Platelet Adenosine Diphosphate Receptors Platelets have a unique relationship with ADP. Not only is the nucleotide a well-known agonist for activation ([835]), it is also selectively sequestered and stored in dense granules (the nonmetabolic pool) for later use as an amplification system for other agonists ([688]). One of the three platelet ADP receptors, P2Y12, appears to be found only in platelets ([836]) and provides the target for clopidogrel and ticlopidine, agents commonly used as antiplatelet agents to prevent heart attacks and strokes ([721]). Although ADP is generally classified as a “weak agonist” for activation ([837]), it has the historic distinction of being the first one recognized ([838]), and it interacts widely and effectively with other agonists, such as thrombin and TxA $_2$, to activate platelets ([839], [840]). Purine receptors for ADP are designated as *P2* and then further classified as *Y* for metabolic paths or as *X* for ion channels. Platelets prove to have two P2Y receptors: P2Y1, acting through phospholipase Cß/Gaq, and P2Y12, inhibiting adenyl cyclase through Gai ([836], [841], [842], [843] and [844]). However, only one P2X ion channel species is found in platelets: P2X1, which is ATP-gated and permits rapid calcium influx from external sites into the cytoplasm ([843], [844] and [845])). Together, the ADP effects on platelets also lead to intracellular calcium flux from intracellular stores, separate from P2X1; this process is accompanied by inositol 1,4,5 phosphate 3 (IP3) formation through PIP2-selective phospholipase Cß isoforms and arachidonate release through phospholipase A $_2$ ([842], [843], [846], [847] and [848]).

Thromboxane A $_2$ Receptors *TxA* $_2$ is a PG-like lipid synthesized almost exclusively by platelets (as opposed to endothelial or other cells) ([849], [850]). It is a prototypic hemostatic/thrombotic agent in view of its short-lived, localized nature and its ability to activate platelets while contracting blood vessels ([851]). The physiology of TxA $_2$ formation is well known: Arachidonate released from phospholipids by phospholipase A $_2$ is oxidized by platelet cyclooxygenase-1 and then isomerized to TxA $_2$, which, in turn, acts on the TxA $_2$ receptor(s) ([852]). The isolated receptor is encoded by a single gene but exists in separate platelet and endothelial forms, presumably due to alternative splicing of the transcript ([853], [854]). The receptor exhibits both higher (induces shape change) and lower (induces aggregation) binding affinities for ligands and depends on ADP release for full activity ([855], [856]).

Additional Agonist Systems: Epinephrine, Serotonin, Vasopressin, and Platelet-Activating Factor Receptors The functional *in vivo* significance of these receptors is less well defined—and much less certain—than those noted above. They are all GPCRs, present in 250 copies per platelet or fewer; each has been studied *in vitro*, with epinephrine emerging as the best-known member of the group ([857]). Epinephrine acts on platelets through the a $_2$ adrenergic receptor ([858]), leading to a drop in adenylate cyclase activity and inducing both first-phase aggregation without shape change and second-phase aggregation through synergy with ADP release ([857], [859], [860]). The study of the platelet serotonin receptor, 5HT2A, as in the forebrain ([861]) has generated interest in the concept that serotonin transport and receptors in platelets might correlate with serotonin metabolism in psychiatric disorders ([862]). However, no firm conclusions have been reached, and serotonin, although stored in dense granules, does not induce platelet aggregation in whole blood ([863]). The vasopressin V1–type receptor is present in fewer than 100 copies per platelet, and physiologic concentrations of the hormone are unlikely to activate platelets directly ([864], [865]). The lipid mediator, platelet activating factor, acts through a specific receptor under specific circumstances (TxA $_2$ synthesis, ADP release), and the significance of the human pathway remains unclear ([866], [867]).

Signaling Molecules and Pathways No attempt is made here to trace specific receptors to specific intracellular GTP-binding elements and then to individual signaling molecules such as a phospholipase C species. The pathways are too complex and interrelated for such a venture to be successful. Rather, major pathways activated during agonist stimulation are simply noted here, and further discussion is provided later in this section concerning cytoskeletal rearrangements. Work on platelet signal transduction has emphasized molecular mechanisms that account for the activation of gpIIb-IIIa for fibrinogen binding, particularly in response to gpIb-based ligand binding and adhesion. However, despite consistent effort, this central and critical linkage(s) remains largely unexplained. Binding of vWF to platelet gpIb does initiate signaling events and must involve the receptor linkages to ?14-3-3 and actin-binding protein ([868], [869] and [870]), but no specific steps that connect gpIb directly with gpIIb-IIIa activation have been definitely defined. The possibility remains that the Ib to IIb-IIIa pathway is basically mechanical and depends on physical connections that are broken by shear forces exerted on IIb-IIIa when platelet movement is stopped through the initial Ib-to-vWF-to-subendothelium relationship. The possibility that such a direct connection exists is supported by the fact that activation of IIb-IIIa is nearly instantaneous after platelet arrest through gpIb. Rapid activation and ligation of IIb-IIIa are required for successful platelet plug formation because the initial, shear-dependent interaction of Ib with vWF is rapidly reversed and lost once the platelet is immobilized and the shear forces, which permitted adhesion, dissipate.

G Protein–Coupled Receptors The basic model for platelet agonist signaling involves a GPCR (i.e., for thrombin, ADP, TxA $_2$) that binds its ligand and subsequently activates one or more pathways through its heterotrimeric G proteins. Perhaps the best-defined examples are (a) the Gia subunit that suppresses adenylate cyclase (this drop in cyclic AMP activates platelets) ([871]) and (b) the Gqa subunit that activates the beta isoform of phospholipase C ([872]). The converse of the Gai effect on cyclic AMP is the inhibitory PGI2 receptor (prostacyclin) that releases the Gas subunit to raise cyclic AMP levels and inhibit platelet function ([873]). The dissociation and function of these a subunits by guanosine diphosphate/GTP exchange, catalyzed by the ligand-bound receptor, are accompanied by the separate activities of the other subunits that function as a ß? dimer to activate PI3 kinase along with phospholipase Cß(s) ([873]) and other signaling molecules.

Phospholipase C and Protein Kinase C Isoforms and Phosphoinositol Hydrolysis The release of IP3 from PI 4,5-P2 is fundamental to platelet activation, because this messenger (IP3) leads to the essential early release of calcium, presumably through the IP3 receptor of the dense tubules, that follows agonist addition ([874]). PI-specific phospholipase C isoforms, specifically beta1 and beta2, also release diacylglycerol from PIP2 that, together with released calcium, stimulates the activity of protein kinase C(s) ([875], [876] and [877]). Although the entire spectrum of protein kinase C substrates remains unclear, one of the main targets is p47 (pleckstrin), which is phosphorylated at several sites and acts in actin reorganization and in PI metabolism ([878], [879] and [880]).

Phosphoinositol Metabolism and Phosphoinositol 3-Kinase Inositol phospholipids, although constituting only a small (<10%) fraction of platelet phospholipids, are intensely active in signaling events and appear to be the focus of synthetic and lipase enzymes that regulate a constellation of substrates and products ([874], [881]).

One of the prominent synthetic enzymes is PI3K, which phosphorylates the different PI species at the 3-position ([882]). The PI3K enzyme(s) appears to interact with several signaling pathways and may play some central and as yet only partially understood role in platelet activation ([883]).

Arachidonate Release and Phospholipase A 2 Generation of platelet TxA_2 appears to be regulated by the availability of the major substrate arachidonic acid (20:4) ([884]). Although the exact pathways of arachidonate release have been extensively studied, the current picture suggests that the bulk of the 20:4 substrate comes from the 2-position of phosphatidylcholine and phosphatidylethanolamine (PE) through the actions of one or more of the isoforms of phospholipase A_2 ([884] , [885]).

Molecular Aspects of Shape Change, Spreading, and Contraction Recent research provides a major advance in our understanding of how platelets change shape, spread, and contract—namely, insight into small GTP-binding proteins that serve a general initiating role in these events ([590] , [625] , [886]). The *Rho* family includes three such platelet proteins that appear to set off separate but related cytoskeletal events: Rac, lamellipodia formation; cdc42, filopodia; and Rho A, focal adhesions and stress fibers ([590] , [887]). A series of proteins translate the initial activation of the *Rho* element to the local, specific end result, including PI3K and related enzymes that produce polyphosphoinositides (PIP2) ([888]); both Wiskott-Aldrich syndrome protein and vasodilator-stimulated phosphoprotein that regulate actin filaments ([889] , [890]); and members of both the serine/threonine (p65PAK family) and tyrosine (pp60 *src* family) kinase families with multiple targets ([891] , [892] and [893]). These pathways converge on a later set of messengers that effect the remodeling of actin filaments ([618]). This next set of agents uncaps, nucleates, polymerizes, and bundles actin, including gelsolin, profilin, thymosin ß 4, vinculin, and zyxin ([613] , [615] , [894]); a variety of additional modulators such as PIP2, mentioned above; myosin, regulated by myosin light chain kinase; and calpains, calcium-dependent proteases that remodel several substrates ([622] , [624]). Altogether, the welter of interactions, substrates, targets, and end results is daunting, and the mix emphasizes the complex regulation of these events ([590]). The overall fact emerges, again, that platelets are actin rich, musclelike fragments, capable of dramatic changes in shape, size, and surface reactivity, that use a host of molecular elements to accomplish the basic goal of plugging vascular holes with an adherent, amorphous, resilient deposit.

Secreted Elements and Molecules Governing Platelet Secretion

Diverse Secreted Proteins: With and without Clear-Cut Function Platelets contain a number of proteins in their a-granules that vary widely in their amount and apparent function. For example, the large amount of the small, platelet-specific proteins PF4 and ß-thromboglobulin does not correlate directly with any obvious, critical contribution to platelet function ([652]). Similarly, megakaryocytes and platelets synthesize and retain a large amount of thrombospondin, but the precise and essential function for this protein remains somewhat unclear ([659]). Recent work demonstrates a new role for PF4. Complexed with heparin and bound to surface Fc?RIIA, PF4 provides a target antigen for the antibodies that mediate heparin-induced thrombocytopenia ([895]). Conversely, with regard to fibrinogen, platelets do not synthesize it but do appear to take it up and concentrate it within granules for its critical role in developing the core of a platelet deposit through aggregation ([648] , [649]). The role of vWF in platelet function is also well defined, and the protein is both synthesized in megakaryocytes and stored in platelets ([661]). However, other adhesive plasma proteins that resemble fibrinogen and vWF, such as vitronectin and fibronectin, are also incorporated into platelet a-granules, but their contribution to function remains unclear.

Molecules of Membrane Fusion Considerable work has led to a general understanding of membrane fusion in a variety of cells ([896] , [897]), and similar insights are now being applied to understanding fusion events in platelets ([898] , [899] and [900]). The challenge is to explain how a granule within a cell or platelet finds a suitable site on the plasma membrane with which to fuse ([896] , [897]). Once fusion occurs, the vesicle or granule contents gain access to the outside milieu, and transport or secretion proceeds. The underlying hypothesis, termed *SNARE* [*s*oluble N-ethylmalei-mide sensitive factor (*N*SF) *a*ttachment protein *re*ceptor], states that vesicles/granules match themselves to a fusion site through the binding of a specific *v*esicle protein (v-SNARE) to a complex in the site or *t*arget (t-SNARE) ([896]). In platelets, three separate granules (a-granules, dense granules, lysosomes) appear to fuse with either the SCCS or the surface plasma membrane, and specific assays that discriminate among these events have led to the identification of molecules of interest ([901] , [902] and [903]). The number of relevant proteins and participants (calcium, diacylglycerol) that regulate each fusion event is large, but considerable progress is being made in this promising area.

Inhibitory Molecules and Pathways In considering the native, nondrug inhibitors of platelets, prostacyclin (PGI2) has been particularly well studied. This unstable, readily hydrolyzed PG is synthesized by endothelial cells and acts through a specific GPCR present on platelets, termed the *IP receptor*, to stimulate adenylate cyclase and raise platelet cyclic AMP levels ([904]). Platelets also respond to the stable PGs (PGE2, D2, F2a) through specific receptors ([905]). A second endothelium-derived platelet inhibitor is nitric oxide that appears to act through a stimulation of guanylate cyclase that raises cyclic guanosine monophosphate ([906]). Additional mechanisms of platelet inhibition involve an endothelial cell ectoenzyme, termed *CD39* or *ecto-ADPase*), that cleaves and inactivates ADP released by platelets ([907]). Platelet activation can also be dampened by receptor desensitization—a process that acts to phosphorylate GPCRs within their cytoplasmic domains ([908]).

Platelet Biochemistry and Metabolism

COMPOSITION: NONIONIC AND IONIC The platelet, after considerable investigation, emerges as a remarkable cell fragment with abundant metabolic capability but minimal ability to synthesize protein because it contains only low levels of RNA and lacks a nucleus. In terms of dry weight, the platelet is composed of approximately 60% protein, 15% lipid, and 8% carbohydrate. Platelet minerals include magnesium, calcium, potassium, and zinc. Platelets contain substantial amounts of vitamin B_{12}, folic acid, and ascorbic acid ([909]). The concentrations of sodium and potassium within the platelet are 39 mEq and 138 mEq, respectively ([910]). This gradient against plasma, apparently distributed in two discrete metabolic compartments, is maintained by an active ion pump, which derives energy from a membrane ATPase of the ouabain-sensitive, Na^+/K^+-dependent type ([910]). Unstimulated platelets maintain a low cytoplasmic Ca^{2+} concentration (~100 to 500 nmol/l) by limiting Ca^{2+} transport from plasma and promoting active efflux of this ion from the cell ([911]). Two pools of calcium are present in platelets: a rapidly turning-over cytosolic pool regulated by a sodium-calcium antiporter in the plasma membrane and a more slowly exchanging pool regulated by calcium, magnesium-ATPase and sequestered in the dense tubular system ([912]). Platelets are, therefore, able to transport calcium from the cytosol by moving it against a gradient into the extracellular space or by sequestration in the dense tubular system.

ENERGY METABOLISM AND GENERATION OF ADENOSINE TRIPHOSPHATE There are several similarities between the energy metabolism of the platelet (Fig. 19.7) and that of skeletal muscle. Both involve active glycolysis and the synthesis and use of large amounts of glycogen ([913]), and in both, the major mediator of intracellular energy use is an actomyosin-like ATPase. The platelet, like muscle, is metabolically adapted to expend large amounts of energy rapidly during aggregation, the release reaction, and clot retraction.

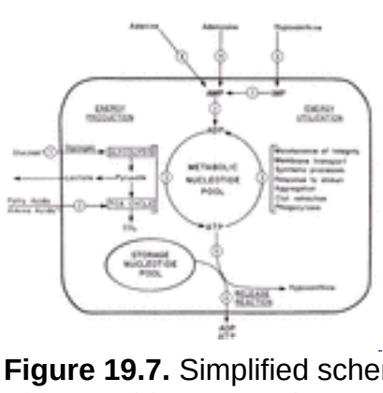

Figure 19.7. Simplified scheme of platelet energy metabolism. Platelet energy is derived from the metabolism of glucose and, to a lesser extent, from the metabolism of fatty acids. Energy is provided in approximately equal amounts by glycolysis and the citric acid cycle. The platelet energy reserve is provided by the metabolic pool of platelet nucleotides that is in a state of continuous turnover. This energy is used for the maintenance of the platelets' structural integrity and in the reactions accompanying the response of platelets to stimuli. The granule-bound storage (nonmetabolic) nucleotide pool is discharged during the release reaction. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; IMP, inosine monophosphate. (Adapted from Hirsh J, Doery JCG. Platelet function in health and disease. Prog Hematol 1972;7:185–234.)

The major energy source for the platelet is glucose, which is rapidly taken up from the plasma (Fig. 19.7, Step 1). Under basal conditions, 40 to 50% of the absorbed glucose is used to provide energy for synthetic functions or is converted into glycogen. Electron microscopy reveals prominent masses of glycogen in some platelets. The glycolytic pathway with its regulatory enzymes (phosphorylase, pyruvate kinase, hexokinase, phosphofructokinase, and glyceraldehyde 3-phosphate dehydrogenase) ([914]), the citric acid cycle, the pentose-phosphate shunt, and the NAD-NADH [nicotinamide adenine dinucleotide–nicotinamide adenine dinucleotide (reduced form)] system are all active in the platelet. Ninety-eight percent of platelet pyruvate is converted to lactate, which leaves the platelet ([915] , [916] and [917]). In addition to glycolysis, platelets contain enzymes for oxidative phosphorylation and fatty acid oxidation (Fig. 19.7, Step 2) ([918] , [919]). ATP production in platelets is affected greatly by the suspending medium, chelating agents, and *in vitro* manipulation of platelets. In plasma, oxidative ATP production by unstimulated platelets is predominant, and all ATP formed by oxidative phosphorylation may be the product of ß-oxidation of fatty acids ([920]); glycogen turnover, the hexose monophosphate shunt, and the citric acid cycle are virtually inactive ([917]). Glycolysis is capable of completely compensating for reduced ATP production when oxidative phosphorylation is inhibited. Platelet stimulation by agents that induce aggregation and release is associated with a marked increase in metabolic activity involving

glycogenolysis ([921]) as well as with glycolysis and oxidation to varying degrees ([914] , [922]). The total amounts of ATP synthesized by the two pathways are approximately equal because of the greater ATP yield per mole of glucose provided by oxidation ([915] , [919]). ATP energy is used in unstimulated platelets to maintain homeostatic levels of H^+, K^+, Na^+, and Ca^{2+} ([923] , [924]).

NUCLEOTIDE METABOLISM AND THE NONMETABOLIC ROLE FOR ADENOSINE DIPHOSPHATE Adenine nucleotides constitute 90% of free platelet nucleotides and are partitioned into at least two different pools, which undergo minimal interchange (Fig. 19.7) ([925]). The metabolic or cytoplasmic pool makes up 40% of total adenine nucleotides; it is used for the maintenance of various energy-consuming cell functions and is retained during platelet release. In large part made up of ATP, this pool is constantly turning over, as revealed by the rapid incorporation of ^{14}C-adenine and ^{32}P-phosphate into ATP. In unstimulated platelets, the relative concentrations of metabolic AMP, ADP, and ATP are maintained by the enzyme adenylate kinase (Fig. 19.7, Step 3) ([926] , [927]). The storage pool, which is present in the dense bodies, contains approximately two-thirds of the total platelet nucleotides, mainly in the form of ADP and ATP ([928]). It is metabolically inactive, does not rapidly incorporate exogenous adenine or phosphate, and equilibrates slowly with the metabolic pool ([929]). Nucleotides in this pool are extruded from the platelet during the release reaction (Fig. 19.7, Step 4) and cannot be replenished after release. ATP hydrolysis is required for conversion of G-actin to F-actin, and the resultant ADP becomes associated with F-actin; this small percentage of platelet ADP bound to actin constitutes one-third of the nucleotide compartment ([930]). Perhaps as much as 40% of all ATP produced is used during the process of actin treadmilling ([931]), and as much as 7% is used in the turnover of the phosphoinositides PIP and PIP2 ([932]). The ATP that is broken down to provide energy for the release reaction is not rephosphorylated; rather, it is irreversibly degraded to hypoxanthine (Fig. 19.7, Step 5), which diffuses out of the cell ([925]). This reaction also proceeds slowly in stored normal platelets ([928]). Hypoxanthine in the plasma may be reincorporated slowly into metabolic AMP by the salvage pathway (Fig. 19.7, Steps 6 and 7) ([928] , [933]). The platelet has only a limited capacity for *de novo* nucleotide synthesis ([934]). In artificial media, adenine nucleotides are synthesized by the platelet from adenine (Fig. 19.7, Step 9) ([927]). The physiologic significance of these pathways is unclear, however, because mammalian plasma does not contain adenine or adenosine. An alternative pathway by which platelet nucleotides are formed presumably is the salvage pathway, the means by which exogenous hypoxanthine is slowly incorporated into metabolic AMP (Fig. 19.7, Steps 6 and 7) ([928]). This nucleotide is formed in the liver, usually is present in the plasma, and may be transported by erythrocytes ([927]). Platelets also contain guanine nucleotides and uracil and cytosine pyrim-idines. The role of cyclic AMP in platelet function has been noted above. Platelet stimulation results in marked activation of ATP-producing pathways ([935]). The steady-state level of ATP decreases, and hypoxanthine accumulates ([935]). In addition, a transient but greatly increased uptake of phosphate by platelets occurs ([936]). Although ATP-requiring processes are activated by platelet stimulation, it is unknown whether or how these are coupled to signal processing in platelets.

LIPID COMPOSITION AND METABOLISM AND THE GENERATION OF ARACHIDONIC ACID Phospholipids constitute 80% of total platelet lipid, with neutral lipids and glycolipids comprising the remainder ([937]). The five major phospholipids identified in human platelets are PC (38% of total phospholipids), PE (27%), sphingomyelin (17%), PS (10%), and PI (5%) ([563]). Studies of platelet subcellular fractions reveal that 57% of total human platelet phospholipids are present in the plasma membrane ([938]). Most of the negatively charged phospholipids (i.e., PE, PI, and PS) are contained in the inner leaflet ([938] , [939] and [940]), an asymmetric arrangement that prevents inappropriate coagulation by sequestering the phospholipids that accelerate plasma coagulation (mainly PS) away from the platelet surface. Such an asymmetric arrangement may be maintained by an aminophospholipid translocase or "flipase" in platelet membranes ([941] , [942]) that selectively pumps PS and PE from the outer to inner plasma membrane; choline-bearing phospholipids would accumulate by diffusion in the outer membrane ([943]). This asymmetry collapses when platelets are activated ([944]). These same phospholipids (i.e., PS and PE that interact with coagulation proteins) redistribute with platelet activation and are thereby exposed on the surface to function in promoting clot formation ([945]). The process appears to be controlled by one or more recently described enzymes, termed *scramblases* ([946] , [947]). Almost all platelet fatty acids are esterified in phospholipids, leaving only trace amounts in the free form. Platelet phospho-lipases are enriched in arachidonate, the precursor of PGs, at their "*sn-2*" position ([884] , [948]). After agonist stimulation, phospho-lipase A_2 activity rises, probably through phosphorylation of the platelet "type IV" isoform, and arachidonic acid is released from membrane phospholipids, predominantly PC ([949] , [950] and [951]). The combination of phospholipase C and diglyceride lipase may contribute to this PG substrate release ([952]). After release, arachidonic acid is oxygenated to form the cyclic endoperoxide intermediate, PGH2, by cyclooxygenase-1 [the recently crystallized platelet form of the major PG-forming enzyme ([953] , [954]), which leads to TxA_2 formation ([884] , [948])]. The lipoxygenase pathway accounts for a small proportion of arachidonate metabolism, producing mainly 12-HETE (12-hydroxy-eicosatetraenoic acid) whose functional role remains unclear ([955]). Neutral lipids, mainly cholesterol, make up approximately 28% of total platelet lipids. Cholesterol is a major constituent of platelet membranes and is also present in the platelet cytoskeleton ([956]). It is synthesized by megakaryocytes but not by platelets. Finally, neutral glycolipids, gangliosides, and ceramides have been detected in platelets ([937]).

Platelet Microparticles, Heterogeneity, and Kinetics

MICROPARTICLES The concept of "platelet dust" or microparticles has attracted a good deal of attention ([957] , [958]). These tiny structures are rich in surface PS and can contribute significantly to the acceleration by platelets of plasma coagulation, specifically factor Xa and thrombin generation ([958]). Apparently formed by calpain- and scramblase-mediated detachment of buds extended from platelet pseudopods ([959] , [960]), microparticles can be visualized by electron microscopy ([961]) and have been found to bind factors Xa, VIII, and Va, along with protein S ([962] , [963]). The composition of microparticles varies with the agonist or stimulus (C5b-9, ionophore A23187, thrombin, tissue factor, shear) involved in their formation ([964] , [965]), but their physiologic significance seems clear—particularly because platelets from a patient with Scott syndrome, a disorder in which clinical bleeding occurs, exhibit defective microparticle formation and function ([966] , [967]).

PLATELET HETEROGENEITY Platelets vary in number, size, density, age, and apparent physiologic effectiveness. The normal platelet count varies between 150 to 400,000 per µl, and normal platelet size (mean platelet volume) varies between 7.5 and 10.5 fl. However, perhaps the main point that emerges from the clinical observation is that some patients with severe thrombocytopenia have little or no bleeding, often with morphologically large platelets on blood smears. This type of largely anecdotal information has spawned the idea that some individuals have "hyperfunctional" platelets that compensate for low numbers by their increased effectiveness ([968]). A literature has developed that supports the idea that young platelets, presumably those recently released from the bone marrow, are larger and more dense, contain more of certain proteins (i.e., PF4), and exhibit some alterations in function as compared to smaller platelets ([969]). Circulating platelets may, indeed, diminish in size during a normal circulating lifespan by shedding some of their surface components, and this process may reflect hemostatic events that do not result in loss of the entire platelet ([970]). It is uncertain whether platelets of different sizes and densities originate from different populations of megakaryocytes ([971]). However, many of the properties of large platelets may reflect unique attributes of platelets recently released from the marrow or proplatelets produced under conditions of accelerated production ([972]).

PLATELET DISTRIBUTION AND SURVIVAL KINETICS

Labeling Platelets labeled with ^{51}Cr (chromate) have been used to estimate platelet lifespan in humans at 8 to 12 days ([973]), and the method has been widely validated ([974]). Alternatively, and more recently, ^{111}In (indium) chelated with 8-hydroxyquinoline has been used to label platelets, as have ^{32}P-labeled diisopropylfluorophosphate, ^{68}Ga (gallium), and nonisotopic methods using aspirin inhibition of TxB_2 formation or biotin ([975] , [976] , [977] , [978] and [979]). Platelet labeling is not commonly used at present for clinical evaluations, but all of the published studies give the same approximate values for distribution and survival.

Distribution Transfusion of ^{51}Cr-labeled platelets into normal subjects results in approximately two-thirds remaining in the circulation—in contrast to nearly 100% in splenectomized patients ([980] , [981]). In addition, administration of epinephrine, which evacuates platelets from the spleen, increases the peripheral platelet count 30 to 50% ([981]). Platelet counts in asplenic patients are not affected. Taken together, these data suggest that approximately one-third of the total platelet mass pools in the spleen. Some studies suggest that the splenic pool consists of the youngest, largest platelets ([982]). The splenic pool exchanges freely with the platelets in the peripheral circulation. The mechanism of splenic sequestration has been hypothesized to result from a longer transit time through the splenic cords (which platelets enter because of their small size) or from binding to the reticular and endothelial cells of the spleen ([983]). Pathophysiologic states can result in 80 to 90% of platelets being sequestered in the spleen, resulting in thrombocytopenia. Release of platelets from the lungs after intracardiac administration of epinephrine has been reported ([984]). Also, platelet counts rise after vigorous exercise, and this rise is not affected by splenectomy ([985]). This nonsplenic pool represents approximately 16% of the total platelet mass.

Lifespan Platelet lifespan, based on the time required to clear labeled platelets from the circulation, has been estimated to be 8 to 12 days in humans. In steady state, when platelet production equals destruction, platelet turnover has been estimated at 1.2 to 1.5 × 10^{11} cells per day ([980] , [986]). Recommendations for estimation of platelet lifespan have been published by the Panel on Diagnostic Application of Radioisotopes in Hematology, International Committee for Standardization in Hematology ([986]), and multiple models for analysis of platelet lifespan have been proposed ([987]). The sites for platelet removal appear to be the spleen ([981]), the liver, and the bone marrow ([988]). Evidence that the primary site for platelet removal is the spleen includes data that platelet survival in dogs increases 47% after splenectomy ([989]), but studies of the effect of splenectomy on platelet lifespan in humans have produced mixed results ([988] , [990]). There is disagreement as to whether platelets are removed from the circulation by a random process or as a result of senescence. Mathematic models, which predict rectilinear platelet survival curves if senescence is the primary component or curvilinear survival curves if random processes predominate ([991]), do not aid in the resolution of this controversy because platelet survival curves not only are a composite of mathematic functions, but also vary with the labeling method used.

Interactions beyond Platelets: The Coagulant System

PLATELET INTERACTIONS WITH THE PLASMA COAGULATION SYSTEM The plasma coagulation “cascade” or “waterfall” involves both extrinsic and intrinsic pathways and generates factor Xa and thrombin through the formation of successive calcium-dependent complexes ([992]). In turn, such complex development occurs primarily on phospholipid surfaces ([993] , [994]); with the discovery that soluble factor Xa bound avidly to FVa on the surface of activated platelets and produced explosive thrombin generation, the idea arose that the surface of activated platelets could be a major site for coagulation reactions ([566] , [568] , [995]). A further elaboration of the concept of “platelet-based coagulation” holds that activated platelets may contain a specific protein(s), linked with surface factor Va, and perhaps missing in Scott syndrome, that provides part of the specific binding site for plasma factor Xa and accounts for the dramatic amplification of factor Xa's ability to generate thrombin ([967] , [995]). At this point, the “long-sought-for protein(s)” remains somewhat uncertain ([568]) and could even be classified under the rubric of “platelet factor 3,” an operational term for an as yet unclear platelet component that accelerates coagulation ([996]). This is, however, an area of active research, and a protein of interest, effector cell protease receptor-1 (EPR-1), has been identified that accounts for part of the factor Xa–binding site. First isolated from leukocytes and endothelium ([997] , [998]), EPR-1 alone can bind factor Xa, but it is found associated with FVa on the surface of activated platelets where it forms part of the factor Xa–binding site, confirmed with the use of an anti–EPR-1 monoclonal antibody ([999]). In view of the fact noted above that thrombin is generated by platelet-bound factors Va-Xa ([1000]), investigators also asked if a similar set of reactions might govern a second and separate set of interactions, involving factor Xa formation through soluble factor IXa interacting first with platelet-bound VIIIa and then cleaving factor X to Xa ([1001]). Similar results were obtained, showing that the presence of activated platelets significantly accelerates factor IXa-VIIIa–dependent factor Xa production, which could be termed an *intrinsic generation* of factor Xa because it does not involve tissue factor necessarily and does proceed through factor IX ([567] , [1001] , [1002] , [1003] , [1004] and [1005]). However, no platelet protein(s) has been defined that combines with platelet-bound factor VIIIa to form a site for soluble factor IXa ([568] , [1005]), and factor VIII, unlike factor V, does not appear to be present within resting, unactivated platelets ([568]). Because the plasma carrier protein for factor VIII, vWF, is synthesized by megakaryocytes, the presence of vWF in platelets does not imply that factor VIII must also be *present within the platelet* ([1006] , [1007]). Platelets also may not take up significant amounts of plasma vWF with its bound factor VIII—a clear difference from their active uptake of plasma fibrinogen ([649]). This system of *intrinsic* generation of factor Xa through platelet-bound factor VIIIa-IXa can provide factor Xa for the “first” FVa–EPR-1 system described above, but *extrinsic* production of factor Xa would also be expected at any site of cellular damage or injury through the well-known pathway of tissue factor and plasma factor VIIa acting on plasma factor X ([1008]). However, such “soluble” or fluid-phase formation of factor Xa may be limited by the plasma inhibitor of the tissue factor pathway termed *tissue factor pathway inhibitor* that binds the complex of factors VIIa and Xa that forms with tissue factor ([1009]). The above-described system of factor Xa generation on platelets leads to a subsequent, related question: namely, the origin of the factor IXa that provides its proteolytic effector ([568]). Prior work indicates that factor IXa can arise through both the well-known factor XIa–dependent step of the “cascade” and a more recently recognized pathway involving tissue factor–factor VIIa ([1010]). The possibility of FXIa involvement has proved to be a fascinating area for investigation and has led to the third aspect of the platelet-coagulation axis concerning both platelet *and* plasma factor XI and the initiation of the intrinsic pathway to form factor IXa ([1011]). One of the major obstacles in understanding plasma coagulation has been our inability to explain the contact system and the dichotomy between factor XI, whose deficiency causes bleeding, and the other contact factors (factor XII, high-molecular-weight kininogen, prekallikrein), whose absence does not cause bleeding ([1012]). At least a partial explanation has come in the form of a “revised model” for coagulation based on the discovery that thrombin can activate factor XI, particularly on platelet surfaces or in the presence of proteoglycans ([1013] , [1014]). In this instance, traces of thrombin, generated through tissue factor from sites of cellular injury, activate plasma factor XI (bound to platelets through the presence of prothrombin itself), which, in turn, activates plasma factor IX and leads to a subsequent dramatic increase in thrombin production ([1015] , [1016] and [1017]). Such a sequence of events is favored by the presence of platelets that protect any surface-bound reactants from soluble inhibitors, such as protease nexin II, and conserve any small amount of initial thrombin by linking it to immobilized protein substrates, away from plasma inhibitors ([1017]). The data are consistent with the clinical observation that the amount of *platelet* factor XI (*not plasma* factor XI; platelet FXI is a “splice variant” relative of plasma factor XI, although the precise role of platelet FXI remains uncertain) determines the bleeding severity in deficient patients, and the information explains how factor XI can be activated regardless of other contact factors ([1018] , [1019]). This work illustrates that platelets play a multifaceted role in coagulation and emphasizes the fundamental difference between *resting* platelets with no ability to accelerate coagulation [except for prothrombin binding to gpIIb-IIIa on resting platelets ([1020])] and agonist- *activated* platelets that are intensely active participants. The question of whether platelet microparticles or whole activated platelets are more relevant/significant in terms of providing the surface for coagulation reactions has been addressed, and whole platelets have been judged to be more relevant ([1021]). Each of the three systems described above produces a critical protease (IIa-thrombin, factor Xa, factor IXa), and each one has both unique and shared features. However, many aspects remain unknown such as the modification of the activated platelet surface by scramblase enzymes, the individual role(s) of anionic phospholipids, and the potential contributions of additional proteins that may interact with platelet-expressed Va (besides EPR-1), factors VIIIa or XIa (besides prothrombin). Regardless of the exact mechanisms involved, the binding of any coagulation factor to a high-affinity binding site on the platelet plasma membrane concentrates that factor locally and can orient it with respect to other factors. Also, multiple studies show that platelet surface–bound coagulation proteins are generally protected from their usual plasma inhibitors ([1022]). Finally, such binding (i.e., factor Xa to activated platelets) can facilitate the rapid delivery of a potent coagulant and potential agonist to a site of vessel injury where it may be most valuable in hemostasis.

“PLASMA” COAGULATION FACTORS WITHIN PLATELETS Three factors (factor V, fibrinogen, and vWF) found in platelet a-granules appear to be the most significant elements in platelet contribution to coagulation (Table 19.6). Platelets have particularly large amounts of fibrinogen, which they do not synthesize, and lesser amounts of vWF, which they do. The origin of FV appears to be a combination of incorporation from plasma and *de novo* synthesis in megakaryocytes ([568]).

TABLE 19.6. Platelet-Associated Coagulation Factors

Protein	Amount Present	Subcellular Localization	Mechanism of Release or Exposure	Proposed Function
Fibrinogen				
Total	5–25 mg/10^{11} platelets [a]			
Surface-associated	0.3–10.0 mg/10^{11} platelets [b, c]	Adsorbed to platelet	Not released	Platelet aggregation by adenosine diphosphate
Intracellular	3–7 mg/10^{11} platelets [a]	Membrane a-granules	Secretion	?Platelet aggregation by thrombin
Factor V	0.25–0.77 mg/10^{11} platelets [b]	a-Granules	Secretion	Receptor for factor Xa
von Willebrand factor	10–64 units/10^{11} platelets [c]	a-Granules	Secretion	Platelet adhesion
Factor XI	1.2–6.1 units/10^{11} platelets [a]	Platelet membrane	Unknown	Initiation of intrinsic coagulation
Factor XIII	50% of the total in blood [a]	Cytosol	Not released	a Subunit of factor XIII
High-molecular-weight kininogen	60 µg/10^{11} platelets [d]	a-Granules	Secretion	?Contact activation of coagulation

[a] Quantitation by bioassay.

[b] Quantitation by radioimmunoassay.

[c] Quantitation by electroimmunodiffusion.

[d] Quantitation by competitive enzyme-linked immunosorbent assay.

The bulk of FV (20% of total factor V in blood) is located in the a-granules, and the thrombin-activated form, factor Va, is the major secreted platelet phosphoprotein ([1023] , [1024]). The distinct and critical role of FV in hemostasis is underscored by the findings in two kindreds of factor V Quebec, in which a selective defect in a-granule factor V (plasma factor V is nearly normal), probably due to excessive granule-based proteolysis, is accompanied by a severe bleeding diathesis ([1025] , [1026]). Platelet fibrinogen, like the plasma form, is a large dimeric protein. However, it constitutes up to 10% of total platelet protein ([1027] , [1028]), and recent evidence shows that, in addition to its well-known role in ADP-induced platelet aggregation, it also appears to be essential for the development of the core region of a developing platelet deposit/thrombus ([1029]). Platelet vWF does not currently have a distinct, described role in platelet function, apart from that of the plasma molecule. It is present in

relatively large amounts in a-granules, and after platelet secretion in response to agonists, it interacts with either gpIIb-IIIa or gpIb ([1030]). Platelet vWF does consist of large multimers and may play a role in platelet adherence to subendothelium ([1031]).

OTHER PLATELET "COAGULATION" FACTORS The numerous platelet proteins that participate in plasma coagulation are listed in Table 19.6. Several additional plasma coagulation factors are associated with platelets along with a variety of coagulation inhibitors as noted below. FXIII is contained in the cytosol and is not organelle associated; it is a fully active subunit of plasma factor XIII. FXIII makes up 50% of the total amount of factor XIII activity in blood. It has been suggested that it provides the a subunit for plasma factor XIII ([1032]). High-molecular-weight kininogen is present in a-granules and is secreted and expressed on the platelet plasma membrane after thrombin activation ([1033]). The function of platelet high-molecular-weight kininogen is unknown. Platelets contain 2.5% of protein S found in whole blood. This protein is synthesized in megakaryocytes, stored in a-granules, and released from platelets on thrombin stimulation ([1034]). It is thought that secretion and binding of this pool of protein S to the platelet membrane localize activated protein C on the platelet surface, and together these promote the rapid inactivation of coagulation factors Va and VIII on membranes ([1035]).

Protease Inhibitors All known plasma protease inhibitors ([1036]) are also localized to platelet a-granules. These include a $_1$-protease inhibitor, a $_2$-macroglobulin, C1 inhibitor, a $_2$-antiplasmin, plasminogen activator inhibitor-1, lipoprotein-associated coagulation inhibitor, protease nexin I (thrombin inhibitor), and protease nexin II (factors IXa and XIa inhibitors).

Clot Retraction When whole blood is placed in a glass tube and simply left to clot for several hours at ambient temperature, clear serum is expressed from the bulk of the fibrin–red cell mass as platelets exert their global contractile potential ([1037]). This ability of platelets to incorporate essentially all the red cells into and to extrude essentially all the serum proteins (except fibrin) and fluid out of the clot has fascinated observers for centuries and led to the inevitable conclusion that this same *in vitro* process might be replicated in the same fashion *in vivo* ([1038]). This is a logical but unproved hypothesis. Formal laboratory study of clot retraction indicates that platelet contractile proteins, such as actomyosin, participate as do the major surface receptor and plasma ligand, gpIIb-III and fibrinogen ([1039]). However, beyond these broadly based studies, relatively few additional details are available to translate this dramatic laboratory event into a physiologic mechanism. However, with current interest and technology to assess the progress on *ex vivo* systems, such observations may be feasible in the near future.

Platelet Function in Hemostasis and Thrombosis

PLATELET ADHESION AND ACTIVATION

Primary hemostasis and arterial thrombosis are the results of a complex series of cell–cell, cell–protein, and protein–protein reactions that involve platelets, leukocytes, subendothelial matrix, and plasma proteins, such as fibrinogen, von Willebrand factor (vWF), and others. The consequences of arterial thrombosis include such events as myocardial infarction (MI), unstable angina, and stroke. These clinicopathologic entities and their associated cellular physiologic mechanisms that are outlined in this chapter collectively account for the largest cause of morbidity and mortality in the Western world.

Platelet Glycoprotein Ib Complex–von Willebrand Factor Interaction and Signaling

For a long time, it has been recognized that interaction of the platelet glycoprotein (gp) Ib "complex" (including the single-chain polypeptides gpIba, gpIbß, gpIX, and gpV) with its primary ligand, vWF, is the receptor–ligand pairing that initiates platelet activation followed by a cascade of events leading to pathologic thrombosis or physiologic hemostasis. A unique aspect of this receptor–ligand interaction is that it requires the presence of high arterial shear rates to take place, thus explaining the predisposition of platelet-rich "white clots" for the arterial circulation over clots found in the venous circulation with its relatively lower shear forces in which clot formation takes place independent of the gpIb complex.

Using a parallel plate flow cytometer, platelet interaction with subendothelial vWF has been characterized as occurring in a biphasic fashion ([1]). In this respect, the rate of translocation of platelets from blood to the endothelial surface increased linearly up to wall shear rates of 1500 sec (-1), whereas the translocation rate remained relatively constant with the wall shear rate between 1500 and 6000 sec (-1). This ability to mediate translocation or rolling of the platelet on vWF is contingent on the gpIb complex, and mammalian cells expressing either the full complex or a complex lacking the gpV subunit were able to roll onto vWF in a gpIba-chain–dependent manner ([2], [3]).

It is clear that arterial thrombus formation is contingent on both the presence of high wall shear rates and interaction between the gpIb complex and vWF. Studies involving the endpoint of real-time thrombus formation that involved comparison of both blood from patients with Bernard-Soulier syndrome (that lacks platelet gpIb complex) and severe (type 3) von Willebrand disease versus normal blood led to the conclusion that gpIb and vWF interaction was required for platelet surface interaction at high shear rates [>1210 sec(-1)], whereas normal thrombus formation at lower shear rates [<340 sec(-1)] was possible with blood deficient in either gpIb or vWF ([4]). In normal blood, thrombus formation was accelerated as shear rate increased, and this served to verify the unique shear flow dependence of this receptor–ligand interaction.

The gpIb complex consists of four transmembrane subunits, each of which is a member of the leucine-rich repeat protein superfamily that participates in cell–matrix interactions throughout nature. Each of the four subunits contains one or more tandem, 24–amino acid leucine-rich repeats flanked by conserved disulfide loop structures at both the *N*- and *C*-termini of the repeats ([5]). gpIba is covalently associated with the gpIbß-chain through disulfide linkage of cysteine residues, and both of these chains are noncovalently associated with gpIX in a 1:1 ratio and with gpV in a 2:1 ratio ([6], [7] and [8]) (Fig. 20.1). The structural aspects of the gpIb complex are examined in greater depth in Chapter 19.

Figure 20.1. Glycoprotein (GP) Ib complex. GPIba disulfide linked to GPIbß is noncovalently associated with GPIX and GPV in the ratio of 2:2:2:1. Phosphorylation sites within the cytoplasmic tails of GPIba (Ser 609) and GPIbß (Ser 166) are indicated by a circled P. (From Berndt MC, Shen Y, Dopheide SM, et al. The vascular biology of the glycoprotein Ib-IX-V complex. Thromb Haemost 2001;86:180, with permission.)

vWF is a large multimeric glycoprotein that circulates in plasma and is also found in platelets and the Weibel-Palade bodies of endothelial cells. Mature vWF is a 2050–amino acid subunit that is disulfide linked into large multimers. It contains three adjacent A domains in the *N*-proximal half of the peptide that collectively regulate the adhesion of platelets to subendo-thelial matrix. In this respect, the A_1 and A_3 domains bind to different matrix collagens, whereas the A_1 domain contains the binding site for the gpIb complex ([9]). The A_1 domain is the primary role player in platelet adhesion because this part of the molecule is believed to change its conformation in response to immobilization and high shear forces, thus making it a high-affinity ligand for the gpIb complex receptor ([10], [11]). It has also been suggested that shear stresses may induce conformational changes in the gpIb complex that may be important in increasing its affinity for vWF ([12]).

To further add to the mystery behind the mechanism of shear dependence in gpIb–vWF interaction, *in vitro* activation of vWF and binding to the gpIb complex occur with generally very low affinity without shear, whereas this shear-free binding exhibits high affinity in the presence of the vancomycin-like antibiotic ristocetin and viper venom proteins, such as botrocetin. Interestingly, studies incorporating anti-gpIba and anti-vWF domain A_1 antibodies have suggested that ristocetin and botrocetin

each appear to use different receptor and ligand-binding sites to facilitate vWF–gpIb complex interaction ([13], [14] and [15]).

The binding interaction between vWF and gpIb appears to involve at least three distinct regions within the *N*-terminal 282 residues of gpIb. Each of these regions appears to be responsible for either direct binding to vWF or modulating its affinity for the ligand ([16]). In this respect, one region (His 1 to Glu 282) that includes a cluster between residues Asp 252 and Arg 293 containing sulfated tyrosine residues and important anionic residues appears to be predominantly responsible for vWF–gpIb complex interaction in the presence of botrocetin over ristocetin ([17], [18], [19] and [20]).

The second region contains the disulfide loop between Cys 209 and Cys 248 along with two naturally occurring mutations (Gly 233 to Val and Met 239 to Val) and two additional mutation sites identified in the laboratory (Asp 235 to Val and Lys 237 to Val) that can individually lead to expression of the pseudo- or platelet-type von Willebrand disease phenotype ([21]). This disorder is associated with a gain-of-function gpIba on platelets that adheres to vWF in the presence of lower concentrations of ristocetin (0.3 to 0.5 mg/ml) than is required for the wild-type phenotype (1.5 mg/ml). It is analogous to type 2B von Willebrand disease, in which high-molecular-weight vWF multimers are absent from the plasma, and similar gain-of-function mutations have been localized to the Cys 509 to Cys 695 disulfide loop of vWF exon 28.

The third region includes the *N*-terminal flanking sequence to the leucine-rich repeat (LRG) motifs and the LRGs themselves. Mutations involving single amino acid residues within these LRGs account for some cases of the congenital bleeding disorder Bernard-Soulier syndrome in which the gpIb complex binds poorly or not at all to vWF. Evidence using mammalian Chinese hamster ovary cells expressing loss-of-function proteins and anti-gpIba monoclonal antibodies has suggested that the more *N*-terminal LRGs may play a more direct role in interaction with vWF ([22]).

GLYCOPROTEIN IB COMPLEX INTERACTION WITH THROMBIN Recent studies have examined the potential role of the gpIb complex in thrombin-mediated platelet activation. The physiologic significance of the interaction of thrombin with the complex has remained relatively controversial. gpIba contains a well-characterized high-affinity binding site for thrombin (see Chapter 19), and thrombin is also capable of cleaving gpV near the surface to release a soluble fragment ([23]). Recent studies have suggested that a relationship exists between thrombin binding to the gpIb complex and cleavage of the seven-transmembrane G protein–coupled protease-activated thrombin receptor, protease-activated receptor (PAR)-1 [see the section Platelet Thrombin (Protease-Activated) Receptors and Signaling], and that accelerated coagulation on the surface of a developing thrombus is a downstream consequence of thrombin–gpIb interaction because of enhanced phospholipid exposure ([24], [25]). These studies support a procoagulant role of this thrombin–gpIb pairing. In contrast, studies using gpV-null mice have suggested that the gpV subunit may act as a negative regulator of thrombin-mediated platelet activation, whereas data from another study suggest that thrombin–gpIb interaction leads to conformational changes in thrombin that reduce its cleavage of fibrinogen ([26], [27]). The phenotype of a gpIba knock-out mouse has been reported and was similar in many ways to human Bernard-Soulier syndrome ([28]). This mouse was then capable of having the wild-type phenotype restored by a human gpIba transgene. Future use of this mouse model might be helpful toward further elucidation of the physiologic role of platelet gpIb complex interaction with thrombin ([29]). In the meantime, the current data extend further support for a role for the gpIb complex as a thrombin receptor on platelets, whereas, recent insights not withstanding, elucidation of the downstream consequences of that interaction with respect to platelet activation and thrombus formation will remain the subject of further investigation. Studies have focused on interaction of the gpIb complex with activated, intact endothelium through ligands other than vWF adherent to subendothelial matrix. These include a study of a reversible association of gpIb with endothelial cell P-selectin, which is examined in more detail in the section Platelets and Endothelium. The interaction of platelet gpIb with the neutrophil adhesion receptor Mac-1 is discussed in the section Platelets and White Blood Cells . One 1999 study has documented the dependence of fibrin-associated platelet procoagulant activity on both the gpIb complex and vWF ([30]).

GLYCOPROTEIN IB COMPLEX SIGNALING When the gpIb complex interacts with its vWF ligand under conditions of elevated shear stress, there is abundant evidence that signaling pathways are activated that lead to (a) elevation of intracellular calcium; (b) activation of protein kinase C (PKC), phosphoinositide 3-kinase (PI3K), and tyrosine kinases such as c-src; and (c) inside-out signaling through the $a_{IIb}ß_3$ integrin followed by platelet aggregation ([16]). Recent attention with respect to downstream events after gpIb receptor occupancy has been directed to the roles of (a) the homodimeric signaling protein 14-3-3, (b) receptor cross-linking, and (c) the immunoreceptor tyrosine-based activation motif activation motif (ITAM)–containing proteins Fc? receptor IIA (Fc?RIIA) and Fc receptor (FcR) ?-chain. 14-3-3? is among the ten isoforms of the 14-3-3 family of proteins that is named according to its electrophoretic gel migration position. Functionally, this family has a wide range of activities, including participating as a DNA damage cell cycle checkpoint protein, regulation of PKC activity, formation of heterotrimers with the signaling kinase Raf and the guanosine triphosphate exchange factor Ras, and so forth ([31], [32] and [33]). Binding sites for 14-3-3 have been identified in the cytoplasmic domains of gpIba, gpIbß, gpIX, and gpV. In this respect, peptide fragments corresponding to overlapping cytoplasmic sequences of the four subunits demonstrated binding *in vitro*, whereas yeast two-hybrid studies documented *in vivo* interaction between 14-3-3? and both gpIba and -ß ([34], [35]). Site-directed mutagenesis and protein binding experiments confirmed the need for phosphorylation of Ser 166 of the 14-3-3 consensus sequence in the gpIbß cytoplasmic domain to permit high-affinity 14-3-3 binding ([35], [36]). More recent findings that have evolved in lieu of the above observations include the binding of fibrinogen to mammalian cell-transfected $a_{IIb}ß_3$ in response to vWF binding to cotransfected gpIb-IX that was inhibited when the 14-3-3 binding domain was deleted from the gpIb-IX transfectant ([37]). Also, the lipid kinase PI3K has been found to play a role in this gpIb-IX dependence of $a_{IIb}ß_3$ activation through its participation in complex formation with the gpIb complex and 14-3-3 ([38]). The reason for these associations would be to regulate, in short order, the formation of inositols phosphorylated in the 3-position within the reorganizing cytoskeleton in response to platelet activation (see the section Role of the Cytoskeleton in Platelet Function) ([16]). It has been shown that the binding between gpIba and 14-3-3 is disrupted in response to binding of the former to vWF under high shear stress, and this disruption is, in turn, blocked by the prostaglandin (PG), prostacyclin (PGI_2) ([36]). Inhibition of platelet activation by PGI_2 works through its interaction with specific G protein–coupled receptors on the platelet surface, resulting in the activation of adenylyl cyclase that induces the formation of cyclic adenosine monophosphate (cAMP). This mediator, in turn, activates cAMP-dependent kinases [also called *A kinases* or *protein kinase A* (PKA)], which phosphorylate specific proteins that inhibit platelet activation. Ser 166 of gpIbß is phosphorylated by PKA that has itself been activated by PG-driven cAMP. It is, therefore, reasonable to speculate that gpIbß–14-3-3 association may be playing a role in maintaining signaling through the gpIb–cytoskeleton complex in a switched-off or resting state and that it is capable of undergoing transition to an activated state when shear-dependent interaction of gpIba with vWF takes place. Many adhesion receptors initiate signaling through cross-linking, and there is evidence to suggest that the gpIb complex may also use this mechanism. gpV subunit surface expression on platelets is roughly half that of the other three subunits (12,000 vs. 25,000 copies per cell). It has also been suggested that two or more gpIba subunits cluster into a complex with the other glycoprotein subunits ([39]). The fact that there is one gpV subunit available in this complex for every two of the other subunits, and that both actin-binding protein (ABP; a membrane skeleton protein that associates with gpIba; see later in the chapter) and 14-3-3 exist as dimers, lends support to the concept of a complex consisting of a pair of gpIba–gpIbß–gpIX trimers joined noncovalently by a single gpV monomer (Fig. 20.1). Two 1999 studies interestingly documented association of the gpIb complex with the 14-kd FcR?-chain ([40]) and with the 40-kd Fc?RIIA receptor ([41]). Both of these proteins contain nonidentical but similar ITAM domain sequences. The FcR?-chain forms a complex with the gpVI monomer and plays an essential role in collagen-mediated platelet activation, as reviewed in the next section. The Fc?RIIA receptor is a member of the immunoglobulin (Ig) superfamily and is without a clearly defined physiologic role in platelets. Occupancy of this receptor by the *C*-terminal Fc domains of Ig leads to platelet activation, and this is blocked by anti-gpIba antibodies, whereas signaling through vWF is also blocked with anti-Fc?RIIA antibodies ([41], [42]). Both ITAM-containing receptors can be coimmunoprecipitated with gpIb ([40], [42]), and both have very similar signaling pathways that involve the tyrosine kinase Syk and phospholipase C (PlC)?2 ([43], [44] and [45]). Although the physical proximities of these three players have recently become apparent, the nature and significance of any physiologic relationships that exist between the gpIb complex and these two ITAM receptors with respect to vWF-dependent platelet activation is presently unclear.

Platelet–Collagen Interaction and Signaling

Collagens are very important activators of platelets in the vascular subendothelium and vessel wall, and thus are prime candidates for therapeutic intervention in patients experiencing a pathologic arterial thrombotic event such as MI or stroke. Platelets have two major surface receptors for collagen, the integrin $a_2ß_1$ and the Ig superfamily member gpVI. The former is considered to be the primary player in platelet adhesion, whereas gpVI is currently believed to play a role in signaling and subsequent platelet activation. In addition to these two surface receptors, the gpIb complex can also be considered an indirect collagen receptor because its subendothelial vWF ligand essentially acts as a bridging molecule between platelets and collagen by fixing itself to the latter that, in turn, acts as scaffolding for the multimers.

The molecular sequence of events by which subendothelial collagen fibrils bind to and activate platelets is presently unknown, and large parts of this area remain controversial and poorly understood ([46], [47]). Collagen supports platelet adhesion through interaction with the integrin surface receptor $a_2ß_1$, although this interaction alone does not support platelet activation ([46], [48]). Laboratory evidence suggests gpVI and the 14-kd FcR?-chain signaling subunit (FcR?-chain) with which gpVI forms a complex are both required for collagen-mediated platelet adhesion and activation ([43], [48], [49], [50], [51], [52], [53], [54], [55], [56], [57], [58] and [59]). In addition to these two players, evidence has recently emerged for the possible roles of additional platelet surface receptor and is reviewed later in this section.

a $_2$ß $_1$ RECEPTOR The platelet collagen receptor to be first identified and characterized was the integrin a $_2$ß $_1$ receptor, also known as *gpIa/IIa*, and on lymphocytes as *VLA-2* ([60]). Integrins are a family of a-ß heterodimers on the surface of cells that carry out a diverse array of interactions between the cell surface and its environment that ultimately leads to changes in cell behavior in response to the ligand–receptor interaction. In all a subunits of integrins, seven tandem repeats are localized to the *N*-terminal end and folded into a seven-bladed ß propeller structure ([61]). The a $_2$ subunit also contains an I domain between the second and third repeats that includes a metal coordination site for Mg $^{2+}$ that is critical for interaction with collagen ([47]). Similar domains are found on the ß subunit, although less is known about these, and it appears that the interaction of a $_2$ß $_1$ with collagen involves only the I domain of a $_2$. The ß $_1$ subunit exhibits a cysteine-rich domain containing CGXC sequences that is close to the membrane surface. This region has protein disulfide isomerase activity that is responsible for regulating conformational changes of the ß $_1$ subunit (which, in turn, alters a $_2$ conforma-tion, increasing its avidity for collagen) in response to inside-out signaling through the cytoplasmic domain ([62] , [67]). Thus, the a $_2$ß $_1$ integrin is probably regulated by this endogenous disulfide isomerase activity that rearranges the cysteine-rich domains of ß $_1$ and thereby alters the high-affinity state of the I domain on a $_2$. In 1991, the so-called two-step, two-site model was proposed by Santoro and colleagues to explain interaction between platelets and collagen ([63]). The hypothesis speculated that collagen needed to first interact with a $_2$ß $_1$ (adhesion) before it was able to initiate transmission of intracellular signals leading to platelet activation. Since then, much evidence has accumulated that the “second site” responsible for platelet activation is gpVI, as outlined below. For this model to hold true, it is presumed that conformational change in a $_2$ß $_1$ would not be a necessary prerequisite for its ability to adhere to collagen. However, recent data have suggested that when the platelet interacts with other agonists besides collagen, subsequent activation will increase the affinity between a $_2$ß $_1$ and collagen ([64] , [65]). This evidence lends support to a $_2$ß $_1$ undergoing some sort of conformational change after inside-out signaling initiated by some noncollagen agonist that then optimizes its adhesive affinity for subendothelial collagen. To further muddy the waters, it is known that under high shear stress conditions typically present in the arterial circulation, the interaction between platelets and collagen is much reduced if either the gpIb complex or its plasma vWF ligand is absent or blocked. So although a $_2$ß $_1$ and gpVI may be principally responsible for platelet adhesion to collagen followed by activation under low shear or static conditions, the prospect of this receptor pair mediating activation in high shear conditions may not be a tenable one without the brakes first being applied by gpIb complex–subendothelial vWF interaction.

GLYCOPROTEIN VI RECEPTOR Although the gpVI receptor was identified on the surface of platelets in 1982, its role in collagen-mediated platelet activation was not appreciated until much later ([66]). The human and murine genes were recently cloned and characterized, and it was found to be a member of the Ig superfamily ([59] , [67] , [68] and [69]). The expression of gpVI in platelets is very closely associated with that of the 14-kd FcR?-chain, which also serves as the signaling subunit for gpVI ([70] , [71]). Expression of gpVI on mouse platelets appears to be dependent on FcR?-chain expression, and the latter has also been found to be critical for collagen-mediated platelet activation ([54] , [71]). gpVI has two Ig C2 loops, and the *N*-terminal loop likely contains the collagen-binding domain ([47]). It appears that gpVI has a requirement for the quaternary structure of collagen to be in a triple helical conformation for the two to associate ([72]). Whether gpVI is capable of participating in platelet adhesion to collagen is unclear. If it is, evidence from one study suggests that it may be through activation of a $_2$ß $_1$ ([73]). Further studies incorporating collagen-related peptides (arranged in triple helical structures with sequences similar to collagen) and the snake venom convulxin as agonists have been shown to signal by clustering gpVI molecules on the surface ([51] , [56] , [74]). However, the idea of gpVI receptor clustering as a platelet activation mechanism applicable to collagen is tempered by consideration of the theoretically much greater distances that would exist between adjacent gpVI binding sites along fibrillar collagen compared with the larger noncovalently linked structures of convulxin in which gpVI binding site distribution is much different ([75]).

PLATELET–COLLAGEN SIGNALING The gpVI signaling pathway has been found to be both essential and sufficient for collagen-mediated platelet activation ([76]). The gpVI/FcR?-chain complex leads to platelet activation through a pathway that has many aspects in common with signaling by immune receptors, such as the Fc receptor family (of which Fc?RIIA is the lone family member found in platelets) and the B- and T-cell antigen receptors (Fig. 20.2). Much of what we know about gpVI signaling has been based on earlier work related to immune receptor signaling ([77] , [78]).

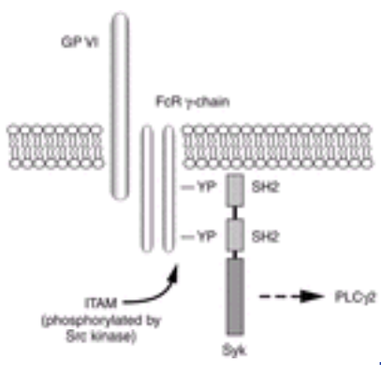

Figure 20.2. Collagen activates platelets through the same pathway as an immune receptor. Cross-linking of the glycoprotein (GP) VI/Fc receptor (R) ?-chain leads to tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motif (ITAM) sequence, enabling recruitment of the tyrosine kinase (Syk) through its tandem Src-homology 2 (SH2) domains. This leads to autophosphorylation and subsequent activation of Syk, which in turn leads to tyrosine phosphorylation of phospholipase C?2 (PLC?2). A large number of proteins are implicated in the regulation of PLC?2, as discussed in the text. YP, phosphotyrosine. (From Watson SP. Collagen receptor signalling in platelets and megakaryocytes. Thromb Haemost 1999;82:367, with permission.)

Immunoreceptors like the Fc receptors and the FcR?-chain all have the ITAM in common. Tyrosine phosphorylation of the ITAM by Lyn and Fyn of the Src family of tyrosine kinases takes place after activation of gpVI. The phosphorylated Src kinase, in turn, leads to activation of the tyrosine kinase Syk after its autophosphorylation ([79]). Syk then initiates a downstream signaling cascade involving the membrane linker of activated T cells (LAT) adapter protein that leads to recruitment to the plasma membrane and activation of the cytosolic second messenger-producing enzymes PI3K and PIC?2. PI3K leads to the generation of PI3,4,5P3 (PIP3), and this, in turn, supports recruitment of a member of the Tec kinase family, Btk, to the membrane along with recruitment of PlC?2 to the membrane signalosome complex ([80]). Syk is critical for collagen-mediated platelet activation through the gpVI/FcR?-chain complex, and knock-out mouse studies have shown that absence of this enzyme leads to loss of phosphorylation of LAT, the adapter SLP-76, and PlC?2 ([43] , [81] , [82]). Adapters such as LAT are modular proteins without enzyme activity that support protein–protein interaction. Many adapter proteins appear to participate in the regulation of PlC?2, including LAT and SLP-76, among others. These proteins appear to come together in T lymphocytes along with PlC?1 to form a LAT/SLP-76 signalosome that is essential for activation of PlC?2 ([83]). SLP-76 is thought to be especially important among adapters in the regulation of PlC?2. Along with the adapter proteins noted above, PI3K and its associated second messenger pathway also play a very important role in the regulation of PlC?2. Using PI3K inhibitors like wortmannin and LY294002, studies have demonstrated significantly reduced PlC?2 activation through gpVI ([84] , [85]). These inhibitors have also been shown to block platelet activation through the Fc?RIIA immunoreceptor, and this demonstrates an additional similarity between signaling pathways of this receptor and the FcR?-chain ([86]). The functional domains of PlC?2 with respect to its translocation to the membrane, the location of its phosphorylation sites, and the downstream signaling consequences of its phosphorylation remain to be determined. This enzyme is known to play a critical role in aggregation and secretion responses to collagen, as demonstrated in PlC?2 knock-out mice and in other studies ([45] , [85] , [87]). The major role of PlC isoforms is concerned with the generation of the second messengers inositol 1,4,5-triphosphate and 1,2-diacylglycerol (DAG) that participate in intracellular calcium homeostasis and activation of PKC, respectively.

GLYCOLIPID-ENRICHED MEMBRANE DOMAINS (MEMBRANE RAFTS) AND PLATELET–COLLAGEN SIGNALING Some of the proteins that are key to signaling through immune receptors, such as the platelet FcR?-chain and Fc?RIIA, have recently been recognized to associate within specialized regions of the membrane referred to as *glycolipid-enriched membrane domains* (GEMs), also known as *membrane rafts* ([88]). GEMs are abundant in cholesterol, sphingolipids, and long-saturated fatty acids along with many of the signaling proteins of ITAM-associated pathways. These domains are attached to the cytoskeleton internally (so cytoskeletal proteins are close to receptor signaling sites), and the extracellular proteins associated with them are glycosyl-phosphatidyl-inositol–anchored proteins (Fig. 20.3). Other cytosol and transmembrane proteins such as LAT, Fyn, and Lyn are attached through palmitoylation of cysteine residues. These proteins and others have been shown to be attracted to GEM sites after membrane receptor activation, although gpVI has also been found in the soluble, non-GEM fractions associated with these experiments.

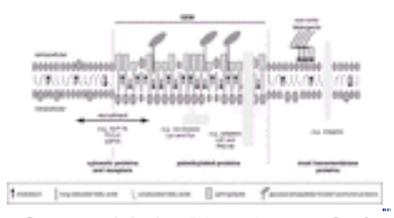

Figure 20.3. Structure of glycolipid-enriched membrane domains (GEMs). Immune receptor signaling is believed to take place in specialized regions of the membrane known as *GEMs*. They are rich in glycoprotein (GP) I–linked extracellular proteins and palmitoylated cytosolic proteins, and many proteins are also excluded from this region. Additional proteins are recruited into GEMs on receptor activation. See text for details. LAT, linker of activated T cells; PLC, phospholipase C. (From Watson SP, Asazuma N, Atkinson B, et al. The role of ITAM- and ITIM-coupled receptors in platelet activation by collagen. Thromb Haemost 2001;86:281, with permission.)

The protein composition of GEMs can be studied with the use of nonionic detergents, such as Triton-X-100, and sucrose density gradient isolation of GEM-associated proteins ([79]). Experiments have demonstrated how proteins associated with collagen signaling, such as Fyn, Lyn, and Syk, are recruited to the GEM fraction after platelet stimulation through the gpVI/Fc?-chain complex that, itself, was also associated with rafts ([89]). Inhibition of both gpVI-associated platelet aggregation and secretion along with tyrosine phosphorylation of signaling molecules was observed when the cholesterol-depleting agent ß-methyl cyclodextrin was incorporated into the experiments of these groups.

Platelet Thrombin (Protease-Activated) Receptors and Signaling

PARs are G protein–coupled receptors that use a unique mechanism to convert an extracellular protein cleavage event into an intracellular activation signal. In this case, the ligand is already part of the receptor per se by virtue of the fact that it is represented by the amino acid sequence SFLLRN (residues 42 through 47) and is unmasked as a new amino terminus after thrombin cleaves the peptide bond between Arg 41 and Ser 42. This “tethered ligand” then proceeds to irreversibly dock with the body of its own receptor to effect transmembrane signaling as shown in Figure 20.4.

Figure 20.4. Protease-activated receptor-1, a typical G protein–coupled receptor. Potential sites are indicated for cleavage by thrombin and cathepsin, *N*-linked glycosylation, and phosphorylation by protein kinases, including protein kinase C (PKC), protein kinase A (PKA), and ß-adrenergic receptor kinase (ßARK). (From Brass LF. Molecular basis of platelet activation. In: Hoffman R, et al., eds. Hematology: basic principles and practice. New York: Churchill-Livingstone, 2000:1755, with permission.)

Thrombin signaling in platelets is mediated, at least in part, by four members of a family of G protein–coupled PARs (PAR-1, -2, -3, and -4) (see previous section for a discussion of the gpIb complex as a thrombin receptor) ([90]). Human platelets express PAR-1 and PAR-4, and activation of either is sufficient to trigger platelet aggregation ([91] , [92]). Mouse platelets express PAR-3 and PAR-4 ([93]). PAR-1, -3, and -4 can be activated by thrombin, whereas PAR-2 can be activated by trypsin, tryptase, and coagulation factors VIIa and Xa but not thrombin ([94] , [95] , [96] and [97]). Presumably, other proteases are capable of recognizing the active sites of these receptors and can thus also trigger PAR signaling.

PAR-1 is the prototype family member and was the first to be cloned and characterized in the human and hamster ([91] , [98]). Synthetic peptide that mimics the PAR-1 tethered ligand (SFLLRN) is capable of functioning as an agonist by activating the receptor independent of cleavage of the 41 residue *N*-terminal exodomain.

The mechanism by which G protein–coupled receptors, such as PAR-1, signal through the G proteins is shown in Figure 20.5. PAR-1 is capable of coupling to members of the G12/13, Gq, and Gi/z families and, thus, is connected to a significant number of intracellular signaling pathways. The a subunits of G12 and G13 are believed to be involved in mediating platelet shape change ([99]), and downstream signaling mediators include Rho family members among others. The a subunit of Gq is needed for platelet secretion and aggregation and participates in activation of PlCß that leads to calcium mobilization and PKC activation ([100] , [101]). The a subunit of Gz is a Gi family member that has been speculated to play an epinephrine-like role in human platelets through inhibition of adenylyl cyclase ([29] , [102]).

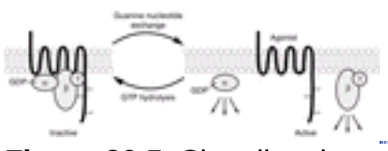

Figure 20.5. Signaling through G proteins and G protein–coupled receptors. Agonist binding to the receptor causes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the guanine nucleotide-binding site of the G protein a subunit. This causes the dissociation of Ga from Gß?, both of which can activate intracellular effectors and ion channels. (From Brass LF. Molecular basis of platelet activation. In: Hoffman R, et al., eds. Hematology: basic principles and practice. New York: Churchill-Livingstone, 2000:1754, with permission.)

The ß-? subunit counterparts of G proteins involved in PAR-1 signaling are involved in a plethora of activities including activation of protein kinases, channels, and lipid-modifying enzymes, such as PI3K, that provides attachment for multiple signaling protein complexes close to the inner leaflet of the cell membrane ([103] , [104] and [105]). Thus, this vast network of signaling pathways mediated through several G protein families is in keeping with the pleiotropic roles thrombin has been shown to exhibit in cellular homeostasis that extends beyond platelet activation to include endothelial cells, leukocytes, smooth muscle cells, and T lymphocytes, along with physiologic processes such as tissue injury, inflammation, angiogenesis, and embryonic development ([29]).

Once it is activated, PAR-1 is subsequently rapidly uncoupled from signaling and internalized into the cell ([315] , [316] and [317]). It is then transported to lysosomes and degraded ([106] , [107] and [108] , [316]). Platelets presumably have no need for a thrombin receptor recycling mechanism, because once activated, they are irreversibly incorporated into blood clots. Conversely, in cell lines with characteristics similar to megakaryocytes, new protein synthesis is needed for recovery of PAR-1 signaling ([106] , [316]), and in endothelial cells, it has been demonstrated that sensitivity to thrombin is maintained by delivery of naïve PAR-1 to the cell surface from a preformed intracellular pool ([106]).

Physiologic differences appear to exist between PAR-1 and PAR-4 on human platelets. When antibodies to the thrombin interaction site of PAR-1 are used, platelet activation is blocked at low, as opposed to high, thrombin concentrations ([318] , [319]). Antibodies that blocked PAR-4 alone had no effect on thrombin-mediated platelet activation. If both receptors were blocked, platelet activation was blocked at both low and high thrombin concentrations ([93]). So it appears that PAR-1 is most efficient at mediating platelet activation at low concentrations of thrombin and that PAR-4 functions in the absence of PAR-1 but only at high thrombin concentrations. Because PAR-1 is capable of mediating platelet activation at low thrombin concentrations, the exact role of PAR-4 in human platelet function is presently speculative. Given the importance of this system with respect to normal hemostasis, PAR-4 may serve as a redundant, back-up receptor to PAR-1, or it may serve as an important receptor for one or more proteases other than thrombin.

Platelet Adenosine Diphosphate (Purinergic) Receptors and Signaling

Evidence that adenosine diphosphate (ADP) plays an important role in both formation of the platelet plug and the pathogenesis of arterial thrombosis has been accumulating since its initial characterization in 1960 as a factor derived from red blood cells that influences platelet adhesion ([109] , [110]). ADP is present in high (molar) concentrations in platelet-dense granules and is released when platelet stimulation takes place with other agonists, such as collagen; thus, ADP serves to further amplify the biochemical and physiologic changes associated with platelet activation and aggregation. Inhibitors of this ADP-associated aggregation include

commonly used clinical agents such as clopidogrel and have proven to be very effective antithrombotic drugs ([111], [112]).

Adenine nucleotides interact with P2 receptors that are ubiquitous among different cell types and have been found to regulate a wide range of physiologic processes. They are divided into two groups, the G protein–coupled or “metabotropic” superfamily named *P2Y* and the ligand-gated ion channel or “ionotropic” superfamily termed *P2X* ([113]). Two G protein–coupled (P2Y) receptors contribute to platelet aggregation. The P2Y1 receptor initiates aggregation through mobilization of calcium stores, and the P2Y12 receptor is coupled to inhibition of adenylyl cyclase and is essential for a full aggregation response to ADP with stabilization of the platelet plug. P2X1 is a third ADP receptor present in platelets, but its exact role remains to be elucidated.

The P2Y1 receptor was first cloned in 1993 from a chick brain complementary DNA library ([114], [115] and [116]). Messenger RNA was later found in megakaryocyte-like cell lines, such as HEL and K562, along with human platelets ([117]). At this point, it was also established by the same group that the purported agonist effects of purified triphosphate nucleotides were, in fact, due to their transformation into diphosphate analogs by the ectonucleotidases present at the cell surface of the platelets and brain capillary endothelial cells being studied ([117], [118]). The P2Y1 receptor has 373 amino acid residues and the prototype structure of a G protein–coupled receptor. It is distributed in various tissues such as heart, blood vessels, testis, and ovary ([113]).

After the characterization of P2Y1, it became clear that a second platelet ADP receptor had to exist that was responsible for the inhibition of cAMP production by ADP that, in turn, was unaffected by blocking P2Y1 ([119], [120], [121], [122], [123] and [124]). The P2Y12 receptor was cloned in 2001 from human and rat platelet complementary DNA libraries using *Xenopus* oocytes ([125]). The receptor indeed showed the ability to display ADP-mediated inhibition of platelet cAMP formation that was not blocked by P2Y1 antagonists. The receptor has been localized to certain regions of the brain, such as the substantia nigra and thalamus, in addition to platelets ([125]). It has been suggested that the thienopyridine compound clopidogrel most likely exerts its antithrombotic effect by way of acting on the P2Y12 receptor through a thiol metabolite that can covalently modify its four extracellular cysteine residues ([126]).

PLATELET P2Y1 AND P2Y12 RECEPTOR ROLES IN ADENOSINE DIPHOSPHATE–MEDIATED ACTIVATION Inhibition of either of the P2Y1 or P2Y12 receptors is sufficient to block ADP-mediated platelet aggregation, and coactivation of both receptors is therefore necessary, through the G proteins Gq and Gi, respectively, for ADP to activate and aggregate the platelet (Fig. 20.6) ([127]). A series of studies involving the use of selective P2Y1 and P2Y12 receptor antagonists, a cAMP inhibitor, gene targeting, and Gq and Gi protein agonists that would theoretically activate the two main G protein pathways associated with ADP stimulation (see below) has led to the conclusion that a signaling event downstream from Gi is required for the conformational change and subsequent aggregation associated with the $a_{IIb}ß_3$ receptor ([122], [124], [127], [128], [129], [130], [131], [132] and [133]).

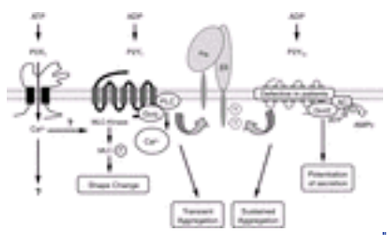

Figure 20.6. Current view of the interplay between the platelet P2 receptors. Two G protein–coupled receptors are involved in adenosine diphosphate (ADP)–induced platelet aggregation, $P2Y_1$ and $P2Y_{12}$. The former is responsible for intracellular calcium mobilization, shape change, and transient aggregation, whereas the latter is coupled to adenylyl cyclase (AC) inhibition and is responsible for amplification of platelet aggregation and potentiation of platelet secretion. Both receptors are required for normal platelet response to ADP. A P2X receptor is also present on platelets and is responsible for rapid calcium influx. It therefore may synergise with the $P2Y_1$ receptor, although its role in platelet activation is not yet established. AMPc, cyclic adenosine monophosphate; ATP, adenosine triphosphate; MLC, myosin light chain; P, phosphorylated; PLC, phospholipase C; Y, phosphotyrosine. (From Gachet C. ADP receptors of platelets and their inhibition. Thromb Haemost 2001;86:227, with permission.)

Studies done with platelets from patients who manifest defective P2Y12, along with experiments involving the study of P2Y1 receptor function in platelet-rich plasma that has high fibrinogen concentrations, have demonstrated that the P2Y1 receptor has roles in activation and aggregation in addition to shape change and that it is fully capable of mounting an aggregation response that is nonetheless transient in nature ([122], [134], [135]). The P2Y1 receptor is an absolute requirement for ADP-mediated aggregation based on knock-out mouse studies, the demonstration that platelets can become refractory to ADP due to desensitization of the P2Y1 receptor, and the observation that adrenaline (which activates the G protein Gi that mediates inhibition of adenylyl cyclase) does not restore aggregation in the presence of P2Y1 selective antagonists ([130], [131], [320], [321], [322] and [323]). Platelet shape change is dependent on two separate G signaling pathways, a Gq-linked release of calcium from internal stores, and a G12/13 link to activation of Rho kinases and Rho guanine nucleotide exchange factors that activate small G proteins ([99], [136], [324]). Although the association of P2Y1 with the Gq pathway is established, the existence of any relationship between the receptor and the G12/13 pathway is presently unclear ([136], [137] and [138]). The primary role of the P2Y12 receptor in platelet activation and aggregation is to amplify and complete the aggregation response to ADP as well as to other agonists ([119], [120], [121], [122] and [123]). In the presence of a high ADP concentration, the receptor is also capable of mediating partial platelet aggregation on its own in P2Y1 and Gq knock-out mice, thus proving that a $_{IIb}ß_3$ conformational change followed by aggregation can actually take place in the absence of calcium mobilization and PKC activation ([131], [137]). In general terms, it appears that P2Y12 is responsible for acting as an ADP costimulus receptor in the presence of low concentrations of other agonists, such as collagen, thrombin, chemo-kines, or IgG, whereas the P2Y1 receptor has a specific role early in platelet activation ([139], [140] and [141]).

