previously discussed for other metacarpal/metatarsal injuries. Horses should be confined to a stall pending decisions on definitive treatment. Wound care and antibiotics are administered as needed.

Treatment of distal fractures There is no strong consensus on the most appropriate way to manage distal splint fractures. Many will heal or become quiescent as non-unions and no longer appear to cause problems.[77,78] Residual lameness/poor performance is generally attributed to chronic suspensory desmitis. However, because the distal portion of the splint bone is highly mobile, healing is often slow and associated with considerable callus (Fig. 17.13). The fragment and associated inflammation appear to cause chronic irritation in some horses. Surgical excision of the fragment reduces the convalescent period and eliminates the fracture as a continued cause for concern. Therefore, it is this author's opinion that *acute* or *clinically active* distal splint fractures are best treated by surgical excision.

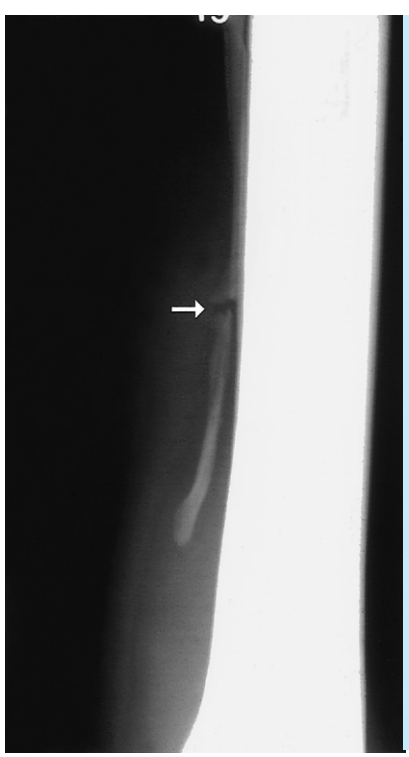

Fig. 17.13 Dorsolateral-to-plantaromedial radiograph of the right metatarsus of a horse with a chronic fracture of the distal aspect of MT-IV. Notice the callus and evidence of non-union (arrow).

Surgery is generally best performed under general anesthesia, but excision under local anesthesia is a viable alternative in some cases. The preparation and approach are similar to that described for splint ostectomy in the previous section, but the incision is considerably shorter. Fractures of the distal third involve the portion of the splint bone not attached to the interosseous ligament. Therefore, excision is relatively easy and can be performed with heavy scissors, again working from distal to proximal while grasping the 'button' to elevate it. The distal fragment, callus and a small segment of the proximal fragment (that involved with the callus), along with associated periosteum, are excised. A small osteotome or bone rongeur can be used for transecting the proximal fragment. Closure and bandaging are carried out in a routine manner.

Aftercare involves 2–4 weeks of stall confinement with increasing daily hand-walking exercise, followed by 2–4 weeks of small paddock turnout or other form of light exercise. Exceptions are horses with concurrent suspensory desmitis, in which case rest and controlled exercise, and other adjunct therapy, are dictated by the extent of the ligamentous injury (the reader is referred to the chapter on tendon and ligament injuries (Chapter 20)). A bandage is maintained for 2–3 weeks and sutures are removed 10–14 days postoperatively. NSAID and antibiotic treatment are at the discretion of the surgeon, but neither is required for an extended period.

Treatment of midbody fractures Treatment for fractures of the midportion of the splint bones involves partial ostectomy, and the technique and aftercare are similar to that described for managing chronic 'splints' in the previous section. Because of motion at the fracture site, healing is often delayed and frequently results in exuberant callus or exostosis, along with chronic pain/lameness, which may be considered as another manifestation of proliferative periostitis/interosseous desmitis or 'splints' (Fig. 17.14).

Treatment for proximal fractures The consequences of partial ostectomy alone for treating fractures of the proximal third of a splint bone are well recognized.[71] These fractures must be managed by either ostectomy with supplemental internal fixation to stabilize the remaining proximal portion or by primary repair using internal fixation. Failure to do so leads to loss of stability of the proximal portion and chronic lameness will result. The exception is MT-IV, in which the entire bone can be excised with a good outcome in many cases.[70]

With respect to fractures that occur during performance, the most common proximal splint fracture is an oblique fracture involving the head, most commonly MC-II

Fig. 17.14 Dorsomedial-to-palmarolateral oblique radiograph of the right metacarpus of a horse with a chronic fracture of the midbody of MC-II.

Fig. 17.15 (A) Lateral radiograph of the proximal left metacarpus and carpus of a Thoroughbred race horse that sustained an oblique fracture of the proximal portion of MC-II during a race. (B) Postoperative radiograph following open reduction and internal fixation using a 3.5 mm narrow dynamic compression plate. Note that screws do not engage MC-III.

(Fig. 17.15A). The fractures involve the articular aspect and are almost always displaced. Surgical repair involves open reduction and internal fixation using a small bone plate. An incision of appropriate length is centered over the proximal aspect of the bone along the palmaromedial or palmarolateral aspect of the limb. Sharp dissection is carefully carried out using a sharp elevator or scalpel to sever the heavy ligamentous attachments and expose the bone. The fracture line is debrided as needed to allow reduction. A 4–6 hole, narrow, 3.5 mm DCP is appropriately contoured and applied using 3.5 mm cortical screws. Screws should not engage the MC-III (Fig. 17.15B). Screws crossing the fracture line can be inserted in lag fashion but this may be difficult, depending on fragment width and fracture configuration, and is not essential if the fracture is well reduced. The incision is closed in multiple layers and a tight, padded bandage is securely applied.

Broad-spectrum antibiotics are administered for 24–48 hours and NSAIDs are administered for 3–5 days postoperatively. A bandage is maintained for 2–3 weeks and skin sutures are removed 12–14 days postoperatively. Horses are confined to a stall for 2 months. Daily hand-walking begins after suture removal. Exercise in a small paddock can begin at the 2-month point. Implants are removed 3 months postoperatively. This can be performed under local or general anesthesia but because of the heavy soft tissue covering is easier under general anesthesia, particularly for implants in MC-II. Screws are removed through stab incisions and the plate is elevated and removed through a small incision over the distal end. An additional 4–6 weeks of limited exercise are allowed before resumption of training once fractures have healed radiographically.

Prognosis

The prognosis for fractures involving the distal aspect of the splint bones is generally very good if there is no concurrent suspensory desmitis.[78,79] The prognosis for horses with suspensory ligament injury is directly related to the severity of the desmitis.

The prognosis following partial ostectomy for management of fractures of the midportion of the splint bones is fair to good and is similar to ostectomy for treatment of recalcitrant 'splints'.[80] In this author's experience, problems tend to arise if horses are not allowed an appropriate period of convalescence and training is resumed too quickly.

The prognosis for the oblique fractures involving the heads of the splint bones treated with internal fixation, in the author's experience, appears to be good but reports involving large numbers of this specific fracture type are lacking.

Etiology and pathophysiology

Etiology

Many distal splint fractures are associated with either axial compressive forces exerted through the proximal aspect of the bone or tension imparted by the attachments to the suspensory ligament. Most fractures of the middle and proximal portions of the splint bones are the result of blunt external trauma. Some oblique fractures of the head of the splint bone, specifically MC-II, may be avulsion fractures or the result of internal torsional forces.

Pathophysiology

Unlike the middle and proximal portions of the splint bones, the distal portion is not tightly adhered to the cannon bone through the interosseous ligament. It is therefore relatively mobile and has fascial attachments to the adjacent branch of the suspensory ligament. During exercise, compressive axial forces on the bone in some cases, or in others flexion and extension of the fetlock joint with the associated elongation and retraction of the suspensory ligament, create cyclic strain on the distal splint bone. If this proceeds at a rate that exceeds the bone's ability to adapt, it weakens and eventually fracture occurs. However, fractures appear clinically as an acute injury. The inherent motion at this location commonly leads to delayed or non-union or healing with a considerable callus.

Enlargement of the suspensory branch, as occurs with desmitis, displaces the distal splint bone abaxially, which may exacerbate the strain on the bone. Local inflammation associated with the desmitis may also lead to osteitis and a predisposition to fracture. However, the temporal relationship between desmitis and fracture is not completely understood and fracture may precede desmitis in some cases.

Blunt trauma from interference in the mid-to-proximal portion of the splint generally results in a short oblique or transverse fracture, but comminuted fractures or fracture of a crescent-shaped fragment are also seen. On rare occasions these fractures are open. (Conversely, open fractures are very common in non-exercise related cases.) Strains exerted on the proximal aspect of the bone (see previous section on 'splints') invariably result in motion and healing with a large callus or exostosis.

Fractures of the head of the splint bone can result from blunt external trauma, but they are also suspected to result from torsional stresses during exercise[69] and in some cases maybe avulsions. In this author's opinion, the oblique fractures of the head of MC-II appear in many cases to be avulsion fractures that presumably occur during hyperextension of the carpus. In addition to the medial collateral ligament of the carpus, the flexor carpi radialis and extensor carpi obliquus muscles insert on the proximal aspect of MC-II.

Epidemiology

Distal splint fractures affect performance horses of all breeds and uses, but are particularly common in race horses. Overall, distal splint fractures more commonly involve the forelimbs, with the exception of Standardbred race horses. For comparison, in Thoroughbreds left MC-IV and right MC-II are the most commonly affected and in Standardbreds fractures of the left MT-II and right MT-IV are most common.[52,78,79] Distal splint fractures are unusual in immature horses (< 2 years of age) and this is thought to be due to a decrease in pliability of the suspensory ligament and an increase in brittleness of the bone as horses age.[71,79] Younger horses are also not in formal athletic training.

Fractures of the middle and proximal portions resulting from interference are seen in all performance horses. Oblique fractures of the head caused by torsional strains during performance are most common in race horses and jumpers.[69]

Prevention

The use of shin boots, and corrective trimming and shoeing to correct gait abnormalities, can minimize the incidence of splint fractures resulting from interference.

Many distal splint fractures are fatigue fractures and concurrent or pre-existing suspensory desmitis may contribute to the development of this injury. Early detection of pre-fracture pathology, using such modalities as thermography and nuclear scintigraphy, along with careful physical examination and recognition of subtle signs of soreness or lameness, should enable early intervention/prevention in some horses.

Stress remodeling ('stress reaction') and stress fracture (avulsion fracture) at the suspensory origin

- Stress reaction and stress fractures at the suspensory origin are two of the three components of the 'high suspensory syndrome'.

- Either disorder may exist as a primary, distinct entity or be associated with desmitis at the suspensory origin.
- Stress reaction affects all types of performance horses.
- Stress fractures are seen most commonly in race horses.
- Pain on palpation of the suspensory origin, but few other overt clinical signs.
- Lameness may have gradual or sudden onset with stress reaction.
- Lameness typically has an acute onset with stress fracture.
- Scintigraphy plays an important role in the diagnosis.
- Treatment involves rest and controlled exercise for 2–6 months.
- Prognosis is generally favorable for either condition.

Stress remodeling or stress reaction, which can be thought of as an enthesitis, and stress or avulsion fractures at the origin of the suspensory ligament, along with desmitis of the suspensory origin, are the three components of the 'high suspensory syndrome'. This section will focus specifically on the primary osseous disorders and the reader is referred to Chapter 20 on suspensory desmitis for details on the primary ligamentous disorder. It is important to remember that although each condition can occur as a distinct injury, an element of both osseous and ligamentous pathology may exist in many cases.

Recognition

History and presenting complaint

Horses with stress reaction typically have a progressive lameness of insidious onset, but cases with apparent acute onset are also seen. Initially, lameness may be intermittent and improve or resolve with short-term rest. Eventually, lameness becomes persistent and worsens as exercise continues, rather than being a lameness that the horse 'warms out of'. In a subset of horses the condition only causes poor performance at peak exertion. An example would be Standardbred race horses that 'bear in or out' (drift into the rail or away from the rail) or frequently break stride during a race.

Lameness in horses with stress fracture is typically acute in onset and is first evident during or shortly after high-speed or hard exercise. Most horses are too lame to continue training. Some horses have a history of low-grade or intermittent lameness (as above) prior to acute fracture.

Physical examination

There are very few overt physical abnormalities in horses with primary osseous disease at the suspensory origin. Soft tissue swelling is minimal or absent (unless concurrent suspensory desmitis is present). Some horses stand 'over' at the knee (slight carpal flexion at rest). Focal pain in the region of the suspensory origin is the primary sign. This is most easily assessed with the limb in flexion and with firm pressure applied by the thumb along the proximal palmar aspect of the metacarpus (or with fingers along the plantar metatarsus), while displacing the flexor tendons medially or laterally.

Lameness examination

Lameness in horses with stress reaction ranges from subtle to moderate – grades < 1–3 of 5. The condition may be present bilaterally, in which case an overt lameness may not be apparent and horses have a change in gait mechanics or loss of action. Lameness in horses with acute stress fracture is typically grade 2–4 of 5. Bilateral fractures are rare. Lameness with either condition may be exacerbated with firm pressure over the suspensory origin and often is more pronounced with the affected limb on the outside of a circle. Lameness may also be exacerbated on soft footing, but this is more consistent with cases of desmitis at the suspensory origin. Lameness with stress fracture may be exacerbated with carpal or tarsal flexion, but this is not consistent.

Diagnostic confirmation

Diagnostic analgesia High palmar or high plantar analgesia will be positive in horses with pain at the suspensory origin. The proximal palmar metacarpus and plantar metatarsus are regions notorious for anatomic nuances that may contribute to misinterpretation of the response to local anesthetic injections.[81] Of chief concern are the distal palmar/plantar outpouchings of the carpometacarpal (CMC)/tarsometatarsal (TMT) joints and their close relationship with the suspensory origin.[82,83]

In the forelimb, a high lateral palmar nerve block[84] is the most specific perineural block for the suspensory origin and is therefore preferred to the traditional high palmar block (high 'four-point' block) or local infiltration of the suspensory origin (see Chapter 14).[85] A comparable technique does not exist for the hindlimb but because the distal plantar outpouchings of the TMT joint are less extensive than the CMC outpouchings, inadvertent intra-articular (IA) injection is less likely in the hindlimb, but this possibility, along with deposition of anesthetic in the tarsal sheath, must be recognized.[83,85]

Similarly, intra-articular injection of anesthetic in the middle carpal (and thus, CMC) or TMT joint can result in a false-positive diagnosis of articular pathology with bony disease at the suspensory origin.

Scintigraphy Nuclear scintigraphy is invaluable in the diagnostic work-up of horses with suspected stress reaction or stress fracture at the suspensory origin.[86,87] The minimal overt clinical signs and potential for misinterpretation of diagnostic analgesia, along with the fact that radiographs are often negative or equivocal in the early stages of stress reaction, make this imaging modality particularly beneficial.

Bone-phase images will reveal focal, mild to intense, abnormal increased radiopharmaceutical uptake in the proximal palmar metacarpus/plantar metatarsus in horses with stress reaction. Uptake is typically moderate to intense in horses with acute stress fracture (Fig. 17.16).

Radiography A full radiographic study of the proximal metacarpus/metatarsus should be obtained in all cases, but the most important views in horses with stress reaction or stress fracture are the dorsopalmar/plantar (DP) and lateral

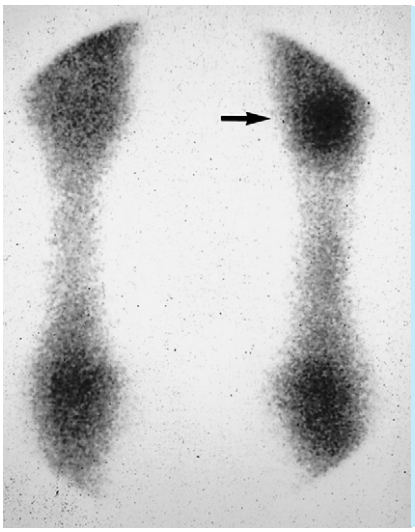

Fig. 17.16 Dorsopalmar bone-phase scintigraphic image of the metacarpal and carpal regions of a horse. Notice the focal area of intense abnormal increased radiopharmaceutical uptake in the proximal left metacarpus associated with an avulsion fracture at the origin of the suspensory ligament (arrow).

or flexed lateral. In the early or acute stages radiographs are often equivocal or may be negative, and correlation of lameness examination and scintigraphic findings is important.

Horses with stress reaction will exhibit varying degrees of trabecular bone sclerosis in the proximal palmar/plantar aspect of MC-III/MT-III at the suspensory origin. Careful evaluation may also reveal osteolytic change in the early stages in some cases. In the forelimbs this is most commonly medially and in the hindlimbs the changes are most commonly laterally (associated with the respective heads of the bipartite suspensory origin). Endosteal proliferative reaction and/or enthesiophyte formation along the palmar/plantar cortex may also be present.

Stress fractures in this location typically appear as an inverted V- or U-shaped radiolucency on the DP view and are often seen as a small crescent-shaped fragment on the lateral or flexed lateral view. Endosteal callus may be identifiable on the lateral view.

Ultrasonography A sonogram should be performed to assess the state of the suspensory ligament although, as previously mentioned, distinct changes indicative of active desmitis are inconsistent and frequently absent. Osseous abnormalities, including irregularity of the cortex or a separate avulsion fragment, may be identifiable.

Thermography In the hands of an experienced operator thermography may be useful for identifying inflammation at the suspensory origin.

Treatment and prognosis

Therapeutic aims

The goal of treatment is to reduce or eliminate strains on the affected area(s) and promote bone healing.

Therapy

Treatment for stress reaction at the suspensory origin involves anti-inflammatory therapy along with rest and controlled exercise, the specifics of which depend a great deal on the severity of the condition and the use and performance demands (i.e. competition schedule) of the horse.

In general, horses should have stall confinement with daily hand-walking exercise until lameness at a trot in-hand has resolved. Exercise is then gradually increased. Time for recovery is highly variable, but a range of 2–6 months is typical. Follow-up scintigraphic examination can be used to monitor healing and enable a more informed recommendation on increases in exercise intensity. Sclerosis will persist after scintigraphic activity has resolved, and therefore radiographs are less helpful in monitoring healing.

Local corticosteroid injection is often effective in alleviating lameness associated with stress reaction in horses whose competition schedules will not allow an extended period of rest. In addition, internal blisters (local infiltration of a counterirritant, typically an iodine-based product) are described anecdotally by many practitioners to be helpful for this condition, particularly when chronic and associated with suspensory desmitis; however, controlled studies are lacking. More recently, application of radial shock wave therapy is gaining popularity for treating this condition but, as with internal blisters, controlled studies at this stage are lacking.

Long toe/low heel conformation is often associated with this condition and may contribute to strain at the suspensory origin. Therefore, corrective trimming to shorten the toes to facilitate breakover may be helpful in these cases. Heel wedges (to elevate the heels) are contraindicated as they will actually increase suspensory ligament strain.[88]

Stress fractures usually heal readily in 3–4 months. Recommendations include 1 month of strict stall rest, followed by 1–2 months of stall confinement with daily hand-walking exercise and then 1–2 months of limited turnout in a small paddock. Follow-up radiographs (± scintigraphy) are taken at approximately 3–4 months to assess healing.

Prognosis

The prognosis for most horses with primary stress reaction or stress fracture at the suspensory origin is good if the condition has been allowed sufficient time to heal. The prognosis with concurrent desmitis at the suspensory origin is much more guarded, particularly in the hindlimbs, and therefore it is important to assess the suspensory ligament in these cases. (The reader is referred to Chapter 20 on suspensory desmitis for details.)

Etiology and pathophysiology

Etiology

Stress reaction and stress fractures at the suspensory origin are cyclic fatigue injuries associated with repetitive strain.

Pathophysiology

Repeated hyperextension of the fetlock joint during exercise with associated cyclic strain on the suspensory ligament is believed to be the primary cause of these conditions. In the

forelimbs, carpal hyperextension is also believed to be a contributing factor. As previously noted, long toe/low heel conformation may exacerbate the strain on the suspensory ligament. Stress reaction at the suspensory origin can be classified as an enthesitis resulting from tearing of Sharpey's fibers and associated inflammation of the underlying bone. Maladaptive remodeling and the onset of a stress fracture follow a pathogenesis similar to that of others and the reader is referred elsewhere for a detailed discussion. Stress fractures are most common in race horses and it is presumably the high-speed cyclic strain that promotes the development of fracture in these cases. Stress fractures can be classified as a form of avulsion fracture.

Epidemiology

Stress reaction at the suspensory origin is seen in all types of performance horses. It appears to be most common in race horses, eventers and show hunters or show jumpers.[86,87] Stress fractures at the suspensory origin are most commonly seen in race horses.[86–89] While the 'high suspensory syndrome', and in particular proximal suspensory desmitis, affects both front and hindlimbs, in the author's experience the primary osseous disorders (stress reaction and stress fracture) are seen more commonly in the forelimbs.

Prevention

Like other bone disorders associated with high-strain cyclic fatigue and/or maladaptive remodeling ('stress-induced bone disease'), prevention of stress reaction and stress fracture at the origin of the suspensory ligament, in theory, should involve both modification of the training regimen and early detection of the subclinical pathologic changes. In actuality, it is impossible to make a blanket recommendation on appropriate training schemes for all ages and uses of athletic horses. Detection of early pathologic changes using advanced diagnostic imaging modalities such as scintigraphy and thermography during the evaluation of horses at high risk for these conditions, or those exhibiting early clinical signs typical of pain at the suspensory origin, with subsequent modification in training intensity is a more realistic approach.

Long toe/low heel conformation exacerbates strain on the suspensory ligament. Therefore, corrective trimming and shoeing to improve hoof balance and shape is also important. However, elevating the heels with wedges and the use of egg bar shoes actually increases strain on the suspensory ligament[88] and their application in these horses should be avoided.

Other proximal metacarpal/metatarsal fractures in performance horses

This group consists of incomplete longitudinal fractures of the proximal palmar cortex of MC-III, dorsomedial articular fractures of proximal MC-III and dorsolateral articular fractures of proximal MT-III. All of these fractures are relatively uncommon compared to other metacarpal/metatarsal injuries and are seen almost exclusively in race horses. Recommended treatment for all is extended rest (3–6 months). The prognosis for the two metacarpal fracture types is generally good.[90–92] The prognosis for the dorsolateral articular fractures of proximal MT-III is more guarded.[93,94] This may be related to the association with osteoarthritis of the TMT joint.

CHAPTER 18

The carpus

Christopher E. Kawcak

Diseases of the carpus commonly affect race horses, in which repeated stress from training and racing can lead to degradative changes within synovium, joint capsule, articular cartilage, subchondral bone and ligaments. These chronic changes often lead to acute problems ranging from synovitis to catastrophic injuries. Identification of the chronic processes prior to the development of acute disease would be ideal and newer diagnostic methods, such as magnetic resonance imaging (MRI), computed tomography (CT) and biomarkers, may help. Most of the acute manifestations of carpal diseases lead to synovial effusion and pain on flexion and radiographic imaging and diagnostic arthroscopy are often necessary to characterize the disease process. Carpal disease in race horses is common and the lesions occur in consistent areas. This permits in-depth clinical study of carpal diseases, allowing practitioners to give an accurate prognosis for a particular injury based on these studies.

Carpal injuries can also affect any other type of equine athlete; however, these disease processes are usually manifested as acute, traumatic injuries which sometimes occur in uncommon areas of the carpus. Consequently, determining prognosis for these types of injuries is often difficult due to the unusual nature of the damage and the lack of large clinical studies.

Synovitis

- Variable lameness with synovial effusion.
- Radiographs are often unremarkable.
- Intra-articular medication is often effective for eliminating signs.
- Horses with synovitis often respond well to medical therapy.

Recognition

History and presenting complaint

Synovitis manifests itself primarily as a lameness associated with significant synovial effusion. Synovial effusion alone in young race horses that are not showing lameness or training problems is not uncommon. However, the effusion may be significant if there is a history of training-associated problems or lameness with the horse.

Physical examination

Synovial effusion in the carpal joints can occur in both the dorsal and palmar aspects. A grading scheme, developed by Ray & McIlwraith (unpublished data, 1995) can be used to grade synovial effusion from 1 to 4. Grade 1 is mild effusion palpable on the dorsal aspect of the carpal joints, while grade 4 is palpable effusion that can also be detected on the palmar aspect of the joint. It is typical to see pain with static flexion in horses with synovitis and pinpoint pain on palpation can sometimes be appreciated in those with synovitis and other injuries leading to synovitis. Heat on palpation is not uncommon in horses with synovitis; however, the presence of topical medications and recent bandaging may influence surface heat.

Most horses with synovitis will be lame at the trot and, in carpal lameness in particular, wide movement to the forelimbs is appreciable. This wide movement occurs because horses with synovitis, and the resulting pain in the carpal joints, do not want to flex their carpi. Consequently, they will

circumduct the limb, leading to a wide moving gait. Furthermore, in cases of carpal synovitis, it is quite common to see worsening of the lameness after flexion.

Special examination

Regional anesthesia of the carpus, although often unnecessary for diagnosis of synovitis, can be accomplished by performing a median and ulnar nerve block after perineural anesthesia below the carpus has been performed. Intra-articular anesthesia is usually not necessary to diagnose synovitis of the carpal joints but occasionally may be needed to confirm carpal disease and rule out other diseases in the limb. As an example, it may be prudent to block the carpal joints and eliminate the lameness there in order to document additional lameness in another area of the limb. Although carpal joint blocks have been described elsewhere, it is important to remember that the radiocarpal and intercarpal joints should be blocked separately. Because heat can be experienced in joints with synovitis, the use of thermography can help to regionalize the area of injury. Furthermore, radiographs are usually negative. However, good-quality radiographs in multiple views are necessary to rule out any small or subtle injuries. In many cases of primary synovitis, it is not uncommon to see soft tissue thickening or dorsal displacement of the fat pad on the dorsum of the carpus on the radiographs.

Advances in ultrasonographic examination of joints have given clinicians a better impression of soft tissue injuries. Because soft tissue injuries can lead to synovitis, documentation of capsular and synovial lining thickening and edema can help not only to diagnose the primary problem but also to monitor therapy over time. Ultrasound also allows the clinician to rule out extracapsular thickenings such as hygromas and synovial hernias. An in-depth review of ultrasonographic examination of joints has been documented.[1]

Synovial fluid can also be evaluated subjectively. It is not uncommon in cases of synovitis to see a watery, clear to light yellow fluid. In some cases, there is increased opacity and flocculants in the fluid. In cases such as this, laboratory examination of the synovial fluid may be necessary to rule out septic arthritis.

Laboratory examination

Synovial fluid analysis results can be variable in cases of synovitis although most white blood cell counts are less than 1000 cells/mm^3 and total protein concentrations are generally between 2.5 and 4.0 g/dL. Biomarker data often show elevated concentrations of prostaglandin E_2.[2,3]

Diagnostic confirmation

The lack of radiographic findings, which rules out osteochondral fragmentation and fracture, is often enough to lead to a diagnosis of synovitis, although a negative diagnostic arthroscopy is needed to be totally convinced that intra-articular ligament disease is not present. It is often difficult to justify diagnostic arthroscopy in cases that are most likely synovitis compared to intra-articular ligament injury; therefore most veterinarians will monitor response to medical therapy. Refractory cases are then easier to justify as needing surgery as synovitis usually responds well to intra-articular medications.

Treatment and prognosis

Therapeutic aims

The goal of therapy is to provide timely, effective anti-inflammatory medications either systemically or locally.

Therapy

Systemic anti-inflammatory medications, such as non-steroidal anti-inflammatory medications or intravenous hyaluronic acid, are the simplest forms of therapy which are often very effective for controlling synovitis. However, intra-articular anti-inflammatory medication in the form of corticosteroids and/or hyaluronic acid may be necessary to provide effective treatment. Physical therapy methods such as ice, hydrotherapy and walking are often used in addition to medications.

Prognosis

The prognosis for synovitis is often excellent for resumption of athletic training with rapid, effective therapy barring predisposing conformational abnormalities, osteochondral disease or intra-articular ligament disease.

Etiology and pathophysiology

Acute injuries can lead to synovitis but in race horses, the chronic effects of training and racing can lead to failure of tissues to adapt properly to training. Early, chronic stress can lead to adaptive changes until a certain threshold is crossed, when degradative changes overcome adaptive changes. This can occur within any tissues. Conformational abnormalities can accelerate the degradative process due to high, focal stresses.

Epidemiology

As stated previously, young race horses typically develop some form of synovitis early in their training. However, most cases of synovitis are secondary to a primary disease entity within the joint, such as osteochondral fragmentation or fracture. Conformational abnormalities, especially offset and/or calf-kneed conformations, can increase the chances of synovitis.

Prevention

Critical evaluation of conformation is essential as gross abnormalities in conformation may cause persistent

abnormal loading and hence synovitis and ultimately osteoarthritis (OA). Careful monitoring during training is also essential as treatment and change in training early in cases of synovitis are helpful.

Capsulitis

- Capsulitis often results in joint capsule thickening.
- Restricted range of motion is common in cases of capsulitis.
- Enthesiophytes are often seen on radiographs.
- Response to treatment is often variable.

Recognition

History and presenting complaint

Capsulitis can be caused by several disease processes so the history can be quite variable. For instance, it is not uncommon to see capsulitis in horses with a history of carpal disease such as osteochondral fractures, fragmentation or ligamentous injuries. However, capsulitis can also result from non-articular diseases, such as extracapsular ligament damage or capsular injury. In some cases, capsulitis can also occur because of acute injury, which may lead to edema and possibly fibrosis of the joint capsule. In some recurrent or unresponsive idiopathic synovitis cases, capsular thickening and scarring can also result. In most of these cases in athletes, the animal will fail to train and will have chronic unresponsive joint disease.

Physical examination

Horses with capsulitis typically show soft tissue thickening over the dorsal aspect of the carpus. However, the severity of effusion can be difficult to appreciate because of this thickening. Range of motion is often restricted and maximal flexion often results in a painful response. At the jog, these horses typically move wide and are often significantly worse after carpal flexion. Occasionally, pain on palpation will be apparent on the dorsal aspect of the carpus, especially in acute cases. Although capsular swelling is difficult to appreciate on the palmar aspect of the joint, it is the author's experience that horses with palmar capsular pain are extremely sensitive to carpal flexion.

Special examination

Horses with acute capsular changes may show no radiographic changes; however, those horses with capsular tearing, especially at the insertion of the capsule into the bone, will often show enthesiophyte formation several weeks after injury (Fig. 18.1). Enthesiophytes can vary in severity and location; however, in most equine athletes, especially race horses, enthesiophyte formation on the dorsal aspect of the carpal bones is quite common. Ultrasound examination of the joint capsule in horses with acute capsulitis will often show edema formation within the capsular tissues, and thickening of those tissues. Thermography may be of some use in acute cases due to the heat and inflammation that commonly occur with capsulitis and capsular tearing. Nuclear scintigraphy may also be helpful in some cases, especially in the flow and soft tissue phases. CT examination may be of little use in these cases unless a primary osteochondral disease process is leading to the capsular change. MRI, on the other hand, would be very helpful in assessing capsular disease and in qualifying the severity of damage.

Laboratory examination

Synovial fluid analysis in horses with capsular damage is often quite variable.

Diagnostic confirmation

As mentioned previously, radiographs are usually only suggestive of capsular changes. In particular, enthesiophyte formation certainly indicates previous capsular insertional damage and periarticular lysis may indicate acute inflammation at the insertion. Even though capsular damage can occur by itself, other intra-articular diseases must be ruled out, either by the special examinations mentioned above or, as in most cases by diagnostic arthroscopy.

Finally, capsulitis is sometimes diagnosed based on response to therapy. For instance, some cases of acute capsular tearing may respond well to intra-articular anti-inflammatory medications. Unlike secondary capsulitis, which occurs in response to other osteochondral diseases, primary capsular damage will usually respond to medical therapy. However, this is dependent upon the severity of damage.

Treatment and prognosis

Therapeutic aims

The principal therapeutic aim is to remove the primary disease. In cases of secondary capsular damage, the primary objective is to remove the intra-articular damage that is leading to capsulitis. Second, inflammation must be reduced by either systemic or intra-articular methods. Finally, because capsular disease often leads to scar tissue formation, methods that help restore function and range of motion are essential to decreasing scar tissue formation. For instance, this author commonly uses passive range of motion, hypothermia, massage therapy and progressive increase in exercise in an attempt to restore proper function to the joint.

Therapy

Arthroscopic removal or fixation of the primary problem is essential to overcoming capsular damage. Systemic and intra-articular anti-inflammatory medications and physical therapy, including passive range of motion, are also essential in dealing with capsular damage. Furthermore, although unsubstantiated

Fig. 18.1
Radiographic image of a carpus showing severe enthesiophyte formation.

experimentally, this author feels that the use of joint supplements such as chondroiton sulfates and glucosamines may be beneficial in cases in which there is capsular damage.

Prognosis

The prognosis in cases with capsular damage can be quite variable. In cases of acute, mild capsulitis or capsular damage, the prognosis is usually quite good with prompt identification of the disease process and therapy. However, severe cases of capsular damage can be quite limiting to the prognosis of an athlete and often require ongoing medical management to continue competing. Decreased range of motion and pain on flexion often hinder the horse's ability to use the limb properly. The prognosis for cases of secondary capsulitis or capsular damage is dependent on the severity and form of the primary disease process.

Etiology and pathophysiology

In most primary cases of capsular damage, an acute sprain type of injury is often the cause of the problem. However, as stated above, repetitive trauma to the joint capsule due to training and racing could lead to chronic changes in the joint capsule, and hence chronic capsulitis. Secondary forms of capsular damage often result from osteochondral damage elsewhere in the joint and failure to treat that primary disease promptly.

Epidemiology

It seems that most cases of carpal disease often result in some form of capsulitis. Only in those very acute cases of primary joint disease will capsulitis not be a factor. However, failure to treat promptly or a 'wait and see' approach to carpal disease will most likely lead to some form of capsular disease. Capsulitis is common in race horses and in retired race horses which are commonly used in other disciplines. In some of the latter cases, the primary osteochondral injury may not be treated because the horse is retired, and hence lead to capsulitis.

Prevention

Aggressive and prompt treatment of the primary cause of secondary capsulitis is essential in order to prevent capsular

damage and thickening. In some cases, failure to treat the primary problem often results in persistent capsular changes that often limit the prognosis of the animal, even though the primary disease may be mild or cured.

Desmitis (intra-articular and extra-articular ligament disease)

- Effusion often persists in the face of medical therapy.
- Radiographs are often unremarkable.
- Diagnostic arthroscopy is often required to establish a diagnosis.
- Fiber tearing is common in athletes.

Recognition

History and presenting complaint

There are no distinguishing historical characteristics for horses with desmitis of intra-articular ligaments.[4]

Physical examination

Similar to the history, it has been shown in a retrospective study that there are no distinguishing clinical characteristics for diagnosis of intra-articular ligament damage that separate it from other forms of carpal disease.[4]

Special examination

Most cases of intra-articular ligament damage present similar to cases of synovitis. In acute cases, these animals show synovial effusion and negative radiographic findings. However, in some cases of avulsion fracture, special views can identify intra-articular ligament damage and nuclear scintigraphy may show increased uptake within the intercarpal area. CT examination has revealed stress reaction in the subchondral bone adjacent to intra-articular ligament sites, which may be indicative of damage at that site.[5] In the future, MRI examination will undoubtedly show intra-articular ligament damage much as it does in humans.

Diagnostic confirmation

Although other diagnostic modalities exist, diagnostic arthroscopy is still the best method, not only to characterize the severity of damage but also to aid in debridement of the torn ligament fibers.

Treatment and prognosis

Therapeutic aims

The primary therapeutic aim is to identify the diseased tissues and debride those torn ligamentous fibers. In cases of avulsion fracture, it is best to remove the avulsed portion of bone.

Therapy

Arthroscopic debridement of tissue ends is essential for treatment of intra-articular desmitis. Furthermore, anti-inflammatory medications and joint supplements may also be beneficial, as is physical therapy.

Prognosis

The prognosis for intra-articular ligament damage is based on the severity of damage; however, in most cases the prognosis is good.

Etiology and pathophysiology

It appears that intra-articular ligament damage is quite common as most horses older than 1 year have some form of tearing.[6] It has also been shown that larger ligaments show some forms of damage at the ultrastructural level. Therefore, it appears that most of these cases are the result of chronic progressive damage, most likely due to training and racing. However, the gross changes have variable clinical effects on equine athletes.

Epidemiology

Recent reports have shown that intra-articular ligament damage is quite common and may even be incidental in most cases. This makes it difficult to determine the clinical significance of these lesions; however, seeing the damage as the only pathologic change on diagnostic arthroscopy and seeing a positive improvement with debridement leads one to believe that in some cases these are significant lesions when no other lesions are present.

Prevention

There appears to be no effective means of preventing intra-articular ligament damage other than identifying the lesions at an early stage in order to prevent secondary joint changes that could lead to OA.

Osteochondral fragmentation (chip fracture)

- Chronic disease processes often lead to osteochondral fragmentation.
- Synovitis is a common feature of osteochondral fragmentation.

- Arthroscopy is the treatment of choice.
- The prognosis is dependent on the severity of articular cartilage erosion.

Recognition

History and presenting complaint

Most horses with osteochondral fragmentation appear to have a history of acute lameness isolated to the carpal joints. However, in some cases, especially in race horses, synovial effusion or synovitis often precedes diagnosis of osteochondral fragmentation.

Physical examination

Clinical signs in horses with osteochondral fragmentation are very similar to those in horses with synovitis.

Special examination

Radiographs are often diagnostic in cases of osteochondral fragmentation; however, radiographs often underestimate the severity of damage (Fig. 18.2).[7] In some cases, the lesions have not been radiographically apparent. CT examination has proven beneficial in diagnosing unusual cases of osteochondral fragmentation, as has MRI.

Laboratory examination

Synovial fluid analysis has not been beneficial for identifying cases of osteochondral fragmentation; however, biomarker evaluation of joint disease has been beneficial in an experimental model of osteochondral fragmentation.[8] In particular, significant changes in articular cartilage matrix components and subchondral bone have been seen with osteochondral fragmentation, and monitoring these changes over time may help in identifying horses that could be prone to fragmentation.[8]

Fig. 18.2
Osteochondral fragmentation present on the distal aspect of the radiocarpal bone.

Diagnostic confirmation

Diagnostic arthroscopy is by far the best means of characterizing osteochondral fragmentation and also has the benefit of allowing for treatment of the disease. However, in most cases radiographs are appropriate for confirming the disease.

Treatment and prognosis

Therapeutic aims

Removal of the fragment is essential for restoring the joint to normal function. Accurate grading of articular cartilage lesions is also essential and, of course, much like all other cases, decreasing inflammation is also essential.

Therapy

Arthroscopic removal of the fragment and use of anti-inflammatory medications are necessary in treating these diseases. Furthermore, chondral supplementation, be it by intra-articular or systemic means, is also beneficial, especially in severe cases of osteochondral fragmentation. In particular, this author uses intra-articular polysulfated glycosaminoglycans in cases of grade 4 erosion (McIlwraith, personal communication, 1997).[10] The author also finds physical therapy to be beneficial in these cases, to limit the amount of capsulitis that can accompany osteochondral fragmentation.

Prognosis

The prognosis varies with articular cartilage erosion severity. In particular, return to racing at equal to or better than before surgery was 71.1% for grade 1 lesions, 75% for grade 2 lesions, 53.2% for grade 3 lesions and 54% for grade 4 lesions.[7]

Etiology and pathophysiology

Evaluation of post-mortem cases, especially by Poole[9] and Norrdin & Kawcak (unpublished data, 1998), has shown that most osteochondral fragments in race horses are acute manifestations of chronic disease processes. In particular, most fragments occur in areas of stress-induced subchondral bone sclerosis, in which microdamage exceeds healing and acute fragmentation results. Poole has also seen attempts at healing, as shown by the presence of granulation tissue at these sites; however, continued training had resulted in fragmentation through the granulation tissue bed.

Epidemiology

Osteochondral fragmentation of the carpus is very common in race horses, particularly in racing Quarter Horses, Thoroughbreds, and Standardbreds. However, in non-racing breeds, it is quite rare and when it does occur, it arises in unusual locations other than the dorsal aspect of the carpus.

Prevention

Again, there is no effective means of preventing osteochondral fragmentation in horses, especially in race horses. However, subtle subchondral bone lysis on radiographic examination and persistent synovial effusion may be indicative of impending osteochondral fragmentation. The genesis of biomarkers may also prove beneficial in early identification of osteochondral fragments.[8]

Osteochondral fracture (slab fracture)

- Horses with osteochondral fracture often present with significant acute lameness.
- Synovitis is a common sign of osteochondral fracture.
- Horses with osteochondral fracture are often very responsive to flexion.
- Radiographs are recommended prior to performing intra-articular anesthesia, which is often not required for diagnosis.

Recognition

History and presenting complaint

Acute, severe lameness often accompanies osteochondral fracture; however, some horses may not be lame acutely but rather may manifest severe lameness within 24 hours.

Physical examination

Horses with osteochondral fracture appear to be severely lame compared to horses with other disease processes within the carpus, and they are very responsive to carpal flexion. In some cases, the horse may actually resent even partial flexion of the carpus and the clinician must take care when performing the flexion test.

Special examination

This author does not recommend intra-articular anesthesia in cases of severe carpal lameness with severe response to flexion. Instead, a complete series of radiographs is essential, including skyline and, in some cases, special views to highlight the fractures. CT and MRI are also valuable, especially in assessing those fractures that are not absolutely clear on radiographs. However, since both modalities require general anesthesia, it is recommended that the surgeon perform these imaging studies just prior to surgery so the fracture can be repaired to prevent further comminution that may occur with recovery.

Laboratory examination

There are no synovial fluid parameters that are specific for osteochondral fracture; however, hemorrhage into the joint is not uncommon.

Diagnostic confirmation

Radiographs and diagnostic arthroscopy are helpful to confirm the diagnosis.

Treatment and prognosis

Therapeutic aims

The aim of therapy is to restore the articular surface to as normal a congruence as possible and to provide axial support to the limb.

Therapy

Internal fixation or removal of the fractured piece via arthroscopy are considered the treatments of choice. Only small fractures or fractures within the palmar aspects of the joints should be removed and usually only if they cannot hold the screw. Since there is often significant articular cartilage loss with these fractures, some form of resurfacing would enhance repair. However, those methods are still in their infancy and surgeons often look towards the use of chondroprotective agents to treat the significant cartilage loss that occurs with these diseases.

Prognosis

In general, the prognosis for successful repair of intra-articular fractures is often poor, especially in race horses; however, the prognosis for third carpal slab fractures is often dependent on the severity of articular cartilage erosion at the site.

Etiology and pathophysiology

Subchondral bone sclerosis is very common in cases of osteochondral fracture, indicating that these fractures may be the result of accumulated microdamage.[9] Furthermore, the proximal portions of these fractures often have fibrous tissue within them, indicating that a chronic pathologic condition may exist prior to acute manifestation of the fracture.

Epidemiology

Osteochondral fractures are quite common in race horses and occur most frequently within the radial fossa of the third carpal bone. Other fracture configurations can occur and fractures can occur within other bones of the carpus.

Prevention

As with the above disease entities, it is difficult to prevent osteochondral fracture. However, close monitoring of horses with persistent carpal disease is essential.

Catastrophic injury (breakdown)

- Catastrophic injury can result from chronic or acute disease processes.
- Catastrophic injuries are often life threatening.
- Aggressive first aid is often needed prior to surgical repair.
- Local and systemic stabilization of the horse is necessary.

Recognition

History and presenting complaint

Horses with catastrophic injuries of the carpus often show acute non-weight bearing lameness and axial instability at the carpal area.

Physical examination

Non-weight bearing lameness with significant instability at the carpal joint, leading to loss of axial support.

Special examination

Radiographic examination is often diagnostic in identifying multiple carpal bone fractures (Fig. 18.3).

Laboratory examination

Laboratory examination is not diagnostic, as clinical signs are absolute in localizing this problem.

Diagnostic confirmation

Diagnostic confirmation is often via radiographs.

Treatment and prognosis

Therapeutic aims

Systemic support of the animal is often essential, as most of these horses will present excited and hypotensive because of sweating. This often seems to be overlooked and acute treatment of systemic effects is critical, especially if the horse is to undergo surgical treatment. Local, effective, temporary stabilization of the carpus is also essential in promoting a good prognosis. This may also help with the horse's temperament in that localized stabilization may allow the horse some degree of weight bearing and have a calming effect. Acute stabilization entails both palmar and lateral support of the carpus via splints and bandaging as described by Bramlage.[10] Ultimate therapy or ultimate treatment for this condition will rely on surgical restoration of axial support.

Fig. 18.3
Acute, traumatic catastrophic injury of the carpus in a Warmblood after a pasture accident. The carpus was physically unstable in the lateral-to-medial direction but was axially stable, resulting in adequate stability with splint application.

Therapy

Again, aggressive first aid and sedation are essential for prompt treatment and transportation of the horse. Stabilization via splints is also essential to allow the horse some degree of comfort and to prevent further damage to the joint. Surgical reduction and internal fixation are often the definitive means of treatment for restoration of axial stability. However, the ultimate goal is pasture soundness for breeding animals. Conservative therapy has also been used in some of these cases, in which cast application, usually via a sleeve cast, has allowed for ankylosis of the joints to occur. Partial or pancarpal arthrodesis has also been used to salvage these horses for breeding.

Prognosis

The prognosis for athletic soundness in these horses is grave. However, prognosis for pasture soundness is often good with acute aggressive therapy.

Etiology and pathophysiology

Catastrophic injury of the carpus can result from either acute or chronic disease processes. As mentioned above, acute diseases can occur due to some sort of traumatic event. However, some acute injuries may be a result of pain elsewhere in the animal that causes either overloading of that limb or abnormal use of the limb. Chronic disease processes can also lead to catastrophic injury of the carpus. In particular, slab fractures that go unrecognized or are not treated, or that are compounded by an acute traumatic event, may lead not only to damage of the slab portion but also to either opposite limb injury or injury to other bones within the same joint.

Epidemiology

Catastrophic injury of the carpus is quite rare, especially in non-racing breeds.

Prevention

Again, there is no definitive means of preventing catastrophic injuries of the carpus but accurate diagnosis of early diseases may be helpful. However, especially in non-racing animals, acute injury to the carpus can occur with jumping or falling, thus limiting any means of prevention.

Stress-induced bone reaction (subchondral sclerosis)

- Failure of subchondral bone to adapt to exercise.
- Response to intra-articular anesthesia is variable.
- Nuclear scintigraphy is often diagnostic.
- Early detection and decreased training are often necessary for successful treatment.

Recognition

History and presenting complaint

Horses with subchondral sclerosis that leads to clinical disease often present with a non-specific history of lameness or, more frequently, a decrease in performance.

Physical examination

Physical examination findings typically show signs of chronic carpal joint disease consisting of joint capsule thickening and pain on flexion. However, occasionally, those signs are not present.

Special examination

Radiographic findings include sclerotic bone, usually in the third carpal bone, with lysis on the proximal joint surface. These findings are best seen on the third carpal bone skyline projection. Care must be taken not to overinterpret this finding as most athletic horses, especially race horses, have this change. The distinguishing thing in cases of clinical disease is the lysis. Nuclear scintigraphy is a good confirmatory modality as horses with stress-induced bone reaction will show intense, focal uptake in the area (Fig. 18.4). Computed tomography can also help to confirm diagnosis. Areas of intense subchondral bone thickening and lysis can be easily seen. Magnetic resonance imaging can also be used to view these changes, especially if subchondral bone edema is present.

Laboratory examination

There are no distinguishing changes in synovial fluid parameters that can lead to a diagnosis of subchondral bone stress

Fig. 18.4
Nuclear scan of a carpus showing intense, focal uptake in the intercarpal joint area.

reaction. However, early work using biochemical markers of bone turnover in synovial fluid and serum indicates that changes in osteocalcin may help to identify the change.

Diagnostic confirmation

Nuclear scintigraphy is often adequate to confirm diagnosis of subchondral stress reaction in the carpus.

Treatment and prognosis

Therapeutic aims

The goal of therapy is to promote bone remodeling in the hope of re-establishing a more compliant subchondral bone. This can either be done through reduced training or by medication.

Therapy

Reduced training may help in re-establishing a more normal subchondral bone. The reinitiation of remodeling, including the osteoclastic function that occurs with rest, along with re-establishment of exercise may help to provide a more normal bone. However, prior to treatment, diagnostic arthroscopy may be needed if subchondral lysis has led to collapse of the overlying articular surface. In addition, some have indicated that subchondral bone forage may also help to stimulate blood flow into the area and thus reinitiate remodeling.

A few medications have also been recommended for this problem. Although not objectively established, isoxsuprine is thought to help in stimulating blood flow in bone. Bisphosphonates, which are used to control osteoporosis in humans, have recently come on the market in Europe for treating bone metabolism abnormalities in horses.

Prognosis

The prognosis for successfully treating subchondral stress reaction is dependent on the severity of the disease and the presence of articular cartilage collapse in the joint. The prognosis with articular cartilage collapse is dependent on the size of articular cartilage erosion and the depth of subchondral bone collapse.

Etiology and pathophysiology

The etiology of subchondral stress reaction has been identified as an inappropriate bone modeling response due to high loads experienced by the bone during exercise (Fig. 18.5). This high stress may be due to faulty conformation or inappropriate use of the limb. However, although not objectively identified, inherent bone metabolism could be at fault. Regardless, the subchondral bone appears to model and thicken as normal with exercise, except that it models to the point of inducing ischemia in the subchondral bone plate, leading to subchondral bone death and degeneration.[9] This degeneration then leads to loss of support and collapse of the overlying articular cartilage.

Epidemiology

Stress-induced bone response is primarily a disease of young race horses that are at the peak of bone modeling and remodeling. The radial facet of the third carpal bone is the primary area affected by the disease.

Prevention

Prevention of this disease is difficult as the onset is insidious and the disease progressive with training. Since there is no hallmark clinical sign of disease onset nuclear scintigraphy may be the only method of identifying stress-induced bone reaction in its early phases and may also be helpful in monitoring its progression. Serum and synovial fluid biomarkers could prove useful in the early detection of this disease, and hence prevention of serious damage.

Osteoarthritis (degenerative joint disease, arthritis)

- OA is usually secondary to other disease processes.
- Diagnosis is based on clinical and radiographic signs.
- Radiographic changes include joint collapse and subchondral sclerosis and lysis.
- Treatment is aimed at management.

Recognition

History and presenting complaint

Most horses with osteoarthritis (OA) have a history of previous joint injury or disease. However, in some cases, the cause is unknown and the development of the disease is insidious.

Physical examination

Most horses with OA of the carpal joints show lameness, joint capsule thickening on palpation, decreased range of motion that leads to pain in response to maximal flexion, and sometimes acquired conformational changes. These changes can include medial collapse of the carpal joints, leading to carpal varus, or persistent flexing of the carpus, leading to carpal contracture.

Special examination

Radiographic findings are often mixed but can consist of osteophyte and enthesiophyte formation, reduced joint space and a mixture of subchondral bone lysis and sclerosis. Nuclear scinti-

Fig. 18.5
A sagittal section of a carpus through the radiocarpal and third carpal articulation showing the gross evidence of subchondral and trabecular bone thickening due to exercise.

graphic findings are often mixed due to the chronic nature of the disease and the variable use of the limb. Computed tomographic findings often include variable subchondral bone sclerosis and lysis as well as the presence of osteophytes and enthesiophytes. Loss of joint space can also be seen. Magnetic resonance imaging is often the best diagnostic test to show loss of articular cartilage, which is the hallmark of OA.

Laboratory examination

Synovial fluid varies in color and viscosity, but usually is thick, orange to red and cloudy. However, in some cases synovial fluid is impossible to obtain which gives the subjective impression of a 'dry joint'. Early work using biochemical markers has shown progressive changes with OA, including reduced aggrecan and collagen content in synovial fluid and serum.

Diagnostic confirmation

Confirmation of the diagnosis is based on historical, physical examination and radiographic findings. The establishment of a chronic, progressive disease isolated to the carpus and the radiographic changes mentioned above often lead to a diagnosis.

Treatment and prognosis

Therapeutic aims

The therapeutic aims in treating OA are to realize that complete resolution of the disease is impossible and instead, management of the disease is needed. To do this, management of pain is a necessity. In some severe cases, elimination of the joint is necessary.

Therapy

The management of pain is varied based on the expected use of the horse, the severity of disease, the severity of compensatory pain and the individual horse's pain tolerance. Consequently several different management schemes must be

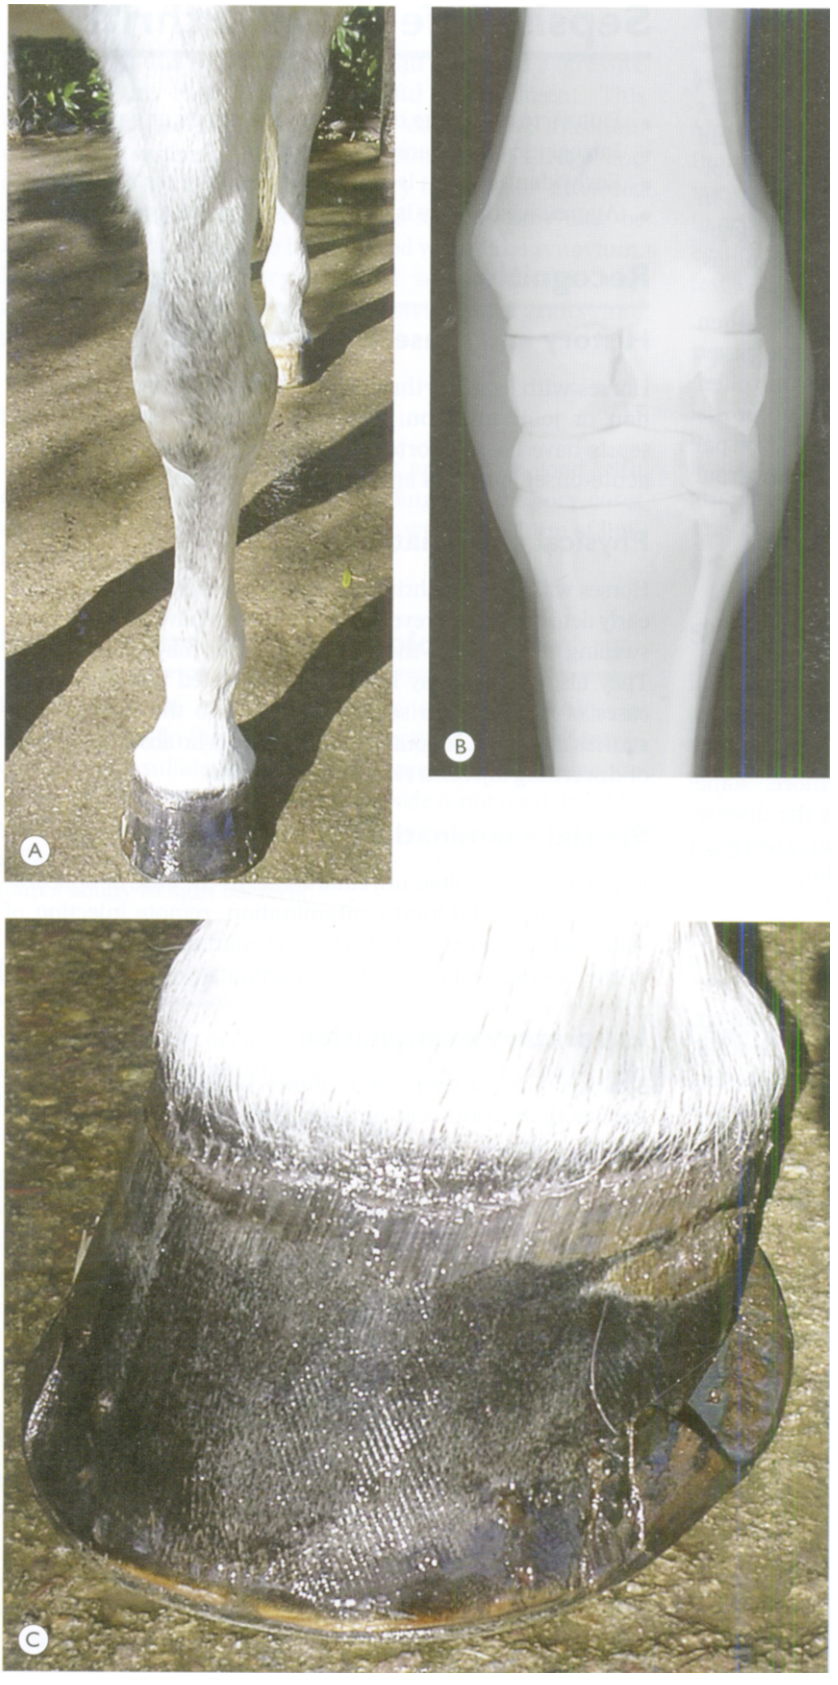

Fig. 18.6
A mare that had lifelong offset knee conformation that led to chronic pain and worsening of a carpal varus conformation. (A) Radiographs showed development of OA changes such as osteophytes and subchondral sclerosis (B), but pain and carpal varus worsening were controlled with shoeing that prevented worsening of lateral hoof breakover. (C) OA progression was prevented with shoeing in this case.

tried before one can be selected (Fig. 18.6). Pain management is often through the use of medications, supplements and/or physical therapy. Medications typically used include NSAIDs, systemic hyaluronic acid or polysulfated glycosaminoglycans and/or intra-articular administration of corticosteroids and hyaluronic acid or polysulfated glycosaminoglycans. A combination of these medications is often used (see Chapter 23). In addition, it is common to use supplements to aid in management of pain, including orally administered glucosamines, chondroitin sulfates, hyaluronic acid and various herbs.

If medical management of joint pain fails to work, then surgical fusion of the joint can be considered. In some cases, the increased likelihood of laminitis in the support limb often leads to the decision to perform surgery. Disease of either the radiocarpal or intercarpal joints justifies a partial carpal arthrodesis, or disease of both joints can lead to a pancarpal arthrodesis.

Prognosis

The prognosis for managing carpal pain due to OA is dependent on several factors, but mostly on the response to therapy. Identification of a management scheme is of the utmost importance in determining a prognosis for the owner and a trial period in which various medications are tried is needed prior to committing to a prognosis. Furthermore, some horses fail to respond to treatment over time as the disease progresses and alteration of a prognosis is needed. The prognosis for arthrodesis techniques is good for breeding animals.

Etiology and pathophysiology

The etiology of OA is varied but usually due to a primary traumatic or developmental disease. The severity of the initiating disease and the success of treatment often dictate the rate of progression of OA. Whether by progressive subchondral bone sclerosis, leading to thinning of articular cartilage, or by primary loss of articular cartilage, leading to subchondral bone sclerosis, the progressive nature of the changes in the joint at the osteochondral junction leads to pain.

Epidemiology

Osteoarthritis of the carpal joints occurs in all breeds and uses of horses, but is most common in the race horse. Many retired race horses that continue a career in another discipline run the risk of OA because of previous injury and continued athletic use. This seems to be the group of horses that require significant management for continued athletic function.

Prevention

Aggressive and prompt treatment of the primary problem and early identification of inherent problems that could lead to OA are needed in order to establish a management scheme early in the course of the disease.

Sepsis (infectious arthritis)

- Failure to recognize open joint lacerations and punctures.
- Iatrogenic causes are not uncommon.
- Early identification is critical to successful treatment.
- Aggressive therapy is critical to successful treatment.

Recognition

History and presenting complaint

Horses with septic arthritis often have a history of a laceration or joint injection, although cases of idiopathic joint sepsis have been reported. Horses with septic arthritis have acute-onset lameness and swelling of the limb.

Physical examination

Horses with septic arthritis are usually severely lame, although early detection may prevent this. They often have heat, pain and swelling in the area of the infected joint and may have cellulitis. They also may or may not have an elevated temperature. In cases of postinjection sepsis, a reaction to the injected substances must be ruled out, although there is no absolute method of discerning injection reaction from sepsis.

Special examination

Radiographs are often unremarkable. In the case of a laceration and potential joint contamination, remote injection of saline into the joint and visual confirmation of fluid flow out of the laceration documents contamination.

Laboratory examination

Synovial fluid analysis often shows white blood cell values greater than 3000 cells/mm^3 and total protein greater than 4 g/dL.

Diagnostic confirmation

Remote saline injection and visualization at the laceration is the best confirmatory method for detecting joint contamination. In the carpus, lacerations on the dorsum of the carpus are common and injection into the palmar pouches is useful to confirm the diagnosis. For established sepsis, whether by laceration or iatrogenic injection, synovial fluid analysis is often confirmatory. However, reaction to injected medication is difficult to distinguish from sepsis and it is recommended to treat cases as septic.

Treatment and prognosis

Therapeutic aims

The aims of therapy are to reduce the bacterial load and fibrin accumulation in the joint, provide appropriate antibiotic therapy and reduce inflammation and pain in the joint.

Therapy

Early recognition of septic arthritis and early and aggressive treatment are essential in successful management. This includes documenting the organism causing the infection, the use of systemic and local antibiotics and lavage and debridement of the joint. In refractory cases, open or closed suction drainage is often needed and synovectomy may be needed if infection is felt to be harbored within the synovium. Long-standing, refractory cases of septic arthritis may require arthrodesis through massive bone grafts and drains.

Prognosis

The prognosis for overcoming septic arthritis is good with early treatment. However, long-standing or refractory cases are less likely to recover or will recover with some form of limiting lameness.

Etiology and pathophysiology

Establishment of infection within a joint may be due to several factors. In the case of joint injections, the use of intra-articular polysulfated glycosaminoglycans has been shown to perpetuate infection if an aminoglycoside is not used. In addition, the basic nature of corticosteroids is to reduce inflammatory cell density in an area, hence limiting the joint's ability to fight bacteria.

Epidemiology

Septic arthritis can occur in any horse, but is more common in athletic horses which are subjected to intra-articular medications.

Prevention

Strict adherence to aseptic injection techniques and early and rapid identification of open joint lacerations are needed in order to prevent septic arthritis.

Developmental orthopedic disease

- Angular limb deformity is a common form of DOD.
- Physitis can result from conformational abnormalities and rapid growth.
- Osteochondrosis is often in the form of subchondral cystic lesions.
- Nutritional and breeding management are the only forms of intervention.

Recognition

History and presenting complaint

Most horses with developmental orthopedic disease (DOD) of the carpus are young and tend to show signs of disease at various stages of development. Angular limb deformities tend to arise early or are acquired as the horse ages. Subchondral cystic lesions can occur within the cuboidal bones and manifest as carpal lameness.

Physical examination

Horses with subchondral cystic lesions of the carpus tend to show either chronic, progressive signs or acute signs. Foals are typically born with some form of carpal valgus, but should improve over time until fully grown. The challenge lies in recognizing normal angulation for a specific age.

Special examination

Radiographs are often the only modality needed to diagnose subchondral cystic lesions within the carpus. Computed tomographic studies have been used to plan for surgical debridement of cysts and to assess follow-up.[5]

Laboratory examination

Synovial fluid analyses are often unhelpful in diagnosing DOD of the carpus; however, serum and synovial fluid biomarker analyses have shown promise in this respect.

Diagnostic confirmation

Radiographs are often all that is necessary to diagnose DOD.

Treatment and prognosis

Therapeutic aims

The primary aim is to correct the problem and then treat the resulting joint disease as described in previous sections.

Therapy

Arthroscopic examination and treatment of subchondral cystic lesions of the carpus are necessary. In addition, medical treatment of the resulting joint disease is needed.

Prognosis

Prognosis is dependent on the size of the lesion and the amount of articular cartilage erosion that is present within the joint. Fracture through a cyst or angular deviation caused by the presence of the cyst must be taken into consideration when formulating a prognosis.

Etiology and pathophysiology

The pathogenesis of DOD is complex and theoretical in some aspects. However, a few things have been proven clinically and experimentally. Trauma to the articular cartilage and subchondral bone has been shown experimentally to cause subchondral cystic lesions in the stifle.[11] The influence of body size and growth rate on the development of DOD has also been proposed, and supported in Warmbloods and Standardbreds, but again, these were shown in the tarsus and stifle.[12] Nutritional imbalances in minerals, energy and protein have also been suggested in the pathogenesis of DOD, as has heredity.[12] Because DOD manifestations other than angular limb deformity are rare in the carpus, there has been little clinical or experimental work done to gain information on the pathogenesis of disease.

Prevention

Nutrition is paramount to prevent DOD in horses. In particular, adequate energy, protein and mineral balance are critical. Furthermore, changes in feed should be gradual. It also appears that genetics may be a factor in DOD and should be considered when inquiring about a certain breeding pair. Some consider trauma to be a factor in the development of DOD and early training should be monitored closely.

Carpal canal syndrome

- Accessory carpal bone fracture commonly leads to carpal canal effusion.
- Idiopathic hemorrhage is not uncommon.
- Osteochondroma can lead to carpal canal effusion.
- Lameness severity is variable.

Recognition

History and presenting complaint

Acute or chronic carpal sheath swelling is seen with this disease with variable degrees of lameness.

Physical examination

Carpal sheath swelling with variable lameness and variable response to flexion is often seen. In chronic cases of the disease, fibrosis may be appreciated medially, but little effusion may be present.

Special examination

Radiographs often reveal an osteochondroma or a reactive area at the physis. In some cases nothing is seen and ultrasound is needed to evaluate soft tissue structures. Hemorrhage into the sheath can be appreciated with ultrasound, as can fibrin and adhesion formation.

Laboratory examination

Synovial fluid analysis is often unremarkable, although in acute hemorrhagic conditions, bright red blood may be seen.

Diagnostic confirmation

Diagnostic confirmation is dependent on the disease process that is present. For instance, osteochondroma may be confirmed radiographically, but deep digital flexor tendon tearing would be seen ultrasonographically. It is not uncommon to see deep digital flexor tendon tearing secondary to osteochondroma formation, warranting ultrasound use when osteochondroma is diagnosed.

Treatment and prognosis

Therapeutic aims

Removal of the primary disease entity and treatment with anti-inflammatory medications are needed. However, with tendon damage, prolonged rest and gradual return to exercise are essential.

Therapy

Tenoscopic exploration of the sheath is often needed, especially in the case of osteochondroma removal. Debridement of deep digital flexor tendon fibers may also be carried out during tenoscopic examination. In addition, anti-inflammatory medications are useful and viscosupplementation may be indicated to prevent adhesion formation. Without the presence of an osteochondroma, drainage and injection of corticosteroids and hyaluronic acid may provide benefit.

Prognosis

Prognosis is often good for injuries to structures within the carpal canal.

Etiology and pathophysiology

The formation of an osteochondroma is thought to be due to the presence of residual physeal tissues within the area and subsequent endochondral bone formation. Hemorrhage into the carpal canal is thought to be a result of osteochondroma fracture, generalized trauma to structures within the sheath or idiopathic.

Epidemiology

In general, carpal canal diseases are rare and can occur in any breed or use of horse.

Prevention

No good form of prevention is available for carpal canal injuries, although removal of osteochondromas is necessary to prevent chronic damage to the sheath and deep digital flexor tendon.

Periarticular disease

- Hygroma can lead to isolated dorsal swelling.
- Synovial hernia is evidenced by palpable swelling between the skin and a joint.
- Synovial fistula leads to effusion of two adjacent synovial structures.
- Synovial fistula often occurs with other lesions.

Recognition

History and presenting complaint

Horses with periarticular diseases of the carpus often present with a history of acute or chronic swelling in the carpal area. However, lameness is often absent with most of these diseases.

Physical examination

Horses with periarticular disease often show dorsal carpal swelling and in the case of synovial fistula formation, swelling may occur in two separate locations, such as two joints or a joint and an associated tendon sheath. Lameness may be absent, but in most cases of synovial fistula, other diseases such as osteochondral fragmentation or OA are present, which in themselves may cause lameness.

Special examination

Radiographs of the carpal area in horses with synovial hernia or hygroma formation are often unremarkable. In horses with synovial fistula formation, it is not uncommon to see radiographic signs of osteochondral fragmentation or OA. Intra-articular or intralesional injection of contrast agent often indicates the connection of the lesion to the joint. However, in some cases such as ganglion formation, the injection may need to be within the joint as a one-way valve may exist that would prevent passage of the contrast agent into the joint from the lesion.

Ultrasonographic examination can show the communication between a hernia and the joint, although the lack of visualization does not rule out its presence.

Laboratory examination

There are no laboratory tests that are helpful in diagnosing these lesions.

Diagnostic confirmation

Arthrographic documentation is often necessary to confirm the presence of these lesions. However, often lesions that communicate to a joint can be visualized arthroscopically.

Treatment and prognosis

Therapeutic aims

Removal of the inciting cause is often necessary.

Therapy

Anti-inflammatory medications and bandaging are often useful in resolving hygroma formation. However, persistence of the lesion occasionally results. Anecdotally, injection of contrast agents into the lesion has resulted in resolution in a few cases. However, surgical resection is sometimes needed and should be weighed against the presence of the existing lesion.

Synovial hernias are often only of cosmetic concern, but their removal is sometimes desired. Primary herniorrhaphy is needed to correct this problem, which requires the creation of an incision in the area. Again, the presence of the scar must be weighed against the cosmetic blemish of the existing hernia.

Treatment of intrasynovial fistula has been documented; however, other lesions, such as osteochondral fragmentation and fracture, should also be treated at the same time.

Prognosis

The prognosis for hygromas and hernias is good although a cosmetic blemish may persist. In the case of synovial fistula, the prognosis is dependent on the severity of the associated lesions.

Etiology and pathophysiology

Trauma is the primary etiology for these lesions.

Epidemiology

Hygroma formation is common although the others are not. Again, horses with dorsal carpal swelling should be monitored to see if they are prone to continual trauma.

Prevention

Early recognition and treatment of dorsal carpal swelling are essential to prevent persistent hygroma formation. Furthermore, careful observation of the animal may show that it persistently strikes the area during eating or play and a change in management during feeding or proximity to other animals may be needed.

Tenosynovitis of carpal extensor tendons

- Jumpers commonly exhibit this after hitting rails.
- Cross-country horses can acquire this from hitting fixed rails.
- Sepsis due to foreign bodies is not uncommon.
- Medical or surgical therapy is often needed.

Recognition

History and presenting complaint

Acute or chronic swelling of the dorsal carpal area is often reported and in some cases, the swelling may represent cellulitis and severe lameness.

Physical examination

In non-septic cases, the swelling is localized to the extensor tendons dorsal and proximal to the carpus. There may or may not be associated lameness, but in most cases there is some discomfort with carpal flexion. In septic cases, a diffuse, painful swelling is present and the horse is usually severely lame.

Special examination

In some long-standing cases, periosteal reaction may be seen on the dorsum of the radius. However, in general, radiographs are often unremarkable. Ultrasonographic examination often shows the increased fluid within the sheath and damage to the extensor tendons.

Laboratory examination

Synovial fluid analysis is essential for confirming the presence of sepsis, but non-septic conditions are often unremarkable in their presentation.

Diagnostic confirmation

Synovial fluid is confirmatory for septic cases and ultrasound is confirmatory in most other cases.

Treatment and prognosis

Therapeutic aims

Non-septic conditions require anti-inflammatory treatments and rest for management of tissue changes. Septic conditions require surgical treatment, drainage and antimicrobial therapy.

Therapy

Anti-inflammatory medications are necessary in any case of tendon sheath swelling. In septic cases, tenoscopy, foreign body removal and debridement are indicated, as is antimicrobial treatment. Persistent cases may require open drainage. Viscosupplementation is often necessary to prevent adhesion formation in any case.

Prognosis

The prognosis is good for return to athletic soundness, although a cosmetic blemish may result. Septic cases are dependent on the ability to overcome the infectious process.

Etiology and pathophysiology

Striking of the carpus on an object is often the cause of this syndrome and in septic cases, a foreign body is sometimes present.

Epidemiology

Traumatic events are usually the cause of tendon sheath swelling, so horses that are used for jumping, especially those that jump fixed structures, may be more at risk for developing the disease.

Prevention

There are no good preventive measures for this disease, except for early recognition of punctures or lacerations into the sheaths, and aggressive treatment once recognized.

CHAPTER 19

Tarsus and stifle

Federico G. Latimer

The stifle joint is the largest and most complex in horses. It has a large range of motion and movements of the patella, distal femur and proximal tibia are highly co-ordinated and precise due to the remarkable anatomic design and function of the bony and soft tissue structures that stabilize the joint. Because of this specialized anatomic construct, injury and developmental or degenerative disease of a specific component will often cause articular instability somewhere else in the joint, making diagnosis and treatment challenging and adversely affecting prognosis for equine athletes. Stifle disease in horses can be developmental, infectious, traumatic or degenerative. Prompt recognition and localization of the disease process within the joint will maximize therapeutic options and improve the prognosis for future athletic use as most degenerative conditions in older horses are usually the result of a previous traumatic injury of a soft tissue or bony structure.

The tarsus in horses has high-motion (tarsocrural) and low-motion (proximal and distal intertarsal and tarsometatarsal) articulations. The severity, clinical presentation, joint affected and progression are variable and can be influenced by breed, conformation (skeletal or bodyweight), athletic use, age at onset and therapeutic regimens used. Many tarsal conditions can be managed medically or surgically such that a large proportion of these patients can successfully return to their previous level of athletic activity.

Stifle

Anatomy

- The equine stifle is composed of the femoropatellar and the medial and lateral femorotibial joints.
- Communication between synovial spaces is unpredictable and they should be considered separate sacs for diagnostic and therapeutic purposes.
- The trochlear groove is centered between the medial and lateral trochlear ridges of the distal femur (Fig. 19.1A).
- The medial trochlear ridge is larger than the lateral and with the patella compromises part of the stay apparatus (Fig. 19.1A).
- The medial collateral ligament and the medial meniscus are fused at the medial joint margin (Fig. 19.1A–C).
- The cranial and caudal cruciate ligaments are extrasynovial and located in the septum between the medial and lateral femorotibial joints.
- The medial and lateral collateral ligaments and three patellar ligaments (medial, middle and lateral) are all extrasynovial.
- The cupped fibrocartilaginous menisci enhance congruity of the round femoral condyles and flat tibial condyles (Fig. 19.1A, C).

Diagnosis and treatment of stifle disease in horses require an understanding of the articular anatomy and joint mechanics. It is important to obtain an adequate history to determine the age, use and duration of the lameness and whether a specific accident or injury precipitated it. Horses with stifle diseases are reluctant to flex the joint when gaiting and the cranial phase of the stride tends to be short, with the foot carried close to the ground. As a result, the gluteal rise on the involved or more severely affected side will be higher but of shorter duration. Walking on an incline or performing an upper limb or stifle flexion test will often exacerbate the lameness.

There may be visible or palpable effusion of any of the synovial sacs and atrophy of the gluteal or quadriceps muscles may accompany long-standing diseases. There may be marked periarticular or ligamentous thickening, crepitus or instability if ligamentous injuries or fractures are present. Intrasynovial anesthesia may help localize the compartment or structures involved. Due to the complexity of this joint, any improvement in the degree of lameness after intrasynovial anesthesia should warrant further investigation as involvement of multiple soft tissue or extracapsular structures may result in an incomplete response (Fig. 19.1A).

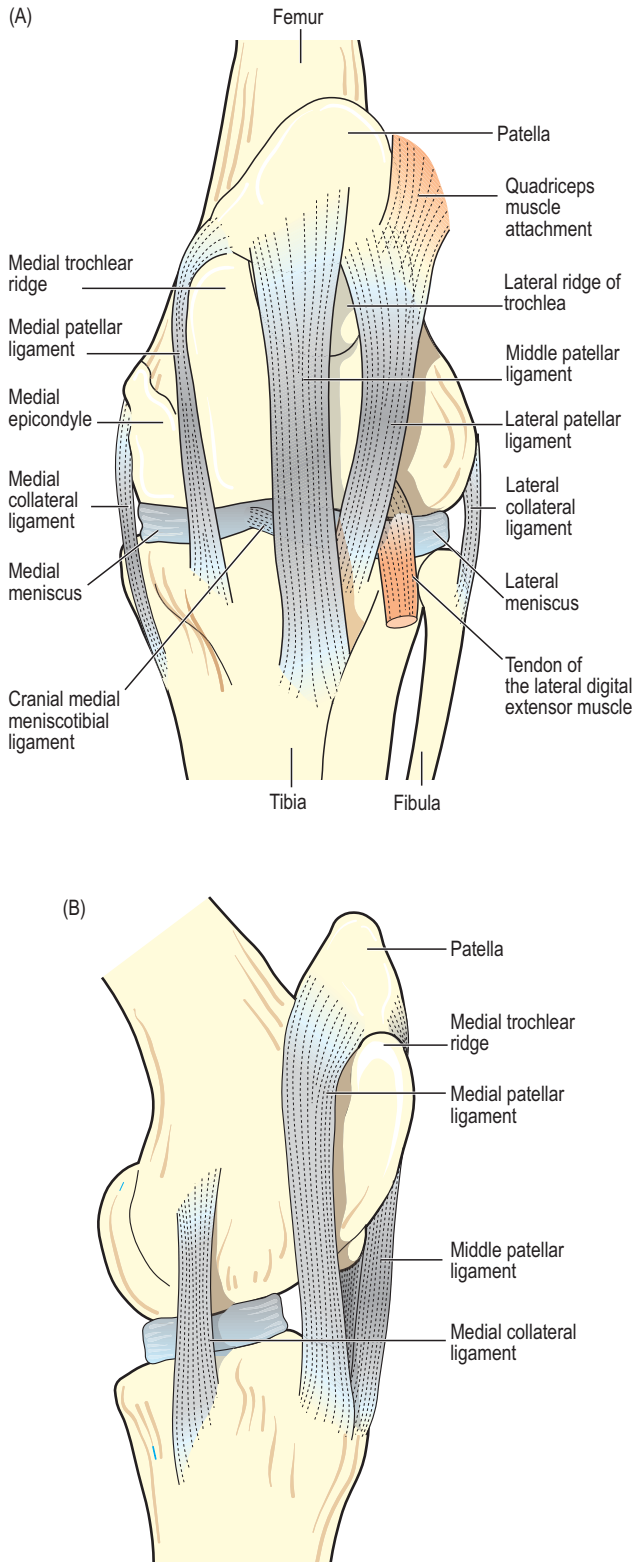

Fig. 19.1
(A) Cranial aspect of the stifle joint. (B) Medial aspect of the stifle joint.

Other diagnostic procedures that can be used for horses suspected of having stifle disease include arthrocentesis for synovial fluid analysis or cultures, radiography, ultrasonography, nuclear scintigraphy, arthroscopy and magnetic resonance imaging. Radiographic views include the lateromedial, caudocranial, 30° caudolateral-craniomedial and caudomedial-craniolateral and the cranioproximal-craniodistal oblique (skyline) of the patella. Ultrasonography can be used to evaluate the patellar, collateral and cruciate ligaments as well as the menisci and articular cartilage of the trochlear ridges (Fig. 19.1A–C). Nuclear scintigraphy will identify areas of increased skeletal or soft tissue inflammatory or metabolic activity. It is

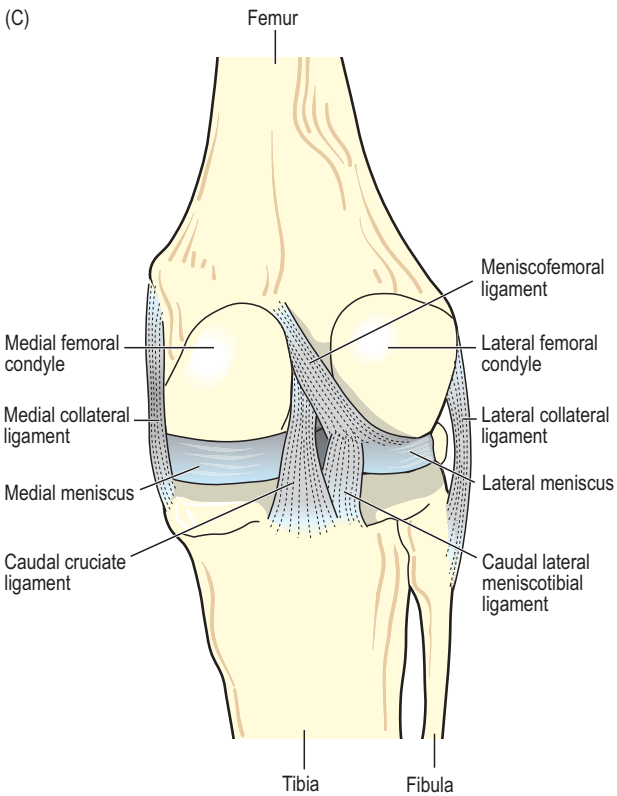

Fig. 19.1
(C) Caudal aspect of the stifle joint.

usually ineffective in identifying subchondral cysts of the medial femoral condyle in horses. Arthroscopy will permit visualization and manipulation of the intra-articular structures for therapeutic or diagnostic purposes.

Collateral ligament injuries

- The paired collateral ligaments (CoL) stabilize the stifle medially and laterally (Fig. 19.1B, C).
- The lateral CoL is reinforced by the lateral musculature of the thigh.
- The medial CoL has limited soft tissue coverage and is more frequently injured in horses.
- The medial CoL attaches to the medial meniscus (MM) at the joint space (Fig. 19.1A, B).
- Injuries to the medial CoL will often lead to significant disruptions of the MM, exacerbating stifle instability.

Horses have paired (medial and lateral) CoL that provide medial to lateral stability to the femorotibial joint.

Recognition

History and presenting complaint Horses with medial CoL injuries will usually present with an acute onset of severe lameness after a traumatic event or fall or with a less dramatic degree of rear limb lameness when the injury is milder or chronic.

Physical examination There will be a variable amount of soft tissue swelling and pain on the medial aspect of the stifle. Chronic injuries may have palpable thickening of the medial CoL, particularly when compared to the unaffected side. Horses with major disruption of the medial CoL will have obvious stifle instability and resent manipulation of the joint. Horses with more subtle injuries will have shortened anterior phase of the stride with decreased stifle flexion, toe dragging and a shorter but higher gluteal rise ('hip hike') on the affected side. Upper limb or stifle flexion and a medial CoL stress test (abduction of the limb distal to the stifle) will exacerbate the lameness.

Special examination Horses with incomplete disruptions of the medial CoL may partially improve after intra-articular analgesia of the medial femorotibial joint due to diffusion of anesthetic into the area around the ligament or because of disruption of the MM that often accompanies this injury. Caudocranial stress radiographs revealing a widened medial joint space or an avulsion fracture of the distal femur or proximal tibia are diagnostic when complete disruptions are present (Figs 19.2, 19.3).[1] Chronic injuries may demonstrate a narrowed medial femorotibial joint space and multiple osteophytes or enthesiophytes on the medial aspect on the

Fig. 19.2
Three-year-old Standardbred filly that presented with a grade 3 lameness of the left rear limb, medial femorotibial joint effusion and marked response to upper limb flexion. The caudocranial radiographic projection reveals narrowing of the medial joint space that was confirmed during arthroscopic surgery as a complete tear of the medial meniscus and cranial meniscotibial ligament.

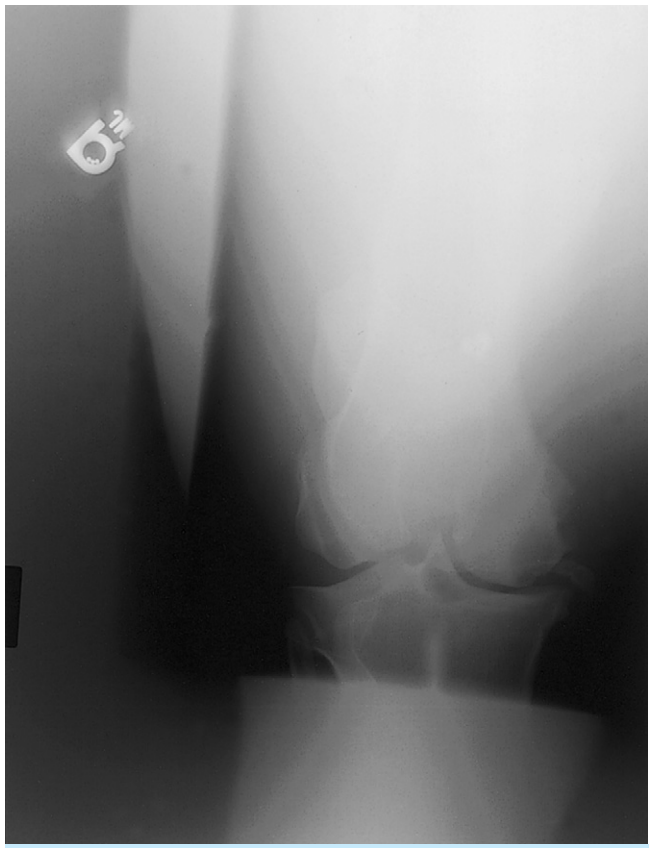

Fig. 19.3
Ten-year-old Quarter Horse mare with mineralization of the axial aspect of the meniscus, collapse of the medial joint space, periarticular osteophyte formation and the presence of a large subchondral cyst on the medial femoral condyle. Arthroscopic surgery revealed a complete tear of the medial meniscus and marked erosion of the articular cartilage of the medial femoral condyle.

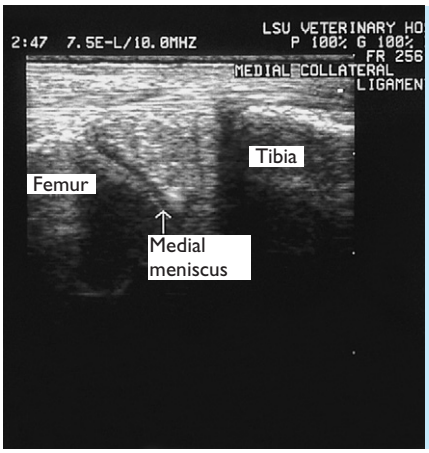

Fig. 19.4
Ultrasonographic image of a medial meniscus injury on the axial aspect of the joint space.

standard radiographic projections.[1] Ultrasonography of the medial CoL and MM can identify the extent of structural disruption and fiber discontinuity (Fig. 19.4).[2,3] The scans can be performed on the axial border of the femorotibial joint with horses standing using a 7.5–10 MHz linear probe (Fig. 19.5). The images should be obtained in a longitudinal and transverse orientation relative to the CoL.[2,3]

Necropsy examination A variable degree of disruption in the medial CoL and MM will be present. Chronic cases exhibit thickening of the medial CoL with fibrillation and erosion of the MM and articular cartilage of the medial femoral condyle along with periarticular bony proliferation.

Diagnostic confirmation Differential diagnoses include other causes of acute and severe lameness originating from the stifle such as fractures of the femur, patella or proximal tibia, cruciate or patellar ligament injuries, sepsis and traumatic patellar luxation. Chronic injuries need to be differentiated from stifle lameness caused by osteochondrosis, synovitis, meniscal injuries and degenerative joint disease secondary to instability or inflammation. The physical examination and the radiographic, ultrasonographic and arthroscopic appearance are diagnostic for medial CoL and MM injuries.

Treatment and prognosis

Therapeutic aims Prevent further damage to the structure(s) involved and reduce the inflammatory response.

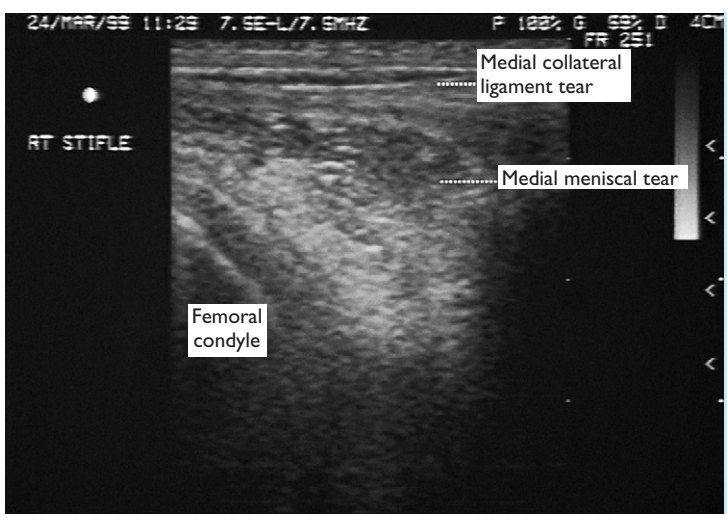

Fig. 19.5
Ultrasonographic appearance of a tear in the body of the medial meniscus in a mature sport horse.

Therapy Stall rest and systemic NSAIDs (phenylbutazone 2.2–4.4 mg/kg, p.o. per day), chondroprotective agents (polysulfated glycosaminoglycans or hyaluronic acid) and/or intra-articular anti-inflammatory therapy (hyaluronic acid and/or corticosteroids) may be beneficial in horses with acute but partial disruptions of the medial CoL. Intra-articular corticosteroids should be used judiciously to minimize inflammation, but repeated use may catabolize articular cartilage and blunt healing responses. Arthroscopic debridement of meniscal abrasions or fibrillation may reduce intra-articular inflammation, thereby preventing osteoarthritis.[4–6] Stall rest for 4–8 weeks followed by gradual increase in hand-walking for 8–12 weeks should be adequate, depending on the severity of the injury. The horse should be re-evaluated radiographically and ultrasonographically at 6–9 months for soft tissue healing and osteoarthritis before considering a return to athletic activity.

Prognosis Horses with significant disruption of the medial CoL will respond poorly to attempts at surgical repair and the ensuing stifle instability and meniscal injury make the prognosis for athletic use or pain-free life very poor.[7] The prognosis for horses with subtle injuries is guarded for athletic use and good for life, depending on the severity of the original injury, the degree of stifle instability and whether degenerative joint disease develops. Horses competing in more demanding athletic disciplines have a very guarded prognosis for full return to function.

Prevention

Proper shoeing (caulks when traction is required), avoiding strenuous activity when footing is poor or placing the horse in competitive events beyond its ability or degree of conditioning and withdrawal from competition if fatigue ensues may help prevent these injuries. Demanding disciplines in horses that are poorly conditioned, lame or schooled improperly may predispose to injuries.

Etiology and pathophysiology

Medial CoL injuries are the result of intense lateral to medial bending stresses during exercise or during a fall. Loss of footing, striking an immovable object or placement of large rotational forces on the stifle during weight bearing can result in CoL injuries in equine athletes. The paired CoL stabilize the stifle medially and laterally and disruptions of the CoL in horses will cause joint instability, impeding ambulation or pain-free exercise. Medial CoL injuries will often involve the MM, adversely affecting joint function.

Epidemiology

Collateral ligament injuries of the stifle are seen more frequently in athletes that jump (event horses, steeplechasers and hunters) or those that participate in disciplines with sudden stops or turns (barrel racing and polo).

Meniscal injuries

- Injuries of the cranial horn or ligament and body of the MM can cause lameness in equine athletes.
- Disruption of the MM can accompany CoL injuries in horses.
- Meniscal injuries can result from crushing forces when the femur rotates over the menisci with the leg in extension.
- Meniscal injuries can be a sequel to stifle instability caused by cruciate ligament disruptions.

Horses have a medial and lateral meniscus. Each cupped fibrocartilaginous meniscus functions to provide stability and congruency between the rounded femoral condyles and the flat tibial condyles at the femorotibial articulation (Fig. 19.1). Each meniscus has a cranial and caudal attachment (meniscal ligaments) to the tibia that maintains it in precise anatomic alignment during locomotion (Fig. 19.1). The medial meniscus and medial CoL are firmly attached to each other at the axial aspect of the joint space.

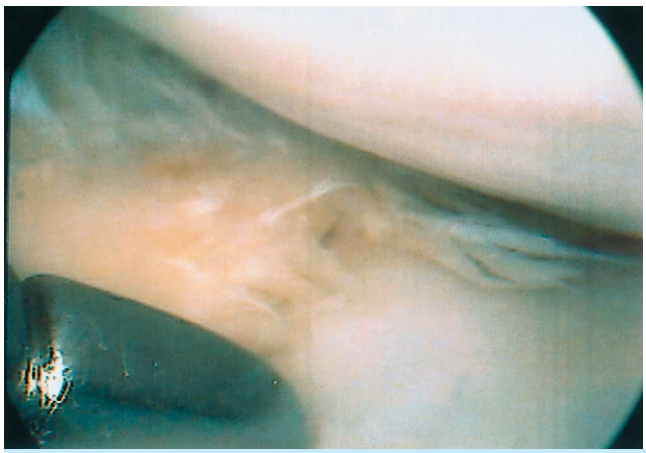
Recognition

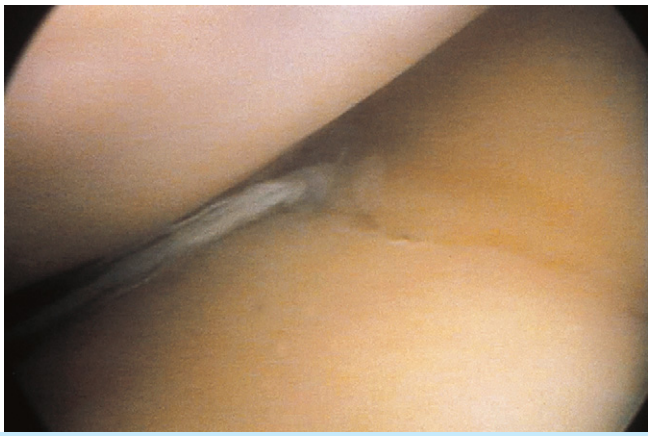
History and presenting complaint The clinical presentation is similar to horses with medial CoL injuries.

Physical examination The physical examination parameters and response to limb manipulation tests will be similar to horses with medial CoL injuries since they often occur simultaneously. The degree of lameness, periarticular thickening and effusion of the femorotibial joint will vary depending on the severity of the injury and duration. In horses with concurrent injury to the cranial cruciate ligament (CrL) the degree of stifle instability will be more pronounced.[8]

Special examination Medial femorotibial joint anesthesia will usually improve the lameness but the response is variable depending on the severity of the injury and additional extracapsular soft tissue or intra-articular cartilage structures involved. Large meniscal tears will cause collapse of the medial femorotibial joint space on the caudocranial radiographic projection (Figs 19.4, 19.5).[1] Degenerative joint disease and loss of femoral condyle cartilage will be evident in chronic cases (Fig. 19.5). Enthesiophytes or osteophytes may also be evident on the cranial aspect of the intercondylar eminence of the tibia or the edges of the femorotibial joint.[1] Ultrasonography or arthroscopy can be used to assess the integrity of the cranial and axial aspects of the MM (Figs 19.6, 19.7). Ultrasonography of the MM can be performed with a 7.5 MHz linear probe along the cranial and axial aspect of the femorotibial joint.[2,3] Defects or injuries of the MM may be imaged as hypoechoic areas in the horn or ligament at the axial or cranial portion of the structure (Fig. 19.5). Concurrent medial CoL injuries will be imaged axially at the attachment to the MM.[2,3]

Necropsy examination Findings are similar to CoL injuries with the severity of the changes dependent on the degree of MM damage and loss of congruity between the femoral and tibial condyles.





Figs 19.6, 19.7
Arthroscopic view of a tear in the medial meniscus.

Diagnostic confirmation Differential diagnoses include other causes of acute lameness originating from the stifle such as fractures, cruciate or patellar ligament injuries, sepsis and patellar luxation. Chronic injuries need to be differentiated from stifle lameness caused by osteochondrosis, synovitis and degenerative joint disease secondary to instability or inflammation. The physical examination and the radiographic, ultrasonographic and arthroscopic appearances are diagnostic for MM injuries.

Treatment and prognosis

Therapeutic aims Prevent further damage to the MM rest and surgical debridement of loose meniscal tissue that may exacerbate synovitis and accelerate the development of osteoarthritis.[8]

Therapy Arthroscopic surgery of the medial femorotibial joint is helpful to determine the extent of the injury and to debride damaged tissue from the MM or cranial meniscal ligaments that incite further inflammation.[4–6,8] In most horses with meniscal lesions, the tear begins approximately 1 cm from the axial edge of the horn of the meniscus and the ligament.[4,6,8] The depth (full versus split thickness), length and degree of tissue separation of the lesion will vary (Figs 19.6, 19.7). Debridement of loose and damaged tissue may diminish the stimulus for joint inflammation. Arthroscopy can also be used to monitor or assess healing before returning to work.[4] The surgical findings can also be used to formulate a more accurate prognosis for future athletic soundness. Horses with full-thickness tears that extend caudally under the femoral condyle probably have a poorer prognosis for full return to function due to the potential for persistent stifle instability.[4,6,8] Stall rest for 4–8 weeks will minimize further damage to the MM and associated soft tissue. Systemic (NSAID and chondroprotectives) and/or intra-articular (hyaluronic acid and/or corticosteroids) therapy can be used to control the deleterious effects of synovitis on intra-articular structures. Healing can be assessed with ultrasonography or repeat arthroscopy to determine the optimal time to initiate hand-walking and eventual return to work.

Prognosis Horses with lesions confined to the cranial ligament and cranial horn of the meniscus have a fair to good prognosis for returning to athletic competition following arthroscopic debridement and prolonged rest (6–9 months).[4,8] Athletes with large tears involving the body of the meniscus as it courses under the femoral condyle, complete avulsion of the cranial attachment and concurrent CoL or CrL damage have a poor prognosis for athletic use.[4,8]

Prevention

The same shoeing, conditioning, schooling and judicious retreat from adverse conditions as previously described for CoL injuries.

Etiology and pathophysiology

Meniscal injuries can result from crushing forces when the femur rotates over the menisci with the leg in extension during high-speed athletic activities or a traumatic event such as a fall or kick.[9,10] Meniscal injuries can occur after joint instability caused by cruciate ligament disruptions. Small lesions confined to the cranial horn or ligament of the meniscus may cause minimal stifle instability but the ensuing synovitis from the damaged soft tissue can cause chronic lameness and, if not treated in a timely fashion, shorten an athletic career. Extensive lesions involving the body of the meniscus or those that occur in conjunction with other soft tissue injuries will often end a career due to the resulting stifle instability.

Epidemiology

Meniscal injuries are more common in horses competing in jumping disciplines, participating in galloping events with sudden stops and turns or during a fall or traumatic event during a competition.[9] Poor footing, extreme course difficulty and inadequate conditioning or talent may also be contributory.

Cruciate ligament injuries

- Cranial CrL injuries in horses always have a midbody component.
- Avulsion fractures at the attachments are less common and occur in combination with the midbody injury.
- Caudal CrL injuries are rare and they usually occur after cranial CrL damage.
- These injuries will often end the career in equine athletes.

Horses have paired (cranial and caudal) CrLs that are extrasynovial and located in the septum between the medial and lateral femorotibial joints (Fig. 19.1A). They provide stability to the stifle joint and limit cranial or caudal movements of the tibia or femur during locomotion. The CrLs are loaded maximally during stifle extension and the caudal CrL is axially rotated during stifle flexion.[11] During weight bearing the CrLs will limit rotation and forward displacement of the tibia and stabilize the medial aspect of the femorotibial joint.[11] Cranial CrL injuries are more common in horses and are often accompanied by other soft tissue injuries (CoL or MM).[8,12] Caudal CrL injuries are often accompanied by cranial CrL injuries but can occur independently.[13]

Recognition

History and presenting complaint Horses with a cranial CrL injury present with an acute onset of moderate to severe lameness and often have a history of a fall, loss of footing with a sudden forceful attempt to regain it or colliding with an immovable object.[9]

Physical examination There is moderate to severe lameness characterized by non-weight bearing or toe-touching gait on the affected limb immediately following the injury. Over time the lameness may improve but the horse will remain reluctant to flex the stifle during the swing phase and will not completely load the tibia during the stance phase of the stride.[9] Effusion of the femorotibial joints is readily discernible. Flexion of the stifle will often be vigorously objected and will worsen the lameness.[9] Stifle instability and worsening of the lameness may be noted if the tibia is repeatedly rocked caudally while the horse is weight bearing (cruciate test). Crepitus or periarticular thickening is uncommon. Atrophy of the thigh and gluteal musculature is common in chronic cases with marked lameness.

Special examination Because the septum that separates the two joints is usually torn, the cruciate ligaments will then be intrasynovial so that anesthesia of the medial and/or lateral femorotibial joint will often improve the lameness considerably.[8,12] However, there will be a residual mechanical instability of the gait with complete disruptions of the cranial CrL. In acute cases, intra-articular anesthesia is rarely necessary. Radiographs are often non-diagnostic because avulsion fractures at the attachments are rare.[14] An avulsion fracture of the intercondylar eminence of the tibia may be observed infrequently with cranial CrL injuries (Fig. 19.8).[14–16] If a weight-bearing lateromedial projection can be obtained, cranial displacement of the proximal tibia relative to the distal femur may be present after complete cranial CrL disruptions. In chronic cases of CrL disruptions, radiographic evidence of degenerative joint disease will be present and mineralization of the damaged CrL may be seen.

Fig. 19.8 Avulsion fracture of the intercondylar eminence of the tibia.

Ultrasonographic imaging of a cranial CrL tear can be performed in the standing horse by directing a 5 or 7.5 MHz linear or curvilinear probe parallel and between the medial and middle patellar ligaments with the stifle fully flexed.[2,3] This requires sedation and/or articular analgesia as many horses with CrL injuries resent this manipulation. Discontinuity of the fiber pattern or size of the structure is suggestive of injury to the cranial CrL. The caudal CrL may be imaged ultrasonographically from the caudal aspect of the femorotibial joint. Arthroscopic surgery will enable accurate evaluation of the CrL and other intra-articular structures.[6] Magnetic resonance imaging or computed tomography would be ideally suited for the diagnosis and quantification of intra-articular soft tissue injuries of the equine stifle.