P2X1 RECEPTOR P2X1 was first discovered in platelets through polymerase chain reaction of transcripts from platelets and megakaryocyte-like cell lines ([142], [143], [144] and [145]). This third platelet P2 receptor is an adenosine triphosphate–gated ion channel (like all other P2X receptors so far discovered) and is known to mediate rapid and selective permeability to cations. On platelets, the P2X1 receptor has been shown to mediate fast calcium entry stimulated by ADP ([146]). P2X1 is a 399–amino acid protein composed of two transmembrane domains, intracellular *N*- and *C*-termini, and an extracellular loop with ten conserved cysteine residues ([113]). At least three P2X subunits are required to constitute a membrane pore, and these receptors are typically expressed on excitable cells, such as neurons. P2X1 knock-out mice should help to elucidate the physiologic role of these receptors in platelets and have not shown any defects in hemostasis to date ([147]). Two other studies have likewise been unable to determine any P2X1 role in platelets, although a fourth has suggested a role for the receptor in shape change ([119], [148], [149]).

ADENOSINE DIPHOSPHATE RECEPTOR SIGNALING ADP is considered a weak agonist by itself compared with collagen or thrombin, for example. Aggregation is typically reversible when stimulated by ADP alone. In addition, low concentrations of ADP serve to amplify the effects of both strong and weaker agonists, the latter including serotonin and adrenaline, among others ([150], [151]). As noted in the preceding paragraphs, ADP signal transduction downstream from the P2Y1 receptor leads to a transient rise in free cytoplasmic calcium due to mobilization from internal stores, and this is followed by secondary store-mediated influx, while a concomitant inhibition of adenylyl cyclase is initiated by ADP stimulation of the P2Y12 receptor. The G protein family member responsible for signaling through P2Y1 to PlCß is Gq, whereas the member responsible for signaling through P2Y12 to inhibit adenylyl cyclase is Gi. ADP also induces a rapid influx of calcium from the external media through ligand-gated calcium channels ([152], [153]). Although partial platelet aggregation without shape change can be seen in P2Y1 and Gq knock-out mice in the presence of high ADP concentrations, the fact that aggregation is not seen at lower concentrations suggests that the Gq-dependent PlCß pathway leading to phosphoinositide hydrolysis and PKC activation is necessary to mobilize calcium after ADP stimulation and is essential for full platelet aggregation to take place in response to ADP ([100], [131], [137], [154], [155]). An additional role for ADP in platelets has been proposed in which it is seen as an important cofactor of PI3 kinase activation that is stimulated through the PAR-1 thrombin receptor ([156]). Similarly, ADP has also been implicated as an important cofactor of platelet activation seen in the settings of experimental cross-linking of the Fc?RIIA immunoreceptor and in patients with heparin-induced thrombocytopenia ([157]). The latter is a disorder in which platelet activation and often serious thrombotic sequelae take place as a consequence of administration of the anticoagulants heparin or low-molecular-weight heparin. In susceptible patients, an autoantibody is generated by the immune system that is directed to a complex on the platelet membrane formed by the heparin molecule and platelet factor 4. The Fc portion of the autoantibody is then capable of activating the platelet through its interaction with the Fc?RIIA receptor. Activation of PI3K has been shown to be a central player in the above two settings. The same Gi protein–associated signaling pathway used by platelet ADP receptors has been found to act in a synergistic fashion when it is triggered either through (a) other platelet receptors such as gpVI, or (b) key downstream players triggered by other receptors, such as PlC?2 ([158], [159]). It has been suggested that concomitant signaling through the G proteins and tyrosine kinases of other receptor pathways may potentially be seen as a general mechanism in which ADP contributes to efficient platelet activation and aggregation ([139], [160]).

Platelet Activation by Soluble Agonists

a_2 ADRENERGIC RECEPTORS AND EPINEPHRINE There is strong evidence that presently unknown signaling mechanisms appear to be playing effector roles in platelet responses to epinephrine. This molecule is unique among platelet agonists because it is considered by most to be capable of stimulating secretion and

aggregation but not cytoskeletal reorganization responsible for shape change. Furthermore, generation of the key signaling enzyme PlC through epinephrine stimulation appears to be dependent on thromboxane A_2 and can thus be blocked with aspirin ([161]). It is interesting, however, that epinephrine stimulation in the presence of aspirin is still capable of leading to the conformational change in the $a_{IIb}ß_3$ receptor that precedes fibrinogen binding and platelet aggregation ([162], [163]). Similarly, the thrombin inhibitor hirudin has been found to block epinephrine-associated aggregation of washed platelets in one study, suggesting that an element of thrombin costimulation of platelets may be needed to document the effects of epinephrine ([151]). Platelet responses to epinephrine are mediated through a_2 adrenergic receptors ([164], [165]), and these responses have been found to vary between individuals, with some donors with otherwise normal platelets manifesting delayed or absent responses ([166]). This delayed-activation phenomenon is similar to that seen in some donors when their platelets are stimulated through the Fc?RIIA receptor, and so the explanation may rest with variable adrenergic receptor expression levels, as is the case with the platelet Fc receptor ([167]).

ARACHIDONIC ACID, THROMBOXANE A_2, AND THROMBOXANE RECEPTORS On platelet stimulation by a number of agonists, arachidonic acid is generated directly by phospholipase A from its membrane phospholipid precursors (PC, PS, and PI) and indirectly by PlC generation of DAG followed by DAG lipase action. Most platelet agonists are believed to activate this process. Three known eicosanoid subsets of biochemical compounds are known to be derived from the formation of arachidonic acid—the prostanoids, leukotrienes, and epoxides. The prostanoids are formed by the cyclooxygenase pathway and include endo-peroxides and thromboxanes along with PGs. The leukotrienes are formed by the lipoxygenase pathway and the epoxides by the cytochrome P-450 epoxygenase pathway. Although all three of these pathways are present in platelets, most of the arachidonic acid ends up being metabolized to thromboxane A_2 ([168]). Thromboxane A_2 is produced in platelets from arachidonic acid through the generation of PGH_2 by the enzyme cyclooxygenase that is irreversibly inhibited by aspirin through acetylation of a serine residue near its *C*-terminus ([169], [170]). PGH_2 is the parent compound for both biologically active prostaglandins, such as PGE_2 and PGI_2, and thromboxane A_2. The former two compounds act to inhibit platelet activation by generating intracellular cAMP, whereas thromboxane A_2 activates platelets. Although PG and thromboxane pathways can be present in the same cell, platelets primarily synthesize thromboxane, and endothelial cells mainly synthesize PGs such as PGI_2, which acts as a local vasodilator and thus indirectly opposes platelet activation and vasoconstriction that accompanies hemostasis and thrombus formation ([170]). Like ADP and epinephrine, thromboxane A_2 is also capable of activating nearby platelets after its release into plasma. It has a very short half-life of 30 seconds before its conversion to the inactive metabolite thromboxane B_2 prevents widespread platelet activation beyond the vicinity of thrombus formation ([171], [172]). Both arachidonic acid and analogs of thromboxane A_2 have been found to activate and aggregate platelets by mediating shape change and phosphorylation of signaling enzymes, such as PlCß, PKC, and so forth ([173], [174]). Signaling events associated with stimulation of the thromboxane A_2 receptor (TXR) further downstream from PlCß and PKC include activation of p38 mitogen-activated protein kinase and the small heat shock protein hsp27 ([175]). The TXR is a member of the seven transmembrane G protein–coupled receptor family and has been localized to the plasma membrane. It is postulated to act with a number of G proteins, including the a subunits of Gq, G11, G12, G13, and Gi2 ([176], [177], [178], [179] and [180]). One isoform of the receptor has been cloned from placenta (TXRa) and the other from endothelium (TXRß). Both are found in platelets and have been found to activate PlCß ([181]). In addition, the a receptor is associated with the activation of adenylate cyclase that leads to generation of cAMP known to inhibit platelet activation, whereas the ß receptor inhibits adenylate cyclase activation after its stimulation. Because thromboxane A_2 is a net agonist, the effects of PlCß activation must somehow outweigh those of adenylate cyclase activation, or megakaryocyte and platelet ß receptor expression levels may outweigh those of a receptor expression levels ([181]).

Physiologic Inhibition of Platelet Activation

One of the many remarkable features of platelets is their ability to remain in a physiologic resting state and resist becoming activated while navigating the heart, arterial and venous circulations, and splenic microcirculation for an average of 10 days. Over this time, platelets can be expected to remain in a quiescent state while they encounter high shear forces, what must be frequent collisions with other circulating cells as well as normal endothelium, and relatively profound turbulence associated with arterial branch points and diseased, yet physically intact arteries and arterioles. Indeed, the pathologic consequences associated with widespread inappropriate platelet activation are life- and limb-threatening when associated with well-characterized clinical disorders, such as thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia. The mechanisms responsible for maintaining the fine balance of keeping platelets in a resting state until they encounter a genuine need to undergo adhesion, activation, and aggregation at the site of vascular injury are almost as diverse as those responsible for mediating these physiologic phenomena.

Some general mechanisms involved in physiologic inhibition of platelet activation include phenomena such as (a) generation of negative regulating molecules by the platelet (e.g., cAMP), endothelium [e.g., PGI_2, nitric oxide (NO), heparan sulfate], and at distant sites (e.g., antithrombin); (b) direct contact of circulating platelets with collagen prevented by a barrier of endothelial cells; (c) generation of an ecto-ADPase by endothelial cells that will metabolize ADP secreted from activated platelets and thus is intended to limit further activation; (d) tendency for blood flow to wash away unbound thrombin from the site of platelet plug formation and hence limit the extent of clot formation; (e) brief half-life of certain key platelet activators such as thromboxane A_2; (f) ability to alter the conformation of a receptor such that it is then able to interact with a specific proaggregatory ligand, as happens with a $_{IIb}ß_3$ and plasma fibrinogen; and (g) the ability to inactivate switched-on receptors associated with activation through biochemical modification such as phosphorylation or their removal from the platelet surface.

Biochemical modification leads to receptor desensitization and occurs with G protein–coupled receptors present on the surface of platelets with the notable exception of PAR-1 because thrombin requires an intact *N*-terminus to activate the receptor ([182]). Desensitization of G protein–coupled receptors is normally mediated through phosphorylation of serine and threonine residues associated with the cytoplasmic side of the receptor by G protein–coupled receptor kinases ([183]). The role of phosphorylation of these residues is to uncouple them from their G proteins and then lay the groundwork for internalization of the receptor through the binding of arrestin proteins ([184], [185]). Some of the physiologic and biochemical phenomena related to inhibition of platelet activation are described below.

INHIBITORY PROSTAGLANDINS As described earlier in the chapter, PGE_2 and PGI_2, along with PGE_1, are examples of PGs generated through the arachidonic acid pathway that play roles with respect to inhibition of platelet activation and aggregation, which are processes mediated in part by other PGs and thromboxanes derived from the same pathway. The inhibitors carry this out through G protein–coupled receptors that regulate adenylyl cyclase–mediated generation of cAMP that in turn activates PKA (or A kinases). PKA then goes on to inhibit other proteins that mediate platelet reactivity through phosphorylation. The receptors of PGs believed to increase cAMP levels in platelets such as PGI_2 have in the past been described as being coupled to the a subunits of Gs, whereas those agents with G protein–coupled receptors that suppress cAMP formation, such as thrombin and epinephrine, are thought to be coupled to Gi ([186]). In addition to these considerations, cAMP levels in platelets are also governed by the activity of phosphodiesterase, the enzyme responsible for cAMP breakdown. This enzyme activity is inhibited by drugs such as the weak antiplatelet agent dipyridamole and the bronchodilator theophylline. The targets through which cAMP and PKA reduce platelet reactivity are incompletely understood. As noted earlier in the section Platelet Glycoprotein Ib Complex–von Willebrand Factor Interaction and Signaling, one substrate for PKA is the ß subunit of the gpIb complex, and this phosphorylation may, in turn, reduce platelet activation through its increased interaction with the 14-3-3? protein ([35], [36]). The 14-3-3 family of proteins exists as homodimers and modulates effector pathways in diverse cell types through interaction with key signaling enzymes ([32]). Other PKA substrates include ABP, myosin light chain, and several as yet unidentified proteins. There are a number of activation-associated processes in platelets that are affected negatively by increased intracellular cAMP generation. These include limitation of phosphoinositide hydrolysis in platelets, which is believed to occur through blockage of the inositol 1,4,5-triphosphate receptor, and inhibition of the resynthesis of the phosphatidylinositol 4,5-biphosphate precursor of DAG formation. These events lead to a smaller increase in intracellular calcium levels associated with cell activation ([187], [188], [189] and [190]).

PLEKSTRIN AND PROTEIN KINASE C INHIBITION PKC is an important serine-threonine kinase with protean effector manifestations in platelet signaling. PKC is actually a family of structurally related molecules, and platelets contain at least the a, ß, and d forms. Once activated, PKC appears to mediate individual roles that, in some respects, may be considered contradictory in nature. These include positive effects like secretion and aggregation, as well as negative effects that can be observed when platelets are incubated with phorbol esters before agonist stimulation. Under these circumstances, the agonist effector-mediated responses are reduced or do not occur, particularly if they are mediated by effectors downstream from phosphoinositide hydrolysis, and this phenomenon may represent a form of negative feedback ([191], [192] and [193]). This is speculated as possibly being due to a shorter duration of signaling for calcium release ([194]). Several platelet proteins are known PKC substrates, and these include plekstrin (P47), myosin light chain (P20), ABP, and the a subunits of the G proteins Gz, G12, and G13. The precise role of plekstrin in platelets is unknown, although its first and last 100 residues are homologous with domains in molecules with roles in signal transduction. These so-called plekstrin homology domains are speculated to play roles in protein–protein interactions, and so phosphorylated plekstrin may be playing a role in the negative regulation of PKC. Data from 1995 suggest that phosphorylated plekstrin may be accomplishing negative regulation of PKC through inhibiting phosphoinosi-tide hydrolysis and the activity of the lipid kinase, PI3K ([195]). Reduced activity of PI3K leads to reduced phosphorylation of PI-4,5-P2 to PI-3,4,5-P3, a molecule that, in turn, is involved in the activation of PKC isoforms ([196]).

OTHER INHIBITORY PROCESSES OF PLATELET ACTIVATION The $a_{IIb}ß_3$ receptor on the surface of activated and resting platelets along with the fibrinogen that binds to stimulated platelets expressing the activated form of a $_{IIb}ß_3$ have been observed to undergo rapid internalization into megakaryocyte and platelet a-granules ([197], [198]). These platelets may not yet be participating in aggregate formation with other platelets. Thus, it has been speculated that this may represent a means by

which the platelet not involved in clot formation may actually be able to return to a resting state ([199]). The *in vivo* evidence supporting this unique platelet inhibitory process is included in a paper describing the transfusion of plasma into an afibrinogenemic patient followed by the demonstration that platelet fibrinogen could be restored faster than new platelets could be produced in the bone marrow ([200]). NO is generated by endothelial cells and platelets from L-arginine in response to shear stress forces and other platelet agonists, such as thrombin and ADP. This molecule works to inhibit platelet activation through the cyclic guanosine monophosphate second messenger generated by guanyl cyclase activation. Endothelial NO synthase activity is enhanced during platelet activation, presumably as an additional means for limiting platelet aggregation.

Platelet Secretion

A detailed description of the biochemical contents of platelet a- and dense granules along with lysosomal granules is included in Chapter 19 and does not require further elucidation here. The current section describes the physiologic process of platelet secretion under normal circumstances.

The extent of secretion of a-, dense-, and lysosomal-granule contents is dependent on the strength of the agonist, occurs in association with platelet activation, and is one of the many downstream consequences mediated by the activation and transport to the internal leaflet of the plasma membrane of PKC. Granule contents that are involved in enhancing activation and aggregation of both their own and other platelets in the vicinity include ADP, vWF, fibrinogen, and calcium ions.

The strongest response a platelet can mount to agonist stimulation includes activation, secretion, and aggregation. The granule secretory (release) phase is most readily documented *in vitro* by the “secondary wave” that denotes a second surge of aggregation activity of a fixed number of platelets in response to release of proaggregatory granule contents. These platelets are exposed to an agonist under the controlled, *in vitro* conditions associated with platelet aggregation studies in which clinical defects in primary hemostasis due to either platelet or endothelial perturbations are further characterized. The secondary wave is typically seen best when the agonist is a weaker one, such as epinephrine, or is a relatively lower concentration of a second relatively weak agonist, ADP. These two agonists require both cyclooxygenase activity and a primary wave of aggregation to induce secretion observable at low calcium concentrations, whereas secreted ADP is known to potentiate the platelet-activating capabilities of a number of other agonists ([201]).

Several studies suggest that the mechanism by which platelet granules (vesicles) fuse with the cell membrane to release their granule contents includes membrane-trafficking events mediated by donor membrane proteins called *v-SNAREs* (vesicle SNAp REceptors), which undergo a lock-and-key form of docking with their compatible and specific target membrane proteins called *t-SNAREs* ([202] , [203]), followed by exocytotic release of their contents. Simultaneous with the exocytosis of platelet granules, it is apparent that there is also inward (centripetal) movement of other intracellular contents, and this may play a role in transporting proaggregatory proteins away from the membrane surface and thus serve as another counterbalancing mechanism for limiting the extent of thrombus formation. Examples of this phenomenon include the internalization of fibrinogen from the surface of activated platelets, along with gpIIbIIIa receptors from the surface of resting and activated platelets, as noted in the preceding section ([199]).

PLATELET AGGREGATION: $a_{IIb}ß_3$ RECEPTOR AND ITS SIGNALING MECHANISMS

Platelet aggregation is a complex phenomenon that is the end result of a series of adhesion- and activation-related processes. The molecular mechanisms involved in platelet aggregation continue to be an area of very active research that also periodically reminds us that there is still much to be characterized about this important aspect of platelet function. Well-known essential components of this process include an agonist, calcium, and the adhesive proteins fibrinogen and vWF. Divalent cations, such as calcium and magnesium, are required for platelet aggregation in trace amounts, and these alter the specificity of the integrin $a_{IIb}ß_3$ for its ligands ([204]). Fibrinogen and vWF play dominant roles in platelet aggregation through binding to $a_{IIb}ß_3$ and also by the ability of the former to generate polymerized fibrin as support for the platelets in a thrombus. The multivalent nature of fibrinogen and vWF allows them to cross-link platelets on binding to $a_{IIb}ß_3$ on stimulated platelets to initiate platelet aggregation.

Fibrinogen and vWF are not the only ligands for integrin $a_{IIb}ß_3$. It was shown in 2000 that mice deficient in both fibrinogen and vWF form thrombi at nearly normal rates ([205]). An example of a molecule recently added to the continually evolving list of $a_{IIb}ß_3$ ligands is the plasma protein, prothrombin. In 1997, Byzova et al. concluded from their investigations that prothrombin is likely to be a stronger ligand for integrin $a_{IIb}ß_3$ when the platelet is in a resting state ([206]) (Fig. 20.7). The prothrombin bound to $a_{IIb}ß_3$ on the resting platelet can be cleaved by nearby factor Xa if the latter is starting to be generated in the vicinity of the receptor. This action leads to release of thrombin from the receptor. The newly generated thrombin may then be available to interact with its G protein–coupled receptors and gpIb complexes on the same and neighboring platelets, resulting in the activation of the platelet and $a_{IIb}ß_3$, which then leads the integrin to favor binding fibrinogen over prothrombin. In addition, platelet transition to an activated state should increase the formation of a prothrombinase complex on the platelet surface, which leads to increased thrombin generation. Activation of prothrombin also then becomes more efficient. This recently characterized set of interactions based on prothrombin and $a_{IIb}ß_3$ interaction is illustrative of one of many ways in which positive feedback is able to lead to amplification of the entire process of coagulation. The characterization of these sorts of molecular interactions is important in leading to new targets for antithrombotic therapy and provides a possible explanation for the failure of some current $a_{IIb}ß_3$ inhibitors.

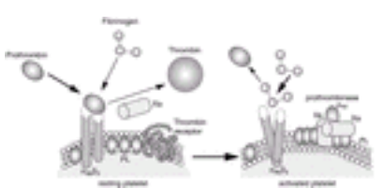

Figure 20.7. Model for prothrombin binding and activation on $a_{IIb}ß_3$ on platelets. See text for details on the model. PL, anionic phospholipid vesicles rich in phosphatidylserine. (From Plow EF, Cierniewski CS, Xiazo Z, et al. $a_{IIb}ß_3$ and its antagonism at the new millenium. Thromb Haemost 2001;86:34–40, with permission.)

The molecular basis of integrin signaling that occurs in platelet $a_{IIb}ß_3$ is an integral part of thrombus formation and is important in understanding this process. gpIIb and gpIIIa were identified as the abnormality present in patients with Glanz-mann thrombasthenia in the 1970s ([207] , [208]). Since that time, they have been extensively studied. They represent the most abundant receptor on the platelet surface. Like all integrin receptors, it is composed of noncovalently linked subunits. Each subunit is encoded by separate genes on the long arm of chromosome 17. Both subunits consist of a large extracellular domain and very short cytoplasmic domains, and together they bind as a heterodimer. Within their combined extracellular domains is the ligand-binding pocket, with surrounding subunit domains conferring its specificity ([209]). Equally important are their short cytoplasmic domains that are critical for transmembrane signaling. These domains act to anchor the receptor to the cytoskeletal elements ([210] , [211] and [212]).

The signaling pathway of the gpa $_{IIb}ß_3$ is complex and has been extensively studied. The intricacies of this pathway are continually being elucidated. Despite this, the terminal effector molecules affecting its activation remain unknown. Central concepts of the signaling pathway include the ideas of inside-out signaling, which involves the processes termed *affinity* and *avidity modulation* ([213] , [214]), and outside-in signaling in which messages are transmitted to the inside of the platelet via the events occurring outside the membrane through $a_{IIb}ß_3$ activation.

These complex pathways were reviewed by Casserly and Topol ([209]) in 2002 and are summarized in Figure 20.8 from their work. Clearly important to hemostasis and thrombosis is the vessel wall. Normally, the undisturbed endothelium contains nonthrombogenic materials that can neutralize activated coagulation factors, increase blood flow, inhibit platelet aggregation, and modulate fibrinolysis. Substances that inhibit platelet activation released by the endothelium include PGI_2, NO, and ADPase. In addition, the platelet itself releases PGE_2 that acts to prevent its own activation. These molecules act via the Gs protein pathway that stimulates protein kinases to modulate various enzymes involved in platelet receptor $a_{IIb}ß_3$ activation (see below) ([215]). They may also act to phosphorylate and inactivate various protein receptor agonists ([216] , [217]).

Figure 20.8. Schematic illustration of a $_{IIb}ß_{3}$ receptor regulation via inside-out and outside-in signaling. ADP, adenosine diphosphate; ADPase, adenosine 5'-diphosphatase; NO, nitric oxide; PGE_2, prostaglandin E_2; PGI_2, prostacyclin; TxA2, thromboxane A_2. (From Casserly IP, Topol EJ. Glycoprotein IIb/IIIa antagonists—from bench to practice. Cell Mol Life Sci 2002;59:481, with permission.)

Primary platelet agonists such as ADP, thrombin, and matrix proteins collagen and vWF effect platelet aggregation through a process known as *inside-out signaling*. This term denotes an integrin property that involves the binding action of agonists to their receptors, leading to activation of numerous platelet functions, including the conformational change of a $_{IIb}ß_{3}$ to a high-affinity state, referred to as *affinity modulation*. Ligand binding is initially reversible and later becomes irreversible in nature ([218]). Therefore, one of the effects of inside-out signaling on a $_{IIb}ß_{3}$ is exposure of the fibrinogen-binding site through signal transduction involving the cytoplasmic domains ([217], [219]). Various regulatory intracellular or transmembrane proteins participate in this process.

Avidity modulation, the less dominant action, acts to cluster the a $_{IIb}ß_{3}$ heterodimers into oligomers through lateral diffusion ([220]). These conversions are critical in allowing a $_{IIb}ß_{3}$ to engage soluble adhesive ligands. These ligands contain the classical integrin recognition sequence RGD, Arg-Gly-Asp, which acts as a bridge between adjacent platelets allowing aggregation to proceed ([221]). In addition, more a $_{IIb}ß_{3}$ translocates to the platelet surface membrane from the degranulating a-granule pool where an additional receptor is stored. These changes facilitate irreversible binding to fibrinogen. An important role for tyrosine kinase– and phosphatase-associated phosphorylation-dephosphorylation in integrin activation exists as assessed by the blockage of fibrinogen binding and platelet aggregation by enzyme inhibitors ([222], [223]).

After ligand binding occurs, a multitude of intracellular signals are generated that are collectively referred to as *outside-in signaling*. This signaling determines the extent to which platelets will spread on a vascular matrix and how resistant they will be to detachment ([224]). The signaling occurs during platelet aggregation via further release of granules and adhesion, which is induced by the binding of adhesive proteins to the extracellular domain of $ß_{3}$. These signals are a determinant of the final clot size.

A short sequence within the cytoplasmic domain of $ß_{3}$, termed the *ICY* (integrin cytoplasmic tyrosine) *domain*, contains tyrosines that become phosphorylated. The importance of this event is exemplified by studies performed using mice deficient in the ICY domain that result in defective clot retraction and aggregation *in vitro* and bleeding defects *in vivo* ([225]). The ICY domain tyrosine phosphorylation recruits cytoskeletal myosin, important in clot retraction, and the adapter protein Shc, involved in platelet stimulation. In addition, multiple other proteins become phosphorylated that mediate effector responses, including Grb2, which activates the Ras signaling pathway, in turn activating phospholipase A_2 via mitogen-activated protein kinase effectors. This event generates arachidonic acid metabolites that stabilize platelet–platelet interactions. Once full spreading and aggregation of platelets occurs, usually within several minutes, focal adhesion kinase is phosphorylated ([226]). The PI3K system is activated once a $_{IIb}ß_{3}$ is engaged, leading to generation of D3 phosphoinositides ([227]). These proteins act to prevent the depolymerization of the actin cytoskeleton, with the result that the platelet aggregate is stabilized ([228]). The end result of this outside-in signaling is a stable platelet clot.

Not only does the a $_{IIb}ß_{3}$ receptor have important roles with respect to platelet function, but it affects coagulation and the inflammatory process as well. It acts to promote the formation of the prothrombinase complex ([229]) and mediates the adhesion of leukocytes to the platelet membrane and endothelium (i.e., vascular inflammation) ([230], [231], [232] and [233]). There have also been reports that it may have a role in cell proliferation ([234]).

Integrin a $_{IIb}ß_{3}$ Antagonists

Antithrombotic agents that act against the a $_{IIb}ß_{3}$ receptor are extensive and represent a targeted therapy against the most prevalent platelet surface receptor. They have had a significant impact on the outcomes of patients with acute coronary syndromes (ACSs) and those requiring percutaneous coronary interventions (PCIs).

Although many anti-a $_{IIb}ß_{3}$ agents have been developed, only a small number are currently approved for clinical use. Examples of approved parenteral agents with various mechanisms of action include the chimeric monoclonal antibody abciximab, the synthetic peptide eptifibatide, and the synthetic nonpeptide tirofiban.

In the 1980s, Coller reported on the first mouse monoclonal antibody directed against the a $_{IIb}ß_{3}$ receptor ([235]), and abciximab was subsequently developed. This antibody binds to a site on the a $_{IIb}ß_{3}$ receptor that is separate from the ligand-binding site and likely acts to sterically hinder ligand access ([209]). Within minutes of receiving the standard bolus dose, roughly 90% of the a $_{IIb}ß_{3}$ receptors are bound ([236]). Abciximab then has a slow rate of dissociation that lasts up to 4 hours, and platelet function can be abnormal for up to 7 days after infusion ([237]).

Eptifibatide is a synthetic cyclic heptapeptide that is based on an RGD sequence that blocks all RGD-recognizing integrin receptors. It binds to the ligand-binding pocket of the a $_{IIb}ß_{3}$ receptor such that it blocks its interaction with fibrinogen and vWF. It has a very rapid onset of action and a low affinity leading to quick dissociation. It is approved for use in both the PCI and ACS settings.

Tirofiban is a synthetic nonpeptide tyrosine derivative that mimics the RGD recognition sequence ([238]). This agent also acts by blocking the ligand-binding region of the a $_{IIb}ß_{3}$ receptor such that it competitively inhibits platelet aggregation. Within minutes, it inhibits platelet aggregation and dissociates from the receptor within seconds. It is approved for use in ACS.

Multiple trials have been conducted to evaluate the efficacy of these and other parenteral a $_{IIb}ß_{3}$ antagonists, and these have been reviewed by Casserly and Topol in 2002 (Fig. 20.9) ([209]). These trials evaluated the drugs in terms of 30-day postintervention or event episodes of death or nonfatal MIs after PCI or ACS. With over 100,000 patients being evaluated in placebo-controlled trials, the absolute and relative risk reductions in PCI with the use of a $_{IIb}ß_{3}$ inhibitors were 2.9% and 34.0%, respectively. After longer-term follow-up of 1 year, the Evaluation of IIb/IIIa Platelet Inhibitor for Stenting (EPISTENT) trial demonstrated a significant reduction in mortality after the use of abciximab in PCI. This effect has not been demonstrated with the other mentioned agents, although significantly fewer studies have been performed with them to date. A metaanalysis of the trials performed using tirofiban and eptifibatide in ACS showed no significant difference in mortality with these agents, but did show that there was a significant reduction in endpoints of death/MI, as well as death/MI/revascularization at 48- to 96-hour, 30-day, and 6-month follow-up ([239]). Less promising results have been seen to date with the oral a $_{IIb}ß_{3}$ inhibitors, and they continue to undergo investigation. One potential advantage of the oral agents may rest with treatment of ischemic complications after PCI and ACS that continue to occur after the period of platelet inhibition produced by intravenous agents. What is clear from all these anti-a $_{IIb}ß_{3}$ clinical studies is that there is much more to be learned about the antagonism of a $_{IIb}ß_{3}$.

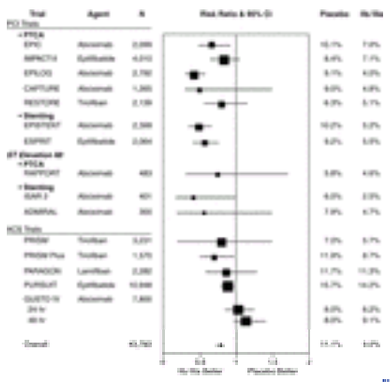

Figure 20.9. Death or nonfatal myocardial infarction (MI) outcomes 30 days into randomized placebo-controlled trials of intravenous a $_{IIb}$ß $_{3}$ blockers. Risk ratio with 95% confidence intervals (CI). Risk ratio box size is proportional to total sample size. Frequency of death or nonfatal MI is shown in columns 5 and 6. ACS, acute coronary syndrome; PCI, percutaneous coronary intervention; PTCA, percutaneous transluminal coronary angioplasty. (From Casserly IP, Topol EJ. Glycoprotein IIb/IIIa antagonists—from bench to practice. Cell Mol Life Sci 2002;59:492, with permission.)

PLATELET RECEPTOR POLYMORPHISMS AND THROMBOTIC RISK

Glycoprotein Ib Complex

The gpIb complex exists as a heptamer with four different subunits: two each of gpIba, gpIbß, and gpIX, and one of gpV (Fig. 20.1). Significant polymorphisms in this complex are found on gpIba in which three appear to influence its function (Fig. 20.10). A mucinlike macroglycopeptide region exists within this subunit in which a variable number of tandem repeats (VNTR) occurs involving duplication of a 13–amino acid sequence once (VNTR D), twice (VNTR C), three times (VNTR B), or four times (VNTR A) ([240], [241] and [242]). This polymorphism leads to polypeptides of varying lengths of 610, 623, 636, or 649 amino acids, respectively. Each repeat can add up to 3.2 nm in length to the extracellular domain ([241]), which, in theory, could extend the binding sites for vWF and thrombin above the plane of the platelet and is most apparent in VNTR A. Therefore, one might conclude that the VNTR A polymorphism could manifest increased predisposition to clotting. Some groups have shown that there is an increased risk for coronary artery disease with the longer variants, VNTR A ([243]) and VNTR B ([244]) (Table 20.1), which may also be risk factors for cerebrovascular disease ([244], [245]).

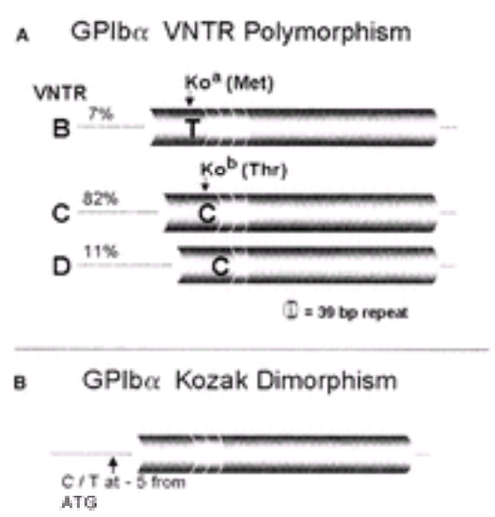

Figure 20.10. Polymorphisms of the glycoprotein (GP) Iba subunit. **A:** The variable number of tandem repeats (VNTR) polymorphism is characterized by the expression of four (VNTR A, not shown), three (VNTR B), two (VNTR C), or one (VNTR D) copy of a 13–base pair (bp) repeat sequence. Percentages shown are gene frequencies in a typical white population with VNTR A less than 1%. Another dimorphism, the Met/Thr at residue 145, is in linkage disequilibrium with the VNTR polymorphism. Thus, the VNTR A and B alleles express only Met 145, and the VNTR C and D alleles express only Thr 145. **B:** In GPIba, a C/T substitution at a position five nucleotides upstream from the adenine-thymine-guanine (ATG) start codon influences an adjacent Kozak sequence and thus the rate of translation of the messenger RNA transcript by the cell machinery. See text for details. [From Kunicki TJ. The role of platelet collagen receptor (glycoprotein Ia/IIa; integrin a $_{2}$ß $_{1}$) polymorphisms in thrombotic disease. Curr Opin Hematol 2001;8:279, with permission.]

CAD–	363	357	332, 358	340, 341, 343, 344, 347, 360, 365

CAD, coronary artery disease; CVD, cerebrovascular disease; MI, myocardial infarction; PL, phospholipid; VNTR, variable number of tandem repeats.
Adapted and updated from Kunicki TJ. Platelet antigen polymorphisms. In: Schechter GP, Berliner N, Telen MJ, eds. American Society of Hematology: Education Program Book. 2000:222–228.

Another polymorphism of the gpIba subunit involves an amino acid substitution at position 145 that switches a threonine for methinonine within a leucine-rich motif ([246], [247]). The Thr:Met alleles are present in a ratio of 9:1 in typical white populations, and the Met 145 allele is associated with the VNTR A and B phenotypes ([248]). This dimorphism is the basis for the human platelet alloantigen-2 antigen system and can participate in platelet transfusion–associated alloantibody formation in multiply transfused patients. It has also been implicated in cardiovascular ([243], [244]) and cerebrovascular ([244], [249]) disease.

A third gpIba polymorphism exists in an upstream region surrounding the translation start site at position -5 from the initiator adenine-thymine-guanine codon and exists as either a T or a C. This is also known as *Kozak sequence dimorphism*. The -5C allele increases the expression of gpIba on the platelet membrane surface by 50% in homozygous individuals ([250], [251]). Most of the data available suggest that this does not lead to a significantly increased risk for cardiovascular or cerebrovascular disease ([252]).

a $_{2}$ß $_{1}$ Receptor

As previously discussed, integrin a $_2$ß $_1$ is a major platelet collagen receptor. It is interesting to note that it has been shown that this receptor's density on the platelet surface correlates with its adhesiveness to type I and type III collagens. The expression level varies up to tenfold between individuals and is linked to specific polymorphisms in the a $_2$ gene.

A single copy of the a $_2$ gene exists in the human haplotype and is present on the short arm of chromosome 5 ([253], [254]). Four a $_2$ alleles have been defined to date. Allele 1 (807T/1648A/2531C) is associated with increased receptor density. Allele 2 (807C/1648G/2531C) and allele 3 (807C/1648A/2531C) are both associated with lower levels of receptor expression. Allele 4 is very rare and is defined by 2531T. It creates the Sit ^{a} alloantigen. Unique restriction sites can differentiate each allele, as shown in Figure 20.11. In addition to these allelic differences, various groups have also reported two dimorphisms (C-52T and C-92G) within the proximal 5' regulatory region that also contribute to the variable expression of a $_2$ß $_1$ ([255], [256], [257] and [258]). In this respect, the presence of either the -52T or -92G polymorphism correlate with reduced expression of platelet a $_2$ß $_1$.

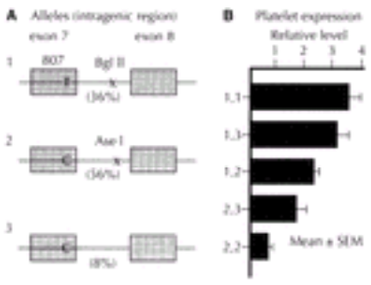

Figure 20.11. Integrin a $_2$ polymorphisms. **A:** Three common a $_2$ alleles that are distinguished by varying splice sites between exons 7 and 8 and their gene frequencies in a typical white population. **B:** Relative expression levels of a $_2$ß $_1$ as controlled by the inheritance of the three alleles. See text for details. SEM, standard error of mean. [From Kunicki TJ. The role of platelet collagen receptor (glycoprotein Ia/IIa; integrin a $_2$ß $_1$) polymorphisms in thrombotic disease. Curr Opin Hematol 2001;8:281, with permission.]

Because the rate of platelet attachment to type I collagen under high shear rate is proportional to the density of the a $_2$ß $_1$ receptors, theoretically, those with allele 1 might be expected to have increased risk of clotting. Overall, the studies investigating a correlation between allele 1 and thrombotic risk have shown equivocal results in MI, a trend suggesting that it is a probable risk factor in cerebrovascular disease and diabetic retinopathy, and a conclusion that it is unlikely to be a risk factor in coronary artery disease or venous thrombosis (Table 20.1).

Most studies have been performed on integrin a $_2$ß $_1$ allele 1 (807T) as a risk factor for MI and warrant discussion. These include case control studies of variable numbers of subjects that have addressed the incidence of MI in patients with coronary artery disease, as well as the occurrence of sudden cardiac death. The study by Santoso et al. ([259]) is the largest study to date that investigated the relationship between the 807T polymorphism and nonfatal MI in younger patients. The most striking association was with patients younger than 49 years of age who had an MI with the highest odds ratio in the study of 2.61. However, there was no association between allele 1 and the presence of coronary artery disease in this group. This latter observation was verified by Corral et al., in whose study the median age of the patients was 52 years. However, there were no subset evaluations performed specifically for age.

There have been very little data to suggest that alleles 2 through 4 are associated with increased risk of thrombosis. However, Kroll et al. published a large study in 2000 that suggested allele 3 was associated with coronary artery disease, possibly via a qualitative rather than quantitative effect ([260]).

Platelet Glycoprotein VI

gpVI is a platelet receptor that, as discussed above, also binds to collagen and induces activation via a pathway that phosphorylates the FcR?-chain ([43], [52], [54], [70]). gpVI recognizes the Gly-Pro-Hyp (hydroxyproline) sequence on collagen. It has been shown in a small number of volunteers that this receptor expression level varies by fivefold ([261]) and possibly corresponds to variations in integrin a $_{IIb}$ß $_3$. However, there is no genetic basis for variation in gpVI expression yet. It may prove to be a useful therapeutic target for patients with ischemic heart disease ([262]).

a $_{IIb}$ß $_3$ Receptor

Three allelic variants are known within the aIIb subunit with differences at residue 837 (Val or Met) ([263]) or 843 (Ile or Ser) ([264]). The most common variant in the white population is Val 837, Ile 843 (human platelet alloantigen 3a,9a). Eight allelic variants exist within the ß $_3$ subunit that vary at six different positions. These include positions 33 (Leu or Pro, human platelet alloantigen 1a or 1b), 40 (Leu or Arg), 62 (Arg or Gln), 143 (Arg or Gln), 407 (Pro or Ala), 489 (Arg or Gln), and 636 (Arg or Cys) ([265]). The dimorphism at position 40 is serologically indistinguishable. The most frequent dimorphism in the white population is Leu 33, Leu 40, Arg 62, Arg 143, Pro 407, Arg 489, Arg 636 (gene frequency, 0.85) ([266]). The allele of importance is Pro 33 (ß-3PI ^{A2}; gene frequency, 0.15), which has been implicated as a potential risk factor for coronary thrombosis ([267]). This allele may confer a lower threshold for agonist-induced platelet responses ([266]). Table 20.1 summarizes the a $_{IIb}$ß $_3$ polymorphisms and their status as possible risk factors for thrombosis. None of the platelet receptor polymorphisms has been consistently linked to deep venous thrombosis.

ROLE OF THE CYTOSKELETON IN PLATELET FUNCTION

Once an agonist has interacted with its platelet membrane receptor and triggered second messenger formation, a key event in platelet activation and subsequent aggregation is the transition of the platelet's shape from the discoid appearance associated with its circulating, resting state to the amorphous, amoebalike appearance with multiple pseudopodial projections that denotes its activation state and readiness to participate in platelet plug formation. The platelet cytoskeleton and its associated signaling proteins are responsible for mediating shape change associated with activation, spreading, secretion, and aggregation. This cytoskeleton is associated with at least 14 different structural proteins that function interdependently as a single unit but can be seen as consisting of three major functional units: (a) a cytoplasmic network consisting mainly of actin, (b) a meshwork of proteins immediately proximal to the cytoplasmic leaflet of the platelet referred to as the *membrane skeleton* (because they contain surface-associated proteins like the gpIb complex), and (c) a microtubule coil that encircles the platelet to contribute to its resting, discoid state. The functional anatomy of these cytoskeletal proteins is described in depth in Chapter 19, and so a relatively brief summary of their role in platelet function is presented in this section.

Transmembrane receptors, such as gpIb and a $_{IIb}$ß $_3$, appear to participate in anchoring the platelets to extracellular matrix in the arterial subendothelium through their extracellular domains, while their cytoplasmic domains are almost simultaneously associating with membrane skeletal proteins in response. In doing so, these surface receptors are providing sites at which tension can be generated by intracellular contractile elements that subsequently lead to shape change and activation of signaling proteins.

The cytoplasmic network consists of actin filaments and their associated proteins, referred to as *intermediate filaments*. In resting platelets, approximately half of actin is structurally filamentous in nature, and this fraction increases to approximately three-fourths during platelet activation ([268]). During this process, the actin filaments are reorganized into longer filaments after their initial breakdown into smaller units. Simultaneously, myosin is phosphorylated by myosin light chain kinase and then associates with F-actin, with the resultant filament then attaching itself to the a subunit of the gpIb complex through ABP ([269], [270]). These filaments are also anchored at sites called *focal adhesions*, where the tyrosine kinase Fak becomes activated after platelet stimulation. Focal adhesions assemble around the a $_{IIb}$ß $_3$ integrin on its conformational change (activation) and so play a very important role in signaling pathways associated with platelet activation by drawing together membrane receptors, the cytoskeleton, and signaling phosphoproteins such as members of the Src family, PI3K, and Syk into close physical proximity ([271]). Other platelet

integrin receptors, such as a $_2$ß $_1$, also organize focal adhesions after binding to their respective extracellular ligands.

It was noted in the section, Glycoprotein Ib Complex Signaling that phosphorylation of Ser 166 in the cytoplasmic domain of the gpIb complex ß-chain has been observed to be mediated by cAMP-associated activation of PKA and that this phosphorylation reduced interaction of gpIbß and the signaling molecule, 14-3-3?. The phosphorylation of gpIbß has also been demonstrated to have a direct inhibitory effect on actin polymerization ([272]) and thus serves as further support that gpIbß phosphorylation may be playing a role in maintaining transmembrane signaling in a switched-off or resting state that is capable of activation when shear-dependent interaction of gpIba with vWF takes place.

The membrane skeleton consists of actin, ABP, talin, vinculin, spectrin, cortactin, a-actinin, and several membrane glycoproteins, as noted above and in Table 19.3. ABP is a 250-kd elongated dimer that associates with the cytoplasmic domain of the gpIba-chain and acts to link the receptor to actin in the early stages of platelet activation, as noted above. ABP has also been found to coisolate with guanosine triphosphate–binding proteins and also binds to several members of the Ras superfamily of low-molecular-weight guanosine triphosphatases that participate in various aspects of cytoskeletal rearrangement ([273] , [274] and [275]). After platelet activation, calpain, the calcium-dependent protease, is activated in aggregating and spreading platelets and cleaves the link between ABP and gpIb. Thus, ABP may be considered a prototype of sorts of membrane skeleton proteins that provides a good example of their important role in terms of interaction with second messengers and other signaling molecules that either may become activated or may act on their substrates after platelet stimulation.

Microtubules have been relatively understudied compared with the above cytoskeletal proteins. Early studies have demonstrated that the submembranous microtubule coil both depolymerizes and repolymerizes in activated platelets, although its organization in resting platelets is unknown ([276] , [277]). The coil consists of a single polymer of tubulin that encircles the platelet periphery and helps to maintain its discoid shape while resting ([278]).

PLATELET–CELL INTERACTIONS

Platelets and Endothelium

The mechanisms behind platelet interaction with vWF, collagen, and other subendothelial matrix molecules exposed as a result of damaged endothelium have been well studied and described in earlier sections of this chapter. In addition to these platelet–subendothelial interaction paradigms, recent evidence has emerged that circulating, unactivated platelets have the capacity (like neutrophils) to roll on tumor necrosis factor-a–mediated activated endothelium *in vivo* and then reversibly adhere to it in a process that is dependent on endothelial cell expression of P-selectin ([279] , [280] , [281] and [282]). The specific counterreceptor on platelets that P-selectin binds to is unclear and could be the gpIb complex or P-selectin glycoprotein ligand 1, or both ([283] , [284]). These two receptors have structural similarities including similar ligand-binding domains. P-selectin is also expressed on the surface of activated platelets and is an a-granule component in resting platelets. Along with endothelial P-selectin, it is not surprising that vWF expressed on activated venous endothelium has also been implicated in platelet adhesion and translocation ([285]). The precise nature of the relationships between these two endothelial molecules and the platelet gpIb complex, and the role different shear forces may have to play in determining which ligand gpIb may preferentially associate with remain to be determined.

In contrast to these observations, activated platelets have also been demonstrated to adhere to intact endothelial cells in a process dependent on a $_{IIb}$ß $_3$ bridging that involves endothelial receptors like a $_V$ß $_3$ and intercellular adhesion molecule-1 interacting with platelet-bound fibrinogen, fibronectin, and vWF ([286] , [287] and [288]). Whether P-selectin expressed on the surface of activated platelets plays any role in their interaction with endothelium is unknown. The fact that P-selectin knock-out mice have been observed to display impaired hemostasis would suggest a potential role in this respect ([289]).

Platelets and White Blood Cells

In addition to the participation of the gpIb complex and P-selectin in the interaction between platelets and intact endothelium described above, these proteins along with the ß $_2$ integrin receptor Mac-1 (a $_M$ß $_2$ or CD11b/CD18) have also been found to participate in interaction between platelets and leukocytes. Platelets contribute to leukocyte rolling and extravasation, which are two well-characterized steps involved in the translocation of the latter cell from the circulation to sites of infection ([290]). Normally, after interaction of endothelial P-selectin with leukocyte receptors such as P-selectin glycoprotein ligand 1, ß $_2$ integrin activation on the leukocyte mediates increased adhesion to endothelium, and that is followed by extravasation.

Neutrophils are also capable of rolling on adherent and activated platelets by interacting with P-selectin expressed on the platelet surface, and they will subsequently display extravasation mediated by activation of Mac-1 ([291]). The a subunits of certain integrins, such as Mac-1, have been found to contain “insert” (I) domains, homologous to the A $_1$ domain of vWF. This observation has taken on added interest since it was shown in 2000 that Mac-1 is capable of binding to the gpIb complex and that this interaction required the I domain of Mac-1 and the leucine-rich repeat region of gpIba ([292]). Mac-1 knock-out mouse neutrophils were incapable of binding to isolated polypeptide fragments corresponding to the extracellular domain of gpIba (called *glycocalicin*). For this reason and others, the role of Mac-1–gpIb complex interaction could turn out to be important with respect to initiating and propagating inflammation associated with the progression of atherosclerotic, purely thrombotic, or atherothrombotic processes.

ROLE OF PLATELETS IN ATHEROTHROMBOSIS

Atherosclerosis is the major cause of vascular occlusive disorders such as coronary artery disease, stroke, and peripheral arterial disease. Every year, more than 4 million patients are admitted to hospitals worldwide with ACS, more than 1.5 million of them in the United States ([293]). Peripheral arterial disease affects up to 12% of the general population and 20% of those older than age 70 years ([294]). The instability associated with atherosclerotic plaque progression enhances the patients' vulnerability to disruption or ulceration, and this is associated with secondary deep vessel wall injury and thrombus formation ([295] , [296] and [297]). It is clear that platelet activation and aggregation play an integral role in the development of thrombus associated with atherosclerotic plaque based on extensive laboratory and clinical experience.

Angiographic studies have shown that the progression of coronary artery disease is neither linear nor predictable ([298]). Severe narrowing or total occlusion can often be documented in arterial segments that appeared normal only months earlier at angiographic examination ([299] , [300]). This unpredictable progression is likely caused by plaque disruption and subsequent thrombus formation that changes the plaque geometry ([295] , [301] , [302]). Such a rapid change in the plaque may result in thrombotic arterial occlusion with associated ACS.

The interior of intact atherosclerotic plaques is rich in components that are highly thrombogenic (e.g., collagen types I and III, fibrinogen/fibrin, thrombospondin), and the luminal surface is relatively nonthrombogenic. In contrast to these observations, the thrombotic response to plaque disruption is dynamic. In this respect, thrombosis, repeat thrombosis, and thrombolysis along with embolization all occur simultaneously in many patients with ACS, and this is considered responsible for intermittent flow obstructions ([303]). The initial flow obstruction is acknowledged as being due to platelet aggregation, but subsequent fibrin stabilization is important to the longevity of the early and fragile platelet thrombus ([304]). Due to reduced flow caused by the platelet thrombus at the plaque rupture site, a red erythrocyte and fibrin-rich thrombus may form and propagate up and down the artery in both directions ([303]).

Coronary angioplasty data collected at the time of ACS have shown that transient vasoconstriction often accompanies plaque disruption or fissuring and thrombosis ([305]). This vasoconstriction occurs with significant wall damage and is dependent on both platelets and thrombin, with the platelet dependence shown to be mediated by serotonin and thromboxane A $_2$ ([305] , [306]). There is also evidence that alteration of the endothelium such as may occur with early atherogenesis (particularly when under the influence of atherosclerosis risk factors) or plaque disruption may cause endothelium to generate more mediators that enhance constriction, such as endothelin-1, and fewer mediators that enhance dilation, such as PGI $_2$ and NO ([307] , [308] , [309] and [310]).

The importance of the role of both arterial wall and systemic inflammation in atherogenesis and its later clinical manifestations, along with the molecular interface between inflammation and thrombosis, have been the subject of much recent attention in the literature ([311] , [312]). An increased number of links between thrombosis and inflammatory mediators have been observed in recent years, and new roles for the platelet in inflammation are becoming apparent as a result ([313]).

As discussed in the previous section, platelets colocalize and directly interact with leukocytes at sites of damaged endothelium that can occur in the setting of hemorrhage, areas of atherosclerotic plaque destabilization, postangioplasty lesions associated with restenosis, and areas of ischemia-reperfusion injury ([313]). These broadly based settings associated with platelet–leukocyte interactions link hemostatic/thrombotic and inflammatory responses. As described in more detail in the previous section, many of the molecular players mediating leukocyte–endothelium interaction have also been found to play important roles coordinating leukocyte attachment and transmigration across layers of platelets adherent to injured vascular intima ([292] , [314]). In addition to this binding of leukocytes to platelets, the binding of platelets to leukocytes influences important white cell effector responses, such as cell activation, signaling associated with integrin activation, chemokine synthesis, and so forth. Thus, it has become clear that inflammation is capable of leading to local thrombosis, and thrombosis is capable of initiating and propagating inflammation. It is likely that progress will continue to be made in the foreseeable future with respect to elucidating the molecular mechanisms linking these fundamental disease processes.

Blood Coagulation and Fibrinolysis

The processes of blood coagulation and fibrinolysis are the primary defense systems of the vasculature. The opposing forces of fibrin clot formation and dissolution maintain hemostasis and preserve vascular function and integrity. Procoagulant events that culminate in a-thrombin generation and fibrin clot formation protect the vasculature from perforating injury and excessive blood loss. Fibrinolysis removes the fibrin clot, restores blood flow, and initiates mechanisms involved in tissue repair and regeneration. *Hemostasis*, therefore, refers to multiple discreet processes that center on a-thrombin generation, fibrin clot formation, and fibrin clot dissolution.

Circulating and adherent cells and circulating and cell membrane–associated proteins carry out key roles in the coagulation and fibrinolytic pathways. Hemostasis is not a passive state but is instead actively maintained by the vascular system. Specific cellular and protein interactions are required to maintain an equilibrium state. When the system is perturbed, precise interactions are likewise required to initiate procoagulant events and to promote fibrinolysis and tissue repair. Each individual process that contributes to hemostasis must operate properly, or the entire system is compromised. A balance between the procoagulant, anticoagulant, and fibrinolytic factors is required to prevent uncontrolled bleeding or, conversely, excessive clot formation ([1]).

Many of the processes involved in hemostasis are still not well understood. Epidemiologic studies have expanded our knowledge about key factors that determine risk for cardiovascular disease. However, cardiovascular disease is still the primary cause of death in the United States and Western Europe. To more effectively treat and, ultimately, prevent cardiovascular mishaps, we continue to examine the processes that contribute to blood coagulation and fibrinolysis. The current concepts governing the roles of protein components and their structures, functions, and regulation are summarized in the following sections.

ESSENTIAL FEATURES OF COAGULATION

MacFarlane ([2]) and Davie and Ratnoff ([3]) provided the first descriptions of the coagulation system in 1964. They proposed a “cascade” or “waterfall” sequence of events in which the reactions occur in a defined series leading to fibrin clot formation. Each reaction shares a similar mechanism in which an inactive zymogen precursor protein is converted to an active enzyme. Generation of the active enzyme requires a multiprotein complex, a surface, and divalent calcium ions (Ca^{2+}). Although some facets of these initial descriptions are still valid, the emerging concept of coagulation and fibrinolysis centers on a complex network of highly interwoven concurrent processes. Procoagulant and fibrinolytic events occur simultaneously with many positive and negative feedback loops regulating the processes. To simplify this intricate mechanism, the reactions that govern hemostasis can be separated into five distinct phases for analysis: *initiation* of coagulation,

propagation of a-thrombin formation, *termination* of the procoagulant response, *elimination* of the fibrin clot, and tissue *repair* and regeneration.

The reactions involved in these five phases share several key features. The nomenclature used to describe the protein components of the reactions is similar. The enzymes and their zymogen precursors are members of the serine protease family that includes chymotrypsin and trypsin and their respective precursors chymotrypsinogen and trypsinogen. The zymogen and enzyme forms of the coagulation proteases are generally distinguished by an *a* added to the zymogen name to signify the active enzyme. For example, *factor Xa* is the active enzyme, and *factor X* is the corresponding zymogen. Factor II, most commonly referred to as *prothrombin*, is the zymogen that on activation becomes factor IIa or thrombin. Procofactors factor V and factor VIII also share this nomenclature, in which the fully functional cofactor forms are designated *factor Va* and *VIIIa*. Other protein cofactor components that are cell membrane–associated, such as tissue factor and thrombomodulin, have only one form and designation.

The mechanisms of the individual reactions are likewise similar in nature. A complex consisting of a serine protease, cofactor protein, and Ca^{2+} assembled on an anionic phospholipid surface activates a zymogen to an enzyme. The prothrombinase complex is the best characterized of these multicomponent catalysts. The prothrombinase complex consists of the enzyme factor Xa, its cofactor, factor Va, Ca^{2+}, and an anionic membrane surface. The prothrombinase complex cleaves the zymogen prothrombin to yield the active enzyme a-thrombin. *In vivo*, the phospholipid surface is provided mainly by platelets and, to some extent, by the endothelium and circulating cells such as monocytes.

The essential features of the hemostatic response include speed, amplification, regulation, and localization. The response to injury must be rapid and properly amplified to ensure an adequate address to the injury. Initiation of the procoagulant response occurs when the vascular milieu is perturbed and the antithrombotic nature of the endothelium is shifted to a prothrombotic state. Membrane surface and tissue elements, such as tissue factor, are exposed and set the stage for the subsequent phases of coagulation.

Assembly of the multicomponent procoagulant complexes on the membrane surface triggers the propagation of the coagulation response. The net result of the activities of these complexes (the intrinsic and extrinsic tenase and prothrombinase complexes) is an explosive elevation of the concentration of the enzyme a-thrombin. This rapid burst of a-thrombin is required to sustain the procoagulant response. a-Thrombin activates circulating platelets, the procofactors factors V and VIII, and the zymogens factors VII and XI ([4], [5], [6], [7], [8], [9], [10], [11], [12] and [13]) and cleaves fibrinogen to yield the fibrin clot. a-Thrombin also activates factor XIII ([14]), a transglutaminase that cross-links and further stabilizes the fibrin clot. Thrombin-activatable fibrinolysis inhibitor (TAFI), also known as *carboxypeptidase U* ([15]) or *procarboxypeptidase B* ([16]), is another zymogen activated in an a-thrombin–dependent fashion ([17]). The resulting enzyme, TAFIa, protects the fibrin clot from proteolysis and subsequent degradation. The propagation phase thus stems blood loss by providing a stable fibrin clot.

Termination of fibrin clot formation involves constitutive inhibitory processes and a clot-initiated dynamic inhibitory process ([18]). The termination phase results in inhibition of the procoagulant enzyme complexes either by direct inhibition of the serine protease components or by inactivation of the cofactor proteins. The termination phase serves to limit the coagulation response and prevent excessive clot formation.

Elimination of the resulting clot is a plasmin-dependent process. The enzyme plasmin cleaves the cross-linked fibrin matrix to produce soluble fibrin peptides ([19], [20]). The mechanism by which plasmin is generated is quite complex and involves several proteins with key roles throughout the hemostatic response.

The solubilization and removal of the fibrin scaffolding of the hemostatic plug are coordinated with processes of tissue repair and regeneration. The extracellular matrix is degraded to allow for cell migration into the damaged area. Cells repopulate the site and re-create the elements necessary to restore the vasculature to its unperturbed state.

Just as these steps must occur rapidly and in a precise choreographed manner, they must also be localized to the site of injury. Localization presents challenges because the hemostatic response occurs under conditions of flow. Localization is controlled on several levels. Unperturbed endothelial cells actively inhibit coagulation by constitutively synthesizing a variety of anticoagulant proteins and inhibitors and inhibitors of platelet activation. The surface of undamaged cells is also not conducive to the assembly and function of the procoagulant protein complexes. The only surface available for procoagulant complex assembly is therefore the damaged site. Enzyme activity is also limited to the site of injury due to high levels of circulating inhibitors. In addition, the procoagulant enzyme complexes are stabilized and exhibit large increases in catalytic efficiency when interacting with a membrane surface. The membrane surface provides for rapid transfer of intermediate products between complexes as well. Surface-dependent two-dimensional transfer of intermediates between complexes increases the rates of complex assembly and function and, ultimately, provides the burst of a-thrombin required for clot formation. If the intermediate products dissociated from and reassociated with the membrane, not only would the rates of complex assembly and function be considerably slower, but also the intermediate enzyme products would be exposed to inhibitors and subject to dilution in the circulation. Surface-dependent interactions that channel intermediates between complexes increase catalytic efficiency, sequester enzyme products at the site of injury, and protect enzyme intermediates from inhibition and dilution ([18], [21]). The essential features of the hemostatic response, speed, amplification, regulation and localization, thus ensure that the response is localized to the area of injury, amplified appropriately according to the severity of the injury, and attenuated to allow for subsequent tissue regeneration ([22], [23]).

OVERVIEW OF PROCOAGULANT PATHWAYS: PRIMARY AND ACCESSORY PATHWAYS

There are two distinct procoagulant pathways. The primary or extrinsic (tissue factor) pathway consists of the intrinsic and extrinsic tenase complexes and the prothrombinase complex (Fig. 21.1). The accessory or intrinsic (contact) pathway is composed of the factor XII–high-molecular-weight kininogen (HMWK)–prekallikrein complex in contact with a negatively charged surface such as glass, dextran sulfate, or kaolin and the factor XIa–HMWK:divalent cation complex in contact with an appropriate cellular membrane. The primary and accessory pathways are initiated by independent routes leading to the activation of factor IX and converge at the intrinsic tenase complex (Fig. 21.1). Regardless of the path chosen, the outcome is the formation of the prothrombinase complex and thrombin generation. Clinical tests differentiate between the two pathways. The activated partial thromboplastin time initiates coagulation through the accessory pathway, whereas the prothrombin time (PT) assay initiates coagulation through the primary pathway ([24], [25] and [26]).

Figure 21.1. Overview of hemostasis. There are two pathways to initiate coagulation: the primary extrinsic pathway (shown on right) and the accessory (historically called the *contact* or *intrinsic pathway*) (shown on left). The components of these multistep processes are illustrated as follows: enzymes (*open circle*), inhibitors (*hatched circles*), zymogens (*open boxes*), or complexes (*open ovals*). The accessory pathway has no known bleeding etiology associated with it; thus, this path is considered accessory to hemostasis. On injury to the vessel wall, tissue factor, the cofactor for the extrinsic tenase complex, is exposed to circulating factor VIIa and forms the vitamin K–dependent complex, the extrinsic tenase. Factor IX and factor X are converted to the serine proteases factor IXa (FIXa) and factor Xa (FXa), which then form the intrinsic tenase and the prothrombinase complexes, respectively. The combined actions of the intrinsic and extrinsic tenase and the prothrombinase complexes lead to an explosive burst of the enzyme thrombin (IIa). In addition to its multiple procoagulant roles, thrombin also acts in an anticoagulant capacity when combined with the cofactor thrombomodulin in the protein Case complex. The product of the protein Case reaction, activated protein C (APC), inactivates the cofactors factors Va and VIIIa. The cleaved species, factors Va_i (FVa_i) and $VIIIa_i$ ($FVIIIa_i$), no longer support the respective procoagulant activities of the prothrombinase and intrinsic tenase complexes. Once thrombin is generated through procoagulant mechanisms, thrombin cleaves fibrinogen [releasing fibrinopeptides A and B (FPA and FPB, respectively)] and activates factor XIII to form a cross-linked fibrin clot. Thrombin-thrombomodulin also activates thrombin-activatable fibrinolysis inhibitor (TAFI) that slows down fibrin degradation by plasmin. The procoagulant response is down-regulated by the stoichiometric inhibitors tissue factor pathway inhibitor (TFPI) and antithrombin-III (AT-III). TFPI serves to attenuate the activity of the extrinsic tenase, the trigger of coagulation. AT-III directly inhibits thrombin, FIXa, and factor Xa. The accessory pathway provides an alternate route for the generation of factor IXa. Thrombin has also been shown to activate factor XI. The fibrin clot is eventually degraded by plasmin yielding soluble fibrin peptides (see Fig. 21.17). HMW, high-molecular-weight.

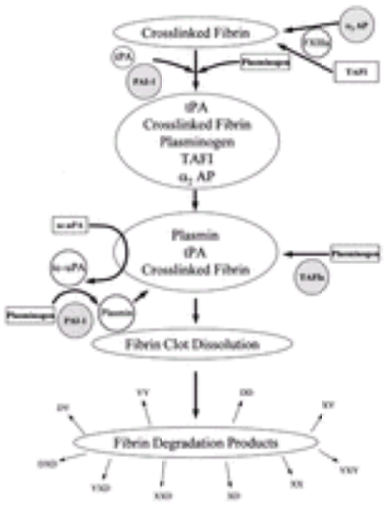

Figure 21.17. Schematic of the dynamic interaction between the proteins and inhibitors of fibrinolysis. Cross-linked fibrin formation is integrated with fibrin clot dissolution and degradation of its products. The enzymes (*open circles*), inhibitors (*hatched circles*), zymogens (*open boxes*), and complexes (*large open ovals*) are illustrated in a simplified form to show this multicomponent process. The key proteins involved are plasminogen, plasminogen activators [tissue-type plasminogen activator (tPA), single-chain urokinase-type plasminogen activator (scu-PA), and two-chain urokinase-type plasminogen activator (tcu-PA)], plasminogen activator inhibitor-1 (PAI-1), a $_2$-antiplasmin (a $_2$-AP), and thrombin-activatable fibrinolysis inhibitor (TAFI). t-PA and plasminogen both bind to the fibrin surface where t-PA is an effective catalyst of plasminogen activation. Initially, plasmin proteolysis of fibrin generates new, higher affinity binding sites for plasminogen, setting up an amplifying loop of plasminogen activation. Reinforcing this process, generated plasmin can convert the single-chain form of urokinase, an ineffective catalyst, to its active form, thus increasing the concentration of available plasminogen activation. Opposing these events are antifibrinolytic mechanisms. a $_2$-AP, both soluble and cross-linked to fibrin, forms complexes with plasmin, rendering it inactive. PAI-1 rapidly reacts with both t-PA and two-chain urokinase, reducing the concentration of plasminogen activators. Formation of activated TAFI (TAFIa) results in removal plasmin-generated COOH-terminal lysine residues, thus suppressing the rate of fibrin lysis. Fibrin degradation occurs by cleavage at the D-E-D domains of fibrin polymers by plasmin to yield a variety of polymers as illustrated (see Fig. 21.16).

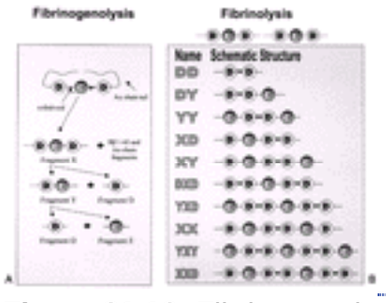

Figure 21.16. Fibrinogenolysis and fibrinolysis. **A:** Fibrinogen is represented as a trinodular structure (D-E-D domains). Each E-domain and D-domain is separated by a coiled-coil domain. The Aa-chain tail is shown as a line. Plasmin digests fibrinogen, yielding various fragments, the largest of which is fragment X. Fragment X contains the two D domains, the E domain, and the a-helical coiled-coils but lacks the C-termini of the Aa-chains and the peptide Bß-chains. Fragment Y consists of the central E domain connected by the coiled-coil to one of the terminal D domains. Fragment Y can be further degraded by cleavage of the coiled-coil domain to release a second D domain and fragment E. **B:** The domain composition of the monomer units of degraded fibrin is indicated by the circles containing a *D* or an *E*. Intermolecular cross-links between the ?-chains are shown as thicker lines connecting the D regions. The structures of the various-sized fragments of cross-linked fibrin monomers resulting from plasmin proteolysis of fibrin are presented.

The designations of primary and accessory pathways are based on clinical evidence of bleeding diseases. Deficiencies of proteins associated with the intrinsic or accessory pathway (factor XII, prekallikrein, and HMWK) do exist but are not associated with abnormal bleeding events, even after surgical challenge ([27], [28] and [29]). However, deficiencies of the protein components of the extrinsic or primary pathway (prothrombin and factors V, VII, VIII, IX, and X) can lead to severe bleeding diatheses ([30], [31], [32], [33], [34] and [35]). Factor XI deficiency may also result in bleeding episodes subsequent to trauma ([36], [37]). The physiologic role of the accessory pathway is therefore not clearly understood ([38]). Factor XI appears to play a more prominent role in coagulation ([39]), although this role is most likely unrelated to its activities in the intrinsic pathway. The importance of factor XI is thought to be due to the activation of factor XI to factor XIa by a-thrombin as part of a positive feedback loop stemming from a-thrombin generation. Factor XIa then functions in the propagation phase of a-thrombin generation in association with the primary pathway ([4]).

Three proteins, factor XII, prekallikrein, and HMWK, are required for activity of the contact or accessory pathway. Factor XII and prekallikrein are zymogens that are activated to generate serine proteases, and HMWK is a nonenzymatic procofactor. Although these proteins have no defined role in normal hemostasis, the accessory pathway factors are thought to play a key role in disseminated intravascular coagulation (DIC) associated with the systemic inflammatory response syndrome ([40], [41]). The accessory pathway may also be important in cardiopulmonary bypass due to contact between blood components and synthetic surfaces ([41]).

The primary pathway of coagulation, the extrinsic pathway, involves the vitamin K–dependent zymogens and serine proteases, cofactor proteins, and Ca $^{2+}$ ions assembled on anionic phospholipid membranes. The complexes display reaction rates 10 ^{5} to 10 ^{6} times greater than the respective serine proteases alone ([21]). The importance of the membrane component in coagulation has been identified by kinetic studies of the prothrombinase complex. In the absence of the membrane surface, the cofactor (factor Va)–enzyme (factor Xa) interaction is relatively weak, with a dissociation constant (K $_d$) of 800 nmol/L ([42], [43] and [44]). The factor Va–lipid interaction (K $_d$ = 3 nmol/L) and factor Xa–lipid interaction (K $_d$ = 110 nmol/L) ([45]) show higher affinity. However, all of the components must be present to generate the high-affinity factor Va–factor Xa–Ca $^{2+}$-membrane complex, with a K $_d$ of 1 nmol/L ([46]). The fully assembled complex is stabilized through factor Va–factor Xa, factor Va–lipid, and factor Xa–lipid interactions ([11], [47], [48]). The stability of the complex is translated into greater catalytic efficiency as well. The prothrombinase complex converts the zymogen prothrombin to a-thrombin 10 ^{5}-fold faster than a physiologic concentration of factor Xa acting alone ([42]).

The three complexes of the primary pathway (extrinsic tenase, intrinsic tenase, and prothrombinase) function in tandem to achieve a rapid burst of a-thrombin generation. The primary pathway of coagulation is initiated or triggered by the interaction of circulating factor VIIa with its cofactor tissue factor ([49], [50] and [51]). In general, the serine proteases associated with hemostasis circulate in their zymogen or inactive forms; however, low levels of circulating factor VIIa are present in blood ([52]). This factor VIIa binds to tissue factor and initiates the procoagulant response. Although low levels of factor VIIa are in continuous circulation, initiation of coagulation is a very specific response. Free factor VIIa is a poor enzyme with virtually no proteolytic activity and does not react with circulating inhibitors in the absence of tissue factor. Tissue factor is an integral membrane protein that is not normally expressed on vascular cell surfaces. Tissue factor is instead constitutively expressed on extravascular cellular surfaces ([53], [54], [55], [56], [57] and [58]) and thus exposed on damage to the endothelial cell layer. Tissue factor is also expressed on peripheral blood cells and endothelial cells stimulated by inflammatory cytokines ([59], [60]).

On interaction of circulating factor VIIa and injury-exposed tissue factor, the extrinsic tenase complex is formed and initiates coagulation by activating factors IX and X. The extrinsic tenase also activates additional factor VII. Factor IXa forms a complex with its cofactor, factor VIIIa, to generate the intrinsic tenase complex, and factor Xa combines with factor Va to form the prothrombinase complex. The factor VIIIa–factor IXa complex serves to activate factor X to factor Xa, providing a more robust source of the enzyme component of the prothrombinase complex. Factor Xa associated with a phospholipid surface, in the absence of the cofactor protein factor Va, activates factor VII to factor VIIa, thus providing a positive feedback loop. The rate of factor Xa–phospholipid activation of factor VII is 24-fold higher than the tissue factor–factor VIIa complex ([61]).

Examination of the roles of the complexes in the primary pathway of coagulation presents a paradox. Because the extrinsic tenase also provides factor Xa, the severe bleeding disorders associated with deficiencies of the intrinsic tenase components factor VIIIa (hemophilia A) and factor IXa (hemophilia B) should not exist. In theory,

activation of factor X by the extrinsic tenase could compensate for the lack of factor X activation by the intrinsic tenase in hemophilias A and B. However, this compensatory mechanism only occurs on clinical administration of supraphysiologic concentrations of recombinant factor VIIa. Physiologic levels of factor VIIa are not able to provide sufficient levels of factor Xa to support normal coagulation in the absence of an adequate intrinsic tenase activity.

Although the roles of the intrinsic and extrinsic tenase complexes may appear to be somewhat redundant, closer examination of the complexes provides a clear picture of their respective functions. When factors IX and X are simultaneously presented to the extrinsic tenase to mimic conditions *in vivo*, factor IXa generation is increased, whereas factor Xa generation is suppressed to approximately one-half the level observed when factor X is the only substrate presented ([62], [63]). Factor IX, not factor X, appears to be the preferred substrate of the extrinsic tenase. In addition, factor IXa, the intermediate species in factor IX activation, is generated more rapidly in the presence of factor X. Factor IXa activation to the final product factor IXa occurs at a higher rate than factor IX activation, thereby providing a burst of factor IXa to form the intrinsic tenase complex. The low level of factor Xa generated by the tissue factor–factor VIIa complex most likely functions in the activation of factor IX. A model of extrinsic tenase behavior suggests that factor IX is converted to factor IXa by the extrinsic tenase or factor Xa–phospholipid complex. Factor IXa is then rapidly converted to factor IXa by the extrinsic tenase ([62], [63]). The factor VIIIa–factor IXa complex subsequently activates the major fraction of factor X to factor Xa and provides the enzyme component for the prothrombinase complex. Measurements of second-order rate constants for factor Xa generation by the intrinsic and extrinsic tenase complexes also support this model. The rate of factor Xa generation by the tissue factor–factor VIIa complex is 1/50th the rate of factor Xa generation by the factor VIIIa–factor IXa complex ([62], [63] and [64]). Both complexes thus have distinct roles in the procoagulant response.

In summary, the procoagulant response is triggered on factor VIIa interaction with tissue factor exposed, expressed, or both, as a result of vascular perturbation. The extrinsic tenase generates low levels of factors IXa and Xa during the initiation phase of coagulation. Factor Xa–phospholipid complexes also assist in the activation of factor IX. Factor IXa combines with factor VIIIa on the membrane surface, and the intrinsic tenase accelerates factor Xa generation 50-fold over the extrinsic tenase. The burst of factor Xa overcomes circulating levels of factor Xa inhibitors and initiates maximal levels of prothrombinase complex activity. Prothrombinase activity subsequently leads to a burst of a-thrombin generation and propagation of the procoagulant response ([62], [63]).

PROCOAGULANT PROTEINS: ACCESSORY PATHWAY FACTORS AND FACTOR XI

The procoagulant proteins that make up the intrinsic pathway or accessory pathway consist of factor XII, plasma prekallikrein, HMWK, and factor XI. These proteins are responsible for the contact activation of blood coagulation. The physiologic role of the intrinsic pathway is not clearly understood but does not appear to be essential for hemostasis because individuals deficient in these proteins do not manifest abnormal bleeding. Factor XI appears to play a more prominent role, unrelated to its activities in the intrinsic pathway, in coagulation after activation by thrombin ([39]). Each of these proteins is described in terms of its gene structure and expression, biochemistry, activation, function, and regulation in regards to hemostasis.

Factor XII (Hageman Factor, Contact Factor)

Factor XII, or *Hageman factor* (HF), is the zymogen precursor of the serine protease factor XIIa. Factor XII is also known as *contact factor* for its role in the initiation of the contact or intrinsic pathway of coagulation on contact with substances such as glass or kaolin. The contact pathway is the basis for the activated partial thromboplastin time clotting assay. Factor XII circulates in plasma at an average concentration of 40 µg/ml (500 nmol/L) ([65], [66]) (Table 21.1). Increased levels of factor XII are seen in postmenopausal women using estrogen replacement therapy and during pregnancy. Animal studies also demonstrate enhanced expression of factor XII by estrogen and prolactin ([67], [68] and [69]). Deficiency of factor XII is not associated with bleeding abnormalities; therefore, the precise role of factor XII in hemostasis is unknown at the present time. However, the components of the contact pathway are believed to provide a link between coagulation and inflammation.

TABLE 21.1. Biochemical Properties of Blood Coagulation Proteins

Protein	Molecular Weight (d)	Plasma Concentration		Plasma Half-Life (days)	Carbo-hydrate (%)	Clinical Phenotype [a]		Functional Classification
		(nmol/L)	(µg/ml)			H	T	
Intrinsic pathway proteins								
Factor XII	80,000	500	40	2–3	17	–		Protease zymogen
Prekallikrein	85/88,000	486	42		15			Protease zymogen
High-molecular-weight kininogen	120,000	670	80		42	–		Cofactor
Low-molecular-weight kininogen	66,000	1300	90		30			Cofactor
Factor XI	160,000	30	5	2.5–3.3	5	±		Protease zymogen
Extrinsic pathway proteins								
Tissue factor	44,000							Cell-associated cofactor
Factor VII	50,000	10	0.5	0.25	13	+	±	VKD protease zymogen
Factor VIIa	50,000			0.1	13			VKD serine protease
Factor X	59,000	170	10	1.5	15	+		VKD protease zymogen
Factor Xa	48,000			3				VKD serine protease
Factor IX	55,000	90	5	1	17	+		VKD protease zymogen
Factor IXa	45,000							VKD serine protease
Factor V	330,000	20	6.6	0.5	13–25	+		Soluble procofactor
B region	150,000				50			
Factor Va	180,000				8			Cofactor
Factor VIII	280,000	0.7	0.2	0.3–0.5		+		Soluble procofactor
Factor VIIIa	170,000							Cofactor
von Willebrand factor	255,000 (monomer)	varies	10		10–15	+		Platelet adhesion, carrier for factor VIII
Prothrombin	72,000	1400	100	2.5	8	+		VKD protease zymogen
a-Thrombin	37,000				5			VKD serine protease
Fibrinogen	340,000	7400	2500	3–5	3	+	±	Structural protein, cell adhesion
Aa	66,500							
Bß	52,000							
?	46,500

A-chain	83,200							
B-chain	79,700				5			

+, presence of phenotype; –, absence of phenotype; ±, some indivduals present with the phenotype and others do not; H, hemorrhagic disease/hemophilia; T, thrombotic disease/thrombophilia; VKD, vitamin K–dependent.

[a] Clinical phenotype: the expression of either H or T phenotype in deficient individuals.

GENE STRUCTURE AND EXPRESSION Human factor XII is produced by a single gene located on chromosome 5 q33-qter ([70], [71]) (Table 21.2). The gene for factor XII spans approximately 12 kilobases (kb) and is comprised of 13 introns and 14 exons ([72]). The intron/exon gene structure is similar to the gene structures of tissue

plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA) ([72]). The promoter does not contain the CAAT or TATA sequences common in other genes, but it does contain two LF-A1 transcription elements characteristic of genes with liver-specific expression. The promoter also contains one estrogen-responsive element ([72] , [73]).

TABLE 21.2. Molecular Genetics of Blood Coagulation Proteins

Protein	Molecular Weight (d)	Gene Location: Chromosome	Gene Size (kb)	Gene Organization: Number of Exons	Messenger RNA Size (kb)
Intrinsic pathway proteins					
Factor XII	80,000	5q33-qter	12	14	2.4
Prekallikrein	85/88,000	4q34-35	30	15	2.4
High-molecular-weight kininogen	120,000	3q26-qter	27	11	3.5
Low-molecular-weight kininogen	66,000	3q26-qter			
Factor XI	160,000	4q35	23	15	2.1

B-chain	79,700	1q31-q32.1	28	12	2.3

BIOCHEMISTRY Human factor XII is synthesized as a precursor protein with a 19-residue signal peptide. The mature factor XII molecule is a 596–amino acid single-chain ß-globulin with a molecular weight of approximately 80 kd ([74] , [75] , [76] , [77] and [78]). It circulates at a concentration of 40 µg/ml (500 nmol/L) with a half-life ($t_{1/2}$) of 2 to 3 days (Table 21.1). The factor XII molecule is composed of two domains: an NH_2-terminal heavy chain and a COOH-terminal light chain. The heavy chain contains several domain structures: fibronectin type I and type II domains, two epidermal growth factor (EGF)–like domains, a kringle domain, and a proline-rich region (residues 277–330) (Fig. 21.2). The light chain contains the serine protease catalytic domain, a region homologous to the B-chain of the enzyme plasmin. The mature factor XII molecule contains approximately 17% carbohydrate. Glycosylation consists of an O-linked fucose at Thr^{90} in the first EGF domain ([79]), N-linked carbohydrates at Asn^{230} and Asn^{414} in the kringle and catalytic domains, respectively, and six O-linked carbohydrates in the proline-rich region ([80]). The factor XII molecule also contains four zinc ion (Zn^{2+})–binding sites ([81]). Zn^{2+} binding to factor XII likely induces a conformation change that promotes activation of factor XII associated with negatively charged surfaces ([82] , [83] and [84]).

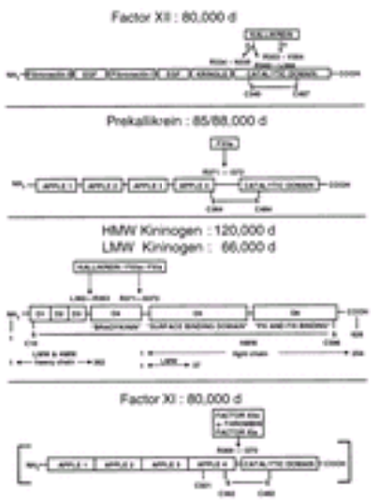

Figure 21.2. Schematic representation of the accessory pathway (intrinsic) proteins. Factor XII (FXII), prekallikrein (PK), high-molecular-weight (HMW) kininogen, low-molecular-weight (LMW) kininogen, and factor XI (FXI) are shown with their various domains depicted as blocks. Activating proteases are placed in a box above the cleavage sites with the specific amino acid residues of the site shown directly underneath. Key interchain disulfide bonds (S-S) are included. For the kininogens, horizontal arrows indicate the amino acid residues defining heavy and light chain regions of the activated forms of the cofactors. Factor XI is illustrated as a monomer. EGF, epidermal growth factor.

ACTIVATION Factor XII undergoes autoactivation on interaction with negatively charged surfaces such as glass, kaolin, dextran sulfate, ellagic acid, celite, or bismuth subgallate ([85] , [86] , [87] , [88] , [89] , [90] , [91] , [92] , [93] , [94] and [95]). This is likely only an artifactual *in vitro* event triggered by the artificial surfaces used in studies of the contact pathway. Although factor XII associates with many physiologically relevant anionic surfaces, including negatively charged phospholipids ([96] , [97] , [98] , [99] , [100] , [101] , [102] , [103] , [104] , [105] and [106]), the autoactivation of factor XII induced by these surfaces *in vitro* does not appear to represent the mechanism for factor XII activation *in vivo* ([107]). Instead, factor XII is most likely activated by a cell membrane–associated proteinase ([108] , [109]). Factor XII, prekallikrein, and HMWK form a complex on anionic phospholipids of the cell membrane, and prekallikrein is cleaved, forming the enzyme kallikrein. Kallikrein then activates factor XII (plasmin activates factor XII as well). Enzymatic activation of factor XII by kallikrein involves a single cleavage at Arg^{353}-Val^{354} to generate an 80-kd two-chain enzyme, a-factor XIIa (factor XIIa, a-HFa, or HFa), composed of an NH_2-terminal heavy chain [relative molecular weight (M_r)= 52,000] and a COOH-terminal light chain (M_r = 28,000) held together by a disulfide bond (Cys^{340}-Cys^{467}) (Fig. 21.2). This cleavage is essential for exposure of the active site in factor XIIa ([110]). Factor XIIa can then bind negatively charged surfaces and activate factor XI and prekallikrein ([111] , [112]). Two secondary cleavages can also occur on factor XII: one outside the disulfide bond (Arg^{334}-Asn^{335}) and one inside the disulfide loop (Arg^{343}-Leu^{344}), generating ß-factor XIIa ($FXII_f$, HF_f) ([113] , [114] , [115] and [116]). ß-Factor XIIa has no surface binding capabilities but is able to activate prekallikrein ([85] , [117] , [118]).

FUNCTION *Factor XIIa* is a serine protease that activates factor XI and prekallikrein by mechanisms dependent on anionic surfaces and the cofactor HMWK ([111] , [119]). Factor XIIa also activates the C1 component of the complement system ([120]). In addition, factor XIIa down-regulates the Fc receptor on monocytes and

macrophages ([121]), induces release of interleukin (IL)-1 and IL-6 from monocytes and macrophages ([122]), and stimulates neutrophils ([123]). Although these roles have no apparent impact on normal coagulation, factor XII/XIIa may be an important link between coagulation and inflammation. Factor XIIa also activates plasminogen to plasmin linking the contact pathway to fibrinolysis ([124]).

REGULATION *C1 inhibitor* is the major inhibitor of both factor XIIa and ß-factor XIIa and irreversibly inhibits both enzymes ([125] , [126] , [127] and [128]). Antithrombin-III and plasminogen activator inhibitor (PAI)-1 also inhibit factor XIIa ([129] , [130] and [131]). Endothelial cells and eosinophils are reported to produce proteins that inhibit factor XII activation but not factor XIIa activity ([132] , [133] and [134]). Amyloid precursor protein likewise is reported to inhibit factor XII activation but not factor XIIa ([135]).

Plasma Prekallikrein (Fletcher Factor)

Plasma prekallikrein, or *Fletcher factor*, is the zymogen form of the enzyme kallikrein. Prekallikrein circulates in plasma at an average concentration of 42 µg/ml (486 nmol/L) ([136] , [137]) (Table 21.1). Approximately 75% circulates in a noncovalent complex with HMWK ([138] , [139]), and the remaining 25% circulates as free prekallikrein. Like factor XII, prekallikrein is a component of the intrinsic or accessory pathway and serves as a link between coagulation and inflammation. Prekallikrein is also linked to fibrinolytic events as well. Plasma prekallikrein deficiency is rare and is not associated with hemostatic defects ([140]).

GENE STRUCTURE AND EXPRESSION The human prekallikrein gene is located on chromosome 4q34-35, close to the factor XI gene ([141]) (Table 21.2). The human plasma prekallikrein gene spans 30 kb and contains 15 exons and 14 introns ([142]). A total of twelve allelic variants have been identified in the 5' proximal promoter and in 7 of the exons. A common polymorphism (30% of the population) leads to replacement of Asn124Ser in the heavy chain of the apple 2 domain of prekallikrein. Two other polymorphisms in the coding region of the protein, His189Pro in the apple 3 domain of the heavy chain and His183Gln, were identified ([142]). Prekallikrein and factor XI are highly homologous, and both human factor XI and rat plasma prekallikrein genes are located on chromosome 4, suggesting a gene duplication event from a common ancestor ([143]). Prekallikrein mRNA has been detected in human kidney, adrenal gland, and placenta, but the liver is considered to be the major site of synthesis ([144] , [145]).

BIOCHEMISTRY Human plasma prekallikrein is synthesized as a precursor with a 19–amino acid signal peptide. It circulates in plasma at an average concentration of 42 µg/ml (486 nmol/L). The mature form of the protein, appearing as a doublet of 85 and 88 kd when analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), is a single-chain fast ?-globulin of 619 amino acids ([124] , [146] , [147]) (Table 21.1). Prekallikrein contains 15% carbohydrate with five N-linked sugar moieties ([144]). Structurally, prekallikrein contains four tandem repeats, called *apple domains*, in the NH_2-terminal portion of the molecule (Fig. 21.2). Each apple domain consists of 90 to 91 amino acid residues including six to eight cysteines that are disulfide bonded to form the distinct domain structure ([144] , [148]). The apple 1 and apple 4 domains mediate the binding of prekallikrein to HMWK ([149] , [150]). The apple domains of prekallikrein are highly homologous to the apple domains of factor XI. Apple domains have only been found in these two proteins, lending support to a gene duplication event from a common ancestor ([141] , [151]). The COOH-terminal region of prekallikrein contains the catalytic site.

ACTIVATION Prekallikrein is activated by factor XIIa in complex with the cofactor HMWK on an anionic surface (Fig. 21.2). Prekallikrein is also activated by ß-factor XII in the absence of a surface ([152]). The factor XIIa complex or ß-factor XII catalyzes the cleavage of the Arg ^{371}-Ile ^{372} bond in prekallikrein. This cleavage is also reported to occur in the absence of factor XIIa when prekallikrein is bound to HMWK on the endothelial cell surface ([108]). The enzyme kallikrein is a two-chain molecule composed of an NH_2-terminal heavy chain (M_r = 53,000) containing the four apple domains and a COOH-terminal light chain (M_r = 36,000 or 33,000) containing the active site ([124] , [144] , [153] , [154]).

FUNCTION Kallikrein is a member of the trypsin family of serine proteases. In the presence of an appropriate anionic surface and the cofactor HMWK, kallikrein activates factor XII to factor XIIa and proteolyzes factor XIIa to ß-factor XII. Kallikrein also undergoes autoproteolysis at Lys ^{140}–Ala ^{141} to yield ß-kallikrein ([155] , [156]). Enzyme activity is significantly reduced on conversion of kallikrein to ß-kallikrein ([154]). Kallikrein cleaves HMWK at two sites to generate the vasoactive nonapeptide bradykinin ([157] , [158]). Bradykinin is a potent vasodilator and stimulates endothelial cell prostacyclin synthesis, resulting in hypotension ([159] , [160]). Kallikrein is also an activator of fibrinolytic zymogens and converts both plasminogen to plasmin and pro–u-PA to u-PA ([124] , [161] , [162]). In addition, kallikrein has been reported to activate neutrophils and stimulate elastase release as part of the hemostatic and inflammatory responses ([163]).

REGULATION C1 inhibitor and a $_2$-macroglobulin are the major inhibitors of kallikrein ([164] , [165]). C1 inhibitor forms a 1:1 stoichiometric complex with kallikrein and abolishes its proteolytic and amidolytic activities ([165] , [166] , [167] and [168]). a $_2$-Macroglobulin inhibits the ability of kallikrein to generate bradykinin and partially inhibits amidolytic activity ([166]). C1 inhibitor and a $_2$-macroglobulin each inhibit equivalent amounts of kallikrein in plasma, but C1 inhibitor acts much more rapidly and plays the major role in reducing kallikrein activity ([169]). Antithrombin-III and antithrombin-III–heparin are slow inhibitors of kallikrein although the antithrombin-III–heparin–HMWK complex is an effective inhibitor ([170] , [171] and [172]). Protein C inhibitor also inhibits kallikrein ([173] , [174] and [175]).

High-Molecular-Weight Kininogen (Fitzgerald Factor, Williams Factor)

HMWK, also known as *Fitzgerald factor* or *Williams factor*, circulates in plasma at an average concentration of 80 µg/ml (670 nmol/L) ([176] , [177]) (Table 21.1). HMWK acts as a cofactor for the activation of factor XII and prekallikrein and is the precursor of the vasoactive peptide bradykinin. A second form of kininogen, low-molecular-weight kininogen (LMWK), is also found in plasma. LMWK can be cleaved to yield bradykinin but has no procoagulant activity. LMWK circulates at an average concentration of 90 µg/ml (1300 nmol/L) ([178]). Deficiencies of HMW and LMW kininogens are rare and are not associated with bleeding diatheses ([179]). The major established function of the kininogens is to serve as a source of bradykinin and thereby contribute to a number of vascular events regulated by bradykinin.

GENE STRUCTURE AND EXPRESSION The two forms of kininogen, HMW and LMW, are the products of a single gene ([180] , [181]) located on chromosome 3q26-qter ([182]) (Table 21.2). The kininogen gene consists of 10 introns and 11 exons and spans 27 kb ([181]). The gene produces mRNAs for the two different forms of kininogen by alternative splicing ([181]). HMWK and LMWK share the coding region of the first nine exons and the portion of exon 10 containing the bradykinin sequence and the first 12 amino acids following the COOH-terminal of bradykinin. Exon 10 also codes for a 56-kd light chain unique to HMWK, whereas exon 11 codes for a 4-kd light chain unique to LMWK. Human liver contains mRNAs for both HMW and LMW kininogen ([180] , [181]); only HMWK is expressed and secreted by human umbilical vein endothelial cells ([183]). Estrogen administration ([184]) and pregnancy ([185]) increase HMWK levels. Conversely, progesterone treatment reduces kininogen gene expression and plasma kininogen levels ([186]).

BIOCHEMISTRY Human HMW and LMW kininogens are synthesized as precursor proteins containing 18 amino acid signal peptides. The mature form of HMWK is a 120-kd single-chain a-globulin of 626 residues, whereas the LMW form is a 66-kd single-chain ß-globulin composed of 409 residues ([177] , [178] , [187]). Glycosylation at a number of shared sites (Asn ^{151}, Asn ^{187}, Asn ^{276}, and Asn ^{383}) and sites unique to HMWK (Thr ^{515}, Thr ^{521}, Thr ^{528}, Thr ^{539}, Thr ^{553}, Thr ^{559}, Thr ^{575}, and Thr ^{610}) presumably accounts for the substantial increase over the masses predicted from the amino acid compositions (70,000 for HMWK and 46,000 for LMWK). The NH_2-terminal heavy chains (residues 1 to 362) of the two forms are identical and consist of three consecutive regions designated domains 1, 2, and 3 (D1, D2, and D3) (Fig. 21.2). Domain 1 has a low-affinity Ca^{2+}-binding site ([188]). Domains 2 and 3 share homology with cysteine protease inhibitors ([189]). Both HMWK and LMWK are potent inhibitors of cysteine proteases such as calpain ([176] , [190]). Domain 3 also contains a cell-binding region ([191] , [192] , [193] , [194] and [195]) and is reported to inhibit a-thrombin activity ([192] , [194] , [196]) and platelet activation ([194] , [196]). The central domain of both kininogens, domain 4 (D4), is the bradykinin region. Domain 4 also contains a cell-binding region ([197]) and a region that inhibits a-thrombin activity ([198]). The two forms of kininogen have different COOH-terminal light-chain regions. The light chain of LMWK (residues 372 to 409) consists of a single domain, domain 5 $_L$ ($D5_L$), with no known function. The light chain of HMWK (residues 372 to 626) is composed of two regions, domain 5 $_H$ ($D5_H$) and domain 6 $_H$ ($D6_H$). Domain 5 $_H$ contains additional cell-binding regions ([191] , [193] , [195] , [199] , [200]) and mediates HMWK binding to anionic surfaces, heparin and Zn^{2+} ([170] , [171] , [201]). Domain 6 $_H$ has binding sites for prekallikrein and factor XI ([202] , [203] and [204]).

ACTIVATION The major role proposed for the kininogens is the release of bradykinin. Kallikrein, factor XIIa, and factor XIa cleave HMWK to release bradykinin (residues 363 to 371) (Fig. 21.2). Kallikrein also cleaves LMWK to release bradykinin. Bradykinin release from HMWK yields a two-chain protein composed of the heavy chain (D1, D2, and D3) disulfide linked (Cys ^{10}–Cys ^{596}) to the light chain ($D5_H$ and $D6_H$). This molecule retains procoagulant activity and binds prekallikrein, factor XI, and anionic surfaces via light-chain interactions ([202] , [205] , [206]).

FUNCTION HMWK functions as a nonenzymatic cofactor in the contact pathway of coagulation and serves as a precursor of bradykinin. HMWK binds anionic surfaces, prekallikrein, and factor XI, thus enhancing their activation by surface-associated factor XIIa. Although most studies of contact activation make use of artificial surfaces, cell membranes may provide appropriate sites for contact activation *in vivo*. Many cells contain kininogens and express kininogen binding sites ([177] , [183] , [207] , [208] , [209] , [210] , [211] , [212] and [213]). There is some evidence to support cell membrane–associated contact activation. Prekallikrein bound to HMWK on platelets or endothelial cells can result in the generation of kallikrein by a factor XIIa–dependent ([108] , [162]) or –independent mechanism ([108]). However, factor XI bound to HMWK on the surface of platelets is not activated to factor XIa ([214]). The biologic significance of the contact pathway of coagulation is not established. In hemostasis, factor

XIa generation most likely occurs by an a-thrombin–dependent pathway, and any factor XIa generated by the contact pathway would not have a measurable impact on coagulation. Bradykinin release as a consequence of these activation events does provide a key vasoactive agent with a variety of roles and directly links the contact pathway to vascular repair processes.

Factor XI (Plasma Thromboplastin Antecedent)

Factor XI, also known as *plasma thromboplastin antecedent*, circulates as a homodimer at an average concentration of 5 µg/ml (30 nmol/L) ([215]) in complex with HMWK ([216]) (Table 21.1). Factor XI is also found in human platelets, and the platelet form accounts for approximately 0.5% of the factor XI antigen in blood ([217], [218], [219], [220] and [221]). Factor XI is the zymogen precursor of the enzyme factor XIa. Unlike the other members of the accessory or contact pathway, factor XIa has an important role in coagulation as part of a positive feedback loop enhancing a-thrombin generation ([4], [13]). Although rare in the general population (~1 in 100,000 individuals), factor XI deficiency is common in the Ashkenazi (European) Jewish population, with approximately 1 in 200 individuals affected by factor XI deficiency ([36], [222], [223], [224] and [225]). Factor XI deficiency can be associated with severe bleeding tendencies ([226]) after injury or surgical trauma. Spontaneous hemorrhage is not common. Factor XI deficiency is unusual in that bleeding abnormalities vary considerably and range from a complete absence of symptoms to life-threatening hemorrhage. The severity of the bleeding complications is also not related to the severity of factor XI deficiency. Individuals with mild deficiency may experience severe hemorrhagic events, whereas individuals with severe deficiency may have no abnormal bleeding ([36], [37], [223], [225], [232], [233], [234] and [235]).

GENE STRUCTURE AND EXPRESSION The gene for human factor XI is located on chromosome 4q35 and spans 23 kb (Table 21.2). The gene contains 14 introns and 15 exons ([146], [236]). Although mRNA for human plasma factor XI has been found in liver, pancreas, and kidney ([237]), the primary site of synthesis is thought to be the liver. Plasma factor XI levels decrease in liver disease, and a patient with no history of factor XI deficiency developed a deficiency subsequent to a liver transplant from a factor XI–deficient donor ([238]). Platelet factor XI is exclusively synthesized in the megakaryocyte ([239]). Human platelet factor XI lacks exon 5 and may be an alternative splicing product of the plasma factor XI gene or a product of a gene specific to megakaryocytes ([239]). There are three major types of genetic mutations associated with factor XI deficiency: (a) intronic point mutations that interrupt exon splicing ([223], [240]); (b) exonic point mutations that lead to mutations in specific amino acids and result in premature polypeptide termination, disruption of dimerization, or reduced protein secretion ([223], [240], [241], [242], [243] and [244]); and (c) nucleotide deletions that lead to decreased protein synthesis ([245], [246]). Two specific exonic point mutations account for the majority of the cases of factor XI deficiency in the Ashkenazi Jewish population. An E117X mutation in exon 5 (type II mutation) introduces a stop codon and results in premature polypeptide termination. The type II mutation accounts for approximately 52% of the cases of factor XI deficiency in the Ashkenazi Jewish population. A F283L mutation in exon 9 (type III mutation) that accounts for 36% of the cases is believed to prevent intracellular dimer formation and protein secretion. These mutations are less frequent in the general population ([222], [223], [240], [244]).

BIOCHEMISTRY Human factor XI is found in plasma and in platelets. The two forms of the protein are somewhat different and may have different functions as well. Plasma factor XI accounts for most of the factor XI antigen in the human system and is a disulfide-linked homodimer (M_r = 160,000), with approximately 5% of its mass made up by carbohydrate (Table 21.1). Each of the two identical polypeptide chains is synthesized with an 18–amino acid signal peptide. The mature polypeptide chain (M_r = 80,000) consists of 607 amino acid residues ([217], [218] and [219]) and has five potential glycosylation sites, although only Asn ^{72}, Asn ^{108}, Asn ^{432}, and Asn ^{473} are glycosylated ([247]). Exons 3 to 10 of the plasma factor XI gene encode four NH_2-terminal tandem sequences termed *apple domains* (apple 1 to apple 4, Fig. 21.2). The apple domains are homologous to the apple domains in human plasma prekallikrein ([247]). Exons 11 to 15 encode the COOH-terminal catalytic domain. Human platelet factor XI lacks exon 5 and amino acids Ala ^{91}–Arg ^{144} in the NH_2-terminus of the apple 2 domain. The mature platelet polypeptide chain (M_r = 55,000) may form a disulfide-linked tetramer of identical subunits (M_r = 220,000) or may be disulfide linked to a platelet plasma membrane protein ([218], [232], [239]). Plasma factor XI circulates in complex with HMWK ([216]). Formation of this complex, mediated by the apple 1 domain of factor XI, is required for factor XI to associate with anionic surfaces ([249]). The apple 1 domain also contains binding sites for a-thrombin ([250]) and prothrombin ([235]). The apple 2, apple 3, or both, domains mediate the binding of factor IX, the substrate of factor XIa ([235], [251], [252], [253] and [254]). In addition to potentially mediating the factor XIa–factor IX interaction, the apple 3 domain contains binding sites for platelets and heparin ([255], [256] and [257]). The apple 4 domain contains the site (Cys ^{321}) involved in the dimerization process. Dimerization is required for efficient intracellular processing and protein secretion ([241]). Factor XIIa associates with a region of the apple 4 domain as well ([258]). The COOH-terminal portion of factor XI contains the catalytic domain.

ACTIVATION Plasma factor XI is cleaved at an internal Arg ^{369}–Ile ^{370} bond to yield a disulfide-linked two-chain activated serine protease (Fig. 21.2). The factor XI homodimer yields two disulfide-linked heavy chains containing the apple domains and two light chains containing the active sites ([259], [260]). Activation of factor XI can be accomplished by factor XIIa and a-thrombin and by autoactivation by factor XIa itself. Activation of factor XI by factor XIIa requires HMWK and an anionic surface. However, deficiencies of factor XII and HMWK do not result in bleeding diatheses, whereas factor XI deficiency is associated with hemorrhage. This suggests that factor XIIa–dependent activation of factor XI as part of the contact pathway is not likely to be the primary route of factor XIa generation in hemostasis. The physiologically relevant pathway for factor XI activation in coagulation is believed to involve a-thrombin ([4], [13], [261]). Factor XI in complex with HMWK binds to the platelet surface via the apple 3 domain ([255]). The rate of a-thrombin activation of factor XI on the platelet surface is greater than the rates of platelet-supported factor XIIa activation and factor XIa autoactivation ([262]). Although platelets appear to play a key role in providing the surface for factor XI activation, the precise mechanism of activation of platelet factor XI and its function remain unclear ([263]).

FUNCTION Subsequent to activation, factor XIa remains bound to the surface. *Factor XIa* is a trypsinlike serine protease that cleaves and activates factor IX in a Ca^{2+}-dependent fashion ([264], [265], [266] and [267]). Factor IXa is the enzyme component of the intrinsic tenase complex that provides the burst of factor Xa for normal coagulation. As part of a positive feedback loop, a-thrombin activates factor XI. In turn, factor XIa generates factor IXa, leading to the high levels of factor Xa that ensure efficient a-thrombin generation ([4]).

REGULATION Factor XIa is regulated by four serine protease inhibitors or serpins: antithrombin-III, a_1-protease inhibitor, C1 inhibitor, and a_2-antiplasmin ([125], [260], [268], [269], [270], [271], [272], [273], [274], [275], [276], [277] and [278]). Factor XIa is also reported to be inhibited by PAI-1 and protein C inhibitor ([131], [280]). In addition, platelets secrete several factor XIa inhibitors ([281], [282], [283], [284] and [285]), including protease nexin-2 (PN2). PN2 is a truncated form of the Alzheimer's ß-amyloid protein precursor and contains a Kunitz-type serine protease inhibitor domain. Platelet-bound factor XIa is protected from inactivation by PN2 ([264]); however, heparin enhances PN2 inactivation of factor XIa. Factor XIa bound to the surface of endothelial cells that secrete heparan sulfate glycosaminoglycans (GAGs) may be readily inactivated by PN2 ([286]).

PROCOAGULANT PROTEINS: VITAMIN K–DEPENDENT PROTEIN FAMILY

The first identification/description of vitamin K–dependent proteins was introduced by Henrik Dam and colleagues at the University of Copenhagen in the late 1920s ([287], [288], [289] and [290]). They demonstrated that chickens fed a lipid-free diet exhibited a hemorrhagic condition. The addition of alfalfa meal or a lipid extract of alfalfa prevented this condition. The active compound, 2-methyl-3-phytyl-1,4-naphthoquinone (phylloquinone), was subsequently isolated from green plants. Further work performed by Doisy and colleagues (Saint Louis, Missouri) ([291]) in the 1930s showed that vitamin K activity in bacteria is also present as a series of menaquinones, 2-methyl-1,4-naphthoquinones substituted at the 3 position with an unsaturated polyisoprenoid chain. The Nobel prize was awarded to Dam and Doisy in 1941 for their discovery of the fat-soluble vitamin K.

Simultaneously, with the discovery of the vitamin, a naturally occurring antagonist, bishydroxycoumarin (dicumarol), was described. This naturally occurring vitamin K antagonist was identified as a toxic agent in spoiled sweet clover causing hemorrhage in cattle. The increase in clotting time was later identified as a function of decreased PT ([292]). This led to the synthesis of several oral anticoagulant analogs and coumarin derivatives, including warfarin.

Vitamin K is essential in the biosynthesis of clotting factors. Its role is essential for the activity of these proteins through a mechanism involving the conversion of 9 to 13 NH_2-terminal glutamic acid residues to ?-carboxy glutamic acid residues (Gla). The enzyme required for this conversion uses a reduced form of vitamin K.

This specific posttranslational modification allows the vitamin K–dependent proteins to interact with Ca^{2+} and a membrane surface to exert their effect. The modification was initially identified and characterized in bovine prothrombin ([293], [294], [295] and [296]). Gla residues were missing or present in decreased amounts in prothrombin isolated from cattle treated with coumarin derivatives. The vitamin K–dependent proteins present in plasma after treatment with anticoagulants lacked biologic activity due to decreased Ca^{2+}-dependent phospholipid binding. Therefore, preventing the formation of Gla residues became a basis for anticoagulant therapy.

Recently, two cDNAs were identified that encode proteins with NH $_2$-terminal Gla domains ([297]). Both appear to be integral membrane proteins but bear no other similarity to the other vitamin K–dependent proteins beyond the Gla domain. Mineralized tissues contain two proteins with Gla residues ([298]). Gla has also been found as a component of the toxin peptides from the marine snail *Conus* ([299] , [300] and [301]). The biologic activity of the toxins has been found to depend on the Gla residue(s). The identification of Gla in invertebrates suggests that vitamin K has a much wider range of biologic functions than previously thought.

The vitamin K–dependent proteins can be divided into two classes: procoagulant (factors II, VII, IX, and X; Fig. 21.3A) and anticoagulant (protein C, protein S, and protein Z; Fig. 21.3B). The vitamin K–dependent proteins are part of a family of serine proteinases (except for protein S and protein Z) related to the trypsin/chymotrypsin superfamily. Sequence homology exists between the proteins at both the gene and the protein level, possibly due to a common ancestral gene ([302] , [303]). Congenital deficiencies of factors II, VII, IX, and X are associated with bleeding tendencies, whereas protein C and protein S deficiencies are associated with thrombotic tendencies. These proteins are composed of separate domains, each of which is characterized by highly conserved regions that fold, independently from the rest of the molecule, into a characteristic three-dimensional shape. The domains of the vitamin K–dependent proteins are illustrated in Figure 21.3. NH $_2$-terminal Gla domains ([9] , [10] , [11] , [12] and [13]) are followed by either a kringle domain in factor II or an EGF-like domain (EGF) in factor VII, factor IX, factor X, protein C, protein S, and protein Z. Protein S contains a thrombin-sensitive region before the EGF domain. The active site is contained within the serine protease domain for factor II, factor VII, factor IX, factor X, and protein C and becomes functional on specific peptide bond cleavages. Protein S is not a serine protease precursor and instead contains a sex hormone–binding globulin–like domain in the COOH-terminus. Protein Z contains a “pseudo catalytic domain” in the COOH-terminus and does not function as a serine protease enzyme.

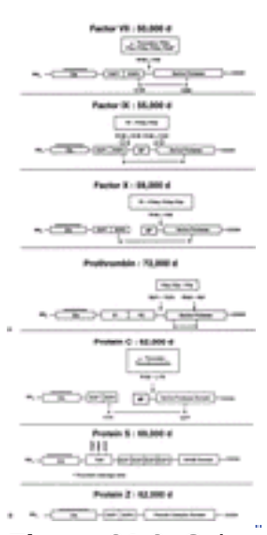

Figure 21.3. Schematic representation of the vitamin K–dependent proteins. The building blocks for these proteins include an NH $_2$-terminal Gla domain with 9 to 13 Gla residues (Y) followed by either an epidermal growth factor (EGF)–like domain in factor VII (FVII), factor IX (FIX), factor X (FX), protein C, protein S, and protein Z or a kringle (K) domain in prothrombin. Protein S contains a thrombin-sensitive region (TSR) before the EGF domain. Active sites are contained within the serine protease domain. Cleavage sites for the conversion of zymogens to their active forms are designated by arrows; activating proteases are placed in boxes above the arrows. Factor IX, factor X, and protein C are activated by proteolytic removal of an activation peptide (AP). Protein S is not a serine protease precursor and instead contains a sex hormone–binding globulin–like domain (SHGB) in the COOH-terminus. Protein Z also contains a “pseudo catalytic domain” in the COOH-terminus and does not function as a serine protease. For reference, the molecular weight for each zymogen is listed, and disulfide bonds (-S-S-) critical to the integrity of the two-chain zymogens or active forms are presented. **A:** Panel illustrates the procoagulant vitamin K–dependent proteins factor VII, factor IX, factor X, and prothrombin. **B:** Panel illustrates the anticoagulant proteins, protein C, protein S, and protein Z. FSAP, factor VII–activating protease; TF, tissue factor.

The synthesis of these proteins occurs primarily in the liver followed by secretion into circulation. However, recently, a functional prothrombin gene product has been found to be synthesized by human kidney cells ([304]). The concentration of circulating zymogens in plasma varies 200-fold from 100 µg/ml for prothrombin to 0.5 µg/ml for factor VII (Table 21.1). Levels present in plasma can be affected by polymorphisms in the promoter or coding region ([305] , [306] and [307]) as well as considered a risk factor for ischemic heart disease ([308]). Cholesterol and triglyceride levels have also been correlated with plasma concentrations of the vitamin K–dependent proteins ([309] , [310] and [311]). Liver function in the synthesis of the clotting factors, dietary intake/adsorption of vitamin K, and drug interactions can affect individuals on anticoagulant therapy ([312] , [313]).

Clearance ($t_{1/2}$) of the vitamin K–dependent proteins varies from approximately 6.0 hours for factor VII to 2.5 days for prothrombin (Table 21.1). Once the zymogen is activated to its serine protease form, it is then inactivated by inhibitors and cleared from the blood.

These activated forms of the vitamin K–dependent proteins are key components in the formation of the vitamin K–dependent coagulation complexes: the *extrinsic tenase* (factor VIIa–tissue factor); the *intrinsic tenase* (factor IXa–factor VIIIa); *prothrombinase* (factor Xa–factor Va); and *protein Case* (thrombin–thrombomodulin) (Fig. 21.4). When all the components for each complex are assembled on the appropriate membrane surfaces (e.g., activated platelets, monocytes, blood cells, or endothelium), the specific reactions occur with rates enhanced by 10^4- to 10^9-fold over enzyme-substrate alone ([21]) (Table 21.3). A simple calculation can illustrate the importance of the rate enhancements achieved through complex assembly (vitamin K–dependent serine protease–cofactor–membrane–Ca^{2+}): If a normal person takes 4 minutes for his or her blood to clot, then in the absence of membrane and cofactor, blood clot formation would take approximately 3.8 years.

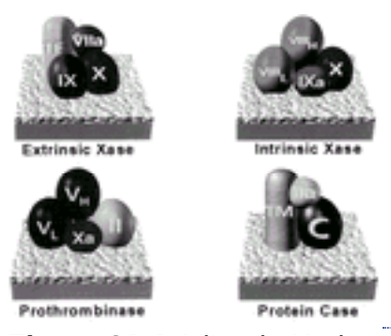

Figure 21.4. Vitamin K–dependent complexes. Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each membrane complex consists of a vitamin K–dependent serine protease [factor VIIa (VIIa), factor IXa (IXa), factor Xa (Xa), or thrombin (IIa)] and a soluble or cell-surface–associated cofactor [factor VIIIa (heavy and light chain $VIII_H$ and $VIII_L$), factor Va (heavy and light chain V_H and V_L), tissue factor (TF), or thrombomodulin (TM)]. Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate(s) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants, enhancing the reaction rates by 10^4- to 10^9-fold. When vascular damage or inflammatory cytokine activation occurs, TF becomes exposed to flowing blood carrying low levels of factor VIIa. The formed extrinsic tenase complex activates the circulating serine protease zymogens factors IX and X. Factor IXa becomes the serine protease for the intrinsic tenase complex, which with its cofactor factor VIIIa, activates factor X to its active protease form factor Xa. Factor Xa formed primarily from the intrinsic tenase combines with its cofactor factor Va to activate II to IIa on the prothrombinase complex. Cofactor regulation occurs when IIa released from the prothrombinase complex binds to endothelial cell surface protein TM to form the protein Case anticoagulant complex. This complex generates activated protein C, which then proteolytically inactivates factors Va and VIIIa. See Color Plate. (From Mann KG. Coagulation explosion. Vermont Business Graphics, 1997, with permission.)

TABLE 21.3. Rate Enhancement by Vitamin K–Dependent Complexes

Complex [a]	Substrates	Fold Enhancement [b]
FVIIa/TF/PCPS/Ca^{2+}	FIX	$>1 \times 10^{9}$ [c]
FVIIa/TF/PCPS/Ca^{2+}	FX	3×10^{4}
FIXa/FVIIIa/PCPS/Ca^{2+}	FX	1×10^{9}
FXa/FVa/PCPS/Ca^{2+}	FII	3×10^{5}
FIIa/TM/PCPS/Ca^{2+}	PC	1×10^{5}

F, factor; PC, phosphatidylcholine; PS, phosphatidylserine; TF, tissue factor; TM, thrombomodulin.

[a] Complexes are assembled on membranes composed of PC and PS (3:1 molar ratio PC/PS).

[b] Rate enhancement is derived from the ratio of catalytic efficiency [number of catalytic events per unit time/Michaelis constant (k_{cat}/K_m)] for the complex to the catalytic efficiency of the free serine protease for a given substrate.

[c] No measurable activation of FIXa by FVIIa without TF and the membrane. The catalytic efficiency of the extrinsic tenase toward FIX is reduced relative to FX.

Gene Structure and Expression

The family of vitamin K–dependent proteins is mainly synthesized in the liver by hepatocytes. Decreased levels of the vitamin K–dependent proteins are apparent indicators of liver dysfunction ([314], [315]). Liver transplantation has been shown either to treat vitamin K deficiency ([316]) or to bring about vitamin K deficiency ([317]). The genes encoding all of the vitamin K–dependent coagulation proteins have been sequenced and are seen in Table 21.2. The difference between the vitamin K–dependent protein genes and most other eukaryotic genes is that the 5'-flanking regions lack TATA boxes. Binding sites for liver-enriched or liver-specific (or both) transcription factors, which are important for hepatic expression of these proteins, are contained within the regulatory region of these genes. A common pentanucleotide motif that occurs in a similar location in the regulatory region of the genes encoding factor VII, factor IX, and factor X may be important in their possible coordinate expression.

Posttranslational Processing

The vitamin K–dependent proteins are synthesized in the liver as pre-prozymogens in a process that requires a dietary intake of vitamin K. They are modified posttranslationally at glutamic acid (?-carboxylation to form ?-carboxy glutamic acid) ([294]) and at aspartic acid and asparagine [ß-hydroxylation to form erythro-ß-hydroxy aspartic acid (Hya) and erythro-ß-hydroxy asparagine (Hyn)] ([75], [318], [319]); they are also modified by sulfation at tyrosine residues as well as the addition of sugar moieties (glycosylation) ([318], [319]). This high degree of posttranslational processing is necessary for the biologic activity of the mature vitamin K–dependent proteins.

PROTEOLYTIC MATURATION The vitamin K–dependent proteins are synthesized in the liver as a single-chain precursor that contains a pre-pro sequence followed by the polypeptide region. The hydrophobic signal peptide (pre-peptide) gets the protein to the endoplasmic reticulum, the first compartment in the secretory pathway. For the vitamin K–dependent proteins to become mature, the polypeptide is translocated out of the first compartment in the endoplasmic reticulum across the lipid bilayer into the lumen of the endoplasmic reticulum. The signal peptide is then removed by a signal peptidase. The propeptide, which plays a role in docking vitamin K–dependent carboxylase ([320]), is removed by an endoproteinase. The release of the propeptide coincides with ?-carboxylation (Gla formation) ([321]) (Fig. 21.5A). Removal of an internal di- or tripeptide in single-chain factor X and protein C occurs, which converts them to their mature two-chain zymogen form. Several studies describe the endoproteinase that cleaves the propeptide and the internal bonds as furin/paired basic amino acid cleaving enzyme ([322], [323] and [324]).

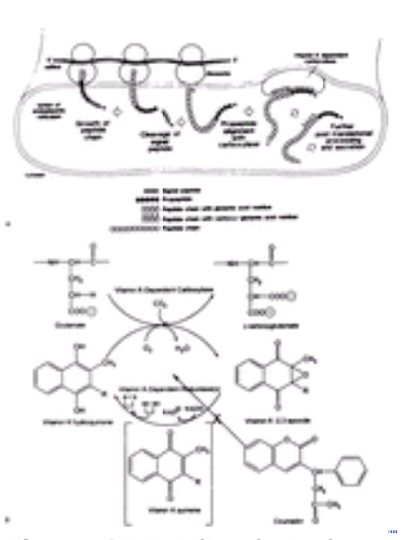

Figure 21.5. Vitamin-K dependent processes. **A:** Schematic representation of the synthesis and posttranslational carboxylation pathway of vitamin K–dependent proteins in the endoplasmic reticulum. (Ffrom Bovill EG, Malhotra OP, Mann KG. Mechanisms of vitamin K antagonism. Baillieres Clin Haematol,1990;3:555–581, with permission.) **B:** The mechanism of ?-carboxy glutamate (Gla) generation by a vitamin K–dependent reaction cycle is illustrated. The regeneration of vitamin K hydroquinone by the vitamin K–dependent reductases is inhibited by anticoagulants, as illustrated by Coumadin.

CARBOXYLATION AND VITAMIN K–DEPENDENT CARBOXYLASE The ?-carboxylation reaction is catalyzed by the enzyme ?-glutamyl carboxylase. This enzyme is located in the rough endoplasmic reticulum and requires the reduced form of vitamin K, oxygen and carbon dioxide ([295]). The carboxylation mechanism involves proton abstraction of the ?-hydrogen of the glutamate residues near the NH_2-terminus of the nascent pre-pro protein (Fig. 21.5B). The generated carbanion at each glutamic acid residue then reacts with free CO_2, forming ?-carboxy glutamic acid. It is this Gla region that mediates the Ca^{2+}-dependent binding of the protein to anionic phospholipid surfaces, thereby assuring close proximity and interaction with other components of the coagulation sequence and with cell receptors for vitamin K–dependent ligands. Without vitamin K, the coagulation protein precursors continue to be synthesized but are not ?-carboxylated. In this form, they are still secreted into plasma but are nonfunctional. The cDNA for the human ?-carboxylase gene was cloned and sequenced by Wu et al. ([325]). The open reading frame predicts a molecular weight of approximately 87.5 kd. Glycosylation of the carboxylase probably accounts for its decreased mobility on SDS-PAGE (94 kd). Vitamin K–dependent carboxylase has been identified in many cell types ([326]). This supports the notion that vitamin K has a wide range of biologic functions. The presence of vitamin K is essential to maintain the ?-carbox-ylation reaction. Vitamin K_1 (phylloquinone) is primarily found in leafy green vegetables and vegetable oils. Additional K activity may be provided by vitamin K_2 (menaquinones) synthesized by intestinal gram-negative bacteria. Synthetic vitamin K_3 (menadione) has no intrinsic activity until it undergoes *in vivo* transformation to the active menaquinone form. These K vitamins are 2-methyl-1,4-naphthoquinones with repeating five-carbon prenyl units at position 3. *In vivo*, vitamin K is recycled in a microsomal oxidation-reduction system for continued use in the ?-carboxylation reaction. To perform the ?-carboxylation reaction, vitamin K has to be present in its reduced hydroquinone form. As the precursor proteins are carboxylated, vitamin K is oxidized to the epoxide. The epoxide in the presence of 2,3-epoxide reductase, using thiols as the reducing agent, yields the quinone form of vitamin K ([327]). A subsequent nicotinamide adenine dinucleotide phosphate– or nicotinamide adenine dinucleotide–dependent quinone reductase reaction resynthesizes the hydroquinone form. The cycle can thus begin again. One important target for anticoagulant therapy is the process required for the regeneration of reduced hydroquinone vitamin K. Anticoagulants that effectively block this reaction include warfarin (Coumadin), dicumarol, and phenprocoumon (Fig. 21.5B). These oral anticoagulants are structurally similar to the quinone form of vitamin K, thereby targeting the reductase enzyme and inhibiting the reduction to the requisite hydroquinone form. The affinity of the anticoagulants for the reductase enzymes determines the efficacy of the drug ([9], [328]). In the United States, the most widely used oral anticoagulant warfarin (Coumadin) is also used as rat poison. It acts as a competitive inhibitor of oxidized vitamin K and interferes with its reduction. Without the regeneration of the reduced form of vitamin K, the vitamin K–dependent protein carboxylase is unable to convert glutamate to ?-carboxy glutamate. Thus, these drugs indirectly affect carboxylation and can be overcome with excess vitamin K. The level of competitive inhibition achieved in Coumadin therapy among individuals taking the same dose regimen is variable. Factors affecting the efficacy of treatment include liver function in the synthesis of the clotting factors, enhancement of effect from other medications, and dietary intake/adsorption of vitamin K ([329]). Therefore, proper monitoring of oral anticoagulant therapy is essential with frequently measured PT and corrected assay sensitivity using the international normalized ratio ([330], [331]).

HYDROXYLATION *Hydroxylation* in the context of vitamin K–dependent proteins refers to the addition of a hydroxyl group (-OH) to aspartic acid and asparagine residues present in the EGF-like domains. The EGF-1 domains of human factors IX, X, protein C, and protein S contain a homologous aspartic acid residue that is hydroxylated to form erythro-ß-hydroxy aspartic acid (Hya) ([75], [332], [333]). Protein S also contains asparagine residues in EGF-2 and EGF-4 domains that are hydroxylated to form erythro-ß-hydroxy asparagine residues (Hyn) ([334]). This posttranslational modification to Hya and Hyn occurs by a ß-hydroxylase enzyme, a 2-oxoglutarate–dependent dioxygenase ([318], [319]). The mechanism of action involves the recognition of a consensus sequence Cys-X-Asp/Asn-X-X-X-X-Tyr/Phe-X-Cys-X-Cys ([334]). The reason for this modification to Hya and Hyn is unclear. No effect has been found on the overall fold of the EGF-1 domain, its affinity, or specificity for calcium ([335]). These modifications also appear to have no relevance on the biologic activity or macromolecular interactions of the vitamin K–dependent proteins ([336], [337]).

GLYCOSYLATION The addition of a carbohydrate moiety as a posttranslational modification to proteins is referred to as *glycosylation*. The vitamin K–dependent proteins contain significant amounts of carbohydrate (Table 21.1 and Table 21.4). Carbohydrate adducts on Asn, Ser, and Thr residues are found in key domains of these proteins, including the activation peptide of factor IX and factor X; the EGF domains in factor VII, factor IX, and protein Z; and the kringle domain in prothrombin. In most cases, the purpose of these modifications remains unknown. However, differences in the properties of the carbohydrate variants of protein C have been noted ([338], [339]).

TABLE 21.4. Human Anticoagulant Proteins and Their Inhibitors: Biochemical Properties

Protein	Molecular Weight (d)	Plasma Concentration		Plasma Half-Life (days)	Carbo-hydrate (%)	Clinical Phenotype [a]		Protein Family	Functional Classification
		(nmol/L)	(µg/ml)			H	T		
Protein C	62,000	65	4	0.33	23		+	VKD	Proteinase zymogen
Protein S	69,000	300	20	1.75	8		+	VKD	Inhibitor/cofactor
Protein Z	62,000	47	2.9	2.5		±		VKD	Cofactor
Thrombomodulin	100,000								Cofactor/modulator
a $_2$-Macroglobulin	735,000	2700–4000	2000–3000	0.002				Complement	Proteinase inhibitor
Tissue factor pathway inhibitor	40,000	1–4	0.1	6.4×10^{-4}–1.4×10^{-3}				Kunitz	Proteinase inhibitor
Antithrombin-III	58,000	2400	140	2.5–3.0	15			Serpin	Proteinase inhibitor
Heparin cofactor II	66,000	500–1400	33–90	2.5	10			Serpin	Proteinase inhibitor
a $_1$-Proteinase inhibitor	53,000	28,000	1500–3500	6	12			Serpin	Proteinase inhibitor
C1 esterase inhibitor	104,000	962	100	0.07	35			Serpin	Proteinase inhibitor
Protein C inhibitor	57,000	90	5	1				Serpin	Proteinase inhibitor

+, presence of phenotype; ±, some individuals present with phenotype and others do not; H, hemorrhagic disease/hemophilia; T, thrombotic disease/thrombophilia; VKD, vitamin K–dependent.

[a] Clinical phenotype: the expression of either H or T phenotype in deficient individuals.

General Structure/Function Features

The vitamin K–dependent proteins, both procoagulant and anticoagulant, share a common protein domain structure. Each has a tripartite design: an NH $_2$-terminal ?-carboxy glutamic acid (Gla) domain, a linker region [kringle domains, EGF-like domains (EGF), or a thrombin-sensitive finger region, or all three], and a COOH-terminal domain usually consisting of a serine protease domain (factors II, VII, IX, and X and protein C) (Fig. 21.3). The Gla domain is involved in the Ca^{2+} ion-dependent binding of vitamin K–dependent proteins to anionic phospholipid membranes. The number of domains in the linker region is variable, and, in general, they are involved in protein–protein interactions. The COOH-terminal catalytic domain seen in factors II, VII, IX, and X and protein C is homologous to the pancreatic serine proteases, trypsin, and chymotrypsin. The nonserine protease domain seen in protein S [a cofactor of activated protein C (APC)] is homologous to sex-hormone–binding globulin ([340]). Protein Z is an enzymatically inactive homolog of factors VII, IX, and X and protein C ([341]). A separate review of the Gla, EGF, and serine protease domains is presented below.

The importance of each of the domains has been uncovered through studies from natural variants that occur in patients with either familial bleeding (i.e., factor IX deficiency/hemophilia B) or thrombotic disease (i.e., protein C deficiency). The situations that can cause a disease state are either deficiency in the level of protein present [cross-reactive material (CRM) negative] or expressed protein that is present but nonfunctional (CRM+). Defects have diverse causes, including mutations that lead to amino acid substitutions in one or more domains, mutations that introduce stop codons resulting in either no expression or expression of truncated proteins, or defects in posttranslational modifications. In the case of combined vitamin K deficiency, a rare hereditary bleeding disorder ([342], [343]), two studies have identified a missense mutation in the ?-carboxylase gene that results in a defective ?-glutamyl carboxylase and thus incomplete processing of the vitamin K–dependent proteins ([344], [345]).

When a hemostatic disorder characterized by a dysfunctional protein (CRM+) is identified, it is through the combination of techniques including protein isolation, *in vitro* studies, and DNA technology that the root of the defect is elucidated. The importance of domains as functional units and of specific amino acid interactions can be uncovered using recombinant DNA technology. Single amino acid substitutions can be introduced into domains or entire domains removed to determine where the intra- and interprotein interactions take place. Structural information through nuclear magnetic resonance spectroscopy and x-ray crystallography provides amino acid assignments and tertiary structure, thus allowing for precise approaches to site-directed mutagenesis studies. The combination of all these techniques results in a map of how the domains are aligned and interact. Further, using computational molecular dynamics can predict conformational changes associated with protein–protein, protein–ligand, and protein–surface interactions. Identifying residues directly involved in binding to membranes, metal ions, or small substrates can lead to new drug therapies.

The first x-ray crystal structure of a vitamin K–dependent protein was obtained by Tulinsky's laboratory for prothrombin fragment 1 (factor II, residues 1 through 155) in the presence ([346]) and absence of calcium ([347], [348]). These results provided information regarding the entire Gla domain, the connector peptide, and kringle 1. In the absence of calcium, only the connector peptide and the kringle can be visualized in the resulting x-ray crystal analysis. Prothrombin is the only vitamin K–dependent protein with a kringle domain. It is likely that organization of the polypeptide chains of the Gla domain is similar for all vitamin K–dependent proteins. To date, several other vitamin K–dependent protein structures have been elucidated ([349], [350], [351], [352], [353], [354], [355], [356] and [357]). Many studies on the individual vitamin K–dependent proteins have been conducted and are detailed under each protein subsection.

All the vitamin K–dependent proteins contain an NH $_2$-terminal Gla domain, and only factors II, VII, IX, and X and protein C contain a serine protease domain. Factors IX, X, and VII, protein C, and protein S contain EGF domains. Several recent reviews have been written on vitamin K–dependent proteins ([358], [359] and [360]).

GLA DOMAIN The Gla domain constitutes the first approximately 50 residues of the vitamin K–dependent proteins (Fig. 21.3). The negative charge elicited from the string of Gla residues ([9], [10], [11], [12] and [13]) contributes to the binding to Ca^{2+} and the generation of the conformation required for binding to anionic phospholipid membranes. This surface *in vivo* is supplied by activated platelets or other blood cells in response to vascular damage through exposure of the internal face of their cell membranes where it is phosphatidylserine (PS) rich ([346], [361]). *In vitro* systems that attempt to mimic coagulation mainly use natural or synthetic preparations of PS and phosphatidylcholine, often at a 1:3 molar ratio. Studies have shown that PS exposure is crucial for cells to support the membrane-bound enzymatic reactions and that PS is more effective than other equally charged lipids ([21], [362], [363]). The striking degree of homology among the Gla domains of the vitamin K–dependent clotting factors suggests that the affinity of the calcium-Gla complexes for phospholipids would also be very similar. However, this turns out not to be the case. The dissociation constants for binding to phosphatidylcholine and PS containing vesicles vary, with K_d values in the range of 50 nmol/L for protein Z and protein S ([364]), 100 to 300 nmol/L for factor X and prothrombin ([365]), 15 nmol/L for protein C ([364]), and 17,000 nmol/L for factor VII ([364], [366]). A systematic analysis of the sequence/structural basis for these divergent membrane-binding properties is available ([358], [364]). The mode of interaction between the Gla domain–containing

coagulation factors and biologic membranes has been difficult to study and is still a subject for debate. Two models of binding have been presented. One involves the bridging of calcium between specific Gla residues and the negative anionic phospholipid membrane components ([366], [367]). A second model involves a major hydrophobic contribution to the membrane binding. X-ray crystallographic ([349], [368]) and nuclear magnetic resonance studies ([369]) have been conducted to elucidate the conformational changes, in the absence and presence of calcium, that occur on Gla domain binding to a lipid membrane. In the absence of calcium, the negatively charged Gla residues appear exposed to the solution, and the hydrophobic residues of the Gla domain are buried in its interior ([370]). On Ca^{2+} binding to the Gla domain, the conformation is altered to expose the hydrophobic residues, making possible their insertion into the lipid membrane. The hydrophobic patch in prothrombin fragment 1 surrounding the first pair of Gla residues was determined to be Phe ^{4}, Leu ^{5}, and Val ^{8}. Site-directed mutagenesis studies of protein C determined these residues (Phe ^{4}, Leu ^{5}, and Leu ^{8}) to be important in membrane interactions ([371], [372] and [373]). The actual mechanism of membrane binding is still under active investigation.

EPIDERMAL GROWTH FACTOR DOMAIN The Gla domain is followed by two tandem EGF domains (EGF-1 and EGF-2) in factor VII, factor IX, factor X, and protein C and four EGF domains (EGF-1 to EGF-4) in protein S ([374]) (Fig. 21.3). The first EGF domain (EGF-1) contains the posttranslationally modified amino acid—ß-hydroxy aspartic acid in the case of factors IX and X, and ß-hydroxy asparagine in the case of protein S ([332], [334], [375], [376], [377] and [378]). An EGF-like domain consists of 40 to 50 amino acids, including six cysteine residues involved in disulfide bond formation. The EGF domains have been evaluated by nuclear magnetic resonance spectroscopy ([360], [379], [380], [381], [382] and [383]). The EGF-2 domains of factor Xa ([355]) and factor VIIa ([357]) have been evaluated by x-ray crystallography. The EGF-like domains are found widely distributed in extracellular and membrane proteins. Proteins containing these domains are involved in blood coagulation, fibrinolysis, complement activation, and microfibril formation in connective tissue and in signal transduction ([335], [384], [385]). These domains are similar to the archetypal protein, EGF, which contains nine of these domains and is derived from a membrane-bound precursor. The structure of the EGF-like domains is dominated by ß sheets and ß turns. Several point mutations in the EGF domain of factor IX have been identified that cause hemophilia B ([386]). Calcium binding sites have been identified in the NH_2-terminal EGF-like domains isolated from factors VII, IX, and X and proteins C and Z, with K_d values ranging from 1 to 5 mM. This Ca^{2+}-binding site is functionally important because vitamin K–dependent proteins that have missense mutations in EGF-1 that disrupt the Ca^{2+}-binding site have reduced biologic activity. In these proteins, the second EGF domain does not appear to bind calcium. The NH_2-terminal EGF domain of protein S does not appear to bind Ca^{2+}. The function of the EGF domain is still unclear. One hypothesis is that it serves as a spacer. A consistent elongation of the molecules of factors VII, IX, and X and protein C and protein S has been noted. The distance between the membrane binding Gla domain and the serine protease domain is crucial to the placement of the active site in an appropriate position relative to the target peptide bond in its substrate ([387]). Calcium binding serves a role in the function of these domains. For example, it has been proposed that for appropriate docking of factor VIIa to tissue factor, calcium binding to the EGF domain is required ([388]). Calcium binding to the EGF domains in non–vitamin K–dependent proteins has been observed in the Notch protein ([389]) and fibrillin ([390]).

SERINE PROTEASE DOMAIN The serine protease domain accounts for approximately one-half the mass of each protein. Peptide bond cleavage at specific sites converts the vitamin K–dependent zymogens to their active serine protease forms (Fig. 21.3). These enzymes are serine proteases in the same family as trypsin and chymotrypsin. The mechanism of proteolysis by chymotrypsin involves a catalytic triad, composed of Asp ^{102}, His ^{57}, and Ser ^{195} (chymotrypsin numbering). The nucleophilic attack is carried out by the hydroxyl group of Ser ^{195} with the imidazole ring of His ^{57} taking up the liberated proton and the carboxylate ion of Asp ^{102} stabilizing the developing charge. More extensive elements of structure (i.e., calcium, membrane, and cofactor binding sites) are required for interactions of enzymes and substrates in the coagulation process. The serine protease domains of all the Gla-containing factors show a high homology to each other and to trypsin and chymo-trypsin, cleaving almost specifically at arginyl residues. However, unlike trypsin, which shows little specificity beyond the requirement for arginyl or lysyl residues at the cleavage site, the activated coagulation factors have extended substrate specificity pockets where only a small number of amino acid sequences are recognized by each activated factor. Despite the high degree of homology between the protease domains of protein C and factors II, VII, IX, and X, each of these factors has a highly specific function in coagulation. Some of this discrimination may be mediated by surface loops and other domains away from the substrate binding pocket that are not highly homologous.

Factor VII (Proconvertin, Convertin)

The vitamin K–dependent single-chain zymogen factor VII (M_r = 50,000), also known as *proconvertin*, circulates in plasma at a concentration of 0.5 µg/ml, or 10 nmol/L ([391], [392]) (Table 21.1). It is synthesized primarily in the liver. The activated two-chain serine protease form, factor VIIa, circulates in plasma at approximately 1% the concentration of its precursor, or 0.1 nmol/L ([52]). The mechanism for the initial activation of this zymogen is unclear. One recently identified candidate is the factor VII–activating protease (FSAP; see section Factor VII–Activating Protease). The function of factor VIIa is to serve as an initiator of the extrinsic pathway of coagulation when bound to its membrane cofactor, tissue factor. Factor VII has the shortest $t_{1/2}$ of all the clotting factor zymogens (~3 to 6 hours) ([393]). Its activated form factor VIIa has a $t_{1/2}$ of 2.4 hours ([394], [395]).

Factor VII deficiency is an autosomal-recessive disorder with wide phenotypic and genotypic variability ([396], [397], [398] and [399]). Its incidence in the general population is approximately 1 in 500,000. In a large French-Canadian kindred, the incidence is approximately 1 in 335 ([400]). Bleeding phenotypes can range from mild to severe and include bruising, epistaxis, postsurgical hemorrhage, and cerebral hemorrhage. Severe bleeding is most commonly associated with plasma factor VII levels that are less than 1% ([401]). Patients have prolonged PTs, and the final diagnosis is established by plasma factor VII coagulant activity (VII:C) using factor VII–deficient plasma and animal thromboplastins, or immunologic quantitation of factor VII antigen, or both ([392], [402]). Treatment of these individuals includes the use of fresh frozen plasma, prothrombin complex concentrates ([403]), factor VII concentrates (plasma derived or recombinant) ([404]), and, recently, liver transplantation ([405]). Due to its short $t_{1/2}$ (~3 to 6 hours), therapy with factor VII concentrates is difficult. Recently, the use of recombinant factor VIIa as a safe and effective treatment for factor VII deficiency has been evaluated ([406], [407] and [408]). During the last decade, supraphysiologic concentrations of recombinant factor VIIa have been used clinically for treatment of patients with hemophilia A or B (factor VIIIa or factor IXa deficiency, respectively) and patients undergoing surgical procedures ([409], [410], [411], [412] and [413]). Recombinant factor VIIa has been suggested for treatment of almost all bleeding disorders ([414]). The mechanism of hemostasis by recombinant factor VIIa is not fully understood, although several hypotheses have been proposed ([415], [416], [417] and [418]).

Studies on the molecular basis for factor VII deficiency have led to the identification of several mutations in the factor VII gene. These mutations have been identified in the splice site ([419]), the promoter region ([420]), the EGF domain ([421]), and numerous single base pair (bp) mutations ([422], [423]). For more detail, there is a factor VII mutation database available at europium.csc.mrc.ac.uk ([424]). Factor VII deficiency in mice is not lethal at the embryonic stage, but factor VII -/- neonates die from hemorrhage within the first days after birth ([425], [426]).

GENE STRUCTURE AND EXPRESSION The factor VII gene is located on chromosome 13 band q34-qter, consists of nine exons, and spans 12.8 kb ([427], [428] and [429]) (Table 21.2). It is located approximately 2.8 kb upstream from the factor X gene. The mRNA encodes a 2.5-kb message ([430]). Alternative splicing of the factor VII gene yields two gene transcripts. One gene transcript contains eight segments as exons, and the second gene transcript contains nine segments as exons. The additional exon, which is unique among the vitamin K–dependent proteins, is in the pre-pro leader sequence. Factor VII mRNA expression is localized in the liver ([431]), where its expression is 6% of the factor X mRNA level ([432]). The 5'-flanking region of the factor VII gene contains binding sites for the liver enriched transcription factor hepatic nuclear factor (HNF)-4 ([433]). Three potential activation peptide-1 binding sites are also contained in this region.

BIOCHEMISTRY Factor VII circulates in plasma (concentration ~10 nmol/L) as a single-chain zymogen of a molecular weight of 50,000 ([391], [428], [434], [435]). Its 406–amino acid structure consists of an NH_2-terminal Gla domain containing ten ?-carboxy glutamate residues, ß-hydroxy aspartic acid at position 63 ([333]), an aromatic residue-rich a-helical region, two EGF domains, and a serine protease domain (Fig. 21.3). The NH_2-terminus, along with the serine protease domain, is involved in the metal binding properties of the protein and its interaction with its cofactor tissue factor ([436], [437] and [438]). The COOH-terminus of factor VII is important in its interactions with factor X ([439]).

ACTIVATION The single-chain zymogen factor VII is activated to its two-chain serine protease form, factor VIIa, through a single peptide bond cleavage between Arg ^{152}–Ile ^{153} (Fig. 21.3). The resulting protease consists of an NH_2-terminal light chain (M_r = 20,000) containing the membrane binding Gla domain (ten Gla residues), linked by a single disulfide bond between Cys ^{135}–Cys ^{262} to a COOH-terminal heavy chain (M_r = 30,000) that contains the catalytic domain. A small amount of activated factor VII (10 to 100 pmol/L) already circulates in the cleaved active two-chain form ([440]). This small portion of plasma factor VIIa has very poor catalytic efficiency in the absence of its cofactor, tissue factor ([441], [442]). The cleavage of factor VII to factor VIIa is catalyzed by several proteases, including a-thrombin ([5]), factor IXa ([443]), factor Xa ([5]), autoactivation by factor VIIa ([444]), factor XIIa ([445]), and FSAP ([446]).

FUNCTION Factor VII is a crucial zymogen in blood coagulation. Factor VII can bind to tissue factor with a subnanomolar K_d and become activated by a number of proteases. Once converted to its active serine protease form and bound to its cofactor, the integral membrane protein tissue factor, it forms the extrinsic tenase

complex (Fig. 21.4). The enzyme complex is so named because it contains a protein, tissue factor, normally extrinsic to the plasma environment. The extrinsic tenase complex (factor VIIa–tissue factor–membrane surface–Ca^{2+}) activates a fraction of the circulating vitamin K–dependent zymogens, factors IX and X, to their serine protease forms ([45], [228], [447], [448]). Thus, it serves to initiate the formation of the intrinsic tenase (factor IXa–factor VIIIa–membrane–Ca^{2+}) and the prothrombinase complexes (factor Xa–factor Va–membrane–Ca^{2+}). *In vitro* studies have shown that the rate of activation by the extrinsic tenase complex is significantly greater (~100,000-fold) than the rate of substrate (factors IX and X) activation by the enzyme factor VIIa alone ([449], [450]). Factor Xa bound to a membrane surface can activate additional factor VII in a positive feedback loop ([5], [61]).

REGULATION Free factor VIIa alone, unlike other serine proteases of the coagulation cascade ([442]), is not readily inhibited by circulating protease inhibitors, including antithrombin-III–heparin complex ([451], [452]). This is most likely due to its poor catalytic efficiency when not bound to its cofactor tissue factor. However, when factor VIIa is bound to tissue factor, antithrombin-III–heparin exhibits significant inhibition of factor VIIa ([453], [454] and [455]). Thus, regulation of tissue factor expression is the primary means to control factor VIIa activity. Paradoxically, in normal hemostasis, factor VII (10 nmol/L) is an effective competitor of factor VIIa (0.1 nmol/L) for binding to tissue factor. This competition down-regulates the level of enzymatically active complex (factor VIIa–tissue factor), thus suppressing initiation of the clotting cascade. Once the extrinsic tenase complex (factor VIIa–tissue factor–Ca^{2+}-membrane) activates factor X to factor Xa, tissue factor pathway inhibitor (TFPI) can form a quaternary complex (factor VIIa–tissue factor–factor Xa–TFPI) with no enzymatic activity ([456]) (Fig. 21.6).

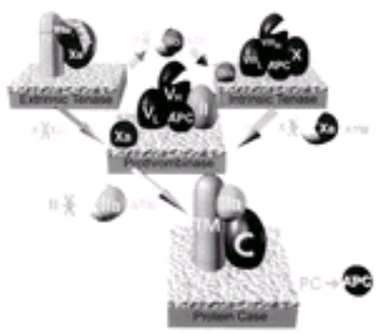

Figure 21.6. Regulation of the procoagulant response. Four vitamin K–dependent complexes are illustrated: the extrinsic tenase, the intrinsic tenase, prothrombinase, and protein Case. The procoagulant response is regulated by the stoichiometric inhibitors antithrombin-III (ATIII) and tissue factor pathway inhibitor (TFPI). ATIII inhibits thrombin, factor Xa, and factor IXa that are free in solution. TFPI inhibits both factor Xa and the factor VIIa–tissue factor (TF)–factor Xa complex. Activated protein C (APC) generated from the protein Case complex [thrombomodulin (TM)-thrombin (IIa)] inactivates FVa and FVIIIa by proteolysis of their heavy chains. PC, protein C. See Color Plate. Factor IX (Plasma Thromboplastin Component, Christmas Factor, Hemophilia B Factor)

The zymogen factor IX is a single-chain vitamin K–dependent procoagulant glycoprotein synthesized in the liver, which has also been referred to as *plasma thromboplastin component*, *Christmas factor*, or *hemophilia B factor*. It circulates in plasma [$t_{1/2}$ = 24 hours ([457])] at a mean concentration of 5 µg/ml, or 90 nmol/L, with a relative molecular weight of 55,000 ([458]) (Table 21.1). In addition, there may be a pool of noncirculating factor IX, which is readily available to the intravascular space, systemically distributed, and sequestered either to the endothelial surface ([459]) or subendothelial components, specifically collagen IV ([460], [461] and [462]). High levels of factor IX have been correlated with an increased risk of venous thrombosis ([463]).

Deficiency of this glycoprotein, known as *hemophilia B*, is considered one of the most common inherited coagulation disorders. The factor IX gene, found on the X chromosome, is a sex-linked recessive bleeding disorder that is found in males. The frequency of this disorder in the general population is approximately 1 in 30,000 males ([458], [464]). It rarely affects females, but several cases have been identified involving a mutation on the factor IX gene ([465], [466]). Acquired hemophilia can also occur due to the generation of autoantibodies ([467]). Many mutations, including large deletions, small deletions, point mutations, and missense mutations, have been identified in factor IX that appear to reduce activity in the presence of normal antigen levels (CRM+) or impair synthesis resulting in reduction of both activity and antigen (CRM–) ([468], [469]). Several specific cases and studies are noted: X translocation ([470]), links to factor V Leiden ([471]), population studies ([472], [473], [474] and [475]), and factor IX Denver ([476]). The point mutation called *factor IX Denver* results in a 100-fold decrease in the binding affinity of factor IXa Denver for factor VIIIa (K_d = 9.9 nmol/L) compared to normal factor IXa ([476]). Mutations in the EGF-1–like domain of factor IX, specifically at Gly^{48}, have also been identified in CRM+ individuals with hemophilia B ([477]). Molecular insights into hemophilia B as well as hemophilia A have been formatted in a recent review with references to accession numbers and locus identification ([478]).

Hemophiliacs experience prolonged bleeding episodes that can be life threatening and lead to chronic disabilities. The clinical presentation or phenotype is not homogeneous. Severe disease is associated with less than 1% functional factor IX, moderate disease with 1 to 5%, and mild disease with 5 to 25%. Female carriers usually have approximately 20 to 50% functional factor IX. Treatment for hemophilia B as well as hemophilia A involves plasma-derived or recombinant factor IX or factor VIII therapy, respectively ([479]). One problem with this therapy is the development of inhibitory antibodies. There is a North American Immune Tolerance Registry to study immune tolerance in hemophiliacs ([480]). An alternative treatment in the last decade has been the use of recombinant factor VIIa at supra-physiologic concentrations (~90 µg/kg). These therapies eliminate the immediate danger of bleeding but do not constitute a cure for the patients. The potential for gene-based therapy for the treatment of hemophilia has become a new avenue for investigation ([481], [482], [483] and [484]). To date, trans-gene therapy has proved successful in animal models, and human trials have been initiated as well ([485], [486] and [487]).

GENE STRUCTURE AND EXPRESSION The gene for factor IX is located on the X chromosome at position q26.3-27.1, near the factor VIII gene ([488], [489] and [490]). The gene contains eight exons and seven introns and has an overall size of 33 kb ([492], [493]). Five cis-acting elements have been identified in the promoter region of the factor IX gene ([494], [495]). These include binding sites for transcription factor C/EBP ([496]), an HNF-1 binding site ([497]), an HNF-4 binding site ([498]), and a site for the D-box binding protein ([499]). Two essential age-regulatory elements, AE5' and AE3', have been identified in the 5' upstream region of the gene encoding factor IX in transgenic mice ([500]). Together, these elements identify the advancing age-associated increase in factor IX gene expression. Single point mutations in the factor IX promoter region have been correlated with a rare form of hemophilia B termed *hemophilia B Leyden* ([494], [501], [502]). Hemophilia B Leyden is characterized by an altered developmental expression of blood coagulation factor IX ([494]). These individuals have increasing levels of factor IX after puberty, or after administration of testosterone, resulting in decreased bleeding instances ([503], [504]). Studies in mice support the role of androgen receptor binding to the factor IX promoter in regulating the developmental expression of factor IX ([505]).

BIOCHEMISTRY Human factor IX is a member of the vitamin K–dependent protein family and circulates in an inactive single-chain zymogen form at a plasma concentration of 5 µg/ml, or 90 nmol/L, with a relative molecular weight of 55,000 ([458], [506]) (Table 21.1). Other names for factor IX include *plasma thromboplastin component* and *Christmas factor*. Its structure consists of 415 amino acids that are separated into a Gla domain (12 Gla residues), two tandem EGF domains [EGF-1 (residues 46 to 84) and EGF-2 (residues 85 to 127)], an activation peptide region, and a serine protease domain ([267], [493], [507]) (Fig. 21.3). Glycosylation in the form of O-linked and N-linked oligosaccharides makes up 17% by weight of the factor IX protein—specifically, O-linked oligosaccharides at Ser^{53} and Ser^{61} in the EGF-1 domain and O-linked and N-linked oligosaccharides at Asn^{157}, Asn^{167}, Thr^{159}, and Thr^{169} in the activation peptide region ([508], [509], [510] and [511]). The Gla domains are crucial for binding to anionic lipid membranes through calcium interactions. The x-ray crystal structure of human factor IX with Ca^{2+} has shown that EGF-1 binds a single Ca^{2+} with residues Asp^{47}, Gly^{48}, Gln^{50}, Asp^{64}, and Asp^{65} functioning as the ligands ([512]). Hydrophobic interactions ([513]) and a salt bridge (Glu^{78}-Arg^{94}) ([514]) between the carboxy end of EGF-1 and EGF-2 have also been identified ([515]). Ca^{2+} binding and hydrophobic interactions lock the domains in a manner that assures biologic activity. Several point mutations in the EGF domain give rise to hemophilia B ([386]).

ACTIVATION Factor IX activation to its serine protease form, factor IXa, is a two-stage process requiring sequential cleavages at Arg^{145} and Arg^{180}, releasing a 35-residue activation peptide with an approximate molecular weight of 11,000 ([516], [517]) (Fig. 21.3). Physiologic activators of factor IX are either tissue factor–factor VIIa (extrinsic tenase complex) ([228], [518]) or factor XIa ([519], [520]). The first step in activation is the cleavage by its physiologic activators between the Arg^{145}–Ala^{146} bond, resulting in factor IXa. This cleavage has been shown to be important in its affinity for its cofactor factor VIIIa ([521]) and has been identified as a molecular defect in factor $IX_{Chapel\ Hill}$ ([522]). The second step is cleavage between the Arg^{180}-Val^{181} bond, resulting in factor $IX_{Chapel\ Hill}$, the active form, also known as *factor IXa*. Both cleavages are required for full biologic activity of factor IXa ([517]). *In vitro*, factor IX has also been shown to be cleaved by factor Xa at Arg^{145} on phospholipid membrane surfaces ([63]), producing the inactive precursor factor IXa and increasing the overall rate of factor IXa production by tissue factor–factor VIIa.

Both cleavage sites, Arg ^{145} and Arg ^{180}, have been identified as single point mutations in hemophilia B ([523]). The x-ray crystal structure of porcine factor IXa has also been solved ([515]). The active serine protease (M_r = 45,000) structure is composed of a heavy chain (M_r = 28,000) and a light chain (M_r = 17,000) covalently associated through a disulfide bond. Factor IXa forms the intrinsic tenase complex with its cofactor factor VIIIa, Ca^{2+}, and a membrane surface primarily supplied by platelets (Fig. 21.4). On formation of this complex, factor X is activated to its serine protease form factor Xa. Factor IXa (the enzyme) alone without its cofactor (factor VIIIa) has poor amidolytic and proteolytic activity (10^{7}-fold less activity).

FUNCTION The main role for factor IXa in blood coagulation is to form the intrinsic tenase complex, which efficiently activates factor X to factor Xa. The complex is so named because the components, including the cofactor, are intrinsic to circulating blood. Tissue factor, the cofactor for the extrinsic tenase complex, is not in contact with circulating blood until the endothelium is damaged. Both complexes activate factor X to factor Xa. The extrinsic tenase complex (factor VIIa–tissue factor–Ca^{2+}-membrane) catalyzes the initial formation (picomolar amounts) of factor Xa, which ultimately participates in prothrombinase complex assembly and the resulting conversion of prothrombin to thrombin allowing clot formation to occur. The intrinsic tenase complex (factor IXa–factor VIIIa–Ca^{2+}-membrane) generates the second burst of factor Xa that results in the propagation phase of the activation of prothrombin to thrombin (Fig. 21.7) ([524]). The intrinsic tenase complex is kinetically more efficient than the extrinsic tenase complex in generating factor Xa. Factor Xa generation by tissue factor–factor VIIa occurs at only 1/50th the rate of factor X activation by the factor IXa–factor VIIIa complex ([62] , [63] and [64]).Without the intrinsic complex being formed, as occurs in situations like hemophilia A or B, factor Xa is not generated in levels sufficient to produce the propagation phase of thrombin generation (Fig. 21.7) ([418] , [525] , [526]).

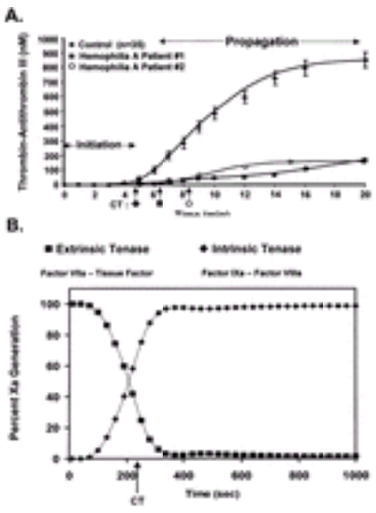

Figure 21.7. Profiles of thrombin and factor Xa generation. **A:** Time course (x-axis: 0 to 20 minutes) of thrombin–antithrombin-III formation (y-axis: nmol/L thrombin–antithrombin-III complex) during whole blood coagulation initiated with 5-pmol/L tissue factor ([526]). Data represent means plus or minus standard error of the means for 35 individuals; thrombin-antithrombin levels reach maximum levels of 900 nmol/L (?) in this group of normal individuals. Clot time (CT) is shown below with the symbols for each curve. Thrombin generation is divided into two phases: an initiation phase and a propagation phase. When two hemophilia A patients were studied (▪,○), CT was delayed, and the propagation phase of thrombin generation was not present ([418] , [525]). By not having factor VIIIa present, the intrinsic tenase complex is unable to generate the additional factor Xa that is required for the burst or propagation phase of thrombin generation. **B:** Computer simulation of the time course of factor Xa generation on activation of the factor VIIa–tissue factor pathway ([524]). Factor Xa concentrations are expressed as percent (%) of maximum level achieved for the extrinsic Xase (▪, tissue factor–factor VIIa: 100% @ 10 pmol/L) and % of maximum for the intrinsic Xase (?, factor IXa–factor VIIIa: 100% @ 1 nmol/L). The factor Xa that is initially produced is via the extrinsic tenase complex. After CT, the majority of factor Xa generated is via the intrinsic Xase. The clot time represents the time point in the computer simulation at which calculated thrombin levels are comparable to thrombin levels (~10 nmol/L) measured in clotting whole blood (see Fig. 21.11).