Necropsy examination At necropsy, variable disruption of the cranial CrL and other articular soft tissue or bony structures is present with synovitis and hemorrhage. Depending on the duration, there may be evidence of secondary degenerative changes within the joint.

Diagnostic confirmation The differential diagnoses include stifle fractures, soft tissue injuries (CrL, MM), hemorrhage or sepsis. Horses with cranial CrL disruptions are usually very lame. The degree of instability and the arthroscopic and ultrasonographic findings are usually diagnostic.[6,8] Arthroscopic findings may include a variable amount of fiber disruption in the cranial and/or caudal CrL, tearing of the septum between the femorotibial joints, widening of the femorotibial joint space, avulsion fractures of the intercondylar eminence of the tibia and meniscal injuries.[6,8]

Treatment and prognosis

Therapeutic aims Minimize further damage to the CrL with rest and control inflammation to allow soft tissue healing. Physical therapy is used to re-establish joint mobility and tissue strength.

Therapy There are no effective surgical procedures available to reinforce or reconstruct the cranial CrL in horses, as

there are in humans, dogs or cattle, due to anatomic differences, biomechanical demands and expectations for eventual outcome. In addition, horses with complete cranial CrL tears have other intra-articular soft tissue injuries that make any attempt at stabilization unrewarding. A medial, cranial and/or lateral arthroscopic approach to the femorotibial joint will allow visualization of the CrL, articular septum and menisci.[4–6] Arthroscopic debridement of loose soft tissue associated with partial cranial CrL injuries and lavage to remove protein debris and inflammatory mediators may be effective in minimizing the deleterious effects of synovitis and enable some athletes to return to work. Small fracture fragments from the intercondylar eminence of the tibia can be removed but care must be taken to avoid further damage to the CrL or its attachment.[15] Larger fragments involving the insertion of the cranial CrL can be secured to the parent bone using cortical screws.[16] Lag screw technique may be contraindicated as it could weaken the fragment, causing it to shatter when the implant is tightened.

Concurrent use of systemic and intra-articular anti-inflammatory or chondroprotective therapy after surgery is indicated. Complete rest (6–9 months) may increase the strength of the repair tissue in the cranial CrL.[8] Hand-walking immediately after surgery is detrimental if any degree of instability is present. Swimming after 4–6 weeks of stall rest will allow the soft tissues to gain strength and increase the range of motion of the joint without loading the healing structures and exacerbating the instability.

Prognosis The prognosis for future athletic soundness is guarded to poor due to the considerable stifle instability that results from CrL injuries. This will restrict pain-free locomotion and will eventually lead to osteoarthritis. Horses with partial injuries without additional soft tissue injuries may return to light work, but return to more demanding disciplines like eventing, jumping or polo may not be a realistic expectation unless the degree of CrL fiber disruption is minimal and stifle stability is not affected.[4] Horses that require constant analgesic or anti-inflammatory medication to remain in work should be retired from competition. Complete CrL tears usually carry a poor prognosis for even a sedentary pain-free life and euthanasia is a humane option.

Prevention

The training and equestrian competition guidelines mentioned for preventing CoL and MM injuries should be applicable in minimizing the occurrence of these injuries.

Etiology and pathophysiology

The cranial CrL is loaded maximally during stifle extension. Most cranial CrL injuries occur when the stifle is impacted or twisted during weight bearing, causing hyperextension.[9] During a fall, internal rotation of the tibia with the stifle fully flexed can exert enough force to tear the cranial CrL. Once disrupted, the stability of the stifle is adversely affected, making precise alignment of the femur and tibia impossible, leading to painful ambulation and degenerative joint disease. Since the CrLs are loaded maximally during stifle extension, most CrL injuries are midbody tears.[11]

Epidemiology

Cranial CrL injuries can occur in any horse involved in athletic competition at high speeds or those that require jumping, sudden turns or body contact that can precipitate a fall.

Osteochondrosis of the stifle

- The stifle is a very common site for osteochondrosis in the horse.
- The lateral trochlear ridge of the femur is the most frequently affected site in the femoropatellar joint.
- The medial femoral condyle is the most frequently affected site in the femorotibial joint.
- The onset of lameness is variable depending on the size and location of the lesion and age and use of the horse.

Osteochondrosis can affect multiple joints in the horse and in the stifle manifests as osteochondrosis dessicans lesions with loose cartilage flaps or subchondral bone cysts with poor-quality subchondral bone for articular cartilage support. These lesions may actually represent the response to exercise-induced trauma after normal pressures are applied to a joint with an abnormal or immature subchondral bone.

Recognition

History and presenting complaint Horses affected with osteochondrosis dissecans (OCD) of the trochlear ridges or patella will usually present with an obvious rear limb lameness that can be localized to the stifle(s) by gait evaluation, limb manipulation and intrasynovial anesthesia. These horses are often younger than 1 year of age and have obvious femoropatellar joint effusion representative of the more severe nature of the lesions. Horses with less extensive lesions may not present until they are older than 2 years of age and the onset and severity of the lameness may not be as obvious. These horses may become increasingly lame with more rigorous work schedules and the degree of femoropatellar joint effusion may be subtle.

Lameness caused by subchondral bone cysts (SC) of the femoral condyle(s) is usually diagnosed in young athletes (2–4 years of age) but can often affect horses as young as 6–9 months of age. It is frequently the cause of a rear limb lameness that becomes evident when affected horses are first placed into work. The lameness is unilateral or bilateral and the severity is largely dependent on the size of the lesion(s) and type of work the horse is performing. The lameness will vary in severity but will often worsen with work and improve after rest. Horses participating in more strenuous athletic disciplines will present earlier than those involved in less active routines (pleasure). Horses will rarely present with both types of stifle osteochondrosis simultaneously.

Physical examination Affected horses have a characteristic gait common to horses with stifle disease (see previous sec-

tions) and will respond similarly to limb manipulations and change in surface incline. Careful attention to limb movements and gait is necessary because the disease is bilateral in approximately 60% of horses,[17] so that the gluteal rise and change in stride dynamics may not be as obvious as in a horse with disease of only one stifle. Horses with OCD of the trochlear ridges or patella have obvious effusion of the femoropatellar joint and those with SC will have effusion of the medial femorotibial joint. Occasionally horses with simultaneous shoulder and stifle OCD will present with a very stilted, shortened gait (walking on egg shells) and kyphosis of the lumbar spine.

Special examination Intra-articular anesthesia of the affected joint will usually result in a dramatic improvement in the lameness. This may not be necessary in horses with marked lameness and effusion of the stifle, but simultaneous OCD of the shoulder joint(s) is not uncommon and it may be necessary to improve the rear leg lameness to allow careful observation of the thoracic limbs.

Radiographs of the stifle are usually diagnostic for the condition. However, there are horses with OC of the stifle that have normal-appearing radiographs that present with effusion of the stifle and a lameness that can be localized to the joint. The lesions in these horses are limited to the articular cartilage and do not extend deep into the subchondral bone, hence the normal-appearing radiographs. These patients will often require arthroscopy of the affected joint for diagnosis and treatment. Ultrasonographic examination of the cartilage of the dorsal aspect of the trochlear ridges with a 5–7.5 MHz probe positioned between the patellar ligaments may reveal cartilage defects in the femoropatellar joint not visible radiographically.

Both stifles should be radiographed, as the condition is commonly bilateral,[17] even though the clinical signs or radiographic changes may be more obvious or severe on one limb. The lateromedial and oblique views are best suited to evaluate lesions of the lateral (most common) or medial trochlear ridge of the distal femur or rarely the patella (Figs 19.9, 19.10). There may be subchondral lucencies or flattening of the subchondral bone, most commonly on the mid to distal aspect of the lateral trochlear ridge but they can occur anywhere on either ridge (Figs 19.9, 19.10).[18–20] Mineralized or ossified cartilage fragments that are attached or loose can also be present along the articular margin of the trochlear ridges, trochlear groove or patella, either within the articular defects or loose at the bottom of the joint.[18–20] The radiographic appearance of these lesions will usually underestimate the severity of the lesions encountered at surgery.[18–20] The caudocranial view will usually reveal the central location of the subchondral cyst of the medial femoral condyle (Figs 19.11, 19.12), and large cysts can often be seen on the oblique and lateromedial views.[21] These cysts can be quite large (Fig. 19.12), have a variable degree of subchondral bone lucency and most will have sclerotic bone surrounding the cyst cavity.[21] In long-standing cases of stifle OC there may be radiographic evidence of degenerative joint disease (DJD) along the articular joint margins. Adequate radiographic technique and equipment is necessary to adequately image the stifle in an adult horse and is especially important in identifying SC. Nuclear scintigraphy is not accurate in identifying SC lesions due to their relative avascularity.

Fig. 19.9 Osteochondrosis dissecans of the lateral trochlear ridge of the femur in a 2-year-old Thoroughbred colt.

Fig. 19.10 Osteochondrosis dissecans of the medial trochlear ridge of the femur in a 2-year-old Thoroughbred filly.

Necropsy examination Variable amounts of articular cartilage erosion and fibrillation are seen with areas of normal-appearing hyaline cartilage detached or inadequately supported by subchondral bone. The subchondral bone bed may be necrotic or filled with granulation or fibrous tissue or fibrocartilage. Chronic cases may have variable amounts of DJD with thinning of the articular cartilage and the presence of wear lines.

Diagnostic confirmation Osteochondrosis of the stifle is differentiated from other causes of stifle lameness by the

gradual onset of the condition and the characteristic radiographic or arthroscopic appearance.

Treatment and prognosis

Therapeutic aims Debride loose cartilage or osteochondral fragments and remove all avascular and unsupported subchondral bone. Allow enough time for the affected articular surfaces to be resurfaced with fibrocartilage.

Therapy The treatment of choice is arthroscopic debridement of the lesions via standard approaches to the femoropatellar or medial femorotibial joint. Trochlear ridge lesions are ideally visualized through an arthroscopic approach between the middle and lateral patellar ligaments with the instrument portal between the middle and medial or lateral patellar ligaments.[17–20] Copious lavage should be used during surgery to remove all cartilage and bone fragments to reduce the inflammatory effects of this debris. If both stifles are affected they should be operated on simultaneously to limit the progression of the disease in the other joint, minimize the anesthetic risk of two surgeries and speed recovery in horses intended for athletic use.

The arthroscopic appearance of OCD lesions in the femoropatellar joint is usually more extensive than the radiographic appearance would indicate and some very distal trochlear ridge or patellar lesions may be surgically challenging. A lateral or cranial arthroscopic approach to the medial femorotibial joint can be used to debride SC lesions of the medial femoral condyle.[6,21,22] The SC lesions will often appear as a subtle dimple of the articular cartilage on the condyle (Fig. 19.13A), which after debridement and forage of all unsupported cartilage and subchondral bone can become rather large defects (Fig. 19.13B).[21,22] These defects may eventually become radiographically indistinguishable or remain as a persistent radiographic defect after the surgery in some relatively sound patients.

Fig. 19.13
(A) Arthroscopic view of a subchondral cyst of the medial femoral condyle.
(B) Arthroscopic appearance of the subchondral cyst in (A) after surgical debridement.

Postoperative pain may be significant in horses with large lesions operated on bilaterally. Use of intra-articular mepivacaine or narcotics (morphine sulfate, 6–15 mg) at the conclusion of surgery will reduce articular pain and often will improve recovery from general anesthesia. Epidural analgesics in the immediate postoperative period may make pain management more effective. Stall confinement for 4–6 weeks after surgery is necessary and a gradual reintroduction to hand-walking started 10–14 days after surgery. Gradual return to exercise after 5 months may be an option for horses with smaller lesions while those with extensive lesions may require 6–9 months of rest. Postoperative use of anti-inflammatory and chondroprotective agents will decrease discomfort and may maximize the quality and quantity of repair tissue in the defect.

Osteochondral grafts harvested from a non-weight bearing area of the joint, autologous, compacted cancellous bone grafts and pluripotential stem cells transformed into cartilage-producing cells prior to implantation into SC have had variable results in improving the quality of tissue that resurfaces these defects in horses.[23–27] Some methods appear promising but are not used at this time due to the morbidity of additional articular defects, the need for multiple surgeries and the unpredictable nature of the results. Improving the quality of repair tissue for articular defects in horses would greatly improve the quality and longevity of many athletic careers.

Conservative treatment of stifle osteochondrosis may be suitable for small OCD lesions and some SC that demonstrate only flattening of the condyle. Horses with OCD of the lateral trochlear ridge or large SC cysts will have a better prognosis for return to athletic function if they are treated surgically with arthroscopy early in the disease process.[18–22] Horses treated conservatively should be rested for 6–8 months with frequent radiographic monitoring for progression of healing. Radiographic resolution of the lesions is usually very slow and incomplete. Often the initiation of exercise will exacerbate the lameness, requiring more aggressive surgical treatment. Conservative therapy may result in loss of the early part of an athletic career if, after a prolonged lay-off, there is no radiographic or clinical improvement and surgery is then required.

Prognosis Stifle OC carries a fair to good prognosis for return to athletic activity in most horses with small to moderate defects.[18–22] Younger horses may benefit from early surgical intervention to curtail progression of the lesion and minimize degenerative articular changes from chronic inflammation.[18–21] Young animals with severe lameness due to stifle OC that is left untreated will spend long periods in recumbency, leading to marked limb deformities and flexural contractions. These horses should be treated surgically early in the disease process to avoid these serious and career-ending complications. The unique biochemical and structural arrangement of hyaline (articular) cartilage makes it capable of withstanding the stresses and loads of vigorous athletic competition. However, articular cartilage defects in older horses do not have the capacity to regenerate hyaline cartilage. These defects are predictably resurfaced with fibrocartilage that does not have the biomechanical capability to withstand the rigors of a strenuous and prolonged athletic career. Horses younger than 2 years of age may have the capability of regenerating some hyaline cartilage, so early surgical intervention may improve the quality of the repair tissue and the integrity of the joint surface. Horses with OCD of the femoropatellar joint may have a better prognosis since the lesions are on a gliding articular surface, in contrast to the usual central weight-bearing surface of the medial femoral condyle where SCs develop. Horses intended for elite athletic use having large femoral SC lesions may not fare as well.

Prevention

Since the disease is multifactorial, complete prevention is unlikely. Maintaining balanced mineral (copper, zinc, calcium and phosphorus) levels in the diet and not overfeeding grain (excess phosphorus) is recommended. Delaying rigorous training may reduce the incidence in horses that are skeletally immature and predisposed to traumatically induced subchondral bone damage and the development of growth cartilage defects.

Etiology and pathophysiology

Osteochondrosis is a developmental disease characterized by disorders of the growing cartilage in the epiphysis and growth plates. This complex biologic mechanism is termed endochondral ossification and it allows for longitudinal bone growth and provides subchondral bone support for all joint surfaces. When this developmental disorder affects the integrity of the articular cartilage due to loss of joint surface support, it will cause joint inflammation (osteochondritis). Other manifestations of this disorder of cartilage development include angular limb deformities, physitis, cervical vertebral malformations and SC.

The disease is multifactorial with genetic (growth rate), nutritional (copper deficiency, calcium and phosphorus imbalance from feeding excess grain), metabolic (vitamin D deficiency) and endocrine (hypothyroidism) influences.[28–31] The predictable locations of many osteochondral articular lesions in the horse are sites where the developing articular cartilage or growth plates are thick, the vascular supply is tenuous but the biomechanical loads are high.[28–31] Therefore, vascular and traumatic insults in these locations are probably very important in the expression of this disease in horses.[21,29–31] The ultimate expression of the disease is unpredictable but controlling some of these factors may help reduce the incidence of the disease in a particular area or farm.

Epidemiology

The disease has worldwide distribution and varied breed predilection. The incidence of the disease may vary from one farm to another and between geographical areas, highlighting the multifactorial nature of the disease. It is a disease of young horses and is reported frequently in breeds used for

speed events such as Standardbreds, Thoroughbreds, Warmbloods and Quarter Horses. Exercise in these breeds at a young age in conjunction with genetic or nutritional predispositions may account for its expression.

Patellar luxation

- Patellar luxations in adult horses are usually the result of severe impact trauma from a fall or collision.
- Lateral luxations are more frequent.
- Affected horses will present with severe lameness and an inability to fix their stifles in extension.
- Radiographs are necessary for diagnosis and to rule out a concurrent patellar fracture.

Horses have three patellar ligaments (medial, middle and lateral). These attach the distal aspect of the patella to the proximal aspect of the tibia (Fig. 19.1A). The medial patellar ligament will be pulled over the medial trochlear ridge of the femur when the stifle is locked in extension. Lateral patellar luxations are more common in horses because the large medial trochlear ridge, particularly in adults, usually prevents medial dislocation. Most luxations are congenital or hereditary and seen in miniature horse or pony foals. In adults or young horses, luxation is secondary to trauma or severe hypoplasia of the lateral trochlear ridge due to osteochondrosis.

Recognition

History and presenting complaint Patellar luxations in adult horses present as an acute onset of severe lameness and swelling of the stifle following a traumatic episode.

Physical examination There is a severe lameness with marked swelling of the involved stifle. Any attempt to fully bear weight on the leg will lead to an inability to fix the stifle in extension. The patella can usually be palpated laterally or may be displaced distally if the attachments of the quadriceps muscle have become detached from the proximal patella.[3,2] The horse will usually resent any attempt at limb manipulation or ambulation.

Special examination Radiographs are usually diagnostic and will reveal the direction of the dislocation.[1] The caudocranial, lateromedial or oblique views are diagnostic for either the more common lateral luxation or the infrequent distal luxation by evaluating the patella in relation to its normal anatomic position in the trochlear groove on the cranial aspect of the femur. A skyline (dorsoproximal to dorsodistal) view of the cranial distal femur will confirm the presence of an empty trochlear groove and the location of the displaced patella.[1] This view may be hard to obtain in a horse with an acute luxation that resists stifle manipulation. The radiographs should be closely evaluated for the presence of any patellar fragmentation, fractures or avulsions that can accompany the luxation. An attempt should be made to evaluate the integrity of the patellar ligaments and medial aspect of the stifle ultrasonographically.

Necropsy examination At necropsy, there is displacement of the patella out of the trochlear groove with variable amounts of hemorrhage, soft tissue swelling, bony fragmentation of the patella or trochlear groove and disruption of the patellar ligaments. In cases secondary to severe OC of the lateral trochlear groove, there will be marked degenerative joint disease, periarticular soft tissue fibrosis, an atrophied trochlear groove and ridge and a variably sized patella in an abnormal lateral location.

Diagnostic confirmation The differential diagnosis for acute onset of stifle swelling and severe lameness includes disruption of intra-articular soft tissue structures (CrL, menisci, CoL), fractures, hemorrhage, sepsis and cellulitis. The radiographic and physical examination findings are diagnostic for patellar luxation.

Treatment and prognosis

Therapeutic aims Replace the luxated patella to its normal anatomic location (trochlear groove) and prevent recurrence.

Therapy Using heavy sedation and possibly a caudal epidural analgesic, the laterally luxated patella should be reduced manually by manipulating it proximally and medially with the horse standing. The manipulation may be difficult and if the horse is attempting to flex the limb while movement of the patella is being attempted, it will make reduction of the lateral luxation impossible. Reduction of the luxation under general anesthesia is generally easier but it will usually re-luxate when the horse attempts to stand and flexes the leg or contracts the quadriceps forcefully. If the luxation can be reduced standing, the horse should be cross-tied for 4–6 weeks to prevent recumbency and extreme joint flexion. Systemically administered analgesics and NSAIDs will help control discomfort and inflammation. Gradual introduction to hand-walking is instituted for another 12–16 weeks, allowing the extracapsular and patellar soft tissue support to adequately fibrose. Ultrasonographic and radiographic imaging should be performed before initiating work to insure complete healing of all the involved structures.

Prognosis The prognosis for soundness is good if there are minimal concurrent injuries to the intra-articular soft tissue structures and the collateral or patellar ligaments. Marked periarticular fibrosis will worsen the prognosis for return to function and luxations accompanied by significant patellar fractures may be difficult to manage to achieve a successful outcome.[3,2]

Prevention

These injuries are usually unforeseen and generally not preventable. However, proper shoeing, schooling and conditioning and avoiding precarious footing conditions may help minimize their occurrence.

Etiology and pathophysiology

These injures are traumatically induced and are usually the result of a fall, collision with a solid object or a kick. A sudden forceful contraction of the quadriceps muscle group during

strenuous activity may lead to disruption of their attachments to the proximal patella, predisposing to distal or lateral luxation.[32]

Epidemiology

This disease occurs infrequently and there are few predisposing factors.

Patellar ligament desmitis

- Horses have three patellar ligaments: medial, middle and lateral.
- The patellar ligaments, particularly the medial, are part of the stay apparatus of the hindlimb.
- Desmitis or tearing of the patellar ligaments in horses is infrequent.
- Avulsion fractures of the distal patella often have a patellar ligament injury associated with them.

Recognition

History and presenting complaint Horses with patellar ligament desmitis will present with an acute or chronic lameness of variable severity.[33] There may be a history of a fall or blunt or sharp trauma.[9]

Physical examination There is usually mild effusion of the femoropatellar joint and palpable thickening of the affected ligament or surrounding soft tissues. The lameness will usually become worse after stifle flexion.

Special examination Intra-articular anesthesia of the femoropatellar joint may improve the lameness slightly due to diffusion of anesthetic around the ligament. The response is more dramatic if fragmentation of the distal patella accompanies the injury. Local infiltration of the area of the ligament with mepivacaine may also improve the lameness to some degree. Fragmentation of the distal patella will be evident radiographically on survey films and mineralization of the ligaments may be evident with chronic injuries. Ultrasonographically, desmitis of the ligaments will appear as hypoechoic or hyperechoic areas with fiber disruption, depending on the stage of the disease. The ligaments may be thickened due to edema or scar tissue or have very reflective areas consistent with mineralization. Ultrasonographic evaluations should be performed with the horse weight bearing and the scans compared to the contralateral limb for ligament size and fiber uniformity.[2,3]

Diagnostic confirmation Patellar ligament desmitis must be differentiated from other causes of acute or chronic stifle lameness. Palpation of thickened or painful patellar ligaments, incomplete response to intra-articular anesthesia and the ultrasonographic appearance of patellar ligament disruption or desmitis are diagnostic.[2,3]

Treatment and prognosis

Therapeutic aims Arthroscopic removal of intra-articular avulsion fragments is indicated if there is a significant response to femoropatellar joint anesthesia and the fragments are radiographically evident.[34] Care must be taken at surgery not to create further damage to the ligament by attempting to extract small but well-embedded fragments that may have little clinical importance.[34] An extracapsular approach for non-articular fragments can be used, but there must be unequivocal presurgical evidence that the fragments are actually the cause of lameness and care must be taken to avoid further damage to the patellar ligament during the procedure.

Rest and systemic anti-inflammatory therapy are indicated for cases of desmitis without bony fragmentation. Usually 8–12 weeks of rest with a gradual return to work will suffice. Horses that had surgery or more severe injuries may require longer rest periods. Healing of the ligament should be monitored ultrasonographically and return to work recommendations made on the basis of these findings.

Prognosis Horses with desmitis, partial tears or small avulsion fractures of the patella have a good prognosis for return to working soundness.[33,34] Complete avulsion or tearing of the middle patellar ligament causes marked stifle instability and is generally unresponsive to treatment, making the prognosis for athletic soundness poor.[32,33]

Prevention

These injuries are infrequent and prevention is difficult.

Etiology and pathophysiology

Blunt or sharp trauma to the patellar ligaments can cause patellar ligament desmitis and a sudden forceful contraction of the quadriceps during a fall or with the stifle in full extension may also lead to these injuries. With a complete tear or avulsion of the middle patellar ligament, marked stifle instability and severe pain will result during ambulation. The patella can be fragmented as a direct result of the impact or from an avulsion of all or part of the attachment of the ligament at the distal border of the patella. Chronic desmitis, intra-articular fragmentation with synovitis and periarticular fibrosis can all lead to persistent lameness in athletes that sustain these injuries.

Epidemiology

Patellar ligament injuries may be more common in horses that event, hunt or steeplechase due to the stresses placed on the structures during jumping or from striking crossrails or obstacles while competing.[9]

Upward fixation and chondromalacia of the patella

- Upward fixation of the patella is usually intermittent but can become persistent.
- Fixation occurs when the medial patellar ligament remains engaged on the medial trochlear ridge during the swing phase of the stride.
- It is more common in younger horses and those with upright conformation.

- Poor quadriceps tone, due to disuse atrophy from injury, inactivity or neurological disease, predisposes to the condition.
- Chondromalacia of the patella can result from instability or weakness of the quadriceps mechanism or patellar ligaments.

Recognition

History and presenting complaint The presenting complaint and history may entail only a change in gait with an exaggerated action to the cranial phase of the stride or complete inability to move the limb with the affected leg fixed in extension. In some routinely active athletes there may be a history of a decline or cessation of their work schedule due to an injury or illness, leading to loss of muscle conditioning that will precipitate the condition once a higher level of activity is resumed. Horses with chondromalacia will present with a rear limb lameness of variable duration and severity.

Physical examination Horses with persistent upward fixation of the patella will present with the affected limb(s) fixed in extension, with an inability to flex their stifle or hock.[33] The distal limb joints can still be flexed. The condition will impede locomotion if bilateral and if unilateral, the horse may advance the affected limb by dragging it in extension. In some horses excessive wearing of the toe in the affected limb(s) will be apparent. In some cases backing the horse, manual pressure on the patella or light sedation may disengage the patella. In many cases it will recur within a short time. Most cases present as intermittent upward fixation with a prolonged posterior stance phase of the stride and a shortened or exaggerated swing phase which can be evident at every stride or only at variable intervals, depending on surface, incline or duration of exercise. Femoropatellar effusion and response to stifle manipulation and a favorable response to intra-articular anesthesia will be evident in horses with chondromalacia of the patella.

Special examination The clinical presentation and history are usually diagnostic in most horses. Limb manipulation, intra-articular anesthesia or radiographs are usually unrewarding. If there is an obvious loss of muscle mass associated with the quadriceps or rear limbs, further diagnostic testing for neuromuscular diseases such as equine lower motor neuron disease, shivers, polysaccharide storage disease or equine protozoal myelitis would be warranted. Young horses with intermittent upward fixation of the patella that present with an upright conformation, flexural contracture or stifle effusion should be evaluated radiographically to determine if there is an underlying developmental orthopedic disease predisposing to the condition.[35] Horses with intermittent upward fixation of the patella may have radiographic evidence of chondromalacia of the patella. Chondromalacia may be the cause or result of upward fixation of the patella and may be a response to chronic inflammation or repeated trauma to the articular cartilage of the patella.[35] The patella may have areas of radiographic lucency or bony proliferation. There may be radiographic evidence of distal medial patellar fragmentation if medial patellar ligament desmotomy was used for treatment of intermittent upward fixation of the patella.

Diagnostic confirmation The principal differential diagnoses include stringhalt, fibrotic myopathy and shivers. Horses with stringhalt will usually have exaggerated hock and stifle flexion that is consistently present at every step and can be severe enough to cause the horse to hit the ventral aspect of the abdomen with the distal limb during walking.[36] The stance phase of the stride in horses with stringhalt is usually normal or shortened. Stringhalt may be unilateral or bilateral, can occur as a herd outbreak and may be related to exposure to certain weeds (*Hypochaeris radicata*; dandelions), trauma or disease of the sciatic or peroneal nerves.[36] Horses with fibrotic myopathy have a pronounced and consistent interruption of the cranial or swing phase of the stride marked by a rapid caudal movement of the affected limb before it makes contact with the ground. The gait in this condition is characteristic and palpation of the semitendinosus and semimembranosus muscles will reveal the fibrotic component of these muscles that will not be apparent in horses with upward fixation of the patella.[35] Shivers will usually present as an exaggerated flexion of the rear limb and flagging or quivering of the tail when the rear limbs are picked up or the horse is backing up or turning in a tight circle. It is often not so obvious when the horse is moving forward in a straight line and may be more common in draft-type horses.[35]

Treatment and prognosis

Therapeutic aims The condition should be differentiated from the previously discussed diseases and the patient thoroughly evaluated for conformational, neurological or orthopedic diseases that may predispose to the condition. If there is an underlying cause, then its removal or treatment will help recovery or resolution of the upward fixation. In cases with marked atrophy of the quadriceps muscle due to neurological disease, identification and resolution of the neurological disease are necessary to restore muscle function and resolve the condition.

Therapy When a lack of muscle tone is present due to inactivity or reduced training schedule, these horses will usually benefit from a gradual reintroduction to work coupled with an increase in the intensity and frequency of exercise until the condition is no longer apparent. For severe cases, exercise regimens that include swimming, underwater treadmill or backing up will increase the strength of the quadriceps muscle group and minimize periods of complete weight bearing that often lead to upward fixation of the patella. As the horse improves, walking up and down a slope will further strengthen the muscles that control patellar movements.

Injection of sclerosing agents such as iodine into or surrounding the patellar ligaments or distal quadriceps has been used clinically to create an inflammatory response in the soft tissue, resulting in fibrosis or 'tightening' of the periarticular connective tissue in an attempt to reduce the occurrence of patellar fixation.[37] Injection of 2% iodine or ethanolamine oleate into the medial or middle patellar ligament in horses

resulted in a significant accumulation of inflammatory cells and fibroplasia of the ligaments.[38] This fibrous reaction may result in contraction and stiffening of the ligaments and may be responsible for the clinical improvement observed when used in cases of intermittent upward fixation of the patella.[38]

Routine desmotomy of the medial patellar ligament for intermittent upward fixation of the patella is not recommended as the practice may lead to chondromalacia and fragmentation of the distal patella when high-speed exercise resumes.[39] Rarely, when the fixation is permanent and cannot be reduced by manipulation or sedation, then a medial patellar ligament desmotomy may be indicated. The procedure is performed in sedated standing horses under local anesthesia.[35] These horses should not be actively exercised for 8–12 weeks to reduce the occurrence of distal patellar fragmentation or chondromalacia. In spite of these precautions, these complications may occur due to chronic trauma to the patella induced by the desmotomy. These horses may require arthroscopic surgery of the femoropatellar joint to remove patellar fragments and any diseased articular cartilage from the patella.[34] Use of anti-inflammatory and chondroprotective drugs in these horses may be of benefit.

Prognosis The prognosis for most athletes with this condition is excellent for resolution if any underlying cause can be identified and treated and the degree of conditioning improved. Horses treated with a medial patellar ligament desmotomy for upward fixation of the patella may develop patellar fragmentation or chondromalacia of the patella. These horses will often present with femoropatellar synovial effusion and lameness. The prognosis for athletic soundness in these horses is guarded.

Prevention

There is no general recommendation on preventing this condition in horses. Maintaining a consistent exercise program of adequate rigor for the particular discipline being pursued is usually all that is required. If predisposed athletes have been removed from training or active exercise for a period of time, an incremental approach to training will be helpful in limiting the disruption caused by this gait abnormality. Reducing or eliminating exercise in horses with a weak quadriceps mechanism and avoiding the indiscriminate use of medial patellar ligament desmotomy may prevent chondromalacia of the patella.

Etiology and pathophysiology

An upright conformation and developmental or orthopedic diseases causing pain during stifle flexion can precipitate the condition. Disuse atrophy or neurological dysfunction of the quadriceps muscle group, limiting the ability to disengage the patella from the medial trochlear ridge as the horse moves, is probably the most common cause for this condition. The condition will affect athletic performance by interfering with the normal range of motion of the stifle joint during locomotion.

Chronic trauma to the posterior aspect of the patella caused by stifle instability (idiopathic or iatrogenic) may lead to chondromalacia of the patella.

Epidemiology

The condition can affect any age and use of horse. It may be more common in younger horses or those with decreased quadriceps tone due to underlying disease or inactivity.

Stifle fractures

- Stifle fractures in adult horses are challenging to treat and often have a guarded prognosis for return to athletic use.
- The patella is the sesamoid bone of the quadriceps muscle group insertion on the proximal tibia.
- Patellar, tibial tuberosity, incomplete distal femoral and condylar fragmentation may all be amenable to treatment, thereby improving the prognosis for return to function.
- These injuries will often have concurrent articular soft tissue or ligament injuries that will make diagnosis, treatment and rehabilitation very challenging.
- Prompt recognition, adequate case selection and excellent clinical therapy are important aspects of managing these injuries in adult horses to restore joint stability and function.

Recognition

History and presenting complaint There is a history of an acute onset of severe lameness of a rear limb after a fall or impact. There may be a complaint of marked swelling, pain or crepitus over the stifle or proximal tibia of the affected limb or an inability to fix the stifle in extension.

Physical examination There is usually a marked degree of lameness present on the affected limb marked by a toe-touching attempt to bear weight or complete non-weight bearing. There may be a variable amount of soft tissue swelling or crepitus centered on the patella or cranial aspect of the tibia. In horses with complete transverse patellar fractures, there may be an inability to maintain the stifle in extension during any attempt at weight bearing, with an obvious protrusion of the distal femoral trochlear ridges.[40] Any attempt to manipulate the stifle will cause marked discomfort and palpation of the periarticular structures will reveal crepitation. There may be obvious soft tissue defects or contusions if the injury resulted from direct impact trauma. These soft tissue injuries need to be completely evaluated to determine if the soft tissues are viable and if communication with the underlying bone or joint is present. Open fractures with devitalized soft tissues will complicate therapy, minimize options and worsen the prognosis.[40] If the fracture has an intra-articular component the degree of femoropatellar and/or femorotibial effusion or hemorrhage will be readily palpable. Horses with distal patellar fragmentation usually present with less severe lameness, femoropatellar effusion and soft tissue swelling.[9,39,41,42]

Special examination Intra-articular anesthesia or limb manipulations are not necessary in horses with complete sagittal, transverse or comminuted patellar fractures or those with tibial tuberosity or distal femoral fractures. The clinical presentation will usually localize the lameness to the stifle. Horses with distal patellar fragmentation or stress fractures will have a less obvious clinical presentation and intra-articular anesthesia or limb manipulations will be necessary.[9,42]

Radiographs of the stifle are necessary to make an accurate diagnosis, formulate a therapeutic plan and determine a prognosis. Transverse or comminuted patellar fractures are imaged on standard lateromedial, caudocranial and flexed lateromedial views. When sagittal patellar or medial patellar avulsion fractures are suspected, the dorsoproximal to dorsodistal (skyline) view (Fig. 19.14) is ideal for imaging the size of the fragments and the location of the fracture line.[42] The caudomedial to craniolateral and caudolateral to craniomedial oblique views are necessary to visualize bony fragments associated with distal patellar avulsions or fragmentation. Distomedial patellar fragmentation may be evident in horses after medial patellar ligament desmotomy was performed for treatment of intermittent upward fixation of the patella.[39,43] The flexed lateromedial or skyline view may be hard to obtain in painful horses. Sedation (detomidine 0.01–0.02 mg/kg i.v. and/or butorphanol 0.01–0.02 mg/kg i.v.) or intra-articular anesthesia may facilitate the manipulations necessary to obtain adequate images. Radiographic quality and completeness will affect preoperative planning and formulation of a prognosis. Tibial tuberosity or distal femoral fractures can be imaged on the lateromedial, caudocranial or oblique views. These radiographs should be carefully evaluated for any intra-articular component or fracture line propagation. Tibial tuberosity fractures may be confused with the active tibial tuberosity physis present in horses up to 3 or 4 years of age and in these cases the lateromedial radiograph of the opposite tibia should be used for comparison.[44,45]

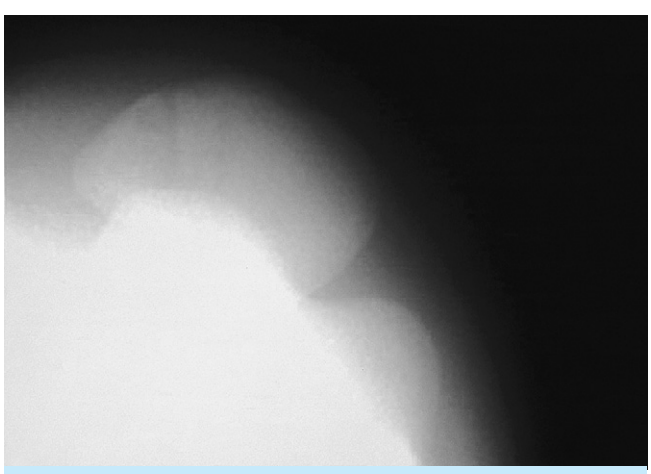

Fig. 19.14
Axial patellar fracture imaged on a dorsoproximal to dorsodistal radiographic projection (skyline) of the patella.

Ultrasonography of the patellar ligaments and the CoL is indicated for all horses with patellar, tibial tuberosity or distal femoral fractures. These scans can be performed standing using a 7.5 or 10.0 MHz linear probe positioned directly over each structure. It is not uncommon to sustain concurrent ligament (patellar, CoL and CrL) or intra-articular soft tissue (MM and articular cartilage) injuries with these fractures.[42,46] Nuclear scintigraphy may be helpful in the diagnosis of incomplete stress fractures or traumatically induced osteitis of the patella, distal femur or proximal tibia.

Diagnostic confirmation The clinical presentation and lameness evaluation will localize the source of lameness to the stifle. Diagnosis of these injuries is dependent on adequate and detailed radiographic studies of the stifle. Special views (skyline) are necessary when unusual fracture configurations are suspected (Fig. 19.14). Ultrasonographic evaluation will reveal concurrent soft tissue injuries. Accurate imaging is imperative to permit optimal therapeutic selection and prognosis.

Treatment and prognosis

Therapeutic aims Before any therapy is attempted, a precise and accurate diagnosis of all affected bony or soft tissue structures is imperative. These injuries adversely affect stifle function and there is no room for tentative or delayed therapeutic efforts that may further compromise function and irreversibly prevent any chance at rehabilitation. When the injuries are severe enough to make repair and rehabilitation unlikely, these horses should be euthanized for humane reasons.

The therapeutic aim is to stabilize fractures that are amenable to internal fixation, remove any intra-articular fragments that cannot be reduced and stabilized but contribute little to joint stability and debride or remove any damaged soft tissues that can promote inflammation.[40,42,47–51] After surgery, every effort must be made to assist the horse during the anesthetic recovery and enforce the required rest periods necessary to insure adequate bony or soft tissue healing. Rehabilitation of joint function is an important therapeutic component for these injuries.

Therapy Patellar fractures are usually treated surgically with internal fixation to re-establish joint stability, articular congruency and quadriceps function.[40,42,47–51] Conservative treatment of patellar fractures with disruption of the quadriceps mechanism (transverse or comminuted) will invariably fail and lead to persistent pain, osteoarthritis and joint fibrosis with contralateral limb breakdown. Sagittal patellar fractures should be treated surgically when there is a palpable fracture line present in the patellar fascia, a fracture gap of greater than 5 mm evident on the skyline view or significant fragmentation of the distomedial aspect of the patella indicating the presence of significant articular disruption.[40] Surgical intervention involves an approach over the patella through the peripatellar fascia and quadriceps muscles with reduction and debridement of the affected tissues.[40] Separate approaches to the medial and lateral aspect of the

femoropatellar joint may be necessary to adequately reduce the fracture. The fracture is maintained in reduction with 4.5 or 5.5 mm cortical or 6.5 mm cancellous screws.[40,49,51] Small axial fractures or distomedial fragments that are too small or comminuted to allow secure internal fixation can be removed (partial patellectomy) with arthroscopy of the femoropatellar joint.[34,39,41,42] Placement of the arthroscope laterally between the middle and lateral patellar ligament will improve visualization of the distomedial aspect of the patella where most of these fragments are located.[34]

Not all distomedial patellar fragments are intra-articular. If their location is determined to be extracapsular due to absence of effusion, lack of lameness or response to intra-articular anesthesia, they should not be removed because the periarticular soft tissue or ligament disruption may cause long-term clinical problems.[34] If there is any doubt as to their intra-articular location, arthroscopic evaluation is preferable to liberal incisions and extensive tissue dissection in an effort to remove the fragments. Non-displaced sagittal fractures (no palpable peripatellar fascial gap or radiographic fracture gap less than 5 mm) will usually heal with a fibrous union after 60–90 days of stall rest.[40] Follow-up radiographs may reveal persistent lucency of the fracture in horses with minimal joint effusion or lameness, indicating fracture stability and adequate joint resurfacing.[40]

Transverse or comminuted patellar fractures must be treated surgically due to complete disruption of the quadriceps mechanism with distraction of the fracture fragments and inability to fix the stifle in extension.[40,49,50] Transverse fractures can be stabilized using 5.5 mm cortical or 6.5 mm cancellous lag screws reinforced with a tension band of 16 or 18 gauge orthopedic wire to neutralize the pull of the quadriceps apparatus.[49] Comminuted fractures are repaired using a combination of lag screws, tension band wiring and removal of small fragments.[40] The aim of any surgical procedure is to restore continuity of the quadriceps mechanism and re-establish congruency of the joint surface.

Arthroscopic approaches to the femoropatellar joint for treatment of patellar fractures are preferable to arthrotomies that are prone to incisional dehiscence due to suture line tension from joint effusion, soft tissue swelling and joint motion.[34,41,42] Every attempt should be made to eliminate all dead space during closure of the incision to minimize incisional complications and implant sepsis. Disruption of the muscular or ligament attachments to the patella will complicate the ensuing instability and place added or abnormal loads on the orthopedic implants and fracture repair. Full limb casts or bandages are contraindicated for managing these injuries as a substitute for surgery or as coaptation after surgery as they will actually increase the distractive forces across the injured tissues.[40]

Assisted and controlled recovery from anesthesia is imperative to minimize disruption of the internal fixation, incisional dehiscence or lateral patellar luxation following partial patellectomy caused by a sudden forceful contraction of the quadriceps muscle. After surgery, cross-tying the patient for 4–6 weeks will prevent recumbency and minimize incisional or orthopedic implant failure.

Administration of NSAIDs and stent bandages of the surgical incision is important to control swelling. The degree of soft tissue damage, presence of closed suction drains, duration of surgery and rigidity of the fracture repair will determine the duration of broad-spectrum antimicrobial drug administration. Patellar fractures will require 5–6 months for adequate bony and soft tissue healing. Atrophy and fibrosis of the articular and periarticular soft tissues are common and physical therapy (swimming) to re-establish range of motion and strength of soft tissues is imperative before a return to riding may resume at 9–12 months. Healing may be delayed due to the constant tension created by the pull of the quadriceps muscle group on the injured tissues. Serial radiographic evaluation for fracture healing and implant positioning should be used as a guide to changes in activity levels during the postoperative period. Patellar fractures may heal with a fibrous union that will be radiographically apparent.[40] Lack of effusion and resolution of the lameness should be used as indicators of healing and guide increasing activity levels.[40]

Tibial tuberosity fractures may be intra-articular if the depth and angle of fracture propagation are steep enough.[44,45] The pull of the quadriceps through the middle patellar ligament will concentrate the distractive forces on the tuberosity during stifle flexion and further displace an existing fracture.[9,44,45]

Non-displaced fractures may be diagnosed radiographically or with scintigraphy and can be treated conservatively with stall rest and cross-tying for 3–6 weeks. They should be serially radiographed to insure that the pull of the quadriceps does not displace the fracture during convalescence. Displaced fractures and those with an intra-articular component should be surgically repaired using a tension band principle to offset the pull of the quadriceps muscle through the middle patellar ligament.[44,45,52,53] The same biomechanical principle may make surgical therapy of non-displaced fractures ideal to speed healing.

Large fractures with an intra-articular component can be repaired using a 4.5 mm broad dynamic compression plate (DCP) with 4.5 or 5.5 mm cortical screws.[44,45,52,53] The 5.5 mm screws have greater holding power and the broad DCP with the staggered screw hole configuration will reduce the probability of inducing horizontal fissures through the fractured tuberosity.[44,52] However, the 4.5 mm narrow DCP is easily contoured to the cranial aspect of the tibia, thereby avoiding placement of the screws in one plane.[45,53] When the plate is secured with 4.5 mm cortical screws it should provide adequate stability for these fractures.[45,53] Alternatively, 4.5 or 5.5 mm cortical lag screws can be used with 16 or 18 gauge orthopedic wire in a tension band principle to secure smaller fractures.[44] Small non-displaced fragments can be left alone to minimize disruption of the attachment of the middle patellar ligament to the tibia during attempts at surgical removal or the fragments can be carefully removed if they are unstable or causing lameness.[45] After surgery horses should be assisted during the recovery and confined to a stall for 6–8 weeks.[44,45,52] Hand-walking or exercise can be gradually introduced after radiographic evaluations of complete fracture healing.

Adult athletes with comminuted or over-riding distal femoral fractures that involve the diaphysis, metaphysis or femoral condyle(s) should be humanely destroyed.[54] The small or comminuted distal fragments are not usually large enough to permit secure fixation with orthopedic implants. Non-displaced distal femoral Salter-Harris physeal fractures that occur in young (18–20 months) horses (Fig. 19.15) will generally respond to conservative treatment and will usually heal in 8–12 weeks.[55] Femoral condylar fragments that involve less than 25% of the caudal aspect of the condyle in an adult horse can be removed surgically via a caudal arthrotomy or arthroscopic approach.[56,57]

Prognosis The prognosis for horses with patellar fractures that can be adequately reduced and secured with implants or have intra-articular fragments removed arthroscopically is favorable for return to athletic competition.[34,40–42,48] Re-establishment of articular congruency and the integrity and function of the periarticular soft tissues will improve the eventual outcome. Horses with partial patellectomies at the proximal or distomedial aspect of the patella have a favorable prognosis if the fragment is small and soft tissue disruption is minimized at surgery.[34,42] Horses with significant comminution of the patella have a worse prognosis due to difficulty in re-establishment of joint congruity.[40]

Horses with tibial tuberosity fractures that are non-displaced or displaced fractures that can be adequately reduced and secured at surgery have a favorable prognosis for return to athletic function if the implants and soft tissues remain intact during the recovery and early postoperative period.[44,45,52,53] Horses in which significant disruption of either occurs postoperatively will have a poor prognosis for use or pain-free ambulation.[44,45,52]

Adult horses with femoral condylar fractures involving less than 25% of the condyle treated surgically (fragment removal) have a good prognosis for return to athletic use.[56] Those with non-displaced distal femoral physeal fractures have an excellent prognosis for full return to function if displacement or limb contracture does not occur.

Non-displaced, incomplete Salter-Harris fracture of the distal femur in a 2-year-old Thoroughbred colt.

Prevention

There is no effective way to prevent these athletic injuries. Attention to footing, conditioning and level of training in light of the degree of difficulty of the endeavor may reduce the possibility of an accident causing one of these injuries.

Etiology and pathophysiology

Patellar fractures in adult horses occur infrequently and are the result of a kick or collision with a fence or crossrail while jumping.[9] When the stifle is flexed (as in jumping) the patella is fixed in the trochlear groove, concentrating the force of the impact on the patella.[9]

Tibial tuberosity fractures are caused by blunt or impact trauma to the cranial aspect of the dorsal tibia, which has little soft tissue coverage to dissipate any disruptive force applied directly to it.[45] The physis of the tibial tuberosity does not completely ossify and fuse with the proximal tibial epiphysis until 2–3 years of age.[44] The quadriceps muscle group attaches to the tibial tuberosity through the middle patellar ligament. This attachment may concentrate distractive forces during contraction or loading of the quadriceps apparatus.[45,52,53] If the fracture line is deep into the tibial cortex and propagates caudally at a steep angle, the fracture will be intra-articular.[44,52]

Distal femoral fractures in adult horses are rare and traumatically induced after a kick or collision. There is often a marked amount of soft tissue trauma associated with these injuries.

Epidemiology

These injuries can occur in any type of athletic horse involved in a discipline in which a sudden loss of footing at high speed can occur or full-speed exercise around or over immovable objects is undertaken.

Tarsus

The equine tarsus has high-motion (tarsocrural) and low-motion (sustentaculocalcaneal, tarsometatarsal, distal and proximal intertarsal) joints. The distal tibia articulates with the medial and lateral trochlear ridges and trochlear groove of the talus (Fig. 19.16). This articulation provides for hock flexion and extension during locomotion. The talus articulates with the flattened central tarsal bone distally and the calcaneus on the plantar aspect of the tarsus (Fig. 19.16). The articulations of the calcaneus with the plantar surface of the talus and the proximal surface of the fourth tarsal bone are low-motion joints. The proximoplantar aspect of the calcaneus projects plantar to the tibia and serves as the attachment of the gastrocnemius tendon (GT), which contributes to hock movement and is part of the reciprocal apparatus of the hindlimb. The superficial digital flexor (SDF) tendon courses over the calcaneus and GT on the plantar surface of the hock

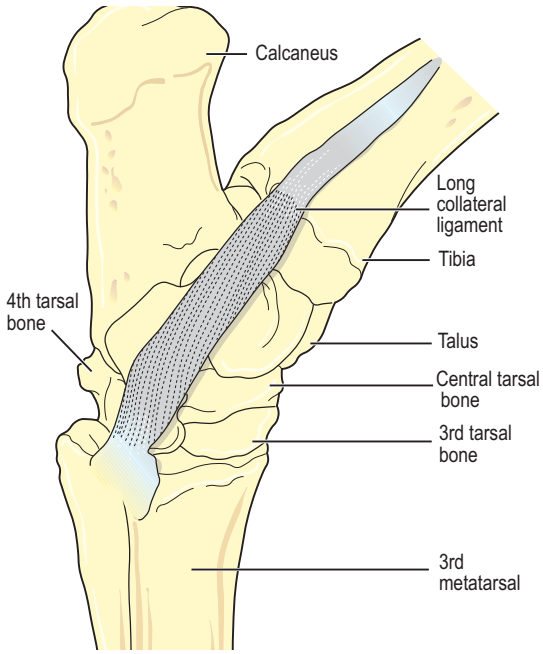

Fig. 19.16
Lateral view of the right equine tarsus.

and eventually attaches to the plantar surface of the proximal and middle phalanx. The medial and lateral edges of the SDF have firm fascial attachments to the calcaneus to maintain its central position over the calcaneus. A bursa separates it from the GT, allowing it to glide over the calcaneus during tarsocrural joint motion. The deep digital flexor (DDF) tendon is encased in the tarsal sheath as it courses medially in the tarsal canal formed by the plantar and distomedial borders of the talus and calcaneus, respectively. The distomedial projection of the calcaneus that encases the DDF plantar to the talus is the sustentaculum tali. Distally, the talus and calcaneus articulate with the central tarsal bone and the proximal aspect of the fourth tarsal bone to form the proximal intertarsal joint (Fig. 19.16). The central tarsal bone articulates distally with the third and fused first and second tarsal bones to form the distal intertarsal joint. The tarsometatarsal joint is the collective articulation of the fused first and second, third and fourth tarsal bones with the second, third and fourth metacarpal bones, respectively (Fig. 19.16). These distal joints are primarily low motion–high impact joints subjected to shear stress, compression and torsion during athletic activity in horses.