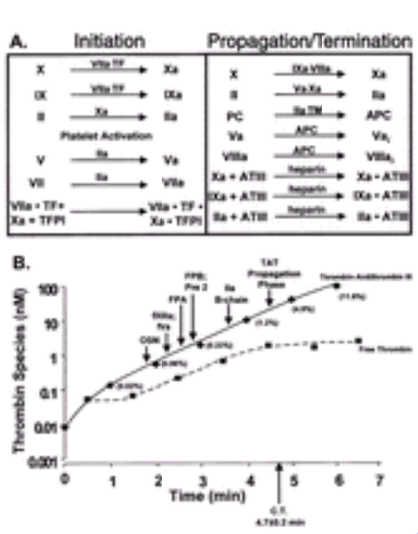

Figure 21.11. Initiation, propagation, and termination of thrombin generation and the procoagulant response. **A:** Low levels of thrombin are required to initiate clot formation (initiation phase) and trigger the coagulation cascade response (propagation phase). The enzymes, cofactors, and inhibitors act together to generate a hemostatic response that can be divided into an initiation phase and a propagation/termination phase. During the initiation phase, factors X and IX are converted to their respective serine proteases factor Xa and factor IXa; low levels of thrombin are subsequently generated by factor Xa. This thrombin then can activate platelets and the procofactors factors V and VIII, which stimulate further thrombin generation during the propagation phase. Thrombin generation is attenuated by shutting down the initiation phase by means of the stoichiometric inhibitor of the extrinsic Xase complex, tissue factor pathway inhibitor (TFPI), followed by antithrombin III (ATIII), which directly inhibits thrombin and factors Xa and IXa. **B:** Time course of early thrombin–antithrombin III (TAT) complex formation from whole blood coagulation of 35 individuals is presented: y-axis, TAT [solid line (?)] and free thrombin [dashed line (▪)] concentrations (nmol/L) are shown on a log scale; x-axis, time in minutes ([526]). Arrows indicate the time and TAT concentration at which each of the indicated events [osteonectin (OSN) release, a marker of platelet activation, factor XIII activation (fXIIIa), fibrinopeptide A (FPA) release, fibrinopeptide B (FPB) release, and prothrombin activation] has entered a phase of rapid activation. The percent of total TAT present at the point of activation is shown in parentheses. APC, activated protein C; C.T., clot time; PC, protein C; TF, tissue factor. (From Brummel KE, Paradis SG, Butenas S, Mann KG. Thrombin functions during tissue factor induced blood coagulation. Blood 2002:100;148–152, with permission.)

When the competitive substrates factors IX and X are simultaneously presented to the extrinsic tenase complex, factor IXa generation is increased, whereas factor Xa generation is suppressed ([62] , [63]). This occurs because the factor Xa initially produced cleaves factor IX at Arg ^{145}, producing factor IXa. Factor IXa is a better substrate for factor VIIa–tissue factor than factor IX; the intermediate is converted to factor IXaß (factor IXa) by cleavage at Arg ^{180} by factor VIIa–tissue factor. This cooperative enzymatic action results in factor IX being an improved substrate for the extrinsic tenase complex, whereas factor X activation is suppressed.

REGULATION Plasma factor IXa is primarily inhibited by antithrombin-III ([527]) (Fig. 21.6). *In vitro* experiments conducted on phospholipid vesicles and cell membranes showed that PN2/amyloid ß-protein precursor (PN-2/APP) can also inhibit factor IXa ([528]). Interestingly, an insect salivary protein, Prolixin-S, has been shown to inhibit factor IXa generation and the intrinsic tenase complex formation ([529]). One strategy to improve existing antithrombotic therapies has been to develop factor IXa inhibitors ([530])—in particular the use of monoclonal antibodies to target factor IX/factor IXa ([531] , [532]). Currently, problems exist in using direct thrombin inhibitors to regulate thrombin activity. Targeting the end product of an amplifying cascade results in a narrow window of therapeutic dose, which is difficult to achieve in clinical practice ([533] , [534] and [535]). The advantages of regulating events upstream (factor IX/factor IXa; the intrinsic tenase complex) as an approach to antithrombotic therapy would be to potentially produce a partial reduction in the magnitude of thrombin formation.

Factor X (Stuart Factor)

The *zymogen factor X*, or *Stuart factor*, is a vitamin K–dependent glycoprotein that is synthesized in the liver and circulates as a two-chain molecule linked by a disulfide bond ([518] , [536]). It has a molecular weight of 59,000, circulates in plasma at a mean concentration of 10 µg/ml or 170 nmol/L, and has a $t_{1/2}$ of approximately 1.5 days ([457] , [537] , [538]) (Table 21.1). In the Leiden Thrombophilia study, a population-based case control study on venous thrombosis, high levels of factor X alone

predicted the risk of thrombosis but were not a risk factor for venous thrombosis when the levels of other vitamin K–dependent proteins were taken into account ([539]).

Factor X deficiency is a rare autosomal-recessive disorder with varied phenotype and genotype. Homozygous factor X deficiency has an incidence of 1 in 1 million in the general population ([540]). Whereas heterozygotes are often clinically asymptomatic, the most severely affected homozygous individuals exhibit extensive bleeding early in life. Multiple factor X deficiency cases have been identified, and the gene defects have been elucidated in individuals with bleeding tendencies ([541] , [542] , [543] , [544] , [545] , [546] and [547]) and in an individual without a bleeding tendency ([548]). As with most deficiencies, the level of factor X expression is indicative of the bleeding response. When factor X levels are approximately 1%, bleeding can include hemarthrosis, soft tissue hemorrhage, and menorrhagia. With functional levels above 15%, bleeding is infrequent and usually mild. Acquired factor X deficiency is rare and is usually associated with light-chain amyloidosis ([549] , [550] and [551]). In amyloidosis, factor X is thought to be adsorbed onto extracellular amyloid fibrils, thereby decreasing the circulating factor X level and increasing bleeding. In these cases, replacement with factor X products is not as effective a therapy for deficiency because it is continuously removed from plasma. Treatment of factor X deficiency can involve the administration of fresh frozen plasma or prothrombin complex concentrates.

The importance of factor X generation is illustrated by transgenic mice with a total deficiency of factor X. Homozygous deficiency (-/-) results in partial embryonic lethality with signs of massive bleeding ([425] , [552]). Those mice that survive to term die within 5 to 20 days from fatal neonatal bleeding. The lethality of factor X knock-out genotype in mice supports the significance of factor X function in hemostasis.

GENE STRUCTURE AND EXPRESSION The gene for factor X spans 27 kb, is located on chromosome 13 bands q34-qter, and yields a 1.5-kb mRNA ([427] , [553] , [554] and [555]) (Table 21.2). The gene for factor X is located near the gene for factor VII. Studies to elucidate the liver-specific expression of factor X have included the characterization of the human ([556]) and murine factor X promoter ([557]). Using a hepatoma cell line that expresses factor X, the first 279 bp of the 5'-flanking sequence upstream from the first AUG proved to be sufficient to confer maximal promoter activity ([556]). From mutagenesis studies, two protein binding sites within the 279-bp fragment were identified that are critical for promoter activity: CCAAT (at -120 to -116) and ACTTTG (at -56 to -51) ([556]). Factor X also lacks a typical TATA box. In the human factor X promoter, the binding proteins HNF-4 (at -73) ([558]), nuclear factor-Y (at -128) ([558]), GATA-4 (GATA element at -96) ([559]), the Sp family of transcription factors I footprinted sites (at -165 and -195) ([559]) have been identified as playing crucial roles in modulating the activity of the proximal promoter of factor X.

BIOCHEMISTRY Human factor X is a vitamin K–dependent glycoprotein of molecular weight 59,000 that circulates in plasma (10 µg/ml or 170 nmol/L) as a two-chain molecule composed of a disulfide-linked light chain (M_r = 16,500) and heavy chain (M_r = 42,000) ([560] , [561]) (Table 21.1). Its structure contains an NH_2-terminal light chain consisting of a Gla domain (11 Gla residues), with a single ß-hydroxy aspartic acid residue, and two EGF-like domains (EGF-1 and EGF-2) (Fig. 21.3). The COOH-terminal heavy chain consists of an activation peptide region and a catalytic (serine protease) domain. Most of the carbohydrate moieties (~15%) are contained within the heavy chain ([537]) in the activation peptide domain ([562]). Ca^{2+} binding in the first EGF domain has been proposed to enhance the structural rigidity of the factor X molecule ([382]).

ACTIVATION Factor X is activated to its serine protease form factor Xa through a cleavage of the activation peptide at Arg^{194}-Ile^{195} (Arg^{52}-Ile^{53} of the heavy chain) (Fig. 21.3). A 52–amino acid activation peptide is released with a relative molecular mass of 12,000. The resulting catalytic serine protease, factor Xa, has a molecular weight of 48,000 and is composed of a light chain (M_r = 18,000) and a disulfide-linked heavy chain (M_r = 30,000). The activation of factor X is catalyzed by factor VIIa–tissue factor (the extrinsic tenase complex) ([447]) and factor IXa–factor VIIIa (the intrinsic tenase complex) ([563]). *In vitro* studies have determined that factor X has to be bound to the membrane before activation ([45] , [564]).

FUNCTION The main function of factor Xa is to form the prothrombinase complex (factor Xa–factor Va–membrane–Ca^{2+}) (Fig. 21.4). Factor Xa is the serine protease enzyme in the prothrombinase complex that catalytically activates prothrombin to thrombin, the key enzyme in blood coagulation. The prothrombinase complex activates prothrombin to thrombin 10^5-fold faster than factor Xa alone ([42]). Factor Xa is a unique regulatory enzyme in that it is formed through both the extrinsic tenase and intrinsic tenase complexes (as mentioned in section Factor IX (Plasma Thromboplastin Component, Christmas Factor, Hemophilia B Factor section). During the initial stages of the hemostatic event, low levels of both factor Xa and factor IXa are generated. Once generated, the limited amounts of factor Xa produced by extrinsic tenase bind to available membrane sites and convert picomolar amounts of prothrombin to thrombin ([39] , [565] , [566]) (Fig. 21.7B). This thrombin then activates factor VIII ([567]) and factor V ([568]), allowing the initial formation of the intrinsic tenase and prothrombinase complexes. Thus, the time period in which factor Xa directly generates picomolar amounts of thrombin is referred to as the *initiation phase of blood coagulation*. The burst or propagation phase of thrombin generation is then obtained from additional factor Xa generated via the intrinsic tenase complex (factor IXa–factor VIIIa–Ca^{2+}-membrane) (Fig. 21.7). The intrinsic tenase complex activates factor X at a 50- to 100-fold higher rate than the extrinsic tenase complex ([62] , [63] and [64]). This burst in factor Xa levels overcomes the levels of factor Xa inhibitors such as TFPI and achieves maximal prothrombinase activity and propagation of the procoagulant event. There is evidence that factor Xa can also trigger intracellular signaling events by increasing endothelial cell cytosolic Ca^{2+} and the release of endothelial cell mitogens ([569]). Mitogenic activity toward smooth muscle cells ([570]) and lymphocytes ([571]) has also been identified. An alternative initiation of factor X to factor Xa has been identified on stimulated cells of monocytic and myeloid differentiation involving the specific adhesive receptor Mac-1 ([572]). A novel factor Xa receptor, effector cell protease receptor-1, has been identified on the surface of a monocytic cell line ([573]). A platelet factor Xa receptor has been described as important in mediating prothrombin binding via factor Xa binding to platelet factor Va ([574]).

REGULATION Once assembled, the extrinsic tenase (factor VIIa–tissue factor–Ca^{2+}-membrane) is rapidly inactivated along with its product factor Xa through the action of TFPI (Fig. 21.6). The factor Xa active site associates with the COOH-terminus of TFPI ([575] , [576]) to localize the TFPI to the membrane. Once localized, the factor Xa–TFPI complex rapidly inactivates tissue factor–factor VIIa, forming a stable quaternary complex, tissue factor–factor VIIa–TFPI–factor Xa. The factor Xa–TFPI complex has been shown to be elevated in cancer patients ([577]). Factor Xa is also inhibited by antithrombin-III ([578]) when not in complex with prothrombinase ([579] , [580]). Its inhibition is enhanced through the use of heparin, which increases the affinity of antithrombin-III for its substrates (i.e., factor Xa). Because factor Xa is a major player in the coagulation cascade, it is a target for regulation by synthetic inhibitors in treating ischemic heart disease and cerebrovascular disease. Many studies are currently under way to develop a new class of antithrombotic agents that target factor Xa ([581] , [582] and [583]). One compound, fondaparinux, a synthetic pentasaccharide, has finished a phase III clinical trial, and results show superiority to the low-molecular-weight heparins in reducing venous thromboembolism ([584]).

Factor II (Prothrombin)

Factor II, also known as *prothrombin*, is a single-chain vitamin K–dependent zymogen that, when activated, yields factor IIa (thrombin), the key enzyme in blood coagulation. The zymogen prothrombin (M_r = 72,000) is the most abundant of the vitamin K–dependent proteins and circulates in plasma at a mean concentration of 1.4 µmol/L or 100 µg/ml ([585] , [586] and [587]) (Table 21.1). Prothrombin is primarily synthesized in the liver with a $t_{1/2}$ of approximately 2.5 days. Low levels of prothrombin expression have been identified in other tissues including brain, diaphragm, stomach, kidney, spleen, intestine, uterine, placental, and adrenal ([588] , [589]). Increased prothrombin levels have been associated with an increased risk of venous thrombosis.

Human prothrombin deficiency is rare because of the autosomal nature of its expression. It was first described by Quick in 1943 ([590]). Deficiencies in prothrombin are classified as either hypoprothrombinemia or dysprothrombinemia and occur due to genetic disorders affecting either transcriptional regulation or protein function ([591] , [592]). These disorders are characterized by variable pathologies extending from mild bruising to clinically severe bleeding ([593]). Homozygotes are characterized by severe bleeding, and heterozygotes either have mild bleeding or are asymptomatic. Prothrombin complex concentrates have been used for prophylaxis and bleeding episodes in individuals with prothrombin deficiency ([403]). The importance of a-thrombin to hemostasis is demonstrated in prothrombin-deficient mice, which experience embryonic and neonatal lethality ([594] , [595] and [596]).

GENE STRUCTURE AND EXPRESSION The 21-kb human prothrombin gene is located on chromosome 11 bands p11-q12 and has been extensively studied ([597] , [598] , [599] and [600]). The prothrombin gene contains 14 exons and 13 introns ([598]) and is transcribed as a pre-propeptide of 622 amino acids ([599] , [600]). The 43–amino acid propeptide mediates posttranslational processing to generate the mature protein of 579 amino acids. The promoter region of the prothrombin gene lacks a TATA box. Many studies have been conducted on the prothrombin gene to identify the polymorphisms that exist and to determine their relationships to thrombophilia. One common polymorphism is the G20210A transition in the 3'-untranslated region of the promoter. This mutation has been linked to familial thrombosis. The G20210A polymorphism of the prothrombin gene has been associated with elevated prothrombin levels and an increased risk for venous thrombosis ([601]). It is one of the most commonly identified genetic risk factors for thrombosis. An additional polymorphism, A19911G, in the prothrombin gene has been identified that can modulate the risk of the G20210A polymorphism in developing deep vein thrombosis ([602]). Several recent reviews have been written on the influence of genetic polymorphisms (including the prothrombin G20210A) and the laboratory diagnosis of thrombophilia ([603] , [604] and [605]).

BIOCHEMISTRY Factor II, prothrombin, is a vitamin K–dependent glycoprotein with a relative molecular weight of 72,000 (8% carbohydrate) and circulates in plasma ($t_{1/2}$ = 2.5 days) at a mean plasma concentration of 1.4 µmol/L or 100 µg/ml (Table 21.1). The initial observations about the structure/function relationship characterizing the prothrombin molecule came about from the partial primary structures of bovine and human prothrombins. Subsequently, the complete primary structure of human prethrombin 2 (residues 272 to 579), which is the precursor of thrombin, was determined ([606]). Finally, the primary structure for bovine prothrombin ([607]) and human prothrombin ([600]) were deduced from isolated cDNAs. The elucidated structure of prothrombin is characterized by an NH_2-terminal Gla domain (residues 1 to 40 with ten Gla residues), followed by two kringle domains (kringle 1, residues 65 to 143; kringle 2, residues 170 to 248) and the serine protease precursor domain (residues 272 to 579). There are three N-linked sugar chains—two in the first kringle domain and one in the catalytic domain of human prothrombin ([608]). The first x-ray crystal structure of a blood coagulation protein fragment, bovine prothrombin kringle 1, was determined in Tulinsky's laboratory in 1986 ([348]). Kringles have been identified as common motifs in many plasma proteins, including prothrombin, plasminogen, t-PA, urokinase, factor XII, and apolipoprotein A ([609], [610]). The kringle 1 domain contains four cysteine residues participating in two disulfide bonds. The role of the kringle 1 domain of prothrombin is still unclear but is suggested to be involved with the interaction of prothrombin and factor Va in the prothrombinase complex ([611], [612]). The NH_2-terminal Gla domain and the first kringle domain together are referred to as *prothrombin fragment 1*. The kringle 2 domain of prothrombin, located in prothrombin fragment 2 (residues 156 to 271), is similar in sequence and presumably in structure. The kringle 2 domain also binds Ca^{2+} and appears to be the primary region in prothrombin that mediates the interaction of the prothrombin molecule with factor Va in the prothrombinase complex ([613], [614]). This latter interaction has been suggested to initiate conformational changes that make reaction sites accessible for enzymatic cleavage of prothrombin ([615]). The sequence of the enzyme a-thrombin is contained within prethrombin 2 (residues 272 to 579).

ACTIVATION Prothrombin is activated to the procoagulant a-thrombin by two cleavages: one at Arg ^{271}-Thr ^{272} and another at Arg ^{320}-Ile ^{321} by the prothrombinase complex (factor Xa–factor Va–phospholipid membrane–Ca^{2+}) (Fig. 21.3). Membrane-bound factor Va serves as the receptor for factor Xa, the catalytic serine protease. The rate of a-thrombin generation by prothrombinase is 3 × 10^5-fold faster than the rate for factor Xa alone at potential physiologic concentrations of the proteins ([42]). The phospholipid membrane surface that supports the prothrombinase complex *in vivo* is assumed to be primarily provided by platelets but can also be provided by other circulating blood cells, such as monocytes and lymphocytes, and by vascular endothelial cells ([616]). The activation of prothrombin by prothrombinase proceeds through an initial cleavage of prothrombin at Arg ^{320}-Ile ^{321}, giving rise to meizothrombin, a two-chain disulfide-linked molecule (Fig. 21.8; pathway A, cleavage at 1). Meizothrombin expresses some of the activities of a-thrombin. However, meizothrombin has impaired fibrinogen clotting ability compared to a-thrombin ([617]). Meizothrombin is subsequently cleaved at Arg ^{271}-Thr ^{272} (Fig. 21.8; pathway A, cleavage at 2), yielding the NH_2-terminal half of the molecule consisting of the Gla domain and two kringle domains (prothrombin fragment 1.2: residues 1 to 271) and a-thrombin. a-Thrombin consists of an NH_2-terminal 49–residue A-chain (residues 272 to 320) disulfide-linked to a COOH-terminal 259–residue B-chain (residues 321 to 579) containing the catalytic triad.

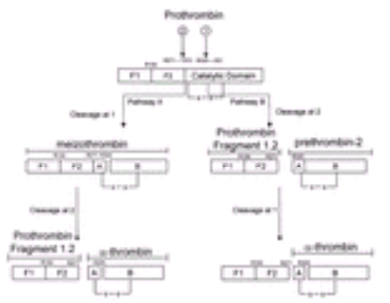

Figure 21.8. Schematic representation of the pathways for prothrombin activation. The generation of a-thrombin from its precursor, the zymogen prothrombin, by factor Xa involves the cleavage of two peptide bonds. The reaction begins either via step 1 (cleavage at R ^{320}-I ^{321}) or step 2 (cleavage at R ^{271}-T ^{272}). Cleavage at 1 (R ^{320}), pathway A, produces meizothrombin. Meizothrombin is composed of a prothrombin fragment consisting of fragment 1 (F1, residues 1 to 155: Gla domain + kringle 1), fragment 2 (F2, residues 156 to 271: kringle 2), and residues 272 to 320 (A-chain) linked by a disulfide bond to the catalytic domain (B-chain). Meizothrombin is generated when the full prothrombinase complex is assembled. Subsequent cleavage at R ^{271} (cleavage at 2, pathway A) generates prothrombin fragment 1.2 (F1 and F2) and the disulfide-linked heterodimer a-thrombin (A- and B-chains). Without a membrane surface present, the pattern of prothrombin cleavage by factor Xa follows pathway B, and cleavage occurs first at site 2, R ^{271}, pathway B, generating prothrombin fragment 1.2 (F1 and F2) and prethrombin-2. Subsequent cleavage at R ^{320} produces the A- and B-chains of a-thrombin.

An alternative cleavage pathway occurs when factor Xa alone acts on prothrombin. In the presence of factor Xa and Ca^{2+}, the initial cleavage occurs at Arg ^{271}-Thr ^{272} and gives rise to prothrombin fragment 1.2 and prethrombin 2 (Fig. 21.8; pathway B, cleavage at 2). Cleavage at Arg ^{320} in prethrombin 2 (Fig. 21.8; pathway B, cleavage at 2) yields a-thrombin. Prothrombin fragment 1.2 remains noncovalently associated with a-thrombin. *In vitro*, a-thrombin is associated (K_d = 10 nmol/L) with prothrombin fragment 2 ([618]) or the latter's precursor prothrombin fragment 1.2, or both ([619]). In contrast to other vitamin K–dependent proteins, the phospholipid binding region is no longer covalently attached to the serine protease domain after prothrombin conversion to thrombin. Thrombin and meizothrombin catalyze cleavage at Arg ^{155} of prothrombin, yielding a truncated molecule called *prethrombin 1* (residues 156 to 579) that lacks the Gla domain. Thrombin can also cleave at Arg ^{284}, yielding a truncated a-thrombin species (residues 284 to 579), which is the form of thrombin found in commercial preparations.

FUNCTION a-Thrombin can be considered the central enzyme in blood coagulation in that it contributes to reactions at all levels allowing for the overall maintenance of vascular fidelity. Its main role is in stemming blood loss through fibrin clot formation ([620]). The series of events that lead up to and occur after fibrin formation also involve protein activation by a-thrombin. These include activation of platelets ([621]), factor VII ([5]), factor V ([622]), factor VIII ([623]), factor XI ([4]), and factor XIII ([14]). a-Thrombin activity also extends from the procoagulant process to anticoagulation and suppression of fibrinolytic reactions. For example, a-thrombin–thrombomodulin activates the anticoagulant protein, protein C ([624]), and the antifibrinolytic protein, TAFI ([17]). Relatively minute concentrations of thrombin are generated during the initiation phase of blood coagulation, primarily due to the factor Xa generated from the extrinsic tenase complex (Fig. 21.7). These levels of thrombin, in the range of 0.5 to 2.0 nmol/L, have been shown to be sufficient for the initiation of rapid activation of platelets, factor XIII, and factor V and fibrin formation in an *ex vivo* whole blood model ([526]). All of these processes occur before the major burst of thrombin generation during the propagation phase of the reaction. a-Thrombin's role continues into the tissue repair and remodeling phase that is necessary to regenerate damaged vascular tissue. a-Thrombin is a potent mitogen ([625], [626]) and stimulates cell division in macrophages ([627]), smooth muscle cells ([628]), and endothelial cells ([629]). a-Thrombin also appears to be involved in the growth and metastasis of tumors by promoting angiogenesis ([630], [631]), possibly through vascular endothelial growth factor ([632]). The roles that thrombin plays in coagulation and beyond are outlined in a recent review ([633]).

REGULATION *In vivo*, the activity of the prothrombinase complex has to be tightly regulated to ensure that adequate but limited levels of a-thrombin are generated. If too much thrombin is continuously generated, localized clot formation can lead to occlusion or systemic thrombosis. Equally, if too little thrombin is generated, hemorrhagic conditions result. Two reaction systems, one covalent and one proteolytic, regulate thrombin generation. Antithrombin-III heparin (or heparan sulfate) is a potent inhibitor of blood coagulation and inhibits both a-thrombin and factor Xa via covalent interactions ([634], [635]). a-Thrombin also participates in its own down-regulation by binding to thrombomodulin on the vascular cell surface and converting protein C to APC. This anticoagulant serine protease then cleaves factor Va and factor VIIIa. The cofactors for the vitamin K–dependent complexes are no longer available for ongoing reactions, thereby eliminating thrombin generation. In *ex vivo* models of blood coagulation, prothrombin levels and antithrombin-III appear to have the most significant impact on a-thrombin generation ([636]). Increased levels of antithrombin-III reduce a-thrombin generation by inhibiting a-thrombin activity and preventing positive feedback ([636]). Decreased levels of antithrombin-III allow for higher levels of prothrombin activation and prolongation of a-thrombin generation ([636]).

PROCOAGULANT PROTEINS: PROCOAGULANT COFACTOR PROTEINS

There are two categories of procoagulant cofactor proteins: the plasma-derived soluble procoagulant procofactors factor V and factor VIII [and its circulating carrier von Willebrand factor (vWF)] and the cell-associated coagulation cofactor, tissue factor. Factor V and factor VIII are highly homologous (40% identity), sharing many structural and functional similarities. The cell-associated cofactor tissue factor is a single-chain transmembrane protein that is composed of extracellular, transmembrane, and cytoplasmic domains.

Tissue Factor (Tissue Thromboplastin, CD142, Coagulation Factor III)

Tissue factor, also known as *tissue thromboplastin*, *CD142*, and *coagulation factor III*, is a transmembrane protein that functions as a nonenzymatic cofactor for factor VIIa in the extrinsic tenase complex. In the absence of injury or stimulus, tissue factor is not ordinarily expressed on cellular surfaces in direct contact with circulating blood. Presentation of tissue factor to the circulation is the event that triggers the procoagulant primary pathway of coagulation (Fig. 21.1). There are no known

mutations or deficiencies of human tissue factor, leading to the speculation that tissue factor is essential for life. In mice, inactivation of the tissue factor gene to create homozygous tissue factor–null mice proves to be lethal during embryonic development ([426], [637], [638], [639] and [640]).

GENE STRUCTURE AND EXPRESSION The tissue factor gene is located on chromosome 1p21-22 ([642], [643]) and spans 12.4 kb (Table 21.2). The gene contains five introns and six exons ([644]). Tissue factor expression can be induced in a number of cultured cell types. Fibroblasts express tissue factor on exposure to serum or mitogenic cytokines ([645], [646]) as do vascular smooth muscle cells and keratinocytes ([647], [648]). Monocytic cells and monocytes isolated from peripheral blood also express tissue factor when stimulated by bacterial endotoxin or other proinflammatory agents ([647], [648]). The presence of these cells may be associated with DIC ([649]). *In vitro*, certain leukemic cell lines constitutively express low levels of tissue factor ([650], [651] and [652]). Tissue factor expression by circulating and nonvascular cells plays key roles in cancer, sepsis, and, perhaps, atherosclerotic plaque formation ([56], [653], [654], [655], [656] and [657]). However, tissue factor in the endothelial cell layer is proposed to trigger coagulation on exposure to the circulation. Cultured vascular endothelial cells express tissue factor on stimulation by IL-1, tumor necrosis factor (TNF)-a, and bacterial endotoxin ([647], [648]). *In vivo*, there is little or no detectable tissue factor expression on unstimulated endothelial cells. Certain conditions such as sepsis, placental villitis, and graft rejection induce tissue factor expression on endothelial cells *in vivo* ([649], [658], [659] and [660]). The mechanism governing tissue factor expression under nonpathologic conditions is presently unknown. Studies of transcriptional control of tissue factor expression in various cell lines have demonstrated that Sp1 sites are important in basal transcription of the tissue factor gene. EGR-1, activation peptide-1, and NF-?ß sites mediate tissue factor expression in response to pathologic stimulation ([640], [661], [662], [663], [664] and [665]).

BIOCHEMISTRY Tissue factor is a single-chain glycoprotein [M_r = 44,000 ([666])] of 261 or 263 amino acids (Table 21.1). It is synthesized with a signal peptide of 32 amino acids. The variability in protein size is due to heterogeneity at the NH_2-terminus ([642], [667], [668]). Tissue factor is a member of the class 2 cytokine receptor superfamily ([669]) and a type I integral membrane protein. The type I designation refers to the location of the NH_2- and COOH-termini. The NH_2-terminus of tissue factor (residues 1 to 219) is extracellular, whereas the COOH-terminus of the protein is intracellular (residues 243 to 263). Tissue factor also contains a hydrophobic membrane-spanning domain (residues 220 to 242) (Fig. 21.9). This domain appears to function solely to anchor tissue factor in the membrane ([670]). The NH_2-terminal domain of tissue factor is composed of two fibronectin type III domains and is glycosylated at Asn^{11}, Asn^{124}, and Asn^{137} ([671]). X-ray crystal structures of tissue factor show that the two fibronectin type III domains are joined at an angle of approximately 120 degrees ([672], [673], [674], [675], [676] and [677]). There are also two disulfide bonds (Cys^{49}-Cys^{57} and Cys^{186}-Cys^{209}) in the NH_2-terminal extracellular region ([678]). At least one of the disulfide bonds is required for tissue factor activity. Glycosylation does not appear to play a key role in determining protein function ([671], [679], [680]). The COOH-terminal cytoplasmic domain is quite short and contains a single cysteine residue (Cys^{245}) that is linked to a palmitate or stearate fatty acyl chain via a thioester bond ([678]). The COOH-terminus also contains a serine that may be phosphorylated ([681]). The function of the COOH-terminus and the importance of these two modifications are not clear, as deletion of this domain has no significant effect on tissue factor procoagulant activity ([670]).

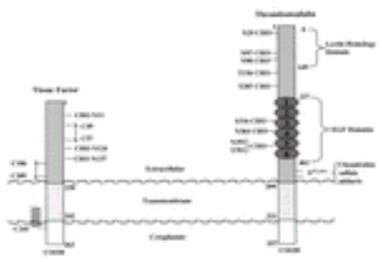

Figure 21.9. Transmembrane cofactors. Tissue factor is composed of an extracellular domain (residues 1 to 219), a transmembrane domain (residues 220 to 242), and a cytoplasmic domain (residues 243 to 263). Two disulfide bonds (S-S) and the sites of the three carbohydrate moieties (CHO) are identified by amino acid residue. One cysteine (C^{245}) contains a thiol ester linkage to a fatty acid. Tissue factor is the cofactor for factor VIIa in the extrinsic tenase complex and is exposed on the subendothelial surface after injury. Thrombomodulin is an endothelial cell-surface glycoprotein composed of five distinct domains. The domain structures include a lectinlike domain (residues 6 to 149), a domain containing six epidermal growth factor (EGF)–like regions (residues 227 to 462), a small extracellular domain rich in threonine and serine residues (two, S^{472} and S^{474}, have been identified as sites of chondroitin sulfate adducts), a membrane-spanning region (residues 499 to 521), and a cytoplasmic tail (residues 522 to 557). There are nine known glycosylation sites (CHO) on the thrombomodulin molecule. Thrombomodulin functions as the cofactor in the protein Case complex and assists in the generation of activated protein C.

FUNCTION The nonenzymatic cofactor tissue factor can bind either factor VII or factor VIIa in a Ca^{2+}-dependent manner and form a high-affinity 1:1 complex. Once bound to tissue factor, the zymogen factor VII is rapidly converted to an active enzyme via limited proteolysis ([682]). The tissue factor–factor VIIa or extrinsic tenase complex activates factor IX and factor X. When tissue factor is exposed or expressed, or both, subsequent to vascular perturbation, low levels of circulating factor VIIa bind to tissue factor, and the extrinsic tenase triggers the procoagulant cascade. Factor VII bound to tissue factor is converted to factor VIIa, augmenting factor IXa and Xa generation. The primary role of the complex is to provide factor IXa and low levels of factor Xa, which serve to promote factor IXa production ([61], [62], [63] and [64]) and to directly catalyze the conversion of trace amounts of prothrombin to thrombin. In the absence of tissue factor, factor VIIa is relatively inert. Once bound to tissue factor, the catalytic activity of factor VIIa is increased 20- to 100-fold depending on the substrate ([444], [683], [684] and [685]). Tissue factor alters the active site of factor VIIa, thus functioning as an allosteric activator of the enzyme. Although the cofactor is necessary for enzymatic activity, complex formation between tissue factor and factor VIIa does not share the same requirements for an anionic phospholipid membrane surface as the other procoagulant complexes. The membrane dependency of the extrinsic tenase complex arises from membrane-mediated substrate delivery. Both factors X and IX bind to anionic membrane surfaces for efficient two-dimensional transfer to the extrinsic tenase.

REGULATION Tissue factor is regulated through availability. The common accepted source of functional tissue factor is through exposure of the subendothelium on vascular damage. However, there is controversy regarding the source and presentation of active tissue factor and whether functional tissue factor circulates in blood ([686], [687], [688], [689] and [690]). Once the tissue factor–factor VIIa complex is formed in the vicinity of an injury, the extrinsic tenase activity is then modulated by TFPI and antithrombin-III reduction of enzymatic activity.

Factor VIII (Antihemophilic Factor, Factor VIII:Antigen, Factor VIII:Coagulant)

Factor VIII, or *antihemophilic factor*, is a nonenzymatic procofactor that circulates in plasma in complex with the large multi-meric protein vWF. Initially, factor VIII and vWF were thought to be a single entity, and early reports on factor VIII were actually measuring facets of vWF structure and function. The factor VIII protein is designated as *factor VIII:Ag* (antigen; VIII:Ag is vWF), and its procoagulant function is designated *factor VIII:C* (coagulant) ([691]). Factor VIII circulates at an average concentration of 0.2 µg/ml (0.7 nmol/L) (Table 21.1). The ratio of factor VIII to vWF is fairly constant and in the range of 1 molecule of factor VIII to 50 to 100 molecules of vWF monomeric units ([692], [693]). vWF acts to regulate the plasma concentration of factor VIII. 1-Deamino-8-D-arginine vasopressin administration elicits an increase in the plasma concentration of vWF and, in turn, increases the plasma level of factor VIII ([694]). vWF also stabilizes factor VIII in plasma. Factor VIII in complex with vWF has a plasma $t_{1/2}$ of approximately 12 hours, whereas factor VIII alone undergoes rapid clearance and has a $t_{1/2}$ of approximately 2 hours ([695], [696], [697] and [698]). Deficiency of factor VIII, or hemophilia A, is a well-characterized X-linked bleeding disorder. Hemophilia A, therefore, occurs almost exclusively in males and occurs at a frequency of 1:5000 to 1:10,000 males. Females with one abnormal factor VIII gene are unaffected carriers. The severity of bleeding in hemophilia A patients is correlated with the level of functional factor VIII in plasma ([31], [699]). Approximately 50 to 60% of hemophilia A cases are severe with factor VIII coagulant activity less than 1% of normal. Severe hemophilia A is manifested in frequent episodes of spontaneous bleeding into joints, muscles, and internal organs. Factor VIII coagulant activity in the range of 1 to 5% of normal (25 to 30% of patients) results in moderate hemophilia A. In the moderate form, abnormal bleeding is generally linked to any trauma, including minor injury. The remaining patients have 6 to 30% of normal factor VIII activity and exhibit mild hemophilia A. In the mild form, factor VIII deficiency results in bleeding events only subsequent to significant trauma or surgery ([700]).

GENE STRUCTURE AND EXPRESSION The factor VIII gene has been mapped to the long arm of the X chromosome in band q28 ([701], [702], [703], [704] and [705]). The factor VIII gene is 186 kb in length and contains 25 introns and 26 exons ([6], [703], [706]). The liver and spleen are thought to be the primary sites of factor VIII biosynthesis ([707], [708], [709], [710], [711], [712] and [713]), although factor VIII mRNA has been detected in other cell types as well ([713]).

BIOCHEMISTRY Human factor VIII has a relative molecular weight in the range of 280,000 (Table 21.1). The heterogeneity in molecular weight is due to proteolysis of the protein in circulation or processing, or both. It is a glycoprotein of 2351 amino acids that is synthesized as a precursor molecule with a 19–amino acid signal peptide ([6], [714]). The sequence of factor VIII is highly homologous to factor V ([715]). The procofactors factor VIII and factor V are organized into discreet structural domains. The NH_2-terminal heavy chains of both proteins contain the A1 and A2 domains (Fig. 21.10). The COOH-terminal light chains contain the A3, C1, and C2 domains. The heavy and light chains are separated by the B domain. The three A domains of factor VIII are homologous to each other and to the A domains of factor

V and ceruloplasmin ([714], [715] and [716]). The C domains of factor VIII share similar intra- and interprotein homology. The C domains of factor VIII are homologous to each other and to the C domains of factor V. The C domains are also homologous to milk fat globule protein and the A-, C-, and D-chains of discoidin 1 ([717], [718]). The B domain of factor VIII is not homologous to the factor V B domain, nor do the B domains of either protein share homology with any known proteins.

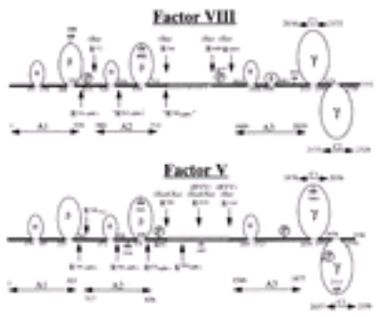

Figure 21.10. Soluble cofactor domain structures (factor VIII and factor V). The disulfide loop structures of factor VIII and factor V defining the a, ß, and ? loops are illustrated as bubbles. a-Thrombin (IIa), activated protein C (APC), factor Xa, and Russell viper venom (RVV) cleavage sites are shown with vertical arrows. The linear domain structures (A1-A2-A3-C1-C2) are illustrated with horizontal arrows bracketed by the beginning and ending amino acid number. The B regions (factor V, residues 710 to 1545; factor VIII, residues 741 to 1649) are represented by the crosshatched regions. Phosphorylation sites are illustrated by a P inscribed in a circle and the phosphoamino acid, serine (S) or threonine (T), illustrated above or below it. Free cysteine thiols are represented by SH and identified by residue number.

The factor VIII molecule is secreted as a two-chain heterodimer as a result of intracellular proteolysis at the B-A3 junction (Arg ^{1649}). Additional cleavages within the B-chain yield A1-A2-B fragments that are variable in length ([719], [720] and [721]). The B domain (residues 741 to 1649) contains 18 of the 25 potential N-linked glycosylation sites in factor VIII and is highly glycosylated. The murine factor VIII B-chain is also heavily glycosylated, suggesting that glycosylation of the B-chain may be important for protein expression or function, or both ([722]). The B domains of factor VIII and factor V are excised during activation of the proteins to generate the cofactor molecules factor VIIIa and factor Va. Factor VIII shares homology with the copper ion (Cu^{+1})–binding protein ceruloplasmin and contains a Cu^{+1}-binding site in the A1 domain ([723], [724]). This site is important for protein function. A similar Cu^{+1}-binding site in the A3 domain does not appear to play a role in protein function. Factor VIII also contains binding sites for vWF, anionic phospholipids, factor IXa, and, potentially, factor X. Factor VIII interaction with vWF requires the NH_2- and COOH-termini of the factor VIII light chain (A3, C1, and C2 domains), although a specific vWF-binding site has been identified between residues 1673 to 1684 on the light chain ([692], [725], [726] and [727]). The vWF-binding site is removed from the factor VIII protein by a-thrombin cleavage at Arg ^{1689}. A phospholipid binding domain is located on the factor VIII C2 domain between residues 2303 to 2332 ([728]). High-affinity factor IXa binding is mediated by the light chain of the factor VIII molecule. The A3 domain contains a high-affinity site for factor IXa localized between residues Glu ^{1811} to Lys ^{1818} ([729], [730]). Residues 552 to 565 in the A2 domain of the factor VIII heavy chain may also play a role in factor VIII interaction with factor IXa ([731], [732], [733] and [734]). Mutations within this region have been documented in the hemophilia A mutation database ([735]). Specifically, Ser558Phe, Val559Ala, Asp560Ala, and Gln565Arg have been described as CRM+ with defective activity resulting in mild hemophilia A. These residues have been shown to be essential for the catalytic efficiency of the factor VIIIa–factor IXa complex while not affecting the binding affinity between the two species ([736]). A model of factor VIII based on the x-ray crystal structure of ceruloplasmin has been used to examine structure/function relationships in the factor VIII molecule ([546], [737]). Based on homology between factor VIII and ceruloplasmin, the factor IXa binding sites in the A2 and A3 domains are likely located in close proximity on the same side of the factor VIII molecule. A factor X binding site may exist on the COOH-terminus of the factor VIII A1 domain ([738], [739]). Factor VIII also contains several tyrosine residues modified by addition of sulfate ([740]). The tyrosine sulfate residues enhance a-thrombin cleavage of the procofactor ([741]). In addition, factor VIII contains biantennary complex-type sugar chains with blood group A or H, or both, determinants ([742]).

FUNCTION The procofactor factor VIII is activated by a-thrombin to generate the cofactor factor VIIIa. Activation by a-thrombin involves cleavages at Arg ^{372} (the A1-A2 junction), Arg ^{740} (the A2-B junction), and Arg ^{1689} in the light chain (Fig. 21.10). The resulting molecule contains three separate polypeptide chains: a light-chain region (A3-C1-C2) bound to the NH_2 region of the heavy chain (A1) in a Ca^{2+}-dependent manner and the noncovalently associated A2 region of the heavy chain. Once formed, the cofactor factor VIIIa binds its serine protease enzyme factor IXa to form the Ca^{2+}- and membrane-dependent complex, the intrinsic tenase (Fig. 21.4). This complex is homologous to the prothrombinase complex. The intrinsic tenase complex catalyzes factor X conversion to factor Xa at a rate several orders of magnitude greater than the enzyme factor IXa alone ([743]). Factor Xa generated via the intrinsic tenase complex (factor IXa–factor VIIIa–Ca^{2+}–membrane) yields the propagation phase of thrombin generation by raising the factor Xa concentration approximately 100-fold over that achieved by the extrinsic tenase complex (Fig. 21.7B) ([524]). Without formation of the intrinsic complex, as occurs in a situation like that of hemophilia A or B, factor Xa is not generated in levels sufficient to produce the propagation phase of thrombin generation (Fig. 21.7A) ([418], [525], [526]). Like the prothrombinase complex, the cofactor (factor VIIIa) interaction with the enzyme (factor IXa) in the presence of divalent cations and an anionic phospholipid surface is a high-affinity interaction with a K_d of 2 nmol/L. The interaction of factor IXa with phospholipid in the absence of its cofactor is of approximately 100-fold lower affinity ([744], [745]).

REGULATION Factor VIIIa function is primarily regulated by dissociation of a fragment (residues 373 to 740) containing the A2 subunit from the heterotrimer. Once the A2 subunit is displaced, factor VIIIa loses all cofactor function. Dissociation is spontaneous and occurs rapidly under physiologic conditions. Factor IXa stabilizes factor VIIIa, delaying dissociation of the heterotrimer and prolonging the transient activity of factor VIIIa ([746], [747]). Factor VIIIa is also regulated by limited proteolysis. Factor IXa cleaves the factor VIIIa A1 subunit at Arg ^{336} and eliminates factor VIIIa function ([747], [748] and [749]). In addition to factor IXa, the A1 subunit of factor VIIIa is cleaved by factor Xa and a-thrombin ([8], [740], [747], [750]). APC is a key anticoagulant enzyme that likewise cleaves the A1 subunit at Arg ^{336}. APC also cleaves the factor VIIIa A2 subunit at Arg ^{562} ([8], [751]). The APC cleavages occur sequentially with the A1 cleavage first and the A2 cleavage second ([752]). Factor IXa protects factor VIIIa from APC cleavage at Arg ^{562}; however, protein S blocks the protective effect ([753]). Although factor VIIIa is proteolytically inactivated by a number of enzymes, spontaneous dissociation is the key regulator of cofactor function.

Factor V (Labile Factor)

Factor V was first recognized as an unstable plasma component necessary for the generation of a-thrombin ([590]). *Factor V* is a large single-chain glycoprotein that circulates in plasma at an average concentration of 6.6 µg/ml (20 nmol/L) (Table 21.1). Factor V is also contained in the a-granules of human platelets, with approximately 18 to 25% of the total factor V present in platelets ([754]). A recent review by Mann and Kalafatis discusses the identification, role in coagulation, and overall importance of factor V in hemostasis ([755]).

Congenital factor V deficiency, or *parahemophilia*, is an extremely rare disorder inherited in an autosomal-recessive manner. Patients can exhibit severe bleeding diatheses. Although complete lack of factor V in humans does not appear to be lethal, factor V–deficient mice experience fatal hemorrhage *in utero* ([756]). Combined deficiencies of factor V and factor VIII have also been observed. Interestingly, combined cofactor deficiencies occur more commonly than factor V deficiency alone ([757]). Recently, the gene for ERGIC-53, a calcium-dependent lectin that serves as a glycoprotein-sorting receptor between the endoplasmic reticulum and the Golgi complex, has been linked to combined factor V and factor VIII deficiency ([758]). Mutations in this gene in patients with combined hemophilia have been described. Factor V deficiency becomes even more complex when platelet factor V is taken into consideration. Patients have been identified with normal functional levels of plasma factor V but deficiencies of platelet factor V that result in bleeding disorders ([759], [760], [761] and [762]). Lack of platelet a-granules and their contents in storage pool disorders leads to deficiency of platelet factor V ([760], [761]). Factor V^{Quebec} is an autosomal-dominant bleeding disorder characterized by mild thrombocytopenia, normal levels of plasma factor V, and degraded platelet factor V with very low activity ([759], [762]). A database on factor V mutation has been compiled by Dr. Hans L. Vos (Hemostasis and Thrombosis Research Center, Leiden University Medical Center, Leiden, The Netherlands; e-mail: h.l.vos@lumc.nl) and is available on request.

GENE STRUCTURE AND EXPRESSION The human factor V gene is located on chromosome 1 bands q21-q25 ([763]) (Table 21.2). The gene spans approximately 80 kb and consists of 24 introns and 25 exons. Transcription and processing yield an mRNA species of 6.8 kb. The intron-exon structure of the factor V and factor VIII genes are quite similar, and the genes likely evolved from a common ancestor. The liver appears to be the primary site of factor V biosynthesis ([715], [764], [765]). Human megakaryocytes express factor V as well ([766], [767] and [768]). Platelet factor V may be derived from circulating plasma factor V ([769], [770]); however, the source of platelet factor V has not been definitively determined ([771]). Bovine aortic endothelial cells ([772]) and vascular smooth muscle cells ([773]) also have been reported to express factor V.

BIOCHEMISTRY Human factor V [M_r = 330,000 ([774], [775], [776] and [777])] is a single-chain glycoprotein of 2196 amino acids derived from a precursor molecule with an amino acid signal peptide (Table 21.1 and Fig. 21.10). Factor V consists of an NH_2-terminal heavy chain (residues 1 to 709: A1-A2 domains), a central B domain

(residues 710 to 1545), and a COOH-terminal light chain (residues 1546 to 2196: A3-C1-C2 domains). The A domains are homologous to those found in FVIII and plasma ceruloplasmin; the C domains are homologous to the slime mold protein discoidin ([778]). Like factor VIII and ceruloplasmin, factor V is also a copper-binding protein ([779]). Factor V undergoes extensive posttranslational modification, including phosphorylation, sulfation, glycosylation, and formation of mixed disulfides between its five free cysteine residues and circulating thiols like cysteine and homocysteine ([780]). Phosphorylation occurs at sites in the heavy chain, B region, and light chain. Phosphorylation at Ser ^{692} affects the rate of inactivation of factor Va by APC ([781]). Factor V is sulfated at a number of sites in the heavy chain (Tyr ^{665}, Tyr ^{696}, and Tyr ^{698}), the B region (Tyr ^{1494}, Tyr ^{1510}, and Tyr ^{1515}) and the light chain (Tyr ^{1565}). The sulfation status of factor V has been related to its function ([782] , [783]). Carbohydrate accounts for 13 to 25% of the mass of factor V ([784]). The heavy chain has nine potential N-linked glycosylation sites. In the B region, 25 asparagine residues are candidates for modification with carbohydrate; carbohydrate accounts for approximately 50% of the mass of the B region. The light chain of factor V has three N-linked glycosylation sites. Differential glycosylation of Asn ^{2182} in the C2 domain is reported to be responsible for the factor V1 and factor V2 variants observed in plasma. The two variants have slightly different molecular masses and charges ([785]). Factors Va1 and Va2 are distinguished by functional differences as well. Factor Va1 does not appear to bind to anionic phospholipid as efficiently as factor Va2 and is not as competent a cofactor in the prothrombin-ase complex as factor Va2 ([784] , [786] , [787] and [788]). The presence of an oligosaccharide at Asn ^{2182} apparently reduces the affinity of factor Va1 for the phospholipid surface and interferes with prothrombinase complex assembly and function. The COOH-terminal fragment of the factor Va light chain (residues 1753 to 2183) that contains the Asn ^{2182} glycosylation site is one of the two regions that mediate membrane association ([789]).

ACTIVATION The procofactor factor V does not bind factor Xa and is essentially completely inactive ([42]). Limited proteolysis of the factor V molecule yields the active cofactor factor Va. Factor Va functions as both factor Xa receptor and positive modulator of factor Xa catalytic potential in the prothrombinase complex. Rate enhancements of 300,000-fold derive from the participation of factor Va in the process of factor Xa activation of prothrombin. a-Thrombin is the primary catalyst of factor V activation *in vivo*. a-Thrombin cleaves factor V at Arg ^{709}, Arg ^{1018}, and Arg ^{1545} ([778]) (Fig. 21.10). The a-thrombin–generated form of factor Va is a heterodimer consisting of an NH_2-terminal heavy chain [M_r = 105,000 (A1-A2 domains)] linked noncovalently to a COOH-terminal light chain [M_r = 73,000 (A3-C1-C2 domains)] ([776] , [790] , [791] , [792] and [793]). The association of the heavy and light chains of factor Va shows a divalent cation dependence. The B domain is excised during proteolysis ([12] , [790] , [792]). Factor Xa cleaves factor V at Arg ^{709}, Arg ^{1018}, and Arg ^{1545}, producing a factor Va molecule similar to the factor Va produced by a-thrombin cleavage ([568] , [794]). Factor Xa cleavage of factor V is less efficient than a-thrombin cleavage ([568] , [794]), although factor V released from stimulated platelets is partially activated and is more efficiently cleaved by factor Xa than plasma factor V ([795]). Other enzymes may also activate or partially activate factor V. Platelet calpain ([796]), cathepsin G, and human neutrophil elastase ([797] , [798]) partially activate factor V. The fibrinolytic enzyme plasmin both activates and inactivates factor V ([799] , [800] and [801]). Plasmin cleavage and inactivation of factor V are hypothesized to play a role in hemorrhage subsequent to thrombolytic therapy by decreasing the level of factor Va cofactor activity ([802]).

FUNCTION Activation of the procofactor factor V yields the functional form factor Va. Factor Va acts as a cofactor for the serine protease factor Xa in the prothrombinase complex. Factor Va forms at least part of the receptor for factor Xa on platelets and serves to anchor factor Xa to the membrane surface ([755]). Factor Va stabilizes the prothrombinase complex and enhances prothrombin activation ([21] , [622]).

FACTOR VA REGULATION AND FACTOR V LEIDEN Factor Va is regulated by proteolytic inactivation by APC. An anionic membrane surface is required for complete cleavage and full inactivation of the cofactor; in the absence of phospholipid, factor Va cleavage is not complete, and the cofactor retains some activity. Protein S, a suggested cofactor for APC, only functions in the presence of a phospholipid bilayer as well. In the presence of a membrane surface, APC cleaves factor Va sequentially at three sites: Arg ^{506}, Arg ^{306}, and Arg ^{679}. Factor Va is initially cleaved at Arg ^{506}. Subsequently, the membrane-dependent cleavage at Arg ^{306} results in complete loss of factor Va cofactor activity. An additional APC-mediated cleavage of factor Va fragments occurs at Arg ^{679}. Loss of cofactor activity coincides with dissociation of the A2 domain of APC-cleaved factor Va in a process similar to the spontaneous dissociation of factor VIIIa ([803] , [804]). The importance of this regulatory mechanism is demonstrated by the “APC resistance” syndrome associated with factor V ^{Leiden} ([805]). Individuals with factor V ^{Leiden} have a G to A substitution at nucleotide 1691 in the factor V gene that results in an Arg ^{506}?Gln mutation at the protein level ([806]). Factor Va ^{Leiden} has normal cofactor activity as part of the prothrombinase complex. However, unlike normal factor Va, factor Va ^{Leiden} is not readily inactivated by APC. The Arg ^{506}?Gln mutation hinders the first step in the sequential series of inactivating cleavages by APC. Factor Va ^{Leiden} retains cofactor activity and continues to promote a-thrombin generation for an extended period of time. Inactivation of factor Va ^{Leiden} by cleavage of the Arg ^{306} bond occurs eventually but is markedly slower than normal factor Va ([807]). The prevalence of the factor V ^{Leiden} mutation is approximately 5% in whites ([808]). Individuals heterozygous for factor V ^{Leiden} have a sevenfold greater risk of thrombosis than normal individuals, whereas individuals homozygous for factor V ^{Leiden} have an 80-fold greater risk of thrombosis ([809]). The risk of thrombosis in individuals with factor V ^{Leiden} is also exacerbated by other genetic and acquired risk factors such as protein C or protein S deficiency, or both, and use of oral contraceptives ([755]). The effects of factor V ^{Leiden} are of considerable interest, as factor V ^{Leiden} is the most common prothrombotic risk factor yet identified ([810] , [811] and [812]).

von Willebrand Factor (von Willebrand Factor:Antigen, Ristocetin Cofactor, von Willebrand Factor Ristocetin:Cofactor)

vWF is a multifunctional protein with several key roles in coagulation. vWF circulates in plasma at an average concentration of 10 µg/ml ([813]) (Table 21.1) and is also contained in the a-granules of human platelets ([814]). However, ABO blood type has a significant influence on vWF levels, with individuals of types A, B, or AB blood having much higher levels of vWF than individuals with type O blood ([815] , [816]). vWF is also known for its role in ristocetin-induced platelet aggregation ([817] , [818]), which is the basis of clinical assays. vWF was first recognized as the missing or defective factor in a severe autosomal-dominant bleeding disorder ([819] , [820] , [821] and [822]). von Willebrand disease is fairly common and is estimated to occur in 1 to 2% of the general population ([823] , [824] , [825] and [826]). vWF is also an acute phase reactant, and vWF levels are elevated as a result of stress, pregnancy, or surgical trauma ([827] , [828] , [829] and [830]).

GENE STRUCTURE AND EXPRESSION The vWF gene is located on chromosome 12 band 12p-12pter and is 178 kb long with 51 introns and 52 exons ([831] , [832] and [833]) (Table 21.2). A pseudogene with approximately 98% homology to the vWF gene has been mapped to chromosome 22 ([832] , [833]). vWF is expressed only by endothelial cells and megakaryocytes ([834] , [835] and [836]). vWF is stored in Weibel-Palade bodies in endothelial cells and in a-granules in platelets ([837] , [838] and [839]). There are several regulatory elements that control vWF expression including GATA-binding consensus sequences in the promoter region ([840]). Endothelial cell–specific expression appears to be regulated by NF1 and Oct-1 binding sites ([837] , [840] , [841] , [842] and [843]). vWF expression is also regulated by complex signaling pathways that are directed by specific cellular environments ([841] , [844] , [845] and [846]). In addition, vWF plasma levels can be regulated through release of vWF from endothelial cell and platelet storage compartments. Platelet activation results in the release of vWF, and endothelial cell vWF release is induced by histamine and 1-deamino-8-D-arginine vasopressin ([847] , [848] and [849]).

BIOCHEMISTRY vWF is a large adhesive glycoprotein that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers. vWF is synthesized as a pre-pro molecule containing a 22–amino acid signal peptide, a propeptide of 741 amino acids, and the mature vWF protein of 2050 amino acids ([850] , [851] , [852] , [853] , [854] and [855]). The pre-pro vWF molecule is comprised of internally repeated A, B, C, and D domains arranged in the sequence D1-D2-D'-D3-A1-A2-A3-D4-B-C1-C2. The A repeats share homology with complement factor B, collagen type IV, chicken cartilage matrix protein, and the I domain of the integrin a-subunit ([856] , [857]). Portions of the C domains are homologous to sequences in procollagen and thrombospondin ([858]). Pre-pro vWF undergoes extensive posttranslational modification to yield the mature vWF protein lacking the D1 and D2 domains. The large vWF propolypeptide copurifies with factor VIII and vWF and is designated *vWF antigen-II*. The mature vWF monomer has a molecular weight of approximately 255,000 based on protein sequence and carbohydrate content ([850] , [851] , [854] , [855] , [859]). The disulfide-linked multimers range in size from dimers (M_r = 600,000) to extremely large multimers of 20 million d. vWF has binding sites for factor VIII, heparin, collagen, platelet glycoprotein (gp) Ib, and platelet gpIIb-IIIa ([860] , [861] , [862] , [863] , [864] , [865] , [866] , [867] , [868] , [869] , [870] , [871] , [872] , [873] and [874]).

FUNCTION vWF has multiple functions in hemostasis. vWF stabilizes factor VIII and protects it from inactivation by APC ([875] , [876]), thus significantly prolonging factor VIII half-life in circulation ([695] , [697] , [698]). vWF is a structural protein and is part of the subendothelial matrix. vWF also acts as a bridge between platelets and promotes platelet aggregation. The primary platelet binding site for vWF is the gpIb-IX-V receptor complex. gpIb-IX-V is an active receptor on unstimulated platelets and serves to promote platelet aggregation and adhesion to vWF in the absence of platelet activation ([373]). This is likely a key element in the procoagulant response serving to recruit and localize platelets to the site of damage before the events that induce platelet activation ([877]). Subsequent platelet activation also induces expression of another receptor complex, gpIIb-IIIa. The gpIIb-IIIa complex recognizes a number of adhesive proteins including vWF. gpIIb-IIIa receptor binding of these adhesive proteins creates a strong network of platelets, other cells, and matrix components. Endothelial cells secrete vWF multimers, which are larger than those found circulating in plasma ([878]). The function of these large multimeric forms of vWF is to bind to and agglutinate blood platelets under high shear rates. These large multimers of vWF are degraded by a specific metalloprotease called *a d*isintegrin-like *a*nd *m*etalloprotease domain with *t*hrombo *s*pondin in type I motifs (ADAMTS)-13 ([879]). In familial and acquired thrombotic thrombocytopenic purpura, ultra-large vWF multimers have been identified and correlated to defective ADAMTS-13 activity ([880] , [881]).

PROCOAGULANT PROTEINS: THROMBIN (FACTOR IIA)

The enzyme a-thrombin, or factor IIa, is the central enzyme in blood coagulation and plays myriad roles in hemostasis as well as additional roles in tissue repair, development, and pathogenic processes ([627], [882], [883], [884], [885] and [886]). a-Thrombin cleaves fibrinogen to generate the fibrin clot ([620], [887], [888] and [889]), converts factor XIII to factor XIIIa to cross-link and stabilize the clot ([14], [890]), and, in association with thrombomodulin, activates TAFI, which delays dissolution of the fibrin clot ([17], [891]). a-Thrombin also acts directly and indirectly to amplify its own production. The procofactors V and VIII are activated by a-thrombin ([622], [623], [715], [892]) as are factor XI ([4]) and, potentially, factor VII ([5]). In an analysis of a whole blood model of coagulation, a time course of thrombin generation and of the protein products of its catalytic activities illustrates that most procoagulant responses to a-thrombin occur during the initiation phase before fibrin formation (Fig. 21.11) ([526]). Less than 0.2% of the final thrombin produced is required to achieve the activation of its primary substrates in blood. After fibrin clot formation, during the propagation phase, the bulk of thrombin is formed (~95%).

In addition, a-thrombin's realm extends to cellular effects. a-Thrombin is the most potent activator of circulating platelets, thus providing the requisite surface for procoagulant activities. The enzyme also acts as a mitogen in a variety of cell types ([625], [626], [627], [628] and [629], [893], [894], [895], [896] and [897]); induces the release of cytokines ([898], [899], [900], [901] and [902]), vasoactive compounds ([903], [904] and [905]), and chemoattractants ([906]) as part of the response to vascular damage; and stimulates events that initiate tissue repair ([907], [908], [909], [910] and [911]).

a-Thrombin likewise acts to indirectly inhibit its own generation through the protein C anticoagulation pathway, a dynamic inhibitory system. a-Thrombin forms the protein Case complex with its cofactor thrombomodulin and activates protein C to APC ([624], [912]). APC cleaves factors Va and VIIIa, thus inhibiting prothrombinase and intrinsic tenase function and blocking a-thrombin formation. The binding of a-thrombin to thrombomodulin both produces a potent anticoagulant and alters a-thrombin reactivity. Once bound to thrombomodulin, a-thrombin no longer recognizes fibrinogen as a substrate and no longer acts in a procoagulant capacity ([913], [914]).

a-Thrombin generation must be tightly regulated to ensure that localized, adequate levels of the enzyme are produced. Markedly decreased levels of a-thrombin due to hypoprothrombinemia or reduced a-thrombin activity due to genetic mutation (dysprothrombinemia) are often characterized by bleeding diatheses ([633], [915]). Conversely, elevated levels of a-thrombin promote the risk of thrombosis. A G?A transition at nucleotide position 20210 (G20210A) in the 3'-untranslated region of the prothrombin gene results in elevated plasma levels of prothrombin ([601]) and is strongly associated with venous thrombotic events ([916], [917], [918] and [919]).

Roles in Coagulation

Most prothrombin activation to a-thrombin proceeds through the obligate intermediate meizothrombin. Both meizothrombin and a-thrombin possess catalytic activity and cleave a variety of substrates. Although meizothrombin is a short-lived intermediate in the activation process, it appears to play several important roles in coagulation. Meizothrombin is a potent vasoactive agent and acts on the adrenergic receptor to induce vascular constriction. The vasoactive potency of meizothrombin is five to seven times greater than that of a-thrombin ([920], [921]). However, the ability of meizothrombin to activate platelets and cleave fibrinogen is greatly reduced compared to that of a-thrombin ([617], [923]). These are major roles for a-thrombin in promoting an efficient and effective procoagulant response. a-Thrombin has long been recognized as the most potent platelet agonist ([621]). a-Thrombin induces release of platelet a-granule contents, including a number of procoagulant and adhesive proteins ([177], [218], [754], [814], [924], [925], [926], [927], [928], [929], [930] and [931]), and of adenosine diphosphate from the platelet dense granules. a-Thrombin also triggers the translocation of anionic phospholipid to the outer leaflet of the platelet membrane. a-Thrombin thus provides a cross-linked platelet mesh and an anionic surface appropriate for procoagulant complex assembly and function.

In addition, a-thrombin generates and stabilizes the fibrin clot. a-Thrombin cleaves the Arg ^{16}-Gly ^{17} bond in the Aa-chain and the Arg ^{14}-Gly ^{15} bond in the Bß-chain of fibrinogen releasing fibrinopeptide A (FPA) and fibrinopeptide B (FPB), respectively ([620]). FPA and FPB release allow formation of overlapping fibrin strands ([887], [888] and [889]). a-Thrombin cleavage of the 37-residue NH $_2$-terminal activation peptide of factor XIII generates the transglutaminase factor XIIIa ([14], [890]). Factor XIIIa cross-links and stabilizes the fibrin clot by catalyzing the formation of intermolecular ?-glutamyl e-lysyl isopeptide bonds between fibrin molecules ([14]). TAFI, also known as *plasma carboxypeptidase B* or *carboxypeptidase U*, is likewise activated in an a-thrombin–dependent manner to provide activated TAFI (TAFIa) ([17], [891]). TAFIa has carboxypeptidase B–like activity and is a key link between the coagulation and fibrinolytic cascades. TAFIa prevents premature clot lysis by cleaving COOH-terminal lysine and arginine residues on fibrin, rendering it a less suitable cofactor in t-PA–dependent plasminogen activation ([932]). At elevated concentrations, TAFIa also directly inhibits plasmin and therefore clot lysis ([932]). In addition, TAFI is a substrate for factor XIIIa and is cross-linked to fibrin and incorporated into the fibrin clot ([933]). The a-thrombin–dependent processes involved in clot formation and stabilization likely occur simultaneously to generate a mature clot that effectively alleviates blood loss ([934]).

a-Thrombin has other key roles in procoagulant events as well. a-Thrombin activates factor XI ([4], [566]) and the procofactors factor V, factor VIII ([622], [623], [715], [892]), and, potentially, factor VII ([5]). Meizothrombin likewise is an efficient activator of factor XI ([935]) and possibly factor V ([936]). Meizothrombin is thought to function to enhance a-thrombin generation by activating factor XI before its final processing to form a-thrombin.

Roles in Anticoagulation

Although a-thrombin is the central enzyme in the procoagulant response, it is also a key mediator of anticoagulant events as well. When a-thrombin binds to the cell membrane–associated cofactor thrombomodulin, the reactivity of a-thrombin is altered. a-Thrombin bound to thrombomodulin no longer cleaves fibrinogen or acts as a procoagulant enzyme ([913], [914]). Instead, the a-thrombin–thrombomodulin complex, or protein Case, cleaves protein C to generate the enzyme APC. APC is a potent anticoagulant and inactivates the cofactors factor Va and factor VIIIa ([913], [937]). a-Thrombin activation of platelets also induces the release of anticoagulant and inhibitory proteins from the a-granules ([282], [938], [939] and [940]).

Roles in Tissue Repair and Regeneration

Tissue repair and regeneration is the final phase of the hemostatic response to injury. Subsequent to lysis of the fibrin clot, multiple cell types choreograph the restructuring of the damaged vasculature. Vascular permeability is increased, and inflammatory cells accumulate at the site of injury. Smooth muscle cells, fibroblasts, and endothelial cells migrate to the site and proliferate. Cellular differentiation, as well as production and remodeling of the extracellular matrix, restores the vascular tissue. a-Thrombin contributes to these processes through a variety of interactions with different cell types. a-Thrombin is a potent mitogen ([625], [893], [894], [895] and [896], [941]) and stimulates proliferation of smooth muscle cells ([628], [897], [941]), macrophages ([627]), and endothelial cells ([627], [629]). The mitogenic effects of a-thrombin are due to direct activation of cellular proliferation or a-thrombin–induced secretion of a variety of growth factors, or both. Platelet activation, an early event in the procoagulant response, results in the release of a plethora of a-granule proteins that regulate cell growth, vascular permeability, and chemotaxis ([294], [942], [943], [944], [945], [946], [947], [948] and [949]). a-Thrombin thus mediates multiple aspects of the hemostatic response to vascular injury from the formation and stabilization of the initial fibrin plug to the final stages of tissue repair and regeneration.

Thrombin Receptors

Many of the effects of a-thrombin on platelets and cells are elicited through a-thrombin interaction with receptor molecules in which a-thrombin binds to a receptor and initiates a signal transduction mechanism. The interaction between a-thrombin and the human platelet thrombin receptor, protease-activated receptor (PAR)-1, however, is characterized by a more unusual mechanism in which the receptor is also a substrate for a-thrombin ([911], [950], [951]). PAR-1 is a 425–amino acid transmembrane protein with a large NH $_2$-terminal extracellular domain ([911], [951]). a-Thrombin cleaves the extracellular region of the receptor at Arg ^{41}, producing a “tethered ligand.” The new NH $_2$-terminus binds back to and activates the receptor ([911], [951]). PAR-1 is also found on T lymphocytes, monocytes, and endothelial cells and mediates the a-thrombin–induced responses of these cells as well.

Two additional a-thrombin receptors homologous to PAR-1 have also been identified: PAR-3 and PAR-4. PAR-3 is expressed on human platelets and endothelial

cells—although at much lower levels than PAR-1 (952). PAR-3 is required for normal a-thrombin–dependent platelet activation in mice (677), but in the human system, the role of PAR-3 appears to be primarily in cellular development. PAR-3 is expressed at high levels on human megakaryocytes, the precursor cells of platelets (677). PAR-4, however, is believed to act in combination with PAR-1 as a dual mechanism to elicit the multiple effects of a-thrombin on human platelets.

Structure/Function Relationships

In vivo, a-thrombin is derived from proteolytic cleavage of prothrombin by the prothrombinase complex (Fig. 21.3 and Fig. 21.8). Cleavage of the Arg ^{320}-Ile ^{321} bond in prothrombin yields meizothrombin. Subsequent cleavage of the Arg ^{271}-Thr ^{272} bond gives rise to fragment 1.2 and a-thrombin. Human a-thrombin cleaves its own NH_2-terminus at Arg ^{284}-Thr ^{285} to generate a stable a-thrombin molecule. The initial form of human a-thrombin has an NH_2-terminal A-chain of 49 residues, whereas the autocatalytically generated stable protein has an A-chain of 36 residues. The COOH-terminal B-chain of a-thrombin has 259 amino acid residues including the catalytic triad residues His ^{363}, Asp ^{419}, and Ser ^{525}.

a-Thrombin is subject to further degradation resulting in stable, degraded thrombin molecules with reduced reactivity (953 , 954 and 955). These degraded forms are designated ß- and ?-thrombin. The degradation of a-thrombin may be autocatalytic or may be due to proteolysis by enzymes other than a-thrombin. Human ß-thrombin is generated by cleavage at Arg ^{382} and Arg ^{393}, which deletes a segment of the a-thrombin B-chain (956 , 957). Cleavage of ß-thrombin at Arg ^{443} and Lys ^{474} deletes an additional segment of the B-chain and results in formation of ?-thrombin. ß- and ?-thrombin retain some activity toward small peptide substrates (921 , 958), factor XIII (959), antithrombin-III (960), and prothrombin (961). However, both ß- and ?-thrombin have no significant ability to cleave fibrinogen or protein C (585 , 960 , 962 , 963). These proteolyzed forms of a-thrombin have been identified as products of the blood clotting reaction *in vivo* (964), but their mechanism of production and function is unknown.

The stable form of human a-thrombin possesses at least five distinct binding sites for substrates, inhibitors, cofactors, apolar molecules, and sodium ions (Na^{+1}). The apolar binding site is located near the catalytic center of a-thrombin (965). The Na^{+1} binding site is in the B-chain in a cavity formed by three antiparallel ß sheets and appears to play a role in determining whether a-thrombin acts as a procoagulant or an anticoagulant. In the presence of Na^{+1}, a-thrombin recognizes fibrinogen as a substrate and acts as a procoagulant. In the absence of Na^{+1}, a-thrombin has increased specificity for protein C and functions in an anticoagulant capacity (966 , 967). The binding of Na^{+1} therefore appears to mediate the dual nature of a-thrombin as both a procoagulant and an anticoagulant.

Exosite I, the fibrinogen binding site, is an anion-binding, electropositive site distinct from, but acting in concert with, the active site of the a-thrombin molecule (967). In addition to fibrinogen, exosite I also recognizes the COOH-terminal domain of hirudin, the hirudinlike region of PAR-1, and the fifth and sixth EGF-like domains of thrombomodulin (967). Detailed information about exosite I is available from the x-ray crystal structure of the a-thrombin–hirudin complex. In solution, the COOH-terminal domain of hirudin is disordered (968 , 969). However, in the a-thrombin–hirudin complex, the COOH-terminus of hirudin inserts into the large groove in the a-thrombin molecule to interact with exosite I. Hirudin also inserts into the active site of a-thrombin (970 , 971 and 972). The high-affinity interaction ($K_d = 2 \times 10^{-14}$ mol/L) between a-thrombin and the inhibitor hirudin is thus stabilized by electrostatic, polar, and hydrophobic interactions (970 , 973).

Exosite II is a second electropositive, anion-binding site located on the opposite side of the a-thrombin molecule compared to exosite I. Exosite II recognizes the COOH-terminal region of the B-chain of thrombin and sulfated polysaccharides such as heparin and the chondroitin sulfate moiety of thrombomodulin (967).

The active site of a-thrombin is responsible for mediating interactions with substrate molecules including fibrinogen, protein C, and antithrombin-III (967). The active site of a-thrombin is similar to the active sites of trypsin and chymotrypsin. However, unlike the relatively nonspecific pancreatic enzymes, a-thrombin also has secondary binding sites, exosites I and II, that confer specificity to a-thrombin. For substrates such as fibrinogen, there may be multiple secondary binding sites (974).

Regulation

a-Thrombin regulates its own production through complex formation with thrombomodulin and activation of protein C (Fig. 21.6). a-Thrombin enzymatic activity is mediated mainly by antithrombin-III. The inhibitory activity of antithrombin-III is potentiated *in vivo* by cell-expressed heparan sulfate GAGs or by pharmaceutical heparins (634 , 635). Antithrombin-III inhibits a-thrombin through formation of a covalent complex with the active site of a-thrombin (975). a-Thrombin–antithrombin-III (TAT) complexes are rapidly cleared from the circulation by the liver (976).

a-Thrombin is also inhibited by a $_2$-macroglobulin, a broad specificity proteinase inhibitor. a $_2$-Macroglobulin does not appear to be a primary inhibitor of a-thrombin but rather functions as a secondary inhibitor (921). Unlike antithrombin-III, a $_2$-macroglobulin does not complex with the active site of its target enzymes. Enzymes in complex with a $_2$-macroglobulin retain the ability to cleave small peptidyl substrates although they are unable to cleave large substrates (977). a-Thrombin interaction with a $_2$-macroglobulin involves limited proteolysis of a $_2$-macroglobulin. Subsequent to cleavage, a $_2$-macroglobulin undergoes a conformation change that traps the enzyme inside the a $_2$-macroglobulin molecule (978 , 979). The a $_2$-macroglobulin–enzyme complexes are rapidly cleared from circulation (980 , 981).

ANTICOAGULANT PROTEINS: DYNAMIC INHIBITORY SYSTEM

The protein C pathway provides a dynamic inhibitory system to regulate a-thrombin production. The activity of this anticoagulant pathway is directly dependent on the level of a-thrombin production. The protein C activating complex, or protein Case, is a membrane-dependent multiprotein complex similar to the membrane-dependent procoagulant complexes (Fig. 21.4 and Fig. 21.6). The key proteins in the protein C pathway are a-thrombin, thrombomodulin, protein C, and protein S.

Protein C

Protein C, first identified as a thrombin inhibitory activity or autoprothrombin II-A (982), is the zymogen form of the enzyme APC. Protein C circulates at a concentration of 4 µg/ml (65 nmol/L) with a $t_{1/2}$ of 8 to 10 hours (983 , 984 and 985) (Table 21.4). The $t_{1/2}$ of protein C is markedly shorter than most other members of the vitamin K–dependent protein family and is the likely basis of the transient hypercoagulable state subsequent to administration of coumarin-based anticoagulants (986 , 987 , 988 , 989 and 990). Homozygous protein C deficiency is associated with severe thrombotic tendencies and can result in fatal neonatal thrombotic events (991). Heterozygous protein C deficiency is associated with increased risk of thrombosis (992 , 993 and 994). The mutation in factor V^{Leiden}, which blocks a key APC cleavage site in factor Va^{Leiden}, is another defect leading to an alteration in the protein C anticoagulant pathway and predisposition to thrombosis.

GENE STRUCTURE AND EXPRESSION The protein C gene is located on chromosome 2 bands q14-q21 and spans 11 kb with eight introns and nine exons (491 , 995 , 996) (Table 21.5). The promoter region contains HNF-1, HNF-3, and Sp1 binding sites that promote gene expression (997 , 998). HNF-3 is a liver-specific transcription factor.

TABLE 21.5. Molecular Genetics of Human Anticoagulant Proteins and Their Inhibitors

Protein	Molecular Weight (d)	Gene Location: Chromosome	Gene Size (kb)	Gene Organization: Number of Exons	mRNA Size (kb)
Protein C	62,000	2q14-q21	11	9	1.8 (1.6)
Protein S	69,000	3	80	15	3.5
Protein Z	62,000	13q34	14	9	—
Thrombomodulin	100,000	20p-12cen	3.7	Intronless	3.7
a $_2$-Macroglobulin	735,000	12p12.3-p13.3	48	36	4.6
Tissue factor pathway inhibitor	40,000	2q31-32.1	85	9	1.4, 4.0
Antithrombin-III	58,000	1q23-q25	13.5	7	1.4

Heparin cofactor II	66,000	22q11	14	5	2.3
a $_1$-Proteinase inhibitor	53,000	14q32.1	5	7	—
C1 esterase inhibitor	104,000	11q11.2-q13	17	8	—
Protein C inhibitor	57,000	14q32.1	11.5	5	—

BIOCHEMISTRY Protein C is synthesized in the liver as a single-chain polypeptide with a pre-pro sequence of 42 amino acids. The pre-pro protein is subsequently processed to remove the leader sequence and the dipeptide Lys ^{156}-Arg ^{157}. Thus, in plasma, most protein C circulates as a heterodimer consisting of a disulfide-linked (Cys ^{141}-Cys ^{277}) heavy and light chain (999, 1000, 1001, 1002, 1003 and 1004). However, approximately 5 to 10% of circulating protein C is the single-chain form (338). The two-chain form of human protein C (M $_r$ = 62,000) is a 419–amino acid glycoprotein with approximately 23% carbohydrate (Table 21.4 and Fig. 21.3B). The NH $_2$-terminal light chain (residues 1 to 155; M $_r$ = 21,000) contains the Gla domain (residues 6 to 29; nine Gla residues) and a hydrophobic region that connects the Gla domain to two EGF domains (residues 55 to 90 and 94 to 134). The COOH-terminal heavy chain (residues 158 to 419; M $_r$ = 41,000) contains the serine protease domain. Residues 158 to 169 constitute the activation peptide domain. A ß-hydroxy aspartate residue (Asp ^{71}) in the first EGF domain is required for Ca $^{2+}$-dependent alterations in protein C. Ca $^{2+}$ binding is mediated by the first EGF domain as well as the Gla domain and the serine protease domain (332, 371, 375, 1006, 1007, 1008, 1009, 1010 and 1011). Leu ^{5} in the NH $_2$-terminus is important in mediating phospholipid binding (373). There are several glycosylation variants (Asn ^{97}, Asn ^{248}, Asn ^{313}, and Asn ^{329}) with two to four N-linked carbohydrate chains (338). The major forms, a-protein C and ß-protein C, have four and three carbohydrate moieties, respectively. All the protein C carbohydrate variants can be activated but appear to have different anticoagulant properties and rates of activation (339).
ACTIVATION Protein C is the zymogen form of the enzyme APC. Protein C is cleaved at the Arg ^{169}–Leu ^{170} bond, releasing its activation peptide from the heavy chain to generate the active enzyme (1012, 1013). The a-thrombin–thrombomodulin complex is likely the major physiologic activator of protein C (1014). There are other activators as well. Plasmin activates and then inactivates protein C (987, 1015). Meizothrombin also binds thrombomodulin and can efficiently activate protein C (617, 1016). Factor Xa has likewise been reported to bind to thrombomodulin and activate protein C (1017); however, this mechanism has not been confirmed in subsequent studies (1018, 1019). Copperhead snake venom also contains a protein C activator (1020).
FUNCTION *APC* is a serine protease with key anticoagulant functions. The most important anticoagulant role for the protein C, or dynamic inhibitory, pathway is the proteolytic inactivation of factor Va. APC inactivates factor Va via a series of proteolytic cleavages, thus inhibiting the generation of a-thrombin. APC also cleaves and inactivates factor VIIIa, although the spontaneous dissociation of the factor VIIIa A2 domain is the probable physiologic regulator of factor Xa generation. Full inactivation of factor Va by APC requires an anionic phospholipid surface, and the rates of APC inactivation of factors Va and VIIIa are enhanced by protein S. APC also has a profibrinolytic effect. This effect is due to TAFI. TAFI is activated by the a-thrombin–thrombomodulin complex and acts to prolong clot lysis. APC cleavage of factor Va inhibits a-thrombin generation, thus reducing a-thrombin–thrombomodulin–mediated TAFI activation (1021). The prolongation of clot lysis by TAFIa likely contributes to the prothrombotic tendencies associated with factor V $^{\text{Leiden}}$ (1022). The endothelial cell protein C receptor provides cell-specific binding sites for both protein C and APC (1023, 1024). Endothelial cell protein C receptor is down-regulated by TNF-a (1023). Monocytes appear to express specific binding sites for APC that are distinct from endothelial cell protein C receptor (1025, 1026). The cell-expressed binding sites may be important in the antiinflammatory properties of APC. APC blocks the septic shock response in animal models (1027, 1028) and reduces the levels of inflammatory cytokines such as TNF-a (1028, 1029). The antiinflammatory properties of APC are also due to inhibition of a-thrombin generation and, therefore, inhibition of the proinflammatory properties of a-thrombin.
REGULATION Protein C activation and APC activity are controlled on several levels. Inflammatory agents such as endotoxin, IL-1ß, transforming growth factor-ß (TGF-ß), and TNF-a regulate protein C activation on endothelial cells (1030, 1031, 1032, 1033, 1034, 1035, 1036, 1037, 1038 and 1039). TNF-a is responsible for down-regulation of thrombomodulin on the endothelial cell surface (1033, 1036, 1037, 1038 and 1039). There are multiple other factors that down-regulate thrombomodulin as well. APC activity is regulated mainly by the protein C inhibitor or PAI-3 (1040, 1041 and 1042).

Protein S

Protein S is a vitamin K–dependent protein that is not a serine protease precursor. Protein S circulates at a plasma concentration at 20 µg/ml (300 nmol/L) (1043, 1044) (Table 21.4). Approximately 40% of protein S circulates in the free form, and the remaining 60% circulates as a 1:1 complex with C4b-binding protein (C4bBP), a regulatory protein of the complement system (1043). Protein S is thought to function as a cofactor for APC in the inactivation of factors Va and VIIIa (175, 1045, 1046, 1047, 1048, 1049 and 1050). The protein S cofactor effect is minimal, however, and does not correlate with the thrombotic pathologies manifested in protein S–deficient patients (1051, 1052, 1053, 1054, 1055, 1056 and 1057). Protein S has also been reported to inhibit prothrombin activation through several mechanisms (636, 1058, 1059 and 1060). Although the precise function of protein S is not clear, protein S is important in anticoagulation.

GENE STRUCTURE AND EXPRESSION The gene for protein S is located on chromosome 3 and spans at least 80 kb (1061, 1062) (Table 21.5). The gene contains 15 exons and 14 introns (1063, 1064 and 1065). A second copy of the protein S gene has also been identified; however, this second gene is likely a pseudogene (1066, 1067). The pseudogene spans approximately 55 kb and differs from the protein S gene in that it lacks exon 1 and has multiple nucleotide substitutions. Protein S is synthesized in the liver (1068, 1069) and by a variety of other cell types including endothelial cells (1070, 1071 and 1072), osteoclasts (1073), and lymphoid cells (1074). Protein S is also found in the a-granules of platelets (939).
BIOCHEMISTRY Protein S (M $_r$ = 69,000) is a single-chain glycoprotein with approximately 8% carbohydrate and 11 Gla residues (537, 1075) (Table 21.4 and Fig. 21.3B). Protein S is synthesized with a signal sequence and propeptide region of 41 amino acids (1063, 1065, 1069, 1076). The mature form of the protein has 635 amino acids and is organized into eight domains: an NH $_2$-terminal Gla domain (residues 1 to 45), an aromatic stack, a 29-residue thrombin-sensitive domain (residues 46 to 75), four EGF domains (residues 76 to 242), and a COOH-terminal domain homologous to the sex hormone–binding globulin and androgen-binding protein (1077, 1078). The Gla domain and EGF domains mediate Ca $^{2+}$ binding (1079). The Gla domain is also involved in interactions with phospholipid membranes (1080). C4bBP binds to the COOH-terminal sex hormone–binding globulin domain (1081, 1082). Protein S reversibly self-associates in the absence of Ca $^{2+}$ (1083).
FUNCTION The precise function of protein S in the protein C inhibitory pathway is not clearly defined. Protein S enhances APC inactivation of factors Va and VIIIa in a phospholipid-dependent fashion (175, 1045, 1046, 1047, 1048, 1049 and 1050). The interaction between protein S and APC alters the structure of APC and moves the APC active site closer to the membrane surface (1084). Protein S may also serve directly in an anticoagulant capacity. Protein S has been reported to bind to factor Xa (1059), factor VIII (1085), and factor Va (1058) and compete for prothrombinase binding sites on the membrane surface (636, 1060). These interactions serve to inhibit prothrombin activation *in vitro* (1086). The C4bBP–protein S complex may inhibit factor X activation as well (1087). Protein S also has addition potential roles outside of anticoagulation. Protein S interaction with T cells promotes T-cell aggregation and proliferation and may serve to regulate inflammatory processes (1088).
REGULATION a-Thrombin cleavage of protein S at Arg ^{49}, Arg ^{60}, or Arg ^{70} in the thrombin-sensitive domain inhibits the ability of protein S to act as a cofactor for APC (1049, 1089, 1090 and 1091). Protein S activity is also regulated by interaction with C4bBP. The 1:1 complex between protein S and C4bBP neutralizes the anticoagulant capacity of protein S. Approximately 60% of plasma protein S circulates bound to C4bBP.

Protein Z

Protein Z, a vitamin K–dependent glycoprotein, is an enzymatically inactive homolog of factors VII, IX, and X and protein C (341). Protein Z was first identified in bovine plasma by Prowse and Esnouf in 1977 (1092) and later in human plasma by Broze and Miletich in 1984 (1093). The name *protein Z* came about from its being the last of the vitamin K–dependent proteins to elute during anion exchange chromatography (1094). Protein Z circulates in plasma in a complex with protein Z–dependent protease inhibitor (ZPI). This inhibitor, ZPI, has been identified as a 72-kd member of the serpin superfamily that contains a tyrosine at its reactive center.

Reports suggest that protein Z behaves as a negative acute phase reactant (1095, 1096). Protein Z levels have been found to be low in newborn infants (1097, 1098) and in individuals with DIC (1099), liver disease (1100), and amyloidosis (1101). High plasma levels have been found in individuals on chronic hemodialysis and with idiopathic thrombocytopenic purpura (1102, 1103). Protein Z levels also appear to be more susceptible to warfarin therapy, drastically lowering its levels to less than 1% over other vitamin K–dependent proteins (1104).

GENE STRUCTURE AND EXPRESSION The gene for protein Z is located on chromosome 13 at band q34 (Table 21.5). It spans approximately 14 kb and consists of nine exons, including one alternative exon (341). The gene organization was similar to that of the other vitamin K–dependent proteins, factors VII, IX, and X, and

protein C. Homozygous and heterozygous protein Z–deficient mice showed no abnormalities in growth and development. Protein Z deficiency has been reported to be prothrombotic in nature in factor V ^{Leiden} mice (1105). Protein Z–deficient mice crossed with factor V ^{Leiden} mice did not have viable progeny. Several clinical studies identified diminished levels of plasma protein Z in patients with unidentified bleeding disorders (1106 , 1107). Protein Z has also been identified in liver disease (1100) and atherosclerosis (1108).

BIOCHEMISTRY Protein Z has a molecular weight of 62,000 and circulates in plasma at a mean concentration of 2.9 plus or minus 1.0 µg/ml (1093 , 1104) (Table 21.4). The plasma $t_{1/2}$ of protein Z is 2.5 days (1104). Structurally, protein Z is similar to factors VII, IX, and X and protein C containing a Gla domain (13 residues) and two EGF domains at its NH_2-terminus (341 , 1109 , 1110) (Fig. 21.3B). However, like protein S, protein Z does not function as a protease. The COOH-terminus contains a region homologous to the catalytic domains present in the serine protease zymogens. The catalytic triad is not present in protein Z, except for the conserved Asp residue (1109 , 1110).

FUNCTION Protein Z is a vitamin K–dependent protein that does not function as a serine protease enzyme. Protein Z circulates in plasma in complex with the serpin protein Z–dependent protease inhibitor (ZPI). The function of protein Z *in vivo* is still unclear to date. It has recently been reported *in vitro* that protein Z inactivates factor Xa by forming a Ca^{2+}-dependent complex with factor Xa bound to phospholipid with the help of ZPI (1111). The significance of this protein Z/ZPI activity is unclear. *In vitro*, protein Z has also been shown to have a weak interaction (K_d = 8.9 µmol/L) with thrombin that facilitates the binding of thrombin to phospholipid surfaces (1112). It is also consumed, like all other coagulation factors and inhibitors, during the course of DIC.

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein constitutively expressed on the surface of vascular endothelial cells (Fig. 21.9). Thrombomodulin is a high-affinity receptor for a-thrombin and acts as a cofactor for the a-thrombin–dependent activation of protein C and TAFI. Thrombomodulin activity on the surface of endothelial cells is decreased by inflammatory cytokines and may contribute to the hypercoagulation characteristic of inflammatory states. Thrombomodulin is expressed widely during fetal development (1114). Homozygous thrombomodulin-deficient mice die *in utero* before the formation of the cardiovascular system, suggesting a potential role for thrombomodulin in mammalian development (1115).

GENE STRUCTURE AND EXPRESSION The human thrombomodulin gene is located on chromosome 20 band p-12cen and spans 3.7 kb (1116 , 1117) (Table 21.5). The gene is unusual in that it lacks introns (1118 , 1119). Thrombomodulin expression has been reported in a variety of cell types, including vascular endothelial cells (1120 , 1121), neutrophils (1122), monocytes (1123 , 1124), platelets (1125), synovial cells (1126), and squamous epithelial cells (1127 , 1128 and 1129). Vascular expression is limited to endothelial cells. Thrombomodulin activity on the surface of endothelial cells is decreased by homocysteine, lipopolysaccharide, IL-1ß, and TNF-a (1030 , 1031 , 1130 , 1131 , 1132 and 1133). Many of these same inflammatory agents that down-regulate thrombomodulin also up-regulate tissue factor, contributing to the hypercoagulation associated with inflammation. Hypoxia also down-regulates thrombomodulin expression (1134). Likewise, thrombomodulin expression is decreased by glucose-modified albumin, which may provide a link to diabetic thrombotic complications (1135). Conversely, dibutyl cyclic adenosine monophosphate, retinoic acid, shear stress, and increased temperature (42°C) up-regulate thrombomodulin activity on endothelial cells (1136 , 1137 , 1138 , 1139 and 1140). Up-regulation of thrombomodulin expression by TNF-a may involve a consensus sequence of a cyclic adenosine monophosphate response element in the 3'-untranslated region of the thrombomodulin gene (1141). Increased thrombomodulin gene transcription due to elevated temperature is mediated by consensus sequence recognition sites for a heat shock element in the 5'-promoter region (1140). Up-regulation of thrombomodulin expression in response to elevated temperature may be a protective mechanism to compensate for the procoagulant effects of the inflammatory mechanism.

BIOCHEMISTRY Human thrombomodulin is synthesized with an 18–amino acid signal sequence followed by a 557-residue polypeptide chain of the mature protein (1116 , 1118 , 1119 , 1142). Thrombomodulin has five different domain structures: an NH_2-terminal domain having weak homology to lectins (residues 6 to 149) such as the asialoglycoprotein receptor (1143), six EGF-like domains (residues 227 to 462), a 34-residue region rich in serine and threonine corresponding to potential O-linked glycosylation sites (residues 463 to 497), a 23-residue hydrophobic transmembrane region (residues 499 to 521), and a COOH-terminal domain (residues 522 to 557) containing several potential phosphorylation sites and one free cysteine residue (Cys^{536}) (Fig. 21.9). The fifth and sixth EGF domains support a-thrombin association (1144). The region required for efficient protein C activation extends from the linker region between EGF domains 3 and 4 through EGF-6 (1145 , 1146 , 1147 and 1148). Ser^{472} and Ser^{474} in the serine- and threonine-rich region are potential sites for chondroitin sulfate addition (1149). The presence of chondroitin sulfate increases the affinity for a-thrombin more than tenfold (1150), thus increasing the ability of thrombomodulin to block fibrinogen cleavage and platelet activation by a-thrombin (1151 , 1152). The chondroitin sulfate moiety also enhances inactivation of a-thrombin by antithrombin-III (1151 , 1153) and modulates the Ca^{2+}-dependence of protein C activation (1150 , 1153). The O-linked sugar domain of thrombomodulin is required for APC generation on cellular surfaces. This domain is extended and rigid and rises approximately perpendicular to the membrane surface. The O-linked sugar domain likely functions to elevate a-thrombin from the membrane surface (1154). The active site of a-thrombin bound to thrombomodulin is located approximately 65 Å from the membrane surface (1155). Although no consensus sequence for internalization via coated pit-mediated endocytosis is found in thrombomodulin, coated and noncoated pit-mediated endocytosis has been observed (1156). Internalization appears to be mediated by the NH_2-terminal lectinlike domain (1157).

FUNCTION Thrombomodulin functions as a cofactor for a-thrombin in the activation of protein C and TAFI. Production of APC by the a-thrombin–thrombomodulin complex is approximately 1000 times faster than by equivalent concentrations of protein C and thrombin. Once bound to thrombomodulin, a-thrombin's procoagulant activities are neutralized. The high-affinity a-thrombin–thrombomodulin interaction is mediated mainly by exosite I on the a-thrombin molecule. Exosite I also binds fibrinogen, and the interaction of a-thrombin with thrombomodulin therefore blocks fibrinogen binding and cleavage. In addition, thrombomodulin induces conformational changes in a-thrombin (1158 , 1159 , 1160 , 1161 , 1162 and 1163). The changes that occur on a-thrombin interaction with thrombomodulin reduce the ability of a-thrombin to generate fibrin, to activate factor V and platelets (1164 , 1165), while increasing the inactivation of a-thrombin by antithrombin-III (1166 , 1167 and 1168). a-Thrombin–thrombomodulin, or protein Case, functions solely in an anticoagulant and antifibrinolytic capacity.

REGULATION There are several potential mechanisms of thrombomodulin regulation on the cell surface. Thrombomodulin expression is down-regulated by endotoxin and inflammatory cytokines (1036). Shear stress, homocysteine, and hypoxia likewise down-regulate thrombomodulin expression (1132 , 1133 and 1134 , 1139). a-Thrombin may also regulate thrombomodulin activity although the results are somewhat controversial. Thrombomodulin-dependent a-thrombin internalization has been reported (1169 , 1170 and 1171). However, the a-thrombin–thrombomodulin complex appears to be stable under some conditions (937 , 1172). In addition, thrombomodulin activity can be regulated proteolytically, mainly by neutrophil elastase (1173 , 1174). Neutrophils decrease thrombomodulin activity via oxidation as well (1175).

ANTICOAGULANT PROTEINS: PROTEINASE INHIBITORS

Proteinases, enzymes that hydrolyze peptide bonds, are found in a wide array of biologic systems, including the blood coagulation process (clot formation and fibrinolysis), digestive system, apoptotic cascades, and the immune system. To keep these systems in balance between activation and inhibition, a complex system of proteinase inhibitors has evolved. In blood, proteinase inhibitors constitute a significant percentage of circulating proteins. In general, proteinases that activate the coagulation and fibrinolytic cascades have highly defined substrate specificities. Coagulation is kept in check through the action of several specific and broad-spectrum proteinase inhibitors. Specific clot formation inhibitors are antithrombin-III and TFPI. Fibrinolysis-specific inhibitors are PAI-1 and a_2-antiplasmin. Together, specific and broad-spectrum inhibitors function to localize, limit, and control hemostasis.

a_2-Macroglobulin

a_2-Macroglobulin is a nonspecific proteinase inhibitor that targets a broad spectrum of protease substrates. It is present in human plasma (M_r = 735,000) at concentrations ranging from 2 to 4 µmol/L (2 to 3 mg/ml) (Table 21.4). a_2-Macroglobulin can also be found at higher concentrations in extravascular fluids (1176). This protease inhibitor can be produced in a variety of cells including hepatocytes, fibroblasts, and macrophages (980 , 1177). a_2-Macroglobulin is also found in several species including the horseshoe crab (1178 , 1179). There are several recent reviews on a_2-macroglobulin (1180).

Reduced levels of serum a_2-macroglobulin in humans have been observed in individuals with chronic obstructive lung disease (1181) and cancer metastasis (1182). In humans, no absolute deficiency has been reported to date, leading to the suggestion that such a congenital deficiency is incompatible with survival. The inactivation of the mouse a_2-macroglobulin gene results in viable mice that produce normal-sized litters but are more resistant to endotoxin challenge (1183). In a later study, it was suggested that this phenotype in mice functions as a neutralizer of transforming growth factor-ß and as an inducer of nitric oxide synthesis (1184).

GENE STRUCTURE AND EXPRESSION The gene encoding human a $_2$-macroglobulin spans approximately 48 kb and consists of 36 exons and 35 introns ([1185]) (Table 21.5). It is located on chromosome 12p12.3-13.3 ([1186] , [1187] and [1188]). The a $_2$-macroglobulin gene is a single copy gene in the human genome. a $_2$-Macroglobulin is synthesized in the liver as a pro–a $_2$-macroglobulin, which contains a 23-residue signal peptide. Three transcription initiations sites, including a TATA box, a TATA-like structure (ATAAA), and a potential HP-1 binding site, have been identified in liver ([1185]).
BIOCHEMISTRY Human a $_2$-macroglobulin circulates in plasma as a tetramer with four identical single-chain subunits with an individual relative molecular weight of 180,000 and a total relative molecular weight of 735,000 ([1186] , [1189] , [1190]). An unusual feature of this protein is that multiple forms may be found in various species and may appear only during acute phase reactions ([980] , [1176] , [1177]). A dimeric form termed *pregnancy zone protein* has been found in human plasma at peak levels during the last trimester; therefore, this protein may be found in human plasma composed either of two or four identical subunits ([1191] , [1192]). a $_2$-Macroglobulin has a unique mechanism by which it achieves broad specificity. The initial step involves the “bait region” of a $_2$-macroglobulin ([979]). This region consists of a 25–amino acid sequence that has sequence motifs appropriate for many proteases ([1193]). After proteolysis in this bait region, a $_2$-macroglobulin undergoes conformational changes that trap the proteinase inside the molecule ([979]). These conformational changes have been referred to as a *slow to fast transition* ([978] , [979]). The active site of the substrate proteinase is not found in complex with the inhibitor. Studies have shown that the entrapped proteinase is no longer able to interact with macromolecular substrates, inhibitors, and antibodies but still appears to retain its ability to react with small substrates and inhibitors ([979]). These complexes are rapidly cleared from the circulation by the endocytic a $_2$-macroglobulin receptor also known as the *low-density lipoprotein receptor-related protein* (LRP). This receptor is found on most mast cells and tissues. The proteinase-inhibitor complex has an approximate t $_{1/2}$ of 2 to 5 minutes ([980]). Another important feature of a $_2$-macroglobulin is the presence of a ß-cysteinyl-?-glutamyl thiol ester ([1194] , [1195]). Studies have shown that these thiol esters may directly react with small nucleophiles, such as ammonia or methylamine, induce a conformational change, and prevent proteinase binding ([1196]). The conformational changes associated with proteolysis of the bait region generate a thiol ester more susceptible to nucleophilic attack, with the result that surface Lys residues of the trapped proteinase can react with it and become covalently linked to a $_2$-macroglobulin. Binding studies *in vitro* have identified specific high-affinity receptors for a $_2$-macroglobulin–proteinase complexes on many cell types, including fibroblasts, macrophages, and hepatocytes ([981]).
FUNCTION One role for a $_2$-macroglobulin is to inhibit a broad range of proteinases. It is distinctive in its capacity to inhibit members from each of four mechanistic classes of proteinases (serine, cysteine, and aspartic proteinases and metalloproteinases). a $_2$-Macroglobulin functions as a secondary inhibitor to serine proteinases in plasma by inhibiting thrombin, kallikrein, and plasmin ([1197] , [1198]). It may also be important in preventing thromboembolic events when there is a congenital deficiency of antithrombin-III or sepsis ([1199] , [1200]). a $_2$-Macroglobulin also inhibits various growth factors and cytokines, including TGF-ß ([1201]), IL-1ß ([1202]), IL-6 ([1203]), acidic fibroblast growth factor ([1204]), basic fibroblast growth factor ([1204]), TNF-a ([1205]), and IL-2 ([1206]). Polymorphisms identified in a $_2$-macroglobulin have been thought to play a role in Alzheimer disease ([1207] , [1208] and [1209]). Overall, the biologic role of a $_2$-macroglobulin *in vivo* is still being elucidated.

Tissue Factor Pathway Inhibitor

TFPI, formerly called *extrinsic pathway inhibitor* or *lipoprotein-associated coagulation inhibitor*, is a multivalent, Kunitz-type plasma proteinase inhibitor. TFPI modulates tissue factor–dependent coagulation *in vivo* by rapidly inhibiting the extrinsic tenase complex (factor VIIa–tissue factor) as soon as it is formed ([230] , [231] , [1210]) (Fig. 21.6). It circulates in plasma at approximately 0.1 µg/ml ([1211]) as a heterogeneous collection of partially proteolyzed forms ([229] , [1212] , [1213] and [1214]) (Table 21.4). Ninety percent of circulating TFPI is found associated with lipoproteins, primarily low-density lipoprotein ([1213] , [1215] , [1216]). Parenteral TFPI is cleared from the circulation primarily by the liver and has an unusually short t $_{1/2}$ (minutes) compared to other proteinase inhibitors.

Many reviews of TFPI have been published ([1217] , [1218] , [1219] , [1220] , [1221] , [1222] and [1223]). The importance of TFPI in blood coagulation has been best illustrated through transgenic mice that have a complete deficiency (-/-) of TFPI. This deficiency is incompatible with birth and survival ([1224]). However, this lethality in mice can be rescued by heterozygous or homozygous factor VII deficiency ([1225]). This implies that diminishing the level of factor VII lessens the need for TFPI-mediated inhibition of the factor VIIa–tissue factor coagulation pathway during embryogenesis ([1225]). When mice are generated that have a combined heterozygous TFPI deficiency and homozygous apolipoprotein E deficiency, they exhibit a greater atherosclerotic burden ([1226]). These observations suggest a role for TFPI in protection from atherosclerosis and as a potential regulator of thrombosis.

To date, there are no known human TFPI-deficient individuals described, which suggests that human embryos with TFPI -/- genotype fail to develop. A role for TFPI in preventing thrombosis and other cardiovascular diseases is currently under intensive clinical and *in vitro* investigation ([1218]). One application and ongoing clinical trial for recombinant TFPI is in the area of sepsis in which patients frequently have reduced TFPI levels ([1227]).

GENE STRUCTURE AND EXPRESSION The human TFPI gene has been localized to chromosome 2 bands q31–q32.1 ([1228] , [1229] and [1230]) (Table 21.5). It spans 85 kb, over half of which consists of the 5' noncoding region. The coding region is distributed over nine exons ([1231]); mature TFPI contains three Kunitz domains that are encoded on separate exons. The gene specifies a protein of 304 amino acids; the first 28 residues comprise a signal peptide. Two variants of TFPI (isoforms a and ß) arising from alternative splicing have been identified; the variable region involves residues 210 to 251 of the primary gene product, spanning a large portion of the third Kunitz domain. TFPI is expressed constitutively by cultured endothelial cells, and its level of synthesis is hardly affected by endotoxin or inflammatory cytokines ([1214] , [1232]). TFPI is not expressed by hepatocytes. TFPI is found bound to low- and high-density lipoproteins located within platelets or noncovalently associated with endothelial cell heparin sulfate proteoglycans ([1211]). TFPI is catabolized in the liver and kidney by uptake/degradation via the low-density LRP or its homologs ([1233]).
BIOCHEMISTRY TFPI (M $_r$ = 40,000) is a single-chain glycoprotein of the Kunitz proteinase inhibitor family ([1234] , [1235]). As isolated, the COOH-terminus of TFPI displays some degradation. Structurally, mature full-length TFPI (276 amino acids in the a isoform) consists of an acidic NH $_2$-terminal region, three tandem Kunitzlike serine protease inhibitor domains (K1 to K3), and a positively charged COOH-terminal region ([1233] , [1234]) (Fig. 21.12). The tandem Kunitz domains are essential for the function of TFPI ([1211]). The Kunitz 1 inhibitor domain (residues 26 to 76) binds factor VIIa–tissue factor. The second Kunitz domain (residues 97 to 147) of TFPI binds the factor Xa active site. The function of Kunitz 3 (residues 189 to 239) still remains unclear. Heparin binds at two heparin-binding sites: a high-affinity site in the COOH-terminal basic region and a low-affinity site between Gly ^{212} and Phe ^{243} in the third Kunitz domain ([575] , [576] , [1236]).

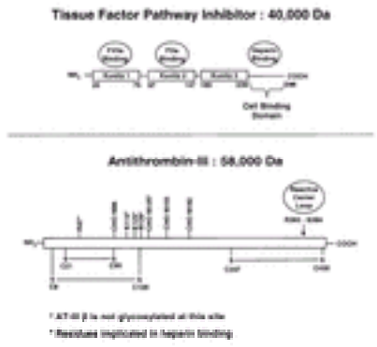

Figure 21.12. Soluble stoichiometric inhibitors. Tissue factor pathway inhibitor (TFPI) has a molecular weight of 40,000 d and contains three Kunitz domains (the residues are illustrated below each domain). TFPI inhibits the serine proteases factor VIIa (FVIIa) and factor Xa (FXa), shutting down the extrinsic pathway of coagulation. Kunitz 1 domain binds factor VIIa, and Kunitz 2 domain binds factor Xa. The COOH-terminus of TFPI contains a basic region, the cell-binding domain, which binds to heparin. Antithrombin-III (AT-III) has a molecular weight of 58,000 d and contains two intrachain disulfide bonds (-S-S-) in its NH $_2$-terminus and one in its COOH-terminus with a carbohydrate-rich domain (CHO) in between. Asn ^{135} is not glycosylated in the ß form of AT-III. The region of interaction between the active sites of target proteases and AT-III is illustrated as a circle (reactive center loop) above the reactive site bond R ^{393}-S ^{394}. Heparin binding occurs in the NH $_2$-terminus [residues are shown with an asterisk (*)] and enhances the rate of inhibition of serine proteases.

TFPI contains three potential N-linked glycosylation sites (Asn ^{117}, Asn ^{167}, and Asn ^{228}), with one or more of these oligosaccharides sulfated during expression by cultured endothelial cells ([1237]). Two O-linked glycosylation sites have also been identified (Ser ^{202} and Thr ^{203}). A significant proportion of TFPI molecules in the blood is truncated to variable extents at the COOH-terminal end (some lacking most of the third Kunitz domain) and has compromised inhibitory activity ([229]). In contrast, TFPI released by heparin infusion is full-length and more active than the truncated forms ([1235]). The inhibitory activity of TFPI is enhanced by heparin. The normal plasma concentration of TFPI is 0.1 µg/ml. It is found either associated with lipoproteins, such as low- and high-density lipoproteins or lipoprotein(a), or

complexed to endothelial cell heparan sulfate proteoglycans ([1238]). On heparin administration, TFPI is released from endothelial cells, causing a two- to tenfold increase in circulating TFPI levels ([1235] , [1239] , [1240]). TFPI release on heparin therapy is responsible for the observed elevation in PT and raises the possibility that a portion of the antithrombotic effect of the polysaccharide may be mediated by TFPI. A minor pool of TFPI (~10% of total TFPI in blood) is located within platelets and is released after stimulation by an agonist such as thrombin ([940]). A large pool of TFPI is rapidly released into the circulation after heparin administration. The qualitative and quantitative properties of TFPI can be altered both by the genotype of an individual and by environmental factors. This is illustrated by *in vitro* experiments in which factor V ^{Leiden} is combined with reduced levels of TFPI. Factor V ^{Leiden}, when combined with low normal (50%) TFPI levels, can produce an unregulated propagation phase of thrombin generation in a synthetic plasma system ([1241]). In a control with normal factor V, the propagation phase of thrombin generation is attenuated substantially at the tissue factor concentrations used in this experiment (i.e., it is near threshold). With factor V ^{Leiden} and low normal TFPI, the propagation phase of thrombin generation is equivalent to a situation in which the protein C regulatory system is totally dysfunctional. This observation suggests the risk of thrombotic pathology. An *in vivo* parallel to this *in vitro* experiment has been reported by Eitzman et al. ([1242]), who showed factor V ^{Leiden} (+, +) mice with reduced but low levels of TFPI (+,–) died of thrombosis.

FUNCTION TFPI is the principal stoichiometric inhibitor of the extrinsic pathway (factor VIIa–tissue factor) of coagulation (Fig. 21.6). The extrinsic pathway generates low levels of the serine proteases, factor IXa (~1 pmol/L), and factor Xa (~10 pmol/L) ([524]). As soon as the proteases are formed, factor Xa can activate prothrombin to generate thrombin, and factor IXa can combine with its cofactor factor VIIIa and form the intrinsic tenase complex to generate more factor Xa. This is followed by the formation of the prothrombinase complex (factor Xa–factor Va), which coverts prothrombin to thrombin. The TFPI mechanism allows the factor VIIa–tissue factor complex to initiate factor Xa formation but then suppresses high levels of factor Xa product formation by this complex. TFPI is the principal regulator of the initiation phase of thrombin generation ([524]) (Fig. 21.11). The actual mechanism involves a rapid interaction between the second Kunitz domain of TFPI with the factor Xa active site; localization of the complex to the membrane surface is mediated by the Gla domain of factor Xa ([576] , [1243] , [1244]). Once surface-bound, the factor Xa–TFPI complex rapidly inactivates tissue factor–factor VIIa. This complex formation depends on the binding of the first Kunitz domain of TFPI to the factor VIIa active site. These interactions together form a stable quaternary complex, tissue factor–factor VIIa–TFPI-factor Xa. Ethylenediaminetetraacetic acid can readily dissociate this inhibited quaternary complex. Inhibition of factor VIIa–tissue factor by TFPI is not completely dependent on the presence of factor Xa because the factor IXa–TFPI complex can also bind to and inhibit factor VIIa–tissue factor. However, the binding affinity of TFPI for factor IXa is significantly less than for factor Xa. The physiologic relevance of this route of inhibition is thus debatable because high plasma concentrations of TFPI are required. At normal plasma concentrations, this multicomponent interaction of TFPI allows basal function of the factor VIIa–tissue factor complex but inhibits it after more extensive activation occurs. When combined with the stoichiometric inhibitor antithrombin-III, a synergistic regulatory effect of blood coagulation occurs by inducing kinetic “thresholds” such that the initiating tissue factor stimulus must achieve a significant magnitude to propel thrombin generation ([1245]). Tissue factor concentrations below the threshold concentration are ineffective in promoting robust thrombin generation because of the cooperative influence of the inhibitors; concentrations in excess of the threshold yield robust and almost equivalent thrombin generation. In a similar fashion, TFPI and the dynamic protein C–thrombomodulin–thrombin system cooperate to provide a threshold-limited, synergistic inhibition of thrombin production ([1246]). In this instance, TFPI slows the initiation phase, whereas the APC system reduces the availability of the cofactors factors Va and VIIIa, thereby shutting down the propagation phase of thrombin generation (Fig. 21.11).

REGULATION TFPI administered intravenously to rats and mice is cleared rapidly from the circulation by liver hepatocytes, which recognize its COOH-terminal region (third Kunitz domain and basic COOH-terminus) ([1247] , [1248] and [1249]). TFPI is cleared by the promiscuous endocytic receptor, low-density LRP. Several lines of evidence suggest that TFPI binding to heparinlike sites on the cell surface may precede its catabolism by LRP. In addition, TFPI appears to be important for factor Xa catabolism. TFPI–factor Xa complexes are cleared by a liver receptor that is distinct from LRP.

ANTICOAGULANT PROTEINS: SERINE PROTEASE INHIBITOR SUPERFAMILY (SERPIN)

Inhibitory serpins are irreversible covalent suicide protease inhibitors. These inhibitors target serine proteases, a family of proteolytic enzymes sharing common active site architectures and common catalytic mechanisms. Key features of these enzymes include a nucleophilic serine hydroxyl moiety that attacks the carbonyl group of the targeted bond and the formation of a transient acyl-enzyme intermediate between the enzyme and the NH_2-terminal part of the substrate polypeptide. *In vivo*, when a serpin successfully reacts with a protease, catalysis of serpin proteolysis is arrested at the acyl-enzyme stage, and the serpin-enzyme complex is cleared from the circulation by specific receptor-mediated processes. Members of this multigene inhibitor family include antithrombin-III, heparin cofactor II, a $_1$-proteinase inhibitor (also known as a $_1$ -*antitrypsin*), C1 esterase inhibitor, protein C inhibitor, PAI-1, a $_2$-antiplasmin, and protein Z–dependent protease inhibitor. Plasminogen activator-1 and a $_2$-antiplasmin are discussed in detail in the section Inhibitors of the Fibrinolytic System , and protein Z–dependent protease inhibitor is discussed briefly in the section Protein Z . Serpins function in diverse physiologic processes including blood coagulation, fibrinolysis, complement activation, angiogenesis, apoptosis, inflammation, neoplasia, and viral pathogenesis ([1250]) (Table 21.6). When a member of the serpin family is either deficient or dysfunctional, several biologic disorders are evidenced, including thrombosis ([1251] , [1252]), emphysema ([1253]), lupus erythematosus ([1254]), liver disease ([1255]), and dementia ([1256]).

TABLE 21.6. Inhibitors

Serpin	System(s) Regulated	Target Protease(s)	Deficiency State
Antithrombin-III	Coagulation	Thrombin, FXa, FIXa, kallikrein [a] , FXIa, and FVIIa [b]	Thrombosis
Heparin cofactor II	Coagulation	Thrombin	Thrombosis in some individuals
Protein C inhibitor	Coagulation	APC, kallikrein	None reported
a $_1$-Proteinase inhibitor	Inflammation	Elastase	Pulmonary emphysema
	Tissue remodeling	Cathepsin G	—
	Coagulation	APC, FXIa, and FXa	—
Plasminogen activator inhibitor-1	Fibrinolysis	Tissue-type plasminogen activator, urokinase-type plasminogen activator	Bleeding
a $_2$-Antiplasmin	Fibrinolysis	Plasmin	Bleeding
C1 esterase inhibitor	Complement	C1r, C1s	Angioedema
	Contact factors	FXIIa, kallikrein	—
	Coagulation	FXIa	—
Protease nexin-1	Coagulation	Thrombin	None reported

APC, activated protein C; F, factor.

[a] Reaction also requires the presence of high-molecular-weight kininogen.

[b] Antithrombin III–heparin inhibits factor VIIa only when bound to tissue factor.

In the past several years, advances have been made to further understand the mechanism of action of serpins ([975] , [1257] , [1258] , [1259] , [1260] , [1261] , [1262] , [1263] and [1264]). Serpins in uncleaved states (native or latent) and cleaved states have been crystallized ([1265] , [1266] and [1267]). Achievement of the first crystal structure for a serpin-protease complex (a $_1$-antitrypsin–trypsin) ([1268]) has confirmed the physical displacement of the tethered protease: The conformation of a $_1$-antitrypsin in the complex is superimposable with that of the isolated cleaved a $_1$-antitrypsin. The crystal structure also revealed that the translocated, tethered protease has undergone an overall 37% loss of structure with its catalytic site radically disrupted.

Inhibitory serpins share a similar backbone structure but expose a variable reactive site loop. This loop binds to the catalytic groove of the target proteases. Serpin specificity derives in part from the sequence of the reactive site loop and also from secondary binding sites ([1269] , [1270]). Initially, the reaction of a serpin and serine protease involves formation of a noncovalent Michaelis complex between the exposed reactive site loop and the protease active site. Exosite interactions between the two molecules or, in some cases, exosite binding of a cofactor, induce structural changes that increase the availability of the reactive site loop. Reversible complex formation is followed by reaction of the active site serine residue of the protease with the serpin “bait” peptide bond to form an acyl-enzyme intermediate. Trapping of this covalent complex between the reactive site loop and the protease appears to involve a process that both physically translocates the reactive loop-protease complex approximately 71 Å from the initial docking site and induces a general disordering of the protease's conformation with consequent loss of any further catalytic activity ([1268]). The energy for translocation and structural alteration of the protease derives from the insertion of the proteolytically released reactive site loop of the

serpin into ß sheet A of its central core. A kinetic partitioning of serpin protease reactions between stable inhibited complexes and mixtures of regenerated enzyme and proteolyzed serpin reflects the relative rates of reactive site loop insertion versus deacylation ([1271]). A number of recent reviews have been written on the known serpin conformations and their biologic significance ([1250], [1272], [1273], [1274], [1275], [1276], [1277], [1278] and [1279]).

Antithrombin-III

Antithrombin-III is a member of the serpin proteinase inhibitory family and circulates in blood as a single-chain glycoprotein with a relative molecular weight of 58,000 ([278]) (Table 21.4). The plasma concentration of human antithrombin-III is approximately 140 µg/ml (2.4 µmol/L) ([1280]). Its $t_{1/2}$ is approximately 61 to 72 hours ([1281], [1282]). Other names for antithrombin-III include *antithrombin-heparin cofactor* and *heparin cofactor*. Despite its name, antithrombin-III inhibits not only thrombin but also many of the other enzymes in the coagulation pathway.

Congenital antithrombin-III deficiency exhibits an autosomal-dominant pattern of inheritance, with an incidence of 1:2000 to 1:5000 ([1283]). The complete absence of antithrombin-III is lethal. Individuals with this deficiency have partial expression of antithrombin-III and are prone to thromboembolic disease ([1284]). Inherited deficiency is categorized by either quantitative defect with a reduction in antigen and activity (type I) or qualitative with reduced antithrombin-III functional activity and normal antigen levels (type II) ([1285]). These defects are caused by a variety of mutations that include insertions, deletions, and missense mutations ([1283], [1286]). Function can be compromised by mutations in the thrombin binding domain or the heparin-binding domain. Unstable variants of antithrombin have been identified in families with severe episodic thrombotic disease. Acquired antithrombin-III deficiency occurs in patients with sepsis or severe traumatic shock ([1287], [1288]). Therefore, studies are being conducted on the use of antithrombin-III as an agent for treating coagulation abnormalities associated with sepsis or other inflammation disorders ([1289], [1290] and [1291]).

GENE STRUCTURE AND EXPRESSION The gene encoding antithrombin-III is located on chromosome 1 in the q23-q25 region ([1292]) and spans 13.5 kb of genomic DNA ([1293]) (Table 21.5). The gene is composed of seven exons and six introns ([1293]). The mechanisms underlying antithrombin-III gene expression are not well established. It is primarily expressed in the liver with low levels detected in the brain and kidney. *Cis*-acting elements and *trans*-acting factors have been identified that regulate constitutive expression of the human antithrombin gene ([1294]).

BIOCHEMISTRY Human antithrombin-III is a single-chain glycoprotein (M_r = 58,000) that circulates in blood at a concentration of approximately 140 µg/ml (2.4 µmol/L) ([278], [1280]). It circulates as two glycoforms, a and ß variants, that contain identical polypeptide backbones but differ in carbohydrate content and heparin affinity ([1295]). The antithrombin-III a variant is the predominant form (~90%) ([1295]). The structure of antithrombin-III a consists of 432 amino acid residues, with three disulfide bonds and four sialylated oligosaccharides at Asn ^{96}, Asn ^{135}, Asn ^{155}, and Asn ^{192} (Fig. 21.12). The carbohydrate residues account for 15% of total mass ([1296], [1297], [1298] and [1299]). The antithrombin-III ß variant is not glycosylated at Asn ^{135}. Antithrombin-III ß binds heparin more tightly than does antithrombin-III a and is observed to preferentially accumulate on the vessel wall when heparan sulfate proteoglycans are exposed ([1300]). The reactive site peptide bond is Arg ^{393}-Ser ^{394}. The first x-ray crystal structure of antithrombin-III that was determined was a cleaved form that diffracted to 3.2 Å resolution ([1301]). Significant differences between structures of antithrombin-III and another serpin, a $_1$-antitrypsin, were identified in the NH_2-terminal region that defines the heparin-binding site. Since then, several x-ray crystal structures of intact antithrombin-III have been solved to 2.6 to 3.0 Å ([1302], [1303]). Interestingly, the crystals that diffracted to 2.6 Å were grown under microgravity conditions on space shuttle mission STS-67 ([1303]). This structural data indicated that antithrombin-III is present in two different conformations: an active form that can inhibit thrombin and form a stable complex with the protease and a form that was inactive as an inhibitor and did not act as a substrate for thrombin. Better definition was also obtained of the residues implicated in the binding of the heparin pentasaccharide (Arg ^{47}, Lys ^{114}, Lys ^{125}, and Arg ^{129}).

FUNCTION Antithrombin-III has a broad spectrum of inhibitory activity with most of its target proteases participating in the coagulation cascade. It is primarily an inhibitor of the serine protease thrombin as well as factor Xa, factor IXa, factor VIIa–tissue factor, factor XIa, factor XIIa, plasma kallikrein, and HMWK ([1304], [1305] and [1306]). Antithrombin-III plays a key role in maintaining hemostasis. Antithrombin-III also displays antiproliferative and antiinflammatory properties that primarily derive from its ability to inhibit thrombin. In addition, latent or cleaved forms of antithrombin-III have antiangiogenic activities ([1307]). Heparins and heparan sulfates potentiate these reactions and are used in the treatment of thrombosis. When antithrombin-III is complexed with heparin, its rate of binding to thrombin increases 1000-fold. The general mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure of the serpin to form a tight, equimolar (1:1) complex. Inactivation is suspected to proceed through covalent bond formation between antithrombin-III and the protease, followed by inactivating structural rearrangements of both antithrombin-III and the protease. However, the exact mechanism of inhibition of serine proteases by antithrombin-III is uncertain. Antithrombin-III inhibits at a slower rate when not bound to heparin because the reactive site loop of antithrombin-III is not completely exposed in the absence of heparin.

Heparin Cofactor II (Leuserpin 2)

Heparin cofactor II, also called *leuserpin 2*, is a relatively newly discovered member of the serpin family. Like antithrombin-III, heparin cofactor II inhibits thrombin in a reaction that is accelerated more than 1000-fold by heparin ([1308]). However, heparin cofactor II is unique in that it is also stimulated by the proteoglycan dermatan sulfate. The plasma concentration of heparin cofactor II is 0.5 to 1.4 µmol/L ([1309], [1310]) (Table 21.4). Its plasma $t_{1/2}$ is approximately 2.5 days. The physiologic role of heparin cofactor II is uncertain at the present time. Low levels of thrombin–heparin cofactor II complexes are detected in normal plasma samples; elevated levels were detected in patients with DIC ([1311]). Although inherited deficiency of heparin cofactor II has been associated with thrombosis, this is not always the case ([1312], [1313]). The incidence of heparin cofactor II deficiency in patients with thromboembolytic disorders appears to be similar to that in the normal population ([1314]).

GENE STRUCTURE AND EXPRESSION The gene encoding human heparin cofactor II, consisting of five exons and four introns, spans approximately 14 kb on chromosome 22 in the q11 region proximal to the breakpoint cluster region ([1315], [1316]). The human heparin cofactor II gene is expressed exclusively in the liver and by a hepatoma-derived cell line ([1317], [1318] and [1319]).

BIOCHEMISTRY Human heparin cofactor II (M_r = 66,000) circulates as a single-chain protein of 480 amino acid residues that contains 10% carbohydrate ([1309], [1316], [1320]). It is glycosylated at Asn ^{30}, Asn ^{169}, and Asn ^{368} and is sulfated at Tyr ^{60} and Tyr ^{73}. It has three cysteines with no identified disulfide bonds. A cationic region of the molecule encompassing residues 163 to 194 constitutes the GAG binding site; dermatan sulfate and heparin bind to heparin cofactor II at nonidentical but overlapping sites in this region ([1321], [1322]). Residues Lys ^{173}, Arg ^{184}, Lys ^{185}, Arg ^{189}, Arg ^{192}, and Arg ^{193} have been specifically implicated in heparin binding ([1323]). The NH_2-terminal region of heparin cofactor II contains a cluster of acidic residues that are thought to interact with the positively charged GAG binding site ([1324], [1325]). This “acidic” tail of heparin cofactor II contains two so-called hirudin domains—Glu ^{56}AspAspAspTyrLeuAsp ^{62} and Glu ^{69}AspAspAspTyrIleAsp ^{75}; in each, the Tyr residue is sulfated. It has been proposed that the NH_2-terminal “acidic” tail is constrained in the native structure through association with the highly cationic heparin-binding region. In the presence of GAG, the acidic region is displaced from the heparin-binding site, thus making it available for binding to the anion-binding exosite I of thrombin ([1326]). However, crystallographic studies of heparin cofactor II indicate that the acidic tail of heparin cofactor II is flexible in the crystal and not associated with the heparin-binding site ([1265]). Other functionally important regions of heparin cofactor II include a chemotactic peptide harbored between residues Asp ^{49} and Tyr ^{60} that is released by leukocyte proteases ([1327]). Residues Phe ^{456} to Ile ^{460} constitute a pentapeptide recognition motif for the hepatic serpin enzyme complex receptor that may be involved in clearance of heparin cofactor II–enzyme complexes ([1328]). The domain of heparin cofactor II with homology to other serpins is at the COOH-terminus of the protein. It exhibits approximately 30% homology to antithrombin-III and other serpins. The reactive site peptide bond is Leu ^{444}–Ser ^{445} ([1329]). This reactive center loop sequence is consistent for an inhibitor with specificity for proteases with a preference for nonpolar residues with relatively bulky side chains in the P1 position. Two such proteases, chymotrypsin and cathepsin G, do react with heparin cofactor II. Thrombin reactivity with heparin cofactor II is unusual because thrombin generally prefers substrates with arginine in the P1 position. Exosite binding interactions, such as that between the hirudinlike sequences of heparin cofactor II and exosite I of thrombin, compensate for the less-than-ideal structure of the P1 residue and allow thrombin to form a productive Michaelis complex with heparin cofactor II ([1265]).

FUNCTION The only coagulation enzyme inhibited by heparin cofactor II appears to be thrombin ([1330]). However, the rate of thrombin inhibition by heparin cofactor II in the absence or presence of GAGs is significantly slower than by antithrombin-III under similar conditions. Considering that the plasma concentration of heparin cofactor II is 25 to 50% that of antithrombin-III and that low levels of heparin cofactor II are not strongly associated with thrombosis, the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned. *In vitro*, heparin cofactor II inhibition of thrombin is stimulated by dermatan sulfate proteoglycans synthesized by fibroblasts and vascular smooth muscle cells ([1331]). Thus, heparin cofactor II may be uniquely suited to regulate extravascular thrombin in areas of vascular endothelium disruption, in which heparin cofactor II would be exclusively stimulated by dermatan sulfate in the subendothelial layers. In addition, heparin cofactor II may participate in regulation of acute inflammation and wound healing by harboring a peptide chemotactic for neutrophils and monocytes that is released by leukocyte proteolysis ([1327]). Heparin cofactor II may also have a role in protection from thrombosis during pregnancy. Increased levels of dermatan sulfate in the

maternal and fetal circulation ([1332]) along with increased levels of heparin cofactor II in pregnant women have been reported ([1333], [1334]).

a $_1$-Proteinase Inhibitor (a $_1$-Antitrypsin)

a $_1$-Proteinase inhibitor is the most abundant circulating inhibitor of the serpin family. It circulates in blood at a concentration of 1.5 to 3.5 mg/ml (28 µmol/L) with a relative molecular weight of 53,000 ([1177]) (Table 21.4). It is synthesized predominantly in the liver and has a t $_{1/2}$ of 6 days ([1335]). a $_1$-Proteinase inhibitor is considered an acute phase reactant ([1336]).

Deficiency in a $_1$-proteinase inhibitor is a common autosomal-recessive disorder (1:1600 to 1:1800) that can potentially be lethal ([1337]). It is found associated with emphysema ([1253]), liver cirrhosis ([1255]), and hepatocellular carcinoma ([1255]). To date, there is no known treatment for a $_1$-proteinase inhibitor deficiency. Progress is under way to develop a therapy based on gene repair ([1338], [1339] and [1340]).

GENE STRUCTURE AND EXPRESSION The gene for a $_1$-proteinase inhibitor is located on chromosome 14 band q32.1, is approximately 5 kb long ([1341]), and contains seven exons and six introns ([1341], [1342], [1343] and [1344]) (Table 21.5). Uniquely, a $_1$-antichymotrypsin, corticosteroid-binding globulin, kallistatin, and protein C inhibitor also map to the same region on chromosome 14 ([1343], [1345], [1346]). These genes are actively transcribed in the liver and cultured hepatoma cells. However, a few other cell types (macrophages and intestinal epithelial cells) express some of these serpin genes ([1347]). Hepatocyte nuclear factor-1a and hepatocyte nuclear factor-4 play important roles in expression of the a $_1$-proteinase inhibitor gene in hepatic, intestinal, and pulmonary epithelial cells ([1348]).
BIOCHEMISTRY a $_1$-Proteinase inhibitor circulates in plasma at 1.5 to 3.5 mg/ml as a single-chain glycoprotein with a relative molecular weight of 53,000 ([1349]) (Table 21.4). a $_1$-Proteinase inhibitor is the most studied of the serpins, with high-resolution crystal structures achieved for the inhibitor by itself and in complex with a target protease ([1268]). The 452–amino acid sequence for human a $_1$-proteinase inhibitor shows two disulfide bridges and four glucosamine-based carbohydrate chains ([1350], [1351]). The reactive site bond that is targeted by serine proteinases is between Met ^{358} and Ser ^{359} ([1352]). Studies using ^{13}C nuclear magnetic resonance spectroscopy of the complex between human [^{13}C] methionine-labeled a $_1$-proteinase inhibitor and porcine pancreatic elastase have shown that a tetrahedral intermediate complex is formed during the serpin-proteinase interactions ([1353]). The three-dimensional x-ray crystal structure of cleaved a $_1$-proteinase inhibitor identified that for activity a $_1$-proteinase inhibitor requires the insertion of a single residue, Thr ^{345}, into ß sheet A ([1354]). This was supported by the x-ray crystal structures of a $_1$-proteinase inhibitor complexed with synthetic peptides that correspond to the unprimed NH $_2$-terminal side of the active site loop ([1355]). The five-stranded ß sheet A of a $_1$-proteinase inhibitor undergoes conformational changes that facilitate and stabilize the insertion into sheet A of the reactive center loop after cleavage by its target serine proteases. The solution structure of a $_1$-proteinase inhibitor has also been characterized by high-flux neutron scattering and by synchrotron x-ray scattering ([1356]).
FUNCTION a $_1$-Proteinase inhibitor can inhibit a wide range of serine proteases. Its primary physiologic target is the inhibition of neutrophil elastase to protect the elastin fibers of the lung. The role of a $_1$-proteinase inhibitor in blood coagulation is minimal. It has been shown to inhibit factor XIa *in vivo* ([1357], [1358]) and factor Xa in purified and plasma systems ([578]). APC complexes with a $_1$-proteinase inhibitor have also been detected by enzyme-linked immunosorbent assay in patients with DIC ([1359]). Inhibition by a $_1$-proteinase inhibitor is heparin independent.

C1 Esterase Inhibitor

C1 esterase inhibitor is a member of the serpin proteinase inhibitor family that is present at 170 µg/ml in blood with a relative molecular weight of 104,000 ([1360]) (Table 21.4). It is predominantly synthesized in the liver. When complexed with a protease (i.e., factor XIa), it has a t $_{1/2}$ of 95 to 104 minutes ([1357]). Targets for C1 esterase inhibitor are found in the complement cascade and the coagulation cascade.

Deficiency in C1 esterase inhibitor can result in hereditary angioedema ([1361]) and has been identified in a patient with lupus erythematosus ([1254]). Cases of acquired C1 esterase inhibitor deficiency have been reported associated with splenic lymphoma ([1362], [1363]). C1 esterase inhibitor–deficient mice show no obvious phenotypic abnormality ([1364]), although, in conjunction with a bradykinin type 2 receptor knock-out, diminished vascular permeability was observed ([1364]). The potential use of C1 esterase inhibitor in the treatment of sepsis, ischemia, and reperfusion is being investigated ([1365], [1366] and [1367]).

GENE STRUCTURE AND EXPRESSION The primary structure of human C1 esterase inhibitor was initially determined by peptide and DNA sequencing ([1368]). The only proteolytic processing that occurs is that a 22-residue signal peptide required for secretion is cleaved. The C1 esterase inhibitor gene is located on chromosome 11, bands p11.2-q13 ([1368]) (Table 21.5). The C1 esterase inhibitor gene consists of eight exons and seven introns and is approximately 17 kb in length ([1369]). *In vivo*, androgens enhance expression of C1 esterase inhibitor. *In vitro* studies show that C1 esterase inhibitor mRNA and protein levels increase after stimulation with ?- and a-interferon, TNF-a, IL-6, and monocyte colony-stimulating factor ([1369]). The molecular defects found associated with C1 esterase inhibitor deficiency include *Alu* repeat–mediated deletions, missense mutations, frameshifts, stop codon mutations, promoter variants, splice site mutations, or deletions of a few amino acids ([1370]). The clinical manifestation of this deficiency is predominantly angioedema.
BIOCHEMISTRY C1 esterase inhibitor is a single-chain glycoprotein containing 478 amino acid residues that circulates with an apparent molecular mass of 104,000 when analyzed by SDS-PAGE. The amino acids account for only 51% of the apparent molecular mass of the circulating protein, with 35% of the remaining mass accounted for by carbohydrate moieties ([1360]). Neutron scattering, x-ray crystal structure determinations, ^{1}H nuclear magnetic resonance spectroscopy, and Fourier transform infrared spectroscopy have been used to study the structure of C1 esterase inhibitor, revealing a two-domain structure ([1371], [1372] and [1373]). The NH $_2$-terminus, containing 113 amino acids, is heavily glycosylated with three N-linked and seven O-linked oligosaccharides. The COOH-terminus contains 365 amino acids with three N-linked oligosaccharides. When C1 esterase reacts with target proteases, the serpin undergoes changes in its whole secondary structure—not only the reactive site loop.
FUNCTION C1 esterase inhibitor is a member of the serpin inhibitor family. It plays an important role in the regulation of the classic complement pathway, specifically as the sole regulator of the activities of C1r and C1s ([1374]). C1 esterase inhibitor's role in coagulation is mainly targeted to the contact activation pathway through the regulation of kallikrein ([166], [1375]), factor XII ([126]), factor XIIa ([128]), and factor XIa ([275], [1357], [1376]). Unlike other serpin inhibitors, such as antithrombin-III, protein C inhibitor, or PAI-1, the activity of C1 esterase inhibitor is not affected by heparin ([1377]).

Protein C Inhibitor (Plasminogen Activator Inhibitor-3)

Protein C inhibitor is a member of the serine proteinase inhibitor family. It is also known as *PAI-3*. Protein C inhibitor is considered nonspecific in that its targets range from the procoagulant, anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen ([1378], [1379]). It is a 57,000 d protein that circulates in blood at a concentration of 5 µg/ml ([1380], [1381]) (Table 21.4). Protein C inhibitor is cleared from the circulation with a t $_{1/2}$ of 1 day. When in complex with a target (i.e., APC), it is cleared from circulation with a t $_{1/2}$ of 20 minutes ([1382]). Hereditary or acquired protein C inhibitor deficiency has not been documented to date ([1383]). A case-control study of thrombophilia showed that high levels of protein C inhibitor might constitute a mild risk factor for venous thrombosis. Protein C inhibitor–deficient mice (-/-) show impaired spermatogenesis and male infertility ([1384]).

GENE STRUCTURE AND EXPRESSION The gene for protein C inhibitor has been mapped to chromosome 14 band q32.1 (Table 21.5). It is 11.5 kb in length and consists of five exons separated by four introns ([1385], [1386]). The organization and location of this gene are similar to those of the genes for a $_1$-antitrypsin and a $_1$-antichymotrypsin, suggesting a common ancestor for these genes ([1385], [1387], [1388]). Human protein C inhibitor is mainly synthesized in the liver ([1381]) but has also been identified in platelets and megakaryocytes ([1389], [1390]), the kidney ([1391]), and the testes, seminal vesicle, and prostate ([1391]).
BIOCHEMISTRY Human protein C inhibitor has a relative molecular weight of 57,000 and circulates at 5 µg/ml ([1380], [1387]). The mature protein contains 387 amino acids; a 19–amino acid signal peptide is present before secretion. Five potential N-linked glycosylation sites were found in the mature protein ([1387]), and their roles in protein C inhibitor activity have been studied by mutational analysis ([1392]). The reactive site bond is located at Arg ^{354}–Ser ^{355}, and a stable 1:1 molar complex is formed between protein C inhibitor and its target proteinases. Protein C inhibitor binds heparin, and its activity is accelerated when in complex with heparin ([1393]);

unlike other related heparin-binding serpins such as antithrombin-III, heparin cofactor II, and protease nexin, the primary heparin-binding site of protein C inhibitor is in the H helix, not the D helix ([1394]).
FUNCTION Protein C inhibitor is a nonspecific inhibitor of serine proteinases and inhibits enzymes in blood coagulation, fibrinolysis, and fertility. The major target of protein C inhibitor, as its name suggests, is APC ([1382] , [1395] , [1396]). This is the physiologically most important inhibitor of APC. Protein C inhibitor has been shown to regulate TAFI activation by inhibiting the thrombin-thrombomodulin complex ([1397]). Its importance as a dual regulator of coagulation and fibrinolysis remains unresolved ([1398]). The importance of the regulation of APC by protein C inhibitor is evident by the use of this complex as a marker for detection of deep vein thrombosis by immunofluorometric assay measurements ([1399]). Other targets for protein C inhibitor include human plasma kallikrein ([173]), factor XIa ([173]), factor Xa, and thrombin. Because there are no documented patients with a deficiency to date, the actual function of protein C inhibitor *in vivo* is yet to be elucidated.

PROTEINS OF CLOT FORMATION

Early efforts to understand how blood clots form were directed at dissecting the vertebrate coagulation system and determining its components. This work revealed the central event in blood coagulation to be the conversion of soluble fibrinogen (factor I) to insoluble fibrin. Basically, this is accomplished when the coagulation enzyme thrombin (factor IIa) removes small polar peptides (termed *fibrinopeptides*) from each fibrinogen molecule forming fibrin. These fibrin molecules noncovalently interact with each other, forming a fibrin web. Fibrin stabilization is accomplished by the action of a second coagulation enzyme (factor XIIIa) that introduces numerous covalent cross-links between these fibrin molecules. The resulting fibrin web is able to capture platelets and red blood cells, effectively sealing the wound and stemming plasma loss.

Factor XIII (Fibrin Stabilizing Factor)

The first apparent suggestion of cross-linked fibrin by factor XIII came in 1923 from Barkan and Gaspar, who reported that fibrinogen preparations, when clotted in the presence of Ca^{2+}, generated clots that were insoluble in weak bases ([1400] , [1401]). Later, in the 1940s, work by Robbins ([1402]), Laki and Lorand ([1403]), and Lorand ([1404]) confirmed the presence of a serum factor that caused the transition to an insoluble clot and termed it *fibrin stabilizing factor*. It was not until 1963 that the International Committee on Blood Clotting Factors acknowledged fibrin stabilizing factor as a clotting factor and termed it *factor XIII* ([1401]).

Factor XIII functions as a transglutaminase that can form cross-linked amide bonds between specific glutamine and lysine residues on polypeptide chains. It plays an important role in hemostasis and thrombosis as well as participating in physiologic processes of cell proliferation and cell migration. FXIII(a) has multiple substrates including fibrin(ogen), fibronectin, a_2-plasmin inhibitor, collagen, vitronectin, vWF, actin, myosin, factor V, and thrombospondin ([1405] , [1406] , [1407] , [1408] , [1409] , [1410] , [1411] , [1412] and [1413]).

GENE STRUCTURE AND EXPRESSION Plasma factor XIII circulates as a heterotetramer comprised of two A-chains and two B-chains. The genes are located on different chromosomes. The gene for the factor XIII A subunit is located on chromosome 6, bands p24–25 ([1414] , [1415]), and spans approximately 160 kb ([1416]) (Table 21.2). The gene has 15 exons specifying a mature protein of 730 amino acids. The circulating product of the B subunit gene is a protein of 641 amino acids. The gene is located on chromosome 1, bands q31–32.1 ([1417]), spans approximately 28 kb, and has 12 exons ([1418]) (Table 21.2). Ten short homologous units, termed *sushi* or *glycoprotein-1 domains*, are coded for by exons 2 to 11 in the B subunit gene ([1419] , [1420]). Proteins associated with regulation of the complement system also contain sushi domains ([1421] , [1422]). Factor XIII deficiency is autosomal recessive and is a rare bleeding disorder. It has a frequency in the general population of 1 in 2 million ([1423]). The phenotype displays varying degrees of bleeding and is typically associated with the absence of cross-linking of fibrin monomers and impaired cross-linking of a $_2$-antiplasmin inhibitor to fibrin ([1424]). Mutations have been identified in both the A and B subunits, with the latter being the least common. Recent reviews by Loewy et al. ([1424]) and Ariens et al. ([1425]) describe the deficiency mutations and polymorphisms for both gene products that have been identified to date. Five common polymorphisms in the A subunit have been identified. Three of these (Val34Leu, Pro564Leu, and Glu651Gln) have allele frequencies greater than 0.2. Adverse effects have not been associated with the Glu651Gln variation; however, young women with the Leu564/Leu564 genotype may be at increased risk of hemorrhagic stroke ([1426]). The (Val34?Leu) polymorphism in the A subunit is found in approximately 25% of the population ([1427]). This Val to Leu replacement takes place three amino acids away from the thrombin cleavage site at Arg^{37}–Gly^{38} ([1427]). Due to its close proximity to the thrombin cleavage site, it has been postulated that this mutation might modulate FXIII activation. Studies suggest that this polymorphism is a determining factor in arterial and venous thrombosis ([1428] , [1429] , [1430] , [1431] , [1432] , [1433] and [1434]). This polymorphism has been suggested to be associated with a protective effect against myocardial infarction ([1428] , [1435]). The Leu encoding allele is lower in patients exhibiting myocardial infarction, deep vein thrombosis, and cerebral infarction. Studies also showed that the Leu34 mutation accelerates factor XIII activation by thrombin and affects fibrin cross-linking ([1436] , [1437] , [1438] and [1439]). This acceleration has been proposed to account for the wide reference range reported for factor XIII activity. A study by Undas et al. ([1440]) demonstrated in a bleeding time blood model that aspirin has a more pronounced effect on factor XIII activation when individuals are carriers of the Leu34 allele. The mechanism underlying the lower risk for myocardial infarction observed in the Leu34 carriers despite faster FXIII activation is still unclear.
BIOCHEMISTRY There are two pools of factor XIII—a plasma pool and an intracellular platelet pool. Plasma factor XIII circulates as a 320-kd A_2B_2 heterotetramer composed of two identical A-chains (M_r = 83.2 kd) and two B chains (M_r = 79.7 kd) ([1441]) (Table 21.1). The A- and B-chains associate noncovalently with an apparent binding constant of 0.4 µmol/L ([1442]). Plasma concentration of factor XIII is approximately 30 µg/ml (94 nmol/L) ([1443]), with a reference interval in the population of 66 to 134% ([1444]). The A subunit contains 730 residues, is not glycosylated, and contains three important functional sites: the catalytic site (Cys^{314}–His^{373}–Asp^{396}), a calcium binding site, and the activation peptide ([1445] , [1446]). The A subunit is arranged into five distinct structural domains: the activation peptide (residues 1 to 37); the beta sandwich (residues 38 to 184); the catalytic core (residues 185 to 515); barrel 1 (residues 516 to 628); and barrel 2 (629 to 730). The activation peptide of one A subunit limits access to the active site cysteine of the other A subunit of the dimer. The B subunit contains 641 residues, is glycosylated, and contains ten sushi domain repeats ([1419]). Each sushi domain repeat contains approximately 60 amino acids and is stabilized by two disulfide bonds. By electron microscopy, the B domain appears as strands that are thin, flexible, and kinked ([1447]). The B-chain has no enzymatic activity and has been thought to function as a carrier of the A subunit ([889] , [1448] , [1449]). Several x-ray crystal structures of the zymogen factor XIII A_2 subunit have been solved to 2.8 Å ([890] , [1450]). These studies revealed a catalytic triad of Cys^{314}–His^{373}–Asp^{396} similar in structure to that observed in cysteine proteases. Crystal structures of thrombin-activated factor XIII have been solved with ([1451]) and without Ca^{2+} ([1452] , [1453] and [1454]). The bone marrow is the primary site of synthesis for the plasma factor XIII A-chain ([1455] , [1456] and [1457]). Intracellular factor XIII is present in platelets, megakaryocytes, and monocytes as the 160-kd A_2 homodimer ([1458] , [1459] , [1460] and [1461]). The intracellular A_2 dimer, located in the cell cytosol, does not contain a leader sequence or carbohydrate, and its amino terminus is acetylated. How the A_2 dimer is transferred out of the cell and which cell type is the primary source of plasma A_2 are not clearly understood ([1462]). Secretion may be accomplished by the same pathway used by other nonclassically secreted proteins in blood, including fibroblast growth factor ([1463]) and the interleukins ([1464]). Approximately 50% of the total potential factor XIII A-chain activity in human blood is found in platelets ([1458]). During fibrin formation, platelet A_2 can be expressed on the platelet surface and plays an important role in fibrin cross-linking. Plasma factor XIII A-chains can also bind to thrombin-activated platelets ([1465] , [1466]). This binding is enhanced by thrombin cleavage of the A-chains as well as the thrombin-dependent activation of the platelet. The association of the factor XIIIa molecule with the activated platelet surface allows it to participate at the platelet-fibrin interface, thereby stabilizing hemostatic plugs. The factor XIIIa binding site on platelets can be degraded by plasmin ([1465]). The B subunit is solely synthesized in the hepatocyte ([1456] , [1467]) and is secreted as a monomer ([1467]). After being secreted, the A and B subunits associate, becoming an A_2B_2 tetrameric molecule in the blood.
ACTIVATION The process by which plasma factor XIII is activated is quite complex. Activation of the zymogen by thrombin occurs in the NH_2-terminus of the A-chains at Arg^{37}-Gly^{38} and releases a 36–amino acid activation peptide from each of the A-chains ([1468]) (Fig. 21.13). Whether immediate dissociation of the activation peptide from the rest of the molecule is part of the activation process is not clear because crystals of thrombin-activated FXIII showed no change in the location and conformation of the activation peptides ([1451]). This was also seen in the ion-bound structures ([1452] , [1453] and [1454]), in which the active site residues remained inaccessible to solvent and substrate. These combined results suggest that exposure of the catalytic residues is likely to occur on substrate binding ([1424]). Calcium is required for factor XIIIa to expose its active site cysteine ([1469] , [1470] and [1471]). Catalytic activity is expressed only after the A-chain dimer is dissociated from the B-chain through a Ca^{2+}-dependent process after thrombin proteolysis ([1448] , [1449]). Fibrin and fibrinogen play important roles as cofactors in the dissociation of the B-chains from thrombin-cleaved factor XIII ([1457] , [1463]). The intracellular form of factor XIII only contains the A-chain; therefore, it does not require the dissociation of the B-chain, but it still requires a calcium-dependent thrombin proteolysis.

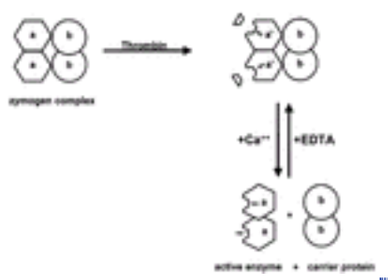

Figure 21.13. Activation of plasma factor XIII. The thrombin-catalyzed activation of plasma factor XIII (A_2B_2; 320,000 d) occurs in two steps. In the first step, thrombin cleaves the (R^{37}-G^{38}) bond. This releases the activation peptides (residues 1 to 37) from the A-chains, producing the inactive intermediate A'_2B_2. Fibrinogen, factor XIII, and thrombin interactions promote this event. In the second step, Ca^{2+} now causes the B-chains to dissociate from the A'_2B_2 intermediate, exposing the active site cysteine, Cys^{314}, of the A subunits. These chains can reassociate in the presence of divalent cation chelators like ethylenediaminetetraacetic acid (EDTA). The enzyme A^*_2 is now capable of catalyzing the formation of isopeptide bonds between glutamine residues and lysine residues of adjoining polypeptide chains. In this model, the A-chains are oriented in such a way as to promote cross-linking of fibrin polymers in an antiparallel configuration.

The process of factor XIII activation in whole blood has been correlated with fibrin formation ([934]). This creates a carefully regulated system that has cross-linked polymers occurring as soon as fibrin is being formed. The rate of thrombin cleavage of plasma factor XIII has been shown to be greatly accelerated by the presence of fibrin polymers ([1472] , [1473] , [1474] and [1475]). This positive feedback network between thrombin, fibrin(ogen), and factor XIIIa ensures that a stable clot can form rapidly to maintain hemostasis.

FUNCTION Activated factor XIII is essential for normal hemostasis and performs numerous functions in pathologic processes ([1401] , [1424]). Being a transglutaminase, activated factor XIII forms isopeptide bonds between the ?-carboxylamide and e-amino groups of glutamyl and lysyl residues, respectively. Factor XIIIa is the only enzyme in the blood coagulation cascade that uses a cysteine for catalysis. To date, no known endogenous inhibitor has been described to regulate this important enzyme. Substrates for factor XIII include fibrin(ogen), fibronectin, a_2-plasmin inhibitor, collagen, vitronectin, vWF, actin, myosin, factor V, and thrombospondin ([1405] , [1406] , [1407] , [1408] , [1409] , [1410] , [1411] , [1412] and [1413]). Fibrin is the main physiologic substrate for factor XIIIa. The basic mechanism involves ?-chain dimerization and a-chain polymerization by creating isopeptide cross-links. This reaction is extremely specific because only protein-bound glutamine residues can be a substrate for factor XIIIa. The structural specificity for this reaction remains poorly defined. It appears to reside within the primary amino acid sequence of the surface-exposed glutamine residues ([1476] , [1477]). How clot stabilization occurs in fibrin formation is covered in the section Polymerization (Fibrin Formation) .

Fibrinogen (Factor I) and Fibrin

This section focuses on the gene structure, structure/function relationships, and the regulation of fibrinogen and its insoluble counterpart fibrin. These topics, although extensively discussed within, have also been the subject of several comprehensive reviews ([1478] , [1479] and [1480]), as well as a 2000 New York Academy of Sciences symposium ([1481]).

Fibrinogen is composed of six polypeptide chains (two Aa-chains, two Bß-chains, and two ?-chains); after posttranslational modification, the mature protein circulates in the blood with an average molecular weight of 340,000 d (Table 21.1). The polypeptide chains are distributed into two symmetrical half molecules each containing one Aa-, one Bß-, and one ?-chain with the NH_2 and COOH-termini oriented in the same direction. The half molecules are linked by noncovalent and disulfide bonds at their amino termini, yielding a linear arrangement of three nodular structures. The outside two domains, formed by the carboxyl-terminal regions of the Bß- and ?-chains of fibrinogen are designated *D*, whereas the central domain that contains the amino termini of all the chains is designated *E*. Between 1.7 and 5.0 g of fibrinogen are synthesized per day by the liver ([1482] , [1483]) with approximately 75% of this fibrinogen secreted into the plasma and the remainder distributed between the lymph and interstitial fluids ([1483]). This translates into a mean plasma level of 2.5 mg/ml with a normal $t_{1/2}$ of 3 to 5 days ([1484] , [1485]). Fibrinogen is considered to be an acute phase reactant, and as such, it is up-regulated two- to tenfold in response to a variety of physiologic stresses including trauma, pregnancy, and tissue inflammation.

Fibrinogen has been found in the blood plasma of all vertebrates, including the most primitive vertebrate, the lamprey. Early phylogenetic work on fibrinogen began with protein sequences obtained for various fibrinopeptides ([1486] , [1487] and [1488]). It was immediately obvious that although these peptides were exceptionally variable, certain features were conserved; without exception, they all contained an arginyl-glycine bond required for thrombin cleavage ([1489]). Determination of the protein sequences for all three chains revealed that they were homologous and were evolved from a common ancestor ([1490]). The ß- and ?-chains share 42% identity within the fragment D domain, although they share no homology with the *C*-terminal a-chain ([1491] , [1492] , [1493] and [1494]). The *C*-terminal a-chain varies greatly between species (molecular weight ranges from 60 to 120 kd).

Sequence data, especially the detailed work determining intron/exon junctures, support the hypothesis that all three fibrinogen genes evolved from a common ancestor through a series of duplications that began approximately 1 billion years ago ([1495] , [1496] , [1497] , [1498] and [1499]). At this point, the ancestral gene duplicated to form both the Aa-chain and a ß/?-chain precursor gene. Then, sometime before the last time lampreys and mammals shared a common ancestor (450 million years ago), the ß/? gene duplicated, forming today's ß- and ?-chains. There is now a growing collection of proteins that share more than 30% sequence identity with both the ß- and ?-chains, including a $_E$C domains ([1500] , [1501] and [1502]), chicken cytotactin ([1503]), mouse T-cell protein ([1503]), sea cucumber ([1504]), and scabrous gene product from the fruit fly ([1505]).

GENE STRUCTURE AND EXPRESSION The fibrinogen locus is comprised of three closely linked genes (specifying the polypeptides Aa, Bß, and ?) found as single copies in a region of approximately 50 kb (bands q23 to q32) of chromosome 4 (1506–1509; reviewed in 1510) (Table 21.2). Both the Aa- and ?-chains are transcribed from the same DNA strand, whereas the Bß-chain is transcribed from the opposing strand ([1495]). The Aa gene contains six exons, whereas the Bß has eight and the ?-chain has ten ([1511] , [1512] and [1513]). Expression of all three genes appears to share a common regulatory mechanism, potentially via their 5'-flanking regions ([1514] , [1515] and [1516]). Therefore, expression for the three chains is coordinately controlled and, at least for the hepatocyte, results in almost equal levels of mRNA for each chain in the cell ([1510] , [1512] , [1517] , [1518]). A single transcription initiation event at the promoter of each chain produces multiple mRNAs due to alternative polyadenylation site selection in all three chains, as well as alternative splicing for both Aa- and ?-chains ([1502] , [1519] , [1520] and [1521]). In the case of the ?-chain, normal processing results in a polypeptide chain ending at $?Val^{411}$ (human numbering); however, approximately 10% of the time during splicing, the last intron is retained as an exon, resulting in a new chain, ?', which ends at $?Leu^{427}$ ([1510] , [1522]). The a-chain also fails to remove the last intron, producing a translated protein product that is 27-kd larger ([1500] , [1501] , [1523]). The resulting larger form of fibrinogen is called *fibrinogen-420* (1 to 2% of circulating human molecules), and the a-chain extension is called a $_E$*C* ([1524]). Interestingly, this new domain shares as much sequence identity (~40%) with the COOH-terminal domain of the ß- and ?-chains as the two share with each other ([1523]). Common polymorphisms of the fibrinogen genes are associated with plasma fibrinogen concentrations as well as susceptibility to, or severity of, atherothrombotic disease ([1525]). Epidemiologic studies have shown a strong association between two polymorphisms of the fibrinogen ß-chain gene and fibrinogen plasma concentration ([1526] , [1527]). However, the majority of the studies did not find any relation with fibrinogen polymorphisms and cardiovascular disease ([1526] , [1527]). The effect of these polymorphisms and vascular disease still remains in question because environmental or intermediate conditions of the phenotype can influence the outcome. This supports the notion of individualized susceptibility to disease, which is determined by the genotype and environmental risk factors.