This complex bony arrangement is held together by a system of collateral ligaments and fascia that alternately tighten or loosen during flexion and extension to maintain precise bony alignment.[58] The *long lateral* collateral ligament (CoL) originates proximally on the lateral tibial malleolus and courses distally to insert on to the calcaneus, fourth tarsal bone, talus and the fourth and third metacarpal bones (Fig. 19.16). The *long lateral* CoL is loose in flexion and taut during extension of the tarsus. The *short lateral* CoL mechanism is composed of three (superficial, middle and deep) ligaments (Figs 19.17, 19.18). All three originate proximally on the lateral tibial malleolus and insert distally on the calcaneus (superficial) and talus (middle and deep). The *lateral short* CoLs are variably tight or loose during flexion or extension of the tarsus. The *medial long* CoL originates proximally at the medial tibial malleolus and inserts distally on the fused first and second tarsal bones and on the talus, central and third tarsal bones by two separate fiber bundles (Fig. 19.19). It is loose during tarsocrural joint flexion and tight during extension. The *short medial* CoL is made up of the superficial, middle and deep *short medial* CoLs (Figs 19.20, 19.21, 19.22). They originate proximally on the medial tibial malleolus and insert distally on the deep fascia, fibrous joint capsule, sustentaculum tali and central tarsal bone. The *medial short* CoLs are variably tight or loose during flexion or extension of the tarsus, with the majority of the deep component remaining tight during the entire range of motion of the tarsocrural joint.[58]

The tarsocrural joint communicates with the proximal intertarsal joint in most horses. Communication between the distal intertarsal and tarsometatarsal joints has been reported to occur in 26%,[59] 35%,[60] or 38%[61] of horses when the tarsometatarsal joint is injected first. Following the same injection, 3–4% of tarsometatarsal joints would be expected to communicate with the proximal intertarsal and tarsometatarsal joint.[59,60] Increasing the volume or pressure of injection of liquid agents does not increase the probability of communication, but will increase the amount of subcutaneous leakage of fluid.[61] The tarsometatarsal and distal intertarsal joints may also communicate with the tarsal

sheath, tendon of the tibialis cranialis and the subtarsal tissues near the origin of the suspensory ligament at the plantar surface of the third metacarpal bone.[60,61] Due to this variable communication between synovial structures of the tarsus, intrasynovial anesthesia or medication of the distal intertarsal or tarsometatarsal joint cannot be accurately predicted to affect more than a single compartment and may have an extrasynovial effect on the suspensory ligament. In addition, any substance placed into one of these joints could diffuse into the tarsal sheath or tarsocrural joint.[60]

Osteochondrosis of the tarsus

- The tarsus and stifle joints are the most frequently affected with osteochondrosis in horses.
- Standardbreds, Warmbloods and draft horses are more frequently affected.
- Osteochondrosis of the distal intermediate ridge of the tibia is the most common lesion in the tarsocrural joint.

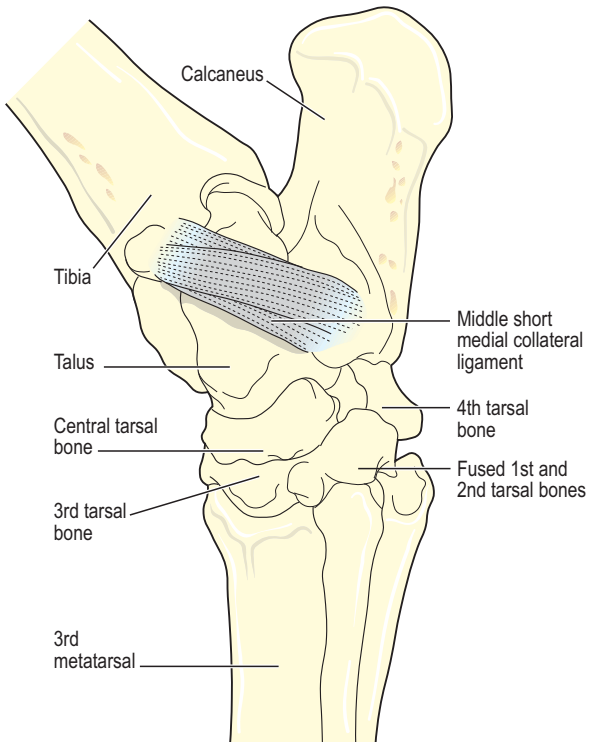

Fig. 19.21
Medial view of the right equine tarsus demonstrating the middle short medial collateral ligament (MSMCoL).

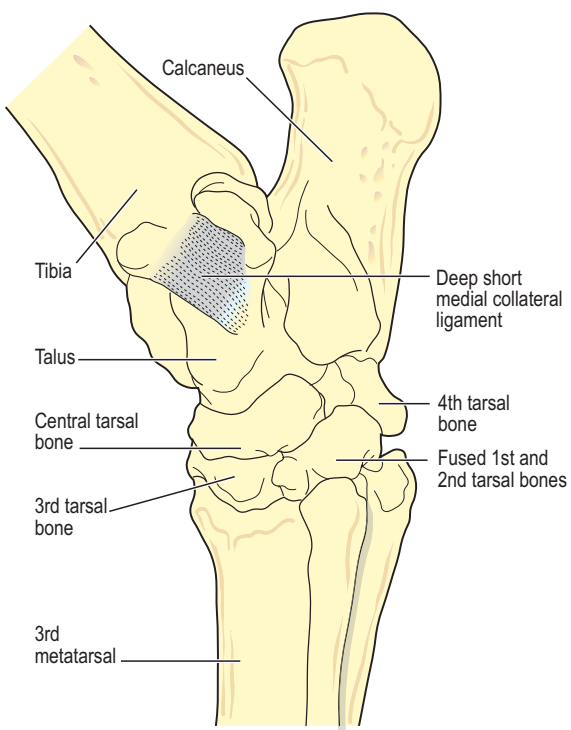

Fig. 19.22
Medial view of the right equine tarsus demonstrating the deep short medial collateral ligament (DSMCoL).

- The lateral trochlear ridge of the talus and medial malleolus of the tibia are the next most frequently affected sites in the tarsocrural joint.
- The degree of effusion and lameness is variable depending on the age and use of the horse.
- In equine athletes that are lame, surgical treatment will minimize the deleterious effects of synovitis on articular cartilage.
- Osteoarthritis and collapse of the intertarsal or tarsometatarsal joints in young athletes is seen with osteochondrosis of these joints.

Recognition

History and presenting complaint The history and clinical presentation of horses with osteochondrosis (OC) of the tarsus is variable. There are mature athletic horses (older than 2 years of age) in which there is no lameness or effusion associated with an OC lesion that is considered an incidental finding on routine tarsal radiographs. There are young horses (less than 12 months of age) that have marked effusion of one or both tarsocrural joints. In most horses of this age group, there is usually no complaint of lameness or the degree of lameness is very subtle. Horses with OC of the tarsus that is affecting athletic performance are usually in training or racing (2–3 year olds). These horses will present with a mild to moderate degree of lameness associated with effusion of the tarsocrural joint.

Physical examination Horses that are symptomatic for OC of the tarsus will present with effusion of the tarsocrural joint. The distension can be subtle or obvious and in horses with marked effusion it can be tight if the distension developed recently after rigorous exercise was initiated or soft if the distension is chronic. In most horses, the degree of lameness varies from mild to moderate and they are rarely markedly lame. A fracture of a tibial malleolus may be mistaken for an OC lesion radiographically, but fractures have an acute onset of swelling and marked lameness associated with them. The lameness is characterized by reduced flexion of the hock during the swing (anterior) phase of the stride. The duration of the weight-bearing or stance phase is usually normal but the horse may drag the toe of the affected limb(s) at a walk or trot. Due to this shortened gait, extended high-speed exercise or collected work where optimal hock flexion is required becomes more difficult for the athlete to perform adequately. Affected Standardbreds may break gait at high speeds, lean on the shafts of the cart during high-speed exercise or pull away from the affected side, making it difficult to keep the horse in a straight line. Since the degree of lameness is often mild, there is usually no gluteal rise accompanying the lameness. Upper limb flexion will exacerbate the lameness in most horses, the duration and severity of the effect being variable. Horses with OC of the small tarsal joints may have severe degenerative joint disease of the distal intertarsal or tarsometatarsal joints. They usually present with a marked lameness with a shortened swing and stance phase, a prominent gluteal rise and a positive response to upper limb flexion.

Special examination Perineural analgesia of the peroneal and tibial nerves should be expected to improve lameness caused by tarsal OC. Horses with osteoarthritis of the intertarsal or tarsometatarsal joint secondary to OC would be expected to improve after this block. Perineural analgesia is usually not required for cases of tarsocrural OC as the degree of effusion raises the index of suspicion for that joint. Intra-articular analgesia of the tarsocrural, intertarsal or tarsometatarsal joints will improve a lameness originating from these joints if they are affected with OC. The use of intrasynovial anesthesia may be of particular value in determining if a radiographically evident OC lesion is the cause of lameness, especially in cases where the degree of effusion is minimal. This may help decide which horses are likely to benefit from surgery to debride the OC lesion. Horses with OC of the small tarsal joints would be expected to improve after intrasynovial anesthesia of the affected joint(s). If the small intertarsal joints are collapsed, it may be difficult to perform the arthrocentesis to effectively block the joint.

Complete radiographic evaluation of the tarsus should be performed in affected horses and these should be obtained bilaterally even if only one tarsus appears to be clinically affected. These include the dorsoplantar, lateromedial, dorsolateral-plantaromedial and dorsomedial-plantarolateral obliques and a flexed lateral view.[62] Osteoarthritis and collapse of the tarsometatarsal and intertarsal joints due to tarsal OC will be evident on all views, but often more obvious on the lateromedial and dorsolateral-plantaromedial oblique.[62] The OC lesion of the distal intermediate ridge of the tibia, lateral trochlear ridge of the talus and medial tibial malleolus are often best imaged on the oblique views (Figs 19.23, 19.24). However, the lesions are also evident on the dorsoplantar and lateromedial views if the radiographic positioning and technique are adequate (Fig. 19.25). Lesions of the distal intermediate ridge and medial malleolus of the tibia consist of variably sized osteochondral fragments still attached to the parent bone (Figs 19.23, 19.24).[63] Lateral trochlear ridge lesions are usually lucent areas on the distal aspect of the ridge accompanied by overlying, variably sized osteochondral flaps (Fig. 19.26).[63] The lesions can vary in size and depth and in some horses marked distal trochlear ridge osteochondral fragmentation may be the predominant radiographic finding. Horses may have radiographically inapparent OC lesions of the trochlear ridges causing lameness and effusion. These may be imaged by ultrasonographic evaluation of the articular cartilage of the trochlear ridges of the talus.[64]

Young horses used in speed events may present with a marked lameness that appears to localize to one tarsus, with minimal effusion of the tarsocrural joint, a radiographically evident OC lesion of the intermediate ridge of the tibia and no radiographic evidence of osteoarthritis of the small tarsal joints. These horses may improve considerably but not completely after intrasynovial anesthesia of the tarsocrural joint. They may have a stress fracture of the distal tibia or talus (see fracture section) that communicates with the tarsocrural joint and the OC lesion is often an incidental finding. The marked lameness of one limb, minimal effusion and partial

Fig. 19.23 Dorsolateral to plantaromedial radiographic view of the tarsus with an osteochondrosis lesion of the distal intermediate ridge of the tibia.

response to intrasynovial anesthesia should raise the index of suspicion for an additional cause for the lameness. Surgical therapy for the OC lesion will not address the source of lameness, may predispose to a catastrophic failure of the affected bone during anesthetic recovery and may lead to premature reintroduction to high-speed work before the stress fracture has healed. To determine the significance of the OC lesion and

if a stress fracture is present, nuclear scintigraphy and/or high-quality radiography is recommended.

Laboratory examination No special laboratory examination is necessary. If there is a doubt as to the etiology for the effusion, cytological evaluation of a synovial sample may help. Horses with osteochondrosis have synovial fluid nucleated cell counts of 1000–5000 cells/μL and protein levels close to or below 2.5 g/dL indicative of a mild synovitis.[65] Horses with traumatically induced synovitis or moderate to severe osteoarthritis have synovial fluid nucleated cell counts between 5000 and 25 000 cells/μL and protein levels of 2.5–4.0 g/dL. Severe inflammation such as occurs with sepsis will result in synovial fluid protein levels greater

than 4.0 g/dL and nucleated cell counts in excess of 30 000 cells/μL.[65]

Diagnostic confirmation Diagnosis is confirmed by the radiographic appearance of the lesions. However, not all horses with radiographically evident tarsocrural OC lesions are clinically affected. Therefore, correlation of the radiographic images with a thorough evaluation of the history, clinical evaluation and lameness examination is necessary to determine the clinical significance of a radiographic finding of tarsocrural OC in young horses. In addition, some horses with radiographically inapparent cartilage lesions may have effusion and synovitis and be clinically lame. Ultrasonography of the articular cartilage of the trochlear ridges of the hock may reveal defects not apparent on radiographs.[64]

Treatment and prognosis

Therapeutic aims The aim of treatment in horses that require therapy is to remove the involved tissue and debride the surrounding area of all loose and unattached cartilage.[63,66] This will remove the stimulus for synovitis and minimize the continued trauma to the affected area during high-speed exercise. In horses treated conservatively with rest or a reduction in the exercise schedule, the aim is to minimize disruption of the OC lesion to allow healing by completion of endochondral ossification with increasing skeletal maturity or by fibrous attachment of the affected area to the parent bone.[67] This will increase stability of the lesion and minimize the development and progression of synovitis. It is difficult to predict how long it will take for conservative therapy to work and how effectively the lesion is ossified or anchored, as radiographic monitoring will usually reveal persistence of the lesion. Return to high-speed exercise may cause a recrudescence of the lameness, necessitating surgical therapy or a more prolonged rest period.[67]

Therapy The preferred therapy for OC of the tarsocrural joint that is causing lameness and effusion is arthroscopic surgery to debride and remove loose osteochondral fragments and cartilage flaps.[63] Since articular cartilage lesions that are radiographically inapparent can perpetuate synovitis, surgical exploration of the joint may be warranted in promising athletes.

Under general anesthesia and with the horse positioned in dorsal recumbency, lesions of the distal intermediate ridge of the tibia are best approached using a dorsomedial arthroscopic portal and a dorsolateral instrument portal.[68] Lesions on the lateral trochlear ridge of the tibia can be approached similarly with the instrument portal placed slightly more laterally to improve access to the lesion.[68] In horses with marked effusion or joint capsule thickening, dorsolateral arthroscopic and instrument portals may be necessary. For surgery on lesions on the medial malleolus of the tibia, the instrument and arthroscope portals are usually reversed.[68] Bandaging and stall rest are continued for 2–3 weeks after surgery. Hand-walking can be started 10–14 days after surgery with limited turnout (paddock) initiated after 30–45 days, depending on the location of the OC and extent of articular cartilage involvement. Horses with uncomplicated distal intermediate ridge lesions usually have a shorter convalescent time. Training is resumed after 90–120 days for most tarsocrural OC. Horses with extensive articular cartilage fibrillation or synovitis will usually benefit from an extended (5–6 months) interruption of strenuous activity. Single-dose intra-articular hyaluronic acid and corticosteroids may be beneficial in decreasing synovitis and reducing the catabolic effects of inflammation on the articular cartilage.

Conservative treatment entails rest or reduction in the exercise schedule for a variable period of time. Younger horses with lesions causing mild lameness and that can be taken out of a rigorous training program may benefit from conservative therapy. The length of the rest period is somewhat arbitrary, but will be at least 60–120 days. The disadvantage of this approach is that if the lameness recurs when high-speed exercise is reinstated then surgery will be required, thereby doubling the lay-off or time away from competition. If performance is being adversely affected (lameness) and the stage of the athletic career will not permit a prolonged lay-off time, then surgery should be recommended. Intra-articular anti-inflammatory medications to control synovitis and lameness will usually result in a clinical improvement, but repeated and frequent use of this approach alone will likely result in a shortened athletic career. The medications may permit pain-free high-speed exercise, but this level of activity will likely further traumatize the lesions causing the lameness, creating more severe synovitis and articular cartilage damage elsewhere in the joint.

Horses with tarsometatarsal or intertarsal osteoarthritis may benefit from intra-articular medications such as hyaluronic acid and/or corticosteroids to improve clinical function. Phenylbutazone (NSAID) can be used to reduce the level of lameness during periods of heavy work. There are regulatory issues with the use of this class of drug and in some jurisdictions and athletic competitions its use is banned. Prolonged use may lead to debilitating gastrointestinal or renal side effects. There may be a therapeutic benefit from the use of parenterally administered polysulfated glycosaminoglycans to decrease articular cartilage degradation and synovitis and promote the production of endogenous hyaluronic acid. These therapeutic regimens may have a limited clinical effect, depending largely on the degree of tarsal bone involvement and joint collapse present. Horses with marked OC of the small tarsal joints that develop severe osteoarthritis may not be able to maintain the level of soundness required to participate in elite athletic competition.[69,70] Surgical and chemical arthrodesis of these joints may be an option and will be discussed later in this chapter.

Prognosis The prognosis for horses with OC of the tarsocrural joint is excellent if there is a favorable response to either surgical or conservative treatment. Horses treated conservatively may be less likely to have a prolonged athletic career, but the performance is usually comparable to unaffected horses while they are actually competing.[63] Horses treated conservatively or surgically are likely to race as successfully as unaffected horses of the same age, breed and use.[63,66,67] The size of the lesion or resolution of the effusion

after surgery do not appear to be as reliable prognostic indicators for horses that undergo arthroscopic surgery for OC of the distal intermediate ridge or medial malleolus of the tibia or the lateral trochlear ridge of the talus. Horses that have erosive articular cartilage lesions at the time of surgery have a guarded prognosis for athletic soundness.

Horses with severe osteoarthritis of the intertarsal or tarsometatarsal joints secondary to OC of these joints have a guarded prognosis for elite athletic use.

Prevention

Osteochondrosis is a multifactorial disease so complete prevention is unlikely. Feeding diets with balanced mineral (copper, zinc, calcium and phosphorus) levels and not overfeeding grain (excess phosphorus) are recommended. Delaying rigorous training until horses have reached skeletal maturity may reduce the incidence of traumatically induced subchondral bone damage and the development of defects during endochondral ossification. Genetic selection away from breeding lines predisposed to OC is controversial because superior racing stock in some breeds may have a genetic predisposition for the disease. In cases of tarsocrural OC, the prognosis for racing performance with treatment is good, making removal of these animals from the breeding pool unrealistic in light of the fact that the disease is multifactorial.

Etiology and pathophysiology

Osteochondrosis is a developmental disease characterized by disorders of the growing cartilage in the epiphysis and growth plates. This complex biologic mechanism is termed endochondral ossification and it allows for longitudinal bone growth and provides subchondral bone support for all joint surfaces. When this developmental disorder affects the integrity of the articular cartilage due to loss of joint surface support, it will cause joint inflammation (osteochondritis). Other manifestations of this disorder of cartilage development include angular limb deformities, physitis, cervical vertebral malformations and SC. The disease is multifactorial with genetic, nutritional (copper deficiency or zinc excess, calcium and phosphorus imbalance from feeding excess grain), metabolic (vitamin D deficiency) and endocrine (hypothyroidism) influences.[28–31] The predictable locations of many osteochondral articular lesions in the horse are sites where the developing articular cartilage or growth plates are thick, the vascular supply is tenuous but the biomechanical loads are high.[28–31] Therefore, vascular and traumatic insults in these locations are probably very important in the expression of this disease in horses.[21,29–31] The ultimate expression of the disease is unpredictable but controlling some of these factors may help reduce the incidence of the disease in a particular area or farm.

Epidemiology

Tarsocrural osteochondrosis is widely distributed and is reported to occur in Standardbreds, Warmbloods, Thoroughbreds, Quarter Horses and draft breeds, among others, with Standardbreds being over-represented. The incidence of the disease may vary from one farm to another and between geographical areas, highlighting the multifactorial nature of the disease. Exercise in these breeds at a young age in conjunction with genetic or nutritional predispositions may account for its expression.

Collateral ligament injuries and tarsal luxations

- Collateral ligament (CoL) injuries of the tarsocrural joint can be treated successfully and affected horses returned to athletic use.
- Radiography, nuclear scintigraphy and ultrasonography may all be necessary to accurately diagnose these injuries.
- Tarsal luxations can occur at the tarsocrural, intertarsal or tarsometatarsal joints.
- Horses with tarsal luxations can be salvaged and restored to light use if they are treated early and aggressively.

Recognition

History and presenting complaint Horses with tarsal luxations will usually present with an acute onset of severe lameness and swelling of the tarsus. There may be a wound associated with the tarsal luxation or it may be a closed injury. There may be a history of a traumatic event such as a kick from another horse, a fall or an accident (collision or fall) while engaged in an athletic competition.

Horses with CoL desmitis will present with a history of rear limb lameness of variable duration and severity depending on the inciting cause and degree of ligament involvement. There may be historical information (fall, kick or slip during competition) that may provide useful details as to the probable etiology. There may have been an initial response to treatment (reduction in lameness with rest and/or medication) only to have a residual component that may be static or progressively deteriorating with prolonged exercise. Standardbred pacers will present with a rear limb lameness of variable severity and increased tarsocrural joint effusion.

Physical examination Horses with tarsocrural luxations will have marked periarticular swelling, crepitus and an obvious angular (valgus or varus) and rotational deformity of the tarsus at presentation.[71–74] Once the distal tibia luxates off the trochlear ridges of the talus, it will remain in this position until it is surgically reduced even if the collateral ligaments are severely damaged or stretched.[73] Open tarsal luxations usually involve the synovial cavity of the affected joint and the articular cartilage can often be visualized through the wound. Damage to the flexor or extensor tendons and major vasculature supply may also accompany these injuries. The limb should be carefully evaluated for concomitant structure involvement before proceeding with attempts at reduction and stabilization as the prognosis worsens with extensive soft tissue damage. Horses with intertarsal or tarsometatarsal luxations may also present with an open

wound, which makes the diagnosis straightforward. Since these joints are flat, horses with closed luxations do not have an obvious angular deformity because the luxation usually propagates from the cranial edge of the joint in a plantar direction.[71,74]

These horses are usually toe touching the limb to the ground and the injury may not be readily apparent except for the obvious swelling around the tarsus. As the limb is manipulated or the horse moves the limb spontaneously, the cranial to caudal instability is easily appreciated. The calcaneus, reciprocal apparatus and suspensory ligament on the plantar surface of the limb limit these luxations to a cranial caudal plane. As the soft tissue swelling increases within hours of the injury, it will stabilize some of the laxity and the swinging movement may not be as appreciable. A high index of suspicion for a tarsal luxation is warranted for any horse with a sudden onset of severe lameness and swelling of the tarsus without a wound, especially if there are few or subtle bony changes radiographically to explain the degree of lameness.

Athletes with tarsal CoL injuries will present with a rear limb lameness of variable severity that worsens with exercise and can usually be markedly exacerbated by upper limb flexion.[75–77] There may be palpable swelling, thickening and pain of the soft tissues surrounding the affected structure. Effusion of the tarsocrural joint or tarsal sheath may be obvious. Tarsocrural joint effusion has been reported as a consistent finding in Standardbred pacers with long CoL injuries.[76]

Special examination Radiographs should be obtained on all horses presenting with an acute onset of severe tarsal swelling, even if a tarsal luxation is obvious.[72,73] Significant concomitant fractures of the tarsus will complicate treatment and markedly reduce the prognosis. In cases of tarsocrural luxations, the radiographic appearance is typical with the trochlear ridges of the talus no longer articulating with the distal tibia.[72,73] The luxation may be in a medial, lateral or dorsal direction. The calcaneus, SDF and CT may limit the development of plantar luxations.

Tarsal radiographs of horses with intertarsal or tarsometatarsal luxations may reveal a widened joint space dorsally at the affected site during the acute phase (Fig. 19.27).[71,74] If the radiographs are taken with the foot on the ground or the soft tissue swelling has stabilized the joint (luxation is reduced), the radiographic diagnosis may not be obvious. Therefore, a stressed lateromedial radiographic view is recommended to identify this injury. The foot is lifted slightly off the ground by an assistant and pulled in a plantar direction to 'open' the affected articulation dorsally and obtain an adequate image of the luxation (Fig. 19.27). The patient will often resent this manipulation, necessitating adequate restraint (sedation and/or lip chain).

Ultrasonography of the CoLs is usually not performed in cases of tarsal luxation due to the swelling present and the fact that significant disruption or stretching of the major supporting soft tissues of the hock occurs with these injuries.

In horses with desmitis of the CoL tarsal radiographs may reveal enthesiophytes at the attachments of the CoL to the parent bone (see previous section).[75–77] There may be dystrophic mineralization of the tissue evident in chronic cases and degenerative joint disease or collapse of the joint space(s) if there is long-standing instability present due to the CoL injury. Ultrasonography of the CoLs of the hock in horses is possible and disruptions of the long components of the medial or lateral CoL are more readily imaged.[78] The more superficial areas of the short portions of the CoLs and long plantar ligament can be adequately imaged.[78] Ultrasonographically there will be disruption of the fiber pattern, hypoechoic fluid accumulation within the ligament or hyperechoic deposition of fibrous or mineralized soft tissue, depending on the stage and extent of the injury. Pronounced periarticular soft tissue swelling may interfere with ultrasonographic imaging of these structures.

Fig. 19.27 Stress lateromedial radiograph of the tarsus of a horse with a luxation of the intertarsal joint, demonstrating widening of the joint space.

Perineural analgesia of the peroneal and tibial nerve should improve most lameness associated with CoL injuries of the tarsus. Nuclear scintigraphy in horses with tarsal CoL injuries will reveal a pattern of increased radioisotope uptake at the attachment of the CoL to the bone (Fig. 19.28).[76] The pattern of uptake and its location will help identify the structure involved (long versus short CoL) and the degree of involvement (single versus multiple areas).[76] Scintigraphy is especially useful in horses with a subtle lameness localized to the hock where radiographic studies are inconclusive. Magnetic resonance imaging would be ideally suited for the diagnosis of CoL injuries of the tarsus in horses.[79]

Laboratory examination If there is effusion of the tarsocrural joint or tarsal sheath and the radiographic diagnosis is equivocal, arthrocentesis of the affected synovial compartment and cytological analysis of the fluid should confirm the traumatic etiology of the effusion.

Necropsy examination At necropsy, there will be disruption of the soft tissue covering of the tarsus in open luxations with exposure of the articular surface and a variable amount of damage to the articular cartilage. There is usually significant disruption of all the supporting soft tissue structures of the hock with these injuries. There may also be significant bony injuries present.

In horses with closed luxations, there will be subcutaneous hemorrhage and edema associated with the injury and

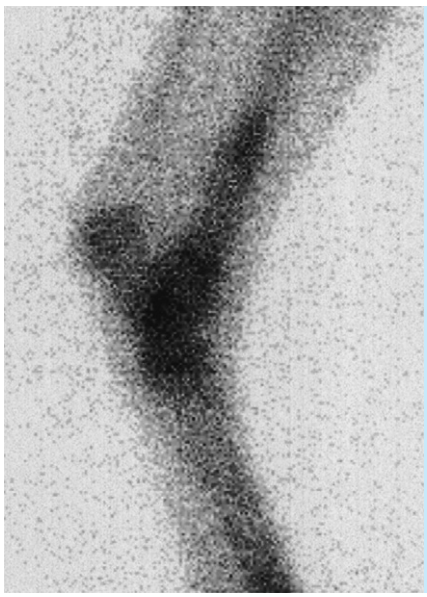

Fig. 19.28
Nuclear scan of the tarsus in a horse revealing increased isotope uptake at the attachment of the collateral ligament on the talus.

disruption of the supporting structures of the tarsal joints (CoLs, fibrous joint capsule). There may be associated bony injuries ranging from small avulsion fractures at the attachments of the CoLs to significant fractures of the talus, calcaneus, tarsal bones or distal tibia.

Horses with desmitis of the CoLs will have variable degrees of fiber disruption or thickening and fibrous proliferation or mineralization of the affected structure(s), depending on the duration of the condition.

Treatment and prognosis

Therapeutic aims The therapeutic aim for horses with any type of tarsal luxation is to reduce the luxation and immobilize the tarsus.[71–74] Major bony injuries are addressed at this time and internal fixation performed when indicated. An adequate period of coaptation and rest must be provided to allow all soft tissue and bony injuries to heal adequately. Most tarsometatarsal or intertarsal luxations treated successfully will result in arthrodesis of these joints. Physical therapy after prolonged coaptation will be important to regain as much as possible of the articular range of motion and supporting soft tissue structure elasticity that is lost due to fibrosis and disuse.

Therapy Horses with open luxations and significant fractures should be carefully evaluated before pursuing treatment. Devitalized soft tissues and septic synovial structures will complicate treatment, increase expense of therapy and worsen the prognosis. In addition, these injuries are difficult to manage effectively when external coaptation is used. Due to the poor prognosis for horses with complicated, exposed and infected tarsal luxations, euthanasia may be considered.

Horses with tarsocrural or tarsometatarsal luxations are reduced with the patient anesthetized. Tarsocrural luxations are difficult to reduce and an adequate plane of anesthesia to create muscle relaxation, limb distraction and patience are often required to achieve reduction. The marked disruption of the supporting structures (CoLs, fibrous joint capsule and fascial sheaths) makes reduction difficult and if accomplished, maintenance of the reduction is unlikely. Intertarsal and tarsometatarsal luxations are usually easy to reduce but maintaining reduction while placing the limb in a cast may be more challenging.

Once reduced, the tarsus should be radiographed to insure that proper alignment was achieved before applying a full-limb fiberglass cast from the foot to the proximal aspect of the tibia (Fig. 19.29). Adequate padding is necessary to minimize the development of cast sores. Particular areas that need adequate protection are the cranial tibial tuberosity, calcaneus and the proximal sesamoids. Excessive padding will compress during ambulation, eventually leading to cast loosening and the development of pressure sores. The limb should be cast with the hock angle near maximal extension appropriate for weight bearing (Fig. 19.29). Care must be taken during cast application to limit moving the tarsus and either losing the reduction on the luxation or creating an unwanted degree of tarsal flexion that will make it difficult for the horse to ambulate in the cast because it will make the affected leg 'shorter' than the contralateral limb. Placement of a frog support on the opposite hindlimb while the horse is anesthetized may help prevent contralateral limb laminitis during the convalescent period. Incorporating a walking bar (aluminum rod) into the cast may be necessary for larger horses to increase the strength of the construct. Smaller patients (ponies and miniature horses) may require only a full-limb Robert-Jones bandage with splints or bars cranially and caudally to achieve effective immobilization. In cases of tarsometatarsal or intertarsal luxation, placement of orthopedic implants to secure the reduced luxation or stabilize large fragments has been described. Implants include lag screw fixation, arthrodesis of the distal tarsal or tarsometatarsal joint(s) with a plate(s) or lag screws. The technique used will vary and depends on the extent and location of the bony injury.

Horses with full-limb casts must be assisted to stand after anesthesia and careful monitoring during the perioperative

Fig. 19.29
The horse in Fig. 19.27 after coaptation in a full-limb cast.

period is required. Some horses adapt very quickly to this form of coaptation, but some will panic and become uncooperative. It will be difficult or impossible for horses to rise if they lie down with the cast limb down. In horses with closed luxations that may have difficulty accepting the cast, placing them in a full-limb bandage overnight and delaying the reduction may be of benefit to allow them to accept the immobilization. Cast sores are a problem with full-limb casts of the rear limb. They should be monitored for exudate, heat or reluctance to bear weight. Any of these is a signal for immediate replacement. These casts will loosen significantly after 10–14 days as the swelling subsides and muscle atrophy ensues, so they need to be changed at that time. Stall rest and casting should be maintained for 4–6 weeks and then a Robert-Jones bandage used for another 4–6 weeks. Hand-walking can be initiated after 90 days and turnout in a paddock after 6 months. Swimming may help restore range of motion and elasticity of the soft tissues and improve tarsocrural joint function. Arthrodesis of the intertarsal or tarsometatarsal joints will usually occur during convalescence from these luxations. Light exercise on flat ground may resume after 9–12 months if the horses are relatively sound and radiographic evaluation reveals minimal degenerative changes in the tarsocrural joint or adequate arthrodesis of the intertarsal or tarsometatarsal spaces.

Horses with desmitis of the CoL need to be rested to allow the collagen in the ligament to be replaced and to organize along the lines of stress.[75,76] Rest should entail stall rest for the first 14–21 days after the injury, with a gradual resumption of hand-walking only (5–10 minutes twice a day) after that time. Systemic NSAID therapy, cold compresses or hydrotherapy and leg wraps are helpful in eliminating soft tissue swelling and restoring adequate circulation to the injured area. Continued activity with further ligament disruption will generate a pronounced fibrovascular response that will eventually fibrose in a very disorganized manner, resulting in an architecturally weakened structure with little elasticity and poor function. This will interfere with joint movement and create a persistent mechanical or painful disruption of the gait.[76] These horses should be monitored ultrasonographically and with nuclear scintigraphy during their convalescence to evaluate ligament healing. When a significant reduction in the size of the original injury coupled with an increased tissue organization has occurred, then a gradual increase in activity is warranted to restore full function. This usually requires 3–6 months of rest. Swimming these patients may be beneficial before starting flat work to increase the strength of the tissues without loading them.

Prognosis The prognosis for horses with tarsocrural luxations of any kind is guarded to poor for athletic performance and life. Open luxations or those associated with significant fractures have a very poor prognosis for life or athletic use. Horses with closed tarsometatarsal or intertarsal luxations without significant fractures of the small tarsal bones may be able to return successfully to rigorous athletic competition or participate in disciplines not requiring frequent stops and turns or collected work (flat racing, trail riding, fox hunting). If a significant amount of soft tissue disruption occurred on the dorsal surface of the hock, the ensuing fibrosis may limit joint motion and prevent a full recovery.

Patients with CoL injuries can return to full athletic use if these injuries are diagnosed early, treated aggressively and rehabilitated properly. Standardbred pacers have a good prognosis for racing as well or better after diagnosis (scintigraphy) and treatment (rest) of long CoL injuries.[76] However, horses with extensive disruption that involves most of the cross or longitudinal section of the ligament(s) will usually not be able to return to rigorous athletic use, especially if mineralization or osteophyte production eventually interferes with joint function.[76]

Prevention

Prevention of these injuries is difficult since they are traumatic in nature. Paying attention to footing and terrain conditions (ice or mud) during strenuous athletic activity may help avoid situations (fall or collision) that may precipitate these injuries. Separating horses likely to fight will reduce the likelihood of kicking injuries. Close attention to tack, shoeing, conditioning and schooling, and matching the difficulty of the athletic competition to the abilities of the horse and rider will all increase the safety of athletic competition.

Preventing lateral CoL desmitis in Standardbred pacers may require not using shoes with lateral trailers that may exacerbate the strain placed on the lateral side of the tarsus when pacing at high speeds. Treating any front limb lameness that may be forcing the horse to shift more weight on the rear limbs to get off the front leg(s) and maintaining a reasonable work/training schedule in light of the athlete's age and level of conditioning may help reduce the frequency of these injuries.

Etiology and pathophysiology

Tarsal luxations and CoL injuries occur in horses after a forceful blow to the tarsus (kick or collision), hyperextension of the hock during a fall or rotation of the tibia while the distal limb is immobilized or rotating in the opposite direction during a sudden or explosive change in direction.

Tarsal CoL injuries in athletes can be caused by the accumulation of microtrauma in these structures during training or competition at high speeds, particularly breeds (Standardbreds) that place maximum stress on their hocks during high-speed racing in a collected gait (pacing).

Epidemiology

Tarsal luxations and CoL injuries can occur in any age, breed and use of horse. It does not appear that horses involved in any specific type of strenuous athletic activity are predisposed to tarsal luxations. However, long or short lateral CoL injuries of the tarsus may be more common in Standardbred horses, especially pacers.[76]

Tarsal fractures or osteitis of the calcaneus or talus

- Fractures of the lateral tibial malleolus are seen frequently in horses and are much more common than medial fractures.
- Lateral tibial malleolar fractures will usually involve some part of the attachment or body of the lateral CoL.
- Distal tibial stress fractures can occur in young Thoroughbred and Standardbred race horses.
- Traumatic soft tissue defects or wounds often accompany fragmentation of the talus and calcaneus in horses.
- Proximoplantar to distoplantar (skyline) and flexed lateral radiographic views are often necessary to adequately visualize these fractures.
- Slab fractures of the central or third tarsal bone occur frequently in young horses during high-speed training or racing.
- Stress fractures of the talus have been documented as a cause of lameness in Standardbred race horses.
- Fractures of the fused first and second or the fourth tarsal bone are rare.

Horses can sustain fractures of the distal tibia or tarsus that can be comminuted, displaced or open. These types of injuries are straightforward to diagnose but challenging and often unrewarding to treat. They will not be discussed in this section. Only the types of tarsus fractures seen more frequently in athletes and that are amenable to treatment or can be diagnostically challenging will be discussed.

Recognition

History and presenting complaint Depending on the inciting cause, location and size of the fracture, there will be a sudden onset of a moderate to severe lameness following a traumatic episode (fall, kick or collision) or high-speed exercise. The location and size of the fracture will determine the degree and location of any observed synovial effusion or periarticular swelling. Horses with the more common non-displaced fractures of the tarsus will usually exhibit a significant improvement in the degree of lameness at a walk or slow jog within a few days of the injury. Horses treated with NSAIDs may show an even more dramatic improvement while on the medication. Some horses with effusion of the tarsal sheath or calcaneal bursa may have a draining tract associated with the synovial structure.

Physical examination Horses with fractures of the malleolus, talus or calcaneus will often present with a moderate to severe lameness depending on the size of the fragment(s), duration of the condition and degree of synovial effusion of the tarsocrural joint, tarsal sheath or calcaneal bursa. The lameness is characterized by decreased hock flexion (reduced arc during the swing phase), shortened stance phase (weight bearing) and a gluteal rise on the affected side. The lameness is always exacerbated by manipulation and flexion of the upper limb.

There is usually some degree of soft tissue swelling, pain and crepitus localized over the area of the fracture. Horses with slab fractures of the central or third tarsal bone are usually very lame immediately after the injury, but improve considerably after a few days.[80,81] There is minimal swelling, crepitus or effusion associated with third tarsal bone fractures at presentation, but there may be effusion of the tarsocrural joint in horses with central tarsal bone fractures.[81] A painful response can often be elicited by deep palpation over the cranial or lateral surface of the affected joint.[81]

Horses with fractures of the calcaneus or talus will usually present with effusion of the tarsal sheath and/or calcaneal bursa. There may be a wound near the calcaneus that can discharge clear synovial fluid or purulent material. The degree of lameness is variable depending on the location of the injury. Horses with osteomyelitis of the calcaneus, sustentaculum tali and/or sepsis of the tarsal sheath are usually very lame.[82,83]

Horses with stress fractures of the talus will usually present with a mild to moderate but persistent lameness of variable duration that worsens with high-speed exercise (pacing or trotting). Tibiotarsal joint effusion is usually present but not dramatic. Upper limb flexion will exacerbate the lameness and analgesia of the joint will relieve it considerably.

Special examination Intrasynovial or intra-articular anesthesia or tibial and peroneal nerve analgesia should provide considerable improvement in affected horses with most types of non-displaced tarsal fractures. This must be done with caution, because the fracture could become displaced or comminuted while the horse is exercised after the block. Any equine athlete that presents for a lameness evaluation with a history of an acute onset of a severe lameness after work, with or without synovial effusion and having no obvious soft tissue swelling or crepitus on the limb, should be assumed to have a stress or non-displaced fracture that could be aggravated by an extended lameness examination. Radiographic imaging of suspect or frequently involved areas and nuclear scintigraphy (after 3–5 days) may be preferable to avoid further damage to an injured osseous structure(s), which could mean a treatable condition becoming the end of an athletic career.

Lateral malleolus fractures are readily seen on the dorsoplantar and dorsomedial to plantarolateral oblique radiographic views of the tarsus (Figs 19.30, 19.31).[84] The fragments are variably sized and the degree of surrounding osseous reaction is an indicator of duration.[84]

Most slab fractures of the third or central tarsal bone are located in a frontal plane or on the craniolateral edge of the bone. Therefore, they are best imaged on the lateromedial or dorsomedial to plantarolateral oblique radiographic views.[80,81] Most are non-displaced and there is minimal dorsal or medial distraction of the slab. They can be 4–8 mm thick and variably wide.[81]

Fragmentation of the calcaneus or sustentaculum tali can be difficult to image on conventional radiographic views if they are small and located on the dorsal, distal or axial surface of the bone. Those on the proximal, caudal and

Figs 19.30, 19.31
Dorsoplantar and dorsolateral to plantaromedial radiographs of the tarsus in a horse with a fracture of the lateral malleolus.

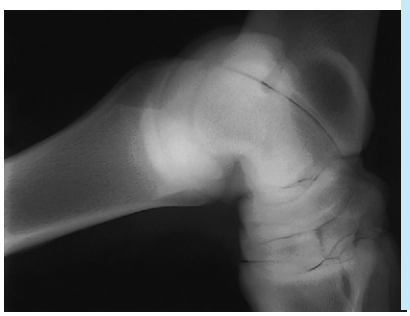
lateral surfaces are easier to identify on conventional views. If axial or distal fragmentation of the calcaneus is suspected or there is distension of the tarsal sheath associated with a wound, a skyline (dorsoplantar to distoplantar) view of the plantar aspect of the tarsus should be obtained (Fig. 19.32). Radiographically there may be marked lysis of the calcaneus or sustentaculum tali associated with bony fragments in horses with osteomyelitis and/or sequestrum formation (Figs 19.33, 19.34). In horses with effusion of the tarsal sheath accompanied by bony proliferation of the sustentaculum tali, contrast radiography of the tarsal sheath can help differentiate between effusion caused by the exostosis and the passive effusion associated with thoroughpin.[85,86] The technique requires aseptic injection of 5–8 mL of a positive contrast agent followed by air (40–45 mL). Horses with passive effusion of the tarsal sheath generally have a smooth outline of the tarsal sheath and associated soft tissue structures evident without the filling defects or soft tissue masses seen with adhesions of the tendon or tarsal sheath frequently identified in horses with chronic tenosynovitis secondary to bony involvement of the sustentaculum tali.

Transverse fractures of the calcaneus are readily apparent on the lateromedial and oblique radiographic projections. These fractures are rare and will have a similar presentation

Fig. 19.32
Skyline (dorsoplantar to distoplantar) view of the calcaneus.

Fig. 19.33
Radiographs of the tarsus of a horse with a sequestrum of the calcaneus associated with a draining tract on the caudal aspect of the tarsus.

Fig. 19.34 Lytic area on the calcaneus of a horse associated with distension of the tarsal sheath and marked lameness.



Figs 19.35, 19.36 Lateromedial and flexed lateromedial radiographs of the tarsus in a Standardbred race horse with stress remodeling of the talus evidenced by subchondral sclerosis of the talus.

to a horse with disruption of the reciprocal apparatus (dropped hock and hyperflexion of the limb during attempts at weight bearing).

Osseous disruption of the talus can usually be seen on the conventional views of the tarsus. Large fractures are readily apparent but distomedial fragments may be visible only on a skyline view of the plantar tarsus and there will be bony lysis when a septic process accompanies the injury within the tarsal sheath. Fractures affecting the trochlear ridges of the talus may be small and located distally on the ridge(s) or groove or they can involve a large portion of the articular surface with marked joint instability, pain and effusion.

Standardbred horses with remodeling or stress fracture of the talus will often have a sclerotic area in the center of the talus, best projected on the weight-bearing lateromedial or flexed lateromedial view of the tarsus (Figs 19.35, 19.36). The degree of sclerosis will depend on the duration and severity of the injury. Nuclear scintigraphy will reveal a very intense but focal area of radioisotope uptake in the talus on the lateromedial, flexed lateromedial and plantar views of the tarsus (Figs 19.37, 19.38). Arthroscopic evaluation of the plantar aspect of the tarsocrural joint will often reveal mild proliferative synovitis, roughening of the distal plantar surface of the tibia and/or mild fibrillation or wear lines in the articular cartilage of the plantar surface of the trochlear ridges or groove of the talus.

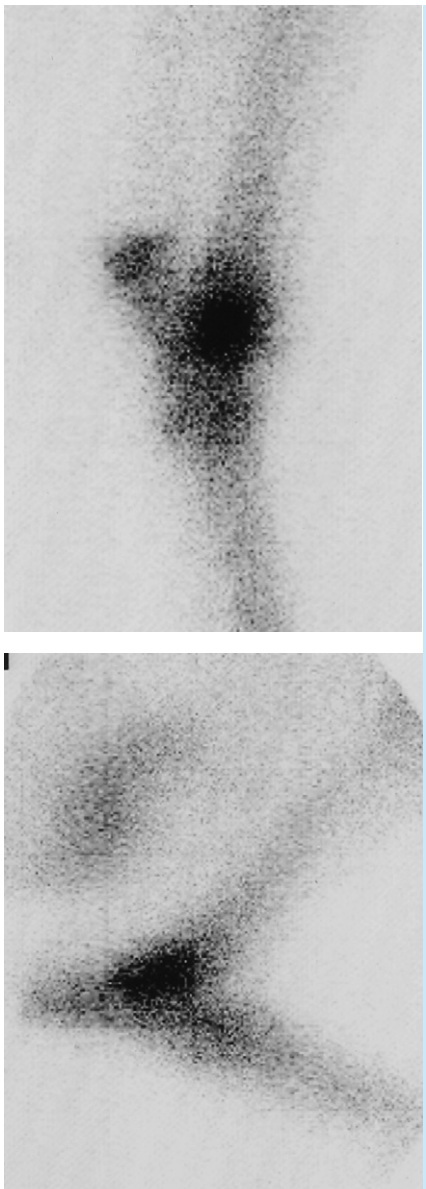
More complex fractures of the talus or fractures of the fused first and second or fourth tarsal bone can be readily imaged on routine radiographic projections. Flexed lateromedial views will allow the calcaneus and sustentaculum tali to rotate distally, permitting better visualization of the proximoplantar aspect of the talus (Fig. 19.36).

Laboratory examination Cytologic evaluation of synovial effusions associated with tarsal fragmentation may help determine if there is a developmental (nucleated cell count (NCC) less than 5000 cells/μL and protein levels (PL) less than 2.5 g/dL), traumatic (NCC of 5000 to 25 000 cells/μL and PL less than 4.0 g/dL) or septic (NCC greater than 30 000 cells/μL and PL greater than 4.0 g/dL) etiology.[65]

Necropsy examination At necropsy there will be variable amounts of soft tissue and bony disruption, hemorrhage and instability, depending on the involved structures and duration. In chronic cases with significant soft tissue or bony involvement, there may be evidence of fibrosis of the soft tissues, articular cartilage degeneration and proliferative or lytic bone depending on the etiology.

Diagnostic confirmation The diagnosis is confirmed by the specific clinical and radiographic appearance of each condition. In horses with remodeling or stress fractures of the talus, the scintigraphic appearance will confirm the diagnosis. Synovial fluid analysis may help determine a definitive diagnosis in horses with tarsal disease that have synovial effusion with equivocal radiographic or clinical findings (see Laboratory examination).

Lateral tibial malleolus and distal trochlear ridge of the talus fractures must be differentiated from OC lesions of the distal tibia or the talus, respectively. Unlike OC, fractures have an acute onset of lameness with effusion and swelling of the tarsus. In addition, there is usually a history of a traumatic episode or onset of lameness after exercise.[84] Ultrasonographic examina-



Figs 19.37, 19.38 Lateromedial and flexed lateromedial nuclear scans of the tarsus of a Standardbred race horse with stress remodeling of the talus.

tion of the long lateral CoL of the tarsus may reveal disruption of the architecture of the ligament, which would be rare in a horse with OC.[78] Fragmentation of the distal aspect of the trochlear ridges of the talus may have a similar radiographic appearance to OC of the talus, but with the fractures there is usually more bony disruption, effusion and lameness.

Treatment and prognosis

Therapeutic aims The therapeutic goal is to stabilize unstable structures, remove loose or devitalized bone or soft tissues, rid tissues of any infectious organisms and provide adequate rest and support to allow adequate healing. Serial monitoring with radiographs or nuclear scintigraphy may be required to critically evaluate the rate and quality of the repair process.

Therapy Slab fractures of the third or central tarsal bone in race horses can be repaired with lag screw internal fixation when return to racing is contemplated.[81,87] Displaced central or third tarsal bone fractures are uncommon, but when they occur and future athletic performance is expected, these fractures should be stabilized surgically. Horses that are treated conservatively (stall rest) may develop osteoarthritis of the affected joint that will adversely affect athletic soundness or return to racing.[80,87] Any residual instability and joint incongruency present will make natural arthrodesis slow and unlikely to provide long-term relief.[80]

Conservative treatment (stall rest) of third tarsal bone slab fractures in race horses appears to have a better prognosis (77%) than in those with central tarsal bone fractures treated similarly (29%).[88] A total of 64% of race horses with central or third tarsal bone fractures treated conservatively returned to their previous level of activity, but a significantly higher proportion (71%) of these were Standardbred or Quarter Horse race horses when compared to Thoroughbred horses with the same injuries.[88] Internal fixation may be more important in Thoroughbred race horses when return to racing is contemplated.

The surgical technique requires general anesthesia and radiographic or fluoroscopic guidance for proper drill and screw placement.[81] These fractures can usually be repaired with a single 3.5 or 4.5 mm cortical screw or a cannulated screw system. The head of the cortical screw is usually not countersunk to reduce the probability of the fragment shattering when the implant is tightened. An incision over the affected joint to identify the center of the fragment and proximal and distal margins of the joint for proper screw placement will expedite surgery. It should minimize the risk of damage to the dorsal tarsal vessels that can occur when the surgery is done with needle guidance through stab incisions. The horses are assisted for the recovery and confined to a stall for 4–6 weeks. Gradual introduction to hand-walking can begin at that time and return to training can occur 4–8 months after repair. Radiographic evaluation may be the best guide for increasing activity levels.

Lateral malleolus fractures should be treated surgically, especially in horses with synovial effusion and lameness.[84] Arthroscopic visualization will allow a thorough evaluation of the entire joint to assess the articular surface for damage, look for and remove any loose osteochondral fragments, inspect the fractured malleolus and flush proteinaceous and tissue debris out of the joint. The fracture fragment(s) can be removed arthroscopically, but it may be difficult to dissect the pieces from under the long lateral CoL and will often require a dorsal and caudal approach. Alternatively, the fragment can be removed quickly and effectively through a dorsal arthrotomy centered over the fragment.[84] Careful dissection will prevent further damage to the long lateral CoL. If the fragment is large enough, where a considerable portion of the attachment of the long lateral CoL is involved, reduction and fixation with a lag screw (4.5 or 5.5 mm cortical screw) will be necessary. Removing these large fragments will cause further damage to the CoL and would perpetuate tarsocrural instability. An adequately centered and securely closed dorsal

arthrotomy of the tarsocrural joint will have little impact on the future athletic performance of horses.[84] Assisted recovery should be used with these horses to limit further damage to the CoL and avoid tarsal luxation. Postoperatively, the limb is kept bandaged for 2–4 weeks to control swelling and reduce the effusion. In some horses, a residual amount of effusion will remain that appears to be inconsequential to future performance. Hand-walking can be initiated at 2–3 weeks after surgery and turnout in 4–6 weeks. Training can resume in 90–120 days depending on the resolution of the majority of the effusion and lameness and the degree of pre-existing damage to the long lateral CoL. If a lag screw fixation was performed, 6–8 months of rest will be required before resuming exercise to insure healing of the malleolus and CoL. Radiographs can be used to assess bony healing.

Fractures of the calcaneus can be treated conservatively or surgically. Fragmentation of the calcaneus or sustentaculum tali is usually accompanied by a soft tissue defect over the lesion and/or marked effusion of the tarsal sheath. Secondary sepsis of the tissue will be manifested as osteomyelitis of the calcaneus and/or sepsis of the tarsal sheath or calcaneal bursa, depending on the location of the wound or bony lesion.[89,90] These cases should be treated aggressively by surgical debridement, antibiotic regional limb perfusion, drain(s), lavage and systemically and/or locally administered specific antibiotic regimen or combination based on culture and sensitivity results of deep tissue (synovial or osseous tissue) gathered at surgery. Removal of devitalized and infected tissue is necessary to speed recovery and minimize the development of deep-seated synovial or osseous infections that will promote periarticular and synovial sheath adhesions that will adversely affect athletic performance.[83,90] Releasing the tarsal retinaculum of the tarsal sheath and transecting adhesions between the DDF and the sheath may reduce swelling and improve mobility.[82] A midtarsal tenotomy of the DDF will decrease motion of the tendon within the sheath, reducing pain and mechanical disruption of healing tissue.[82] This is considered a salvage procedure and athletic performance after its use is unlikely.

Endoscopic approaches to the tarsal sheath and calcaneal bursa have been described and can be used to effectively debride infected tissue and remove osseous fragmentation within these synovial structures to minimize dissection.[91,92] Endoscopic approaches may limit postoperative adhesion formation and restrictive scar tissue deposition.

After complete transverse fractures of the calcaneus, the attachment of the gastrocnemius tendon will displace the proximal fragment with luxation of the SDF, disabling the reciprocal apparatus of the hindlimb. These horses must be treated surgically with a tension band repair on the caudal aspect of the calcaneus to counteract the distractive forces of the pull of the gastrocnemius on the calcaneus. Plates, screws and/or wires can all be used depending on the size and location of the fragments. If the SDF is luxated, it is repaired simultaneously.[93,94] The repair is protected with a full-limb cast during recovery and the first 2–4 weeks following surgery, and full-limb bandages to limit hock flexion used for another 4–6 weeks. Casting alone is insufficient to neutralize the pull of the gastrocnemius and SDF. Radiographic monitoring for healing is recommended. Due to the extensive soft tissue attachments to the calcaneus, implant removal may be necessary as soon as bony healing occurs to limit fibrosis and interference with normal function. Even with uncomplicated healing, the ensuing fibrous scar tissue from the trauma and surgical exposure will often limit joint mobility, thereby adversely affecting future athletic performance.

Fractures of the talus may be confined to the dorsal or plantar articular surfaces of the trochlear ridges. These fragments are best removed arthroscopically or via an arthrotomy, depending on size and location. Stress fracture or remodeling of the talus as seen in pacing or trotting race horses will respond to rest. Return to training recommendations are based on repeat scintigraphic evaluations with resolution of the inflammatory focus. Non-displaced fractures of the talus can be repaired with lag screw fixation if the articular surface is minimally disrupted and there are pieces large enough where one or two cortical screws will adequately reduce and secure the fracture. The size of the implants and surgical approach are dictated by the location and configuration of the fracture. Comminuted fractures with complete collapse of the tarsocrural joint are not amenable to repair and these patients should be humanely destroyed. Casting may be necessary during recovery and the immediate postoperative period, but if the repair is well secured then assisted recovery should suffice. Removal of the implants is usually not necessary, but the return to athletic use will be influenced by the degree of articular involvement or damage to soft tissue structures such as the collateral or plantar ligaments. Sufficient bone, articular cartilage and soft tissue healing to allow return to work may require 4–8 months. Limited activity (hand-walking or turnout) can begin after 4–6 weeks of stall rest.

Fractures of the fused first and second or fourth tarsal bone are rare. Choice of therapy (conservative or surgical) will depend on the size of the fragment, location and articular involvement. Fractures or fragments that are minimally displaced will usually heal without surgical intervention. These tarsal bones are not subjected to the compressive forces that the third and central tarsal bones experience and conservative therapy may be sufficient for adequate healing. This approach may not be suitable for performance horses because a fibrous union with articular or periarticular degenerative changes could result in residual lameness during high-speed or rigorous exercise. Larger fragments may have to be removed or secured with lag screws. If the fracture is unstable or the articulation of the bone with the splint bone, central tarsal bone or talus is compromised, then an attempt at surgical repair is justified. Approach and choice of implant is determined by the size and location of the fragment(s). Convalescence and return to work are as described before.

Rehabilitation of the soft tissues as soon as possible after surgery will restore range of motion to the joint and decrease the morbidity associated with disuse and fibrosis. This may be as important as surgical therapies in bringing these athletes back to work. Range of motion exercises

with the joint and swimming may be useful adjuncts to exercise regimens to rehabilitate periarticular soft tissues.

Prognosis Establishing a prognosis for these tarsal fractures is challenging. In order to have a realistic expectation for return to athletic performance, a thorough assessment of the ligamentous, synovial cavity, articular and bony involvement is important. Horses with extensive damage to the CoL, SDF, fibrous joint capsule or articular cartilage have a very guarded prognosis for athletic use, even if a surgical procedure successfully removed fragmentation, secured loose fractures or resolved sepsis. Horses with fragmentation of the dorsodistal or very plantar aspect of the trochlear ridges, fractures of the lateral malleolus, slab fractures of the central or third tarsal bone and stress fractures of the talus will have a good prognosis for return to function with proper therapy.[81,84] Standardbred race horses with slab fractures of the third tarsal bone treated surgically or conservatively appear to have a good prognosis for return to racing.[81,88] Thoroughbred race horses or other racing breeds may not fare as well with central tarsal bone fractures treated conservatively.[88] In other retrospective studies, the outcome of conservative treatment of central or third tarsal bone fractures in race horses has been unfavorable.[80,87] Horses with more complex injuries (transverse calcaneal or complete talus fractures) have a poor prospect for returning to high-level athletic activity.

Involvement of the tarsal sheath or calcaneal bursa secondary to a proliferative bony response after a fracture or osteomyelitis carries a good to guarded prognosis for athletes.[85,89] If soft tissue fibrosis restricts motion and obliterates the synovial lining of these cavities necessary to allow unrestricted movement of tendons or ligaments, the prognosis is unfavorable. If treated early and aggressively, horses with osteomyelitis of the sustentaculum tali and tarsal sheath effusion may return to athletic competition.[82,90]

Early and consistent physical therapy may improve the prognosis and shorten the convalescent period for these athletes.

Prevention

There are no definitive recommendations that can be made to prevent these tarsal injuries. Most are traumatically induced from a sudden internal or external application of force that is difficult to predict or avoid. Good horsemanship and avoiding conditions that could predispose to these injuries is adequate. Stress fractures in young race horses often result from accumulated stresses (loads) and non-adaptive bone modeling or remodeling in response to strenuous exercise. Varying exercise regimens by reducing distance work in favor of speed work may decrease the accumulation of microtrauma that can cause these injuries.

Etiology and pathophysiology

The etiology of these injuries is accumulated microtrauma (stress fractures in race horses) or single event application of external (kick or collision) or internal (fall or slip) torque sufficient to disrupt the osseous and soft tissue structures.

Thoroughbred or other performance horses that have a wedge-shaped conformation of the craniolateral aspect of the third tarsal bone may be predisposed to sustaining a slab fracture of this bone during high-speed training or racing,[95] by presumably concentrating compressive forces along the trough in the wedge.

These injuries will adversely affect performance by disrupting the function of the tarsus during joint movement and weight bearing, and by causing marked discomfort. Residual articular cartilage erosions in weight-bearing areas, instability, tarsal sheath adhesions, calcaneal bursa fibrosis or osteoarthritis that persists or develops after therapy will adversely affect athletic performance due to pain and loss of motion.

Epidemiology

These injuries can affect any breed, age or use of horse. It appears that stress fractures of the talus, slab fractures of the central or third tarsal bones and lateral malleolar fractures are more common in young Thoroughbreds and Standardbreds in training or racing.

Osteoarthritis or inflammation of the intertarsal, tarsometatarsal and talocalcaneal joints

- The tarsometatarsal and distal intertarsal joints of a wide range of equine athletes are commonly affected by osteoarthritis.
- Horses involved in activities that increase stress on the tarsus are predisposed to osteoarthritis of the small joints.
- Disciplines commonly affected include three-day event horses, jumpers, Standardbred race horses, barrel racers, reining and dressage horses.
- The clinical presentation and therapeutic approach are variable and will largely depend on the age, use and severity of the condition.
- Talocalcaneal osteoarthritis is rare, traumatically induced and usually ends the career.

Recognition

History and presenting complaint Osteoarthritis of the tarsus can affect athletes at a young age (in training) or at later stages of their athletic careers. They will present with a rear limb(s) lameness of variable severity and duration that may improve with rest, only to recrudesce when placed back in work. Affected athletes can sometimes warm out of the lameness after a short period of work or will get worse when they are forced to work vigorously with their rear limbs while in a collected posture (dressage or approaches to obstacles for jumping). This disease is often insidious in onset and some chronically affected horses will refuse to perform certain movements under tack and may even object vigorously by tail

swishing, bucking, refusals at jumps and an unwillingness to take or stay in a particular leg lead.

Horses with talocalcaneal degenerative joint disease will commonly have a history of trauma preceding the lameness.

Physical examination There is usually no external soft tissue swelling or effusion evident on the rear limb(s) and affected horses may have straight-legged (post-legged) or a tarsal valgus or varus (cow or sickled hocks) conformation. The medial aspect of the intertarsal and tarsometatarsal joints may appear thickened or have a boxed appearance in some horses.

The severity of the presenting lameness will vary dramatically but generally these athletes have decreased hock flexion (reduced arc during the swing phase), a shortened stance phase (weight bearing) and a shortened gluteal rise on the affected side. The lameness can be variable but sometimes imperceptibly exacerbated by flexion of the upper limb (hock flexion) or inward pressure on the second metacarpal bone (15–30 seconds) followed by trotting (Churchill test). When ridden in a collected fashion, the lameness will often become more apparent than when being trotted in hand or lunged.

Special examination Perineural analgesia of the tibial and peroneal nerve or intra-articular anesthesia of the tarsocrural, tarsometatarsal or intertarsal joint(s) will usually improve the lameness and reduce the response to upper limb flexion. Intra-articular anesthesia of the intertarsal and tarsometatarsal joint is not always specific for that compartment. The middle and bottom joints communicate in approximately 26–35% of horses and anesthetic can also diffuse into the tarsal sheath or proximal intertarsal or tarsocrural joint after injection into the tarsometatarsal joint space.[59–61] The plantar extension of the synovial sac of the tarsometatarsal joint may cover the origin of the suspensory ligament so that substances injected into this joint can affect this structure by diffusion also.[60] Care must be taken when evaluating the horse in a straight line in hand after perineural or intra-articular analgesia. If the lameness was worse when lunged or ridden in a collected fashion, then the evaluation after the blocks should be performed during lunging or riding.

Fig. 19.39 Periarticular osteophytes in a horse with osteoarthritis of the intertarsal joint.

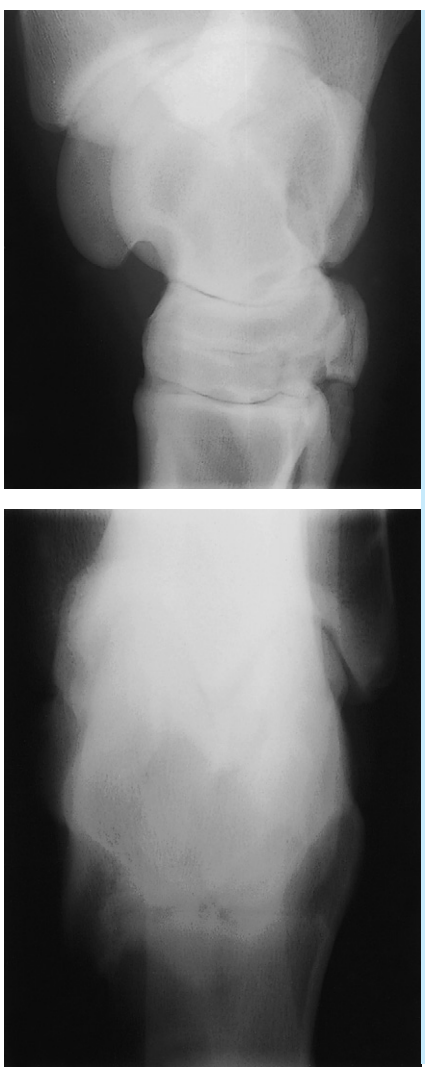
Standard radiographic views of the tarsus in horses affected with osteoarthritis of the small tarsal joints will demonstrate some degree of joint space collapse, periarticular osteophyte production (Fig. 19.39) or bony lysis (Figs 19.40, 19.41). The disease often begins on the dorsomedial surface of the joint(s). The radiographic changes, when present, are consistently seen on the lateromedial and dorsolateral to plantaromedial oblique projections. However, there are many young horses that participate in activities in which excessive strain is placed on the hocks that will have a

Figs 19.40, 19.41 Oblique and dorsoplantar views of the tarsus in a horse with osteoarthritis and lysis of the distal intertarsal joint.

tarsal lameness localized to one or both distal joints but have normal-appearing radiographs. This is seen frequently in Standardbred race horses and some young horses used for dressage and jumping disciplines. This is presumably because the disease is early and affecting only the articular cartilage or periarticular soft tissues which are indistinguishable radiographically. Horses in which this clinical presentation is common include Standardbred race horses, Quarter Horses participating in reining or roping and young dressage, jumping or Western pleasure athletes of any breed.

Race horses and other athletes that participate in jumping disciplines with inflammation of the small tarsal joints that do not have evidence of osteoarthritis radiographically will often have increased uptake of the isotope in one or both affected tarsi when nuclear scintigraphy is performed.[96,97] Any horse with involvement of the intertarsal or tarsometatarsal joint(s) with normal-appearing radiographs would likely benefit from this diagnostic tool.

Horses with degenerative joint disease of the talocalcaneal joint will have radiographic evidence of bony lysis and sclerosis at the normally smooth contour of the articulation between the talus and calcaneus (Figs 19.42, 19.43).



Figs 19.42, 19.43 Oblique and skyline radiographs of the tarsus in a horse with osteoarthritis of the talocalcaneal joint.

Diagnostic confirmation Horses with proximal suspensory ligament disease may appear clinically similar to horses with tarsal disease, have a positive response to upper limb flexion and may also respond favorably to anesthesia of the tarsometatarsal joint.[60] Care must be taken when interpreting the response to this block and during the clinical assessment because these horses are often unilaterally involved whereas distal tarsal joint involvement is usually bilateral. Careful palpation and ultrasonographic and/or radiographic or scintigraphic examination of the attachment of the proximal suspensory ligament will reveal an area of ligament disruption, cortical bone discontinuity or radioisotope uptake typical of this condition.

The radiographic appearance and clinical examination are usually diagnostic. Horses with radiographically normal tarsi should be evaluated with scintigraphy. There will usually be a diffuse pattern of radioisotope uptake in the tarsometatarsal and/or intertarsal joints.

Treatment and prognosis

Therapeutic aims The aim of therapy is to reduce intra-articular inflammation and the discomfort associated with motion and compression of these joints. Reducing or eliminating articular pain should permit adequate joint movement and loading and this should provide joint flexion and propulsion. The therapeutic aims are either medical or surgical. Medical therapy is directed at minimizing inflammation and includes intra-articular or systemically administered anti-inflammatory medications. Surgical therapy is aimed at creating a stable arthrodesis of the affected joint to eliminate movement and provide for pain-free ambulation. The choice of therapy is determined by the use, age and extent of articular involvement in the individual patient and owner expectations.

Therapy Medical therapy for horses with osteoarthritis of the tarsus includes intra-articular or parenterally administered drugs. Parenteral NSAIDs (phenylbutazone) to reduce inflammation and pain are commonly used for managing this disease. The dosage (2.2–4.4 mg/kg, daily) is often tailored to the individual horse depending on the severity of the disease and the patient's training or competitive schedule. A tapering 2–3 week dosing schedule is often used in an attempt to reduce the discomfort and inflammation while the work schedule is maintained at a reduced level until the horse can sustain an adequate work schedule while being comfortable. Regulatory bodies governing competitive sport often restrict the use of NSAIDs or any other medication, either banning their use completely or allowing them only under very strict guidelines.

Intra-articular corticosteroids (methylprednisolone, betamethasone, triamcinolone) or chondroprotective agents (hyaluronic acid) alone or in combination can be used successfully to reduce inflammation and the catabolic effects of the inflammatory cascade on articular cartilage. This will often permit the patient to return successfully to athletic activity for a variable period of time. These joints should be injected aseptically and the horses are routinely rested for 3–7 days after the injection to allow any soft tissue damage from the arthro-

centesis or hemorrhage to subside. The duration of relief can vary from days or weeks to months. It appears that horses with advanced osteoarthritis and marked radiographic degenerative changes may not respond as favorably or for as long as less severely affected horses. In addition, horses that have had repeated intra-articular injections at decreasing intervals with a marginal response will often not have a favorable or prolonged response to this form of therapy.

The decision to use this form of therapy will depend on clinical impression, radiographic findings, success of previous therapies, duration of the condition and use of the horse. It is probably more suitable for a horse with mild to moderate disease (clinically and/or radiographically) that has been infrequently treated by this route. Horses with severe disease, in heavy work and that have not responded favorably (improved lameness or prolonged response) to previous intra-articular injections are less likely to have a favorable long-term outcome with this therapy.

The tarsometatarsal or distal intertarsal joints are the most frequently treated. The degenerative joint disease of the tarsometatarsal joint may contribute to tarsal lameness more often and more severely than the other small tarsal joints. Other joint involvement should be determined by intra-articular anesthesia and radiographic evaluation. If both distal joints are involved, they should be treated separately since communication between joints does not exceed 38% of joints.[59–61] Numerous techniques have been described for injection of these joints and the reader is referred to these descriptions for specific details.[65]

This form of therapy will allow the horse to remain athletically active while the lameness is managed. This is particularly important in young athletes or horses competing in seasonal events where more invasive approaches would limit their use during this time. The goal is to limit joint inflammation. Repeated use of intra-articular corticosteroids will enhance catabolism of the articular cartilage, promoting the degenerative changes. This may explain why many horses that have been treated repeatedly become refractory and develop more advanced forms of the disease with time and use. It is very unlikely that joint collapse and organized arthrodesis will result from this approach and most horses will have persistent joint spaces in spite of numerous intra-articular injections over a prolonged period of time.

Systemic administration of chondroprotective agents such as hyaluronic acid and polysulfated glycosaminoglycans is frequently used alone or in combination with intra-articular medication. Regimens vary using intramuscular (polysulfated glycosaminoglycans) or intravenous (hyaluronic acid) injections at intervals ranging from every week to once a month. Oral administration of chondroitin sulfate or glucosamines is also widely used. The extent of oral absorption of these products may be unpredictable depending on individual patient differences and quality of the preparation. The effectiveness of these forms of therapy is less predictable but there appear to be cases in which they were clinically effective in providing relief for tarsal lameness for a protracted period of time. Removal of the medications or supplements resulted in recrudescence of the lameness.

Adequate heel support to maintain a straight pastern axis and a rolled or squared toe allows easier breakover of the foot, reducing the arc of flight and subsequent concussion of the joint surfaces during high-speed or collected work. The use of heel caulks or trailers may increase the rotational forces placed across the joint surfaces in horses during high-speed exercise, especially in Standardbreds. Avoiding their use may limit development and/or expression of the condition. In horses with sickle or cow hocks, attempts to induce breakover of the medial toe may be of benefit in limiting uneven loading of the joint surfaces.

Acupuncture has been used for many musculoskeletal disorders in horses and may have a therapeutic role in the treatment of tarsal disease in equine athletes. Lack of an appropriate duration or extent of response is an important determinant for continuation of this form of therapy alone or whether an alternative therapeutic regimen is indicated.

Surgical therapy for this disease is aimed at achieving arthrodesis of these joints by various means. Use of stainless steel cylinders to secure a cancellous bone graft in the spaces between joints in an effort to promote an arthrodesis has been successfully described but not widely accepted for clinical use.[98] A diode laser has been used effectively to remove the articular cartilage to arthrodese the distal tarsal joints in equine athletes.[99] The procedure is performed with the horse anesthetized. The joint spaces are localized with needles using radiographic or fluoroscopic guidance. Once the needles are positioned in the desired joint, they are used as cannulas to introduce the laser fiberoptic cable into the joint. Laser energy is used to remove the articular cartilage from the majority of the joint surface.[99] Exposing subchondral bone surfaces in apposition will promote the formation of an arthrodesis and joint stability. These horses are hand-walked for 4–6 weeks after laser treatment. Light flat work is then begun with a gradually incrementing exercise regimen begun after a couple of weeks. Laser arthrodesis may reduce the perioperative morbidity associated with other surgical techniques (drilling) or chemical fusion.[99]

Drilling the joint surfaces in an effort to remove the articular cartilage has also been described as a method to promote arthrodesis.[100] With this technique the tarsometatarsal and distal intertarsal joints are identified with radiographic guidance from the medial aspect of the tarsus. Using three separate 3.5 mm drill passes from an incision on the medial aspect of the joint, the individual joint(s) are then drilled in a fan-shaped manner towards the opposite side (lateral) of the joint. The joints are bandaged and the horse kept in a stall for 7–14 days at which time hand-walking is begun if the patient can tolerate it. Some patients may become very painful after surgery and remain recumbent. Discomfort should be controlled using NSAIDs or epidurally administered analgesics such as morphine or xylazine. Arthrodesis of these joints may take 6–9 months to complete and it is not uncommon for these horses to be out of work for up to 12 months and have a poorly cosmetic bony thickening of the medial aspect of the tarsus.[100] They may have a residual lameness present in spite of the fact that the joint(s) appear to be radiographically

fused. All other causes of lameness must be ruled out before contemplating this surgical procedure in any horse. In addition, it would be best suited for horses in which other forms of medical or surgical therapy have failed and that have radiographic evidence of severe osteoarthritis.

Arthrodesis using internal fixation has been described using a single 4.5 mm cortical lag screw placed from distal to proximal through the third metacarpal bone into the third and central tarsal bone to compress the joints.[100] Application of a fingerplate or a T-plate on the medial aspect of the tarsus with 3.5 or 4.5 mm cortical screws placed into the central and third tarsal and third metatarsal bones to bridge the joints and compress them has also been reported as a suitable alternative to drilling the joint surfaces.[100] It appears that use of a stabilizing implant on the medial aspect of the joint may reduce the number of horses in which failure of arthrodesis occurs when compared to drilling alone but it does not appear to reduce the convalescent period, which may be 6–12 months irrespective of procedure used.[100]

Chemical fusion with sodium monoiodoacetate has been advocated as a therapeutic option for horses with osteoarthritis of these joints.[101,102] This chemical is caustic and extremely chondrotoxic. It will induce arthrodesis by irreversibly damaging the articular cartilage, exposing subchondral bone surfaces. Either single[102] or three injections of 150 mg of filtered chemical administered at 3-week intervals[101] have been used to achieve chemical arthrodesis of the tarsal joints. The joint space must be localized with radiographic guidance prior to injecting this substance into the joint. Contrast arthrography is warranted to make sure there is no communication of these joints with the proximal intertarsal, tarsocrural or tarsal sheath synovial spaces. Movement of the chemical into any of these cavities could be disastrous and prematurely terminate an athletic career. Extra-articular placement of the chemical will cause cellulitis and may lead to tissue necrosis with loss of some soft tissue coverage requiring prolonged wound therapy. Similar to the drilling surgical arthrodesis, these horses may be very uncomfortable for 12–36 hours after the procedure, requiring appropriate analgesia. Hand-walking or light riding can be initiated in 7–10 days after the first injection.[101,102] There will be a radiographically evident collapse of the joint space(s), but there is usually incomplete radiographic evidence of arthrodesis in clinical cases.[102] In normal horses, the radiographically evident arthrodesis approaches 89%.[101] Prolonged swelling, chronic pain and lameness have been reported after its use.[102] Chemical arthrodesis may not be a suitable first choice of therapy for most affected horses.[102]

Few therapeutic choices would be expected to provide relief of lameness in athletes with talocalcaneal degenerative joint disease. Theoretically, arthrodesis of the joint could be attempted but there are no reports of this procedure or long-term follow-up of its use in athletes.

Prognosis The prognosis for athletic performance is good for most horses. Those horses affected with severe degeneration and arthritis of the intertarsal or tarsometatarsal tarsal joints at an early age have a guarded prognosis for maintenance of soundness with medical therapy and surgical options may offer an improvement but for some high-level athletes, the degree of improvement may not be enough to permit a successful athletic career in the more demanding disciplines.

Horses with talocalcaneal degenerative joint disease have a guarded prognosis for use in athletic endeavors.

Prevention

Prevention of this disease in horses is difficult. Delaying heavy work in young athletes may reduce articular damage in those predisposed to the disease. Proper shoeing to provide breakover of the center or medial aspect of the foot may be of benefit. Horses with straight-legged, sickle or cow-hocked conformation are predisposed and selecting away from this type of conformation may be sensible. Indiscriminate use of intra-articular corticosteroids in performance horses that present with rear limb lameness is probably detrimental to the long-term health of these joints and may predispose many athletes to premature development of osteoarthritis of these joints. Adequate localization of the lameness to these joints through diagnostic blocks and radiographic evaluation may limit the number of horses that are treated unnecessarily.

Etiology and pathophysiology

This disease is caused by multiple factors, among them conformation (sickle and cow-hocked and straight-legged), athletic use (dressage, jumping, reining horses, Standardbred race horses), angular limb deformities (valgus or varus) centered on the tarsus,[103] osteochondrosis or juvenile spavin[70] and incomplete ossification of the tarsal bone leading to tarsal bone collapse in foals.[104] These conformational faults or eccentric joint loading due to type of work being performed may contribute to the development of tarsal inflammation and osteoarthritis due to axial loading of the joints and/or shear stresses placed on the distal rows of tarsal bones during competition.

Trauma appears to be the inciting cause of most cases of talocalcaneal degenerative joint disease.

Epidemiology

Degenerative joint disease of the intertarsal or tarsometatarsal joints can affect nearly any breed of horse involved in any athletic endeavor. It is common in horses participating in dressage, jumping, gaited and Western performance disciplines, pacers and trotters.

Gastrocnemius tendon (GT), plantar ligament and superficial digital flexor (SDF) tendon injuries of the tarsus

- Most distal GT injuries present as a tendinitis rather than avulsion fractures or complete disruption.
- The SDF can luxate medially or laterally after disruption of the facial attachments to the calcaneus.
- Desmitis of the plantar ligament is caused by excessive tension on the plantar surface of the tarsus (sprain).
- Moderate or severe GT or SDF injuries carry a poor prognosis for athletic soundness.

Recognition

History and presenting complaint These horses can present with an acute onset of moderate to severe swelling of the caudal aspect of the tarsus or around the calcaneus. Horses with disruption of the caudal portion of the reciprocal apparatus (SDF and gastrocnemius) of the hindlimb will present with an acute onset of severe lameness.[105,106] However, GT or SDF tendinitis or plantar ligament desmitis will more often present with a chronic lameness of variable severity and less obvious swelling on the proximoplantar or plantar aspect of the hock.[107] These injuries can occur after high-speed exercise or after a fall or traumatic episode (collision or impact) during a competition. Tendinitis or dislocation of the SDF, tendinitis of the GT or plantar ligament desmitis can be observed in horses competing in high-speed events or jumping disciplines.[9]

Physical examination Horses with tendinitis or dislocation of the SDF, tendinitis of the GT or plantar ligament desmitis will present with a mild to moderate lameness depending on the severity of the injury and duration of the condition. There may be diffuse swelling over the point of the hock or more discrete thickening of the SDF or GT at the site of injury. The lameness evident at presentation is usually exacerbated by flexion of the upper limb. When luxated, the SDF can be manually luxated and reduced onto the calcaneus but will not stay in its normal anatomic position during ambulation.[93,94] The tendon will luxate to the side opposite to where the retinaculum and ligamentous attachments to the tarsus (calcaneus and talus) are located (if the lateral attachments are torn, the tendon will luxate medially).[93]

Horses with disruption of any part of the caudal portion of the reciprocal apparatus (SDF and gastrocnemius) of the hindlimb will present with an acute onset of severe lameness. In cases with disruption of the stay apparatus, an inability to completely fix the hock in extension during attempts at weight bearing is often present.[105,106] The disruptions in the stay apparatus are usually proximal (distal femur) and there is no swelling or pain around the tarsus. Although the disease appears to involve the hock due to its dropped appearance, there is no disruption of the tarsal structures. Distal GT disruptions, avulsion or transverse fractures of the calcaneus appear similar clinically (dropped hock), but there is obvious swelling of the calcaneus and/or GT.

Special examination Perineural analgesia of the peroneal and tibial nerves above the tarsus will usually improve the degree of lameness in horses with desmitis of the plantar ligament or tendinitis of the SDF or GT proximal to the tarsus.[107] It will usually also eliminate or reduce the positive response to the upper limb flexion. Horses with plantar ligament desmitis may improve after intrasynovial anesthesia of the tarsometatarsal joint space if any of the anesthetic diffuses from the joint to the surrounding ligament. Care must be taken to assess the area on the plantar surface of the tarsus for any swelling or thickening that may be indicative of plantar ligament desmitis before anesthetizing the joint.

Ultrasonographic evaluation of the tendons (SDF or GT) or plantar ligament can be performed standing using a 7.5 MHz probe.[107] Ultrasonographic images will usually reveal variably sized areas of tendon or ligament hypoechogenicity associated with fiber disruption and fluid accumulation (edema and/or hemorrhage).[107] The size of the lesions should be measured sagittally and transversely and as a percentage of the area of the structure and the images recorded. This will serve as a baseline quantification of the original injury for prognostic purposes and allow for comparisons during healing. With chronic desmitis or tendinitis, the ultrasonographic pattern will reveal thickening of the involved structure and a variable amount of hyperechoic tissue characterized by fiber pattern disorganization that is consistent with fibrosis. Ultrasonography of horses with a complete tear of the GT will reveal a total disruption of the GT in a transverse plane and in those with a transverse fracture of the calcaneus, cortical disruption of the calcaneus is also readily apparent.

Ultrasonographic examination of the SDF is not necessary to diagnose luxation of the SDF, but it should be performed to make sure that there are no concurrent extensive tendon defects that may worsen the prognosis.

Routine radiographs of the tarsus (all standard views and a skyline) should be obtained to identify avulsions or fractures of the calcaneus or enthesiophytes at the insertions of these soft tissue structures. Nuclear scintigraphy may be useful in subtle cases with a more chronic duration.

Laboratory examination There are no specific laboratory examinations indicated for these conditions.

Necropsy examination At necropsy, acutely affected horses will have soft tissue swelling with hemorrhage and/or edema. The involved structure (SDF, GT or plantar ligament) will be variably enlarged or disrupted and the defect(s) filled with fresh hemorrhage, clotted blood or granulation tissue. In more chronic cases there will be less peritendinous soft tissue swelling and the affected structure will be thickened by the presence of mature fibrous tissue. The histological appearance of the tissues would be similar in that more acute lesions would be characterized by blood elements and granulation tissue and chronic cases by fibrosis.

Diagnostic confirmation Disruption of the distal portion of the reciprocal apparatus is diagnosed by the clinical appearance and the ultrasonographic and radiographic findings.[105,106] Disruptions of the plantar portion (SDF) of the reciprocal apparatus are usually proximal and do not directly involve the hock. Disruptions of the distal portion of the dorsal part of the reciprocal apparatus (GT) are rare and usually involve the calcaneus but can occur anywhere along the structure.[106] Radiography and/or ultrasonography will identify the affected structure. Luxation of the SDF is diagnosed by the clinical appearance and history.[93]

Tendinitis (SDF or GT) or desmitis (plantar) is diagnosed by clinical appearance, lameness examination, ultrasonography and radiography.[107] These injuries must be differentiated from other causes of tarsal lameness. Horses with plantar ligament desmitis may improve after anesthesia of the tarsometatarsal joint (see previous section). Perineural analgesia (tibial and peroneal) will improve the lameness in cases of tendinitis, but intrasynovial anesthesia will not. This serves to differentiate tarsal conditions from those proximal to the tarsus.

Treatment and prognosis

Therapeutic aims The aim of therapy is to surgically stabilize or repair the affected tissue in cases of SDF luxation or bony calcaneal injuries (see fracture section). In cases with desmitis or tendinitis, the aim is to rest and rehabilitate the patient to allow deposition of collagen in an organized and functional pattern that will allow the affected structure to regain its previous biomechanical function and tissue strength necessary for athletic performance.

Therapy In cases with complete disruption of the dorsal or both portions of the reciprocal apparatus, therapy consists of full-limb coaptation to permit fibrosis of the structure.[105,106] Cases with complete disruption of the reciprocal apparatus will rarely respond to coaptation as the cast will not immobilize the limb completely, leading to cast disease and contralateral limb laminitis before useful fibrosis of the reciprocal apparatus occurs. Partial disruptions may respond better to this form of therapy, as there is still one intact part of the system (SDF or GT) left. Disruptions of the reciprocal apparatus that involve all or part of the calcaneus have been discussed in the previous section.

Cases of desmitis (GT) or tendinitis (SDF) should be rested until healing is complete when evaluated ultrasonographically. This may require up to 6–12 months, since many of these injuries are either quite large or very chronic with significant fibrosis and a poor blood supply. Inadequate or incomplete healing is not uncommon.[107] There are no described surgical procedures available to augment healing and most surgical interventions would probably increase the amount of tissue damage. Medical therapy during the acute stages consists of NSAID administration and regional cold therapy to reduce inflammation. Therapeutic heat, shock waves or ultrasound application (extracorporeal shock wave therapy or therapeutic ultrasound) during the convalescent period may help increase circulation and promote healing. Intralesional administration of medications has not met with universal acceptance due to the unpredictable clinical and histological results when used for tendon or ligament defects. Rehabilitation of the soft tissues should be initiated as soon as there is enough healing to support a controlled increase in activity without disrupting the repair tissue. This early mobilization will improve the reorganization of the tissue and restore soft tissue elasticity. This is particularly important when SDF or GT injuries are located within the calcaneal bursa(s), where deposition of scar tissue and adhesions will adversely affect tarsal function irrespective of the strength or completeness of the repair. Adhesions or diseased tissues within the calcaneal bursa can be debrided and lavaged via an endoscopic approach to minimize further soft tissue trauma.[91] The approach consists of a distal scope (or instrument) portal and a proximal instrument (or scope) portal at the limits of the bursa to converge on the affected area.[91]

Luxation of the SDF is usually treated surgically to reposition the tendon and repair the retinaculum and attachment to the talus/calcaneus.[93,94] The repair is performed in lateral recumbency with a direct incision over the affected side. The tendon is repositioned and the disrupted edges of the retinaculum are sutured with a pre-placed interrupted mattress pattern of one or two absorbable (polidioxanone) or non-absorbable (nylon) monofilament suture. A synthetic mesh (Marlex) has been successfully used to repair a medial SDF luxation in an adult horse that eventually returned to work.[93] These horses should be assisted to stand after surgery. Using some form of external coaptation (cast, Robert-Jones bandage, splints) to prevent hock flexion during the first 4–6 weeks after surgery is important to avoid disruption of the repair and reluxation of the tendon. Once the repair tissue is strong enough to permit removal of the coaptation, hand-walking is initiated to strengthen the repair tissues. Swimming or range of motion exercises will minimize the restrictive effects of the scar tissue and adhesions.

Prognosis Horses with partial or complete disruption of the reciprocal apparatus have a poor prognosis for future athletic performance.[105,106] Even with adequate fibrosis and healing, there will be some residual excessive tarsal flexion remaining that will make athletic competition unlikely.

Tendinitis of the GT carries a guarded prognosis for future athletic performance. These injuries are often chronic when diagnosed and they can affect a significant portion of the tendon.[107] The chronicity, extent and restriction of motion by the scar tissue will all combine to decrease the prognosis for athletic use.[107]

Luxations of the SDF with or without accompanying tendinitis have a guarded prognosis for return to athletic performance, especially those athletes competing in higher level athletic disciplines. Early recognition, surgical repair, limited soft tissue damage and aggressive rehabilitation may all help improve the prognosis in horses with these injuries.

Prevention

There are few specific recommendations that can be made to prevent these injuries. Adequate footing during competition, good horsemanship skills and attention to husbandry may help reduce their occurrence. Early recognition of athletes with GT tendinitis may improve the prognosis by allowing adequate therapy (rest, rehabilitation, extracorporeal shock wave) to be instituted prior to the development of debilitating scar tissue, large defects and adhesions.

Etiology and pathophysiology

These soft tissue injuries of the hock are traumatic in nature and can occur from impact trauma or a fall/slip during athletic competition. The injury results from either externally or internally applied forces (sprain) that exceed the biomechanical load limits of the affected structure.

Epidemiology

These injuries are more likely to occur in athletes participating in strenuous disciplines such as, but not limited to, flat racing, jumping and three-day eventing.

CHAPTER 20

Soft tissue injuries: tendinitis and desmitis

Carol Gillis

Introduction

Thirteen percent of equine athletes sustain a soft tissue injury sufficiently severe to require a period of rest each year. Horses at greatest risk are those whose work load is increasing rapidly, for example, horses undertaking work at racing speed prior to their first race or dressage horses training to achieve the next training level.

Tendons and ligaments have a slow metabolic rate of activity and require a period of 8–14 months to return to the normal tensile strength range after damage. Confinement and rehabilitative exercise needed for optimum healing are expensive and time consuming; therefore an accurate diagnosis of all injuries currently affecting the horse is very important to allow for simultaneous treatment. Tendons and ligaments in varying locations respond to treatment and rehabilitation in a relatively similar fashion so even if one is confronted with a new or unusual injury, basic treatment principles apply. Although the published prognosis is fair or even poor for many soft tissue injuries, early diagnosis, good client compliance with repeated clinical and ultrasound examinations and a controlled exercise program tailored to the stage of healing of the injured tendon or ligament have improved the prognosis for most injuries. The prognosis for return to full athletic soundness is often good when using these principles, as long as adequate care and time are provided to allow for complete healing.

Superficial digital flexor tendinitis (bowed tendon)

Recognition

History and presenting complaint

Horses presented for superficial digital flexor (SDF) tendinitis are usually in full athletic use. Affected horses often have a workload that consists primarily of galloping and/or jumping (Fig. 20.1). Most tendon injuries are due to cumulative damage rather than a single event, the exception being a fall or a strike from another limb. Horses often develop clinically apparent pain, swelling and lameness 2–3 days following SDF injury.

Physical examination

Lameness ranges from grade 1 to 3 of 5 and is often transient or intermittent. It often resolves rapidly with the use of ice and anti-inflammatory agents. There may be pain on palpation, heat and swelling at the lesion site. These signs may not be apparent as the lameness resolves. Affected horses frequently exhibit a decrease in performance ability after the initial lameness resolves.[1,2]

Fig. 20.1
Horse competing in the stadium jumping phase of the Rolex Three-Day Event (CCI****).

Luxation of the SDF tendon from its attachment to the calcaneus often presents as an acute injury during exercise, particularly in polo ponies and eventers. An audible pop may be heard, followed by acute lameness. As luxation usually occurs laterally, the tendon can be seen coursing down the lateral aspect of the tarsus. Within a few days, massive swelling of the limb obscures anatomic details if the injury is not treated aggressively for inflammation.

Differential diagnosis for lesions in the metacarpal/metatarsal region is usually limited as the SDF tendon is readily palpated and separated from deeper structures. Carpal sheath synovitis may be associated with proximal SDF tendinitis. Digital sheath synovitis may be associated with SDF tendinitis in the fetlock region. Differential diagnosis in the pastern region includes damage to the sesamoidean ligaments or the collateral ligaments of the proximal

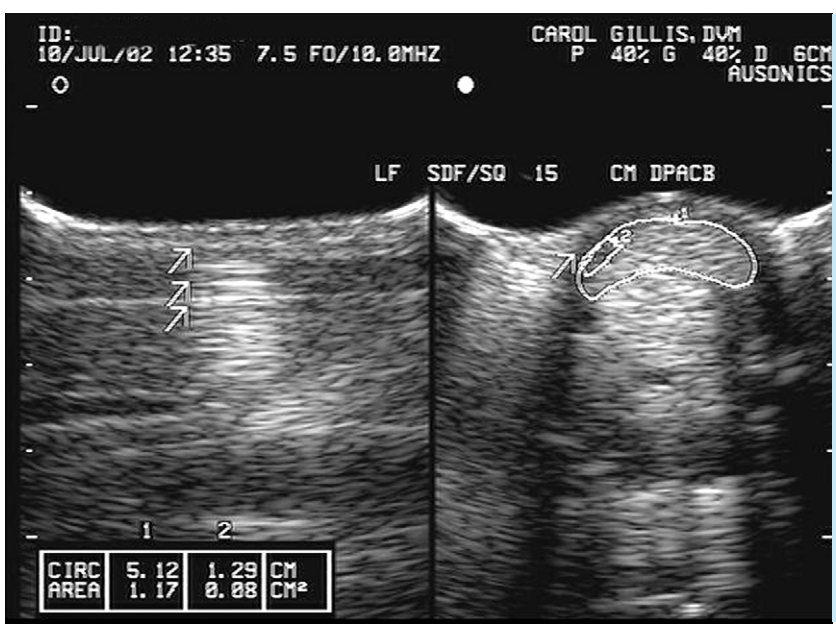

Fig. 20.2
Ultrasonographic image of a SDF tendon core lesion showing a subcutaneous organizing hematoma in the short-axis (right-hand) view as indicated by the arrow.

interphalangeal or distal interphalangeal joints. The foot must always be ruled out as a source of pain.

Special examination

For SDF branch lesions, a low palmar digital nerve block generally provides analgesia. For SDF lesions in the metacarpal/metatarsal region, a high palmar nerve block resolves the lameness.[3]

Increased size of the affected tendon region combined with loss of echogenicity and normal parallel linear fiber pattern observed with diagnostic ultrasonography provides the definitive diagnosis (Figs 20.2, 20.3, 20.4).[1,4–10]

Tenoscopy of the carpal and digital sheaths can provide additional diagnostic information as well as further treatment options. For example, under arthroscopic guidance debridement of frayed tendon fibers and resection of proliferative synovium and adhesions may be performed.[11,12]

Treatment and prognosis

Therapeutic aims

Control inflammation and prevent further tendon injury either directly, through reducing tendon fiber swelling and

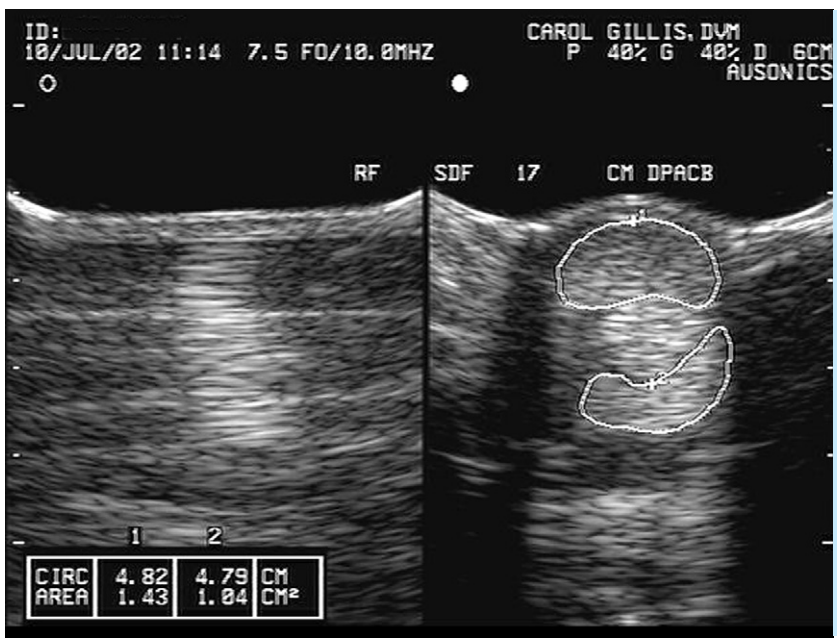

Fig. 20.3
Ultrasonographic image of chronic, generalized SDF tendinitis in the metacarpal region. The tendon is enlarged, hypoechoic and has a fair fiber pattern.

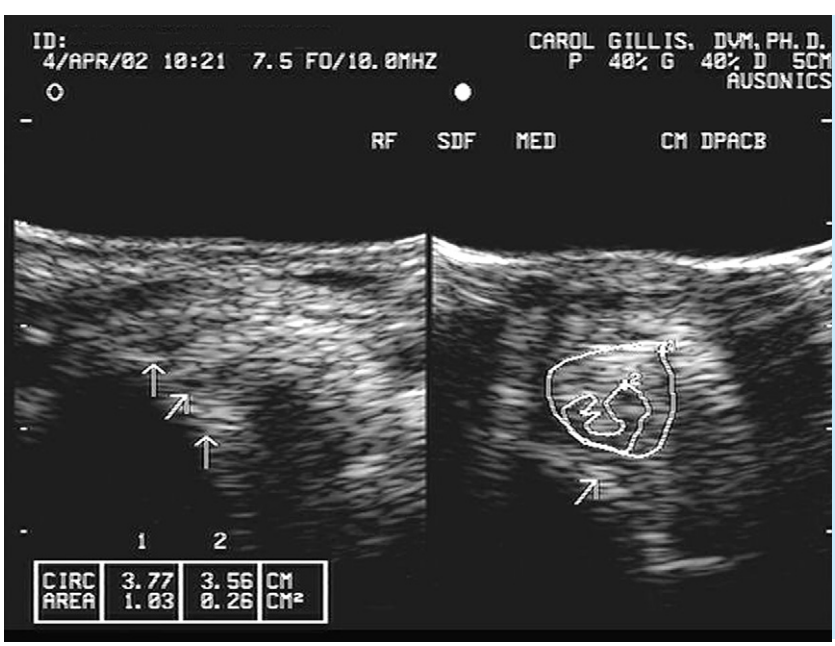

Fig. 20.4
Ultrasonographic image of a SDF medial branch core lesion in the pastern at the level of insertion.

influx of inflammatory mediators, or indirectly through further exercise.

- To provide adequate tendon support, primarily through shoeing.
- To provide adequate rest followed by graduated increases in exercise to allow for optimum tendon healing

Therapy

Initial therapy is directed at controlling excessive inflammation and should include anti-inflammatory therapy such as 1 g of phenylbutazone orally twice daily for 2–3 weeks, based on injury severity.

Cold therapy, such as ice for 20 minutes 2–3-times/day for 3 weeks, is an effective adjunct to reduce inflammation. Treatment with intramuscular polysulfated glycosaminoglycan, 500 mg every 4 days for seven treatments, has been shown to improve tendon healing.[13]

Foot conformation should be evaluated early in the course of injury. Good caudal heel support should be provided using an egg bar shoe that extends to the level of the heel bulbs. Any break in pastern/hoof axis should be corrected at the same time.

Stall (12'by 24') confinement with hand-walking should be initiated following examination. Unless the tendon is so severely damaged that rupture appears likely (rare), hand-walking is an important part of treatment and should not be delayed.

Bandaging is useful to decrease edema in the surrounding tissues. Bandages will not provide significant tendon support. Any concurrent lameness, even slight or chronic, should be treated at the same time.

Table 20.1 Exercise protocol following the first examination (0–60 days). Horse is confined to a stall and equivalent size paddock (12′ × 24′)

Injury	0–30 days	30–60 days
Mild	Hand-walk 15 minutes twice daily	Increase walking time by 5 minutes per week
Moderate	Hand-walk 10 minutes twice daily	Increase walking time by 5 minutes per week
Severe	Hand-walk 5 minutes twice daily	Increase walking time by 5 minutes per week

Table 20.2 Exercise protocol following the second examination (60–120 days). Horse is confined to a stall and equivalent size paddock

Progress	60–90 days	90–120 days
Good	Ride at walk 25 minutes daily, increasing by 5 minutes per week	Ride at walk increasing 5 minutes per week
Fair	As above	As above
Poor	Hand-walk 60 minutes per day	Ride at walk 20–30 minutes daily

Table 20.3 Exercise protocol following the third examination (120–180 days). Horse is confined to a 40′ × 40′ paddock

Progress	120–150 days	150–180 days
Good	Add 5 minutes trot every 2 weeks	Add 5 minutes trot every 2 weeks
Fair	Ride at a walk 60 minutes daily	As above
Poor	Re-evaluate case and discuss further	Treatment options

Table 20.4 Exercise protocol following the fourth examination (180–240 days). Horse can be turned out after riding exercise when it has been cantering 10 minutes for 1 week

Progress	180–210 days	210–240 days
Good	Add canter 5 minutes every 2 weeks, can turn out after exercise	Add canter 5 minutes every 2 weeks, begin ground pole work for jumping
Fair	Add trotting 5 minutes every 2 weeks	Add canter 5 minutes every 2 weeks
Poor	Re-evaluate case and discuss further treatment options	Re-evaluate case and discuss further treatment options

Table 20.5 Exercise protocol following the fifth examination (240–300 days)

Progress	240–270 days	300–330 days
Good	Racing speed work, begin once weekly jumping or other competitive training	Ready for competition
Fair	Add canter 5 minutes every 2 weeks	Full flat work; no racing speed work or jumping
Poor	Re-evaluate case and discuss further treatment options	Re-evaluate case and discuss further treatment options

Following an initial period of stall rest and hand-walking, the SDF tendon should be re-evaluated using physical examination and ultrasonography to assess healing. Increasing exercise should be based upon examination findings rather than time elapsed. When allowed free exercise, the horse should be confined to a space small enough so that it can only walk until the patient is at 20 minutes trot during controlled exercise. Please refer to Tables 20.1–5 for detailed exercise protocols.