Afibrinogenemia *Inherited* or *congenital afibrinogenemia* is an autosomal-recessive disorder characterized by a total lack of fibrinogen in the plasma. This disorder, originally described in 1920, now affects more than 150 families, putting the estimated prevalence in the general population at approximately 1:1 million ([1510] , [1528] , [1529]). It is usually detected at birth with uncontrollable bleeding from the umbilical cord. The phenotype varies from mild to severe with some patients experiencing spontaneous intracranial hemorrhage and splenic rupture throughout life, as well as bleeding after minor trauma ([1530] , [1531]). It has been suggested that the presence of functional vWF, which allows platelet thrombus formation in the absence of fibrin, may be responsible for the phenotypic variation observed ([1532] , [1533]). Most patients respond well to replacement therapy ([1534]). To date, 86% of all afibrinogenemia results from a truncation mutation in the fibrinogen alpha gene ([1529]). Investigation of the roles that both fibrinogen and fibrin play *in vivo* has been greatly enhanced by the creation of transgenic mice either lacking fibrinogen ([1535]) or expressing a modified form of fibrinogen ([1536]). The fibrinogen-deficient mice (Fib $Aa^{-/-}$) were often able to survive to sexual maturity even though they had no immunologically detectable levels of any chain (Aa, Bß, ?) in circulation ([1535]). As expected, plasma from these deficient mice was unable to clot *in vitro* even when combined with exogenous thrombin. In addition, the plasma did not support platelet aggregation *in vitro*. This is consistent with the view that fibrinogen bridges platelets via activated receptors (e.g., $a_{IIb}ß_3$) ([1537]). However, *in vivo*, these mice are able to form platelet thrombi and are often able to withstand spontaneous

bleeding episodes ([1533]). The resilience of the Fib Aa $^{-/-}$ mice is probably due to the fact that all factors required for thrombin generation and platelet activation are present and that platelets have alternative ligands for their activated receptors that are capable of supporting adhesion and thrombus formation ([1528]). Breeding experiments crossing fibrinogen-deficient mice with other mice deficient in a hemostatic factor are providing insights into the roles fibrinogen and fibrin play *in vivo*. For example, mice with combined deficiency in both fibrinogen and vWF were found to form stable thrombi, although platelet deposition was found to be delayed and unstable ([1533]). However, crossbreeding plasminogen (Plg $^{-/-}$)-deficient mice with fibrinogen-deficient mice eliminated many of the spontaneous pathologies [conjunctivitis, pulmonary lesions, terminal vessel thrombosis, ulceration or prolapse of the rectum, and wasting ([1538] , [1539])] normally associated with the Plg $^{-/-}$ genotype, including death at 6 months. In addition, the delayed tissue repair observed in Plg $^{-/-}$ mice after arterial challenge ([1540]), corneal damage ([1541] , [1542]), or skin incision were all corrected by the removal of fibrinogen. These data, in combination with other data not discussed here, support the concept that the physiologic role for the plasminogen activation system is fibrin lysis ([1543]).

Hereditary Dysfibrinogenemias Like many of the other coagulation disorders, classic dysfibrinogenemias were frequently recognized by the mother when her child bled abnormally. These disorders are associated with prolonged thrombin times usually caused by a point mutation in one of the chains, but clinically, the patient presents with normal plasma fibrinogen concentrations. Hypofibrinogenemias, on the other hand, are associated with low plasma fibrinogen concentrations (<1.5 mg/ml) due to a mutation(s) that can affect transcription, mRNA processing, translation, chain processing and assembly, excretion, or stability of the mature protein ([1544]). Hypofibrinogenemias can be classified into four groups according to the effect of the mutation: (a) mutations that affect intracellular processing, (b) retention in the endoplasmic reticulum, (c) intracel-lular assembly, and (d) Aa-chain truncations ([1530] , [1531] , [1544]). Dysfibrinogenemias can be divided into five groups based on their specific action: (a) mutations that impair or impede thrombin, (b) defects in the construction of protofibrils, (c) impaired lateral association of protofibrils, (d) defects in interactions with other substances, and (e) other unknown mechanisms ([1544]). Thus, most common mutations are those that impede conversion of fibrinogen to fibrin by thrombin, which catalyzes the hydrolysis of the bonds between Arga ^{16}-Glya ^{17} and Argß ^{14}-Glyß ^{15} releasing FPA and FPB, respectively. The active site of thrombin is highly specific for an arginine in the P1 position as observed by the human variant replacement of Arga ^{16} by His, which leads to delayed release of FPA ([1545]) or Cys, resulting in no release of FPA ([1546] , [1547]). In the case of Argß ^{14}, only a Cys variant [fibrinogen Christchurch ([1548])] has been observed. The identification of these mutations, originally through protein chemistry methods and now using DNA technology, has provided unique insights into the structural/function relationships of fibrinogen and fibrin. These mutants were originally gathered and published in the *Index of Variant Human Fibrinogen* ([1549]), but with the advent of the Web, the material has been converted to a dynamic database (http://www.geht.org/databaseang/fibrinogen/) ([1550]). As of October 2002, 300 molecular abnormalities were present in the database, with 185 found in the Aa-chain (74 were Arga ^{16} mutations), 33 in the Bß-chain, and 82 in the ?-chain (26 were Arg? ^{275} mutations).

Biosynthesis Pulse chase experiments in a human hepatic carcinoma line have shown that there is a large intercellular pool of both Aa- and ?-chains, but it is the Bß-chain synthesis that limits assembly in the rough endoplasmic reticulum ([1551] , [1552]). However, in both chicken and rat hepatocytes, it seems to be the Aa-chain that limits fibrinogen assembly ([1552] , [1553]). Several extrahepatic sites of fibrinogen synthesis have been identified, including human cervical epithelial cells ([1554]) and lung alveolar epithelial cells ([1555]). ?-Chain-only synthesis has been observed *in vivo* in the brain, lung, and bone marrow ([1556] , [1557]). The physiologic role remains to be determined for any of these proteins. After synthesis but before secretion, a number of posttranslational modifications occur (Table 21.7). For example, all three chains are originally synthesized with signal peptides that are removed during or after passage across the membrane ([1558]). In addition, both the Bß- and ?-chains are glycosylated with a biantennary carbohydrate (M $_r$ º 2500 d) being added to Asn? ^{52} on the ?-chain much earlier than the Asnß ^{364} on the Bß-chain ([1556] , [1559] , [1560] , [1561] and [1562]). When synthesized, fibrinogen is fully phosphorylated (Sera ^{3} and Ser3a ^{46}), but in its circulating form, only 20 to 30% of these sites are still phosphorylated ([1563]). The first residue on the Bß-chain is also posttranslationally modified to form pyroglutamic acid, thus removing its free amino terminus.

TABLE 21.7. Key Features of Human Fibrinogen Chains

	Aa	aEC	Bß	?	?'
Total number of residues	610	236	461	411	427
Expression level (%)	98	2	100	90	10
Fibrinopeptide length	16		14		
Thrombin cleavage site	Arg ^{16}-Gly ^{17}		Arg ^{14}-Gly ^{15}		
Newly exposed N-termini	Gly ^{17}-Pro-Arg-Val		Gly ^{15}-His-Arg-Pro		
Cross-linking sites					
Acceptor (Gln)	328, 366			398	
Donor (Lys)	508–584			406	
Number of calcium-binding sites	?	1	2	1	1
Carbohydrate linkage site		667	364	52	52
Phosphorylation site	3, 346				

BIOCHEMISTRY AND ACTIVATION The fibrinogen molecule contains two copies of three separate polypeptide chains designated *A*a, *B*ß, and ? (Table 21.7). These are arranged into two identical half molecules containing a single copy of each polypeptide chain. The region of interaction between the two half molecules, involving the six NH $_2$-termini of the polypeptides, is called the *central domain* or the *N-disulfide knot* ([1486] , [1564]). There are 11 disulfide bonds in this region, three of which link the two half molecules. A variety of experiments, in which one or more of the 29 intra- and interchain disulfides were removed or small deletions made, revealed that for dimer formation both disulfide bonds and the noncovalent interactions of the amino termini are important ([1565] , [1566] , [1567] , [1568] and [1569]). The common form of the Aa-chain contains 610 amino acid residues with a M $_r$ of 66,500. It is not glycosylated but does have two phosphorylation sites (Ser ^{3} and Ser ^{346}). Thrombin cleavage of the Arg ^{16}-Gly ^{17} bond of the Aa-chain releases FPA. The Aa-chain of fibrinogen has sites appropriate for factor XIIIa–catalyzed formation of cross-links ([1570]) as well as consensus integrin recognition sites at residues 95 to 98 and residues 572 to 575. The Bß-chain is comprised of 461 amino acids and displays a M $_r$ of 52,000. It is glycosylated at a single site (Asn ^{364}) and has a Ca $^{+2}$ binding site (residues 381 to 385). Thrombin cleavage of the Arg ^{14}–Gly ^{15} bond releases FPB. No residues in the Bß-chain participate in cross-link formation. The ?-chain of fibrinogen is made up of 411 amino acids with a M $_r$ of 46,500. It is glycosylated at Asn ^{52} and has a Ca $^{2+}$ binding site (residues 318 to 324) and donor (Gln ^{398}) and acceptor (Lys ^{406}) sites for cross-link formation. A comprehensive history of early fibrinogen and fibrin structure/function relationships can be found in an excellent review by Blombäck ([1481]). In the first recorded structural experiment, Bailey et al. ([1571]) placed both a concentrated solution of fibrinogen (which forms a viscous strand) and a fibrin thread in an x-ray beam. The resulting patterns were indistinguishable not only from each other, but also from the patterns of keratin and myosin. They all showed a characteristic 5.1 Å–repeat spacing that was later determined to be due to supercoiled a helices ([1572]). Around this same time, a different physiochemical “picture” of fibrinogen was emerging. Techniques including electrophoresis, ultracentrifugation, viscosity measurements, and light scattering were coming into vogue and determined that fibrinogen was a prolate ellipsoid with a length between 500 to 700 Å, an axial ratio between 5 to 20 Å, and a molecular weight near 340 kd ([1573] , [1574] , [1575] and [1576]). Hall and Slayter ([1577]) produced shadow-cast photographs of fibrinogen and observed three, unconnected globules in a line. The center globule was the smallest, with a diameter of approximately 50 Å; the terminal globules were found to be of equivalent size, approximately 60 Å. The total molecule length was estimated to be 475 Å; thus, the connections between the globules were approximated to 150 Å, and Cohen ([1578]) suggested that these globules could be linked by a helices, which would explain the characteristic a-helix 5.1 Å–repeat spacing observed in the fiber diffraction. This trinodular structure has become known as the *Hall and Slayter model of fibrinogen*. A period of debate ensued because the images of the three globules could not be repeated with any of the new and more sensitive electron micrograph techniques becoming available; rather, often a single large globule was observed, prompting other models for fibrinogen ([1579] , [1580]). The matter was finally resolved in 1979, when Fowler and Erickson ([1581]) produced a definitive series of electron micrographs using both the newer negative staining and older shadow-cast techniques to produce images equivalent to Hall and Slayter's. In retrospect, the long delay in confirming Hall and Slayter's work is due to the fact that native fibrinogen is a fragile entity that is easily denatured under many of the conditions used. The reconstruction of fibrinogen from both enzymatic and chemical fragmentation products has allowed an exact picture of the structure and function of fibrinogen to emerge. Many fragments were subjected to protein sequencing, and the sequences reassembled until the whole structure was determined. These fragments also gave insights into the polymerization process as well as the shape of fibrinogen. Because plasmin is the natural protease for fibrin removal, it was the obvious choice for initial fragmentation. Nussenzweig et al. ([1582]) characterized such a fibrinogen lysate that was chromatographed using a diethylaminoethyl cellulose column. The resulting peaks were denoted *A* through *E*, and it was determined that the pools D and E contained the bulk of the material, with an approximate mass ratio of 2:1. This coordinated well with the Hall and Slayter model in which pool E would represent the center globule and the terminal globules would be found in pool D and called *fragment E* and the terminal globules would be found in pool D and called *fragment D* ([1583]).

Thus, fibrinogen is a symmetric molecule, with a dyad axis drawn through fragment E. Much effort has been expended in trying to crystallize fibrinogen. The first view was an 18-Å structure of a modified bovine fibrinogen ([1584]), later refined to approximately 4 Å ([1585]). The modification was a partial proteolysis that predominantly removed the *C*-terminal a-chains. However, the density for the central domain was “poorly defined.” The first look at an unmodified fibrinogen was the 5.5-Å followed by 2.7-Å structures of chicken fibrinogen ([1586] , [1587]). Chicken fibrinogen was chosen as a target because it has the shortest a-chains that lack a series of repeated sequences found in most other species ([1500] , [1588] , [1589]) (Fig. 21.14). This structure provided the first atomic resolution view of the central domain of fibrinogen, although the a domains were too disordered to allow the chain to be traced. Recently, a 35-kd digestion product of fragment E (FE $_5$) was solved at 1.4 Å ([1590]), which correlates well with the observed fragment E region in the 2.7-Å chicken fibrinogen structure described above.

Figure 21.14. Chicken fibrinogen (PDB: 1M1J). A ribbon diagram depicting the 2.7-Å structure of chicken fibrinogen. All six NH $_2$-termini are gathered together in the central or E domain. Three chains [a-, ß-, and ?- (shaded differently)] extend out from this domain through coiled-coils in either direction forming the terminal or D domains. Individual subdomains (ßC, ?C, ß?C, ?'?C) of the D domains as well as carbohydrates (CHO) are indicated. Note the carboxy termini of the a-chains are not visible in this structure. (Adapted from Yang Z, Kollman JM, Pandi L, et al. Crystal structure of native chicken fibrinogen at 2.7 Å resolution. Biochemistry 2001;40:12515–12523.)

The structure of the a-chain extension (a $_E$C) from fibrinogen-420 ([1591]) confirmed the strong sequence homology observed between the ß and ?, with a root mean square difference of less than 1.3 Å measured between chains ([1521]). As predicted, a calcium-binding site and a carbohydrate cluster were found. The most striking difference between the a $_E$C domain and either the ß or ? domains was the binding “hole”; although it still remains well defined by loops, none of the charged residues required for sequestering a charged “knob” remain. It has been speculated that this “hole” may be reminiscent of an archetypical fibrinogen molecule with a role in lectin binding ([1591]). The first atomic resolution structure in the fibrinogen field was for a human recombinant ?-chain ([1592]). As predicted, the fold of the ?-chain was unique and was not represented in the structural databases ([1491]). The 2.9-Å structure of a core fragment of human fibrinogen (fragment D) has been achieved. Fragment D, an 86-kd three-chained structure, consists of a “plough shape” with coiled-coils forming the handle and the two globular ß and ? domains forming the furrow ([887]). As expected, the ß and ? domains share the same fold ([1592] , [1593]) and are oriented approximately 130 degrees apart. These observations have been confirmed in a recent structure of lamprey fragment D ([1594]) and a recombinant human fragment D ([1595]). These structures, although informative, failed to explain how the three chains interacted with each other or how they were arranged in the globules observed in Hall and Slayter's electron micrographs. To date, a crystal structure of intact human fibrinogen has not been solved.

POLYMERIZATION (FIBRIN FORMATION) In 1952, Ferry ([1596]) proposed a half-staggered overlap model to explain the polymerization process. This model can be expressed succinctly in terms of “knobs” and “holes” ([1490]). When thrombin removes the fibrinopeptides, it creates new amino termini on the a- and ß-chains called *knobs*. Because the knobs are located in the central globule E domain of the Hall and Slayter model, the holes for them to fit into must be present on the terminal D domains. To accommodate the half-staggered overlap model, the knobs on one molecule interact with holes in two different molecules. Reciprocally, a knob from each of these molecules fits into the holes on the first molecule's fragment D. The availability of holes in fibrinogen has been experimentally demonstrated when it is bound to immobilized fibrin on a Sepharose column ([1597]). The NH $_2$-terminal disulfide knot (produced by cyanogen bromide cleavage of fibrinogen and containing fragment E), when activated by thrombin, could bind either fibrinogen or fragment D ([1598]). Therefore, the knobs must reside in the central domain and the holes in the fragment Ds. The binding site of the a and ß knobs were localized to the ?- and ß-chains, respectively, using fragment D digested to different extents ([1599]). To identify the polymerization hole in the ?-chain, recombinant ?-chain crystals were soaked in a solution containing a peptide mimic of the knob ([1593]). As was expected, the hole was preformed and contained a strong electronegative potential that was neutralized on the binding of the doubly positively charged peptide. The binding interaction was noncovalent and comprised of only ionic and hydrogen bonds ([1600]). The existence of a ß-chain hole and that this hole binds the ß-chain knob were confirmed with a double-D x-ray crystal structure in which peptide knobs for the a- and ß-chains were present ([1601]). In another study using combinations of peptide knobs, it was determined that the ß hole is not fully formed until the knob is present ([1602]). Apparently, when the peptide enters the hole, one side of the hole swings approximately 10 Å to hold the ß knob securely, releasing a Ca $^{2+}$. This conformational change may be the basis for the acceleration of fibrin formation observed in the presence of the peptide ligand GHRP ([1480] , [1599]). No evidence has been found for an analogous mechanism with the ? hole; rather, the ? hole seems always ready to accept an a knob. In that regard, in the absence of an a knob, the ß knob readily binds to both holes ([1602]). No examples of an a knob ever occupying a ß hole have been seen. This process, the conversion of fibrinogen to fibrin, can be separated into three congruent processes: (a) removal of the fibrinopeptides, (b) assembly, and (c) covalent stabilization. We examine each in depth in the following sections.

Fibrinopeptide Release Many early investigators tried to determine the differences between fibrinogen and fibrin. Their molecular weights were identical, and fibrinogen was the more electronegative of the two ([1603]). In the conversion of fibrinogen to fibrin, thrombin catalyzes the hydrolysis of Arg-Gly bonds removing small, polar amino terminal pieces (fibrinopeptides) from the a- and ß-chains ([1604] , [1605]). Cleavage of Aa–Arg ^{16} by thrombin releases FPA and forms fibrin I. The release of two FPA peptides exposes a site in the E domain that aligns with a complementary site in the D domain to form overlapping fibrils. Subsequent cleavage by thrombin at Bß–Arg ^{14} releases FPB and leads to the formation of fibrin II, presumably increasing lateral aggregation of the protofibrils. FPA and FPB vary in length (between 13 to 21 amino acids in various mammals) and constitute less than 2% of the total mass ([1606]). Early studies in citrated plasmas or purified fibrinogen found that FPA and FPB are released at very different rates, with FPA being released first ([1604] , [1607] , [1608] and [1609]). A sequential model for release has been postulated in which thrombin binds equally to both chains, but the presence of FPA hinders the release of FPB because thrombin is unable to undergo a required conformation change ([1610] , [1611] , [1612] and [1613]). As polymerization process proceeds, the FPB release rate continues to increase, suggesting that a polymerization-induced structure change facilitates its release ([1610] , [1611] , [1614]). When the fibrinogen to fibrin conversion is studied in a nonanticoagulated whole blood system, the pattern of fibrin formation based on fibrinopeptide release is different from that seen in citrated plasma or purified fibrinogen ([934]). Bettelheim and Bailey ([1615]) first hypothesized that on FPA and FPB release these newly exposed amino termini (knobs) must be the principal contact sites during polymerization. In human fibrinogen, the a-chain knob, after FPA release, begins with the sequence GPRVV, whereas the ß-chain, after FPB release, starts with GHRPL. Synthetic peptide GPR derivatives based on the a knob were found to bind to both fibrinogen and fragment D and inhibit fibrin monomer polymerization ([1599]). Peptides based on the ß knob also bound to both fibrinogen and fragment D but were unable to inhibit fibrin monomer polymerization. In analogous studies, venoms can be used to selectively remove only FPA without activating factor XIII, and fibrin will still form ([1616] , [1617]). Although it appears morphologically the same, this type of fibrin lacks the normal strength of fibrin ([1618] , [1619] and [1620]). Removal of only FPB (without FPA release) results in fibrin formation in lampreys ([1489]), but human fibrinogen clots only if the temperature is maintained below 15°C ([1621]). In fact, Doolittle et al. ([1480]) postulated that the ß knobs act like claspers in ß holes, thus holding abutting molecules together rather than being involved in lateral growth.

Fibrin Assembly The release of the fibrinopeptides from fibrinogen results in the formation of an intermediate termed *fibrin monomer*, which is all but indistinguishable from fibrinogen. In purified systems, removal of either FPA or FPB leads to the formation of the fibrin dimer through the noncovalent—charge-charge (salt links) and hydrogen—bonds between the knobs and the holes ([1622]). As fibrin monomers continue to be generated, the dimer elongates from both ends as a two-stranded molecule until it reaches approximately 30 monomers when it becomes a protofibril ([1607] , [1623] , [1624]). The second step in fibrin assembly is the lateral association of protofibrils into thicker fibrin fibers ([1623] , [1624]). These fibers are formed from the association of between 14 and 22 protofibrils ([1625]). Because protofibrils, not dimers, are required for this step, it is believed that the forces involved in lateral association are weak and, therefore, only become “strong” in large numbers. Fragment D, specifically the ß-chain, is likely responsible for this aspect of fiber growth ([888] , [1626] , [1627]). Clots are known to branch, although how this is accomplished is not clear. For example, perhaps a protofibril can attach and form a link between two growing fibers ([888] , [1628]), or perhaps this is the role for the *C*-terminal region of the a-chains ([1629] , [1630]). The presence or absence of carbohydrates also seems to affect branching ([1562]). Fibrin lore specified that removal of only FPA produced fine clots composed of only protofibrils and thin fibers and that FPB removal was required for lateral growth and the formation of thicker clots ([1607] , [1631]). This myth was dispelled by Weisel ([1632]), who performed extensive electron micrograph analysis on fibrin created with only FPA, only FPB, or both removed and found an almost invariant fiber diameter of 85 plus or minus 13 nm. The goal of a clot is to build a scaffold of sufficient mechanical strength to serve as a hemostatic plug. Interestingly, only 20% of a clot is actually protein—the remainder is solvent ([1633]). The description of fibrinogen activation and fibrin assembly has been based on studies using citrated plasmas or purified proteins, or both. To understand the *in vivo* process of fibrin formation, a system with nonanticoagulated blood has been used; in this experimental model, the pattern of fibrin formation based on fibrinopeptide release is different from systems using citrated plasma or purified fibrinogen ([934]) (Fig. 21.15). In this study, cleavage of FPA and subsequent clot formation occur just before the propagation phase of thrombin generation. At the point of visual clot formation, virtually all fibrinogen (and some product already cross-linked) disappears from the fluid phase of the reaction. Thus, the “clot” appears to be a mixture composed of fibrin I and fibrinogen. The insoluble material present in the fibrin clot is virtually all cross-linked by factor XIIIa, whose activation is nearly simultaneous with FPA removal. Therefore, the transglutaminase factor XIIIa is available to cross-link the ?-chains of initial fibrinogen/fibrin I clot. In purified systems, it has been observed that FPB removal precedes the cross-linking reaction. However, in the whole blood clotting model, the FPB antigen epitope is found associated with the ß-chain after clot formation has occurred. FPB release proceeds at a slower rate than FPA release, occurs after ?-? dimer formation, and only reaches approximately

38% of its theoretical maximum value. These results makes one wonder about the true role of ß knobs in clot formation because FPB release does not appear to be required for factor XIIIa cross-linking to occur. Subsequent to FPB release in whole blood, a carboxypeptidase B–like enzyme cleaves FPB, generating des Arg FPB ([934]).

Figure 21.15. Schematic representation of whole blood fibrin formation. Thrombin at the beginning of clot formation simultaneously acts on fibrinogen (D-E-D) and factor XIII (fXIII). A portion (~40%) of fibrinopeptide A (FPA) is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent molecules. Activated factor XIII (fXIIIa) simultaneously cross-links adjacent D domains (D=D). Thus, the initial soluble fibrin clot is composed of fibrinogen, fibrin, and ?-? dimers with fibrinopeptide B (FPB) still attached. The initial clot is continuously acted on by thrombin, releasing the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The released FPB is selectively acted on by a carboxypeptidase B–like enzyme (CPB) cleaving the carboxyl terminal arginine to produce des-Arg FPB. The significance of this cleavage is still unclear. See Color Plate. (From Brummel KE, Butenas S, Mann KG. An integrated study of fibrinogen during blood coagulation. J Biol Chem 1999;274:22862–22870, with permission.)

Fibrin Cross-Linking To strengthen the "weak" (noncovalent) interactions holding the dimers and protofibrils together, factor XIII (a transglutaminase found circulating in the plasma) is activated to factor XIIIa by thrombin in the presence of Ca^{2+} to link the side chains of lysyl and glutamyl residues by isopeptide bonds. Thrombin activation of factor XIII activation has been shown to coincide with FPA release during the initiation phase of thrombin generation ([526] , [934]). The concentrations of thrombin (based on thrombin–antithrombin III complex) needed for factor XIII activation, FPA release, and FPB release have been calculated to be 0.8 plus or minus 0.3 nmol/L, 1.3 plus or minus 0.4 nmol/L, and 1.7 plus or minus 0.5 nmol/L, respectively ([526]). It has been proposed that as many as six cross-links can form between a fibrin monomer and its neighbors ([1634] , [1635]) and that the presence of these cross-links increases the strength, chemical resistance to urea, and lysis by plasmin ([1402] , [1403] , [1636] , [1637] , [1638] , [1639] and [1640]). Early in fibrin assembly, factor XIIIa has been shown to link Gln? [398] and Lys? [406] in reciprocal cross-links between adjacent *C*-terminal ?-chains ([1408] , [1641]). These cross-links are termed *longitudinal* or *end-to-end cross-links* when linked between adjacent monomers in the same strand of the protofibril ([1642]). However, if the cross-link exists between monomers on opposing strands, then the link is termed *transverse* ([1627] , [1630]). This has created some controversy in the field: The crystallographers believe in only longitudinal cross-links based purely on distance constraints, because the links were not resolved in the electron density ([887] , [1602]); however, the electron micrograph people believe that their data prove transverse cross-links exist, and the crystallographers become confused on a rearrangement that occurs in the formation of the plasmin-derived DD fragment ([1643] , [1644]). Once the majority of ?-chain cross-links are inserted, then a much slower process begins to insert multiple cross-links between neighboring a-chains ([1645]). Because each a-chain has two glutamyl acceptor sites and five potential lysine donor sites, a complex cross-linked network can result ([1646]). The result is cross-linked fibrin, which is more resistant to clot lysis ([1640] , [1647]). Factor XIIIa also covalently attaches a $_2$-plasmin inhibitor (the principal fibrinolytic inhibitor) to a chains in the clot, thereby increasing resistance to degradation ([1648] , [1649]).

FUNCTION Fibrinogen is the final clotting factor that is activated during the coagulation cascade. Its function in hemostasis is to stem blood loss. It serves as a molecular bridge to support intraplatelet aggregation, and it is the precursor of fibrin, which is the main component of the protein scaffolding of the forming hemostatic plug. Platelet aggregation critically depends on fibrinogen binding to activated platelets via the platelet fibrinogen receptor gpIIb-IIIa. Fibrin adhesion to stimulated platelets is also important in thrombus formation. Fibrinogen/fibrin also regulates thrombin activity by interactions that include the proteolytic cleavage by thrombin of fibrinopeptides to form a fibrin clot and thrombin exosite binding to fibrin, which potentially limits the diffusion of thrombin, thereby regulating clot propagation. The structure, stability, and duration of the insoluble counterpart fibrin are controlled by an interplay between fibrin formation and fibrinolysis, which includes other molecular and cellular components. An important enzyme for the structure and stability of the fibrin clot is the transglutaminase factor XIIIa. Its function is to cross-link fibrin and other adhesive proteins including integrin receptors providing a stable network. Once activated, the fibrinolysis inhibitor called *TAFI* functions to attenuate fibrinolysis by removing *C*-terminal lysines from fibrin. This appears to be critical in the stabilization of the fibrin clot by reducing the number of sites available for plasminogen binding, thus reducing the rate of plasmin generation with consequent prolongation of fibrin dissolution ([1650] , [1651]). TAFI has also been shown to play a role in the premature lysis of clots from hemophilic plasma ([1652]). Fibrinogen is primarily recognized for its role in hemostasis but is also required for competent inflammatory reactions. Fibrinogen is an acute phase reactant, with levels increasing during inflammation. During these situations, fibrinogen functions as a bridging molecule in cell–cell interactions. Fibrin and fibrinogen constitute a matrix that can allow for the modulation of cellular responses through a variety of different cell types including endothelial cells, epithelial cells, leukocytes, platelets, and fibroblasts. Cellular receptors that can bind fibrinogen and fibrin include the integrins $a_{IIb}ß_3$, $a_Vß_3$, and $a_5ß_1$ and the cellular adhesion molecules intercellular adhesion molecule-1 and vascular endothelial cadherin. Although the function of fibrinogen and fibrin as a barrier to stemming blood loss through the dense fibrin network appears central to hemostasis, the findings from fibrinogen-deficient mice suggest that compensating mechanisms exist. Homozygous Aa-chain–deficient mice are born with normal appearance and without elevated fetal mortality ([1535]). These mice have no detectable levels of the Aa-, Bß-, and ?-chains in their blood ([1535]). Therefore, the maintenance of hemostasis in these animals is most likely derived from normal thrombin generation and the support of platelet aggregation and adhesion by vWF. Most clinical assays use fibrin formation as a means to assess hemostatic status (PT and activated partial thromboplastin time). The formation of a visible fibrin clot occurs during the initiation phase of coagulation at very low levels of thrombin (10 to 30 nmol/L), or approximately 3 to 5% of the total amount of thrombin produced ([526] , [565]). The majority of thrombin (~95%) is generated after clot formation during the propagation phase, which is overlooked when a fibrin endpoint assay is used ([526]). In congenital hemophilia A and B, only a slight prolongation of clot time is observed; the major impairment is in thrombin generation during the propagation phase of the reaction (Fig. 21.7) ([804]). Thus, most catalyst and thrombin formation is ignored using the current technology for evaluating clinical hemorrhagic risk or thrombosis. The survivability of the afibrinogenemic genotype in mice and male patients also supports this concept that critically important events are taking place beyond the endpoint of fibrin formation.

REGULATION OF FIBRIN LYSIS The coagulation system prevents blood loss at the site of injury, filling one role in hemostasis. However, there must also exist mechanisms to limit the coagulation system and processes to remove a clot once it is no longer needed. This role is filled by the fibrinolytic system that uses elements from plasma, platelets, tissue, and other blood cells to regulate the degradation of fibrin. The main player is the zymogen plasminogen that on activation becomes plasmin, a serine protease, whose primary physiologic role is the degradation of the fibrin clot and extracellular matrix molecules. Even though the plasmin cleavage sites are similar for both fibrinogen and fibrin, we consider them separately for clarity.

Fibrinogenolysis Marder ([1653] , [1654]) proposed a scheme for fragmentation of fibrinogen based on his own detailed studies and the work of others ([1655] , [1656]). In the first step, fibrinogen is converted to fragment X (M_r º 247,000) by the removal of the *C*-terminal a-chain as well as the first 42 amino acids of the ß-chain ([1657] , [1658]) (Fig. 21.16). Fragment X remains clottable before it is split asymmetrically, forming fragment Y (M_r ~150,000), fragment D (M_r ~88,000), and some small detritus relating to the coiled-coil region. Finally, fragment Y is further split into fragment D and fragment E (M_r ~50,000), and some more detritus are released.

Fibrinolysis Differences observed in the degradation products between fibrinogen and fibrin are due to the presence of the cross-links, not a change in the specificity of plasmin, which predominantly attacks the coiled-coil region between fragment E and fragment D. Degradation of cross-linked fibrin is much slower than fibrinogen in large part due to the inaccessibility of the plasmin cleavage sites ([1657] , [1659] , [1660]). The first step in degrading cross-linked fibrin is the removal of the a-chains so that the coiled-coils are exposed. As the coiled-coils are cleaved, different-sized fragments are released ([1661]). The smallest of these degradation products are double-D (M_r ~180,000), also known as *D-dimer*, a soluble fragment in which the two D fragments are linked by two isopeptide linkages, and a fragment with the stoichiometry D_2E (termed *DY*; M_r ~235,000), a double-D and a fragment E held in place by strong, noncovalent bonding ([1662] , [1663]). A large number of intermediate-sized fibrin degradation products arising from cleavages between the fragment D and fragment E region are also generated (Fig. 21.16). The largest of these fragments is the XXD (two fragment Xs and a fragment D) with a mass in the range of 595 kd. Some of these complexes (i.e., D-dimer) have been identified in the blood of patients with various thrombotic or thrombolytic disorders.

PROTEINS OF THE FIBRINOLYTIC SYSTEM

Clot formation is integrated with clot dissolution to maintain hemostasis. The biochemical mechanisms of clot dissolution center on fibrin-specific activation of plasminogen to plasmin. The key proteins involved are plasminogen, plasminogen activators (t-PA and u-PA), PAI-1, a $_2$-antiplasmin, and TAFI (Fig. 21.17).

Plasminogen

Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. Plasminogen circulates in plasma at an approximate concentration of 200 mg/L (2 µmol/L) (Table 21.8). Hereditary plasminogen deficiency has been described and displays either as a deficiency of plasminogen antigen and activity (type I) or a normal antigen level but reduced activity (type II, dysplasminogenemia) ([1664]). Thrombophilia and ligneous conjunctivitis are clinical manifestations associated with homozygous deficiency; the impact of heterozygous deficiency remains in dispute. Homozygous plasminogen-deficient mice are viable but exhibit severe thrombosis with systemic fibrin deposition and die prematurely ([1665] , [1666]).

TABLE 21.8. Proteins and Inhibitors of the Fibrinolytic System: Biochemical Properties

Name	Molecular Weight (d) [a]	Amino Acid Number	Plasma Concentration		Half-Life	Carbohydrates (%)
			(mg/L)	(nmol/L)		
Plasminogen	88,000	791	200	2000	2.2 days	2
Tissue-type plasminogen activator	70,000	527	0.005	0.07	2.4 min	7/13
Urokinase-type plasminogen activator	54,000	411	0.002	0.04	5 min	7
Thrombin-activatable fibrinolysis inhibitor	58,000	401	4.5	75	10 min [a]	23 [b]

[b] Estimated value calculated from difference of molecular weight determined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and weight of sum of amino acids derived from complementary DNA.

GENE STRUCTURE AND EXPRESSION The plasminogen gene is located on the long arm of chromosome 6 at band q26-q27 ([1667] , [1668]) (Table 21.9). It spans 52.5 kb of DNA with 19 exons. It is in close proximity to two genes for apolipoprotein A and for the plasminogen-related genes A and B ([1669] , [1670] and [1671]). The first exon codes for the signal sequence; each of the five kringle domains is encoded by two exons as is the activation peptide. Plasminogen expression is normally stable with the regulation of the activity of the fibrinolytic system occurring mainly via the regulation of the plasminogen activators and their inhibitors. However, levels of plasminogen increase in response to inflammatory processes; plasminogen is an acute phase reactant protein ([1570] , [1668]). Two sequence elements common to acute phase reactant genes have been located at position 76–81 and -553 to -558 ([1668]). Other potential regulatory transcriptional elements have been identified including HNF-1, AP-1, CREB, and GATA ([1671]).

TABLE 21.9. Proteins and Inhibitors of the Fibrinolytic System: Molecular Genetics

Name	Molecular Weight (d)	Chromosome	Gene (kb)	Exons	Messenger RNA (kb)
Plasminogen	88,000	6p26-q27	52.5	19	2.9
Tissue-type plasminogen activator	70,000	8p12-q11.2	32.7	14	2.7

PAI, plasminogen activator inhibitor.

BIOCHEMISTRY Plasminogen is synthesized in the liver and is present in a wide variety of tissues and body fluids, including saliva, lacrimal gland secretions, seminal vesicle fluid, and prostate secretions ([1672]). Plasminogen circulates in plasma at an approximate concentration of 200 mg/L (2 µmol/L). It has a circulating t $_{1/2}$ of 2.2 days ([1673]). The t $_{1/2}$ in disease states in which the fibrinolytic system is activated can be shortened dramatically. Human plasminogen is a single-chain glycoprotein of a relative molecular weight of 88,000 containing 2% carbohydrate (Table 21.8 and Fig. 21.18). Two major carbohydrate variants of plasminogen are found in roughly equal amounts in human plasma; plasminogen variant 1 is glycosylated at two sites, Asn ^{289} and Thr ^{346}, whereas plasminogen variant 2 is glycosylated only at Thr ^{346}. Isoelectric focusing of either of these major carbohydrate variants, even when the proteins are isolated from a single plasma donor, reveals additional heterogeneity derived from variable sialic acid content ([1674] , [1675] , [1676] and [1677]). Heterogeneity in the primary sequence of plasminogen has also been observed, reflecting the presence of two high-incidence polymorphisms and a number of low-incidence polymorphisms in the human population. Functional differences between the two major carbohydrate forms have been reported ([1678] , [1679] , [1680] , [1681] and [1682]). An additional glycosylation site at Ser ^{249} containing a trisaccharide has been identified ([1683]).

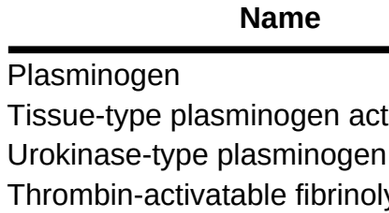

Figure 21.18. Schematic of plasminogen. Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. Human plasminogen is a single-chain glycoprotein of a relative molecular weight of 88,000 d containing 2% carbohydrate (CHO). CHO variants are shown for plasminogens 1 and 2. The primary structure of plasminogen contains 791 amino acids segregated into an NH $_2$-terminal activation peptide domain (residues E ^{1}-K ^{77}), a region containing five kringles (K1–K5; residues K ^{78}-R ^{561}), and a catalytic domain (residues V ^{562}-N ^{791}). Proteolysis by plasmin at one of several potential sites in this NH $_2$-terminal region results in a degraded form of plasminogen; the most common product is K ^{78}-plasminogen. Cleavage by plasminogen activators at R ^{561}-V ^{562} results in plasmin.

The primary structure of plasminogen contains 791 amino acids segregated into an NH $_2$-terminal activation peptide domain (residues Glu ^{1}-Lys ^{77}), a region containing five kringles (K1-K5; residues Lys ^{78}-Arg ^{541}), and a catalytic domain (residues Val ^{562}-Asn ^{791}) ([1667] , [1684] , [1685]) (Fig. 21.18). As secreted into the blood, plasminogen has a glutamic acid at its NH $_2$-terminus. Proteolysis by plasmin at one of several potential sites in this NH $_2$-terminal region results in a degraded form of plasminogen; the most common product is Lys ^{78}-plasminogen. Removal of the NH $_2$-terminal peptide region results in a major structural change in the plasminogen molecule, yielding a species of plasminogen that has a higher affinity than Glu-plasminogen for fibrin and is a better substrate for plasminogen activators ([1686]). The primary site for Lys-plasminogen formation is at the fibrin clot; the t $_{1/2}$ of Lys-plasminogen is shorter than the full-length molecule (t $_{1/2}$ = 0.8 days). Each kringle domain contains 78 to 80 amino acids. The K1 and K4 kringle domains have been identified as containing sites that are responsible for regulating the binding

of plasminogen to fibrin ([1687], [1688]), a $_2$-antiplasmin ([1689]), histidine-rich glycoprotein ([1690]), the kininogens ([1691]), thrombospondin ([1692]), and cell-surface receptors. These sites on the plasminogen kringles (called *lysine binding sites*) bind lysyl residues in the target molecules; COOH-terminal lysyl residues are bound more avidly. Lysine analogs (i.e., e-aminocaproic acid and tranexamic acid) can compete with lysyl residues in proteins for binding to plasminogen and, hence, are useful inhibitors of fibrinolysis ([1693], [1694]). The conformational change associated with the removal of the NH $_2$-terminal activation peptide also occurs on binding of lysine or its analogs to the appropriate kringles in Glu-plasminogen ([1694], [1695] and [1696]). The shape of the Glu-plasminogen molecule changes from a prolate ellipsoid of axial ratio 2.6 to a more random coil-type structure of axial ratio greater than 5, similar in dimension to Lys-plasminogen ([1697], [1698]). A fragment of plasminogen comprising K1-K4, also known as *angiostatin*, has been shown to inhibit angiogenesis ([1699]). The catalytic domain of plasminogen (Val ^{562}–Asn ^{791}) shows considerable homology to trypsin and other serine proteases and includes the catalytic triad (His ^{603}, Asp ^{646}, and Ser ^{741}) typical of these proteases.

FUNCTION Plasminogen is a zymogen devoid of enzymatic activity until converted to the serine protease plasmin by cleavage of the Arg ^{561}–Val ^{562} peptide bond by plasminogen activators such as u-PA and t-PA (Fig. 21.19). In plasma or bound to fibrin in a blood clot, cleavage of this peptide bond by either t-PA or u-PA converts Glu-plasminogen into Glu-plasmin, a two-chain enzyme that can degrade fibrin, fibrinogen, and a number of other molecules. Plasmin is composed of a heavy chain (kringle domains) and a light chain (catalytic domain) that are attached by two disulfide bonds. Glu-plasmin can autodigest by cleaving itself—most commonly at Lys ^{77} to generate Lys-plasmin ([1700], [1701]). Inhibition of plasmin by a $_2$-antiplasmin is the primary route for regulation of plasmin's hemostatic function; suppression of plasmin activity beyond the locale of fibrin deposition is imperative if systemic fibrinogenolysis is to be prevented. Plasmin bound through its lysine binding sites to fibrin reacts more slowly with a $_2$-antiplasmin than when free in solution: This differential reactivity effectively localizes plasmin activity to the fibrin surface.

Figure 21.19. Molecular forms of plasmin(ogen). Plasminogen in its native form has a glutamic acid at residue 1 and is referred to as *glu-plasminogen*. Glu-plasminogen has a molecular weight of 88,000 d and contains 791 amino acids. Cleavage at R ^{561}-V ^{562} in glu-plasminogen by plasminogen activators [tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA)] yields glu-plasmin. Glu-plasmin consists of an NH $_2$-terminal heavy chain linked by two disulfide bonds to a catalytic domain. At the localized clot level, plasmin that is formed can cleave glu-plasminogen at the NH $_2$-terminal bond K ^{77}-K ^{78} to yield lys-plasminogen. Lys-plasminogen can be activated by plasminogen activators that hydrolyze the R ^{561}-V ^{562} bond to yield lys-plasmin.

Plasminogen Activators

The process of plasminogen activation can occur through three distinct pathways: (a) the intrinsic activator system (analogous to the contact system of blood coagulation), (b) the extrinsic activators (t-PA and u-PA), and (c) an exogenous activator system involving pharmacologic agents (thrombolytic drugs). The pathway used *in vivo* appears to be the extrinsic pathway. However, both the intrinsic as well as exogenous activator systems could play an important role in human disease.

INTRINSIC ACTIVATORS The body has evolved a mechanism to recognize invasion by foreign substances. Many of these foreign substances contain negatively charged surfaces that allow the activation of the intrinsic (contact) pathway consisting of factor XII, prekallikrein, HMWK, and factor XI. Plasminogen can interact with this intrinsic pathway of blood coagulation to generate plasmin. There is continued debate as to the extent to which the intrinsic pathway functions in regulating normal fibrinolysis. It has been estimated that this pathway contributes only approximately 15% of the total fibrinolytic activity in human plasma ([1702]). Several studies have established that kallikrein and factors IXa and XIIa can directly activate plasminogen to plasmin ([1703], [1704], [1705] and [1706]). At this time, it is best to conclude that the physiologic significance and relevance of the contact system in fibrinolysis are not entirely clear. It has been suggested that individuals with factor XII deficiency as well as deficiencies in some of the other intrinsic coagulation factors may have a subtle, but potentially significant, defect in fibrinolysis under certain clinical conditions. Additional studies are needed to address this controversial subject.

EXTRINSIC ACTIVATOR: TISSUE PLASMINOGEN ACTIVATOR There are two dominant extrinsic activator systems in the body: t-PA and u-PA. These activators have unique structures and properties that affect the specificity and rate of plasmin generation. The t-PA molecule is predominantly a product of endothelial cells ([1707], [1708], [1709], [1710] and [1711]); it is also produced by vascular smooth muscle cells ([1712]), neuronal cells ([1713]), megakaryocytes ([1714], [1715]), mast cells ([1716], [1717]), monocytes ([1718]), and fibroblasts ([1719]). Factors that regulate its secretion and release from the endothelium are important mediators of blood clotting or inflammation. These include thrombin, histamine, acetylcholine, bradykinin, epinephrine, ILs, shear stress, and vasoocclusion ([1720], [1721]). t-PA antigen is present in normal plasma at approximately 5 µg/L (70 pmol/L) ([1722], [1723], [1724], [1725] and [1726]) (Table 21.8). Functional concentrations have been reported to be less than 20 pmol/L with remainder of the t-PA antigen found in complex with PAI-1 ([1723], [1727], [1728]). The t $_{1/2}$ in plasma is quite short, with pharmacokinetic modeling indicating a t $_{1/2}$ of 2.4 minutes for active t-PA and 5 minutes for the t-PA/PAI-1 complex ([1729], [1730]). The t-PA molecule and the t-PA/PAI-1 complex are cleared from the plasma by two specific cell receptor systems in the liver as well as receptor-mediated clearance by endothelial cells [1731 (review), 1732,1733].

Gene Structure and Expression The human gene for t-PA is found on chromosome 8, bands p12-q11.2, and spans 32.7 kb ([1734]) (Table 21.9). There are 14 exons with distinct structural motifs encoded by individual exons ([1735], [1736] and [1737]). The processed transcript codes for a protein product of 562 amino acids: Residues 1 to 23 comprise the signal peptide, whereas residues 24 to 32 function as a propeptide region. Further processing removes residues 32 to 35 to yield the circulating protein product. The 5'-flanking region of the t-PA gene extends more than 9500 bp with a functional retinoic acid response element identified at -7300 bp ([1738]) and a multihormone responsive enhancer localized to the region -7145 to -9758 bp ([1739], [1740] and [1741]). A number of *cis*-acting elements have been identified in the proximal promoter region. A transcription initiation site 209 bp upstream of the translation start site was initially identified. A consensus TATA sequence was identified 22 bp upstream from this transcription start site ([1736], [1737]). Subsequently, a TATA-independent transcript initiation site 99 bp upstream from the translation start site was identified as the primary site of transcription initiation in fibroblasts ([1742]) and endothelial cells ([1743]). The significance of t-PA transcripts with different-length 5'-untranslated regions is not established; deletion of the entire 5'-untranslated region of t-PA was observed to increase the stability of the t-PA transcript ([1744]). Translational control of t-PA gene expression has been observed in some cell types, implicating a regulatory role for the 3'-untranslated region of the t-PA transcript ([1745], [1746]). A number of polymorphisms of the t-PA gene have been identified. A 311-bp *Alu* insertion/deletion polymorphism within the eighth intron of the t-PA gene has been extensively studied ([1747], [1748], [1749], [1750], [1751] and [1752]). A similar polymorphism in the angiotensin-converting enzyme gene has been linked to plasma levels of this enzyme ([1753]). In contrast, no correlation of plasma t-PA levels with its *Alu* polymorphism has been observed ([1749], [1750] and [1751]). With one exception ([1747]), clinical studies have indicated no correlation between this polymorphism and the incidence of stroke or myocardial infarction ([1749], [1750] and [1751]). A single nucleotide polymorphism (-7351 C/T) in a Sp1 binding site in the far upstream enhancer element of the t-PA gene has been linked to the vascular release rate of t-PA *in vivo* ([1754]) and to the frequency of occurrence of first myocardial infarction ([1755]). No cases of congenital deficiency of t-PA have been reported. Transgenic mice lacking a functional t-PA gene developed normally and displayed a normal basal hemostatic phenotype ([1756]). Mice in which both the t-PA and u-PA genes were disabled had shortened lifespans and experienced severe, spontaneous thrombotic episodes ([1756], [1757]).

Biochemistry The t-PA molecule is a serine proteinase with molecular weight of 70 kd ([1758]) (Table 21.8 and Fig. 21.20). It was originally isolated as a single polypeptide chain of 527 amino acids ([1759]) with an NH $_2$-terminal serine residue; full-length t-PA has an NH $_2$-terminal extension of three amino acids (Gly-Ala-Arg) ([1760], [1761] and [1762]). Numbering in this chapter is based on Ser ^{1}–t-PA, the most extensively studied form due to its availability as a recombinant product.

Figure 21.20. Fibrinolytic proteins tissue-type plasminogen activator (t-PA) and single-chain urokinase-type plasminogen activator (sc-uPA). The t-PA molecule is a serine proteinase with a molecular weight of 70,000 d. The single-chain t-PA molecule is an efficient plasminogen activator in the presence of fibrin and is converted

into a somewhat more active two-chain molecule by cleavage of the peptide bond between R ^{275} and I ^{276}. This cleavage is performed primarily by the action of plasmin during fibrinolysis. The A-chain contains a fibronectin fingerlike domain, an epidermal growth factor (EGF)–like domain, and two kringle domains. The kringle 2 domain and the finger domain of t-PA are involved in the binding of t-PA to fibrin. The light or B-chain of t-PA contains the active site catalytic triad. sc-uPA is a serine protease of 411 amino acids with a molecular weight of 54,000 d and is an ineffective catalyst. Plasmin or plasma kallikrein can hydrolyze the K ^{158}-I ^{159} peptide bond, converting sc-uPA into the fully active two-chain form (two-chain urokinase-type plasminogen activator). u-PA is composed of an EGF domain (EGF, residues 7 to 43), a single kringle domain (residues 50 to 131), a connecting peptide region (residues 132 to 157), and the serine protease-type catalytic domain (residues 159 to 411). One glycosylation site (CHO) is present in the serine protease domain.

The single-chain t-PA molecule is an efficient plasminogen activator in the presence of fibrin ([1763], [1764], [1765] and [1766]) and is converted into a somewhat more active two-chain molecule by cleavage of the peptide bond between Arg ^{275} and Ile ^{276} ([1675], [1764], [1765], [1766] and [1767]). This cleavage is performed primarily by the action of plasmin during fibrinolysis; factor Xa and kallikrein can also catalyze this conversion. The t-PA molecule divides structurally and functionally into two major regions with the Arg ^{275}-Ile ^{276} bond as the boundary: The 38-kd NH $_2$-terminal portion (Ser ^{1}-Arg ^{275}), called the *heavy* or *A-chain* in the two-chain molecule, contains structures involved in fibrin binding, fibrin-specific plasminogen activation, and plasma clearance mechanisms; and the 28-kd catalytic region (Ile ^{276}-Pro ^{527}), called the *light* or *B-chain*, is homologous to the proteolytic domain of other serine proteases. Specifically, the A-chain contains a fibronectin fingerlike domain ([1768]), an EGF-like domain ([1769]), and two kringle domains ([348], [1770]). The finger domain extends from residues 4 to 50 and is involved in the binding of t-PA to fibrin ([1771], [1772]). The binding of the finger region to fibrin is not blocked by e-aminocaproic acid ([1773]). The finger domain of t-PA has sequence homology and structural homology ([1774]) to similar structures found in fibronectin. Selected mutations in the finger or the EGF domain have been shown to result in prolonged half-lives *in vivo* for the modified t-PA molecules, indicating a role for these regions in uptake mechanisms ([1775], [1776]). The kringle domains of t-PA span residues 87 to 176 (kringle 1) and residues 176 to 262 (kringle 2). The biologic role of kringle 1 remains undiscovered ([1771], [1772] and [1773]). The kringle 2 domain is involved in the binding of t-PA to fibrin ([1771], [1772]). This binding interaction is blocked by lysine and its analogs such as e-amino-caproic acid ([1771]), indicating the presence of a plasminogen-like lysine binding pocket. The overall crystal structure of t-PA kringle 2 ([1777]) resembles that of kringle 4 of plasminogen although differences are observed in the arrangement of residues forming the lysine binding sites ([1777], [1778], [1779] and [1780]). The light or B-chain of t-PA contains the active site catalytic triad of this serine protease (His ^{322}, Asp ^{371}, and Ser ^{478}) ([609], [1759], [1781]). Both the single- and two-chain forms of t-PA cleave plasminogen at Arg ^{561}-Val ^{562} to yield the enzyme plasmin. The catalytic efficiency of single-chain t-PA toward plasminogen in solution and toward tripeptide paranitroanilide substrates is lower than the two-chain form ([1764], [1766], [1782]). Both forms exhibit enhanced and roughly equivalent rates of proteolysis of plasminogen when fibrin is present ([1764]). The t-PA molecule has three potential N-linked glycosylation sites and one O-linked site. The O-linked site is found at Thr ^{61} in the EGF domain ([1783]). The presence of a fucose at this site appears to facilitate the uptake of t-PA by hepatocytes ([1784]). Two major carbohydrate variants of t-PA have been identified. Type I is glycosylated at Asn ^{117} (kringle 1), Asn ^{184} (kringle 2), and Asn ^{448} (catalytic domain), whereas type II is glycosylated only at Asn ^{117} and Asn ^{448} ([1785], [1786]). The presence of carbohydrate at Asn ^{184} appears to down-regulate the fibrinolytic activity of type I t-PA by interfering with the association between the lysine binding site of its kringle 2 domain and fibrin.

Regulation Regulation of t-PA activity in blood is accomplished by three primary mechanisms: control of its catalytic potential via the fibrin dependence of plasminogen activation; control of systemic levels of functional t-PA by the concerted processes of rapid t-PA removal by hepatic clearance and of inhibition by the circulating serpin PAI-1; and control of t-PA activity levels at the site of injury by the competing processes of increased t-PA secretion by traumatized and recruited cells versus PAI-1 release by activated platelets. t-PA manifests its full fibrinolytic potential only when bound to fibrin ([1787], [1788] and [1789]). This binding interaction aligns t-PA and plasminogen on the fibrin surface so that the catalytic efficiency of t-PA is enhanced several hundred-fold. This is vital to the localization of plasmin generation at the site of fibrin deposition. Systemic t-PA levels in blood are under highly dynamic control characterized by maintenance of relatively low levels of the protein (70 pmol/L) with a high clearance rate (t $_{1/2}$ = 2.4 minutes) and by maintenance of an extremely effective inhibitor, PAI-1 (second-order rate constant for complex formation = 10 ^{7} to 10 ^{8} M $^{-1}$second $^{-1}$), at a circulating concentration several-fold higher than t-PA. The release of t-PA from the vessel wall is another important regulator of fibrinolysis ([1790], [1791]). The rate at which clots lyse is dependent on how rapidly t-PA is secreted by the relevant cells in the vicinity of an injury ([1792], [1793]). For example, activated platelets secrete serotonin that can induce endothelial cells to release t-PA; they also release PAI-1 from their a-granules. Although only a fraction of this PAI-1 is in the active form, it functions to down-regulate plasminogen activation ([1794], [1795] and [1796]).

EXTRINSIC ACTIVATOR: UROKINASE PLASMINOGEN ACTIVATOR The other major extrinsic activator in the blood is u-PA. This activator was first identified in the urine ([1797], [1798] and [1799]), where it is present at relatively high concentrations (40 to 80 µg/L) ([1799], [1800]). It was subsequently detected in the media of cultured human kidney cells, endothelial cells, malignant cell lines, tumors, and in plasma ([1801], [1802], [1803] and [1804]). u-PA is a serine protease and is synthesized as a single-chain molecule called *prourokinase* or *single-chain u-PA* (scu-PA). The plasma concentration of scu-PA ranges from 2 to 4 ng/ml (37 to 74 pmol/L) ([1805]) (Table 21.8); the t $_{1/2}$ of scu-PA is quite short, approximately 5 minutes, and metabolism occurs in both the liver and the kidney. scu-PA has a very low level of proteolytic activity ([1806]). Plasmin can hydrolyze the Lys ^{158}–Ile ^{159} peptide bond converting scu-PA into the two-chain form (tcu-PA) ([248], [1797], [1807], [1808]). The mechanism in blood by which scu-PA is converted into tcu-PA still remains poorly defined. It has been postulated that, within a thrombus, t-PA initially activates plasminogen bound to fibrin to form plasmin, and that it is this fibrin-localized plasmin that then converts scu-PA into tcu-PA ([1809], [1810] and [1811]). This process results in an amplification of the rate of plasmin formation. The main site of urokinase-driven plasminogen activation appears to be extravascular where it has an important role in promoting degradation of extracellular matrix by triggering the activation of plasminogen and, possibly, matrix metalloproteinases ([1812]). Regulation of urokinase is important to normal and pathologic processes including embryogenesis, wound healing, tumor cell invasion, and metastasis ([1813], [1814]). Inhibitors of urokinase have been shown to suppress the growth of primary tumors and to interfere with metastasis of tumor cells ([1815], [1816], [1817], [1818], [1819], [1820], [1821] and [1822]).

Gene Structure and Expression The human u-PA gene spans 6.4 kb with 11 exons ([1823]) and is located on chromosome 10, band q24 ([1824]) (Table 21.9). The overall intron-exon arrangement is similar to that of the t-PA gene. The primary amino acid sequence of the purified, intact two-chain molecule has been determined ([1825], [1826] and [1827]), and the cDNA has been isolated and sequenced ([1828]): The gene specifies a protein of 431 amino acids, with the first 20 residues constituting a signal peptide. The disruption of the urokinase gene (u-PA -/-) in mice is not lethal ([1756]). These mice did not display spontaneous thrombi in their vasculature. The phenotype of u-PA -/- mice included occasional minor fibrin deposits in the liver and intestine, excessive fibrin deposits in chronic nonhealing skin lesions, and increased susceptibility to bacterial infections ([1756], [1829], [1830] and [1831]).

Biochemistry u-PA is a single-chain glycoprotein containing 411 amino acids (M $_r$ = 54,000) (Table 21.8 and Fig. 21.20). It has 12 disulfide bonds with one (Cys ^{148}-Cys ^{279}) serving to link the catalytic domain (B-chain) to the NH $_2$-terminal domain (A-chain). Posttranslational modifications include glycosylation at Asn ^{302}, addition of a single fucose residue at Thr ^{18} ([1832]), and regulatory phosphorylation at Ser ^{138}/Ser ^{303} ([1833]). u-PA is composed of an EGF domain (residues 7 to 43), a single kringle domain (residues 50 to 131), a connecting peptide region (residues 132 to 157), and the serine protease-type catalytic domain (residues 159 to 411). The EGF domain contains the residues essential for urokinase binding to the urokinase receptor ([1834]) and appears to be the domain responsible for the ability of urokinase to induce cellular proliferation and differentiation ([1835], [1836] and [1837]). The function of the kringle domain of urokinase remains to be established. It displays no binding affinity for fibrin. Recent evidence indicates that the kringle domain may have a role in mediating the process by which urokinase stimulates smooth muscle migration ([1838], [1839] and [1840]). Residues His ^{204}, Asp ^{255}, and Ser ^{356} form the catalytic triad of urokinase; unlike the single-chain form of t-PA, they are not properly positioned for efficient catalysis. scu-PA does not form complexes with PAI-1 or react with peptidyl chloromethylketones that inhibit the two-chain form; scu-PA–catalyzed hydrolysis of tripeptide paranitroanilide substrates proceeds with 0.1 to 0.4% the efficiency of tcu-PA ([1841], [1842]), and plasminogen activation by scu-PA appears to be equally inefficient when compared to tcu-PA ([1811], [1843]). The urokinase molecule is asymmetric in shape with the growth factor, kringle, and catalytic domains arranged like differently configured beads on a string ([1832], [1844], [1845] and [1846]). A crystal structure for the entire urokinase molecule has not been accomplished. However, a crystal structure at a resolution of 2.5 Å has been reported for the catalytic domain. The molecule used was a recombinant, nonglycosylated human u-PA (residues 159 to 411) with its active site histidine residue derivatized with a peptidyl chloromethylketone ([1847]). The catalytic domain of u-PA has the expected overall topography and S1 specificity pocket of a trypsinlike protease, an S2 pocket of hydrophobic character, and a solvent-accessible S3 pocket suitable for binding a wide range of amino acid side chains. The crystal structure of a mutant urokinase catalytic domain (residues 159 to 404: C122A and N302Q) at a resolution of 1.5 Å has also been reported ([1848]).

Activation Conversion of single-chain urokinase to an active two-chain form occurs principally through hydrolysis of the Lys ^{158}-Ile ^{159} bond. This molecular form, referred to as *high-molecular-weight tcu-PA*, is comprised of NH $_2$-terminal heavy chain (residues 1 to 158) linked by one disulfide bond to the catalytic domain. In the blood, during fibrinolysis, plasmin is the primary catalyst of this conversion; in addition, both kallikrein and factor XIIa ([248]), products of the intrinsic pathway of coagulation, hydrolyze this bond. A number of other proteases that cleave the Lys ^{158}-Ile ^{159} bond have also been identified including several cathepsins ([1849], [1850], [1851] and [1852]), mast cell tryptase ([1853]), nerve growth factor-? ([1854]), human T-cell serine proteinase-1 ([1855]), and FSAP ([1856]). A second, catalytically active form of two-chain urokinase, known as *low-molecular-weight tcu-PA*, is found in plasma when fibrinolysis is stimulated. It is formed by an additional plasmin cleavage at Lys ^{135}–Lys ^{136}. This yields a truncated heavy chain containing most of the connecting peptide region (residues 136 to 158) linked to the catalytic domain by the Cys ^{148}-Cys ^{279} disulfide bond. This cleavage produces a more efficient enzyme, and this low-molecular-weight form is used clinically for thrombolytic therapy. Another

low-molecular-weight form of scu-PA arises from cleavage of the Glu ^{143}-Leu ^{144} bond by the matrix metalloproteinases Pump 1 and metalloproteinase 3 ([1857], [1858] and [1859]). This form appears to be a better clot-lysing agent than low-molecular-weight tcu-PA ([1860]). Neutrophil cathepsin G and elastase from granulocytes cleave scu-PA at the Ile ^{159}-Ile ^{160} bond yielding a two-chain molecule that is inactive ([1861], [1862]). Thrombin ([248], [1863], [1864]) and, more efficiently, the thrombin-thrombomodulin complex ([1865]) cleave scu-PA at Arg ^{156}-Phe ^{157} yielding an inactive two-chain urokinase species. The release of the dipeptide Phe ^{157}-Lys ^{158} from the catalytic domain is catalyzed by cathepsin C ([1850]) or plasmin ([1866]).

Function t-PA appears to be the primary plasminogen activator in the vasculature, with fibrin-localized scu-PA conversion to tcu-PA acting as an amplifying rather than initiating mechanism for plasmin formation ([1811], [1867]). Direct scu-PA activation of Glu-plasminogen bound to COOH-terminal lysine residues found in partially proteolyzed fibrin has been proposed as contributing to clot lysis ([1868], [1869] and [1870]). This catalytic role of scu-PA, although direct, still depends temporally on t-PA–derived plasmin to create the circumstance (plasmin proteolyzed fibrin) under which it can contribute to overall fibrinolysis.

EXTRINSIC ACTIVATOR: FACTOR VII–ACTIVATING PROTEASE Recently, a novel serine protease in human plasma has been described that can support coagulation by activating factor VII ([446], [1871], [1872]). It was originally described as plasma hyaluronan binding protein and was isolated by adsorption to immobilized hyaluronic acid as a disulfide-linked heterodimer ([1872]). Independently, a thrombinlike amidolytic activity was purified from commercial prothrombin complex concentrates ([1873], [1874]). Sequencing data indicated that this protease and plasma hyaluronan binding protein were the same proteins. Subsequently, the protease from prothrombin complex concentrates was shown to be a potent activator of factor VII and termed *FSAP* ([446]). This protease has also been shown to be an efficient activator of single-chain urokinase. Its single-chain precursor has been purified from plasma ([1875]).

Gene Structure and Expression FSAP has been mapped to chromosome 10, bands q25–q26 ([1876]). It spans 35 kb and is composed of 13 exons (Table 21.8). Its transcript specifies a protein of 560 amino acids; the first 23 amino acids comprise the signal peptide sequence. Two single nucleotide polymorphisms have been identified: One, called *FSAP Marburg I* (SNP-1), yields a Gly511Glu substitution near the COOH-terminus of the protease resulting in impairment of its scu-PA activating properties ([1877]). The clinical relevance of this polymorphism has not been assessed. The second polymorphism, Marburg II, contains a Glu370Gln mutation that does not appear to have an effect on the catalytic properties of FSAP.

Biochemistry and Activation FSAP is a single-chain glycoprotein containing 537 amino acids with a M_r of 64 d ([1872]). It circulates at a concentration of approximately 12 µg/ml (190 nmol/L; Table 21.8). It is composed of 5% carbohydrate and is glycosylated at Asn ^{31} (NH_2-terminal strand) and Asn ^{184} (kringle domain) ([1875]). The structure consists of an amino terminal strand (residues 1 to 52) that is followed by three EGF-like domains (residues 53 to 166), a kringle domain (residues 170 to 254), and a COOH-terminus serine protease domain (residues 290 to 537). FSAP has structural regions that are homologous to those found in hepatocyte growth factor activator ([1878]). It binds to GAGs such as heparin. The conversion to the active two-chain form requires cleavage of the Arg ^{290}–Ile ^{291} bond. This generates a heavy chain (residues 1 to 290) and a light chain or catalytic domain (residues 291 to 537). The two chains are linked by a single disulfide bond (Cys ^{278}-Cys ^{412}). The active site residues of this serine protease are Asp ^{382}, His ^{339}, and Ser ^{486}. Preparations of single-chain FSAP rapidly convert to the two-chain form. Whether this is due to an intrinsic activity of the single-chain molecule or to trace amounts of the two-chain form in single-chain preparations has not been resolved ([1879]). Heparin promotes conversion of single-chain FSAP preparations to the two-chain form ([1880]). The high-molecular-weight form of two-chain urokinase has been shown to convert single-chain FSAP to the two-chain form and may represent a physiologic activator ([1875]). The rate of this reaction is affected by heparin. In addition to factor VII and single-chain urokinase, other substrates for FSAP, determined from *in vitro* assays, include factor V/factor Va, factor VIII/factor VIIIa, fibrinogen, single-chain t-PA, fibronectin, and vitronectin ([1871]). Similar to plasmin, two-chain FSAP binds to aprotinin. *In vitro* assays indicate that it also complexes with serpins such as C1-inhibitor ([1881]), a_2-antiplasmin, and antithrombin III–heparin ([1856], [1882]).

Function The physiologic function of FSAP still is unclear. The ability of two-chain FSAP to convert factor VII to factor VIIa in the absence of tissue factor suggests that it could contribute to the maintenance of normal factor VIIa (100 pmol/L) levels in blood or perhaps contribute to the localized production of factor VIIa at the site of vascular injury. In a system of synthetic hemophilia (factor VIII deficiency), two-chain FSAP has been shown to correct the hemostatic defect ([446]). Similar results have been found with the addition of exogenous factor VIIa to hemophilia blood ([418]). The two-chain form of FSAP appears to be an efficient activator of single-chain urokinase, comparing favorably with plasmin when heparin is present ([1856]). It has been suggested ([1871]) that GAG binding properties of FSAP may localize it to cell surfaces and extracellular matrix proteins where it may play a role as an initiator of urokinase-dependent proteolytic cascades.

INHIBITORS OF THE FIBRINOLYTIC SYSTEM

A wide variety of natural inhibitors of fibrinolysis exist in plasma, blood cells, tissues, and extracellular matrices. These natural inhibitors can act either to inhibit plasmin directly or to block the conversion of plasminogen to plasmin (Fig. 21.17). In this section, TAFI, PAI-1, PAI-2, and a_2-antiplasmin inhibitor are reviewed in terms of their gene structure and expression, biochemistry, and function.

Thrombin-Activatable Fibrinolysis Inhibitor

TAFI (E.C.3.4.17.20) (reviews: 1883,1884) is a plasma zymogen with homology to procarboxypeptidases A and B. Its plasma concentration is 75 nmol/L (4.5 µg/ml) (Table 21.8). TAFI is synthesized in the liver and is thought to circulate in blood in complex with plasminogen. Activation of TAFI yields an exopeptidase (TAFIa) with carboxypeptidase B–like substrate specificity: It catalyzes the removal of basic amino acids (arginines, lysines) from the COOH-termini of polypeptides. Its primary physiologic activator appears to be the thrombin-thrombomodulin complex, thus defining TAFIa as a coagulation-dependent activity ([891]). COOH-terminal lysines that appear in fibrin as it degrades have been identified as the primary substrates for TAFIa (Fig. 21.21). The initial phase of plasmin proteolysis of fibrin produces products that amplify plasminogen activation by t-PA. These fibrin degradation products thus constitute a positive feedback process, thereby accelerating clot lysis. COOH-terminal lysines that appear in fibrin as it is degraded by plasmin function as additional binding sites where efficient plasminogen activation can occur. Removal of these terminal lysine residues by TAFIa reduces the number of plasminogen binding sites, thus serving to down-regulate the rate of plasmin generation and thereby the rate of clot lysis. Thus, TAFI/TAFIa functions as an antifibrinolytic factor by suppressing the positive feedback pathway of fibrinolysis. The importance *in vivo* of the TAFI/TAFIa-mediated regulation of fibrinolysis remains to be established. Several studies involving animal models of thrombosis ([1885], [1886], [1887] and [1888]) have provided *in vivo* evidence consistent with the proposed role of the TAFI/TAFIa system in regulating fibrinolysis. However, TAFI knock-out mice develop normally and prove no more sensitive to a wide range of hemostatic challenges than their wild-type littermates ([1889]). In humans, TAFI antigen concentration has been correlated with an increase in risk for deep vein thrombosis ([1890], [1891]).

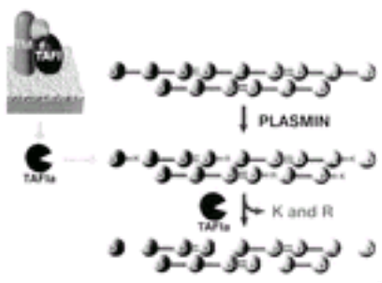

Figure 21.21. Mechanism of thrombin-activatable fibrinolysis inhibitor (TAFI) effects toward fibrinolysis. Thrombin-thrombomodulin (IIa-TM) cleaves TAFI to its active carboxypeptidase form TAFIa. TAFIa interferes with fibrinolysis by cleaving COOH-terminal Arg (R) or Lys (K) residues made available as a consequence of partial plasmin digestion of the fibrin clot. Removing these residues attenuates the self-amplifying mechanism of fibrin-based plasmin formation wherein partial plasmin proteolysis of fibrin increases the number of binding sites (COOH-terminal lysines) available for efficient plasminogen activation. See Color Plate. (From Mann KG. Coagulation explosion. Vermont Business Graphics, 1997, with permission.)

The nomenclature associated with carboxypeptidase B–type activity in serum reflects the history of its isolation and characterization. The presence of a carboxypeptidase B–type activity in serum that differed from that of carboxypeptidase N, a previously characterized enzyme found in plasma, was first reported by two groups: Hendriks et al. ([15], [1892], [1893]) named the enzyme *carboxypeptidase unstable* because of its short $t_{1/2}$ compared to carboxypeptidase N; Campbell and Okada ([1894]) named their activity *carboxypeptidase R* because of its apparent preference for substrates with COOH-terminal arginine residues, again in contrast to carboxypeptidase N, which showed a selectivity for COOH-terminal lysines. Subsequently, Eaton et al. ([16], [1895]) purified a novel plasminogen-binding protein from human plasma, which, based on sequence homology and enzymatic properties, proved to be a procarboxypeptidase. They named this *protein plasma procarboxypeptidase B*. Independently, Bajzar et al. ([17]), using an assay designed to detect the factor responsible for thrombin-dependent inhibition of fibrinolysis, purified a protein from human plasma. Initial characterization of this protein indicated that it was a procarboxypeptidase B–type protein, which converted to an active

carboxypeptidase on treatment with thrombin. This group named the protein *TAFI*. Further characterization established that TAFI is identical to protein plasma procarboxypeptidase B ([16], [932]). Whether carboxypeptidase R and carboxypeptidase unstable are identical to TAFI has not been resolved because of differences in the reported molecular mass and subunit structure of these proteins.

GENE STRUCTURE AND EXPRESSION TAFI is a member of a multigene family that includes the pancreatic and mast cell carboxypeptidases but not other carboxypeptidases with a specificity for basic amino acids such as carboxypeptidases N, M, H, and D ([1896], [1897]). TAFI shares a 34 to 40% amino acid identity with its family members and exact conservation of cystine residues and residues critical for catalysis, zinc binding, and substrate binding. The human gene for TAFI maps to chromosome 13 ([1898]) and is comprised of 11 exons within 48 kb of DNA ([1896]) (Table 21.9). When the TAFI gene is compared with the genes from rat pancreatic carboxypeptidases A1, A2, and B and human mast cell carboxypeptidase A, the positions of intron/exon boundaries are conserved, whereas the intron lengths diverge significantly. The TAFI promoter lacks a consensus TATA sequence but does have a 70-bp sequence in the 5'-flanking region of the gene that is required for liver-specific transcription ([1896]). Transcription is initiated at multiple sites. Primer extension analysis of human liver Poly (A) $^{+}$ RNA identified nine major transcription start sites with similar frequencies of usage ([1896]). The TAFI transcript is polyadenylated at three different sites. The TAFI transcript encodes a gene product of 423 amino acids. The first 22 amino acids comprise a signal peptide that is absent in the circulating form of the protein. Three single nucleotide polymorphisms in the coding region of the human TAFI gene have been identified, resulting in two distinct isoforms of TAFI: a base change of C to T at base 678, resulting in a silent mutation; a base change of A to G at base 505, yielding a Thr to Ala substitution at amino acid position 147; and a base change of C to T at base 1057, resulting in an Ile to Thr substitution at TAFI residue 325. No functional difference was observed between purified TAFIa (Ala ^{147}) and TAFIa (Thr ^{147}) ([1899]). However, purified TAFIa (Ile ^{325}) showed greater activity and stability than TAFIa (Thr ^{325}). The plasma concentration of TAFI antigen has been observed to vary approximately tenfold in the human population. The origin of this variability appears to be primarily genetic ([1900]). Polymorphisms in the TAFI gene that have been shown to be strongly associated with plasma TAFI levels include a number in the 5'-flanking region ([1890], [1901]), the 3'-untranslated region ([1901]), and the coding region ([1902]).

BIOCHEMISTRY The TAFI transcript specifies a preprotein of 423 amino acids comprised of a signal peptide, an activation peptide domain, and a catalytic domain. Removal of the signal peptide yields the circulating zymogen of 401 amino acids (45 kd); when analyzed by SDS-PAGE, the apparent molecular weight of TAFI is 58 kd (Fig. 21.22). The difference in mass derives from a high level of glycosylation involving all four of the potential sites (Asn ^{22}, Asn ^{51}, Asn ^{63}, and Asn ^{86}) present in the activation peptide domain (residues 1 to 92). In addition to its structural role in suppressing the catalytic potential of TAFI, the activation peptide domain mediates the association in blood of TAFI with plasminogen ([16]). The sequence of the catalytic domain (residues 93 to 401; 35 kd) displays exact conservation when compared to pancreatic and mast cell carboxypeptidases of cystine residues and residues critical for catalysis, Zn $^{+2}$ binding, and substrate binding ([16], [1896]). The activated form of TAFI is a carboxypeptidase that catalyzes the removal of arginine or lysine residues from the COOH-termini of polypeptides. TAFIa is inhibited by agents that can chelate Zn $^{2+}$, such as o-phenanthroline, and by 2-guanidinoethylmercaptosuccinic acid, a specific inhibitor of pancreatic and mast cell carboxypeptidases ([16], [17]). TAFIa is an unstable enzyme at physiologic pH and temperature ([15], [16] and [17]). At 37°C, TAFIa has a functional $t_{1/2}$ of approximately 10 minutes; its loss of activity is coincident with a significant change in conformation ([1903]).

Figure 21.22. Schematic of thrombin-activatable fibrinolysis inhibitor (TAFI). Activation of TAFI (M_r = 58,000) yields an exopeptidase (TAFIa) with carboxypeptidase B–like substrate specificity: It catalyzes the removal of basic amino acids (arg-inines, lysines) from the COOH-termini of polypeptides. TAFI contains 401 amino acids with four glycosylation sites in its activation peptide region. It is activated by thrombin-thrombomodulin (IIa/TM) and plasmin-glycosaminoglycan complexes (Plm/GAG) by hydrolysis of the R ^{92}–A ^{93} bond.

ACTIVATION The activation of TAFI requires the cleavage of the zymogen at Arg ^{92}, yielding an activation peptide of approximately 15 kd and an active carboxypeptidase of 35 kd (Fig. 21.22). Trypsin ([16]), plasmin ([16], [1904]), plasmin–anionic GAG complex ([1904]), thrombin ([16], [17]), thrombin-thrombomodulin complex ([891]), and meizothrombin-thrombomodulin complex ([1016]) all catalyze this reaction *in vitro*. A ranking of these catalysts in terms of relative catalytic efficiency shows the following order: thrombin-thrombomodulin (1.0) > meizothrombin-thrombin (0.1) = plasmin–anionic GAG (0.1) > plasmin (0.006) > thrombin (0.0008). The relative contributions of thrombin and plasmin to TAFI generation *in vivo* may be regulated by the availability of their respective cofactors at the site of vascular injury: cell-associated thrombomodulin versus the extent of exposure of subendothelial extracellular matrix.