Surgical options If an anechoic or mostly anechoic core lesion is seen on ultrasonographic examination, ultrasound-guided tendon splitting to decompress the core lesion should be performed as soon as possible, ideally 2–14 days following injury, to prevent further compression injury of the surrounding normal fibers.

If a subcutaneous hematoma is detected, injection of hyaluronic acid between the tendon and the skin should be performed as soon as possible, ideally 2–14 days following injury to attempt to prevent development of adhesions between the subcutaneous tissue and the SDF tendon.

Superior check ligament desmotomy has been shown to improve SDF appearance in the short term; long-term results have been less encouraging. Superior check desmotomy has been associated with significantly increased strains on the SDF tendon and SL.[14] Horses treated surgically were 1.2 times more likely to develop recurrent or new injuries after returning to training than horses managed non-surgically. Race horses that have undergone a superior check ligament desmotomy are 5.5 times as likely to suffer a subsequent suspensory ligament injury as are horses without desmotomy.[15]

Palmar annular ligament (PAL) desmotomy is very helpful in treatment of SDF injuries that extend to the distal metacarpal/metatarsal region. Resection of the PAL relieves compression of the enlarged SDF and allows for improved tendon gliding. This procedure is most effective when performed soon (within 4 weeks) after SDF tendon injury. If the procedure is not performed, the proximal portion of the SDF on subsequent ultrasound exams will appear to be healing at a normal rate, while the portion of the SDF just proximal to and at the level of the PAL will heal poorly. Resection is still useful as a treatment for chronic distal SDF tendon injury, although improved healing of the tendon is less dramatic. Although several surgical repair methods have been described for SDF tendon luxation, aggressive medical therapy provides a good long-term outcome without the complications that can occur following surgical attachment/stabilization at the original site on the calcaneus.

An experimentally promising treatment that may improve tendon healing in the future is the use of growth factor(s).[16]

Prognosis

The prognosis is excellent for life and good for return to full athletic use, if aggressive treatment followed by controlled rehabilitation is performed. If the tendon appears 95% healed based on size, echogenicity and fiber pattern on the final ultrasound exam, the horse is at no greater risk of reinjury than of any athletic use injury upon return to full work. A superficial digital flexor tendon that has luxated from its calcaneal attachment also has a good prognosis with aggressive medical treatment for inflammation and a full rehabilitation program.

Etiology and pathophysiology

The SDF tendon, in conjunction with the suspensory ligament, acts to keep the fetlock from extending to the ground when the horse is weight bearing. The SDF actively participates in limb flexion during the swing phase of locomotion through contraction of the SDF muscle.

The SDF tendon has little margin of safety as horses in full work such as galloping or jumping generate forces near to its breaking strength.[17,18] Factors that place excess load on the tendon, such as muscle fatigue which places increasing load on the much smaller, tendinous portion of the muscle/tendon unit, poor hoof conformation/shoeing or lameness in another limb, place the tendon at increased risk of failure.

Once a few fibers are damaged, strength is reduced and the tendon is predisposed to further fiber rupture with continued work. Hemorrhage at the site of ruptured fibers and associated inflammatory mediator release cause further fiber damage, either through compression by expansion of the hematoma or from the detrimental effects of inflammatory products.

Athletic performance deteriorates in horses with SDF tendinitis due to initial lameness, followed by prolonged tendon weakness during the recovery phase. If excessive exercise is attempted while the tendon is relatively weak, the risk of tendon reinjury is high, leading to a repetitive syndrome of repeated short periods of acute lameness followed by longer periods of inability to perform regular work. If the tendon is damaged repeatedly, fibroblast damage occurs (tendinosis), resulting in inability to generate normal repair collagen. At this stage the tendon's ability to heal is compromised.

Prevention

SDF tendinitis prevention consists of:

- increasing workload gradually rather than abruptly. A 5% increase in workload per week is generally a safe guideline
- being attentive to hoof shape and shoeing to avoid a long toe, low heel configuration and to prevent a break in pastern/hoof axis
- early recognition and treatment of other lameness to prevent compensatory tendon overload
- recognition that certain conformational faults, particularly 'back at the knee' conformation, load the SDF additionally and place the horse at increased risk of tendon injury when in full work.

Deep digital flexor tendinitis

Recognition

History and presenting complaint

Forelimb deep digital flexor (DDF) damage occurs most frequently in the pastern region of horses used for athletic pursuits which involve twisting and turning, such as endurance riding in rough terrain or roping. In the foot region of fore- and hindlimbs, DDF tendinitis often occurs in middle-aged horses. It is often concurrent with navicular disease, particularly navicular bursitis. Hindlimb metatarsal region DDF tendinitis is most frequently seen in hunters/jumpers, again often middle-aged geldings that have had years of work.

Physical examination

Grade 1–3 out of 5 lameness is observed and is often intermittent or transient. Heat, swelling and pain will be present on palpation of the DDF.

Differential diagnoses depend on location; in the metacarpal/metatarsal region, inferior check ligament desmitis is the major differential. Tarsal sheath synovitis may be associated with hindlimb DDF tendinitis. In the pastern the SDF tendon and the sesamoidean ligaments must be included in the differential diagnoses. Digital sheath synovitis is often associated with pastern region DDF tendinitis. In the foot, navicular bursitis, navicular bone changes and other causes of heel pain should be considered as differential diagnoses.

Special examination

Diagnostic nerve blocks will localize the region of the DDF involved and begin the process of elucidating the source(s) of heel pain, if present. Radiographs of the foot will provide information regarding bone and joint involvement

Diagnostic ultrasonography will define the presence and extent of DDF damage. For the most optimal examination of the DDF within the hoof, as well as the navicular bursa and the impar ligament, the shoe should be removed and the frog should be pared to provide a level surface for good transducer contact. The foot should be soaked overnight to further soften the tissues. The insertion of the DDF on the solar aspect of the distal phalanx, the navicular bursa and the impar ligament can then be evaluated for disease (Fig. 20.5).[19]

Treatment and prognosis

Therapeutic aims

- To control inflammation and prevent further tendon injury either directly, through reducing tendon fiber swelling and influx of inflammatory mediators, or indirectly through further exercise.
- To provide adequate tendon support, primarily through shoeing.
- To provide adequate rest followed by graduated exercise to allow for optimum tendon healing

Therapy

For general tendinitis medical treatment, please refer to the section on SDF tendinitis (pp 415–416).

DDF tendinitis in the region of the navicular bone is frequently associated with navicular bursitis. If this is the case, therapy should include injection of the navicular bursa with hyaluronic acid and steroid. Injection of the coffin joint rarely provides sufficient clinical and ultrasonographic signs of resolution of bursitis, even if the horse responds to coffin joint anesthesia. Reasons could include:

- diffusion of local anesthetic across membranes which are not sufficiently permeable to allow diffusion of larger molecules[20]
- anesthesia of local nerves proximal to the bursa, causing reduction in pain that was not the result of reduction of inflammation within the bursa.

Tarsal sheath synovitis may be treated medically in a similar fashion to the digital sheath (see following section). Tenoscopy of the sheath is an effective treatment for chronic/complicated cases with extensive synovial membrane proliferation and/or adhesions.[21]

Prognosis

Prognosis is good for return to athletic use if the tendon alone is involved. Concomitant tarsal sheath synovitis, digital sheath synovitis, and navicular bursitis need to be aggressively managed or they may prove to be the limiting factor(s) in future athletic performance. If not aggressively treated, DDF tendinitis and synovial sheath synovitis can progress to massive adhesions and a non-functional limb over time (Fig. 20.6).

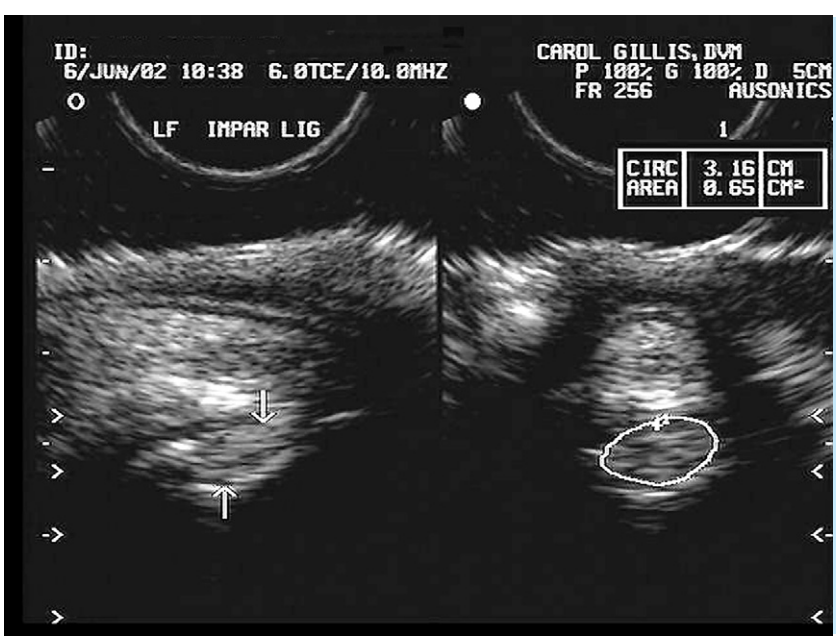

Fig. 20.5
Ultrasonographic image of impar ligament desmitis showing swelling, loss of echogenicity and a fair fiber pattern. The impar ligament origin on the navicular bone is to the left and its insertion on distal phalanx is to the right on the long-axis (left-hand) view.

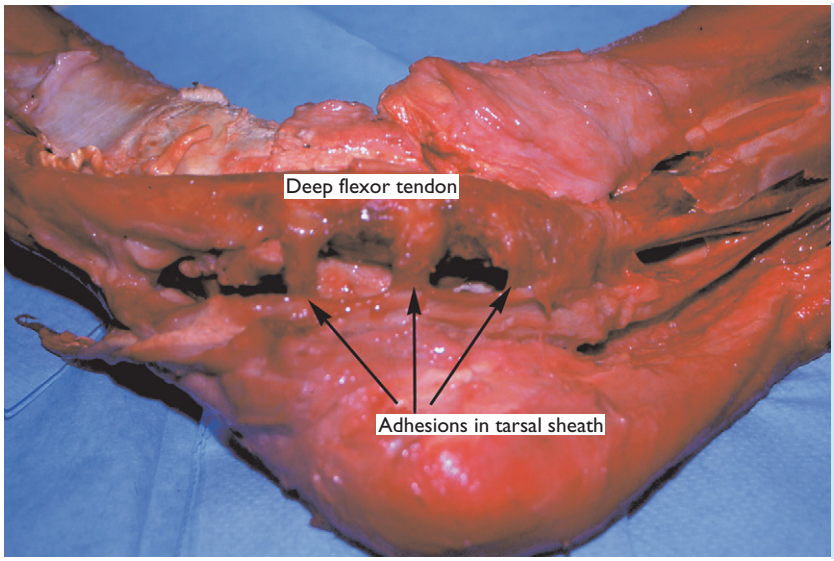

Fig. 20.6
Tarsal sheath severe chronic synovitis with adhesions to a thickened, fibrous DDF tendon.

Etiology and pathophysiology

The DDF tendon acts to keep the third phalanx/toe of the hoof from overextending and actively participates in flexion of the limb during the swing phase of locomotion through contraction of the DDF muscle. Factors that place excess load on the tendon include the following.

- Muscle fatigue, placing increasing load on the much smaller, tendinous portion of the muscle/tendon unit, poor hoof conformation/shoeing or lameness in another limb.
- Once a few fibers are damaged, strength is reduced and the tendon is predisposed to further fiber rupture with continued work.
- Hemorrhage at the site of ruptured fibers and associated inflammatory mediator release cause further fiber damage either through compression by hematoma expansion or the detrimental effects of inflammatory products.

Athletic performance deteriorates in horses with DDF tendinitis due to initial lameness, followed by prolonged tendon weakness during the recovery phase. If excessive exercise is attempted while the tendon is relatively weak, the risk of tendon reinjury is high, leading to a repetitive syndrome of repeated short periods of acute lameness followed by longer periods of inability to perform regular work. If the tendon is damaged repeatedly, fibroblast damage occurs (tendinosis), resulting in inability to generate repair collagen.

Prevention

DDF tendinitis prevention consists of:

- increasing workload gradually rather than abruptly. A 5% increase in workload per week is generally a safe guideline
- being attentive to hoof conformation and shoeing to avoid a long toe, low heel configuration and to prevent a break in pastern/hoof axis
- early recognition and treatment of other lameness to prevent compensatory tendon overload
- recognition that 'heel pain' may be due to excess strain on the DDF and that navicular bursitis my lead to secondary adhesions between the bursa and the DDF, leading to DDF damage.

Accessory ligament of the deep digital flexor tendon desmitis

Recognition

History and presenting complaint

Desmitis of the accessary ligament (AL) of the deep digital flexor tendon (DDFT) is usually observed in horses that are starting into regular work if the condition is developmental or in middle-aged horses (12–16 years) which have been in regular use, particularly as jumpers.

AL desmitis can also occur secondary to moderately severe to severe SDF tendinitis, if the SDF tendon becomes sufficiently enlarged to contact the medial and lateral borders of the AL. Adhesions may subsequently develop which cause AL inflammation and damage.[22]

Physical examination

Grade 2–3 out of 5 lameness is present and is usually persistent. Heat, swelling and pain are felt on palpation, most often at the AL/DDF junction in the palmar/lateral midmetacarpal region. AL desmitis occurs less frequently at the origin of the ligament.

Differential diagnoses include DDF tendinitis and suspensory ligament desmitis. The AL is often damaged at the mid-metacarpal level, where its fibers join those of the DDF tendon.

Special examination

A high two-point nerve block (lateral and medial palmar nerves) should ablate the lameness and will confirm that the lameness is localized to the metacarpal region.

Diagnostic ultrasonography will reveal AL enlargement, loss of echogenicity and deterioration of fiber pattern[23] and reveal if there is any contact with the borders of the SDF tendon. The DDF tendon may be completely encircled and compressed by the SDF and the AL and may be an additional source of the chronic pain often associated with AL desmitis (Fig. 20.7).

Treatment and prognosis

Therapeutic aims

To control inflammation and prevent further ligament injury either directly, through fiber swelling and inflammatory mediators, or indirectly through further exercise. To provide adequate ligament support, primarily through shoeing. To provide adequate rest followed by graduated exercise to allow for optimum ligament healing.

Therapy

For general therapy please refer to the section on SDF medical therapy (pp 415–416).

Surgical desmotomy of the AL is a final option. The client must commit to a full 6–10 month healing process. Within 4 weeks of surgery granulation tissue will fill the gap between the resected AL ends. The AL will initially be 2–4 times normal size, then over months of rehabilitation ligament repair will occur, with a functionally lengthened and healed AL if surgery and rehabilitation have been successful.[24–27]

AL desmotomy in weanlings to correct contracted tendon/club foot syndrome should be followed by a controlled exercise program. It is possible for the horse to develop clinical signs of desmitis when the partially healed ligament is subjected to the forces generated by athletic training years later.

Prognosis

Prognosis is fair for return to athletic use. The AL causes more long-term lameness than other tendon/ligament injuries.[25,28] Often diagnosis is delayed until AL desmitis is chronic and severe, which limits the potential for healing. Horses with AL desmitis respond most favorably to a gradual return to work, often with 4–5 days of work maximum with rest days in between. Breakdown of adhesions between the AL and the SDF tendon may cause transient pain. If the pain, heat and swelling do not respond to 3–4 days of ice, NSAIDs and walking, an ultrasonographic examination is indicated to assess the AL for reinjury.

Etiology and pathophysiology

Factors which cause contracted tendons in foals, such as congenital malformation,[29] diet and exercise, contribute to AL desmitis, as this ligament is part of the affected DDF/AL complex. Chronic overuse of the AL due to hyperextension of the limb during athletic work is a second predisposing factor in the older horse, as are changes in biomechanical properties due to the aging process.[30]

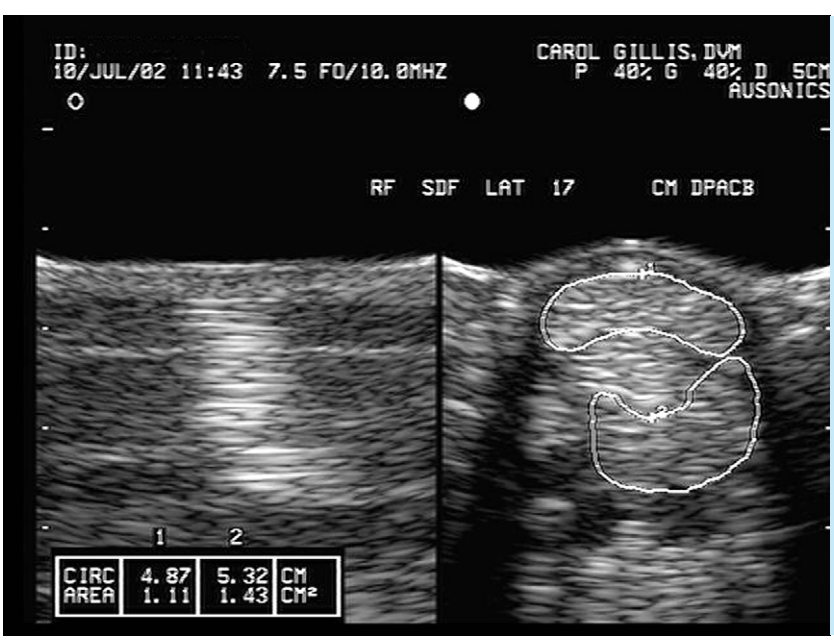

Fig. 20.7
Ultrasonographic image of SDF/AL adhesion compressing the DDF tendon. The cross-sectional area #1 indicates the SDF, cross-sectional area #2 indicates the AL.

Prevention

We are currently unable to detect excess tension on the AL prior to inflammation resulting in pain, heat and swelling.

Prevention of AL desmitis hinges primarily on very careful hoof balance, as many horses with AL desmitis have had long-term high heels on the affected limb and low heels on the opposite limb. Over time this condition tends to become more pronounced.

This condition may have been initiated when the patient was a foal, therefore careful attention to hoof trimming in the foal is a primary preventive step. Attempting to lower the high heel substantially often results in acute AL pain which may be quite severe. It is preferable to raise low heels on the opposite limb until the foot/pastern axis is balanced and then very gradually lower the high heels.

Suspensory ligament desmitis

Recognition

History and presenting complaint

Suspensory ligament (SL) desmitis is seen most frequently in horses that trot for long periods of time, such as Standardbred race horses, endurance horses and dressage horses. Often, pain, heat, swelling and lameness are noted 1–3 days following hard work or competition. Lameness may resolve quickly following the use of NSAIDs, cold therapy and rest, only to return when the horse is worked vigorously again. Hindlimb SL desmitis is often mistaken for disease of the distal tarsal joints. Treatment of the distal intertarsal and tarsometatarsal joints with steroids may reduce inflammation of the SL temporarily and cause reduction of clinical signs until further SL damage occurs. The complaint with these patients is often that 'they only respond short term to hock injections'.

Physical examination

Grade 1–3 out of 5 lameness is observed and is often intermittent or transient. The SL branches are readily palpated for pain, heat and swelling. The SL origin and body, particularly in the hindlimb, are nestled between MCII-III-IV (MTII-III-IV) and are covered superficially by the flexor tendons, so may only reveal clinical signs on careful deep palpation.

It is helpful to differentiate between hock joint pain and SL damage to compare the horse's response to hindlimb flexion and to deep pressure on the SL body with the heel off the ground but without limb flexion (Fig. 20.8). Rarely, the extensor branches of the SL are injured, resulting in pain, heat and swelling of the affected branch in the dorsolateral or dorsomedial pastern. Differential diagnoses include DDF/AL damage, metacarpophalangeal joint or collateral ligament injury and tarsal joint disease.

Fig. 20.8
Pressure being placed on the proximal hind SL on the medial aspect of the proximal third metatarsal bone.

Special examination

Median and ulnar nerve blocks will provide forelimb analgesia with suspensory desmitis.[3,31,32] In the hindlimb, interpretation of nerve blocks is complicated by the potential for anesthesia of the proximal SL and the tarsal sheath when using a high plantar nerve block[33] or, conversely, the possibility of blocking the proximal SL when using a tarsometatarsal joint block.

Radiographic examination of the proximal metatarsus/metacarpus and the tarsus or carpus respectively will help determine if there is concomitant joint disease. Also, changes in proximal metatarsus/metacarpus bone density may indicate abnormalities at the suspensory origin.

Diagnostic ultrasonography will reveal enlargement of the SL, loss of normal echogenicity and deterioration of fiber pattern.[34–36] To fully examine the origin/proximal SL body in the hindlimb, it is necessary to place the ultrasound probe in

a line just below the 'chestnut' and to aim in a dorsolateral direction, otherwise the large proximal portion of MTIV obscures half or more of the SL.

Treatment and prognosis

Therapeutic aims

To control inflammation and prevent further ligament injury either directly, through ligament reduction of fiber swelling and inflammatory mediators, or indirectly through further exercise. To provide adequate ligament support, primarily through shoeing. To provide adequate rest followed by graduated exercise to allow for optimum ligament healing.

Therapy

For general therapy please refer to the SDF tendon section (pp 415–416).

Suspensory ligament injuries respond very favorably to the provision of caudal heel support through the use of an egg bar shoe that extends to the level of the heel bulbs. Horses which stride up to the front feet with the hind feet can wear bell boots to deter shoe pulling. Many horses tolerate egg bars sufficiently well to wear them through the rehabilitation phase and on into return to competition.

Particularly in the first 2 weeks following injury, 'splitting' using an 18 gauge needle and ultrasound guidance is effective for decompression of lesions in the proximal SL body.

Prognosis

Prognosis is good for return to athletic use.

Etiology and pathophysiology

See above.

Prevention

The suspensory ligament functions with the SDF tendon to prevent the fetlock from extending to the ground during stance phase. Tendon and ligament respond to appropriate training by increasing in strength.[37] Ensuring that the equine athlete is trained in a stepwise consistent program, gradually building in difficulty, so that muscle fatigue never becomes sufficient to transfer the bulk of the horse's force on to the much smaller tendons and ligaments, is the best prevention for ligament injury. As in human athletes, a history of rapidly increasing work intensity, particularly upon return to work from another injury or as a young horse enters work or a new training situation, is commonly found as a precursor to ligament or tendon injury.

The second group of athletes which sustain ligament injury are the horses which regularly train using a repetitive protocol; for example, a mature dressage horse which often works 1–2 hours 6 days per week and which repeats the same maneuvers many times each exercise session. This horse, likely working in a balanced fashion on fore- and hindlimbs, subjects his hind suspensory ligaments to wear and tear injury. Prevention entails cross-training such as hacking on a long rein 1–2 times per week and having a complete rest day, with harder work interspersed between training days. This allows for repair of microdamage to the SL incurred on training days.

Long plantar ligament desmitis (curb)

Recognition

History and presenting complaint

Swelling along the plantar/lateral aspect of the calcaneus to the proximal aspect of MTIV is observed. Long plantar ligament (LPL) desmitis most frequently occurs in Standardbred race horses and in jumpers. Differential diagnoses include SDF tendinitis and subcutaneous swelling due to trauma.

Physical examination

Grade 1–2 out of 5 lameness is observed and is often transient. Pain, heat and swelling on palpation of the ligament are found.

Special examination

Diagnostic ultrasound will reveal enlargement, loss of echogenicity and deterioration of fiber pattern.

Treatment and prognosis

Therapeutic aims

To control inflammation and prevent further ligament injury either directly, through fiber swelling and inflammatory mediators, or indirectly through further exercise. To provide adequate ligament support, primarily through shoeing. To provide adequate rest followed by graduated exercise to allow for optimum ligament healing.

Therapy

For general therapy please refer to the SDF tendon section (pp 415–416). The LPL is not a weight-bearing tendon so it can be more readily rested. Generally LPL desmitis healing is sufficiently complete in 4–5 months to allow return to work.

Prognosis

Prognosis is excellent for return to athletic use.

Long digital extensor tendinitis

Recognition

History and presenting complaint

This injury is often seen in horses which jump solid fences such as steeplechase or eventing competitors. The usual presenting complaint is of swelling over the dorsal surface of MTIII and intermittent lameness.

Physical examination

Grade 1–2 out of 5 lameness. Pain, heat and swelling are felt on palpation of the long digital extensor tendon. Damage may extend into the lateral digital extensor tendon as well.

The long digital extensor tendon has a synovial sheath on the dorsum of the tarsus; this may also be involved, filling with hemorrhage, excess synovial fluid, synovial proliferation and adhesions.

Special examination

Diagnostic ultrasound will reveal enlargement of the tendon, loss of echogenicity and deterioration of fiber pattern. Synovitis of the tendon sheath will also be seen, if present, as excess fluid with an increased cell content, synovial proliferation and/or adhesions (Fig. 20.9).

Treatment and prognosis

Therapeutic aims

To control inflammation and prevent further tendon injury either directly, through fiber swelling and inflammatory mediators, or indirectly through further exercise. To provide adequate tendon support, primarily through shoeing. To provide adequate rest followed by graduated exercise to allow for optimum tendon healing.

Therapy

For general therapy please see the section on SDF tendinitis treatment (pp 415–416).

As extensor tendons are located on the dorsal surface of the bony column of the limb, they do not bear the brunt of the horse's weight as flexor tendons do. This allows the extensor tendons to rest and healing occurs more quickly than in flexors, generally being sufficiently complete in 4–6 months to allow return to work.

The extensor tendon sheath, if affected, should be treated at the time of diagnosis with intrathecal injection of anti-inflammatory medication such as hyaluronic acid.

Extensor tendon injuries are often associated with skin wounds or dermatitis secondary to hitting solid fences. These must be treated vigorously to reduce local inflammation and allow tendon healing to progress.

Prognosis

Excellent for return to athletic use.

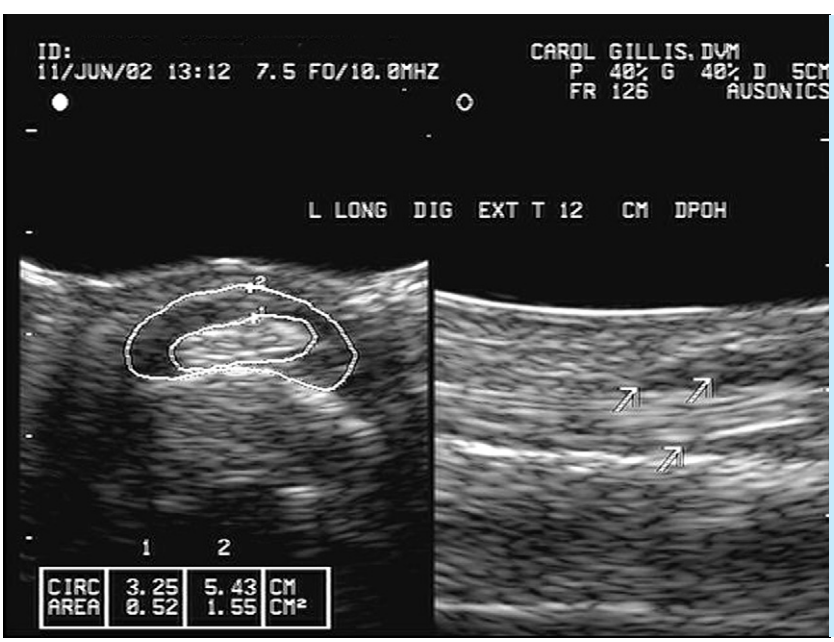

Fig. 20.9
Ultrasonographic image of LDET sheath effusive synovitis. The cross-sectional area #1 indicates the LDET, cross-sectional area #2 indicates the surrounding sheath filled with hypoechoic fluid.

Prevention

As extensor tendon injuries are often associated with a direct blow to the limb from a fence, the most practical prevention is protective boots for the dorsal surface of MTIII.

Common digital extensor tendinitis

Recognition

History and presenting complaint

See long digital extensor tendinitis (above). Long digital extensor tendinitis, as well as tendon laceration, is far more frequently encountered than common digital extensor tendinitis.[38]

Physical examination

Grade 1–2 out of 5 lameness is observed and is often transient and intermittent. Pain, heat and swelling are felt on palpation. The tendon sheath on the dorsal surface of the carpus may also be warm, swollen and sensitive to palpation.

Special examination

Diagnostic ultrasound will reveal enlargement of the tendon, loss of echogenicity and deterioration of fiber pattern. Synovitis of the tendon sheath will also be seen, if present, as excess, often cellular fluid, synovial proliferation and/or adhesions.

Treatment and prognosis

See long digital extensor tendinitis (above).

Straight sesamoidean ligament desmitis

Recognition

History and presenting complaint

Desmitis of the straight sesamoidean ligament (SSL) is usually seen in horses which twist and turn as part of their sport, such as eventers and cutting horses, or which work on uneven ground, such as endurance horses. This injury also occurs fairly frequently in pasture.

Physical examination

Grade 2–3 out of 5 lameness is observed. Pain, heat and swelling are encountered on palpation of the palmar/plantar aspect of the flexed limb. Differential diagnoses include other sesamoidean ligament injury, collateral ligament damage or pastern joint disease.

Special examination

Nerve block at the abaxial sesamoid level will greatly improve or ablate the lameness. Radiographs may reveal bone changes at the site of SSL origin at the base of the sesamoid bones or, more commonly, at the insertion on palmar P2. Diagnostic ultrasound will reveal enlargement, loss of echogenicity and deterioration of fiber pattern. A wedge of muscle tissue located at the SSL insertion on P2 can appear to be a lesion. Placing the limb in strong extension will compress the muscle, while a true lesion will remain unchanged.

Treatment and prognosis

Therapeutic aims

To control inflammation and prevent further ligament injury either directly, through fiber swelling and inflammatory mediators, or indirectly through further exercise. To provide adequate ligament support, primarily through shoeing. To provide adequate rest followed by graduated exercise to allow for optimum ligament healing.

Therapy

For general therapy please refer to the SDF tendon section (pp 415–416).

Caudal heel support through the use of an egg bar shoe to the level of the heel bulbs is very helpful for this injury.

Prognosis

Prognosis is good for return to athletic use.

Etiology and pathophysiology

Torsion of the foot/pastern produces excessive force on the pastern ligaments if:

- the horse is fatigued and muscle contraction is not assisting normally in foot/pastern placement
- the fetlock is sinking excessively during weight-bearing phase due to long toe, low heel foot conformation, muscle fatigue or uneven footing.

Prevention

Balanced shoeing appropriate for the terrain and a well-conditioned horse that does not fatigue excessively during competition are the best prevention.

Oblique sesamoidean ligament desmitis

Recognition

History and presenting complaint

Oblique sesamoidean ligament (OSL) desmitis is usually seen in horses which twist and turn as part of their sport, such as eventers and cutting horses, or which work on uneven ground, such as endurance horses. This injury also occurs fairly frequently in pasture.

Physical examination

Grade 2–3 out of 5 lameness is observed, usually persistent. Pain is elicited on palpation of the affected branch from the base of the sesamoid bone to palmar PI.

Differential diagnoses include other sesamoidean ligament injury, collateral ligament damage or pastern joint disease.

Special examination

Nerve block at the abaxial sesamoid level on the affected side will improve or ablate the lameness. Radiographs may reveal bony changes at the base of the sesamoid or at OSL insertion on palmar (plantar) P1. Diagnostic ultrasound will reveal enlargement, loss of echogenicity and deterioration of fiber pattern.

Treatment and prognosis

See straight sesamoidean ligament (above).

Collateral ligament desmitis of the metacarpophalangeal/ metatarsophalangeal, proximal interphalangeal joints and distal interphalangeal joints

Recognition

History and presenting complaint

Usually seen in horses which twist and turn as part of their sport, such as eventers and cutting horses, or which work on uneven ground, such as endurance horses (Fig. 20.10). This injury also occurs fairly frequently in pasture.

Physical examination

Grade 2–4 out of 5 lameness is observed. Pain, heat and swelling are palpable on the affected ligament. Palpation is easiest when the distal limb is flexed. Signs of joint inflammation (distended joint and pain on flexion) will be present in acute cases. In chronic cases, osteoarthritis may be present, resulting in reduced flexion and a thickened joint capsule.[39]

A low four-point nerve block (medial and lateral palmar/plantar and palmar/plantar metacarpal/metatarsal nerves) greatly improves or ablates the lameness at the level of the fetlock and distal and the abaxial sesamoid block will improve or ablate lameness at the level of the proximal interphalangeal joint. Intra-articular anesthesia generally improves, but does not ablate the lameness.

Fig. 20.10
An endurance horse in competition in the Tevis Cup (100 mile).

Special examination

Stress radiographs may reveal medial/lateral joint laxity if damage results in significant ligament laxity. Bony abnormalities at the origin of the collateral ligaments or insertion may be detected. Diagnostic ultrasound will reveal ligament enlargement, loss of echogenicity and loss of normal fiber pattern. The insertion of the collateral ligaments of the distal interphalangeal joint cannot be evaluated using ultrasound because of the interposition of the hoof capsule.

Treatment and prognosis

Therapeutic aims

To control inflammation and prevent further ligament injury either directly, through fiber swelling and inflammatory mediators, or indirectly through further exercise. To provide adequate ligament support, primarily through shoeing. To provide adequate rest followed by graduated exercise to allow for optimum ligament healing.

Therapy

For general therapy please refer to the SDF tendon section (pp 415–416).

Shoeing with a $\frac{1}{2}''$ extension at the midquarter of the affected side of the hoof will provide support and make the horse more comfortable, as well as reducing stress on the collateral ligament. Shoeing in this manner may be difficult to maintain if the medial collateral ligament is damaged, as the horse may tend to pull the shoe with the opposite foot. Large bell boots may be helpful in preventing this. Shoeing should be maintained for 4–6 months. Extensions may be decreased to $\frac{1}{4}''$ inch as clinical and ultrasonographic signs improve.

Horses with collateral ligament damage may be lame for up to 90 days following injury. Confinement and regular hand-walking exercise are essential.

Often the joint develops synovitis or capsulitis following this type of injury; treatment of the joint with intra-articular hyaluronic acid, as well as intramuscular polysulfated glycosaminoglycan (PSGAG) therapy and oral glucosamine, are helpful to relieve joint inflammation. If there has been hemorrhage into the joint, the horse may be in extreme pain and the joint may need to undergo lavage to rid it of inflammatory products. In cases of complete rupture, surgical repair of the ligament may be necessary.[40,41]

Prognosis

Prognosis is good for return to athletic use.

Prevention

Balanced shoeing which provides adequate foot support is an important preventive measure. A well-conditioned horse will withstand the stresses imposed in competition with less chance of injury than a poorly conditioned horse.

Biceps brachii tendinitis/ bicipital bursitis

Recognition

History and presenting complaint

The injury often occurs due to being kicked by another horse or by hitting a solid object such as a fence. Stress injuries are uncommon.

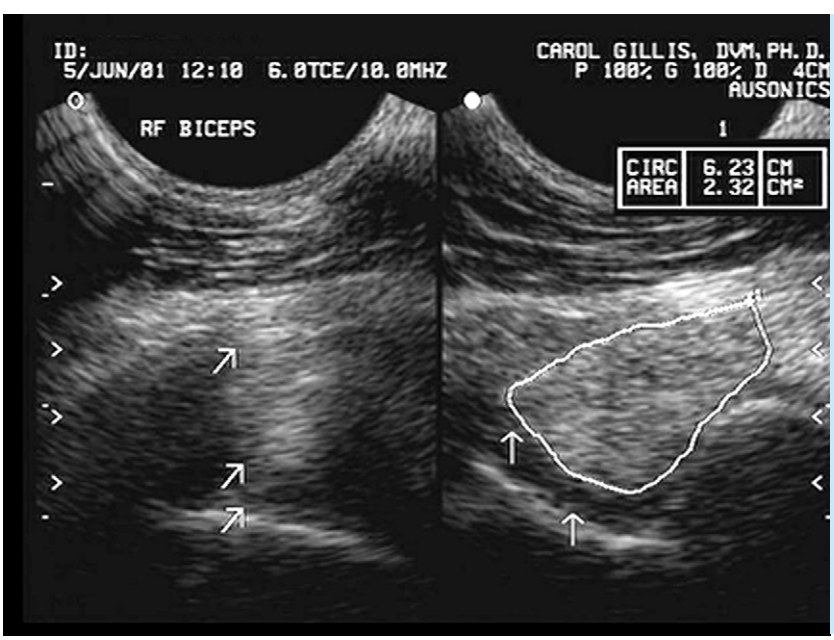

Fig. 20.11
Ultrasonographic image of biceps tendinitis/bicipital bursitis. The short-axis (right-hand) view arrows are indicating synovial proliferation in the bursa.

Physical examination

Pain on palpation of the biceps tendon is usually evident. A tendency to stand with the affected limb slightly caudal to the normal one is frequently seen. Pain on extension of the tendon and compression of the bicipital bursa by pulling the limb caudally may also be seen.

Special examination

A radiographic skyline view will reveal concomitant humeral tubercle injury/pathology. Diagnostic ultrasound will reveal tendon enlargement, loss of echogenicity and fiber pattern.[42] Bicipital bursitis is almost always seen concomitantly. Excess fluid (greater than 3 mm depth) will be seen. The fluid will be anechoic if there is effusive synovitis present or hypoechoic if it is in the early proliferative phase. Adhesions, if present, may be seen between the bursa and the biceps tendon (Fig. 20.11).

Treatment and prognosis

Therapeutic aims

See section on SDF tendon (pp. 414–415).

Therapy

For general therapy, please see the section on SDF treatment (pp 415–416).

Bicipital bursitis, if present, should be treated as soon as it is recognized. Initial treatment should be made with intrathecal hyaluronic acid to prevent adhesion formation and relieve inflammation. The bursa can be readily accessed using a 19 gauge $1\frac{1}{2}''$ needle under ultrasound guidance and confirmation of injection into the bursa can be recorded (Fig. 20.12). Often 2–4 injections are required over a period of 4–6 months to resolve the synovitis. As tendon healing progresses, a steroid may be added to hyaluronic acid to

Fig. 20.12
Ultrasound-guided bicipital bursa injection.

increase the anti-inflammatory effect. Physical therapy, such as massage and therapeutic ultrasound to relieve biceps muscle spasm and improve comfort, tends to improve healing.

Prognosis

Chronic biceps tendon/bursa injuries with scar tissue and adhesions respond poorly to treatment, with approximately 25% of such cases returning to athletic use. Early detection of the injury combined with aggressive medical and physical therapy improves the prognosis to 70% return to athletic use.

Etiology and pathophysiology

Direct crushing of the tendon against the humeral tubercles is the most common etiology for biceps brachii damage and concomitant bursitis.

Prevention

This injury is often due to an accident such as a fall or a kick.

Ligament of the dorsal spinous processes

Recognition

History and presenting complaint

Horses with this problem often present with sore or cold backs. They also often resent being saddled or mounted or refuse to jump or to take up a gait, usually the canter. This injury can be seen in any type of equine athlete.[43,44]

Physical examination

Pain on palpation of the affected portion of the dorsal spinous ligament is evident.

Special examination

Radiographs of the dorsal spinous processes may reveal concomitant osteoarthrosis. Diagnostic ultrasonography will reveal enlargement, loss of echogenicity and deterioration of the normal fiber pattern of the affected dorsal spinous ligament.

Treatment and prognosis

Therapy

For general therapy please refer to the section on SDF treatment (pp 415–416).

Horses with dorsal spinous ligament damage may require a prolonged period of exercise such as ponying or walking and trotting on an exerciser before being worked under saddle.

Prognosis

Prognosis is good for return to athletic use.

Ligaments of the tuber sacrale

Recognition

History and presenting complaint

Jumpers are particularly susceptible to this injury. Signs may also develop after a fall, either in work or loose in pasture. Horses are usually presented for evaluation of a 'bump' at the croup (sacroiliac region) or changes in gluteal muscle balance.

Physical examination

Persistent grade 1–3 out of 5 lameness is observed. The tuber sacrale are often uneven when viewed from behind the horse due to concomitant sacroiliac joint subluxation and/or crushing of the tuber sacrum. There is often gluteal wasting of the affected limb.

Special examination

Diagnostic ultrasonography will reveal enlargements, loss of echogenicity and deterioration of fiber pattern of the affected ligament(s).

Treatment and prognosis

See dorsal spinous process ligaments.

Gastrocnemius (achilles) tendinitis

Recognition

History and presenting complaint

Achilles tendon damage is often seen after a fall or after having the hindlimb trapped in a fence or gate.

Physical examination

Persistent grade 1–3 out of 5 lameness is observed. Pain, heat and swelling of the affected portion of the tendon are

palpable. The tarsus will be dropped if sufficient damage of the tendon has occurred.

Special examination

A tibial nerve block will improve the lameness.[45] Diagnostic ultrasound will reveal enlargement, loss of echogenicity and deterioration of fiber pattern. The tendon is seen proximally as two muscular heads, which join at the musculotendinous junction. Just proximal to the tarsus the gastrocnemius tendon twists from its position superficial to the SDF tendon and becomes deep to it.

Treatment and prognosis

Therapy

For general therapy please see the section on SDF tendinitis (pp 415–416). Core lesions, if seen, can be decompressed effectively in the acute stage (less than 2 weeks) using ultrasound guidance.

Prognosis

Prognosis is fair to good for return to athletic use.

Prevention

This is usually an accidental injury.

Digital sheath syndrome

Recognition

The digital sheath is a complex synovial structure[46,47] which surrounds the superficial (SDF) and deep (DDF) flexor tendons from proximal to the fetlock joint distally to midpastern. Normally, the synovium secretes a small amount of fluid which promotes gliding of the flexor tendons around the palmar/plantar aspect of the fetlock joint. With inflammation the sheath can become greatly distended, reaching to midmetacarpus proximally and/or 'herniating' palmar to the SDF tendon on the midline.

History and presenting complaint

Generally, digital sheath (DS) synovitis presents as a cumulative wear and tear type of injury which progresses over time. Horses have often been in hard work for a period of time and progress from a non-painful blemish to a syndrome that causes gradual lameness.

Physical examination

Clinical signs of digital sheath synovitis reflect the degree of inflammation, which is divided into three stages. It is not uncommon for athletic horses to present with mild to moderate effusion of the digital sheaths (stage 1 synovitis) of both

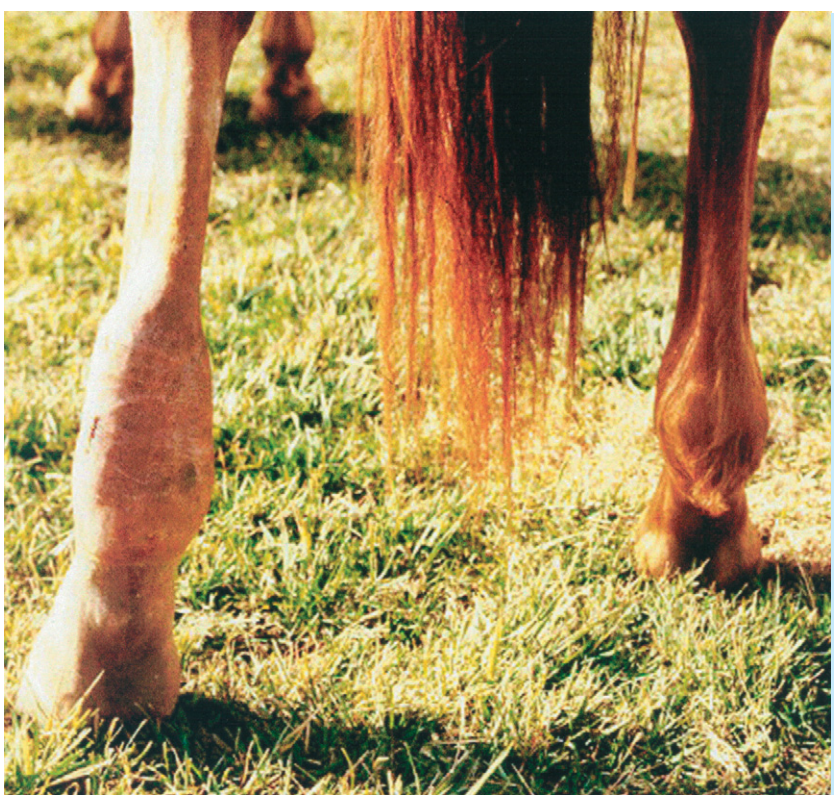

Fig. 20.13
Digital sheath, showing distention of the lateral pouch.

forelimbs, both hindlimbs or all four limbs. Often, sheath distension decreases following exercise. The distension is fluidly fluctuant on palpation. The patient is sound, non-painful to sheath palpation and negative to fetlock flexion. The lay term often used to describe stage 1 DS synovitis is 'wind-puffs'.

If synovitis progresses from the effusive stage to synovial proliferation (stage 2), clinical signs include mild to moderate lameness. This is often first seen as an attempt by the horse to guard the affected sheath by failing to fully extend the fetlock, manifested as a decreased drop in the fetlock during the stance phase of gait in comparison to the opposite fetlock. The digital sheath will feel firm rather than fluid on palpation and one aspect of the sheath, usually the lateral aspect, will be more distended (Fig. 20.13). The horse will be positive to fetlock flexion, as this maneuver compresses the sheath.

If synovitis progresses to stage 3, synovial proliferation and inflammatory product secretion may cause the patient to be severely lame.[48] The horse will be reluctant to place the heels of the foot on the ground and may not tolerate fetlock flexion. The digital sheath will be distended, painful and firm on palpation.

Often, stage 2 and stage 3 digital sheath synovitis are accompanied by damage to either the superficial or deep flexor tendons.[49] This is probably due to the same wear and tear process that caused sheath synovitis. The synovitis advances by prolonged exposure to inflammatory mediators circulating in the sheath, being compressed by synovial proliferation and, finally, due to active pulling on the tendons by adhesions within the sheath. Palmar annular ligament (PAL) desmitis, likely due to chronic stretching of the ligament by the distended digital sheath, may result in a thickened PAL[50] which further compresses the digital sheath, causing a cycle of increasing inflammation, swelling and constriction.

Special examination

Low four-point nerve block will improve/ablate lameness. Ultrasonographic examination of stage 1 synovitis reveals a moderate amount of fluid in the affected sheath(s), with no evidence of synovial proliferation or adhesions between the tendons and sheath walls.

Ultrasonographic examination of stage 2 synovitis will reveal distension of the sheath with fluid and proliferative synovium. Proliferative tissue may also begin to cover the surfaces of the flexor tendons. Ultrasonographic examination of stage 3 synovitis will reveal extensive synovial proliferation, often covering the surfaces of the flexor tendons, and one or more adhesions between the tendons and the sheath wall (Fig. 20.14). At any stage, but particularly in stages 2 and 3, SDF, DDF or PAL pathology may also be observed.

Treatment and prognosis

Therapeutic aims

Inflammation of the digital sheath should be vigorously treated to reduce excessive synovial proliferation and the onset of restrictive scar formation.

Therapy

Treatment of stage 1 synovitis is medical and may consist of 3–4 weeks of rest, anti-inflammatory medication, cold hosing/icing of the affected limb(s), administration of intramuscular PSGAG (more effective for this syndrome than hyaluronic acid) and supplementation with oral glucosamine. Foot balance should be checked and lameness in any other limb should be recognized and treated.

Treatment of stage 2 synovitis includes the above plus injection of the affected sheath with hyaluronic acid[51] (Fig. 20.15), followed by 2–3 weeks of rest (confinement plus

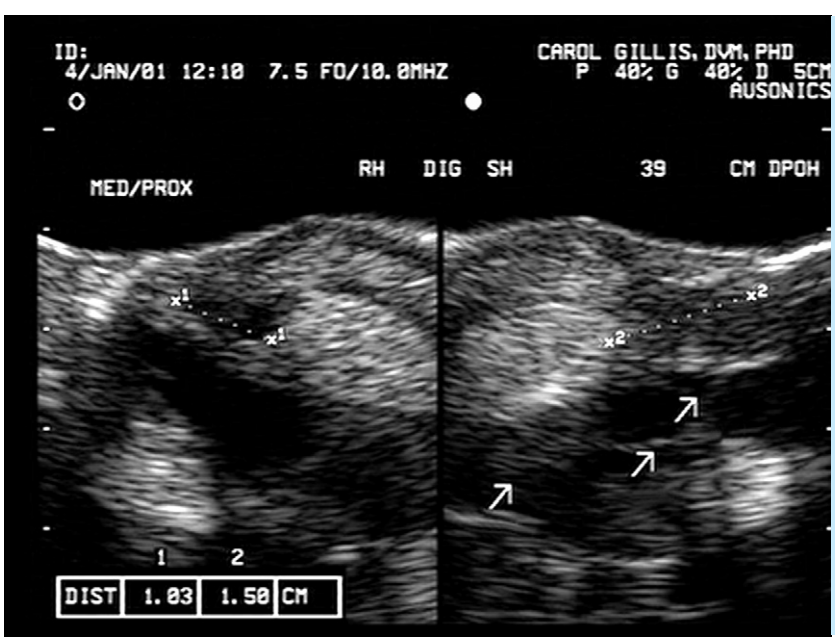

Fig. 20.14
Ultrasound image of DS synovitis with adhesions, as indicated by the arrows in the short-axis (right-hand) view.

Fig. 20.15
Digital sheath injection.

hand-walking). Patients that do not respond promptly and fully to medical treatment require tenoscopy to remove excess proliferative synovial tissue and adhesions. The PAL may be resected[52] tenoscopically at this time to provide relief from compression.

Treatment of stage 3 synovitis requires medical and surgical treatment, as outlined above for stage 2.

Surgical intervention In cases with thickening and constriction of the annular ligament, some portion of the surgery must be designed to relieve the restrictive effects of this structure. Resection of the PAL[53,54] will temporarily interrupt the inflammatory cycle but regrowth of the ligament is inevitable and unless the primary problem of synovitis is corrected, the end result will be a progressively more painful sheath that has distended to meet its new dimensions following PAL resection.

Tenoscopic exploration will detect abnormalities of the tendon sheath, superficial digital flexor tendon, deep digital flexor tendon and intersesamoidean ligament (Fig. 20.16). Proliferative masses can be removed with the assistance of a radiofrequency debrider. Adhesions present between the tendons and the tendon sheath are also debrided.