FUNCTION Thrombin cleavage of fibrinogen yields insoluble fibrin polymers and soluble fibrinopeptides, all bearing COOH-terminal arginine residues. These COOH-terminal arginines are substrates for TAFIa, and the kinetics of their release in an *in vitro* clot lysis system ([1651]) and whole blood system where des-Arg FPB was detected ([934]) have been reported. The significance of this removal of arginine residues from these sites is not known. The activation of many of the cofactors and zymogens of the coagulation and fibrinolytic cascades results in the generation of functional proteins with COOH-terminal arginines or lysines. Their status as TAFIa substrates is unknown. Bradykinin and several enkephalins have been shown *in vitro* to be good TAFIa substrates ([1895]); to date, only circumstantial evidence connects TAFIa and bradykinin *in vivo* ([1905]). Extensive *in vitro* data ([1021], [1650], [1651] and [1652], [1903], [1906], [1907]) attest to the ability of TAFIa to slow the rate of fibrin degradation by plasmin generated *in situ*. Proteolysis of insoluble fibrin by plasmin proceeds through repetitive cleavages at lysine residues terminating in the formation of soluble fibrin degradation products. Before solubilization, each cleavage shortens the fibrin molecule and generates a new COOH-terminal lysine residue. COOH-terminal lysines in partially degraded fibrin have been shown to function as potent cofactors for t-PA–catalyzed activation of Glu-plasminogen ([1908], [1909], [1910], [1911] and [1912]). Removal of the COOH-terminal lysines by TAFIa thus reduces the number of sites available for plasminogen binding, thereby reducing the rate of plasmin generation with consequent prolongation of fibrin dissolution ([1650], [1651]) (Fig. 21.21). TAFIa functions as an attenuator of fibrinolysis ([1883]), and thus an adequate rate of TAFIa generation may be critical in the stabilization of the blood clot. For example, plasmas with specific deficiencies in the coagulation pathway showed reduced rates of thrombin production, decreased levels of TAFIa, and premature clot lysis ([1652], [1886], [1913]).

REGULATION TAFI circulates in plasma bound to plasminogen ([16]) and is a substrate for FXIIIa, which catalyzes its covalent attachment to fibrin ([933]). Whether these two mechanisms for concentrating TAFI at the site of fibrin formation contribute to the function of TAFI *in vivo* is not established. It has been proposed ([1884]), because the thrombin-thrombomodulin complex has a Km 10 to 20 times the plasma concentration of TAFI, that rates of TAFI activation would vary directly with changes in TAFI concentration. A plasma inhibitor of TAFIa has not been described. Carboxypeptidase inhibitors from potato ([1914]) and the leech ([1915]) active against TAFIa have been identified. TAFIa is an unstable enzyme under physiologic conditions ([15], [16] and [17]). It undergoes a spontaneous conformational change with a $t_{1/2}$ of 10 minutes at 37°C ([1903]). This appears to be the primary route of inactivation because proteolytic cleavage at Arg ^{302} by thrombin or plasmin has now been identified as secondary to and dependent on the inactivating conformation change ([1916], [1917]). TAFI plasma concentrations vary significantly in the human population. Although genetic factors appear to be the largest contributor to this variation ([1901]), a growing number of stimuli have been shown to affect TAFI plasma concentration ([1891], [1900], [1918], [1919], [1920] and [1921]). It has been proposed, in light of the intrinsic instability of TAFIa and the absence of a specific inhibitor, that control of the concentration of TAFIa through control of the level of TAFI gene expression is the primary regulator of TAFI/TAFIa system *in vivo* ([1922]).

Plasminogen Activator Inhibitor-1

PAI-1 is the primary physiologic inhibitor of plasminogen activation in blood, targeting u-PA and t-PA. It also appears to have a role, independent of its antiproteolytic function, in tissue remodeling by interfering with vitronectin-dependent processes of cell adhesion and migration. Congenital deficiency of PAI-1 is rare with homozygous individuals displaying abnormal bleeding in response to trauma ([1923], [1924], [1925], [1926] and [1927]). In a normal population, plasma PAI-1 concentration varies over a 15-fold range (6 ng/ml to 80 ng/ml) ([1928], [1929]) and exhibits a circadian variation ([1930]) (Table 21.8). Some of this variability stems from polymorphisms in the PAI-1 gene; however, a larger fraction of the variability appears to derive from the responsiveness of PAI-1 gene expression to a wide variety of physiologic effectors and conditions as well as pharmacologic agents ([1931]). Higher levels of plasma PAI-1 prolong fibrin removal by shortening the functional lifetime of plasminogen activators, thereby shifting hemostasis to a more thrombotic state ([1932]). The $t_{1/2}$ of PAI-1 in blood is less than 10 minutes. Potential sites of constitutive PAI-1 synthesis in humans include the liver, spleen, adipose tissue, and cells of the vasculature including endothelial cells, smooth muscle cells, macrophages, and megakaryocytes. The relative contributions from these sources to plasma PAI-1 levels in normal or specific pathologic conditions remain unresolved. The major fraction of PAI-1 in blood is present in platelets, apparently synthesized and stored in the a-granules during the maturation of megakaryocytes ([1933]). Although 75 to 80% of platelet PAI-1 is present in the latent form, there appears to be enough active PAI-1 released from platelets at sites of thrombus formation to contribute to the suppression of fibrinolysis ([1794], [1795] and [1796]).

PAI-1 is a single-chain protein with an M_r of 50,000 with 13% of its mass comprised of carbohydrate (Table 21.8). It is a typical serpin with its reactive site bond, Arg

^{346}–Met ^{347}, positioned in an exposed loop region ([1934]) where it is available for complexation with its target proteases. However, this conformation, with the reactive site accessible to proteases, is unstable ($t_{1/2}$=90 minutes), reverting spontaneously to a latent form of the inhibitor in which the reactive loop is buried in ß sheet A of the protein core; this positioning of the reactive loop is observed in PAI-1 and other serpins after cleavage of the reactive site bond ([1935]). Plasma PAI-1 circulates in noncovalent association with vitronectin ([1928], [1936]) (Kd =0.05 nmol/L); *in vitro*, this association results in a twofold increase in its functional $t_{1/2}$ and, in the presence of heparin, increases PAI-1 reactivity with thrombin ([1472]).

GENE STRUCTURE AND EXPRESSION PAI-1 is an inhibitory serpin with significant sequence homology to a_1-antitrypsin, antithrombin-III, and a_1-antichymotrypsin ([1277], [1937], [1938], [1939], [1940], [1941], [1942] and [1943]). It shares the fundamental structural plan of these serpins: three ß sheets, nine a-helices, and a reactive site loop. PAI-1 is distinguished from the other inhibitory serpins in that it lacks cysteine residues. The human gene for PAI-1 is located on chromosome 7 bands q21.3-q22 in close proximity to the loci for erythropoietin, paraoxonase, and cystic fibrosis ([1944], [1945]) (Table 21.9). It covers 12.2 kb of DNA with nine exons specifying the 23 amino acids of the signal peptide and 379 amino acids of the mature protein ([1946], [1947], [1948] and [1949]). Introns, totaling approximately 9000 bp, define boundaries of individual structural subdomains or are found in random coil regions of the protein ([1946], [1947]). The transcription start site is located 25 bp downstream of a consensus TATA sequence ([1947], [1949]). The 5'-flanking region of the PAI-1 gene shows an extensive region of nucleotide sequence identity with the 5'-flanking region of the gene encoding t-PA ([1948], [1949]). The 3' region of the human PAI-1 gene contains alternative polyadenylation sites resulting in two mRNA species of different lengths (2.4 and 3.2 kb) ([1946]). Normal plasma levels of PAI-1 antigen range between 6 and 80 ng/ml. Polymorphisms in the PAI-1 gene appear to correlate with different plasma levels of PAI-1; thus, genotype-specific regulation of PAI-1 regulation accounts for some of the observed variation in the normal population. Nine polymorphisms have been described, with three of these the subject of human population studies ([1950]). A polymorphism located 675 bp upstream of the transcription start site consists of a single guanine insertion/deletion variation (4G/5G) leading to a sequence of four or five guanine nucleotides in the promoter ([1951]). Individuals homozygous for the 4G polymorphism have the highest levels of PAI-1, heterozygotes show intermediate levels, and those homozygous for the 5G allele have the lowest levels ([1952], [1953], [1954], [1955] and [1956]). The basis of this differential expression of the PAI-1 gene appears to be the specificity of a transcriptional repressor protein that binds the 5G allele and not the 4G allele ([1956]). The predictive relationship between the 4G/5G genotype, plasma PAI-1 level, and the risk of thrombosis is controversial ([1957], [1958]). The two other polymorphisms investigated both *in vitro* and in human population studies include an eight-allele $(CA)_n$ repeat in intron 3 ([1959]) and a two-allele Hind III restriction fragment length polymorphism of the 3'-flanking region. Individuals with one of the homozygous genotypes associated with the Hind III site exhibit higher plasma PAI-1 activity than the complementary homozygous individuals ([1959]). *In vitro* studies of the Hind III polymorphism have shown genotype-specific regulation of PAI-1 synthesis by a number of effector molecules ([1960], [1961], [1962] and [1963]). Congenital PAI-1 deficiency is a rare disorder with homozygous PAI-1–deficient individuals showing abnormal bleeding after trauma or surgery ([1923], [1924]). A study of an extended family with 19 heterozygotes and 7 individuals homozygous for a null mutation in the PAI-1 gene found no significant developmental or other abnormalities in the homozygotes beyond abnormal bleeding episodes ([1926]). Homozygous PAI-1–deficient mice display normal fertility, viability, and development with no identified histologic abnormalities ([1964], [1965]). A mild hyperfibrinolytic state and greater resistance to venous thrombosis were reported. Mice with combined homozygous deficiency of PAI-1 and a_2-antiplasmin show normal fertility and development while displaying a higher fibrinolytic capacity ([1966]). However, this increase appears to depend on the a_2-antiplasmin deficiency alone, suggesting a less critical role for PAI-1 in the regulation of fibrinolysis.

BIOCHEMISTRY PAI-1 is a single-chain glycoprotein of 379 amino acids that has no cysteine residues. It is an inhibitory serpin with a reactive site bond, Arg ^{346}–Met ^{347}, positioned in a surface-exposed, disordered loop of 20 amino acids ([1934]). Reaction with t-PA or u-PA involves rapid formation (second-order rate constant = 10^7 to 10^8 M^{-1}second $^{-1}$) of a reversible complex; specific interactions between a negatively charged region (amino acids 350 to 355) of the PAI-1 molecule and positively charged regions in t-PA ([1967], [1968]) or in u-PA ([1969]) are important to this initial association. Cleavage of the reactive site Arg ^{346}Met ^{347} bond in PAI-1 by the protease triggers a large conformational change in both the inhibitor and protease that renders the protease unable to efficiently hydrolyze the normally transient ester linkage between its active site serine residue and the carboxyl moiety of a targeted peptide bond. PAI-1 converts to an inactive (latent) form spontaneously; it can be returned to its active conformation by treatment with denaturants ([1970]). The crystal structure of latent PAI-1 indicates that the reactive site loop is inserted into the ß sheet A of the molecule making it unavailable to proteases ([1971]). The crystal structure of a mutant PAI-1 stabilized in the active conformation by substitutions at four sites (N150?H; K154?T; Q319?L; M354?I) shows the reactive site bond to be located at the apex of a flexible, exterior loop ([1934]). The vitronectin binding site of PAI-1 involves five residues located on the exterior of the molecule ([1972]). Extensive structural differences have been noted when this region is compared in active and latent conformations of PAI-1 ([1934]). Stabilization of the conformation of this region of PAI-1 by the PAI-1 vitronectin binding interaction presumably impedes the insertion of the reactive site loop into ß sheet A of the molecule.

FUNCTION PAI-1 is the central physiologic inhibitor of the plasminogen activator t-PA in blood. It reacts with both the secreted, single-chain form of t-PA and the two-chain form generated by plasmin during the process of fibrin dissolution. Both PAI-1 and t-PA are characterized by high turnover rates (t-PA, $t_{1/2}$ = 3 to 4 minutes; PAI-1, $t_{1/2}$ = 10 minutes) with functional PAI-1 circulating concentrations maintained at least at several-fold molar excess over the concentration of functional t-PA (14 pmol/L). From the circulating concentration of PAI-1 and the second-order rate constant for the association of PAI-1 with either form of t-PA (10^7 to 10^8 M^{-1}second $^{-1}$), the predicted $t_{1/2}$ of t-PA is less than 1 minute: This is consistent with the observation that approximately 80% of the t-PA antigen in plasma (70 pmol/L) is found complexed with PAI-1. PAI-1–t-PA complexes have a clearance half-time of approximately 5 minutes ([1729]). Although other plasma proteins have been identified *in vitro* with inhibitory activity toward plasminogen activators (PAI-2, PAI-3, protease nexin), only PAI-1–plasminogen activator complexes have been detected *in vivo* ([1040], [1973]). PAI-1 is an important inhibitor of u-PA. Unlike t-PA, PAI-1 forms complexes only with the two-chain form of urokinase; it does not complex with the single-chain form of urokinase. The second-order rate constant for the association of PAI-1 and tcu-PA is in the range of 10^8 M^{-1}second $^{-1}$.Conversion of circulating scu-PA (37 to 74 pmol/L) to tcu-PA occurs at sites of fibrin lysis. Urokinase also is involved in physiologic and pathologic processes such as embryo development, wound healing, cell migration, inflammation, and metastasis of tumor cells. A large body of *in vitro* work supports a regulatory role for PAI-1 as a protease inhibitor in u-PA–mediated events outside the vasculature. PAI-1 also appears to be involved in regulating cell adhesion and migration by a mechanism independent of its function as a protease inhibitor. Its high-affinity association with the somatomedin B domain of vitronectin makes it an effective competitor with other ligands such as urokinase-type plasminogen activator receptor (uPAR) ([1974], [1975], [1976] and [1977]) and integrins including $a_V ß_3$ ([1978]) that also bind to vitronectin at this site. The ability to interfere with the binding of such cell-associated ligands to matrix-associated vitronectin suggests a role for PAI-1 as a regulator of the interaction of cells with the extracellular matrix.

Plasminogen Activator Inhibitor-2

PAI-2 is a member of the serpin subfamily designated the *ovalbumin-related serpins*. It was initially identified in human placenta as an inhibitor of urokinase ([1979]). It has also been referred to as the *placental-type PAI* ([1979], [1980], [1981], [1982], [1983] and [1984]). It is not normally detected in plasma although it has been detected in human thrombi ([1985]). During pregnancy, PAI-2 is found in plasma at levels that may exceed those of PAI-1 ([1973]). PAI-2 appears to have significant functions within the cytoplasm of certain cell types and in the extracellular region outside of the vasculature where it may regulate urokinase-dependent events. Its role in hemostasis remains problematic. PAI-2 (-/-) null mice developed normally and did not display any phenotypic abnormalities ([1986]).

GENE STRUCTURE AND EXPRESSION The gene for PAI-2 is located on chromosome 18, band q22.1, and spans 16.5 kb ([1987], [1988], [1989], [1990], [1991] and [1992]) (Table 21.9). Its transcript specifies a protein of 415 amino acids that lacks a cleavable NH_2-terminal signal sequence. PAI-2 is synthesized and secreted by human white blood cells such as monocytes and macrophages and cells of epithelial lineage such as keratinocytes and certain tumor cells ([1993], [1994], [1995] and [1996]). A large number of agonists have been shown to affect transcription rates of the PAI-2 gene (reviewed in 1997–1999). For example, the PAI-2 gene has been shown to respond dramatically to TNF ([2000]) and to lipopolysaccharide ([2001]). In human monocytes, exposure to lipopolysaccharide induced approximately a 100-fold increase in PAI-2 mRNA levels ([2002]). Posttranscriptional regulation of PAI-2 mRNA levels has also been documented ([2003], [2004]). Regulation of the stability of PAI-2 mRNA has been shown to derive in part from an AU rich–mRNA destabilizing determinant in the 3'-untranslated region ([2004]) and from an mRNA instability element identified within exon 4 of the coding region ([2005]).

BIOCHEMISTRY AND FUNCTION There are two forms of PAI-2: an intracellular nonglycosylated form (M_r = 47 kd) and a secreted glycosylated form (M_r = 60 kd) (Table 21.8). Glycosylation occurs at Asn ^{75}, Asn ^{115}, and Asn ^{339}. PAI-2 is structurally distinguished from other serpins by the presence of a unique 33-residue long loop (CD loop: residues 66 to 98) positioned between helices C and D. This solvent-exposed loop region has two glutamine residues (Gln ^{83} and Gln ^{86}) that have been shown to be sites for FXIIIa-catalyzed cross-linking of PAI-2 to fibrinogen ([1985], [2006]). PAI-2 cross-linked to fibrinogen remains functional after its fibrinogen carrier is converted to insoluble fibrin ([2006]). The CD loop has also been implicated in the association of intracellular PAI-2 with other cytoplasmic proteins ([2007]). The crystal structure of PAI-2 at 2 Å-resolution has recently been reported using a PAI-2 mutant lacking the CD loop ([2008]). The reactive site bond (Arg ^{380}–Thr ^{381}) is located in a highly disordered reactive center loop extending from Thr ^{367} to Pro ^{386}. PAI-2 is a serpin inhibitor that can inhibit plasminogen activators: The

second-order rate constants defining its interactions with two-chain urokinase (1×10^{6} M^{-1}second $^{-}1$) and two-chain t-PA (2×10^{5} M^{-1}second $^{-1}$) are approximately 100-fold lower than those characterizing the reaction of PAI-1 with these proteases. Unlike PAI-1, PAI-2 reacts very slowly with the single-chain form of t-PA. Unlike PAI-1, PAI-2–t-PA or PAI-2–u-PA complexes have not been detected in plasma. Thus, it has been suggested that PAI-2 may not play an important role in regulating intravascular clot lysis; however, fibrin deposition at sites of chronic inflammation within blood vessels may represent an instance in which monocyte-derived PAI-2 could end up cross-linked to fibrin, thereby exerting some effect in the vasculature (1985 , 2006). An extravascular role for PAI-2 in aspects of tissue remodeling and wound healing that depend on urokinase catalysis is consistent with the observed induction of PAI-2 production by inflammatory mediators in cell types such as keratinocytes and macrophages. The nonglycosylated form of PAI-2 is found in the cytosol of a number of cell types. Data supporting a diverse set of roles for intracellular pools of PAI-2 include effects on cellular differentiation (2009), cell proliferation (2010), TNF-a-induced apoptosis (2011 , 2012), signal transduction (2013), and, in monocytes, multiple roles in modulating adhesion, proliferation, and differentiation (2014).

a $_2$-Antiplasmin

a $_2$-Antiplasmin (or a $_2$-plasmin inhibitor) is the primary plasmin inhibitor in human plasma (2015 , 2016 , 2017 and 2018) and thus is an important regulator of fibrinolysis. Congenital deficiency of a $_2$-antiplasmin is rare, with homozygous individuals displaying a severe to moderate bleeding disorder (2019). a $_2$-Antiplasmin is a single-chain glycoprotein with a calculated mass of 58 kd (2020) and a relative molecular weight of 70 kd when assessed by SDS-PAGE. It is present in plasma at a concentration of 70 mg/L (Table 21.8). The primary site of synthesis is the liver although the kidney may be another contributing source (2021); its *in vivo* $t_{1/2}$ is 2.6 days (2022 , 2023). Two NH $_2$-terminal variants of a $_2$-antiplasmin are isolated from human plasma in roughly equivalent amounts: a $_2$-antiplasmin Met ^{1}, the full-length protein secreted into the blood, and a $_2$-antiplasmin Asn ^{1}, lacking the first 12 amino acids (Asn ^{13} in a $_2$-antiplasmin Met ^{1}) (2024 , 2025). a $_2$-Antiplasmin is a member of the serine protease inhibitor superfamily. It forms a stable 1:1 stoichiometric complex with plasmin that has no proteolytic or esterase activity (2017 , 2018 , 2026). It is structurally distinct from related serpins in having a 51–amino acid extension at its COOH-terminus (1350 , 1351). This region mediates a $_2$-antiplasmin binding to specific regions (lysine binding sites) on the kringle domains of plasminogen and plasmin (2027 , 2028 and 2029). Approximately 30% of a $_2$-antiplasmin in human plasma lacks part of this COOH-terminal region (residues 449 to 464). This truncated form appears to be functionally inert in plasma (2029 , 2030), although it has been shown, when purified, to slowly form complexes with plasmin (2031 , 2032).

The a $_2$-antiplasmin molecule has three domains defining its role in fibrinolysis: the reactive site (Arg ^{376}–Met ^{377}) and the plasminogen binding site, both of which are critical to its reactivity with plasmin (2027 , 2028 , 2033), and a cross-linking site mediating the attachment of a $_2$-antiplasmin to the a-chain of fibrin during clotting (1407). The binding of the plasminogen binding domain of a $_2$-antiplasmin to a lysine binding site of plasmin has been shown to occur more rapidly than the association between the active site of plasmin and the reactive site of a $_2$-antiplasmin (2034). Thus, the rate of binding of a $_2$-antiplasmin depends primarily on the availability of the lysine binding sites(s) of plasmin. This dependence of the rate of inhibition on an exosite interaction between the two molecules results in the differential reactivity of a $_2$-antiplasmin with its primary targets in clotting blood: plasmin released into the circulating blood ($t_{1/2}$ = 0.1 second) versus plasmin bound through its lysine binding sites to fibrin or cellular sites at the site of vascular injury ($t_{1/2}$ = 10 seconds).

GENE STRUCTURE AND EXPRESSION a $_2$-Antiplasmin is a member of a multigene family of serine protease inhibitors that includes a $_1$-antitrypsin, antithrombin-III, PAI-1, and a $_1$-antichymotrypsin (1277 , 1351 , 1937). These serpins interact with their target proteases at a reactive Arg-X peptide bond positioned in a loop structure located 30 to 40 amino acids from the inhibitor COOH-terminus. a $_2$-Antiplasmin differs from other members of its family in having a 51–amino acid extension at its COOH-terminus. The human gene for a $_2$-antiplasmin is located on chromosome 17, band p13 (2035), and is comprised of ten exons distributed over 16 kilobases of DNA (2036) (Table 21.9). The 5'-untranslated region and leader sequence are interrupted by three introns; a TATA box sequence is found 17 nucleotides upstream from the transcription initiation site. Exons 4 through 10 code for the protein, with exon 10 specifying both the reactive site and the unique COOH-terminal plasminogen binding site. To date, only 13 cases of congenital a $_2$-antiplasmin deficiency have been described; five of these cases have been characterized at the molecular level, with family members in each case providing cohorts of heterozygotes for study (2019). The transmission is autosomal recessive. Bleeding problems vary from severe to moderate in homozygotes; the majority of heterozygotes have no bleeding problems, although exceptions have been described (2037 , 2038). One instance of congenital deficiency, a $_2$-antiplasmin Enschede (2039), is characterized by dysfunctional full-length a $_2$-antiplasmin at normal plasma concentrations. All other cases involve quantitative defects with the four characterized instances showing mutations in the coding exons (2040 , 2041 and 2042) or an intron splicing donor site (2043) with consequent truncated, nonsecreted peptide products. Homozygous a $_2$-antiplasmin–deficient mice have been generated (2044). They display normal fertility, viability, and development and show no overt bleeding disorder.

BIOCHEMISTRY a $_2$-Antiplasmin is a single-chain glycoprotein of 464 amino acids containing 13% carbohydrate with an apparent molecular weight of 70 kd when analyzed by SDS-PAGE (Table 21.8). Glycosylation occurs at Asn ^{99}, Asn ^{268}, Asn ^{282}, and Asn ^{289}. a $_2$-Antiplasmin contains four cysteine residues but only one S-S bridge (2045). It is a member of the a $_1$-proteinase inhibitor class of the serine proteinase inhibitor superfamily (1277 , 1351). a $_2$-Antiplasmin functions as the primary inhibitor of plasmin in blood (2022). It is synthesized primarily in the liver with a signal peptide of 27 amino acids and circulates at a concentration of 1 µmol/L with a $t_{1/2}$ of 2.6 days (2022 , 2023). Isolation from plasma yields both Met ^{1}–a $_2$-antiplasmin (464 amino acids) and a truncated form with an NH $_2$-terminal Asn (Asn ^{13}–a $_2$-antiplasmin) (2024); whether the truncated form is an artifact of purification is not established (2044). Plasma a $_2$-antiplasmin is also found to have two COOH-terminal forms: a slow-reacting, nonplasminogen binding form (30%) that lacks the terminal 26 amino acids and the fully active molecule with an intact COOH-terminal extension (2029 , 2031). Conversion to the nonplasminogen binding form occurs in the blood (2030). a $_2$-Antiplasmin has three functionally important domains: a reactive site, a plasmin/plasminogen binding site, and a cross-linking site. The reactive site of the inhibitor is the Arg ^{376}–Met ^{377} peptide bond (1350). a $_2$-Antiplasmin reacts with plasmin in a two-step process: first, a rapid (second-order rate constant = 2 to 4 $\times 10^{7}$ M^{-1} second $^{-1}$), reversible interaction to yield a 1:1 complex ($K_d = 10^{-10}$ M); second, a slower first-order ($t_{1/2}$ = 166 seconds) formation of a covalent bond between the active site seryl residue of plasmin and Arg ^{376} of a $_2$-antiplasmin with subsequent release of a COOH-terminal fragment (residues 377 to 464) of a $_2$-antiplasmin. The plasmin/plasminogen binding domain is located within residues 439 to 464, with Lys ^{452} acting as the key residue (2027 , 2028). It complexes with lysine binding site(s) located in the kringle structures of plasminogen and plasmin, exhibiting at least a tenfold stronger binding to plasmin (1689). Lysine binding sites on kringles 1 (1689 , 2046) and 4 (2047) have been identified as the points of interaction with a $_2$-antiplasmin although their relative importance individually is not resolved (2047). Maximum rates of a $_2$-antiplasmin inhibition of plasmin require the unimpeded interaction of both the plasminogen binding domain and the reactive site of a $_2$-antiplasmin with their respective target domains in the plasmin molecule (2034). Cross-linking of a $_2$-antiplasmin at Gln ^{14} to the a-chain of fibrin is catalyzed by activated FXIII (2048). *In vitro*, Asn ^{13} a $_2$-antiplasmin is more efficiently cross-linked to fibrin (2049).

FUNCTION a $_2$-Antiplasmin is the primary plasmin inhibitor in human plasma. Its effective concentration in plasma is in the range of 0.5 µmol/L: Approximately one-third of the circulating pool (1 µmol/L) is poorly reactive (2029 , 2031), and another fraction is bound to circulating plasminogen (K_d = 4 µmol/L) (2034). a $_2$-Antiplasmin stabilizes the fibrin scaffolding of the developing blood clot by attenuating the rate of plasmin-driven fibrinolysis and protects against systemic degradation of fibrinogen and other proteins by plasmin. Fibrin, as the key cofactor for efficient t-PA activation of plasminogen, localizes plasmin generation to the site of fibrin formation. Generated plasmin is partitioned: One fraction is surface-associated through binding interactions between its lysine binding sites and active site and insoluble fibrin; the other fraction mixes with the circulating blood. a $_2$-Antiplasmin rapidly inhibits solution phase plasmin ($t_{1/2}$ º 0.1 second), preventing systemic fibrinogen degradation until more than 50% of its neutralizing capacity has been exhausted (2022). The rate of inhibition *in vitro* of fibrin-bound plasmin by a $_2$-antiplasmin decreases by at least a factor of 100 ($t_{1/2}$ =10 seconds) (2050). This decrease in reactivity reflects the dependence of the rate of inhibition on the availability of both the lysine binding and active sites of plasmin. Offsetting this, a $_2$-antiplasmin is accumulated on fibrin through a factor XIIIa–catalyzed tethering of the NH $_2$-terminal of a $_2$-antiplasmin to the a-chain of fibrin. Approximately 20% of the available a $_2$-antiplasmin is rapidly bound to fibrin. This process has been shown to play a significant role in stabilizing the fibrin clot against lysis (1649).

PHYSIOLOGIC REGULATION OF FIBRINOLYSIS

The physiologic regulation of fibrinolysis centers on controlling the rate and location of plasmin formation. Under quiescent conditions, there is little systemic plasmin formation. t-PA is a poor catalyst of the conversion of plasminogen to plasmin in the absence of fibrin; in addition, circulating levels of active t-PA are continually

suppressed by reaction with PAI-1, thus further reducing the potential for solution phase plasminogen activation by t-PA. scu-PA has negligible activity toward plasminogen in solution. Further, there is no gradual accumulation of plasmin in the blood because the circulating concentration and efficacy of a_2-antiplasmin limit the $t_{1/2}$ of plasmin formed away from a fibrin surface to 0.1 second. Thus, significant plasmin formation occurs only after the formation of fibrin. t-PA and plasminogen bind to fibrin as the clot forms, localizing plasmin generation to the clot. Initial plasmin degradation of fibrin actually increases the number of plasminogen binding sites in the fibrin, thus amplifying plasmin formation rates. Plasmin also cleaves scu-PA to generate the active two-chain form of the catalyst, further enhancing rates of plasmin activation. In addition, fibrin-bound plasmin is protected from inactivation by circulating a_2-antiplasmin. These mechanisms ensure that plasmin formation is not premature, that plasmin formation is localized to the clot, and that the extent of plasmin formation is tied to the amount of fibrin present, thus allowing the process to efficiently dissolve thrombi of different sizes.

Regulation of fibrinolysis is achieved through a dynamic balance between profibrinolytic and antifibrinolytic processes maintained by complex interactions between circulating proteins, clot-based factors, and endothelial cells. Recruitment of the proteins key to fibrinolysis to the site of injury occurs simultaneously with the initiation of fibrin formation. The fibrin clot not only serves as a substrate, but also acts in a role similar to the phospholipid surface in coagulation, functioning as a surface for the activation and localization of fibrinolytic proteins. The association of plasminogen and t-PA with fibrin enhances the rate of plasminogen activation by t-PA. Plasmin bound to fibrin is protected from inhibition by a_2-antiplasmin ([1993], [2034], [2051]). These mechanisms both enhance fibrinolysis and serve to limit proteolytic activity to the clot. However, profibrinolytic processes are balanced by antifibrinolytic responses. PAI-1 associates with fibrin and inactivates t-PA and u-PA within the meshwork of the clot ([2052]). Factor XIIIa cross-links and stabilizes the fibrin clot and renders it less susceptible to plasmin proteolysis. Factor XIIIa also cross-links a_2-antiplasmin to fibrin; this incorporation has been shown to play an important role in fibrin clot stabilization ([1648], [1649]). TAFIa removes COOH-terminal lysines from partially proteolyzed fibrin, thus reducing the number of plasminogen binding sites and attenuating the rate of plasmin formation. In addition, activated platelets release PAI-1 and a_2-antiplasmin at the fibrin surface, thus supplementing the ongoing down-regulation of plasmin levels by the plasma pools of these serpins ([2053], [2054], [2055], [2056] and [2057]).

Cellular Regulation of Fibrinolysis

The fibrin clot and, thus, fibrinolysis are localized to the surface of the blood vessel at sites where the normally nonthrombogenic façade presented by the endothelium is either mechanically removed or altered in its molecular composition. The unperturbed endothelium secretes PAI-1 ([2058]) and is actively antifibrinolytic. Once the endothelial layer is disturbed, a-thrombin is generated, and fibrin formation proceeds at that site ([2059]). Intact endothelial surfaces in the vicinity of the injury become "activated" via interaction with products of the coagulation cascade, shifting from an antifibrinolytic to a profibrinolytic state. "Activated" endothelial cells express t-PA and u-PA as well as specific receptors for the plasminogen activators ([2060], [2061] and [2062]). t-PA is likely the primary activator of plasminogen at the fibrin surface ([1787], [1860], [2063]). u-PA has profibrinolytic activity but appears to be primarily associated with extracellular matrix degradation and initiation of tissue repair and remodeling ([2064], [2065] and [2066]).

In addition to receptors for plasminogen activators, receptors for plasminogen have been identified on a number of cell types including platelets, monocytes, fibroblasts, and endothelial cells in which they appear to localize and accelerate plasmin formation. Plasmin generated at the cell surface is protected from serpin inhibitors by binding to specific cell receptors. Therefore, the cell surface can serve as a sanctuary for plasmin activity.

Urokinase-Type Plasminogen Activator Receptor

uPAR is synthesized and expressed by normal and malignant cells including monocytes, neutrophils, fibroblasts, platelets, and endothelial cells ([2064], [2067], [2068], [2069], [2070], [2071], [2072] and [2073]). The primary function of uPAR is to localize u-PA–mediated plasmin generation to the cell surface. uPAR binds both single-chain u-PA and plasminogen via high-affinity interactions forming a ternary complex that enhances plasminogen activation ([2069], [2074]) and initiates proteolysis of the extracellular matrix ([2075]). The receptor is a heterogeneously glycosylated single-chain polypeptide (M_r = 50,000 to 60,000) of 313 amino acids ([2076]). Although uPAR is an integral membrane protein, there is no defined transmembrane sequence. uPAR is instead anchored to the cellular membrane by a glycosyl-phosphatidylinositol moiety ([2077]). The glycolipid is most likely attached to Gly^{283} indicating that the mature protein consists of 283 amino acids ([2077], [2078]). The neutrophils of individuals experiencing the hematopoietic stem cell disorder paroxysmal nocturnal hemoglobinuria, a disease in which these glycosyl-phosphatidylinositol moieties are lacking, show impaired transendothelial migration ([2071], [2079]). The absence of the receptor may play a role in the hypercoagulable state associated with this disorder.

Tissue-Type Plasminogen Activator Receptors

Many structurally unrelated components that bind t-PA have been described. These receptors can be separated into two distinct functional groups: activation receptors and clearance receptors. Activation receptors are described as localizing t-PA onto a cell surface and enhancing the activation of plasminogen by t-PA ([2080]). Receptors in the activation category include annexin II (42 kd) ([2081]), heparan sulfate and chondroitin sulfate–like proteoglycans ([2082]), cytokeratin 8 and 18 ([2083], [2084]), and tubulin ([2085]). In patients with promyelocytic leukemia, overexpression of the t-PA receptor annexin II has been associated with a hyperfibrinolytic state resulting in bleeding ([2086]). The t-PA receptor(s) on endothelial cells is poorly defined [for descriptions of these receptors see Bachmann ([1664])].

Clearance receptors are responsible for clearing t-PA from the circulation and its subsequent degradation. These receptors control not only the plasma concentration of t-PA but also the levels of inactive t-PA/PAI-1 complexes. t-PA clearance occurs principally in the liver and involves two different receptors: the mannose receptor and the LRP/a_2-macroglobulin receptor. The mannose receptor is a major t-PA receptor and binds t-PA with a high-affinity K_d of 1 to 4 nmol/L ([2087], [2088] and [2089]). Liver endothelial cells and Kupffer's cells bind t-PA via the mannose receptor. The other major pathway for t-PA clearance is through the LRP/a_2-macroglobulin receptor. This receptor has a relative molecular weight of 600 kd ([1664]). This receptor mediates the clearance of t-PA, t-PA/PAI-1, and u-PA/PAI-1 complexes; toxins; cytokines; apolipoprotein E–enriched chylomicron remnants; and complexes of a_2-macroglobulin ([2090]). Free and PAI-1–complexed t-PA have also been shown to be cleared from the circulation through a glycoprotein 330-kd LRP receptor and a 130-kd very-low-density lipoprotein receptor ([2090], [2091] and [2092]).

Role of Platelets in Regulation of Fibrinolysis

Platelets are vital to procoagulant events and contribute to the fibrinolytic process as well. Platelets bind both t-PA and plasminogen and support plasmin generation ([2093], [2094] and [2095]). Plasmin bound to the platelet surface is also protected from inhibition by a_2-antiplasmin ([2096]). Platelets likewise contribute to the antifibrinolytic mechanism. Activated platelets release PAI-1, a_2-antiplasmin, C1-esterase inhibitor, and a_2-macroglobulin, which function to inhibit plasminogen activators and plasmin. Therefore, platelets, when present at high concentration, can promote thrombosis and inhibit fibrinolysis.

Several studies have shown that plasmin can directly modify the function of platelets ([2097], [2098], [2099], [2100], [2101] and [2102]). When plasmin is present at a low concentration, it can inhibit platelet aggregation by arachidonic acid metabolism or by proteolysis of membrane glycoproteins. At high plasmin concentration, a proteolytic modification of the platelets occurs that affects fibrinogen binding and platelet aggregation. Plasmin is also able to increase the number of plasminogen binding sites on the surface of platelets, an alteration that may function as a positive feedback loop for t-PA–mediated plasmin production. Increasing the size of the pool of fibrin-localized, platelet-bound plasminogen would augment the other readily activatable pool, plasminogen bound to fibrin, thereby increasing the amount of plasminogen available for efficient t-PA activation. Plasmin has also been shown to degrade the platelet-binding site for factor XIIIa, decreasing the rate of clot stabilization ([2074]).

CONCLUSION

This chapter describes the process of blood coagulation by dividing it into sections based on procoagulant, anticoagulant, and fibrinolytic enzymes, cofactors, and inhibitors in the overall process of fibrin formation and fibrin dissolution. The role of each protein is described as either essential or accessory to hemostasis. The overall process of blood coagulation and fibrinolysis is better described when all the players are considered as contributing to a threshold-limited, complex, intertwined process that together promotes hemostasis.

Our understanding of the coagulation process has ancient historical roots; the accomplishments of numerous clinical and basic investigators has provided a relatively

complete description of the inventory, connectivity, and dynamics of the overall process that occurs after vascular injury. Significant progress has been made in achieving a complete set of x-ray crystal structures for all the proteins involved in these processes (Table 21.10). The challenge for the future is the use of this knowledge in the development of new technology for the advancement of diagnosis, prophylaxis, and treatment of vascular disease.

TABLE 21.10. Highest Resolution X-Ray Structures of Human Procoagulant, Anticoagulant, and Fibrinolytic Proteins and Their Inhibitors

Protein	Structure	Resolution (Å)	PDB Code [a]
Procoagulant proteins			
Intrinsic pathway			
Factor XII	N/A		
Prekallikrein	N/A		
High-molecular-weight kininogen	N/A		
Low-molecular-weight kininogen	N/A		
Factor XI	N/A		
Vitamin K–dependent			
Factor VII	VII zymogen (des Gla)	2.0	1JBU
	VIIa (des Gla)	2.4	1KLJ
	VIIa + TF extracellular domain	2.0	1DAN
Factor IX	IXa + inhibitor (benzamidine)	2.8	1RFN
Factor X	Xaß (des Gla)	2.2	1HCG
Factor II	Prethrombin 2 + inhibitor (hirugen)	2.0	1HAG
	Prothrombin fragment 1 (bovine)	2.3	2PF1
	a-IIa + inhibitor (D-Phe-L-Pro-L-Arg-chloromethyl ketone)	2.4	1ABJ
	a-IIa + inhibitor (borolog)	1.8	1A3B
Cofactors			
TF	Extracellular domain	1.7	2HFT
	VIIa + TF extracellular domain	2.0	1DAN
Factor VIII	C2 domain	1.5	1D7P
Factor V	C2 domain	1.9	1CZT
von Willebrand factor	A1 domain	2.3	1AUQ
	A3 domain	1.8	1ATZ
Anticoagulant proteins			
Dynamic inhibition			
PC	APC (des Gla)	2.8	1AUT
	Gla domain of APC + PC receptor	1.6	1LQV
Protein S	N/A		
Protein Z	N/A		
Thrombomodulin	Epidermal growth factor–like domains 4-6 of thrombomodulin + IIa	2.3	1DX5
Proteinase inhibitors			
a_2-Macroglobulin	N/A		
TFPI	Second Kunitz domain of TFPI + trypsin	2.6	1TFX
ATIII	Intact-active ATIII + intact-latent ATIII	3.2	1ATH
	Plasma a-ATIII	2.6	1E05
	Plasma ß-ATIII	2.6	1E04
Heparin cofactor II	Heparin cofactor II	2.4	1JMJ
a_1-Proteinase inhibitor	a_1-Proteinase inhibitor	2.0	1QLP
C1 esterase inhibitor	N/A		
PC inhibitor	Elastase cleaved form	2.4	1LQ8
Proteins of clot formation			
Factor XIII	XIII zymogen	2.0	1EVU
	XIIIa	2.5	1FIE
Fibrinogen	(Chicken)	2.7	1M1J
Fibrin	D-dimer	2.3	1FZC
Fibrinolytic system			
Proteins			
Plasminogen	Catalytic domain	2.0	1QRZ
Tissue-type plasminogen activator	Single-chain + inhibitor (EGR-cmk)	3.3	1BDA
	Two-chain + inhibitor (benzamidine)	2.3	1RTF
Urokinase-type plasminogen activator	Two-chain + inhibitor (BMZ)	1.8	1GI8
Factor VII–activating protease	N/A		
Inhibitors			
TAFI	N/A		
PAI-1	Latent form	2.1	1DVN
	Active form	2.4	1DVM
PAI-2	Stabilized mutant	2.0	1BY7
a_2-Antiplasmin	N/A		

APC, activated protein C; AT, antithrombin; BMZ, 2-2-hydroxy-phenyl-1-benzoimidazole-5-carboxamide; EGR-cmk, Glu-Gly-Arg chloromethyl ketone; N/A, not currently available; PAI, plasminogen activator inhibitor; PC, protein C; TAFI, thrombin-activatable fibrinolysis inhibitor; TF, tissue factor; TFPI, tissue factor pathway inhibitor.

Endothelium: Angiogenesis and the Regulation of Hemostasis

NORMAL ANGIOGENESIS

Blood circulation requires the production and maintenance of a vast network of vessels that have specialized functions depending on their organ location. The vascular network involves a complex interaction between endothelial cells (EC), specialized cells such as smooth muscle cells and pericytes, and the extracellular matrix. *Vasculogenesis* is the *de novo* development of vessels ([1]). It is mainly seen at the embryonic stage of development with the differentiation of a common pluripotent precursor, the hemangioblast, into endothelial and hematopoietic cells. *Angiogenesis* is the development of new vessels from preexisting vessels ([1]). It is an essential process for wound healing and the maintenance of the integrity of the vascular network. Pathologic angiogenesis is seen in disease states including cancer, retinal, and autoimmune diseases ([2]).

As outlined by Conway, Collen, and Carmeliet ([1]), physiologic angiogenesis is a well-organized stepwise process that involves dilation and increased permeability of the parent vessel, dissolution of the extracellular matrix, division and migration of EC, cord formation and the development of lumina, and, finally, the maintenance of new vessel integrity. The entire process involves the complex and choreographed effects of multiple inducers and inhibitors (Table 22.1).

TABLE 22.1. Activators and Inhibitors of Angiogenesis

Activators	Function	Inhibitors	Function
VEGF, VEGF-C, PlGF, and homologs	Stimulate angiogenesis, permeability; stimulate lymphangiogenesis, pathologic angiogenesis.	VEGFR-1, soluble VEGFR-1, and NP-1	Sink for VEGF, VEGF-B, PlGF (VEGFR-1), and VEGFR $_{165}$ (NP-1)
VEGFR	VEGFR-2: angiogenic signaling; VEGFR-3: (lymph) angiogenic signaling.	Ang2	Ang1 antagonist; induces vessel regression in absence of angiogenic signals
Ang1 and Tie2 receptor	Ang1: stabilizes vessels, inhibits permeability.	TSP-1	ECM proteins; inhibits EC migration, growth, and adhesion
	Ang2: destabilizes vessels before sprouting.	TSP-2	Inhibits angiogenesis
Platelet-derived growth factor-BB and receptors	Recruit smooth muscle cells.	Meth-1, Meth-2	Contain metalloprotease, thrombospondin, and disintegrin domains
TGF-ß $_1$, endoglin, TGF-ß receptors	Stabilize vessels by stimulating ECM production.	Angiostatin and related plasminogen kringles	Inhibit EC survival and migration
Fibroblast growth factor, hepatocyte growth factor, monocyte chemotactic protein-1	Stimulate angiogenesis, stimulate arteriogenesis.	Endostatin	Inhibits EC survival and migration
Integrins a $_V$ß $_3$, aVß $_5$	MMP receptors.	Vasostatin, calreticulin	Inhibit EC growth
VE-cadherin, platelet-EC adhesion molecule	EC junctional molecules, promote EC survival.	Platelet factor-4	Heparin-binding molecule; inhibits binding of bFGF and VEGF
Ephrins	Regulate arterial/venous specifications.	Tissue inhibitors of metalloproteinases, MMP inhibitors	Suppress pathologic angiogenesis
		Proteolytic fragment of MMP	Inhibits binding of MMP2 to a $_V$ß $_3$
Plasminogen activators, MMPs	Cell migration and matrix remodeling; liberate bFGF/VEFG from ECM; activate TGF-ß $_1$; generate angiostatin.		
Plasminogen-activator -inhibitor-1	Stabilizes nascent vessels (prevents ECM dissolution).	IFN-a, -ß, -?; IL-4, -12, -18	Inhibit EC migration, IFN-a down–regulates bFGF
Nitric oxide synthase, cyclooxygenase-2	Nitric oxide/prostaglandins stimulate angiogenesis and vasodilation.	Prothrombin kringle 2 antithrombin fragment	Suppresses EC growth
AC133	Angioblast differentiation.	Prolactin fragment; secreted protein (acidic and rich in cysteine) fragment	Inhibits bFGF and VEGF; inhibits EC binding and activity of VEGF

Ang, angiopoietin; bFGF, b-fibroblast growth factor; EC, endothelial cells; ECM, extracellular matrix; IFN, interferon; IL, interleukin; Meth, metalloproteinase and thrombospondin; MMP, matrix metalloproteinase; NP, neuropilin; PlGF, placental growth factor; TGF, transforming growth factor; TSP, thrombospondin; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

Adapted from Conway EM, Collen D, Carmeliet P. Molecular mechanisms of blood vessel growth. Cardiovasc Res 2001;49:507–521.

The first step in angiogenesis is vasodilation. This is mediated through the activation of the soluble guanylate cyclase by nitric oxide (NO) ([3]). NO also up-regulates vascular endothelial growth factor (VEGF) production ([4]). By causing intercellular adhesion molecules to redistribute (platelet-EC adhesion molecule-1 and VE-cadherin, among others), VEGF induces an increase in vascular permeability ([5], [6]). The VEGF-induced increase in vascular permeability is negatively controlled by angiopoietin-1 (Ang1) through its receptor, Tie2 ([7]). The next key step to vascular development is the dissolution of the extracellular matrix, which is accomplished by proteases belonging to the matrix metalloproteinase family ([8], [9]). These proteases also induce the liberation of EC growth factors from the extracellular matrix, including VEGF and basic fibroblast growth factor. The action of matrix metalloproteinases is negatively controlled by a family of protease inhibitors, the tissue

inhibitors of metalloproteinases ([10]).

Degradation of the extravascular matrix allows the development of the key element of the angiogenesis process, namely, EC division and migration. The list of factors that stimulate this process is extensive (Table 22.1), but a key role is played by VEGF in concert with Ang1 ([6], [11], [12], [14], [15] and [16]). Angiopoietin-2 (Ang2) could have angiogenic effects in the presence of VEGF, whereas it is antiangiogenic in the absence of VEGF ([14], [15], [16] and [17]). The role played by the endothelial NO synthase and NO has been the subject of controversy, with reports showing that NO has both pro- and antiangiogenic effects ([18], [19], [20] and [21]). Other factors that stimulate angiogenesis include basic fibroblast growth factor and platelet-derived growth factor ([22], [23] and [24]). EC growth is negatively controlled by endogenous angiogenesis inhibitors that include angiostatin, endostatin, interferons, and antithrombin III ([25], [26], [27] and [28]). EC then migrate in large part through the action of integrins (a $_{V}$ß $_{3}$ and a $_{V}$ß $_{1}$) ([29]). The end result of EC division and migration is sprouting and the formation of cords ([1]). This is followed by lumen formation, which is controlled by different VEGF isoforms, Ang1, and integrins ([1], [15]). Thrombospondin-1 acts as an endogenous inhibitor of lumen development ([1]).

Once formed, new vessels survive for years ([1]). This prolonged survival is maintained by the interaction of VEGF with its receptor VEGFR-2, phosphoinositide 3-kinase, ß-catenin, and VE-cadherin ([1], [30]). The angiopoietins also play a role in maintaining vessel survival through their receptors Tie1 and Tie2. Ang1 stabilizes the vessel, whereas Ang2 has an opposite effect ([14], [15], [31]) (see below). An essential element in the maintenance of the integrity of vessels is their “coating” with smooth muscle cells and pericytes ([32]). Evidence suggests that vascular smooth muscle cells and EC have a common precursor ([33]). On stimulation with platelet-derived growth factor-BB, these precursor cells differentiate into smooth muscle cells, whereas VEGF stimulation drives them to differentiate into EC ([33]). Besides providing physical support for endothelial vessels, smooth muscle cells and pericytes are a source of factors that are important for the maintenance and control of vascular integrity and function ([1], [32]). The extracellular matrix plays a key role in that respect by being a dynamic storage site for growth factors and proenzymes that are important in vessel function and angiogenesis ([1]).

Vascular Endothelial Growth Factor and Its Receptors

VEGF is the pivotal factor controlling angiogenesis. As such, it is the best-studied angiogenic factor. Several proteins belong to the VEGF family and include VEGF (also known as *VEGF-A*), VEGF-B, VEGF-C, VEGF-D, and placental growth factor ([14]). Although VEGF-A is the main angiogenic factor discussed here, VEGF-B seems to play an important role in coronary vascular development ([34]). VEGF-C is essential for lymphangiogenesis by interacting with the VEGFR-3 receptor ([35]). The function of VEGF-D has yet to be determined ([14]).

Being the major regulator of angiogenesis, VEGF is a mitogen and survival factor for EC ([11], [14]). As mentioned above, it is also a potent inducer of vascular permeability, an essential step in the angiogenic process ([1], [11], [14]). It has two well-characterized receptors, VEGFR-1 and VEGFR-2 (also known as *Flt-1* and *Flk-1/kinase domain receptor*, respectively) ([14]). They are both tyrosine kinases. VEGFR-2 is the main effector of a VEGF-induced chemotactic and mitogenic response in EC. VEGFR-2 also mediates the EC's permeability effects ([14]). The role of VEGFR-1 in EC response to VEGF has not been totally elucidated. However, it seems to negatively control the VEGF effects by acting as a decoy ([14], [36], [37]). Indeed, mice that have been engineered not to express VEGFR-1 have evidence of excess and disorganized angiogenesis ([36]).

Angiopoietins and Their Receptors

Angiopoietins and Tie receptors play an important role in angiogenesis. To date, four angiopoietins have been identified ([14]). However, only Ang1 and Ang2 have been fully characterized. They interact with the Tie tyrosine kinase receptors, mainly Tie2. Ang1 plays an important role in stabilizing the vasculature ([14]). Supportive cells express Ang1 and interact with EC through the Tie2 receptor. Genetically engineered mouse embryos that lack Ang1 develop a normal primary vasculature. However, they do not undergo further vascular remodeling ([16]). Transgenic mice that overexpress Ang1 have evidence of vascularization characterized by larger vessels rather than a greater number of vessels ([15]). Additionally, those vessels are resistant to leak, further supporting the role of Ang1 as a stabilizing factor.

The function of Ang2 has been more difficult to characterize ([14], [17]). It too binds with high affinity to the Tie2 receptor. Transgenic overexpression of Ang2 in mice is embryonically lethal and induces a phenotype that is similar to Ang1 or Tie2 knock-out experiments. Thus, it has been suggested that Ang2, by acting as an antagonist of Tie2, negates the stabilizing effects of Ang1 on the vasculature. As such, Ang2 may be a destabilizing factor that helps initiate angiogenesis and vascular remodeling ([14]).

Angiogenesis in Normal and Malignant Hematopoiesis

There has been mounting evidence suggesting the presence of a common precursor for EC and hematopoietic cells ([38]). This hemangioblast gives rise to both EC and hematopoietic cells in embryonic development. Embryonic stem cells express VEGFR-2 and can give rise, depending on culture conditions, to hematopoietic progenitor cells and angioblasts ([38]). Stimulation of hematopoietic stem cells with growth factors, including kit ligand, interleukin-3, granulocyte-macrophage colony-stimulating factor and granulocyte colony-stimulating factor, induces the release by those cells of VEGF, which then induces the release of hematopoietic growth factors by bone marrow EC ([38]). Thus, there is a dynamic interaction between hematopoietic and endothelial elements in the bone marrow. This interaction seems to modulate, at least in part, hematopoiesis.

Several recent studies have shown evidence of increased angiogenesis in hematopoietic malignancies ([39]). Such evidence has been demonstrated in multiple myeloma and lymphomas, as well as acute and chronic leukemias ([39], [40], [41], [42], [43], [44], [45], [46], [47] and [48]). Malignant hematopoietic cells have been shown to produce angiogenic factors, including VEGF ([39]). Expression of angiogenic factors has been suggested to have prognostic significance in hematopoietic malignancies, although results have been variable ([39]). Similar to the effect observed in normal hematopoiesis, VEGF stimulates the production of hematopoietic growth factors by EC ([39]). Consequently, malignant cells exploit their environment to their advantage by developing a synergistic relationship with EC (Fig. 22.1). This has led to the active investigation of antiangiogenic agents as a novel therapeutic strategy for hematologic malignancies.

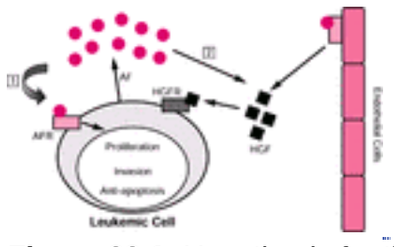

Figure 22.1. Hypothesis for the role of angiogenesis in leukemia. **1:** Angio-genic factors (AFs) produced by leukemic cells can stimulate cell growth and invasion or inhibit apoptosis (autocrine mechanism). **2:** AFs produced by leukemic cells can also stimulate endothelial cell proliferation and the production of endothelial cell hematopoietic growth factors (HGFs) (paracrine mechanism). AFR, angiogenic factor receptor; HGFR, hematopoietic growth factor receptor. (From Dickson DJ, Shami PJ. Angiogenesis in acute and chronic leukemias. Leuk Lymphoma 2001;42:847–853, with permission.)

In addition to the effects of vascular endothelium in modulating and responding to angiogenic stimuli, vascular endothelium also influences other functions ([49], [50]), including vasoconstriction, selective permeability, hemostasis, antigen presentation, and the inflammatory response. The EC surface is a dynamic interface between soluble and cellular constituents of the blood and the remainder of the body. Techniques to culture endothelium ([51]) have permitted investigation into the multifaceted roles of this tissue. However, there are biologic differences between *in vivo* and cultured EC; for example, cultured EC have at least a tenfold greater proliferation rate than *in vivo* EC ([50]). There may be other functional differences between native and cultured EC as well.

Vascular injury results in a complex host response. Atherogenesis is one of the best characterized vascular responses and is extensively reviewed elsewhere ([52], [53]).

A brief discussion of EC structure and EC regulation of hemostasis follows.

ENDOTHELIAL CELL STRUCTURE

Individual EC measure approximately 20 × 50 μm ^{2} in surface area. The total vascular surface area in a normal adult is estimated to be greater than 1000 m ^{2} ([54]). However, the geometry of the vascular system is not static. As indicated in Figure 22.2, the surface area facing a unit volume of blood differs, depending on the vascular bed being considered. For example, the surface area to volume ratio is approximately 1000 times greater in capillaries than in large blood vessels ([55]). This vascular geometry has implications for regulation of hemostasis and is discussed below.

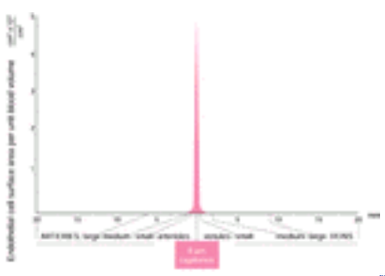

Figure 22.2. Relationship of vascular surface area to volume in the vascular system. Diameters are plotted from published data. (From Rushmer RF. Properties of the vascular system. In: Cardiovascular dynamics. Philadelphia: WB Saunders, 1976. Modified from reference [55], with permission.)

EC are anchored to the vessel wall by basement membrane secreted by EC and smooth muscle cells. Basement membrane contains a large number of connective tissue components, including collagen, microfibrils, glycosaminoglycans (GAG), fibronectin, and thrombospondin ([54]). These components may serve as ligands for a number of cell adhesion processes important in angiogenesis, hemostasis, vascular repair, and inflammation ([50], [56]).

EC typically exist as a cell monolayer, exhibiting contact inhibition and a cobblestone appearance (Fig. 22.3). Two types of cell–cell junctional structures have been reported—adherens junctions and tight junctions. These structures regulate permeability and maintain polarity ([57]). Two cell receptors thought to be important in EC monolayer organization are platelet–EC adhesion molecule-1 ([58]) and vascular cadherin ([59]). CD146 (MelCAM) is associated with the EC cytoskeleton and likely serves as an EC junction component ([60]). Members of the junctional adhesion molecule family appear to be components of tight junctions ([61]).

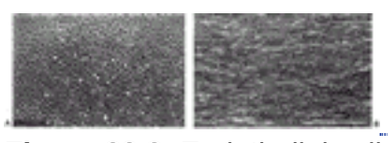

Figure 22.3. Endothelial cell morphology. **A:** Cultured human umbilical arterial endothelial cells with the typical cobblestone appearance (phase-contrast, ×100). **B:** Scanning electron photomicrograph of a primate aorta. The bar indicates a distance of 100 μm. (From Faggiotto A, Ross R, Harker L. Studies of hypercholesterolemia in the nonhuman primate. I. Changes that lead to fatty streak formation. Arteriosclerosis 1984;4:323–340, with permission of the American Heart Association.)

EC contain unique intracellular structures called *Weibel-Palade bodies* ([62]); these organelles contain the adhesion protein von Willebrand factor, which is secreted constitutively and also in response to cell stimulation ([63]). The Weibel-Palade body membrane contains P-selectin, which is expressed on the EC surface after EC activation. When expressed on the vascular surface, P-selectin mediates neutrophil and monocyte adhesion to the vessel wall ([64]). Selectin-independent platelet adhesion to endo-thelium has also been reported ([65]). Integrins mediating platelet–EC and leukocyte–EC interactions are discussed in Chapter 20 and Chapter 10, respectively. Additional EC proteins have been reported to undergo regulated release or cell-surface expression, including tissue plasminogen activator (TPA), interleukin-8, endothelin-1, and multimerin ([66]). These and other proteins may be contained in Weibel-Palade bodies or other distinct organelles. The regulated secretion of these EC proteins has been reviewed ([66]).

Endothelial Cell Phenotypes: Resting versus Activated

The concept of differing EC phenotypes [e.g., resting (constitutive) vs. activated] has been applied to numerous EC functions ([67]), including the inflammatory response, regulation of coagulation, angiogenesis, and so forth. This chapter focuses on EC phenotypes as related to the functions of angiogenesis, and hemostasis and thrombosis. Other EC functions have been reviewed elsewhere ([50], [52], [67]).

THE VESSEL WALL AND HEMOSTASIS: GENERAL CONCEPTS

The three major cell types of the normal vessel wall are EC (intima), smooth muscle cells (media), and connective tissue elements, such as fibroblasts (adventitia). The circulating coagulation proteins contained in the blood are in immediate contact with quiescent vascular endothelium that normally presents a thromboresistant surface in that EC are unable to initiate coagulation ([68], [69]) or promote platelet adhesion and activation ([70], [71], [72] and [73]). Thus, in the absence of vascular trauma or perturbation (activation), blood remains fluid as a result of antithrombotic activities expressed by EC. However, after traumatic vascular injury, exposure of blood to cells within the vessel wall, especially fibroblasts, or to extracellular matrix (subendothelium) results in rapid initiation of coagulation because fibroblasts ([68]) and subendothelium containing EC remnants ([74]) constitutively express tissue factor (TF) procoagulant activity. Alternatively, perturbation (activation) of EC by stimuli, such as cytokines ([75]), may induce altered EC hemostatic function (in the absence of vascular injury), resulting in net EC expression of thrombotic activity. These hemostatic properties of unperturbed and perturbed EC are critical in determining the coagulant balance of the vessel wall and the extent of activation of coagulation.

A cell-based model of hemostasis has been presented in which fibroblasts or perturbed EC express TF to initiate coagulation; amplification and propagation of coagulation then occur on the platelet surface. Modulation of coagulation occurs via EC antithrombotic activities and plasma protease inhibitors ([76]).

ANTITHROMBOTIC PROPERTIES OF UNPERTURBED ENDOTHELIUM

Antithrombotic mechanisms responsible for unperturbed (native) EC thromboresistance are illustrated in Figure 22.4. Major antithrombotic properties can be classified as antiplatelet activities, anticoagulant activities, and fibrinolytic activities.

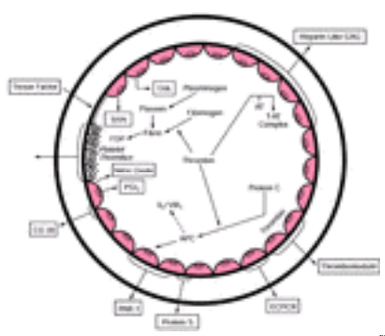

Figure 22.4. Vessel wall antithrombotic properties. The major antithrombotic properties are depicted in boxes. Heparin-like glycosaminoglycans (GAG), such as

heparan sulfate, catalyze inactivation of serine proteases, such as thrombin (T) and factor Xa, by antithrombin (AT). Formation of the T-thrombomodulin complex activates protein C to activated protein C (APC). The endothelial cell (EC) protein C receptor (ECPCR) promotes protein C activation. Binding of APC to EC-bound protein S (and factor V) promotes proteolysis of factors Va and VIIIa (*dotted line*), inhibiting coagulation. APC also possesses antiinflammatory properties that are mediated by EC protease-activated receptor (PAR)-1. This APC activity requires ECPCR (not shown). Secretion of vessel wall prostacyclin (PGI_2) and nitric oxide and expression of CD39 limit platelet thrombus formation at sites of vascular injury. Tissue plasminogen activator (TPA) is secreted and bound to EC to initiate fibrinolysis. Secretion of tissue factor pathway inhibitor (TFPI) by EC suppresses tissue factor–mediated initiation of coagulation. Dermatan sulfate–catalyzed activation of heparin cofactor II and an inhibitor to contact activation are not illustrated in the figure. FDP, fibrin degradation products. (Modified from Rodgers GM. Hemostatic properties of normal and perturbed vascular cells. FASEB J 1988;2:116–123.)

Antiplatelet Activities

Vascular endothelium inhibits platelet function by several mechanisms. The EC plasma membrane does not permit adherence of resting platelets ([77]). Additionally, EC synthesize and secrete three potent antiplatelet agents: prostacyclin (PGI_2), NO (also called *endothelium-derived relaxing factor*), and certain adenine nucleotides. PGI_2 is constitutively synthesized by EC cyclooxygenase (prostaglandin H synthase) and phospholipase A_2 in response to thrombin ([78]) and other vasoactive agonists ([79]). In addition to PGI_2's ability to prevent adhesion of activated platelets to EC, this agent also possesses potent vasodilating properties ([71]). PGI_2 inhibits platelet function by increasing levels of platelet cyclic adenosine monophosphate. Aspirin inhibits the synthesis of PGI_2 by irreversibly acetylating and inactivating EC cyclooxygenase ([80]). Recovery of PGI_2 production by EC occurs with subsequent EC synthesis of cyclooxygenase.

A second inducible form of cyclooxygenase, called *cyclooxygenase-2*, has been identified in a variety of cells, including EC ([81] , [82]). Both cyclooxygenase proteins are homologous, with similar molecular weights and structural features. Investigators believe that cyclooxygenase-2 mediates the vascular response to injury and inflammation.

NO is thought to be important primarily in regulating vascular tone ([83] , [84]), although this agent is also a potent inhibitor of platelet adhesion to vascular endothelium ([72]). Constitutive and inducible pathways generate NO from the terminal guanidino nitrogen of arginine in a reaction catalyzed by NO synthetase ([83] , [85]). The constitutive mechanism generates small amounts of NO and mediates physiologic responses. Increased synthesis of NO occurs in response to cytokines (inducible pathway), such as tumor necrosis factor, to mediate inflammatory events ([84]). Both the constitutive and inducible forms of NO synthetase are present in EC ([86]). Other stimuli to NO generation include adenosine diphosphate (ADP), thrombin, shear stress, and bradykinin ([50]). EC-derived NO also inhibits leukocyte adhesion, as well as vascular smooth muscle cell proliferation. Elevated levels of cyclic guanosine monophosphate result from NO stimulation and mediate the biologic activities of this antiplatelet agent. Synthesis of NO is insensitive to the effects of aspirin.

A third EC antiplatelet property is ectoenzymes that rapidly metabolize ADP and adenosine triphosphate to adenosine monophosphate and adenosine ([87]). ADP is a potent platelet agonist, and adenosine is a potent inhibitor of platelet function. Thus, EC can convert a platelet agonist to an antiplatelet agent by this mechanism. EC ectoenzymes are insensitive to the effects of aspirin. This ectoenzyme antiplatelet property of EC may explain earlier reports of EC thromboresistance to platelet adhesion. The EC ecto-ADPase responsible for inhibition of platelet function is CD39 ([88]). Deletion of this EC receptor in mice results in a prothrombotic state and platelet dysfunction ([89]).

Anticoagulant Activities

Vascular EC synthesize and express heparinlike GAG, such as heparan sulfate and dermatan sulfate, on their luminal surface ([90]). These GAG catalyze the inactivation of serine proteases, such as thrombin and factor Xa, by protease inhibitors, such as antithrombin and heparin cofactor II, respectively, via formation of a covalent protease–antiprotease complex. Of these two protease inhibitors, antithrombin is considered to be more important ([91]). The molecular basis for the effect of heparin in promoting antithrombin neutralization of serine proteases involves interaction of a specific pentasaccharide sequence of the EC heparinlike molecule with an allosteric site on the antithrombin molecule ([90] , [91]). This interaction results in conformational changes in antithrombin that permit more efficient binding to protease molecules. *In vivo*, antithrombin molecules are associated with EC GAG ([90]), providing a mechanism for instantaneous control over activation of coagulation. Surprisingly, mice deficient in the enzyme responsible for generating the pentasaccharide activity do not show a procoagulant phenotype ([92]). Nevertheless, this heparan sulfate–antithrombin mechanism is considered to be an important natural anticoagulant process because deficiency of antithrombin is associated with a thrombotic tendency ([93]). In contrast, the clinical relevance of the heparin cofactor II mechanism is uncertain ([94]).

Another key vascular anticoagulant activity is the protein C pathway that consists of two plasma proteins—protein C and protein S—and an EC receptor, thrombomodulin (Fig. 22.4). EC synthesize and express protein S ([95]) and thrombomodulin ([96]), whereas protein C is synthesized by the liver. Thrombin generation leads to thrombin's binding to thrombomodulin; the thrombin–thrombomodulin complex then activates protein C to generate activated protein C (APC) ([97]). APC binds to protein S, resulting in inhibition of coagulation by proteolysis of two coagulation cofactor proteins, factors Va and VIIIa. Inactivation of factors Va and VIIIa prevents further thrombin formation. The involvement of factor V in mediating the anticoagulant effect of APC has been described ([98]). It appears that APC down-regulation of coagulation (proteolysis of factors Va and VIIIa) occurs more efficiently on vascular endothelium, rather than on platelets ([99]).

An additional component of the protein C pathway exists—the EC protein C receptor (ECPCR). This protein binds protein C to enhance protein C activation by the thrombin–thrombomodulin complex ([100] , [101]). ECPCR is found primarily on large vessel endothelium ([102]) and is induced by thrombin stimulation. Blocking ECPCR with a monoclonal antibody in a primate model indicates that ECPCR plays a major role in *in vivo* protein C activation ([103]).

Certain components of the protein C pathway possess additional anticoagulant activities. For example, APC also possesses profibrinolytic activity that results from the ability of APC to neutralize plasminogen-activator inhibitor-3 (PAI-3) activity ([96]). Thrombomodulin may also inhibit factor Xa ([104]). Recurrent thrombosis has been associated with deficiency or abnormality of the protein C pathway components, indicating that this anticoagulant mechanism is relevant for *in vivo* hemostasis.

APC has recently been recognized to exert activities other than those associated with anticoagulant properties. In gene expression studies using microarray techniques, APC was found to modulate antiinflammatory and cell survival pathways. APC suppressed adhesion molecule expression, decreased activity of the nuclear factor-?B transcription pathway, and inhibited apoptosis ([105]). This regulated EC gene expression may explain the efficacy of APC in the treatment of sepsis ([106]). Recent information suggests that APC uses the ECPCR to signal EC via the protease-activated receptor (PAR)-1 pathway (discussed below) ([107]).

Regulation of TF procoagulant activity by a plasma protein called *TF pathway inhibitor* (TFPI) has been described ([108] , [109] and [110]). This protein is synthesized primarily by EC ([111]) and is an important regulator of TF–factor VIIa activation of factor X (discussed in Chapter 21). Additionally, TFPI can inhibit vascular cell proliferation ([112]). TFPI may be important in *in vivo* hemostasis because administration of this inhibitor in the setting of TF-induced disseminated intravascular coagulation reduces thrombosis ([113]); however, no link with human thrombotic disease has been definitively established ([110]). TFPI present in atherosclerotic plaque reduced TF activity ([114]). Heparin or low-molecular-weight heparin releases TFPI from EC storage sites ([115]).

Fibrinolytic Activities

EC synthesize and secrete plasminogen activators, primarily TPA, in response to stimulation by thrombin or vasoactive stimuli, such as histamine and vasopressin ([116]). TPA has been localized to the Weibel-Palade organelles in EC ([117]). Specific EC receptors for TPA exist ([118]). In response to inflammatory mediators, EC synthesize another plasminogen activator, urokinase ([119]), which activates plasminogen in the fluid phase or bound to fibrin ([120]). Activation of plasminogen by TPA generates plasmin; localization of TPA and plasminogen to the fibrin clot leads to physiologic fibrinolysis and release of soluble fibrin degradation products (Fig. 22.4). Fibrin degradation products possess potent antiplatelet and antithrombin activities and contribute to the anticoagulant effect of fibrinolysis. Activation of plasminogen is regulated by PAIs. The major inhibitor of TPA is PAI-1; PAI-1 is secreted by vascular EC ([121]) but is also present in platelet a-granules ([122]). This inhibitor also regulates urokinase activity ([123]). PAI-2 is a less significant inhibitor of TPA primarily found in placenta ([123]). Details of the fibrinolytic mechanism and

its regulation are discussed in Chapter 21.

PROTHROMBOTIC PROPERTIES OF UNPERTURBED ENDOTHELIUM

Unperturbed EC possess procoagulant activities that promote coagulation after vascular injury or perturbation ([75]). However, in the absence of initiating stimuli, these activities remain latent and do not contribute to thrombosis. Major prothrombotic activities of resting EC include binding sites (receptors) for coagulation zymogens or proteases [factor XII ([124]), factor XI ([125]), factors X and Xa ([126] , [127] , [128] and [129]), factors IX and IXa ([126] , [130] , [131]), and thrombin ([132])] and cofactor proteins [high-molecular-weight kininogen ([133] , [134]), factor VIIIa ([131]), and factor Va ([135])] and synthesis and expression of factor V ([136] , [137]) and von Willebrand factor ([138]). Resting EC can also activate bound factor XII and promote functional cleavage of prekallikrein ([124]). Investigators have also reported a factor XII–independent pathway for prekallikrein activation on EC; this activation is mediated by an EC-associated thiol protease ([134]). Additionally, when high-molecular-weight kininogen is bound to EC, factor XI (XIa) can associate with EC to promote factor IX activation ([139]). On the other hand, EC also secrete an inhibitor to contact activation ([140]). The role of EC in activation of intrinsic coagulation has been reviewed ([141]). These prothrombotic activities are illustrated in Figure 22.5.

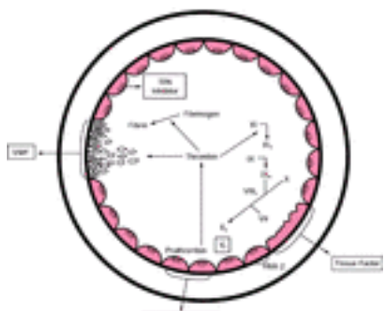

Figure 22.5. Vessel wall prothrombotic properties. The major prothrombotic properties are depicted in boxes. Expression of tissue factor activity initiates coagulation, and endothelial cell (EC) synthesis of factor V promotes thrombin formation. Thrombin formation is enhanced by feedback activation of factor XI. Vessel wall injury also promotes platelet adhesion and thrombus formation by exposure of subendothelial von Willebrand factor (VWF). An inducible EC prothrombin activator may directly generate thrombin. EC can be induced to express an activator of factor V (Va). Thrombin exerts multiple procoagulant activities, including platelet activation and cleavage of fibrinogen, resulting in the fibrin clot. Thrombin binding to thrombomodulin activates thrombin-activatable fibrinolysis inhibitor to down-regulate fibrinolysis (not shown). EC secretion of tissue plasminogen activator (TPA) inhibitor further stabilizes the fibrin clot by preventing fibrinolysis. Also not shown are EC binding sites for coagulation zymogens or proteases. Protease-activated receptor (PAR)-2 is activated by the tissue factor–factor VIIa complex and factor Xa to contribute to EC activation by pathologic stimuli. (Modified from Rodgers GM. Hemostatic properties of normal and perturbed vascular cells. FASEB J 1988;2:116–123.)

EC receptors for coagulation proteases permit assembly of complexes consisting of cofactor proteins, proteases, and zymogen substrates that result in optimal activation and localization of coagulation ([142]). Whereas factor V is secreted primarily into the fluid phase ([136]), von Willebrand factor is secreted both into plasma and the subendothelium, providing a source of adhesive protein for the platelet response to vascular injury ([143]).

HEMOSTATIC PROPERTIES OF PERTURBED ENDOTHELIUM

In this discussion, the term *EC perturbation* means exposure of EC to diverse stimuli, such as traumatic vascular injury, certain cytokines, atherogenic stimuli [homocysteine, modified low-density lipoprotein (LDL)], lipopolysaccharide (endotoxin), immune complexes, and certain infectious organisms. From this list, it is obvious that a variety of inflammatory, infectious, or malignant disorders, as well as metabolic defects, may be associated with hemostatic dysfunction due to altered EC hemostatic properties (Table 22.2). With the exception of traumatic vascular injury, alteration of these key EC coagulant properties is not associated with cytotoxicity or EC desquamation. The major hemostatic properties reviewed in this section include TF activity, thrombomodulin activity (protein C pathway), factor V activation, and fibrinolytic activities (TPA, PAI-1). In general, these activities are concordantly regulated, with stimuli that induce TF expression also suppressing protein C activation and fibrinolysis. The net result of these events is that the perturbed EC surface is converted from an antithrombotic surface to a prothrombotic surface.

TABLE 22.2. Effect of Perturbing Stimuli on Endothelial Cell Hemostatic Properties

Stimulus	Tissue Factor	Tissue Factor Pathway Inhibitor	Protein C Pathway	Fibrinolysis
Cytokines				
Interleukin-1	? (193)	—	? (194)	? (172)
Tumor necrosis factor	? (195)	? (145)	? (195)	? (196)
Atherogenic stimuli				
Homocysteine	? (197)	—	? (198)	? (199)
Oxidized low-density lipoprotein	? (187, 200)	—	? (187)	? (201)
Lipopolysaccharide (endotoxin)	? (202)	—	? (203)	? (204)
Infectious organisms	? (188, 189, 190 and 191)	—	? (189, 192)	—
Miscellaneous stimuli				
Thrombin	? (205)	—	? (96)	? (206)
Phorbol esters	? (207)	—	—	—
Immune complexes	? (208)	—	—	—
Shear	? (174)	—	—	—
Fibrin	? (209)	—	—	—
Nitric oxide	? (13)	—	—	—

?, increased activity; ?, decreased activity; —, not described.

NOTE: The effects of cytokines, atherogenic stimuli, lipopolysaccharide, infectious organisms, and miscellaneous stimuli on endothelial cell tissue factor activity, protein C pathway, and fibrinolysis are summarized. In general, decreased endothelial cell fibrinolysis induced by these stimuli is associated with decreased tissue plasminogen activator secretion and increased plasminogen-activator inhibitor-1 secretion. In general, the protein C pathway refers to thrombomodulin and protein C activation. References are listed in parentheses.

The key hemostatic activity induced by EC perturbants is TF expression, because TF is considered to be the major initiator of coagulation ([144]). Details of the regulation of cellular TF activity are given in Chapter 21. Table 22.2 summarizes the stimuli reported to induce EC TF activity. Expression of EC TF antigen in pathologic human and primate tissues using immunohistochemical methods has been reported ([145] , [146] , [147] and [148]), including vascular tissue from patients with sickle cell anemia ([149]) and skin biopsies from patients treated with intradermal cytokines ([145]). EC TFPI activity is reduced in skin biopsies after cytokine treatment ([145]).

EC TF procoagulant activity may be modulated by a novel EC protease, PAR-2. PARs represent a group of G–protein coupled receptors present in EC and other tissues ([150]). Thrombin or other proteases cleave the amino terminus of the receptor exodomain; the amino terminus fragment then binds to the cell-associated domain of receptor to activate the protease ([151]). In EC and fibroblasts, activated PAR-1 is internalized and sorted to lysosomes; this process terminates thrombin

signaling ([150]).