Paramount to the success of this procedure is the strict adherence to an aggressive postoperative protocol, including medical therapy as outlined above, for a period of weeks followed by a clinical and ultrasonographic re-evaluation.

Prognosis

Prognosis for stage 1 synovitis is good. As long as the horse is in full athletic use, medical treatment may be required to prevent progression to stage 2 synovitis. Prognosis for stage 2 synovitis is good for full athletic work, if appropriate treatment is performed in a timely manner.[52] Prognosis for stage 3 synovitis is fair for full athletic use. Without treatment, these patients may progress to lameness even at a walk.

Etiology and pathophysiology

Either acute direct trauma or overextension of the fetlock can cause hemorrhage into the sheath space that initiates a marked inflammatory reaction. Alternatively, repetitive

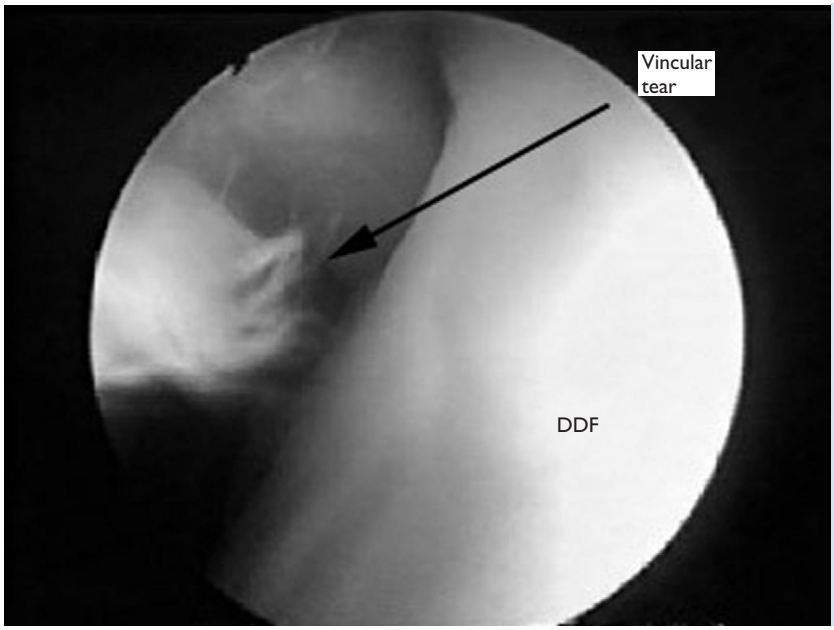

Fig. 20.16
Intratenoscopic photograph showing a tear in the vinculum. (Courtesy of Dr Tom Yarbrough.)

fetlock extension over time results in an ongoing inflammatory process.

CHAPTER 21

Back and pelvis

Leo B. Jeffcott and Kevin K. Haussler

Introduction and historical perspectives

Historical reports of back disorders in horses provide few firm facts from the many lengthy accounts in old farriery and veterinary textbooks. In 1876 Lupton remarked that back injuries 'are among the most common and least understood of equine afflictions'.[1] In those days diagnosis was based simply on clinical observation (Fig. 21.1) and the opinions expressed were many and varied. These early writers were often excellent horsemen and were particularly knowledgeable on aspects of conformation. In relation to the incidence of spinal damage, Youatt believed that the short-backed horse showed less tendency to back problems and could be expected to carry more weight and possess greater endurance, but it did not have much potential for speed.[2] The long-backed horse was built for speed but was much more prone to weakness when ridden. Conformationally correct horses should have a gentle ventral curve immediately behind the withers, followed by a straight line to the lumbar region. An increase in this vertebral curvature (i.e. lordosis, saddle-backed, sway-backed) would increase the tendency to weakness and strain. Dorsal curvature (roach-back), however, was considered to be a more severe defect, which seriously impaired usefulness and performance.

Back problems in horses cause a considerable degree of wastage and lost performance in almost all types of athletic horses. However, reports of their incidence are limited to a survey from general practice in the United Kingdom in the 1960s that showed an incidence of only 0.9% in 6588 horses.[3] This is probably an underestimate and no breakdown of these cases into the specific diagnosis was made, but a later review of 443 horses with back problems did categorize cases further into osseous, soft tissue and miscellaneous disorders.[4] Definitive diagnosis is often difficult due to vague clinical signs and the lack of good pathological reports.[5,6] This has inevitably resulted in widespread controversy engendering many unsubstantiated opinions, which only increase the state of confusion. Much of this controversy has resulted from the general dearth of knowledge of the functional aspects of the equine thoracolumbar spine and scientific studies on the pathogenesis of back problems in horses. It is also clear that many horses perform poorly without an underlying back problem and many other horses perform surprisingly well in spite of one. In recent years there has been an encouraging progression of studies and biomechanical research to improve this situation.[7–12] There is also much more willingness for those involved with traditional methods of clinical medicine to work closely alongside those involved with spinal manipulative therapy and

Fig. 21.1
A test for rick of the back (from reference[1]).

complementary medicine.[13] The purpose of this chapter is to try and combine all these aspects for the benefit and treatment of suspected cases of back pain.

Anatomic and functional considerations

Thoracolumbar vertebral column

Individual vertebrae are connected by an intricate system of ligaments and musculotendinous structures that provide stability while at the same time supporting movement of the vertebral column. The three principal mechanical functions of the vertebral column are:

1. protection of the spinal cord and associated nerve roots (i.e. vertebral arch)
2. providing support for weight bearing and soft tissue attachment (i.e. vertebral body and vertebral processes)
3. maintaining movement for flexibility and locomotion (i.e. articulations, ligaments, and muscles).

The equine thoracolumbar vertebral region consists of an average of 24 individual vertebrae, based on the typical vertebral formula (C7, T18, L6, S5, Cd15–21).[14] Variations in the number of vertebrae within the thoracolumbar vertebral region are common and are often compensated by a reduction or increase in the number of vertebrae in an adjacent vertebral region.

Vertebral motion segment

The structural and functional unit of the vertebral column is the vertebral motion segment. A vertebral motion segment consists of two adjoining vertebrae and interposed soft tissue structures (Fig. 21.2). The typical vertebra is characterized by a vertebral body, vertebral arch and vertebral processes that vary in each vertebral region according to structural and functional demands. The vertebral body is a ventral cylindrical structure covered dorsally by the vertebral arch, which includes bilateral pedicles and laminae. Vertebral processes include one spinous process, two transverse processes and two pairs of cranial and caudal articular processes on each vertebra. Mamillary processes are additional vertebral processes found only in the thoracolumbar region that provide added paraspinal muscle attachment sites. Dorsally, the articular processes create bilateral synovial articulations (i.e. zygapophyseal joints) that provide segmental stability and mobility to the vertebral motion segment. Ventrally, the vertebral bodies and intervertebral disks form fibrocartilaginous joints that also provide segmental vertebral stability and mobility. Additional connecting soft tissues include both short and long spinal ligaments and muscles. The vertebrae, vertebral articulations and ligaments are innervated segmentally by sensory branches of the dorsal rami and recurrent meningeal nerves. These nerves mediate nociception and proprioception within the vertebral column.

The vertebral motion segments of the upper cervical region (i.e. occiput-C1–C2) are a highly mobile, specialized joint complex. The cervical vertebrae have rudimentary spinous processes and characteristic transverse foramina for the passage of vertebral vessels. The thoracic vertebrae are characterized by tall spinous processes (highest at T4–6), costal articulations and an anticlinal vertebra at T16. The lumbar vertebrae have long, horizontally flattened transverse processes and intertransverse joints in the caudal region (L4–S1) that are unique to horses. The sacrum is usually made up of five fused segments and has bilateral sacroiliac joints for articulation with the pelvis. The caudal vertebrae are characterized by progressively rudimentary vertebral arches and vertebral processes.

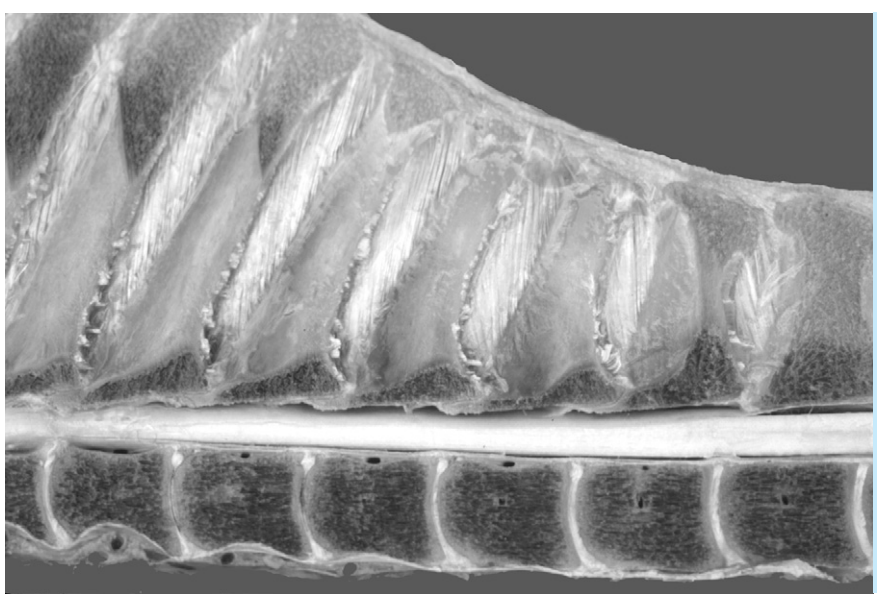

Fig. 21.2
Sagittal section of the thoracic vertebral region (T8–T14) demonstrating osseous vertebral structures and supporting spinal ligaments.

Vertebral body and intervertebral disk

The vertebral bodies form the foundation on which the remaining vertebral structures are placed. The cranial vertebral body is convex in shape and the caudal vertebral body is concave (Fig. 21.2). Therefore, most equine intervertebral joints resemble a ball-and-socket configuration, which provides stability without restricting mobility. Vertebral bodies provide support for weight bearing, connective tissue attachment and muscular attachment sites for the diaphragm and psoas muscles in the lumbar vertebral region. The intervertebral disks connect adjacent vertebral bodies and together are classified as fibrocartilaginous articulations. An intervertebral disk consists of an outer annulus fibrosus and central nucleus pulposus. The nucleus pulposus is rudimentary in the thoracolumbar vertebral regions compared to the cervical and caudal vertebral regions (Fig. 21.2). The dorsal and ventral longitudinal ligaments, and the costovertebral ligaments, provide additional reinforcement to the periphery of the intervertebral disk. The intervertebral disk is active in weight bearing, axial shock absorption and maintaining vertebral flexibility. The outer one-third of the intervertebral disk is innervated by both proprioceptive and nociceptive fibers.

Spinous processes

The spinous processes project dorsally from the vertebral arch and vary in size, shape and orientation in different vertebrae and vertebral regions (Fig. 21.3). The spinous processes function as a series of levers for muscle and ligamentous attachment that provide support and movement to the vertebral column. Spinal extension and rotation are produced by contraction of muscles attached to the spinous processes. The supraspinous ligament stabilizes the apex of the spinous processes and aids in resisting excessive spinal flexion. The spinous processes in the cranial thoracic vertebral region are angled caudally and elongated in the region of T2 to T12 to form the withers. The cranial thoracic vertebral region must resist forces produced by the head, neck and forelimbs, whereas the caudal thoracic and lumbosacral vertebral region has to resist significant forces associated with the rear limbs and locomotion. The divergent spinous processes of the lumbosacral junction produce a wide interspinous space, compared with the adjacent interspinous spaces.[15–17] The lumbosacral spinous process divergence supports an increased range of motion at the lumbosacral junction without the risk of spinous process impingement.

Articular processes

Two pairs of cranial and caudal articular processes arise dorsolaterally from the vertebral arch. An articular surface on the articular processes contributes to the formation of bilateral synovial articulations (i.e. zygapophyseal joints). The articular surfaces in the thoracic vertebral region lie horizontally (i.e. dorsal plane) with the cranial articular surfaces facing dorsally and the caudal articular surfaces facing ventrally. Vertebral motion in the thoracic vertebral region is limited mostly to rotation and lateral flexion. The lumbar vertebral region has articular surfaces that predominantly lie vertically (i.e. sagittal plane). Vertebral motion in the lumbosacral vertebral region is limited mostly to dorsoventral flexion. The articular processes function in support and movement of the vertebral arch. The amplitude and direction of segmental vertebral motion are related to the size, shape and orientation of the articular surfaces and functional status of the articulations.[15,16,18] Regional and overall spinal motion is due to the cumulative effects of small amounts of segmental vertebral motion. The zygapophyseal joint capsule has a dense outer fibrous layer, vascular central layer and an inner layer consisting of the synovial membrane. The zygapophyseal joint capsule is richly innervated with sensory nerve fibers from the medial branch of the dorsal rami of several adjacent nerve roots. Proprioception and nociception are two important neurologic functions of the zygapophyseal joints.[19,20] Multilevel spinal innervation of the zygapophyseal

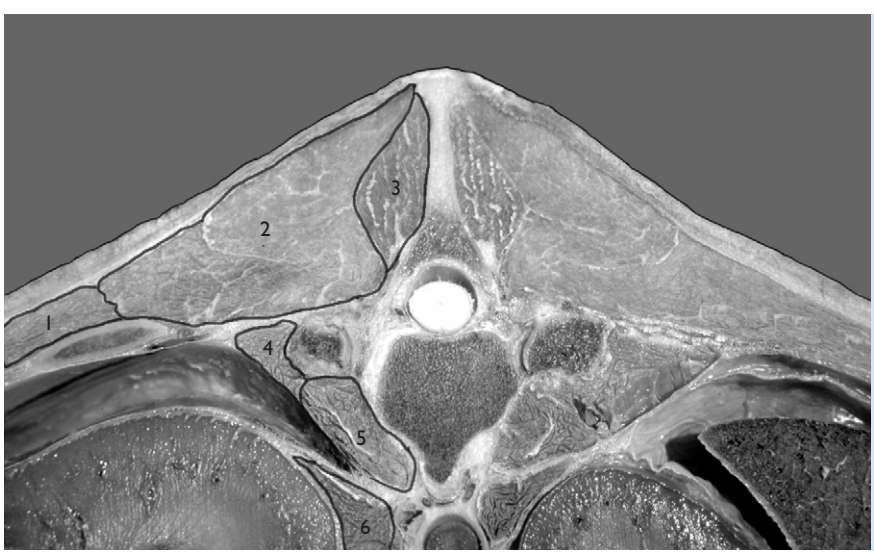

Fig. 21.3

articulation produces non-localized pain patterns, which contribute to the difficulty of identifying and localizing back problems.[21]

Transverse processes

The transverse processes provide support and movement to the vertebral column via muscular and ligamentous attachments. Transverse processes are used as lever arms by the deep spinal muscles to maintain posture and to induce rotation and lateral flexion.[21] In the thoracic region, the transverse processes contain articular surfaces that contribute to the costotransverse articulations. The lumbar vertebral region has elongated, horizontally flattened transverse processes that provide attachment sites for the large dorsal paraspinal muscles and ventral psoas muscles. Species of the genus *Equus* have intertransverse synovial articulations between the transverse processes of the last two or three lumbar vertebrae and at the lumbosacral junction.[15,16] Biomechanically, the intertransverse joints aid in the transfer of propulsive forces from the hindlimbs to the vertebral column and provide resistance to lateral bending and axial rotation of the spine.

Sacroiliac joint

The pelvis articulates with the vertebral column at bilateral sacroiliac articulations, located at the junction between the ventral wing of the ilium and the dorsal wing of the sacrum (Fig. 21.4). Dynamically, the sacroiliac joints aid in locomotion via transfer of hindlimb propulsive forces to the vertebral column.[22] The articular surfaces of the sacroiliac joint are nearly flat and closely apposed to support gliding movements. The sacroiliac joint is usually L-shaped with the convex border directed caudoventrally. The sacroiliac joint capsule is thin and closely follows the margins of the sacroiliac articular cartilage. The sacroiliac joint is supported by three bilateral sets of strong sacroiliac ligaments that act to support weight of the caudal vertebral column. The dorsal sacroiliac ligaments, consisting of a dorsal and lateral portion, connect the tuber sacrale to the sacrum. The interosseous sacroiliac ligaments are the most robust of the sacroiliac ligaments, spanning the space between the ventral wing of the ilium and the dorsal wing of the sacrum. The ventral sacroiliac ligaments connect the ventral wings of the sacrum to the ilium. The sciatic nerve, cranial gluteal nerve and cranial gluteal artery and vein travel through the greater sciatic foramen, immediately ventromedial to the sacroiliac articulation.

Spinal ligaments

A series of long and short spinal ligaments contribute to vertebral column stability. Three separate longitudinal spinal ligaments span the length of the vertebral column and provide regional vertebral stability. The nuchal ligament in the cervical vertebral region continues as the supraspinous ligament in the thoracolumbar vertebral region and joins the tips of the spinous processes. The dorsal longitudinal ligament connects the dorsal vertebral bodies within the vertebral canal and acts to reinforce the intervertebral disk (Fig. 21.2). The ventral longitudinal ligament attaches to the ventral vertebral bodies and blends with fibers of the intervertebral disk. The short spinal ligaments interconnect individual vertebral structures and function to protect the spinal cord and to provide segmental vertebral stability. Interspinous ligaments connect adjacent spinous processes. The ligamenta flava span the space between adjacent vertebral laminae. Specialized costovertebral and costotransverse ligaments provide additional stability to the thoracic vertebral region and ribs. The intertransverse ligaments connect adjacent transverse processes in the lumbar vertebral region and limit lateral flexion. The intervertebral disk can be considered a specialized connective tissue structure that connects adjacent vertebral bodies.

Fig. 21.4
Transverse section at the lumbosacral and sacroiliac articulations. Outline of the muscles represented are: (1) gluteus medius, (2) sacrocaudalis dorsalis, (3) iliopsoas (psoas major and iliacus). The tuber sacrale and the interosseous and ventral sacroiliac ligaments are also shown.

Intrinsic spinal muscles

Muscles that attach only to the axial skeleton are considered intrinsic spinal muscles. The spinal musculature can be categorized into epaxial or hypaxial muscle groups based on their location compared with the transverse processes of the vertebral column. The epaxial muscles lie dorsal to transverse processes, are segmentally innervated by dorsal branches of spinal nerves and produce spinal extension and lateral flexion. Hypaxial muscles lie ventral to transverse processes, are segmentally innervated by ventral branches of spinal nerves and produce spinal flexion and lateral flexion. The thoracolumbar fascia is an aponeurosis that serves as an attachment site for many spinal and proximal limb muscles. The thoracolumbar fascia is strong and attaches to the thoracolumbar spinous processes and the cranial edge of the ilial wing. The largest group of epaxial muscles is organized into three parallel columns. These include (from lateral to medial) the iliocostalis, longissimus and spinalis muscle groups (Fig. 21.3). The iliocostalis muscles are a thin muscle group that attaches to the angle of the ribs and the tips of the lumbar transverse processes. The longissimus muscles are by far the largest and longest group of back muscles. These muscles primarily attach to the dorsal spinous and transverse processes of the thoracolumbar vertebral region and the wing of the ilium and help to support the weight of saddle and rider. The spinalis muscles cover the lateral aspects of spinous processes of the withers and may be compromised by a narrow saddle. The transversospinalis muscle group is the deepest and most medial muscle group (Fig. 21.3) and is largely composed of multifidi muscles in the thoracolumbar vertebral region. The multifidi muscle group is a series of short musculotendinous units that originate from transverse, articular and mamillary processes and insert on adjacent spinous processes. These short muscles span 2–4 vertebrae and are segmentally innervated by dorsal spinal branches.

The epaxial muscles produce spinal extension when activated bilaterally, and lateral flexion and rotation when activated unilaterally. Superficial muscle groups usually span one or more vertebral regions, whereas deep spinal muscles usually only span a few vertebrae.[22] The spinal musculature is important for movement, posture and flexibility. The superficial spinal muscles are usually more dynamic and play a role during regional vertebral motion, energy storage and force redistribution during locomotion.[22] Deep, short spinal muscles have more of a static function and are active in segmental stabilization, proprioception and posture.

Extrinsic spinal muscles

Muscles that have attachments on the proximal limbs and the axial skeleton can be considered extrinsic spinal muscles (or extrinsic limb muscles). The general function of the extrinsic spinal muscles is to induce proximal limb motions required in locomotion or to assist vertebral mobility, depending on whether the vertebral column or limbs are held stationary relative to each other. The shoulder girdle muscles can be categorized into dorsal or ventral muscle groups.[23] The dorsal muscles of the shoulder girdle act to suspend the forelimbs from the neck and trunk. The dorsal shoulder muscles include the brachiocephalicus, omotransversarius, trapezius, rhomboideus, cutaneous trunci and latissimus dorsi. The ventral muscles of the shoulder girdle function in suspending the neck and trunk from the forelimbs. The ventral shoulder muscles include the subclavius, superficial pectoral, deep pectoral and serratus ventralis.

The pelvic girdle muscles are best characterized as cranial-caudal and lateral-medial muscle groups.[23] The cranial muscles of the pelvic girdle function in hindlimb protraction and hip flexion. Muscles in this group include the sartorius, iliopsoas, tensor fasciae latae and rectus femoris. The caudal muscles of the pelvic girdle produce hindlimb retraction and hip extension. Muscles in this group include the biceps femoris, semitendinosus and semimembranosus. The lateral muscles of the pelvic girdle mostly cause hindlimb abduction and include the superficial, middle and deep gluteal muscles. The medial muscles of the pelvic girdle produce hindlimb adduction and include the gracilis, pectineus and adductor muscles.

The hypaxial or sublumbar muscles include the psoas minor, psoas major and iliacus. The psoas minor and psoas major originate on the ventral vertebral column (T16 to L6) and insert on the pelvic inlet and lesser trochanter of the femur, respectively. Together, the psoas major and iliacus form the iliopsoas, the largest flexor of the coxofemoral joint (Fig. 21.4). If the rear limb is stabilized, then the iliopsoas muscle induces flexion of the lumbar spine and pelvic flexion about the sacroiliac articulations.

Diagnostic challenges

Back pain perception

Quantifying the degree of pain in horses and establishing the precise site of pain has always been difficult[24] and horses with back pain are no exception. The situation is further complicated as the major clinical sign recognized in many horses with a back problem is impaired performance and not thoracolumbar pain. On the other hand, many horses apparently perform satisfactorily in spite of some low-grade back pain. To add to this confusion, some horses appear to be naturally sensitive or 'thin-skinned' and resent being groomed or palpated along the back. In these patients, both owners and clinicians can falsely interpret an evasive response to innocuous stimuli as a sign of back pain. Another difficulty in the assessment of back pain involves the condition known as 'cold back' in which there is apparent hypersensitivity over the back with a transient stiffness and ventroflexion (i.e. extension) of the spine as the rider gets into the saddle. There are usually no other demonstrable clinical signs, although in severe cases the horse may buck and rear when first ridden. In some instances the back is roached (i.e. flexed) and the

back muscles are kept rigid. The initial stiffness from being saddled or mounted usually wears off within a few minutes and thereafter no effect on performance is noted. Whether this condition is actually painful, associated with some previous back pain or is merely a matter of temperament is unclear.

Many of the difficulties in clinical diagnosis of back problems would be solved if some meaningful criteria for the assessment of pain and an objective system of quantifying it could be established. In human medicine, back pain is considered to be as much a problem of pain as a problem of the back. The origin of primary back pain is irritation of the dorsal nerve roots and the branches of the spinal nerves. The back, like most tissues of the body, is equipped with a specific system of nerve endings that are particularly sensitive to tissue dysfunction (Fig. 21.5). Nociceptive receptors are represented in the back by plexiform and freely ending arrangements of unmyelinated nerve fibers. Nociceptive fibers are distributed throughout the skin and subcutaneous tissues, adipose tissues, fasciae and ligaments, periosteum, dura mater, adventitia of blood vessels and fibrous capsules of interneural articulations and sacroiliac joints. In normal circumstances this receptor system is relatively inactive but it is activated when chemical, mechanical or other damaging factors are applied to the tissues containing the unmyelinated nerve endings. Primary back pain therefore results from trauma or irritation of these nociceptive receptor nerve endings. Various other pain syndromes are recognized in man and include secondary, referred and psychosomatic backache, but their importance in the horse is unproven as yet.

Another important factor to be considered is the marked variation in response to pain. Even in humans a meaningful measurement of 'pain threshold' is unrealistic as patients can vary in the intensity of their experience of pain from day to day and even at different times during the day. In horses, temperament is felt to be an important contributory factor. It is suggested that the lowered performance is sometimes due to the horse attempting to 'save its back' even though the clinical signs of pain have abated some time previously. Some credence has been given to this idea by the induction of back pain in trotting horses.[25] Pain was induced by multiple injections of concentrated lactic acid into the left longissimus dorsi muscle. The effect was local pain, stiffness and a noticeable reduction in performance capacity as analyzed by high-speed cinematography on a treadmill. The principal sign of induced back pain in these horses was not lameness, but stiffness and reduced competitive performance.

Lack of specific clinical signs

The most common reason for presentation of a back problem is for poor performance rather than overt back pain. It is not surprising, therefore, that the clinical signs involved will be many and varied and often not specifically related to a pathoanatomic site in the thoracolumbar spine.[26] For these reasons each potential back case should be viewed as a diagnostic challenge and should receive as holistic approach to both diagnosis and treatment as possible.[6] A definitive diagnosis is more often made by the elimination of other differential diagnoses rather than by identification of specific clinical signs related to spinal pathology.[27]

Difficulties of palpating the anatomical structures involved

Many of the lesions associated with back problems involve osseous structures of the thoracolumbar spine that are difficult, if not impossible, to palpate effectively (e.g. vertebral bodies, articular and transverse processes). In the thoracolumbar spine it is only possible to palpate the small apexes of the dorsal spinous processes, although this will vary to some extent with body conditioning and the presence or amount of longissimus muscle atrophy. Locating the site of pain in the back muscles is also difficult as typical palpation procedures may precipitate spasm or contraction of the entire longissimus muscle. The longissimus muscle runs the entire length of the back from its origin at the caudal cervical spine to the insertion on the wing of ilium and sacral spinous processes. The sacroiliac and lumbosacral joints are also

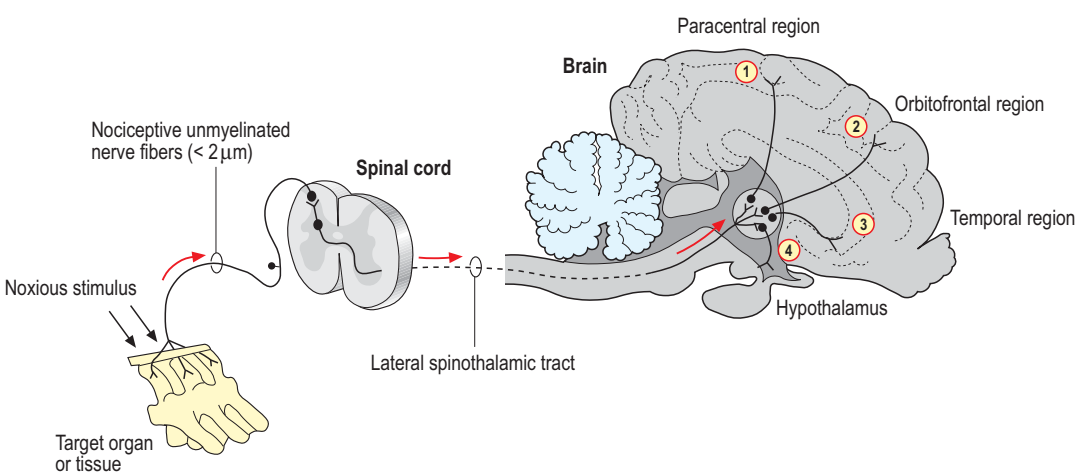

Fig. 21.5 Pain pathways associated with the thoracolumbar spine.

virtually impossible to palpate; the nearest one can get is by rectal palpation. The supraspinous ligament and a portion of the dorsal sacroiliac ligaments are readily palpable, but unfortunately other vertebral or pelvic ligaments (e.g. interspinous, ventral sacroiliac, etc.) are not accessible.

Dearth of appropriate pathological studies

There have been no systematic pathological studies on a large series of back cases in horses. There have been a number of studies on congential deformities[28,29] and reports on diskospondylitis.[30,31] Some investigations on acute and chronic sacroiliac disease have been reported.[32,33] Much has been written about the clinical and surgical treatment of over-riding or impinged dorsal spinous processes (i.e. kissing spines),[34] but very little research has been done on its etiopathogenesis. The widespread use of ultrasonography to diagnose soft tissue injuries of the epaxial structures has dramatically increased the ability to diagnose desmitis, but no pathological studies have been completed to confirm these clinical findings.[35,36]

Box 21.1 Distribution of the general categories of chronic back problems (1992–97).

Total number of horses	268
Primary back problem	268
Secondary back problem	105
Tertiary back problem	32
Total diagnoses	395

Frequency of multiple lesions at multiple sites

Many back problems in horses are associated with chronic or long-standing injuries. It is also common for there to be more than one spinal lesion that contributes to the clinical signs and poor performance. A breakdown of diagnoses of one of the authors' cases (LBJ) from 1992 to 1997 shows a total of 395 diagnoses made from 268 cases presented for examination of the back to a referral clinic (Box 21.1). It is particularly common for cases of over-riding or impinged dorsal spinous processes to be associated with injury of the supraspinous ligament, sacroiliac disease or low-grade hock

Table 21.1 Differential diagnoses to consider for a horse with potential back problems

Type of back problem	General category	Specific lesion or problem
Primary back problem	Soft tissue injury	Longissimus muscle strain
		Supraspinous ligament sprain or desmitits
		Dorsal sacroiliac ligament sprain or desmitits
		Exertional rhabdomyolysis (tying up)
		Non-specific soft tissue injury
	Osseous injury	Conformational or developmental abnormality
		Over-riding or impinged dorsal spinous processes
		Osteoarthritis (e.g. articular processes)
		Vertebral fracture
		Spondylosis
		Diskospondylitis
		Spinal neoplasia (primary and secondary)
	Neurologic disorders	Equine protozoal myeloencephalitis (EPM)
		Equine degenerative myeloencephalopathy (EDM)
		Equine herpesvirus myeloencephalitis (EVH–1)
		Equine motor neuron disease (EMND)
	Tack associated	Poor saddle fit or excessive pressure
	Idiopathic	No clinical abnormalities detected
Secondary back problem		Hindlimb lameness (e.g. spavin)
		Forelimb lameness
		Neck problem (e.g. stenotic myelopathy)
		Acute sacroiliac injury
		Chronic sacroiliac disease
		Pelvic fracture
Presumed back problem		Bad temperament
		Lack of ability (rider or horse)
		Lack of fitness
		Improper tack fit or use
		Dental problems

lameness. Therefore confirmation of such secondary lesions can have important implications for the management and prognosis of horses with primary back problems.

Types of back problems

A serious stumbling block to progress in the diagnosis and treatment of equine back problems is the wide range of opinions that exist. This is true not only within the veterinary profession, but between veterinarians and physical therapists, horse owners and trainers. The lack of authenticated reports and specific studies in this field makes it impossible to set standards for definitive diagnosis and therefore clear guidelines for treatment. The primary clinical sign of back problems in horses is a loss or reduction in performance, whatever the underlying pathogenesis; other clinical signs may be more difficult to precisely define.

Opinions vary as to whether horses genuinely suffer from back problems at all or whether the signs exhibited are referable to damage elsewhere in the skeleton. In our experience genuine back problems do occur, but in a variety of forms (Table 21.1). First, there are those with identifiable lesions in the thoracolumbar spine or epaxial structures (i.e. primary back problems). A second important category are those due to secondary back problems that occur as a result of the pressure or strain exerted from lesions in the appendicular or axial skeleton (i.e. particularly fore- or hindlimb lameness). Finally, there is a category of apparent or alleged back problems which, despite popular opinion, have limited anatomic or pathophysiologic evidence to support their occurrence (Table 21.2). This group of 'back problems' forms the basis of much controversy between veterinarians and other professionals (e.g. chiropractors) or non-professionals (e.g. lay practitioners). These difficulties are exacerbated by the fact that many horses suffer low-grade and chronic lesions. Malalignment or displacement of the caudal thoracic or lumbar dorsal spinal processes is reputed to be a common cause of back trouble in horses.[37] One or more spinous summits are said to become laterally displaced (i.e. 'out of place') and these can apparently be replaced by sharp pressure at the appropriate site (i.e. 'put back into place'). From an anatomic point of view this claim is not acceptable; these structures are not moveable like this either in life or at post-mortem. In spite of the tendency for intervertebral disks to degenerate with age in the thoracolumbar spine, they do not appear to cause any clinical signs similar to those seen so commonly in humans and in dogs. Nerve 'pinching' and peripheral nerve lesions are often claimed to be important causes of back problems, but as yet there has been no scientific evidence to substantiate this belief in horses.

Table 21.2 Conditions alleged to cause back problems in horses for which there is currently no definitive scientific evidence

General category	Specific lesion or problem
Vertebral subluxation	Subluxation of thoracolumbar vertebral bodies or articular processes Misalignment of thoracolumbar dorsal spinous processes
Intervertebral disk injury	Intervertebral disk prolapse or herniation
Peripheral neuropathy	Compromise of thoracolumbar spinal nerves at the intervertebral foramen

Frequency of spontaneous recovery

Many of the problems causing poor performance in horses are long-standing (i.e. many weeks or months in duration) and there is a tendency for these cases to recover spontaneously. In a survey of cases followed over 2 years, a 65% recovery rate was reported irrespective of the diagnosis and the treatment or management regime.[5] The prevalence of spontaneous recovery therefore can hamper elucidation of diagnosis and make evaluation of treatment regimes difficult.

Relationship of back pain to lameness

Lameness is not a typical feature of horses suffering primary back problems. However, secondary back pain is often associated with lameness as the underlying condition causing poor performance. Most primary back cases exhibit only low-grade hindlimb lameness, which is often bilateral and most commonly associated with hock injury. A study in which back pain was induced using lactic acid injections into the longissimus muscles did not produce any signs of hindlimb lameness.[25]

Causes of sacroiliac joint pain or injury have been postulated to be the result of sacroiliac or lumbosacral osteoarthritis, sacroiliac desmitis or sprain, sacroiliac subluxation or luxation, pelvic stress fractures, complete ilial wing fractures or sacral fractures.[38] Additional differential diagnoses include thrombosis of caudal aorta or iliac arteries, exertional rhabdomyolysis, trochanteric bursitis and impinged dorsal spinous processes in the lumbar vertebral region.[39] Horses with presumed thoracolumbar vertebral problems may also have concurrent chronic sacroiliac joint injuries. In a report on 443 horses with back problems, chronic sacroiliac joint problems were identified in 15%.[4] Clinical signs of lower hindlimb lameness may overlap and mimic signs of presumed sacroiliac joint pathology. It is important that a thorough and complete lower limb lameness evaluation is completed prior to or in conjunction with a proximal hindlimb or sacroiliac joint work-up.

Diagnostic protocol to assess back problems

A standardized protocol should be used to systematically examine horses with potential back problems (Box 21.2).

Box 21.2 Diagnostic protocol for the evaluation of horses with potential back problems

Case history
- Signalment and use of the horse
- Onset and duration of clinical signs
- Response to treatment, particularly NSAIDs and manipulation
- Temperament and ability to perform
- Assessment of management and training routine
- Evaluation of predisposing factors
- Experience of the rider

Clinical examination
- Visual inspection of conformation, posture and musculoskeletal symmetry
- Gait evaluation: in hand, lunged, ridden or driven
- Evaluation of concurrent lameness
- Neurologic evaluation
- Postexercise palpation and manipulation
- Soft tissue and osseous palpation
- Regional and segmental joint manipulation
- Rectal palpation
- Examination of tack, particularly saddle fit

Diagnostic imaging
- Radiographic examination – osseous pathology
  Standing: lateral view of the thoracolumbar (T2–L4) and sacrocaudal (S2–Cd4) regions
  General anesthesia: ventrodorsal view of the lumbosacral (L4–S5) region
- Ultrasonography – articular or spinous processes, supraspinous or sacroiliac ligament desmitis
- Nuclear scintigraphy – active inflammation or bone turnover
- Thermography – back or gluteal muscle injury, altered vasomotor tone
- Linear tomography – sacroiliac joint pathology

Laboratory examination
- Hematology
- Biochemistry: muscle-derived enzymes (AST and CK), before and after exercise test
- Serology: vitamin E and selenium levels, viral isolation
- Cerebrospinal fluid analysis
- Muscle biopsy

Additional diagnostic aids
- Diagnostic injections of interspinous spaces, articular processes or sacroiliac joint
- Electrical muscle stimulation
- Therapeutic trial of NSAIDs – effect on performance
- 'Slap test' for evidence of cervical vertebral stenosis causing hindlimb ataxia

History

The value of obtaining a thorough clinical history cannot be overestimated, as the clinical signs and behavioral changes of thoracolumbar disorders are many and varied.[27] Details dating back to the time when the owner first acquired the horse are extremely helpful in deciding whether or not one is dealing with a genuine back problem. In this regard, information on management, tack and performance should always be sought.

Acute versus chronic onset

The history in acute back injuries is usually straightforward as some traumatic incident will have been noticed. For example, young horses with multiple fractures of the dorsal spinous processes from T2 to T10 often have a history of rearing up and falling over backwards onto the withers. Most acute cases involve soft tissue injuries and strain of the longissimus muscles is particularly common.

Chronic problems are commonly encountered when no obvious initiating incident is recognized. One consistent feature of a long-standing back problem is an alteration in the horse's behavior or temperament. This may be insidious in onset and it may take some time before the owner fully appreciates that the change has taken place (e.g. a normally good-natured horse becomes sour and rather fractious to handle or there may be a loss of enthusiasm to work). There also seems to be a correlation between nervous or temperamental horses and the presence of back problems.

Use of the horse

There also seems to be an association with the type of back injury and the type of work the horse is involved in. Jeffcott reported that the differences in incidence of specific back problems varied quite noticeably according to whether the horse jumped at speed, jumped competitively or was not used for jumping at all.[5] Acute sacroiliac strain or subluxation was more prevalent in horses jumping at speed, whereas impinged or over-riding dorsal spinous processes were most common in showjumpers. The incidence of soft tissue damage was much the same in both of these groups and age was not nearly such an important factor in equine back disorders as it is in humans. Spondylosis appeared more frequently in mares, whereas over-riding dorsal spinous processes was most often seen in short-backed Thoroughbred geldings.

Sacroiliac pain is common in dressage horses and causes impaired performance, usually without lameness. Standardbred harness racing also shows a high incidence of sacroiliac and hindquarters problems but over-riding or impinged spinous processes are rare. Back injuries in reining, barrel racing and rodeo horses are not common but are usually associated with muscle injuries. In endurance horses back problems resulting from long periods of extreme exercise and saddle-induced injuries are common.

Concurrent lameness and loss of performance

Positive clinical signs at exercise may include uni- or bilateral hindlimb lameness, a loss of enthusiasm for work or an inability to stride out at fast paces. Owners will often mention a stiffness in the hindlimb action and a loss of suppleness of the back when ridden, although the action when loose in the paddock appears satisfactory. Jumping with a fixed hollow back is frequently encountered or there may well be a reluctance to jump, particularly combination-type fences. The horse may also lose its fluidity and timing during jumping and

become tense, tending to rush over the fences. Signs of head shaking and an increased tendency for tail swishing are other occasional features found in horses with back problems.

Medication and treatment

Since many back problems are chronic in nature, the horse may well have received multiple treatments before your examination. It is therefore important to know what type of medications or therapy have been tried and whether or not they provided any improvement. A clinical trial of phenylbutazone (2 g, p.o., b.i.d. for 4–5 days) is often used to assess the inflammatory component of a back problem. The use of non-steroidal anti-inflammatory drugs (NSAIDs) will often produce an improvement in osseous or articular pathologies although this may be partial and short-lived. A similar clinical trial of methocarbamol (15–44 mg/kg, p.o., s.i.d.) will help some horses with muscle-related back soreness or hypertonicity. Inquiries into the response to rest or changes in activities, such as cross-training, are often helpful in assessing the mechanism of action of the back problem. Some horses, like humans, appear to get burnt out when asked to do repetitive or monotonous disciplines without any changes in routine. Many forms of physiotherapy or spinal manipulative treatment may give temporary improvement, but a lasting success is unlikely without establishing a definitive diagnosis of the back problem.

Management and training ability

It is common for owners to blame poor competitive ability on a problem in the thoracolumbar spine when it is simply due to poor schooling or equitation. It is now well recognized that the most consistent feature in a back problem is a loss of performance, particularly in the ability to jump effectively. Acute soreness in the back muscles is often associated with falling or some other traumatic incident, but a history of obvious pain in the thoracolumbar spine is not always reported, particularly in long-standing cases. Horses with severe back pain may have difficulty in standing to urinate or defecate or there may be a reluctance to lie down or to roll. There may also be resentment to placement of a blanket or to grooming over the loins and hindquarters. In some cases the farrier may note resentment to having a hindlimb picked up or difficulty in standing while being shod.

A history of resentment to any weight on the horse's back is sometimes reported with a tendency to collapse behind when ridden. Saddling up may become a problem, particularly when the girth is tightened. The horse may buck when first mounted, although this is usually due to temperament rather than back pain. The owner may also note reluctance to move backwards or reining back when being ridden. Dramatic signs of bucking and rearing are not usually associated with acute back injuries as it is too painful for the horse to fully flex or extend the spine.

Query into the size and the time spent in stalls, paddocks, or turnout in pasture is indicated for any horse with back problems. In humans, a primary contributing factor for recurrent back problems is bed rest and inactivity.[40] Horses that are stalled for the majority of the day or large portions of the year do not have the opportunity to maintain back flexibility, which may contribute to back stiffness and dysfunction. In addition, horses that are turned out in paddocks with knee-deep mud, large rocks, poor footing or steep hills may aggravate pre-existing back problems.

Rider ability

Equestrian competition involves two athletes – the horse and the rider. There is no question that poor riding can either predispose to a back problem or exacerbate an existing one. Inexperienced or poor riders may blame the poor performance of their horse on a back problem when in fact the blame lies with them. It is also crucial that the saddle used not only fits but is also appropriate for the type of work or competition being undertaken.

Predisposing factors

The conformation and intended use of the horse can have an important bearing on the injury involved. For example, specific spinal malformations (e.g. lordosis and scoliosis) tend to predispose to injury through the inherent weakness of the thoracolumbar spine.[5] These conditions place extra strain on the epaxial muscles of the back that can lead to recurrent soft tissue injuries. The majority of horses do not have severe gross deformities, but conformational defects are common. Horses which are short-backed with restricted flexibility of the spine tend to exhibit more vertebral lesions than the longer backed horses, which have relatively more suppleness and seem to be more prone to muscular or ligamentous strain. Large-framed horses with comparatively weak hindquarters appear to be more susceptible to sacroiliac problems.

Age and gender of the horse are not nearly as important as predisposing factors as they are in humans. The highest incidence of back problems in horses is during middle age, 5–10 years of age,[4] although older horses, like elderly humans, are susceptible to loss of vertebral column flexibility, joint degeneration and loss of muscle strength. Aged horses also have increased healing times and increased chances of having chronic conditions or abnormal musculoskeletal compensations from prior injuries.

Management problems

There are a wide range of management issues that may lead either to a back problem or a suspected one from poor performance. Many of these issues may be due to inexperience or ignorance by the owner and result in inappropriate management, producing signs suggestive of back pain.

Temperament

Horses with an excitable temperament seem to be more prone to back-related problems. This may simply be due to low pain threshold or hypersensitivity, but hyperexcitability often results in excessive tension or spasm of the back muscles. This in

turn reduces spinal flexibility and causes impaired impulsion from the hindquarters, which is seen clinically as poor hindlimb action and performance. In some instances these horses become uncontrollable and will buck and kick violently rather than settle down to exercise properly. A careful examination is required in these horses to be confident there is no underlying spinal pathology or pathoanatomic explanation for the perceived avoidance behavior suggestive of back pain. In addition to employing diagnostic imaging, a short course of analgesics (e.g. NSAIDs) is useful as some improvement would be expected if any musculoskeletal inflammation or injury exists.

Cold back

The signs of a cold back are usually exhibited when the saddle is put on, the girth tightened or as the rider mounts. The horse will then dip or roach its back and keep it very stiff as it moves off. In most cases these signs disappear quickly and within a few minutes the horse's performance is satisfactory. There is no doubt that horses with a cold back worry owners a great deal. In our experience, many of these cases are not associated with underlying pathological findings and are therefore thought to be temperamental or behavioral in origin. There are many different ways to manage these horses, including using saddle pads, warming the horse up before saddling (e.g. lungeing) or medicating mares with estrogen.

Mares in season

Owners sometimes report that mares in estrus have associated back pain and poor performance. It is often difficult to substantiate these claims, although some mares do improve during the winter or if medicated with estrus-suppressive drugs (e.g. altrenogest). Rectal palpation and evaluation of abnormal ovarian structures are indicated in any mare with recurrent or refractory back problems.

Schooling and work regime

Failure to keep a horse properly fit for its purpose may lead to fatigue or muscle strain. Horses can be bored with a dull work schedule and become soured or reluctant to work. This can easily be misinterpreted as poor performance related to a back problem.

Dental problems and bitting

General management of the teeth is part of good equine husbandry. Any problem in the mouth, from sharp teeth to an inappropriate bit, can lead to evasion when working. Affected horses often have a raised head carriage, tension or stiffness of the back muscles and poor hindlimb impulsion.

Inspection

Visual inspection is often the most important initial aspect of examining horses with back problems. The general temperament and behavior are evaluated for signs of pain or discomfort. Horses with back problems often have a sudden change in behavior and become easily irritated by previously innocuous stimuli. Pinning the ears, swishing the tail, refusal to move or exaggerated movements away from everyday objects (e.g. curry comb or saddle pad) are signs of changes in behavior.

Evaluation continues with observation of the patient from a distance while turned loose in the stall or paddock while assessing the use and co-ordination of the limbs and trunk. The exam is focused on evaluating the dynamic characteristics of the musculoskeletal system. Owners may report that the head or neck is carried in an abnormal position, the trunk is held rigid or the horse refuses to move or bucks when asked to go forward. The horse should be able to readily raise and lower its head and neck and bend the trunk to either side. Neck injuries can present as the inability to lower the head

Fig. 21.6
Examination of the horse's back while restrained in stocks. The clinician uses a set of steps to facilitate palpation and manipulation of the thoracolumbar spine.

and neck to graze or, just as common, the consistent inability to raise the head and neck above a certain level. Both instances often have a history of substantial head or neck trauma associated with getting the head or neck trapped in a fence or pulling back or flipping over in the cross-ties. It is important to note the general body conditioning of the horse and to differentiate poor condition (i.e. cachexia) from specific wastage of the longissimus, gluteal and thigh musculature. The presence of any lumps, scars, saddle marks on the back or any undue curvature of the spine must also be noted as they may have some bearing on the underlying condition.

A more detailed examination of the back is best carried out with the horse restrained in stocks (Fig. 21.6). However, it is important that the horse is not stressed or tense, as this will make assessment of back pain even more difficult. If the horse resents the stocks it is better to carry out the examination in the stable. For in-hand evaluation, the horse should be standing quietly and comfortably with all four limbs on a firm, level surface. The horse is then evaluated for the static characteristics of the musculoskeletal system, which include conformation, posture and muscular and osseous symmetry.

Conformation

Conformation is defined as the static or structural relationship of body segments, whereas postural analysis involves the dynamic or functional assessment within and between body regions. Vertebral column conformation is evaluated with special attention to neck development, height and shape of the withers, length of the trunk relative to the height and osseous pelvic symmetry. Conformationally, it is thought that short-backed horses have a higher incidence of osseous disorders whereas long-backed horses are more prone to soft tissue injuries.[6]

Posture

The posture is evaluated for head and neck carriage, development and symmetry of the trunk, tail carriage and a preferred or shifting stance. Alterations in trunk posture include lordosis (sway-back), kyphosis (roach-back) and scoliosis. Abnormal spinal curvatures are often readily visualized and are common primary presenting complaints. Altered spinal posture has both structural and functional etiologies that can often be differentiated based on history, onset and duration of the condition. Congenital vertebral malformations often produce structural changes in the trunk conformation, whereas developmental injuries produce functional changes in the trunk posture. In adult horses, acute changes in spinal curvatures are often functional adaptations to back pain or muscle imbalances. Correction of the underlying problem often returns the trunk to its original posture. Excessive lordosis is often an age-related change in trunk posture and may be improved with induced trunk elevation (i.e. flexion) and abdominal muscle-strengthening exercises. Horses with sacropelvic injuries will often carry their tail off to one side, lack tail tone or movement or have an abnormal tail set.

Muscular symmetry

The pectoral region, dorsal scapular and wither region, epaxial and gluteal muscles are carefully evaluated for abnormal muscle development and left-to-right asymmetries. This is a crucial part of the examination and needs to be carried out in as objective a fashion as possible. Muscular asymmetries are often due to disuse or neurogenic atrophy.[27] Alterations in the pectoral or pelvic girdle muscles need to be localized to the affected muscles, to aid in the differentiation of a primary lower limb, upper limb or vertebral column dysfunction. Localized or segmental muscle atrophy of the epaxial muscles may be due to vertebral segment dysfunction or a consequence of poor saddle fit. Generalized back muscle atrophy needs to be differentiated from lack of muscle development (i.e. poor conditioning) and disuse atrophy associated with chronic hindlimb lameness. Neurologic diseases that produce local or regional muscle atrophy (e.g. equine protozoal myeloencephalitis) need to be ruled out in horses that present with back problems and gluteal muscle asymmetry. It is unwise to assume that instances of asymmetric hindquarters or a 'hunter's bump' are caused by sacroiliac damage.

Osseous symmetry

The dorsal midline of the back is viewed from above (i.e. by standing on a mounting block behind the horse) with the

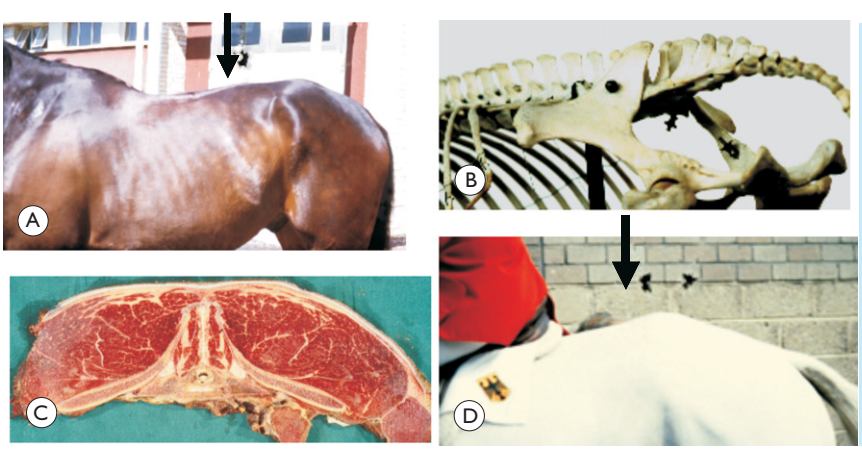

Fig. 21.7
Photograph of a hunters' bump and associated muscle wastage in the lumbar and gluteal regions. (A) Five-year-old Thoroughbred gelding with prominent lumbar spinous processes. (B) Horse's skeleton showing the pelvic and lumbosacral region with the lumbar and sacral spinous processes. (C) Transverse section of the quarters showing the wings of ilium and normal musculature of the region. (D) Fourteen-year-old showjumper with prominent tuber sacrale and poor muscling of quarters.

horse standing squarely on all four limbs to see if the back is straight and evenly developed bilaterally. Any lateral curvature of the spine is suggestive of a degree of muscle spasm on one side (i.e. spastic scoliosis). The presence of a so-called 'hunter's bump' may be seen in some horses although it is not necessarily associated with overt clinical signs of a back problem. This feature is associated with a prominence of the tuber sacrale due to atrophy of the longissimus and gluteal muscles (Fig. 21.7). Changes in the height of the tuber sacrale should be assessed relative to the apex of the second sacral spinous process (S2). Visual acuity is high and even slight (<5 mm) deviations can be perceived. Confirmation of pelvic bone asymmetry can also be performed by palpating the main skeletal features (i.e. tuber sacrale, tuber coxae and tuber ischii) while standing directly behind the horse or by getting two assistants to identify the osseous landmarks for left and right comparisons.

The following guidelines are helpful.

- Unilateral gluteal muscle atrophy on one hindquarter without pelvic bone malalignment: suspect hindlimb lameness (hock or stifle) or acetabular damage.
- Elevation of one tuber sacrale with or without gluteal muscle atrophy: suspect thickening and damage to dorsal sacroiliac ligament or stress fracture of wing of ilium on opposite side (i.e. lowered quarter).
- Lowering of tuber sacrale with muscle atrophy and lowering of the ipsilateral tuber coxae: suspect ipsilateral chronic sacroiliac disease or ipsilateral complete ilial wing fracture.
- Lowering of tuber coxae without lowering of tuber sacrale or tuber ischii: suspect fracture of the tuber coxae.
- Lowering of tuber ischii without deviation of tuber sacrale or tuber coxae: suspect fracture of tuber ischii.

Evaluation of tack fit and use

Saddle fit

A frequent cause of back discomfort can be either an inappropriate saddle used or the saddle not fitting properly. Most poorly fitting saddles produce pressure or pinching over the caudal withers region, hence the appearance of white hairs in the midline. Horses change shape, particularly the contour of the back, when they are out of work (i.e. deconditioned) or if they have an increase in bodyweight. Many saddle-fitting techniques provide a static assessment of the fit of the saddle to the shape and contour of the withers and back. Unfortunately, saddles do not come in a wide variety of sizes for individual fit and comfort, like clothes or shoes for humans. Most horses have to conform to only a few different tree widths and saddle types. Ideally, the saddle should fit comfortably and provide as large an area of contact as possible to help to distribute the rider's weight across the withers and back musculature. Computerized pressure pads help to provide both a static and dynamic assessment of saddle fit, pad thickness and placement, rider influences and changes in pressure associated with different gaits.

Assessment of saddle fit begins with checking the tree for straightness, symmetry and intact bars. The panels are evaluated for left-to-right symmetry and any lumps or depressions that might contribute to uneven pressure. The gullet should be 2–3 fingers wide to provide clearance for the dorsal spinous processes and to provide uniform weight distribution on the panels. The best saddles have wide panels that provide maximal weight distribution of the rider over the thoracolumbar epaxial musculature. Deep palpation of the entire fleece surface of the Western saddle should be done to identify any sharp points from nails or loose conchos.

The owner is asked to place only the saddle, without any pads, on the horse's back in the usual position. The analogy of properly fitting shoes (i.e. saddle) and the appropriate socks (i.e. saddle pad) to your feet works well for assessing saddle fit in horses. The chances are that if the shoe does not fit your foot then adding socks will not, in most instances, make the shoe fit any better. Optimally, there should be 2–3 fingers width of dorsal clearance between the pommel at the front of the saddle and the spinous processes of the withers. If there is less clearance, then the additional weight of the rider in the saddle will most likely reduce the space and cause direct contact and dorsal wear of the pommel on the withers. Greater than three fingers width of clearance is indicative of too narrow a tree that will cause increased lateral pressure on the withers. The rider may also feel unstable in the saddle due to an elevated center of gravity relative to the horse.

Most saddles are positioned with the front panels over the caudal border of the scapula. During locomotion, the scapula normally rotates caudally as the forelimb is fully protracted. If the panels are not flared outward slightly to accommodate the scapula, then the scapula cannot rotate caudally during limb protraction. This results in a shortened stride of the forelimbs. This is a common fault of many Western saddles with rigid, non-flared front panels. The contact between the front panel and the caudal scapula should be constant and uniform. An analogy of the desired pressure is the contact felt with your hand as it slides between the seat of the chair and the bottom of your thigh when you are sitting down. Saddles that are too wide will have increased pressure and contact at the dorsal withers, but the bottom of the panel will gape and protrude away from the lateral scapula. Saddles with too narrow a tree will have severe focal pressure on the dorsal scapular cartilage and you will not be able to fit your hand between the saddle and the scapula, even without the weight of the rider in the saddle. A simple correction on most horses is to slide the saddle back 0.5 to 1″ off the dorsal scapula. The seat should remain level to maintain rider comfort and to prevent unnecessary cranial or caudal displacements of the rider.

Saddle pads

The use of extraneous saddle pads or wedges is often a sign of potential saddle fit problems. When it comes to saddle pads, less is often better. The saddle pad should be tented up into the gullet of the saddle so that it provides clearance over the withers and dorsal spinous processes. Unfortunately, gel pads

and other specialty pads often do not extend to the ventral edge of the front panel and cause a step defect and concentration of forces at the edge of the pad, which usually occurs directly over the caudal border of the scapula. Properly fitting saddles and pads can be evaluated by the dirt or sweat marks present on the saddle pad. Proper fit is identified by the presence of a symmetric or butterfly-shaped dirt pattern, indicative of uniform panel contact over the dorsum of the withers and back. Asymmetric, clean or dry spots on the saddle pad suggest bridging or uneven saddle contact. Blankets, if not fit properly, can also cause severe wear injuries over the withers.

Restraint devices

Evaluation of proper tack fit and use requires that the horse and rider are evaluated while participating in their specific equestrian activities. Harness racing utilizes a plethora of restraint devices, such as stickers, overchecks and hobbles, that need to be assessed as potential contributors to back problems. Additional tack that needs to be evaluated is the appropriate use and fit of the noseband or cavesson, standing or running martingales, draw reins and the chambon during lungeing exercises. Most of these devices are used to correct altered body positioning or use associated with pain or avoidance, inexperience, inability or the induction of artificial gaits. If horses are sound and have good flexibility and strength, then most of these devices are unnecessary.

Gait evaluation

A careful examination at exercise is an important part of the clinical assessment of a horse with a potential back problem. Gait analysis for back problems focuses on evaluating regional vertebral mobility and pelvic motion symmetry, in addition to the typical lameness assessment. Gait analysis may help to rule out lower limb disorders and rule in vertebral dysfunction although limb lameness has been reported in about 85% of horses with back problems.[41] Motion asymmetries, restricted vertebral or pelvic mobility, not tracking straight or lack of propulsion are a few characteristics that are evaluated. Tape on the vertebral column midline may help to visualize subtle lateral bending motion asymmetries or scoliosis. Tape on the tuber coxae may help to visualize subtle pelvic motion asymmetries.

Exercise in hand

The horse is first walked and then trotted on a loose rein in hand in a straight line to detect any obvious abnormalities in gait. Many horses with chronic back trouble show a restricted hindlimb action with poor hock flexion and a tendency to drag the toes of one or both hindlimbs. If there is moderate to severe pain, a wide straddling hindlimb gait is usually seen, but in horses with a low-grade problem the action behind will be very close (i.e. plaiting). Next, the horse is turned as short as possible in both directions to induce lateral bending of the trunk. If back pain is present and there is loss of suppleness, turning is often difficult, resulting in rather jerky movements and spasm of the back muscles. On backing there is sometimes an initial reluctance to move, then the head is raised, the back arched more than usual and some spasm of the back muscles occurs. Another sign of discomfort is the dragging of the forelimb toes on moving backwards. Horses with chronic sacroiliac joint injury will often resent being backed up or down a slope. Severe lameness in one or both hindlimbs is not usually a feature of a thoracolumbar disorder and diagnostic nerve blocks should be used to differentiate this from a genuine back problem. Mild shifting lameness or simply an unevenness of action of one hindlimb is much more commonly seen in horses with back problems. Flexion tests (i.e. spavin test) rarely have any effect on the gait in horses with primary back problems, but are very useful in identifying secondary hock or stifle problems.

Lungeing exercise

A session of 10–15 minutes exercise on the lunge line in a sand ring helps to critically assess a horse's gait. This also provides an opportunity to see any improvement or deterioration in the action as the horse warms up. Horses with stiff backs often show exaggerated contractions or spasms of the longissimus muscles with each stride although this is also seen in horses that are unfit. Horses with restricted hindlimb gait often show poor tracking of the hindfeet (i.e. placement of the hindfeet behind the imprint of the ipsilateral forefoot) and a tendency to drag or plait with the hindtoes. The head carriage may be elevated and the horse looks uncomfortable in work. A poor action is usually best seen at the trot. Some horses with back pain will lunge only at a collected canter. Some difficulty is often seen when changing gait (i.e. transitions) along with an inability to lead on the correct leg (i.e. disunited). The action behind appears to lack impulsion and swishing of the tail is often a feature. However, tail swishing is not always indicative of back pain. Placing a surcingle around the thorax and tightening it has also been used to demonstrate acute or active back pain.

Ridden or driven exercise

Evaluation of the response to placing a saddle and being ridden is important for a complete assessment of horses with back problems. Inspection of the tack for proper use and fit is always suggested on initial examination. Saddles and restraint devices should be evaluated for proper fit, padding and positioning on the horse. It is useful to see the horse saddled up and to note if there is any pain or resentment to tightening the girth or when mounting. A horse may have a 'cold back' when mounted, but this does not necessarily imply an underlying spinal problem. The horse should next be ridden in its intended use or discipline by its regular rider, if possible, during a routine training exercise to assess back and limb use at the walk, trot and canter. Showjumpers should also be jumped over the type of fences that usually cause the most challenge (i.e. combination-type fences). For harness racing horses it is of great benefit to have the horse

driven so as to assess the performance and trotting or pacing gait at fast exercise.

Postexercise examination

After allowing the horse to cool down, it should be exercised in hand again to see if there is any change in the action. This is particularly useful in horses with a low-grade exertional myopathy (i.e. mild rhabdomyolysis or tying up) as they show increased stiffness of the hock and hindquarters.

Orthopedic evaluation

The objective of carrying out an orthopedic evaluation of suspected back cases is to be able to rule out or identify concurrent cervical problems and distal limb lameness, and so assist in confirming a primary thoracolumbar or lumbosacral condition.

Cervical conditions

Neck pain or stiffness will often be associated with poor performance, thoracolumbar stiffness and restricted hindlimb impulsion. Systematic palpation of the cervical region may pinpoint a painful region. Flexion and lateral bending of the neck, either manually or by offering food or a treat to induce cervical bending, will confirm neck stiffness. Further diagnostic tests, including scintigraphy, radiography and thermography, are indicated to confirm diagnosis of a neck problem.

Forelimb lameness

Gait evaluation in a straight line and on the lunge line should highlight the presence of forelimb lameness. Hoof testers, flexion tests and diagnostic nerve or joint blocks assist in identifying and localizing the site of forelimb lameness.

Hindlimb lameness

Gait evaluation may be more difficult particularly if lameness is mild and bilateral (e.g. hock or stifle). Horses with chronic sacroiliac joint injuries often have compensatory stiffness and pain in the proximal hindlimb.[39] Induced hock flexion (i.e. spavin test) is often negative in horses with back problems.[33] In many cases the use of nuclear scintigraphy will help in identifying areas of increased bone activity that may be the seat of lameness. Hoof testers, flexion tests and diagnostic nerve or joint blocks should confirm that you are not dealing with a primary back problem.

Neurologic evaluation

The majority of horses with back problems do not have concurrent neurologic disorders. If a neurologic disease is suspected, then a thorough neurologic evaluation should be pursued before any further back evaluation or imaging modalities are completed. A neurologic examination is indicated in the evaluation of horses with back problems to rule out traumatic, infectious and toxic etiologies. Postural reactions also help to assess the proprioceptive status (i.e. ataxia), weakness or spasticity, which often occur in spinal cord compromise.[42] Suspect horses are moved in tight circles to evaluate fore and hindfoot placement and backed up to assess willingness, strength and co-ordination of the hindlimbs. Walking up and down curbs or over ground poles also helps to assess foot placement. Horses with back pain may drag the hindlimbs.[27] Once a neurologic disease has been diagnosed or treated, any residual back problems should be assessed in light of the past or current neurologic signs.

Medical evaluation

Rectal palpation

Rectal palpation is an important diagnostic test in horses with back problems. Soft tissue injuries, osseous pathology and articular instability of the sacropelvic region may not be evident externally, but only palpable internally. It is also possible to rule out urogenital or gastrointestinal causes of back pain (e.g. colic, infection, masses). The psoas major and psoas minor muscles are palpable at the ventral aspect of the lumbar vertebrae. The iliacus and psoas major together form the iliopsoas muscle, which lies along the lateral wall of the pelvic inlet. These hypaxial muscles are evaluated for pain, swelling (i.e. hemorrhage) or asymmetry, and muscle hypertonicity. In horses with vague, upper hindlimb lameness, the terminal aorta and iliac arteries also need to be examined for the presence of strong and regular pulses or possible thrombi.

Osseous palpation during rectal examination is useful for evaluating pelvic or sacral fractures, pelvic canal symmetry and lumbosacral or sacroiliac degenerative joint disease. Acute pelvic fractures produce substantial pain and possible crepitus with rocking of the pelvis side-to side. Bony callous or bony asymmetries palpable on the shafts of the ilium or ventral sacrum are indicative of prior fractures. The ventral aspects of the caudal lumbar vertebrae are evaluated for irregular bony proliferation, indicative of spondylosis. The sacroiliac joints lie deep to the bifurcation of the iliac arteries, at the dorsolateral pelvic canal. Some horses with acute sacroiliac joint injuries will strongly resent deep palpation either unilaterally or bilaterally over the sacroiliac joint region. Rectal palpation while walking or during externally induced pelvic motions (e.g. dorsoventrally or laterally) helps to directly assess lumbosacral and sacroiliac joint motion internally. Rectal palpation for chronic sacroiliac joint subluxation is usually unrewarding and not diagnostic unless bony proliferation, excess sacroiliac joint motion or joint crepitus during externally applied movements is identified.[39]

Laboratory analysis

A thorough laboratory diagnostic work-up, when clinically indicated, is important for the appropriate differential diagnosis and rehabilitation of horses with back problems. Two

common serum enzymes indicative of skeletal muscle injury or inflammation include creatine kinase (CK) and aspartate aminotransferase (AST). Lactate dehydrogenase (LDH) is not as specific for skeletal muscle injury but the elevation of specific isoenzymes does have diagnostic value.[43] In most instances, these enzymes are not elevated in horses with primary back problems. In suspect horses, a submaximal exercise tolerance test can be performed in a treadmill or after trotting for 10 minutes.[27] Baseline serum samples are taken prior to exercise and compared to 4-hour (peak CK) and 24-hour (peak AST) postexercise values. Urinalysis is indicated if exercise-associated muscle damage (i.e. exertional rhabdomyolysis) is suspected in horses with back muscle pain or hypertonicity. The presence of myoglobinuria is indicative of recent or active ongoing muscle injury.[43]

Hematology is indicated in suspected vertebral osteomyelitis and diskospondylitis to evaluate the presence of anemia, hyperproteinemia, hyperfibrinogenemia, leukocytosis or neutrophilia.[42] Cerebrospinal fluid (CSF) analysis and culture is useful if meningitis is also present. Electrolyte imbalances can be found in exhausted endurance horses, especially when coupled with dehydration or poor thermoregulation. To rule out hyperkalemic periodic paralysis (HYPP), serum potassium levels or the submission of whole blood for genetic testing may be indicated in Quarter Horses with muscle fasciculations and weakness.[43] Serum vitamin E (α-tocopherol) and selenium levels are important in the pathogenesis of nutritional myodegeneration (white muscle disease), sporadic exertional rhabdomyolysis and equine degenerative myeloencephalopathy (EDM). In suspect horses, whole-blood analysis of selenium-dependent glutathione peroxidase (GSH-Px) may also be indicated to assess the selenium status.[43]

Viral isolation and PCR techniques on nasopharyngeal swabs or peripheral blood samples are indicated in suspected outbreaks of equine herpesvirus myeloencephalitis (EVH-1).[42] Paired serum titers can reveal elevated or increasing titers in suspect horses. Serology (e.g. titer or Western blot) may also be indicated in horses with a history or clinical presentation suggestive of Lyme disease or equine protozoal myeloencephalitis (EPM). However, due to difficulties in serology interpretation, synovial tissue biopsies and CSF immunoblot analysis are preferred tests. CSF analysis may reveal elevated protein levels, xanthochromia or pleocytosis in cases of EVH-1, polyneuritis equi, EPM and equine motor neuron disease (EMND). CSF creatine kinase may also be elevated in horses infected with EPM or EMND.[42]

Muscle biopsies may be indicated to rule out EMND, polysaccharide storage myopathy (PSSM) and recurrent exertional rhabdomyolysis (RER).[44] Muscle biopsies provide assessment of muscle fibers, neuromuscular junctions, nerve branches, connective tissue and blood vessels.[43] Both light and electron microscopy, combined with histochemistry, are required for the diagnosis and prognostication of muscle disorders. Dietary analysis is indicated in horses with RER and PSSM. High grain diets may need to be replaced with fat supplementation, rice bran and access to high-quality hay.

Physical examination

The focus of the physical examination of the vertebral column is to identify if a back problem exists and to localize the injury to either soft tissue, osseous or neurologic structures. Traditional orthopedic and neurologic evaluations are important adjunctive assessments used to rule out other, more common causes of lameness and neurologic disorders. The spinal examination also helps to determine if the back problem is acute or chronic and if the vertebral dysfunction is segmental and localized or regional and diffuse.

Subjective assessment and grading of back problems

Vertebral dysfunction is most often characterized by localized pain, muscle hypertonicity, reduced joint motion and subsequent functional disability. The challenge, as with any musculoskeletal injury, is to identify the specific musculoskeletal structures affected and quantify the associated disability or altered function. The most common categorization of musculoskeletal injury consists of mild, moderate or severe degrees. Further quantification may involve the use of a 0–10 scale in an attempt to objectively monitor changes in pain, muscle hypertonicity, reduced joint motion or functional disability (Table 21.3). Subjective parameters can then be assigned a numerical value that can be assessed before and after treatment. The progression or regression of the individual parameters can then be recorded over time since most clinical back problems tend to be chronic or recurrent in nature.

Regional joint motion

Joint range of motion can be assessed either regionally via induced vertebral movements or segmentally via motion palpation of individual vertebral motion segments. Vertebral range of motion is evaluated to detect whether a particular movement is normal, restricted or hypermobile. Regional causes of vertebral movement restrictions may include intra-articular pathology (i.e. osteoarthritis), periarticular soft tissue adhesions, musculotendinous contractures or protective muscle spasms.

Active range of motion The diagnostic evaluation of regional active range of motion (AROM) involves using a carrot or other treat to induce flexion, extension and lateral bending of the neck and trunk. The willingness, coordination and amount of vertebral motion are compared bilaterally. Resistance, struggling to grasp the treat and left-to-right range of motion asymmetries are documented. Similar procedures can be used therapeutically as stretching exercises to increase neck or trunk range of motion.

Active lateral bending range of motion The horse is positioned parallel against the stall wall to stabilize the trunk and pelvis and to provide a surface for the horse to lean against if needed during the active stretches. The positioning also helps to prevent the horse from chasing the treat holder around the stall during the evaluation. The treat is directed towards the elbow and held against the lateral girth region. This

Table 21.3 Subjective assessment and grading of spinal dysfunction

Grade	Scale	Pain	Muscle hypertonicity	Joint stiffness	Overall functional ability
Absent	0	No clinical evidence of pain	No clinical evidence of muscle hypertonicity	No clinical evidence of joint stiffness	Full functional capability
	1	Mild pain	Mild muscle hypertonicity	Mild joint stiffness	Mild restriction in ability
		Precipitate with firm pressure only	Precipitate with firm pressure only	No resistance to any induced movement	Able to work at the walk and trot
		Localized pain	Segmental muscle hypertonicity	Segmental joint stiffness	Able to perform while ridden
Mild	2	Deep structures affected	Unilateral muscle hypertonicity	Unilateral joint stiffness	Work limited during canter, gallop or jumping
		Soft tissue *OR* osseous structures	One muscle group affected	Good overall flexibility	Unable to do advanced maneuvers
		Chronic pain condition	No fasciculations induced with firm palpation	Reduced dorsoventral *OR* lateral bending	Noticeable dysfunction during certain activities
	3	Occasional, mild reaction to grooming	Hypertonicity varies with applied pressure	Stiffness due to muscular restrictions	Mild inco-ordination present
	4	Moderate pain	Moderate muscle hypertonicity	Moderate joint stiffness	Moderate restriction in ability
		Precipitate with moderate pressure	Precipitate with moderate pressure	Tolerates some induced movements	Able to work adequately at the walk
		Regional pain	Regional muscle hypertonicity	Regional joint stiffness	Difficult to perform with rider
Moderate	5	Superficial *OR* deep structures affected	Unilateral *OR* bilateral muscle hypertonicity	Unilateral *OR* bilateral joint stiffness	Work limited to walk or trot only
		Several soft tissue *AND* osseous structures	Two different muscle groups affected	Limited flexibility in one *OR* more directions	Unable to do lateral work or inclines
		Chronic *OR* acute pain condition	Fasciculations induced with firm palpation	Reduced dorsoventral *AND* unilateral bending	Performs activity with much effort
	6	Consistent, moderate reaction to grooming	Hypertonicity worse with applied pressure	Stiffness due to connective tissue restrictions	Moderate inco-ordination present
	7	Severe pain	Severe muscle hypertonicity	Severe joint stiffness	Severe restriction in ability
		Precipitate easily with mild pressure or touch	Precipitate easily with mild pressure or touch	Resents any induced movements	Able to stand comfortably
		Generalized pain	Generalized muscle hypertonicity	Generalized joint stiffness	Unable to perform with rider
Severe	8	Superficial *AND* deep structures affected	Bilateral muscle hypertonicity	Bilateral joint stiffness	Work limited to walk only
		Multiple soft tissue *AND* osseous structures	Multiple muscle groups affected	Poor flexibility in multiple directions	Unable to back up
		Acute pain condition	Spontaneous fasciculations present	Reduced dorsoventral *AND* bilateral bending	Resents all activities
	9	Consistent, strong avoidance response	Constant, severe muscle spasms	Stiffness due to intra-articular restrictions	Severe inco-ordination present
Incapacitated	10	Severe, generalized, unrelenting pain	Severe, generalized, constant muscle spasms	Severe, generalized joint stiffness	Unable to perform at any level
		All soft tissue and osseous structures affected	All muscle groups affected bilaterally	No flexibility induced in any direction	Unable to stand comfortably

motion assesses mid to lower neck flexibility in lateral bending and rotation. Normally, horses should be able to readily touch their nose to the girth and hold the stretch for 5 seconds. The treat is then advanced along the ribs towards the point of the hip (i.e. tuber coxae). This motion assesses trunk flexibility in lateral bending. Normally, horses should be able to readily touch their nose to the point of the hip and hold the stretch for 5 seconds. Horses with back pain or stiffness will not be able to reach their nose to their tuber coxae and notable left-to-right asymmetries in range of motion will

be seen if a back problem only affects structures on one side of the body. The distance of the nose from the tuber coxae can be measured (e.g. 10″ or able to reach the 15th rib) and changes assessed over time.

Active flexion range of motion A treat is directed cranially between the forelimbs and towards the front feet. This motion assesses flexion flexibility of the mid to lower neck and withers. The clinician needs to place a hand on the ipsilateral carpus to prevent knee flexion during the range of motion assessment. Normally, horses should be able to readily touch their nose between the front feet and hold the stretch for 5 seconds. Those with pain or stiffness in the withers or back will not be able to reach their nose to their front feet and will flex one or both of their knees to compensate while reaching for the treat.

Passive range of motion Passive range of motion (PROM) is assessed by measuring the amount and characteristics of joint motion beyond the active joint ranges of motion. These procedures require muscle relaxation so that passive joint motion can be induced and evaluated. However, there may be a high risk of injury if the excessive forces are applied to the body regions, without protective muscle tone. This is especially true when evaluating joint range of motion while under sedation or anesthesia. Most passive joint range of motions are assessed segmentally in non-sedated horses with more refined and detailed motion palpation techniques (see later section).

Active assisted range of motion Active assisted range of motion (AAROM) or spinal reflexes are often assessed with firm pressure applied to specific body regions that secondarily induce characteristic vertebral column movements. Diagnostically, the induced movements are graded as reduced, normal and exaggerated. Therapeutically, the induced movements are often held for a set period of time to induce stretch of hypertonic muscles and creep relaxation of shortened connective tissue (i.e. fascia or ligaments) or to strengthen weak or unco-ordinated agonist muscles via concentric contractions.

Wither elevation Firm pressure applied along the ventral midline at the level of the sternum and cranial linea alba will induce elevation of the withers via isometric contraction of the thoracic portion of the serratus ventralis muscle. Pressure is applied with the fingertips or fingernails of one or both hands. Normally, horses will readily elevate the withers and midthoracic vertebrae (T7–T17) approximately 3–4 cm and hold the position for 5–10 seconds. Horses with cranial thoracic pain or stiffness will not be able to elevate the withers and will resent the applied pressure. Caution needs to be applied to horses with girth sensitivity or pain, since they often resent the applied pressure and may kick out with a hindlimb. This exercise is often indicated therapeutically to induce relaxation of a hypertonic spinalis muscle associated with poor saddle fit (i.e. too narrow a tree).

Trunk elevation Firm pressure applied bilaterally along the muscular groove between the biceps femoris and semitendinosus muscles induces elevation of the back via isometric contraction of the rectus abdominis muscle. The muscular groove is located approximately 10 cm (4″) lateral to the base of the tail. Pressure is applied bilaterally with equal pressure from the fingernail of the index fingers or needle caps, if needed. A variation of the technique involves the application of firm manual compression at the sacrocaudal junction but the response is often less consistent or dramatic. Normally, horses should readily elevate the thoracolumbar vertebrae (T12–L5) approximately 10–12 cm. The induced movement should be controlled and co-ordinated and able to be held for 20–30 seconds. Horses with back pain or stiffness will not be able to elevate the trunk and will resent the applied pressure. Other horses may immediately flex their pelvis and slightly hop upwards on the hindlimbs or step away from the applied pressure. This exercise is similar to muscular efforts required during collection while performing certain dressage movements. It is often indicated therapeutically to induce relaxation of the thoracic or lumbar longissimus muscle hypertonicity associated with back pain, poor collection and coupling of the lumbosacral region and lack of impulsion from the hindlimbs.

Spinal reflexes Firm pressure applied unilaterally along the length of the longissimus muscles will induce localized contraction of the stimulated back or croup musculature. Light pressure with a needle cap or ballpoint pen is applied either along the long axis of the spine or transversely across the longissimus or middle gluteal muscles. There seems to be some confusion as to the clinical significance of the observed response to the applied stimuli. Some clinicians place significance on exaggerated or rapid movement away from the applied pressure, which is believed to be indicative of muscle pain. However, horses often have differing amounts of skin sensitivity or inconsistent responses to various stimuli, which may not be reliable indicators of back pain.[27] Some clinicians believe that resistance or lack of movement away from the applied pressure is clinically significant and indicative of severe muscle guarding or pain and the horse is unable or unwilling to move its back despite the applied pressure. In the author's opinion, the procedure often appears to be an unnecessary and noxious stimulus for most horses with back pain. Other, less noxious means of assessment are more informative in most horses with back pain. The procedure should be reserved for very stoic horses, where a question exists about the ability to actively lateral bend or flex and extend the trunk.

Blunt pressure applied unilaterally to the epaxial musculature will induce three characteristic and repeatable spinal reflexes. The first portion of the reflex occurs as a stimulus is applied to the saddle region (T10–L3). Normally, the horse will respond with an induced contralateral lateral bending and extension of the trunk away from the applied stimulus. Horses with back pain may have an exaggerated response and will rapidly and dramatically move away from the applied stimuli. Other horses, presumably due to excessive muscle guarding or nervousness, will not move away from the applied stimulus and will resist moving their trunk in the characteristic pattern of contralateral lateral bending and extension. The second portion of the reflex occurs as a stimulus is continued along the cranial croup region (L4–S3). Normally, the horse will respond with an induced extension

of the lumbosacral joint. Horses with back pain may have an exaggerated response and will rapidly and dramatically move away from the applied stimulus. Horses with hypertonic or injured iliopsoas muscles would theoretically resent any induced extension of the lumbosacral junction due to secondary stretching of the iliopsoas muscles. The third portion of the reflex occurs as a stimulus is continued along the caudal croup region (S4–tuber ischii) along the muscular groove between the biceps femoris and semitendinosus muscles. Normally, horses will respond with an induced flexion of the lumbosacral joint and ipsilateral lateral bending of the trunk towards the applied stimuli. Horses with back pain may have an exaggerated response to the applied stimuli and will rapidly and dramatically immediately flex the pelvis and step away from the applied pressure. Bilateral application of pressure in the same location will induce flexion of the lumbosacral joint without lateral bending, as described above.

Soft tissue palpation

Any palpation of the musculoskeletal system requires a quiet and co-operative patient. Horses that are moving around and not willing to stand quietly are difficult to assess fully for back problems. The horse's response to being approached and its anticipation of palpation are often used as an indication of potential back pain or hypersensitivity. Many owners will report a change in behavior (i.e. pinned ears, swishing tail) as a horse with back pain anticipates being touched or having the saddle placed on its back. Other complaints include a newly developed sensitivity to being groomed in one particular location on the trunk. The hallmarks of vertebral segment dysfunction include localized pain and abnormal paraspinal muscle tonicity.[45]

Palpation is often a reliable technique used to localize and identify soft tissue and osseous structures for changes in texture, tissue mobility or resistance to pressure.[6,46] The soft tissue layers are evaluated from superficial to deep without simply increasing digital pressure but also shifting attention with discrete palpatory movements. Shapes of structures, transitions between structures and attachment sites may also be palpated.[40] Soft tissue texture and mobility can be compared between the skin, subcutaneous tissues, thoracolumbar fascia and muscle.

Skin and subcutis Acute back pain and inflammation will produce local areas of palpable heat, whereas chronic back problems can be identified by focal regions of colder temperatures, relative to the surrounding or contralateral tissues. Thermography provides an objective measure of temperature variations within the superficial tissues of horses with back problems. The hair, epidermis, dermis and subcutaneous tissues should be evaluated systematically with detailed palpation and observation for potential contributing factors to back pain or discomfort. The hair coat is evaluated for changes in hair texture or alopecia, which are often indicative of abnormal saddle or blanket wear. Asymmetric dirt or sweat patterns after removal of the saddle pad are also important indicators of poor saddle fit. A common presenting complaint for horses with back problems is localized sensitivity to routine grooming or brushing.

The skin around the withers should be evaluated for evidence of acute injuries associated with poor saddle fit or improper blanket wear, which are characterized by localized hair loss, open skin lesions (saddle galls) and signs of inflammation. Chronic saddle fit or blanket wear lesions are identified by the presence of white hairs and scar tissue over the dorsal or lateral aspects of the withers. In some horses, localized sites of edema or hives may occur after riding with a poor-fitting saddle or pad.[27] The epidermis should be evaluated for scabs, scrapes, lacerations, fly bites (ventral dermatitis), sarcoids and dermatophilus (rain scald), which may be primary causes of back pain or are irritated with saddle or girth placement. The dermis is palpated over the trunk region for eosinophilic granulomas or melanomas. Eosinophilic granulomas may regress spontaneously or enlarge and become ulcerated with continued friction in the saddle region. The subcutaneous tissues are palpated for edema or cellulitis, masses, fat deposits and the mobility of the skin over the underlying loose connective tissue. Chronic scar tissue, adhesions and fibrosis may produce back pain if the affected tissues are restricted or pulled on during locomotion or trunk movements. Blood vessels, nerves and lymph nodes are important structures that reside within the subcutaneous tissues.

Connective tissue palpation Connective tissue structures, such as the fascia and ligaments, are systematically evaluated for clinical signs of acute or chronic injury.

Fascia The dense connective tissue that forms the superficial and deep fascia is systematically evaluated for masses, rents, scar tissue and tonicity. The overlying skin and subcutaneous tissues are mobilized by a firm, broad contact. The superficial fascia is assessed for smoothness and uniform tonicity or compliance. The superficial fascia typically forms a superficial covering of muscle bellies, whereas the deep fascia forms folds of connective tissue between muscle bellies and anchors to deeper osseous structures. Severe or deep trauma to the myofascial tissues (e.g. kicks, deep lacerations or abscesses) can produce residual fibrosis that limits adjacent muscular activity and fascial extensibility. The thoracolumbar fascia is the most prominent fascia of the trunk and is particularly evident at the thoracolumbar junction as it blends medially with the supraspinous ligament. In the lumbar region, the thoracolumbar fascia attaches to the cranial aspects of the tuber sacrale and iliac wing, deep to the overlying middle gluteal muscle.

Spinal ligaments The spinal ligaments are systematically palpated for masses, fiber disruption, fibrosis and signs of desmitis (i.e. swelling or pain). The nuchal ligament forms a broad attachment to the dorsal apexes of the spinous processes of the withers and continues caudally as the supraspinous ligament. The supraspinous bursa lies between the nuchal ligament and the T3–T5 dorsal spinous processes. The supraspinous bursa is not normally palpable, unless distended or possibly infected (i.e. fistulous withers). Firm digital pressure is applied dorsally and laterally to the nuchal and supraspinous ligaments and ligamentous attachments at the dorsal spinous processes. The entire length of the

supraspinous ligament is palpated by lateral compression between the index finger and thumb. The induction of spinal flexion will cause the supraspinous ligament to be more prominent and readily palpable.

Pelvic ligaments Unfortunately, most of the pelvic ligaments are inaccessible due to their location deep to the gluteal musculature or within the acetabular region of the hip. The dorsal portion of the dorsal sacroiliac ligament and the caudal portion of the sacrosciatic ligaments are the only palpable ligaments of the pelvic region. The dorsal sacroiliac ligaments are palpable in the croup region as two large round ligaments that originate on the caudal aspect of the tuber sacrale and converge caudally on the sacral spinous processes. Firm digital pressure is applied dorsally and laterally to the dorsal sacroiliac ligaments, bilaterally and individually, to lateralize any localized pain or swelling, indicative of desmitis. The caudal attachment of the sacrosciatic ligament at the tuber ischii is palpable and should be evaluated for pain and symmetry in tonicity. Horses that consistently carry their tail off to one side or have a history of sacral fractures may have palpable differences in sacrosciatic ligament tonicity. The trochanteric bursa is located between the tendon of the accessory gluteal muscle and the greater trochanter of the femur. Like other bursae, it is not palpable unless inflamed or distended. Trochanteric bursitis often presents as upper hindlimb lameness and not as a back problem.

Muscle palpation The trunk and pelvic musculature is evaluated systematically from superficial to deep with detailed palpation of abnormal muscle tonicity, pain or fasciculations. Muscle palpation is done with light but firm pressure applied by a broad contact with the entire hand, not only the fingertips, which may unduly localize the applied pressure and precipitate a pain response (i.e. false positive). Regional muscle tone and development of the neck, trunk and proximal limb musculature is assessed and compared left to right. Muscles are then individually identified and evaluated for masses, fibrosis, swellings or depressions. Individual muscles and their attachments are assessed unilaterally and then compared bilaterally for tonicity and the response to manual palpation (i.e. sensitivity). Local or regional alterations in temperature or texture are carefully palpated for signs of active inflammation.

Muscle development Muscle evaluation begins with observation and palpation of the neck, shoulder, pectoral, wither, trunk, gluteal and thigh muscle development and symmetry. Muscle atrophy can be due to partial or complete denervation, disuse, malnutrition or immune-mediated disorders.[43] Obese horses are often difficult to palpate due to poor muscle development and indistinct myofascial borders. Epaxial muscle development is assessed by laying a hand transversely across the longissimus and middle gluteal muscles. Horses with exceptional back muscle development should have a palpable convexity or outward curvature of the muscles along the entire distance from the withers to the croup. Deconditioning or poor flexibility may contribute to epaxial muscles that are palpably flat between the dorsal spinous processes and the ribs laterally. Horses with chronic back problems or poor saddle fit will have a palpable concavity or inward curvature of the epaxial muscles at the withers or along the trunk. Asymmetries in muscle development may be palpable cranial to caudal, medial to lateral or left to right. The thoracic portion of the spinalis muscle is the most commonly affected muscle in the wither region. The longissimus muscle is the most commonly affected trunk muscle. The middle gluteal and the vertebral portions of the biceps femoris, semitendinosus and semimembranosus muscle are common areas to visualize or palpate muscle asymmetries in the pelvic region.

Muscle tonicity The general muscle tone varies between horses and breeds. Nervous or excited horses will have overall increased muscle tone, whereas stoic, depressed or systemically ill horses will have reduced or sometimes flaccid muscle tone. Arabians tend to carry more muscle tone whereas most Warmbloods or draft breeds will allow deep palpation of their generally relaxed muscles. Muscle tonicity is an indirect measure of muscle activity or contraction. Electromyography (EMG) provides a direct assessment of muscle activity but it is not readily available in most clinical situations and it is often difficult to perform and interpret.[43]

Muscle tonicity is categorized as hypotonicity, normal tonicity and hypertonicity. Normal epaxial muscles are not contracted in a quietly standing horse, but are relaxed and malleable. Muscle hypotonicity or flaccidity is indicative of neuropathies, such as disuse or denervation atrophy. Muscle hypertonicity is the most commonly palpable abnormality in horses with acute or chronic back problems and can have either neural or myopathic origins.[43] Generalized muscle hypertonicity may affect a small portion of a muscle (i.e. trigger point), an entire muscle belly or a regional group of muscles. Muscle spasms are an acute, severe form of muscle hypertonicity, with substantial pain and loss of muscle function. Detailed palpation and a thorough knowledge of muscular anatomy will help to identify which muscle or muscles are primarily affected, and which adjacent muscles are likely to have secondary guarding due to common biomechanical or neurologic factors. In general, localized muscle hypertonicity is considered an acute or primary back problem whereas regional longissimus muscle hypertonicity is often associated with a chronic hindlimb lameness or systemic disease.

Trigger points are characterized as localized bands or foci of muscle contracture and pain within a muscle belly.[47,48] Muscle contractures are not associated with normal neural firing and subsequent depolarization of the muscle membrane.[43] Trigger points occur in consistent and predicable locations, presumably due to alterations in local muscle function caused by changes in posture or biomechanics. In horses with back or pelvic problems, focal hypertonic muscle bands with a lower pain pressure threshold (i.e. increased sensitivity) can often be found in the middle gluteal muscle. The clinical significance of trigger points in the middle gluteal muscle is difficult to determine since they do not always correlate with the presence or severity of lameness or back problems.

Muscle spasms or splinting are characterized as involuntary, pronounced and unremitting muscle contractions in response to severe and unrelenting pain (e.g. colic) or meta-

bolic disturbances (e.g. electrolyte imbalances or exertional rhabdomyolysis). Horses with acute or severe back pain may present with muscle splinting but other underlying medical conditions that may be more life threatening or critical need to be ruled out immediately. Muscle splinting severely restricts the ability to evaluate trunk mobility and the palpation of underlying soft tissue structures. Therefore, medical treatment of the primary problem or the administration of muscle relaxants is often required before a complete evaluation of the vertebral column can be accomplished.

Muscle pain The assessment of muscle pain is often subjective and is dependent on the evaluator's tactile skills and interpretation of clinical significance. The clinical assessment of acute versus chronic pain is relatively straightforward but determination of the exact etiology and appropriate treatment regime are diagnostically challenging. Acute muscle pain is characterized by heat, firm swelling or edema, substantial hypertonicity and pain and dysfunction of the affected muscle region. Acute muscle pain may be due to direct trauma (e.g. kick or other blunt trauma) or metabolic disorders (i.e. exertional rhabdomyolysis). The thoracic portion of the spinalis muscle is a common site of muscle pain, associated with a poor-fitting saddle (i.e. too narrow a tree). Chronic muscle pain has a more neurogenic basis and is due less to direct inflammatory mediators.

Horses with acute sacroiliac joint injuries may have localized sensitivity to palpation of the gluteal musculature and surrounding soft tissues in the dorsal croup region.[33] Protective muscle spasms may be palpated in the adjacent middle gluteal musculature and the vertebral portions of the biceps femoris, semitendinosus and semimembranosus muscles. A localized region of edema may occasionally be palpated over the lumbosacral junction[38] but this is not a specific finding related to sacroiliac joint injury.

Algometry In humans, the diagnosis of chronic fatigue syndrome or fibromyalgia is often based on the presence of decreased pain thresholds at a set number of standardized musculoskeletal locations. The clinical syndrome of myofascial pain in horses is common and quite similar to humans. Unfortunately, we often have a poor understanding of the etiopathogenesis and the objective assessment of muscle pain. Algometry (dolorimetry) of soft tissue structures provides an objective measure of muscle or ligamentous pain pressure thresholds (i.e. the minimum force that causes discomfort or pain).[49] It utilizes a force gauge and plunger to measure left-to-right asymmetries or identify subnormal values.[48] In horses, normal algometry values for soft tissue landmarks are typically 20–30 pounds/cm.[2] Horses with myofascial pain often have algometry values of less than 10 pounds/cm.[2]

Guarding of the back is an exaggerated response to typically innocuous stimuli or sudden movements. This abnormal response is commonly seen in nervous horses or those with back pain. Pronounced muscle guarding with movement away from any anticipated contact or placement of the saddle is considered abnormal. Horses should not react adversely to any grooming or superficial or deep muscle palpation[27] although a few sensitive horses may have a mild, temporary avoidance to deep muscle palpation. Any exaggerated attempts to avoid palpation or the presence of prolonged muscle contractions or fasciculations should be considered abnormal. Horses with back pain and muscle soreness may have localized areas of muscle fasciculations depending on the amount and type of pressure applied.

Muscle fasciculation Muscle fasciculations are usually indicative of profound muscle weakness, electrolyte imbalances or primary muscle pathology although, muscles may fasciculate at characteristic locations distant to an area of palpation.[27] In humans, this is indicative of referred pain, which is difficult to truly assess in horses due to the lack of verbal feedback. In horses with back or gluteal muscle pain, it is common to find areas of muscle fasciculations in the mid-lumbar longissimus muscles when firm, localized pressure is applied to hypertonic or painful areas (i.e. trigger points) within the middle gluteal muscles. This is an intriguing response since the motor innervation of the reactive lumbar longissimus muscles is provided segmentally by dorsal branches of the spinal nerves of L2–L4 and the middle gluteal muscle is innervated by ventral branches of the spinal nerves that contribute to the cranial gluteal nerve (L6–S2).

Osseous palpation

Osseous palpation involves evaluating osseous structures for pain, morphology, asymmetries and alignment. Individual thoracic, lumbar and sacral spinous processes are palpated for a painful response with firm digital pressure applied to the osseous structures of the dorsal midline.[50] Typical signs of discomfort include tossing the head upwards, extension of the back or withers away from the applied pressure or localized secondary muscle spasms. Algometry (pain pressure thresholds) of osseous landmarks provides an objective measure of bony pain and allows monitoring of the effectiveness of treatment protocols. Normal algometry values for osseous landmarks are higher than soft tissue values and typically exceed 30–40 pounds/cm^2. Horses with bone pain often have osseous algometry values less than 10 pounds/cm^2.

Dorsal spinous processes The morphology of individual dorsal spinous processes is compared to adjacent spinous processes. It is common to palpate seemingly higher, wider or laterally displaced dorsal spinous processes. However, unless there is also localized pain or muscle hypertonicity adjacent to the affected dorsal process, then the spinous process deviation is probably not clinically significant. Individual spinous process deviation is common but it is not often associated with spinous process fracture or vertebral malposition (i.e. bone out of place), as is commonly thought. Overlapping or malaligned dorsal spinous processes are often caused by spinous process impingement, developmental asymmetries in the neural arch or isolated dorsal spinous process deviation of unknown etiology.[51,52] Palpably taller or wider dorsal spinous processes occur presumably due to avulsion fractures or osseous proliferation within or at supraspinous ligament insertion sites (i.e. enthesiopathies). Radiographs, ultrasonography and scintigraphy are useful modalities to

document the cause of palpable differences in dorsal spinous processes.

Tuber sacrale The tuber sacrale of the pelvis are palpated for height asymmetries and pain response to manual compression. Unilateral or bilateral prominence of the tuber sacrale may be noted, but is not usually clinically significant unless associated with clinical signs of localized pain or inflammation or positive findings on diagnostic imaging (e.g. scintigraphy). In acute sacroiliac injuries, asymmetry in gluteal muscle development is uncommon, unless pronounced osseous pelvic asymmetry is also present. Firm digital pressure applied to the dorsal aspect of the tuber sacrale has been reported to produce a variable and inconsistent pain response.[53] In the author's opinion, dramatic and consistent pain responses have been produced in affected horses with specific provocation tests that are useful to establish a presumptive diagnosis of sacroiliac joint injury or pelvic stress fractures. The procedure involves simultaneous manual compression of the dorsal aspects of both tuber sacrale, which induces a bending moment on the iliac wing and presumably compresses the sacroiliac articulations (Fig. 21.8). Normally, horses will not have any response or only a mild response to the applied pressure. Mild contraction of the lumbar longissimus muscles and slight extension of the lumbosacral joint is normal for most horses. Acutely affected horses may have a dramatic reaction to this manipulation and will demonstrate severe longissimus muscle contractions and sudden collapse of the hindlimbs which is indicative of pelvic injury or sacroiliac joint pain.[27] Practitioners should gradually apply increasing pressure since affected horses may actually collapse in the hindlimbs and fall to the ground if excess force is applied to the painful tuber sacrale. This test is not specific for sacroiliac joint pathology, as horses with incomplete or stress fractures of the ilial wing may respond even more dramatically to the applied pressure.

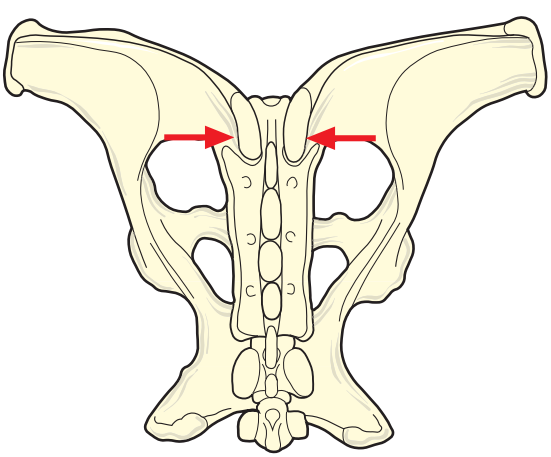

Fig. 21.8
Forces applied during a sacroiliac joint provocation test (dorsal view). Firm pressure is applied bilaterally with both hands, compressing the dorsal aspects of the tuber sacrale.

The apex of the second sacral spinous process is a reliable landmark used to evaluate relative tuber sacrale displacement. Normally, the dorsal apices of the tuber sacrale and the second sacral spinous process lie in close apposition and follow the contour of the croup. Using palpation, ultrasound or radiographs, a physical discrepancy in height can often be identified between the dorsal profile of the sacral spinous processes (which should remain constant, unless fractured) and the potentially ventrally or dorsally displaced unilateral or bilateral tuber sacrale. In this manner, either unilateral (i.e. tuber sacrale height asymmetry) or bilateral tuber sacrale displacement (i.e. hunters' or jumpers' bumps) can be diagnosed, depending on whether one or both tuber sacrale are elevated relative to the apices of the sacral spinous processes. Tuber sacrale height asymmetry is evident in sacroiliac joint subluxation (the higher side is affected) and complete ilial wing fractures (the lower side is affected). Bilateral tuber sacrale displacement has an unknown clinical significance and may be present in many high-level competition horses.[38] Theoretically, the hunters' or jumpers' bumps may provide a longer lever arm for the strong longissimus and thoracolumbar fascia to produce extension at the lumbosacral joint, resulting in increased impulsion and range of hindlimb motion with subsequent improved performance.

Pelvis Lateral compression of the tuber coxae and tuber ischii is indicated in horses with acute pelvic lameness to help rule out complete pelvic fractures. Palpation or auscultation of the dorsal pelvic region during repetitive side-to-side movements also assist in the diagnosis of pelvic crepitus. Normally, the tuber sacrale move in unison during locomotion. A palpable or visible independent movement of the tuber sacrale at a walk or during treadmill locomotion is indicative of sacroiliac joint luxation or a complete pelvic fracture. Horses with acute sacroiliac joint injuries may also resent flexion of the contralateral hindlimb. Rectal palpation is also indicated to assess osseous morphology (e.g. displaced fracture fragments or callus) and soft tissue pain or swelling (i.e. hemorrhage) in horses with suspected pelvic fractures.

Segmental joint motion

A vertebral motion segment is the functional unit of the spine and includes two adjacent vertebrae and the associated soft tissues that bind them together. To utilize palpation in the evaluation of the musculoskeletal system fully, an understanding of how joint motion is assessed is required.[40] Joint motion can be categorized into three zones of movement: physiologic, paraphysiologic and pathologic. The physiologic zone of movement includes both active and passive ranges of motion and is the site where joint mobilization is applied. Moving an articulation from a neutral position first involves evaluating a range of motion that has minimal, uniform resistance. As the articulation is moved toward the end of that range of motion there is a gradual increase in the resistance to movement (i.e. joint end-feel). End range of motion starts when any change in resistance to passive joint manipulation is palpable. Joint end-feel is evaluated by bringing the