There are at least four members of the PAR family ([150]). Human PAR-1, PAR-3, and PAR-4 can be activated by thrombin, and it is proposed that their *in vivo* role is sensing thrombin generation ([150]). EC contain both PAR-1 and PAR-2 ([150] , [152]), but thrombin does not activate PAR-2. Rather, data indicate that PAR-2 may be activated directly by TF–factor VIIa and indirectly by TF–factor VIIa–generated factor Xa ([153]). It has been proposed that PAR-2 may function as a coagulation protease "sensor" and thereby contribute to EC activation by pathologic stimuli ([153]). Stimulation of EC PAR-2 also increases TF expression ([152]). EC PAR-2 may mediate additional thrombin-induced vascular functions, including leukocyte adhesion ([154]) and mitogenesis ([155] , [156] and [157]). Studies investigating embryonic development indicate that PAR-1 messenger RNA is abundant in EC, suggesting that PAR-1 signaling in EC is important in vascular development ([158]). PAR-1 also mediates the EC response to APC; APC and ECPCR cleave PAR-1 to initiate signaling events ([107]). Figure 22.6 illustrates the interactions between the TF–factor VIIa complex and EC PAR-2, with resulting alteration of EC function.

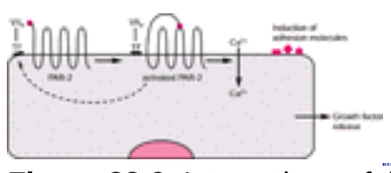

Figure 22.6. Interactions of the tissue factor (TF)–factor VIIa complex with the endothelial cell protease-activated receptor (PAR)-2 and their consequences. Expression of endothelial cell TF results in TF-dependent factor VIIa activation of PAR-2. Cleavage of the amino terminus of PAR-2 reveals a tethered ligand sequence that binds to PAR-2 to initiate signaling, triggering responses that include calcium influx, expression of surface adhesion molecules for leukocytes, and release of growth factors ([150] , [153]). Activation of PAR-2 may also enhance endothelial cell expression of TF activity ([152]) (*dotted line*).

An additional mechanism for EC generation of thrombin has been reported. Perturbed EC express a prothrombin activator that can generate thrombin independent of the intrinsic and extrinsic coagulation pathways ([159]). Nonvascular cells have also been reported as constitutively expressing a prothrombin activator ([160]). The description of trypsin expression by cultured EC and by vascular EC *in situ* suggests that a variety of EC-derived proteases may also regulate blood coagulation ([161]).

Because both EC ([137]) and platelets ([162]) can activate prothrombin, the question arises as to the importance of EC in thrombin generation. One study observed synergism of thrombin generation when a reconstituted model containing EC, platelets, and purified coagulation proteins was tested ([163]). Synergy was maximal at platelet concentrations less than 1×10^{8}/ml ([163]). Thus, in thrombocytopenic states, the large surface area of vascular endothelium, especially in the microcirculation ([55]), may play a role in amplifying platelet prothrombin activation ([163]).

Regulation of the anticoagulant protein C pathway by EC perturbants has also been a subject of interest because of the recurrent thrombotic disorders associated with deficiency of protein C pathway components (proteins C and S) ([96] , [97]). Down-regulation of the protein C pathway has focused on thrombomodulin, the EC membrane protein that activates protein C after complexing with thrombin. Several mechanisms have been identified to explain the role of thrombomodulin in down-regulating protein C activation. Thrombomodulin has structural homology to the native LDL receptor ([164]), a prototypical membrane receptor involved in endocytosis. The effects of tumor necrosis factor on the protein C pathway appear to result from enhanced endocytosis and subsequent degradation of thrombomodulin ([165]). Additionally, tumor necrosis factor, a cytokine that reduces protein C activation, has been reported to inhibit transcription of thrombomodulin RNA ([166]).

Homocysteine suppression of thrombomodulin activity represents a unique mechanism by which a thrombotic stimulus reduces protein C activation. Blood levels of homocysteine are increased in a metabolic disorder associated with thrombosis and vascular disease (homocysteinemia, homocystinuria). Homocysteine possesses a free sulfhydryl group, whereas thrombomodulin and protein C both contain disulfide-rich domains. Reduction of key disulfide bonds in thrombomodulin and protein C by homocysteine (or other sulfhydryl amino acids) results in impaired function of these molecules and inhibition of protein C activation ([167]). Inflammatory mediators also suppress activity of the ECPCR, contributing to diminished protein C activation ([168]). Both thrombomodulin and the ECPCR are down-regulated in atherosclerotic vascular tissue from patients with coronary artery disease ([169]).

Perturbed EC can activate cell-associated factor V to enhance vascular thrombin generation. For example, homocysteine treatment of cultured EC induced a factor V activator and increased factor Xa–catalyzed prothrombin activation. This cellular activator cleaved factor V in a manner distinct from the cleavage profile generated by thrombin ([170]). A similar factor V cleavage profile was induced by incubation of factor V with atherosclerotic vascular strips from an animal model of hypercholesterolemia ([171]).

Another important EC hemostatic property regulated by relevant perturbing stimuli is secretion of PAI-1 and TPA. Treatment of cultured EC with interleukin-1 results in both diminished TPA secretion and increased PAI-1 secretion ([172]). Increased amounts of PAI-1 relative to TPA diminish vascular fibrinolytic activity, resulting in enhanced thrombotic potential because of failure to lyse fibrin thrombi.

In addition to the humoral and biochemical stimuli discussed above, biomechanical forces (shear stress) can regulate EC gene expression. For example, either laminar or turbulent shear stress has been reported to differentially regulate a large number of EC genes, including adhesion molecules and growth factors, as well as hemostasis proteins ([173]). Shear stress also attenuates cytokine-induced EC TF expression ([174]). These data indicate that vascular endothelium is responsive to biomechanical stimuli. A uniquely flow-induced EC gene is the transcription factor, lung Kruppel-like factor, which may be an important regulator of EC function ([175]).

Diversity of Endothelial Cell Hemostatic Properties

There is significant heterogeneity in arterial, venous, and capillary EC with regard to expression of hemostatic and other functional activities ([176]). For example, aortic EC express more factor V activity than do venous EC ([127]), and PGI_2, a major metabolite secreted by human venous EC, is not substantially produced by human capillary cells ([177]). Different fibrinolytic and anticoagulant properties have been reported between cultured venous and capillary EC ([178]). Increases in blood flow lead to up-regulation of NO synthase messenger RNA in aortic, but not pulmonary, arterial EC ([179]). Vascular anticoagulant activity in the microcirculation is reinforced by geometric aspects of the vessel wall ([55]). For example, the thrombomodulin concentration in the microcirculation would increase more than 1000-fold ([55]) compared to a large vessel. Consequently, in large vessels, thrombin circulates freely to catalyze coagulation, whereas in the microcirculation, thrombin exists mostly bound to thrombomodulin, promoting anticoagulation ([97]).

The differential concentration of thrombomodulin in large versus small vessels may also affect vascular fibrinolysis in specific vascular beds. Thrombin-activatable fibrinolysis inhibitor is stimulated by low thrombomodulin concentrations but decreased at high concentrations of thrombomodulin ([180]). This implies that enhanced fibrinolysis would be seen in the microcirculation that contains high levels of thrombomodulin activity.

These data suggest a vascular model in which procoagulant activities are dominant in the arterial circulation and anticoagulant activities are dominant in the microcirculation. This distribution of vascular hemostatic properties is consistent with the necessity for rapid thrombin generation and fibrin clot formation after arterial injury, while providing the venous and microcirculation with anticoagulant mechanisms to protect against thrombosis ([75]). Unique EC environments may also explain localization of certain pathologic processes. For example, verotoxin-induced EC platelet thrombi localized to arterioles and capillaries may be explained by distinct responses of EC to verotoxin ([181]), and endogenously generated NO is more effective in inhibiting thrombosis in venules than in arterioles ([182]).

Clinical Relevance of Vascular Endothelial Cell Hemostatic Properties

At least two types of clinical disorders relate directly to EC hemostatic dysfunction. Most obvious is the group of patients with inherited thrombotic disorders in which genetic abnormality of an EC-derived or -regulated protein is causal in thromboembolic disease. Known disorders in this group include deficiencies of protein C and protein S, defective synthesis or release of TPA, enhanced PAI-1 secretion, and mutant factor V (factor V Leiden) synthesis (also termed *APC resistance*). Table 22.3

summarizes the inherited thrombotic disorders, which are discussed in greater detail in Chapter 61. The lower portion of the table lists EC hemostatic properties that, if abnormal, would be predicted to result in a thrombotic tendency; however, these latter disorders have not yet been identified clinically in association with inherited thrombosis. One of the disorders, TFPI deficiency, may, however, be important as a thrombosis modifier ([183]).

TABLE 22.3. Inherited Thrombotic Disorders and Their Relationship to Endothelial Cell Hemostatic Properties

Antithrombin deficiency
Protein C deficiency
Protein S deficiency [a]
Activated protein C resistance (factor V Leiden) [a]
Thrombomodulin deficiency [a]
Dysfibrinogenemia
Plasminogen deficiency
Tissue plasminogen activator deficiency [a]
Excess levels of plasminogen-activator inhibitor-1 [a]
Homocysteinemia [a]
Heparan sulfate deficiency
Endothelial cell protein C receptor deficiency
Tissue factor pathway inhibitor deficiency

NOTE: The top portion of the table lists the known inherited thrombotic disorders. The bottom portion of the table lists three endothelial cell hemostatic properties that would be predicted to be associated with a thrombotic tendency, but have not yet been clinically proven.

[a] Disorders associated with defective endothelial cell hemostatic mechanisms. This association is made because vascular endothelium has been identified as a site of synthesis of the particular coagulation protein or because the particular condition alters endothelial cell function (as in homocysteinemia).

A second group of disorders consists of inherited or acquired diseases that result in accumulation of components in the blood that perturb EC hemostatic properties. Examples of the inherited disorders in this group include homocysteinemia and familial hypercholesterolemia. Heterozygous or homozygous homocysteinemia leads to elevated levels of homocysteine, secondary vascular damage, and perturbation of EC hemostatic function and thrombosis ([184] , [185]). In familial hypercholesterolemia, elevated levels of LDL lead to modification (oxidation) of the lipoprotein by the vessel wall with generation of oxidized LDL ([186]). Oxidized LDL can markedly perturb EC hemostatic function and thereby contribute to thrombotic events associated with vascular disease ([187]). Other acquired diseases associated with perturbed EC hemostatic function include inflammatory disorders in which elevation of plasma cytokine levels may occur or in certain infectious disorders associated with gram-negative bacteria (endotoxin) ([75]). Infection of vascular endothelium by *Enterococcus* ([188]), the herpes simplex virus ([189]), *Rickettsia rickettsii* ([190]), or *Chlamydia pneumoniae* ([191]) organisms has been reported to alter vascular coagulant properties, especially induction of TF activity. Topical administration of tumor necrosis factor enhanced EC expression of TF and down-regulated TFPI and thrombomodulin ([145]). Patients with meningococcal sepsis had skin biopsies demonstrating down-regulation of EC thrombomodulin and the ECPCR ([192]).

Red Cell, Platelet, and White Cell Antigens

This chapter reviews the biochemistry and importance of various blood group antigens with a focus on red cells, platelets, and white blood cells. Because the circulating blood cells originate from a common progenitor cell, it is not surprising that there are a number of common blood group antigens. But what is surprising is the fact that the various cell lineages have so many unique and different antigens. Studies characterizing the red cell antigens were first performed approximately 100 years ago, whereas studies investigating the platelet and white cell antigens were performed much more recently. There are a number of explanations for this, including the earlier recognition of red cells and the early attempts to transfuse these cells. Additionally, red cells have proved to be not only more plentiful but also easier for investigators to work with. Indeed, the early techniques used to study red cell antigens, such as primary and secondary agglutination reactions using direct and indirect antiglobulin tests, proved so robust that they are still used today.

The nomenclature used for red cells is complex, yet historically interesting. Until recently, there was no attempt to be systematic. In the past, some blood groups were named after the individual (*Kell* is derived from Mrs. Kellner) or animal (*Rh* is derived from the rhesus monkey) lacking the antigen. Others were named after the discoverers (e.g., LW was named for Landsteiner and Weiner). Finally, some names are best described as quaint (e.g., the Lutheran blood group system was named according to a mislabeled blood sample). As is discussed, a more systematic approach for naming antigenic systems of red cells, platelets, and white cells is now used. However, the traditional names are still frequently used and, to add to the confusion, a number of laboratories continue to use other traditional nomenclatures (e.g., the Fisher-Race terminology continues to be used for the Rh system).

For biologists, a compelling question presents itself: What are the purposes of blood group antigens? For the majority of antigens, the answer is unknown, but there is increasing evidence that suggests certain antigens participate in host defense. Blood group antigens of red cell, platelet, and white cells can be made of proteins, carbohydrates attached to proteins, or lipids. Within each category, the antigen can be intrinsically produced during the formation of that cell, or it can be adsorbed from the plasma. Similarly, the antigens can be attached to the surface of the cell, can be partially embedded within the membrane (phosphatidyl-inositol glycan), or can be transmembrane. Recognizing this, investigators have grouped red cell antigens according to the functional activities of their associated carbohydrate, lipid, or protein ([1]). These include functions such as membrane stabilization, transport across the membrane, receptor function, enzymatic activity, and others. However, it is important to emphasize that although these blood group antigens are one component of this particular function, there is little evidence that they exist solely for this function. Consequently, although it is interesting to understand how a protein or carbohydrate associated with a blood group antigen contributes to a cell's integrity, it may not be the sole explanation for the presence of the antigen.

Any discussion of blood group antigens must touch on disease associations. In this review, we also comment on generally agreed on associations. Readers should be cautious about the reported associations between certain blood groups and diseases, as these associations could be collateral to other factors. However, there is general agreement that infectious agents, especially parasites and some bacteria, have led to blood group antigenic selection. Perhaps this is best exemplified by the geographic distribution of the Duffy blood group system, which is encoded by two alleles. The Fy(a–b–) phenotype is rare in most populations, with the exception being blacks originating from West Africa. Studies have demonstrated that the Duffy glycoprotein (gp) can serve as a receptor for *Plasmodium vivax*, an etiologic agent of malaria; hence, there is a strong selection advantage for those individuals not expressing this gp [i.e., Fy(a–b–)].

These dramatic observations and other studies provide indirect evidence that perhaps the major biologic advantage of antigens on cells is to enhance the ability of the species to distinguish self from nonself. Hence, one can anticipate in the ongoing “evolutionary warfare” between species and their invaders that when a microorganism uses a component of a blood group to invade that cell, spontaneous mutations producing another blood group would have a selective advantage. Additionally, nonhazardous mutations, which do not provide advantage or disadvantage, might not necessarily be deleted. It is likely that this helps to explain the enormous number of blood groups found on red cells, platelets, and white cells. Some of these blood groups are common (typically termed *public systems* within the platelet nomenclature), whereas others are rare (termed *private systems*).

This chapter summarizes red cell and platelet blood groups by first summarizing the approach to nomenclature and then reviewing the common blood groups.

RED BLOOD CELL ANTIGENS

In humans, 26 blood group systems with 228 antigens have been identified. Additional antigens have been identified but have not been assigned to established systems. Red blood cell antigens may be proteins, glycoproteins, or glycolipids. Most red cell antigens are synthesized by the red cells; however, some antigens, such as those of the Lewis and Chido/Rogers systems, are adsorbed onto the red cell membrane from the plasma. Some red cell antigens are specific to red cells; however, others are found on other cells throughout the body.

The importance of red cell antigens is multifold. Since the work of Landsteiner in the early 1900s, it has been recognized that knowledge and understanding of blood groups are essential for transfusion therapy. In routine practice, it is necessary to determine the compatibility of certain red blood cell antigens between the blood donor and the blood recipient. This is because individuals who lack antigens on their red blood cells can form alloantigens, or be alloimmunized, if they are exposed to blood expressing the antigen. This might occur with transfusion of blood products or during pregnancy. Antibodies that react with red blood cell antigens can cause problems such as delayed and immediate hemolytic transfusion reactions (HTRs) and hemolytic disease of the newborn (HDN). Furthermore, the study of red cell antigens and the associated membrane structures allows for a greater understanding of the physiology of red blood cells. For example, abnormalities of some blood group systems, such as Rh and Kell, may be associated with both functional and morphologic changes in the red cells. Finally, study of the inheritance of blood group antigens provides a greater understanding of the mechanisms of gene expression.

In this chapter, the red cell antigen groups are presented in order of clinical importance. The summary tables given in each antigen section list important clinical information and the most important antigens of each blood group system. As noted, many red cell antigens have an interesting but inconsistent approach to nomenclature. However, because these (as well as the platelet antigens) are commonly used, they are used along with the nomenclature proposed by the International Society of Blood Transfusion (ISBT).

International Society of Blood Transfusion Terminology

The ISBT Working Party on Terminology for Red Cell Surface Antigens was established in 1980 with the goal of creating a uniform nomenclature. Blood antigens were categorized into systems, collections, and series. The most recent monograph produced by the Working Party was produced in 2001 and included blood group

antigens categorized into 26 systems, five collections, and two series ([2]).

SYSTEMS A blood group system is genetically discrete from other blood group systems and consists of one or more antigens governed by either a single gene locus or a complex of two or more closely linked genes with virtually no recombination events occurring among them. There are currently 26 recognized systems (Table 23.1).

TABLE 23.1. Blood Group Systems

ISBT Number	System Name	System Symbol	Number of Antigens	Antigens	Gene Name	Chromosomal Location
001	ABO	ABO	4	A, B, AB, A1	*ABO*	9q34.1-q34.2
002	MNS	MNS	43	M, N, S, s, U, He, Mi^{a}, M^{c}, Vw, Mur, M^{g}, Vr, M^{e}, Mt^{a}, St^{a}, Ri^{a}, Cl^{a}, Ny^{a}, Hut, Hil, M^{v}, Far, s^{D}, Mit, Dantu, Hop, Nob, En^{a}, ENKT, N', Or, DANE, TSEN, MINY, MUT, SAT, ERIK, Os^{a}, ENEP, ENEH, HAG, ENAV, MARS	*GYPA, GYPB, GYPE*	4q28-q31

Accessed January 5, 2003.

COLLECTIONS The concept of collections was introduced into the ISBT terminology in 1988 to bring together related sets of antigens (genetically, biochemically, or serologically), which could not correctly be classified as systems because they have not been shown to be genetically distinct from all existing systems. Eleven collections were first identified. Three of these collections have subsequently been recognized as systems (Gerbich, Cromer, and Indian), and three of these collections have been incorporated into other systems (Auberger, Gregory, and Wright into Lutheran, Dombrock, and Diego, respectively); thus, five collections are currently recognized (Table 23.2).

TABLE 23.2. Collections of Antigens

ISBT Number	Name	Symbol	Antigen Number	Antigen Symbol	Antigen Incidence (%)
205	Cost	COST	205001	Cs^{a}	95
			205002	Cs^{b}	34
207	Ii	I	207001	I	>99
			207002	i	Low incidence
208	Er	ER	208001	Er^{a}	>99
			208002	Er^{b}	<1
209		GLOB	209001	P	>99
			209002	P^{k}	Low incidence
			209003	LKE	98
210			210001	Le^{c}	1
			210002	Le^{d}	6

NOTE: Obsolete collections include 201 Gerbich, 202 Cromer, 203 Indian, 204 Auberger, 206 Gregory, and 211 Wright.

SERIES An antigen may be assigned a number if it is a low-frequency antigen (the 700 series) or if it is a high-frequency antigen (the 901 series). A *low-frequency antigen* is an antigen that has an incidence of less than 1% in most populations tested, similar to the platelet designation of “private.” The 700 series currently consists of 21 antigens (Table 23.3). *High-frequency antigens* are antigens with an incidence of greater than 90% in most populations, similar to the platelet “public” system. Originally, high-frequency antigens were assigned to the 900 series. However, because so many of the original antigens assigned to the 900 series have been reassigned to collections, the 901 series was created. There are currently 11 antigens in the 901 series (Table 23.4).

901015		ABTI	>99	Yes
901016		MAM	>99	Yes

Each blood group antigen is given an identification number consisting of six digits. The first three numbers represent the system to which the antigen has been assigned. The second three digits identify the antigen. Each system also has an alphabetic symbol. For example, the ABO system is number 001, and the A antigen is the first antigen of that system; thus, it has the ISBT number 001001 or ABO001. By convention, the zeros may be omitted, and numbers are separated by a dot (i.e., the A antigen would be 1.1 or ABO1). This terminology is useful for databases and as a classification system; however, most clinical laboratories still use traditional terminology.

Red Cell Blood Group Systems

ABO (ISBT 001) AND HH (ISBT 018) BLOOD GROUP SYSTEMS

Summary of Important Characteristics of ABO Antibodies

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Anti-A	Yes	Immunoglobulin (Ig) M; some IgG	Yes	Yes	Common (53%)
Anti-B	Yes	IgM; some IgG	Yes	Yes	Common (87%)

The ABO blood group system was discovered by Landsteiner in 1900 when he noticed that the red cells of some individuals could be agglutinated by the serum of others. It remains the most important of all blood group systems for several reasons: (a) When the ABO antigen is not expressed on the red cell, individuals always have ABO antibodies in their plasma, with the stimulus for antibody production being a variety of environmental agents; and (b) the ABO antibodies formed are frequently mixtures of both IgM and IgG antibodies, both having thermal reactivity at 37°C and both capable of activating complement. These unique characteristics of the antigens and antibodies of the ABO blood group system provide optimal conditions for rapid red cell destruction if ABO-incompatible blood is transfused—a clinical scenario termed an *acute HTR*. There are three allelic genes in the ABO blood group system (*A*, *B*, and *O*) that are inherited in mendelian fashion (Table 23.1). Both *A* and *B* are codominant alleles, whereas *O* is a recessive allele. Hence, these three genes result in four different phenotypes: A, B, AB, and O. An individual with the A phenotype can be homozygous for the A gene (*AA*) or heterozygous (*AO*). Similarly, the B phenotype can be the result of homozygous (*BB*) or heterozygous (*BO*) gene inheritance. The genotype of the AB phenotype is *AB*, and the group O phenotype is always genetically *OO*. Thus, there are four ABO group phenotypes (A, B, AB, and O) that arise from six possible genotypes (*AA*, *AO*, *BB*, *BO*, *AB*, and *OO*). The frequencies of ABO phenotypes are variable among different ethnic populations. In whites, the O and A phenotypes are the most common, occurring in greater than 40% of the population. The B phenotype is found in approximately 10% of whites, and the AB phenotype is the least frequently encountered in only 3% of individuals. Around the world, the *B* gene is the rarest ABO blood allele, with the highest distribution frequency in central Asia. The *A* allele is found in 10 to 35% of individuals throughout the world. The populations with the highest frequency of the *A* gene are unrelated and distributed in the aborigines of northern Scandinavia and northern America. The *O* gene is the most common of the ABO alleles; hence, the O phenotype tends to be the predominate phenotype throughout the world, particularly in South and Central America. The population with the lowest frequency of individuals with the group O phenotype is found in central Asia where blood group B is more common. The alleles normally occupy the same position of a paired chromosome. Rarely, individuals may inherited both *A* and *B* alleles on the same chromosome (*cisAB* alleles) due to mutation or unequal crossing over of the chromosomes.

ABO Genes The *A*, *B*, and *O* genes all locate together: 9q34.1-q34.2. The genes consist of at least seven exons spanning over 18 kb in the DNA genome. *A* and *B* genes differ in seven nucleotides, resulting in different substrate specificity of the encoded enzyme. The difference in substrate specificity is mainly determined by the amino acids 266 and 268 in exon 7 ([3]). The *O* gene is due to either a frameshift mutation leading to a stop codon or, rarely, a mutation producing a nonfunctional enzyme. Numerous mutations are found for *A*, *B*, and *O* genes, but the most common mutation is A_2. The A_2 gene has two nucleotides different from the A_1 gene, which results in diminished enzymatic activity and, consequently, weakened antigen expression. For example, a red cell with A_1 phenotype carries more than

800,000 A antigens, but only 250,000 A antigens are present in a red cell with the phenotype A $_2$ ([4]). Similarly, weak subgroups of group B have been described due to mutations of the *B* gene.

ABO Antigens The antigens of the ABO system are located on carbohydrate oligosaccharide chains, which are parts of glycosphingolipids or gp molecules. There are four different types oligosaccharide chains: Type 2 and type 4 oligosaccharide chains are predominantly on the red cell membrane; type 1 chains are found in plasma, saliva, and body fluids; and type 3 chains are found in the mucins secreted by gastric mucosa or ovarian cysts. The genes of the ABO system do not encode directly for the antigens but encode for enzymes that add specific sugars to the red cell membrane. These sugars are the ABO red cell antigens that are detectable with serologic testing. The *A* gene encodes for the transferase a([1], [3]) *N*-acetyl-galactosaminyl-transferase, which adds an *N*-acetyl-galactosamine to the red cell membrane. The *B* gene encodes for the transferase [a([1], [3]) galactosyl-transferase], which adds a galactose to the red cell membrane. In an individual with the AB phenotype, the A and B transferases coexist and compete for the same substrate. The *O* allele encodes for a nonfunctional transferase; hence, a specific sugar is not attached to the red cell membrane as a result of inheriting this gene. Mutations of the *A* and *B* genes result in amino acid substitutions within the transferases, and this translates into weakened expression of the A and B antigens (frequently classified as subgroups). The most common subgroups associated with the *A* gene are A $_1$ and A $_2$. The A $_1$ subgroup occurs in approximately 80% of group A individuals, and the A $_2$ subgroup is present in approximately 20%. The other subgroups of A are less frequently encountered, with the A $_3$ subgroup occurring in 1 in 1000 individuals. The clinical relevance of A and B subgroups is of greater significance in blood donors than recipients. Because of the weakened antigen expression on the red cells of an individual who has inherited a subgroup gene, it is possible that serologic phenotyping of red cells results in misclassification of the red cell phenotype as group O. For a blood recipient, this would not be a problem, as group O blood is compatible with all other groups (universal donor); however, if a donor unit of blood from an individual with an A or B subgroup is misclassified as group O and transfused to an O individual, intravascular hemolysis could result. Both the A and B transferases add sugar moieties to a substrate on the red cell membrane, which is encoded by the *H* gene. The *H* gene locus is located at chromosome 19q13.3, and the genes inherited at this locus are inherited in a mendelian manner. Two genes have been identified at this locus: H is the gene most frequently inherited, and it encodes for an enzyme termed *H transferase type II* [a([1], [2]) fucosyl-transferases; FUT1], which adds an L-fucose to the terminal galactose molecule of oligosaccharide chains in an a([1] and [2]) linkage. This structure is called *H substance*, and it is to this structure that the A and B transferases add specific sugars resulting in A and B antigens. The rare allele sometimes inherited at the H locus is h. This h gene encodes for a nonfunctional transferase. If the *h* gene is inherited in the homozygous state (*hh*), L-fucose molecules (H substance) are not present on the red cell membrane. Without the presence of H substance on the red cell membrane, the A and B transferases, even when present, are not able to add the specific sugars that give A and B antigen specificity. This *hh* genotype is known as the *Bombay phenotype*: Serologically, the red cells group as an O; however, unlike the true O phenotype, which has large amounts of H antigen on the red cells, red cells from the Bombay phenotype lack H antigen (Fig. 23.1). Children of a parent with the Bombay phenotype (*hh*) may have normal A or B antigen expression, or both, if they inherit the dominant *H* gene from the other parent. The clinical relevance of the Bombay phenotype relates to the ability of these individuals to form not only anti-A and anti-B but also anti-H. The presence of all three of these antibodies makes it difficult to find compatible blood if transfusion is required. The only compatible blood for an individual with the Bombay (*hh*) phenotype is blood from another Bombay individual, and this phenotype is extremely rare.

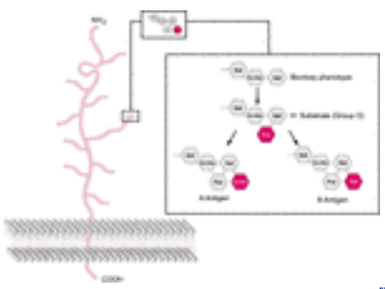

Figure 23.1. Biosynthesis of ABO blood group antigens. The antigens of the ABO system are located on the carbohydrate of type II oligosaccharides. H transferase is required to add fucose to the oligosaccharide chain and form H substance. Without the presence of H substance, A transferase and B transferase are not able to add terminal sugar moieties to the oligosaccharide chain. Fuc, L-fucose; Gal, D-galactose; Glc-NAc, D- *N*-acetyl-glucosamine.

The ABO(H) antigens are found not only on red cells but also on other blood cells, in most body fluids (except cerebrospinal fluid), and on the cell membranes of tissues such as intestine, urothelium, and vascular endothelium. The expression of ABO(H) antigens on the red cell membrane and tissue membranes is controlled by the *Hh* genes. The expression of ABO(H) antigens into body fluids is controlled by the *Sese* genes. The *Sese* genes, similar to the *Hh* gene, are located at chromosome 19q13.3; however, they are not part of the ABO system. The dominate *Se* gene codes for H transferase type 1 [a([1], [2]) fucosyl-transferase; FUT2]. Without the prior addition of a fucose to the oligosaccharide chains, A and B antigens would not be expressed in the body secretions, irrespective of the presence of A and B transferases (Fig. 23.1). Despite the wide distribution of ABO(H) antigens in various cell membranes and body fluids, the normal physiologic function of these glycoproteins and glycolipids is largely unclear. The carbohydrate moieties of the ABO(H) antigens might contribute to the formation of glycocalyx. However, based on the observation that individuals who lack all ABH antigens (Bombay phenotype) have normal red cell survival and function, the role of ABO antigens in maintaining a state of health is unknown ([5]). There is some evidence that ABO blood groups may be associated with certain diseases. Gastric cancer has been reported to be more prevalent in individuals with blood group A, but peptic ulcer is more often in those with group O ([6]). The normal range of von Willebrand factor (vWF) antigen level varies among individuals with different ABO blood groups. Individuals with blood group O have the lowest vWF antigen level, followed by group A, then group B, and, last, group AB ([7]).

Antibodies and Clinical Significance All immunocompetent individuals produce antibodies against the missing ABO(H) blood group antigens (Table 23.5). Anti-A and anti-B production does not require red cell stimulation through transfusion or pregnancy but occurs predominately through environmental exposure, such as bacteria ([8]). Anti-A and anti-B are usually detectable within 3 to 6 months after birth ([9]). By 5 years of age, the titers of anti-A and anti-B antibodies reach maximum and persist throughout adulthood. The titers of IgM anti-A and anti-B antibodies may gradually decline with advanced age ([10]). Newborn infants do not usually have a significant amount of anti-A or anti-B in their plasma; therefore, pretransfusion testing is not usually required for transfusions within the first 4 months of life. Infants born to alloimmunized mothers are an exception to this rule, as other specific blood group antibodies may have crossed the placenta and may be present in the infant's circulation.

TABLE 23.5. Summary of ABO Genes and Antigens

Phenotype	Antibody	Antigen	Gene Product	Gene
A	Anti-B	*N*-acetylgalactosamine	A transferase	9q34.1-q34.2
B	Anti-A	D-galactose	B transferase	9q34.1-q34.2
AB	None	*N*-acetylgalactosamine and D-galactose	A transferase and B transferase	9q34.1-q34.2
O	Anti-A and anti-B	L-fucose	Absent or nonfunctional A or B transferase	Absent or nonfunctional gene
A $_2$	Anti-B and variable amount of anti-A $_1$	*N*-acetylgalactosamine	A transferase	9q34.1-q34.2

The “naturally occurring” anti-A and anti-B antibodies are predominantly IgM, although variable amounts of IgG may be present. Like most IgM immunoglobulins, these antibodies can activate complement. ABO antibodies are especially effective at complement activation for two reasons: The antibodies have thermal activity reacting at body temperature, and the high density of antigen sites on the red cell membrane allows for large numbers of antibody to bind to the cell membrane. Therefore, the transfusion of ABO-incompatible blood typically presents as acute intravascular hemolysis. ABO antibodies are not a major cause of HDN for several reasons: Antibody inhibition can occur by soluble A or B substance, or both, in the plasma of some infants; A and B antigens are not specific for only red cells (hence, the red cell is not the only target); and antibodies specific for sugar molecules tend to have a weaker binding affinity than antibodies reacting with protein antigens such as the D antigen. In routine blood group typing, the transfusion recipient's red cells are typed using commercial sources of anti-A and anti-B antibodies (forward or cell typing). The presence of anti-A and anti-B in the serum/plasma of the recipient is detected by testing the serum/plasma against group A and group B red cells (reverse or serum typing). The interpretation of these two tests must agree for the patient's blood group to be assigned. Sometimes, the serum and cell grouping do not agree; this is termed *ABO discrepancy*. The laboratory proceeds with additional testing in these circumstances to correctly identify the patient's ABO group. Discrepancies in ABO grouping are found in various diseases. For example, the ABO(H) antigens may be weakened in some types of leukemia or cancer, mutations of *ABO* alleles, and diseases associated with chromosome 9 translocations. Alternatively, an individual may acquire an ABO antigen on his or her red cells (i.e., acquiring a B antigen after bacterial infections and acquiring an A antigen associated with Tn activation of the red cells) ([11]).

RH BLOOD GROUP SYSTEM (ISBT 004)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)

Anti-D	Yes	IgG; some IgM	Yes	Yes	Common (15%)

The Rh blood group system was discovered by Landsteiner and Weiner in 1940 ([12]). They injected rabbits with red cells from the Rhesus monkey, and the antibody produced was initially termed *Rh* and is now known as *anti-D*. Unlike the ABO blood group system, Rh antibodies are not environmentally stimulated; however, the D antigen is highly immunogenic, causing anti-D formation in up to 70% of D-negative individuals who are exposed to D-positive blood. Anti-D is IgG and is known to cause HTRs and HDN.

Rh Terminology Three different systems of nomenclature have been developed to describe the genes and antigens of the Rh blood group system antigens: the Wiener system, the Fisher-Race system, and the Rosenfield numeric terminology. Wiener proposed that the Rh antigens were the products of a single gene ([13]). The Fisher-Race nomenclature was based on the theory that reactions observed with various Rh antisera could be explained by three pairs of allelic genes: Cc, Dd, and Ee ([14]). Genetic analysis does not support either of these models. However, both the Wiener notation and the Fisher-Race nomenclature remain widely used today because of familiarity. In 1962, Rosenfield proposed a system of nomenclature that was based on serologic findings ([15]). The symbols were used to convey phenotypic information rather than genetic information ([16]). In this system, the antigens are numerically named in order of their discovery or assignment to the Rh blood group system. The various nomenclatures for common Rh system antigens are listed in Table 23.6.

TABLE 23.6. Rh Blood Group System: Antigens

Rosenfield Numeric Terminology	Fisher-Race Terminology	Wiener Terminology
Rh1	D	Rho
Rh2	C	rh'
Rh3	E	rh?
Rh4	c	hr'
Rh5	e	hr?
Rh6	ce (f)	hr
Rh7	Ce	rh_i
Rh8	C^w	rh^{w1}
Rh9	C^x	rh^x
Rh10	V (Ce^s)	hr^v
Rh11	E^w	rh^{w2}
Rh12	G	rh^G

Genes The Rh antigens are encoded by two genes: *RHD* and *RHCE*. The genes are located at chromosome 1p36.2-p34 (Table 23.1). *RHD* encodes the D antigen, whereas *RHCE* encodes for the Cc and Ee antigens. The d antigen does not exist; however, by convention, *d* is used to connote the absence of the D antigen. *RHD* and *RHCE* each contain ten exons and are distributed over 69 kilobase pairs (kbp) ([17]). Both the *RHD* and the *RHCE* genes encode for similar polypeptides of 417 amino acids with 12 membrane-spanning domains ([17]). In the red cell membrane, these two polypeptides form a complex with a gp termed the *Rh-associated glycoprotein* (RhAG), which is encoded by the *RHAG* gene (*RH50*) on chromosome 6. The functions of the Rh antigens are unknown, although, based on the phenotype of Rh_{null} cells (see section Rhnull Phenotype), there is a suggestion that the Rh antigens might play a structural role in the red cell membrane. The structure of the Rh antigens suggests that they are transport proteins and the RhAG protein may play a role in the transport of ammonium ([15]).

Antigens There are 45 antigens that have been assigned to the Rh blood group system: D, C, E, c, e, f, Ce, C^w, C^x, V, E^w, G, Hr_o, Hr, hr^s, VS, C^G, CE, D^w, c-like, cE, hr^H, Rh29, Go^a, hr^B, Rh32, Rh33, Hr^B, Rh35, Be^a, Evans, Rh39, Tar, Rh41, Rh42, Crawford, Nou, Riv, Sec, Dav, JAL, STEM, FPTT, MAR, and BARC (Table 23.1). Of the 45 antigens in the Rh blood group system, the most common and important are D, C, E, c, and e. Although individuals can become alloimmunized to the C, c, E, and e antigens after red cell exposure through transfusion or pregnancy, these antigens are much less immunogenic than D. Less than 3% of individuals exposed to the C, c, E, and e antigens become alloimmunized; hence, pretransfusion testing is not routinely performed to match for these antigens. The principal phenotypes of the Rh blood group system and their frequencies are outlined in Table 23.7.

TABLE 23.7. Rh Blood Group System: Principal Phenotypes

Haplotype Based on Antigens Present		Frequency (%)		
Fisher-Race	**Wiener**	**Whites**	**Blacks**	**Asians**
DCe	R^1	42	17	70
DcE	R^2	14	11	21
Dce	R^0	4	44	3
DCE	R^z	<0.01	<0.01	1
ce	r	37	26	3
Ce	r'	2	2	2
cE	r?	1	<0.01	<0.01
CE	r^y	<0.01	<0.01	<0.01

An individual is considered to be Rh positive if his or her red cells express the D antigen. The term *Rh negative* refers to the absence of the D antigen. The absence of the D antigen occurs in approximately 15 to 17% of individuals in white populations and is less frequent in other populations ([18]). In white populations, the absence of the D antigen is usually due to the deletion of the RHD gene ([18]). In Asian and black populations, the absence of the D antigen is usually due to an inactive RHD rather than a gene deletion ([19], [20]).

Cis Product Antigens $Ce(rh_1)$ is an antigen that almost always accompanies C and e when they are encoded by the same haplotype ([16]).

Cc and Ee Variant Antigens Various Rh antigens appear to be determined by alleles of the Cc and Ee antigens. Variants of C include C^w(Rh8), C^x(Rh9), and MAR. Variants of the E antigen include E^w(Rh11) and E^T(Rh24). Variants of the e antigen include hr^B (Rh31), hr^s (Rh19), or e^s(Rh20).

G Antigen (Rh12) The G antigen is found on any red cell that also has the C or D antigen.

Weak D Phenotype Some red cells that express the D antigen require prolonged incubation with the anti-D reagent for agglutination to occur. These red cells are considered to be D antigen–positive and are described as *weak D*, formerly termed D^u. The weak D phenotype is thought to occur by one of three mechanisms: (a) inheritance of an RHD gene encoding for a weakened expression of D; (b) interaction of the D gene with other genes; and (c) inheritance of an RHD gene missing some epitopes. In the first mechanism, the weak D phenotype is due to an RHD gene encoding for a D protein with reduced D antigen expression ([16]). This is more common in the black population and generally occurs in association with the *Dce* haplotype. In the white population, weak D is less common but may occur in association with the haplotype *DCe* or *DcE* ([16]). In the second mechanism, the weak D phenotype occurs as a result of the position of the D gene. This is most easily conceptualized using the Fisher-Race terminology. Red cells from individuals with a C gene in a *trans* position to the D gene (i.e., *Dce/Ce*) have weakened expression of the *D* gene due to the *C* gene on the opposite chromosome. Individuals with the weak D phenotype by either of these two mechanisms do not form alloantibodies after exposure to D-positive red cells. Finally, the third mechanism, sometimes termed *partial D*, occurs when individuals lack part of the D antigen complex. The D antigen is thought to be a mosaic consisting of several individual parts or epitopes. Most D-positive individuals inherit the gene encoding the entire D antigen. However, the partial D phenotype describes red cells that are deficient in components of D, resulting in a decreased expression of the D antigen (weak D). Individuals with partial D may produce anti-D if transfused with D-positive red cells. The weak D and partial D phenotypes have implications for the practice of transfusion medicine. Donors with weak D red cells should be considered Rh(D) positive. It is important that donor blood with weak D not be mislabeled as Rh(D)

negative because the weak D antigen would be capable of inducing an immune response if this blood were transfused to an Rh(D)-negative individual ([16]). It is generally recommended that patients who phenotype as weak D can be transfused with Rh(D)-positive blood, and weak D individuals who are pregnant do not require prophylaxis with Rh immune globulin.

Rh null Phenotype The Rh $_{null}$ phenotype occurs when red cells do not express Rh antigens. This phenotype occurs because of at least two mechanisms. First, the inheritance of an abnormal *RHAG* gene appears to result in the absence of the Rh antigen expression despite the presence of normal *RHD* and *RHCE* genes ([21]). This is termed *regulator type Rh* $_{null}$. The second mechanism is termed *amorph type of Rh* $_{null}$ and involves the inheritance of a mutation in the RHCE genes in association with a D-negative background ([21]). The Rh $_{null}$ phenotype is associated with abnormalities in the red cell membrane causing stomatocytosis and hemolysis. The presence of the Rh proteins in the red cell membrane appears to be necessary for the expression of other membrane proteins such as the LW, Duffy, and U antigens. Rh $_{null}$ cells have been demonstrated to lack the LW and Fy5 antigens and have weakened expression of the S, s, and U antigens ([22]). Fortunately, the Rh $_{null}$ phenotype is rare, as these individuals form an alloantibody (anti-Rh29) that reacts with all other red cells except Rh $_{null}$ when they are transfused. Thus, obtaining compatible blood can be challenging.

Antibodies and Clinical Significance Most Rh antibodies are IgG, although some may be IgM. They are usually not capable of activating complement. Anti-D is one of the most common Rh antibodies due to the high immunogenicity of the D antigen. Anti-D can cause severe HDN and HTR. The frequency of anti-D has greatly decreased with the use of prophylactic Rh immune globulin administration to Rh(D)-negative mothers during pregnancy and at delivery if the infant is Rh(D) positive. Antibodies against C, c, E, and e can be associated with mild HTR or HDN ([18]).

KELL BLOOD GROUP SYSTEM (ISBT 006)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Anti-K	Yes	IgG; rarely IgM	Yes	Yes	Very common (98%)
Anti-k	Yes	IgG; rarely IgM	Yes	Yes	Rare (<2%)

The Kell blood group system was discovered in 1946 and was named after Mrs. Kellner, the mother of the first child discovered to be affected with HDN due to Kell antibodies ([18]).

Genes and Antigens The Kell blood group system consists of 23 antigens: K, k, Kp ^{a}, Kp ^{b}, Ku, Js ^{a}, Js ^{b}, Ul ^{a}, K11, K12, K13, K14, K16, K17, K18, K19, Km, Kp ^{c}, K22, K23, K24, VLAN, and TOU. The antigens are coded by a complex of genetic loci, known as the *Kell locus*, which is located at 7q33 (Table 23.1). The *KEL* gene contains 19 exons distributed over 21.5 kbp ([17]). There are at least four subloci in the complex, each of which has an allele for a high-frequency antigen (k, Kp ^{b}, Js ^{b}, and KEL11) and for one or more alleles for a lower-frequency antigen (K, Kp ^{a} and Kp ^{c}, Js ^{a}, and KEL17) ([23]). The most common haplotype is k/Kp ^{b}/Js ^{b}/Kel11. The phenotype frequency of the Kell antigens is shown in Table 23.8. The k antigen is a high-frequency antigen that is present in more than 98% of whites and blacks. The K antigen is much less common.

Adapted from AABB Technical Manual, 14th ed. Bethesda, Maryland: American Association of Blood Banks, 2002; and Denomme GA, Rios M, Reid ME. Molecular protocols in transfusion medicine. San Diego: Academic Press, 2000.

The *KEL* gene encodes a type 2 integral membrane protein containing 732 amino acids ([17]). The protein has enzymatic activity, and it has been demonstrated *in vitro* to cleave big endothelin-3, which is a peptide with vasoconstrictor activity ([24]). The Kell protein is associated with the Kx protein in the red cell membrane [see section Kx Blood Group System (ISBT 019)] ([25]). Individuals have been identified who do not express the Kell protein (Kell $_{null}$ phenotype) and who are healthy with no structural or functional abnormalities of their red cells identified.

Antibodies and Clinical Significance The K antigen is very immunogenic. Only the D antigen has greater potential to induce alloimmunization. Because of this, anti-K is often encountered. Anti-K typically is induced by blood transfusion. The antibody tends to be IgG. Anti-K is clinically significant and has been implicated in both HTR and HDN. There is poor correlation with maternal anti-K titer and disease severity ([26]). Furthermore, HDN associated with anti-K tends to be less severe than HDN caused by anti-D. This is thought to occur because the Kell antigens are well expressed on fetal cells and appear on erythroid progenitor cells. It is postulated that anti-K, in addition to causing hemolysis, also causes a suppression of erythropoiesis ([27], [28]). The k antigen is also highly immunogenic. However, because only individuals not expressing the k antigen (i.e., KK phenotype) produce anti-k, and because the k antigen is present in most individuals, anti-k is much less common. Anti-k has been associated with both HDN and HTR. The other Kell blood group system antibodies are much less common but are also clinically significant.

DUFFY BLOOD GROUP SYSTEM (ISBT 008)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Fy [a]	Yes	IgG	Yes	Yes	Common (34%)
Fy [b]	Yes	IgG	Yes	Yes	Common (17%)

The Duffy blood group system was discovered in 1950 in the serum of a multiply transfused male, Mr. Duffy ([18]).

Gene and Antigens The Duffy system consists of six antigens, Fy [a], Fy [b], Fy3, Fy4, Fy5, and Fy6, which are encoded at the Duffy locus on chromosome 1 (1q22 and q23) (Table 23.1). The gene, *FY*, contains two exons distributed over 1.521 kbp ([17]). The antigens, Fy [a] and Fy [b], are encoded by a pair of codominant alleles. The phenotypes of the Duffy system and their frequencies are presented in Table 23.8. The most common phenotype in the white population is Fy(a+b+), and the most common phenotype in the black population is Fy(a–b–). The Fy [x] antigen represents a form of weak Fy [b]. The Fy5 antigen is defined by an interaction of the Duffy and Rh gene products ([16]). The antigens Fy [a], Fy [b], and Fy6 are sensitive to denaturation by enzymes such as papain, ficin, or a-chymotrypsin. Fy3 and Fy5 are not sensitive to enzyme denaturation. The Duffy gene encodes for a glycoprotein that is found on red cells as well as other tissues including brain, heart, lung, kidney, and spleen. On red cells, the gp has been identified as a receptor for various chemokines ([29]). The gp is also the receptor for *Plasmodium vivax*. Therefore, individuals who do not express Fy [a] or Fy [b] on their red cells are not susceptible to this form of malaria. In parts of Africa where malarial infection is common, most individuals are Fy(a–b–), likely due to natural selection ([16]).

Antibodies and Clinical Significance The Duffy antibodies are usually IgG. Anti-Fy [a] is a common alloantigen. Fy [a] is considered clinically significant, as it has been associated with HDN and HTR. Anti-Fy [b] is uncommon. It has been associated with mild HTR but not HDN ([16]). The other Duffy antibodies are much less common.

KIDD BLOOD GROUP SYSTEM (ISBT 009)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Jk [a]	Yes	IgG; rarely IgM	Yes	Yes	Common (23%)
Jk [b]	Yes	IgG; rarely IgM	Yes	Yes	Common (28%)

The Kidd blood group system consists of three antigens: Jk [a], Jk [b], and JK3 (Table 23.1). The system was named for the woman (Mrs. Kidd) whose serum was found to contain the antibody, and the antigen was named Jk for the initials of the woman's child (John Kidd) affected by HDN ([30]).

Gene and Antigens The Kidd blood group system gene is located at chromosome 18q11-q12. The gene, *SLC14A1*, also known as *JK* or *HUT11*, is distributed over 30 kbp and contains 11 exons ([17]). It encodes for the urea transporter hUT-B1 ([31]). The principal phenotypes of the Kidd blood group system and their frequencies are outlined in Table 23.8. The antigens Jk [a] and Jk [b] are found at relatively the same frequencies in the white populations but differ in other ethnic groups such as blacks and Asians ([17]). The Jk(a–b–) phenotype is rare and is found primarily in the Polynesian population ([32]). These null red cells have been demonstrated to be resistant to lysis by 2M urea; however, this phenotype is not associated with shortened red cell survival or clinical symptoms ([33]).

Antibodies and Clinical Significance The Kidd antibodies are usually IgG but occasionally are IgM. These antibodies tend to be short-lived; therefore, they are frequently not detected before transfusion. However, they are capable of a rapid amnestic response and have been associated with severe delayed HTRs. The antibodies have also been associated with HDN.

MNS BLOOD GROUP SYSTEM (ISBT 002)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Anti-M	Seldom	IgG; some IgM	Few	Few	Common (22%)
Anti-N	No	IgM; rarely IgG	No	No	Very rare (<1%)
Anti-S	Occasionally	IgG; some IgM	Yes	Yes	Common (45%)
Anti-s	Yes	IgG; rarely IgM	Yes	Yes	Very rare (<1%)

The MNS blood group system was discovered in 1927. The M and N antigens get their names from the letters in the word immune, because anti-M and anti-N antibodies were discovered in the sera of rabbits immunized with human red cells. The letter *I* was not used because it was felt this would be confused with the number *1* ([34], [35]). The S antigen was named after the city in which it was discovered—Sydney ([35]).

Genes and Antigens The MNS blood group system consists of 43 antigens: M, N, S, s, U, He, Mi [a], M [c], Vw, Mur, M [g], Vr, M [e], Mt [a], St [a], Ri [a], Cl [a], Ny [a], Hut, Hil, M [v], Far, s [D], Mit, Dantu, Hop, Nob, En [a], ENKT, N', Or, DANE, TSEN, MINY, MUT, SAT, ERIK, Os [a], ENEP, ENEH, HAG, ENAV, and MARS (Table 23.1). The M and N antigens are carried on glycophorin A, whereas the antithetical antigens, S and s, are carried on glycophorin B. They are encoded by the *GYPA* and *GYPB* genes located at chromosome 4q28-q31. *GYPA* has seven exons distributed over 60 kbp ([17]). *GYPB* has five exons and is distributed over 58 kbp ([17]). Glycophorin A has been demonstrated to be a receptor for certain malarial parasites as well as for bacteria and viruses. Other proposed functions of glycophorin A include regulation of transport of band 3 to the red cell membrane and complement regulation ([32], [36], [37]). The main phenotypes and frequencies of the MNS blood group system are listed

in Table 23.8.

Antibodies and Clinical Significance Anti-M and anti-N antibodies are typically IgM and are reactive at cold temperatures. Antibodies against M and N are naturally occurring (environmentally stimulated). They are not generally considered to be clinically significant. Rarely, anti-M has been implicated in cases of HDN and HTR ([38], [39], [40] and [41]). Anti-N has not been associated with HDN or HTR. In contrast, antibodies against S, s, and U are capable of causing HTR and HDN ([32]). Anti-S and anti-s tend to be IgG and occasionally are IgM.

P BLOOD GROUP SYSTEM AND RELATED ANTIGENS (ISBT 003)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
P1	Rare	IgM; rarely IgG	No	Rare	Common (21%)

The first P system antigen was discovered by Landsteiner and Levine in 1927 ([16]). Initially, the group was thought to include the P, P^k, and LKE antigens, but these antigens have subsequently been assigned to the globoside antigens [see section GLOB Collection (ISBT 209)] ([16]).

Genes and Antigens The P blood group system consists of a single antigen: P1 (Table 23.1). P1 is the product of a galactosyl-transferase encoded by the gene *P1*, which is located at chromosome 22q11.2-qter ([17]). The P1 antigen is similar to the ABO antigens because it is comprised of a chain of sugars linked to glycolipids on red cells (Fig. 23.2). P1 is formed when ß-D-galactose (Gal) is added in an a([1], [2], [3] and [4]) linkage to paragloboside ([16]). In the white population, 79% of individuals express the P1 antigen ([16]).

Figure 23.2. The relationship among ABO, P, and Ii blood group systems. These antigens are located on terminal oligosaccharides. Among these blood groups, the structure in common is lactosylceramide (red sugar moieties). Lewis blood group antigens also share similar structures, but they are not synthesized in red cells. Fuc, L-fucose; Gal, D-galactose; Gal-NAc, D- *N*-acetyl-galactosamine; Glc, D-glucosamine; Glc-NAc, D- *N*-acetyl-glucosamine.

Antibodies and Clinical Significance Anti-P1 is naturally occurring and is commonly found in individuals lacking the P1 antigen. Anti-P1 is usually IgM. It has not been reported to cause HDN and has been associated with HTR only in rare instances ([42]). Identification of anti-P1 is aided by the fact that the activity of the antibodies is inhibited by hydatid cyst fluid or pigeon egg white ([16]). Individuals who lack the P1 antigen who also do not express the P and P^k antigens may produce anti-P,P1,P^k, also known as *anti-Tj*^{a}. This antibody is IgM and has been associated with severe hemolytic reactions ([43], [44]).

LUTHERAN BLOOD GROUP SYSTEM (ISBT 005)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Lu^a	Seldom	IgM; some IgG	Mild	No	Very common (92%)
Lu^b	Seldom	IgG; some IgM	Mild	No	Very rare (0.1%)

The first Lutheran blood group antibody (anti-Lu^a) was found in 1946 in the serum of a previously transfused patient named Lutteran. The label on the sample was misread, and the blood group system was named Lutheran ([32]).

Genes and Antigens The Lutheran blood group system consists of 18 antigens: four pairs of antigens (Lu^a/Lu^b, Lu6/Lu9, Lu8/Lu14, and Au^a/Au^b) and ten independent antigens (Lu3, Lu4, Lu5, Lu7, Lu11, Lu12, Lu13, Lu16, Lu17, and Lu20) (Table 23.1) ([32]). The antigens are encoded by the *LU* gene located at chromosome 19q13.2-q13.3. The gene contains 15 exons and is distributed over approximately 12 kbp ([17]). The gene products include the Lutheran gp, which is 597 amino acids long, and a spliced version of the B-cell adhesion molecule, which is 557 amino acids in length ([17], [32]). The Lutheran gp is a member of the Ig superfamily and has been demonstrated to act as a receptor for laminin ([45], [46]). The principal phenotypes of the Lutheran blood group system and their frequencies are outlined in Table 23.8.

Antibodies and Clinical Significance The Lutheran antigens are not very immunogenic; therefore, antibodies in this system are rare ([32]). Anti-Lu^a and anti-Lu^b are usually IgG and are reactive on the indirect antiglobulin test. Anti-Lu^a has not been implicated in HTR but has been implicated in mild HDN ([32]). Anti-Lu^b has been associated with mild, subclinical HDN ([47]).

LEWIS BLOOD GROUP SYSTEM (ISBT 007)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (in White Population)
Le^a	Seldom	IgM	No	Rare	Rare (6%)
Le^b	Seldom	IgM	No	Rare	Common (22%)

The Lewis blood group system is different from other blood group systems, as the antigens (Le^a and Le^b) are formed in the plasma and absorbed onto the red cell membrane. This unique feature has implications for transfusion practices for several reasons: (a) Transfused red cells always absorb Lewis antigens from the plasma of the transfusion recipient; hence, within several days of the transfusion, the phenotype of the circulating transfused red cells is the same as the patient's red cell phenotype; and (b) soluble antigen in transfused plasma has the potential to inhibit Lewis system antibodies that may be in the plasma of some individuals.

Genes and Antigens The two alleles (*Le* and *le*) are inherited in mendelian fashion. *Le* is the dominant allele, and *le* is the recessive allele. The *Le* (*FUT3*) gene is located on chromosome 19 (19p13.3) ([48], [49]) and is closely linked to the *Hh* and *Sese* genes. There are 11 different mutations of *Le* gene ([50], [51]). The silent *le* allele is due to mutations that result in defective gene products. The *Le* gene encodes for an enzyme, a(1,3/1,4) fucosyl-transferase (FUT3, H transferase type 3), which adds fucose molecules to carbohydrate precursor chains (Fig. 23.3). The enzyme itself is a type II membrane-bound protein of 361 amino acids ([52]).

Figure 23.3. Differences between ABO **(A)** and Lewis **(B)** blood groups. ABO blood group antigens are synthesized in the red cells on type II oligosaccharides, but Lewis blood group antigens are produced in the plasma on type I oligosaccharides and then adsorbed onto the red cell surface. Type II oligosaccharide chains differ from type I chains in the linking position of the terminal galactose moiety. The Le gene encodes type III H transferase, which adds a fucose group (red-colored fucose group) to the second-last sugar moiety of the type I oligosaccharide chain. Synthesis of the Le^c and Le^d antigens does not depend on the activity of the Le gene. Fuc, L-fucose; Gal, D-galactose; Gal-NAc, D- *N*-acetyl-galactosamine; Glc, D-glucosamine; Glc-NAc, D- *N*-acetyl-glucosamine.

Antigens As mentioned previously, Lewis antigens (Le ^{a} and Le ^{b}) on the red cells are not intrinsic to the red cell membrane but are absorbed from the plasma onto the cells ([53]). The antigenic epitopes are located at the fucose moieties of glycosphingolipids. The biosynthesis of the antigens Le ^{a} and Le ^{b} involves two different pathways. The formation of antigen Le ^{a} is catalyzed by the enzyme FUT3 that adds a fucose group to the type 1 oligosaccharide precursor chain (Fig. 23.3). In individuals with FUT2 (*SeSe* or *Sese* genotypes), most type 1 oligosaccharide precursor chains are converted to an intermediate product similar to the H antigen. The intermediate product is subsequently catalyzed by the enzyme FUT3 and forms the Le ^{b} antigen. Therefore, the phenotypes Le(a–b+) and Le(a+b–) are not due entirely to the *Le* gene but depend on the presence or absence of the *Se* gene. This relationship between the *Se* and *Le* genes has practical implications for the laboratory. For example, the easiest way to determine an individual's secretor status is to type his or her red cells to determine their Lewis phenotype. The Le(a+b–) phenotype indicates that the individual is a nonsecretor; the Le(a–b+) phenotype indicates that the individual is a secretor; and the Le(a–b–) phenotype does not allow secretor status to be assigned. If the *Se* gene product (FUT2) is partially active, such as in individuals with *Se* ^{w} , some type 1 precursor chain is converted to Le ^{a} antigen, and the remaining is converted to Le ^{b}. The resultant phenotype, Le(a+b+), is rare in whites but common in Asians. The fucose residual may also be added to type 2 oligosaccharide precursor chain and form the Le ^{x} and Le ^{y} antigens that are similar to ABO(H) antigens in biochemical structure. In the Lewis blood group system, the phenotype distribution varies among different ethnic groups. The Le(a–b+) phenotype is found in 70% of the white population and approximately 50% of the black population. The Le(a–b–) phenotype is less common in the white population but is found in approximately 30% of the black population. The Le(a+b+) phenotype is rare in both the white and black populations (Table 23.8). In addition to red blood cells, Lewis antigens are found on other cell surfaces, such as gastric mucosa. They are also found in the lipopolysaccharide envelope of *Helicobacter pylori* ([54]). Although the gastric mucosa predominately expresses Le ^{a} and Le ^{b}, the cell envelop of *H. pylori* mainly expresses Le ^{x} and Le ^{y} ([54]). The relationship between the Lewis antigens and the pathogenesis of *H. pylori* infection is uncertain. The similarity of the antigens may deceive the host immune system and facilitate the colonization of *H. pylori* ([55]). In a murine model, *H. pylori* infection has been shown to induce antibodies cross-reactive to gastric mucosa and contribute to the development of chronic gastritis and peptic ulcers ([56]). However, this has not been firmly established in humans because no concordance in the expression of the Lewis antigen has been found between the bacteria and the host ([57] , [58]). Some studies showed that Le ^{b} and H antigens on the gastric mucosa mediated the binding of *H. pylori* ([59]) via a binding protein (blood group antigen-binding adhesin) ([60]). However, other studies demonstrated that *H. pylori* adherence is not dependent on the Lewis antigen ([61]). Similarly, it is disputed whether blood group O is a risk factor for peptic ulcer disease ([62] , [63] and [64]). The isoform antigens Le ^{x} and Le ^{y} may be found as neoantigens on malignant tissue ([65]).

Antibodies and Clinical Significance Like the ABO system, antibodies specific for Lewis antigens are naturally occurring, being formed through exposure to environmental antigens. The antibodies are usually IgM, complement activating, and reactive at or below room temperature. Although Lewis antibodies have been reported to cause HTRs, this does not usually occur for several reasons. First, although Lewis antibodies can activate complement, the process is relatively slow, thus allowing the inhibitors within the complement cascade to stop the process before the membrane attack complex is activated. Second, soluble antigen present in the plasma of the transfused blood product can cause inhibition of the antibody, preventing subsequent binding of antibody to transfused red cells. Finally, within 24 to 48 hours of transfusion, the transfused red cells absorb Lewis antigens from the patient's plasma, taking on the Lewis phenotype of the patient's own red cells. This latter mechanism also prevents delayed transfusion reactions from occurring. Lewis antibodies have the potential to be clinically relevant if the antibody causes *in vitro* hemolysis during serologic laboratory testing. When these " *in vitro* hemolytic antibodies" are detected, they should be considered clinically relevant, and antigen-negative blood should be selected for transfusion. Lewis antibodies do not cause HDN because they are IgM and do not cross the placenta. Furthermore, Lewis antigens are poorly developed on fetal red cells. Anti-Le ^{a} antibody is more common than anti-Le ^{b} antibody. Both anti-Le ^{a} and Le ^{b} antibody are found in individuals with the Le(a–b–) phenotype. In contrast, individuals with the Le(a–b+) phenotype do not develop anti-Le ^{a} because of the presence of residual Le ^{a} antigen in the secretions.

DIEGO BLOOD GROUP SYSTEM (ISBT 010)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Di ^{a}	Yes	IgG; some IgM	Yes	Rare	Very common (>99.9%)
Di ^{b}	Yes	IgG; some IgM	Yes	Rare	Very rare (<0.1%)

The Diego blood group system consists of 21 antigens: Di ^{a}, Di ^{b}, Wr ^{a}, Wr ^{b}, Wd ^{a}, Rb ^{a}, WARR, ELO, Wu, Bp ^{a}, Mo ^{a}, Hg ^{a}, Vg ^{a}, Sw ^{a}, BOW, NFLD, Jn ^{a}, KREP, Tr ^{a}, Fr ^{a}, and SW1 (Table 23.1). Fr ^{a} and SW1 represent recent additions to the system ([2]).

Gene and Antigens The Diego system antigens are carried on the band 3 protein. The antigens are encoded by the gene *DI*, which is found at chromosome 17q21-q22 (Table 23.1). *DI* contains 20 exons and is distributed over 228 kbp ([17]). Band 3 is a multipass transmembrane protein that serves as an anion transporter. The Di ^{a} antibody was initially found in the serum of a Venezuelan woman and was implicated in HDN ([66]). The principal phenotypes of the Diego blood group system and their frequencies are outlined in Table 23.8. The expression of the antigen Di ^{a} is almost exclusively restricted to populations of Mongolian descent, such as American Indians, Chinese, and Japanese ([67]).

Antibodies and Clinical Significance Anti-Di ^{a} and anti-Di ^{b} are usually IgG and are detected by the indirect antiglobulin test. HDN has been reported with both anti-Di ^{a} and anti-Di ^{b} ([68] , [69] , [70] and [71]). HTR is rare but has been reported ([72]).

YT BLOOD GROUP SYSTEM (CARTWRIGHT) (ISBT 011)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Yt ^{a}	Rare	IgG	No	Yes	Very rare (0.2%)
Yt ^{b}	Rare	IgG	No	Yes	Very common (91.9%)

The Yt system consists of two antigens: Yt ^{a} and Yt ^{b} (Table 23.1). The system was named after Cartwright, the individual discovered producing the antibody. Because all of the other letters in the individual's name were already being used, the last letter, *T*, was selected. The letter *Y* was placed first to denote "why not T?" ([32]).

Gene and Antigens The *ACHE* gene is located at chromosome 7q22.1. It encodes for an acetylcholinesterase, which is a dimerized glycosyl phosphatidylinositol (GPI)-linked gp in the red blood cell membrane. Its function is unknown; however, the molecule is enzymatically active. Yt ^{a} and Yt ^{b} antigens result from a single amino acid substitution, which does not appear to affect the enzymatic activity of acetylcholinesterase ([73]). The antigens are antithetical. Yt ^{a} occurs with a frequency of approximately 99%, and Yt ^{b} has a frequency of approximately 8% (Table 23.8) ([74]).

Antibodies and Clinical Significance Antibodies against the Yt antigens are usually IgG. They do not activate complement. Yt antibodies have been implicated in delayed HTR but not in HDN.

XG BLOOD GROUP SYSTEM (ISBT 012)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Xg	No	IgG	No	No	Common (males, 34.4%; females, 11.3%)

The Xg blood group system consists of two antigens: Xg ^{a} and CD99 (Table 23.1). The Xg antigen was discovered in 1962 by Mann in the serum of a multiply transfused male. Because the antigen frequency appeared to differ between males and females, the antigen was named Xg ^{a}, as it appeared to be controlled by the X chromosome. The *g* in the name stands for Grand Rapids, the hometown of the patient ([75]).

Gene and Antigens The gene encoding Xg ^{a} is found at Xp22.3. The gene is not subject to lyonization or X inactivation. The Xg ^{a} antigen is located on a

sialoglycoprotein. The antigen is only weakly expressed on the red cells of infants. The Xg ^{a} antigen is resistant to treatment by sialidase and dithiothreitol (DTT); however, it is sensitive to treatment with proteolytic enzymes ([76]). The principal phenotypes of the Xg blood group system and their frequencies are outlined in Table 23.8.

Antibodies and Clinical Significance Anti-Xg ^{a} antibodies are usually IgG and may be able to activate complement. There have been no documented cases of HTR or HDN with these antibodies.

SCIANNA BLOOD GROUP SYSTEM (ISBT 013)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Sc1	No	IgG	Rare	No	Very rare (<1%)
Sc2	No	IgG	Rare	No	Very common (>99%)

The Scianna blood group system consists of three antigens: Sc1, Sc2, and Sc3 (Table 23.1).

Gene and Antigens The gene for this system is located on chromosome 1p35-p32 and is linked to *Rh*. The Scianna gene encodes a gp, the function of which is not known. The Sc1 antigen is a high-frequency antigen, with the incidence in most populations being close to 99.9% (Table 23.8) ([17]). Sc2 is antithetical to Sc1 and is present in approximately 1% of the population ([17]). The antigens are resistant to treatment of red cells with proteolytic enzymes such as papain, ficin, trypsin, a-chymotrypsin, and sialidase ([32]).

Antibodies and Clinical Significance The Scianna antibodies are usually IgG. Scianna antibodies can activate complement and have been reported to cause mild HDN ([77]). The antibodies have not been associated with HTR.

DOMBROCK BLOOD GROUP SYSTEM (ISBT 014)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Do ^{a}	Rare	IgG	No	Yes	Common (33.3%)
Do ^{b}	Rare	IgG	No	Yes	Common (17.2%)

The Dombrock blood group system consists of five antigens: Do ^{a}, Do ^{b}, Gy ^{a}, Hy, and Jo ^{a} (Table 23.1).

Gene and Antigens The gene for the Dombrock blood group system, *DO*, is found at chromosome 12p13.2-p12.1 ([78]). The antigens in the Dombrock system have been demonstrated to be carried on a GPI-linked gp ([79] , [80] and [81]). Homology studies suggest that the Dombrock gp is a member of the adenosine 5'-diphosphate ribosyl-transferase ectoenzyme gene family ([82]). However, the function of this molecule is uncertain, as no enzymatic activity has been demonstrated on the red cells ([83]). The antigens Do ^{a} and Do ^{b} are antithetical. The frequencies of the three main phenotypes defined by these antigens are listed in Table 23.8. The antigens Gy ^{a}, Hy, and Jo ^{a} are high-incidence antigens, with gene frequencies of greater than 99% in all populations studied ([84]). The antigens are resistant to papain or ficin treatment but sensitive to trypsin, pronase, or DTT (200 mmol/L) treatment ([83]).

Antibodies and Clinical Significance The Dombrock antibodies are usually IgG and do not activate complement. They have not been associated with HDN, but the antibodies have been associated with severe HTR ([85]).

COLTON BLOOD GROUP SYSTEM (ISBT 015)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Co ^{a}	Yes	IgG	No	Yes	Very rare (0.3%)
Co ^{b}	Yes	IgG	No	Yes	Very common (90.3%)

The Colton blood group system was discovered in 1967. It consists of three antigens: Co ^{a}, Co ^{b}, and Co3 (Table 23.1).

Gene and Antigens The Colton blood group antigens are encoded by a gene located at 7q14. The gene, *CO*, contains four exons distributed over 2.2 kbp ([17]). The gene encodes a gp called the *channel-forming integral protein-1* or *aquaporin-1*. Channel-forming integral protein-1 functions as a water transport channel. The antigen is strongly expressed in the proximal tubules and cortical collecting ducts of the kidney and is responsible for 80% of water reabsorption in the kidney ([83]). In red cells, channel-forming integral protein-1 is responsible for osmotic water permeability ([1]). Individuals with the null phenotype, Co(a–b–), have red cells with markedly reduced osmotic water permeability but no obvious phenotype abnormality and are apparently healthy ([1]). The principal phenotypes of the Colton blood group system and their frequencies are outlined in Table 23.8.

Antibodies and Clinical Significance Antibodies against the Colton blood group antigens are usually IgG and may activate complement. These antibodies are clinically significant and have been implicated in acute and delayed transfusion reactions ([86]).

LANDSTEINER-WIENER BLOOD GROUP SYSTEM (ISBT 016)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
LW ^{a}	Yes	IgG; some IgM	Yes	Yes	Very rare (<1%)
LW ^{b}	Yes	IgG; some IgM	Yes	Yes	Very common (>99%)

The Landsteiner-Wiener blood group system consists of three antigens: LW ^{a}, LW ^{ab}, and LW ^{b} (Table 23.1).

Genes and Antigens The gene encoding the Landsteiner-Wiener blood group system antigens, LW, is found at chromosome 19p13.3. The *LW* gene contains three exons distributed over 2.6 kbp ([17]). It encodes the LW gp. The LW gp is an intercellular adhesion molecule and has been demonstrated to bind to CD11/CD18 integrins located on leukocytes ([87]). It is hypothesized that its function may involve being a marker for lymphocyte maturation and differentiation ([32]). The frequencies of the Landsteiner-Weiner blood group system phenotypes are outlined in Table 23.5. LW ^{a} is the most commonly expressed antigen, found in more than 99% of whites. The expression of LW antigens is influenced by the expression of the Rh blood group system D antigen. Individuals who are D antigen–positive have increased expression of LW antigens compared to those individuals who are D antigen–negative ([88]).

Antibodies and Clinical Significance Antibodies to the LW antigens are usually IgG but are occasionally IgM. The antibodies have been associated with mild HDN and HTR. Production of LW autoantibodies may occur in conditions associated with transient loss of LW antigens ([89]). Conditions associated with loss of LW antigens include Hodgkin disease, lymphoma, leukemia, sarcoidosis, and solid malignancies ([32]).

CHIDO/RODGERS BLOOD GROUP SYSTEM (ISBT 017)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Ch	No	IgG	No	No	Rare (2%)
Rg	No	IgG	No	No	Rare (2%)

The Chido and Rodgers system consists of nine antigens: Ch1–6, Rg1, Rg2, and WH (Table 23.1). The Chido antigen was initially described by Harris et al. ([90]). The antigen was described as nebulous because the antigen strength was variable. The Chido and Rodgers system is not comprised of true red cell antigens, as they are not actually located on intrinsic structures of the red cell. Instead, they are on the fourth component of the complement system (C4), which becomes bound to red cells. However, the antigens are detected on the surface of red cells by conventional methods and were therefore initially considered to be red cell antigens and were included in the ISBT terminology as the seventeenth system (ISBT 017).

Genes and Antigens The genetic loci of the Rodgers and Chido antigens are closely linked and are located on chromosome 6 in genes closely linked to major histocompatibility complex (MHC) II. Both genes encode complement components. The *CH* gene contains 41 exons and encodes for C4b ([17]). The *RG* gene contains 41 exons distributed over 21 kbp and encodes for C4a ([17]). The Chido antigen is located on the C4d fragment of C4b ([91] , [92] and [93]). The expression of the antigen is variable, as it is determined by the concentration of plasma complement, which is genetically determined ([94]). The Rodgers antigen is located on the C4a component of complement ([91] , [93]). The principal phenotypes of the Chido/Rodgers blood group system and their frequencies are outlined in Table 23.8. Ch1 to 6 and Rg1 and Rg2 have frequencies greater than 90%, whereas WH has a frequency of approximately 15%. The antigens are sensitive to treatment with proteases and resistant to treatment with sialidase, DTT, and acid ([76]). Inherited low levels of C4 have been demonstrated to be associated with various autoimmune disorders including autoimmune chronic active hepatitis ([95] , [96]). Individuals who are Ch– (lack C4b) have an increased risk of bacterial meningitis. Individuals who are Rg– (lack C4a) have an increased risk of systemic lupus erythematosus ([96] , [97]).

Antibodies and Clinical Significance Antibodies in the Chido/Rodgers system are usually IgG and do not activate complement. They are not clinically significant. Antibodies to these antigens are typically found in individuals who have been transfused. They generally do not cause HTR but may result in anaphylactic reactions if large volumes of plasma are transfused ([98] , [99]). These antibodies have not been implicated in HDN.

KX BLOOD GROUP SYSTEM (ISBT 019)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Kx	No	IgG	No	No	Very rare (<0.1%)

The Kx blood group system consists of one antigen: Kx (Table 23.1).

Genes and Antigens The Kx antigen is carried on the XK protein, which is encoded by the *XK* gene. The *XK* gene is located on the short arm of the X chromosome (Xp21.1). The structure of XK resembles a glutamate transporter; however, its actual cellular function has not yet been determined ([26]). In the red blood cell membrane, the XK protein is found in a complex with the Kell gp. The two proteins are covalently linked by a disulfide bond ([25]). It is thought that the expression of the XK protein is required for the normal expression of the Kell antigens on red cells. The XK protein has the structure of a membrane transporter protein; however, its function is not known ([100]). Patients with absent XK, due to gene deletions or mutations, are said to have McLeod syndrome. The McLeod phenotype is inherited in an X-linked pattern, unlike the *KEL* gene, which has an autosomal mode of inheritance ([26]). The *McLeod syndrome* is a condition occurring in males characterized by decreased expression of the Kell blood group system antigens, acanthocytes, hemolytic anemia, and elevated serum creatinine kinase ([1]). Associated symptoms include muscle wasting, decreased deep tendon reflexes, choreiform movements, and cardiomyopathy ([100]). The McLeod phenotype may also occur in patients with X-linked chronic granulomatous disease. X-linked chronic granulomatous disease has been demonstrated to occur because of deletion of or mutations in the *CYBB* gene, which is also located on the X chromosome at a location discrete from that of the *KEL* locus. The association between the two disorders is due to deletions of parts of the X chromosome that include both genes ([101]). Other X-linked conditions that have been associated with the McLeod phenotype include retinitis pigmentosa and Duchenne muscular dystrophy ([102] , [103] and [104]).

Antibodies and Clinical Significance Patients who lack the Kx antigen form alloantibodies if they are transfused with antigen-positive blood. Patients with the McLeod phenotype who have been transfused have been reported to form anti-Kx ([105] , [106]). It is suggested that these patients receive Kx-negative blood, but there are no reports of the antibody causing HDN or HTR. Furthermore, some patients without clinical or hematologic features of the McLeod syndrome have been demonstrated to form an IgG autoantibody with Kx specificity ([107]). The autoantibody does not appear to cause hemolysis.

GERBICH BLOOD GROUP SYSTEM (ISBT 020)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Ge2, Ge3, Ge4	Rare	IgG	Rare	Rare	Very rare (<0.1%)
Wb, Ls [a], An [a], Dh [a]	Rare	IgG	Rare	Rare	Very common (>99%)

The Gerbich blood group system was discovered in 1960 and is named for a patient who lacked the antigen, Mrs. Gerbich ([32]).

Gene and Antigens The Gerbich blood group system contains seven antigens: Ge2, Ge3, and Ge4, which occur at high frequencies, and Wb, Ls [a], An [a], and Dh [a], which occur at low frequencies (Table 23.1). The principal phenotypes of the Gerbich blood group system and their frequencies are outlined in Table 23.8. The antigens are encoded by the *GYPC* gene on chromosome 2 (2q14 and q21) ([81]). The gene contains four exons distributed over 13.5 kbp ([17]). The antigens are carried on glycophorin C or glycophorin D, or both. The functions of glycophorin C and glycophorin D are thought to involve the structural integrity of the red cell membrane, as the glycoproteins are involved in linking the red cell membrane and the membrane skeleton ([108]). This is supported by the fact that red cells deficient in the Gerbich antigens, called the *Leach phenotype*, are elliptocytes ([109]). Glyco-phorin C can serve as a binding site for *Plasmodium falciparum* ([110]).

Antibodies and Clinical Significance The antibodies against the Gerbich blood group system tend to be IgG. These antibodies have only rarely been reported to cause HDN or HTR ([32] , [111]).

CROMER BLOOD GROUP SYSTEM (ISBT 021)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Cr [a]	Seldom	IgG	No	Yes	Very rare (<1%)

The Cromer blood group system was discovered in 1965 and named after Mrs. Cromer, the first patient found to produce the antibodies ([32]).

Genes and Antigens The Cromer blood group system consists of ten antigens: Cr [a], Tc [a], Tc [b], Tc [c], Dr [a], Es [a], IFC, WES [a], WES [b], and UMC (Table 23.1). The antigens in the Cromer blood group system are encoded by the CROM gene located at chromosome 1q32. The gene contains 11 exons and is distributed over 40 kbp ([17]). The antigens are located on a gp called *decay-accelerating factor* (DAF). DAF accelerates the decay of C3 and C5 convertases, thus inhibiting the amplification of complement activation by both the classic and alternate pathways. DAF is also a receptor for *Escherichia coli* and enterovirus ([112]). Individuals with the null phenotype of the Cromer system, known as the *Inab phenotype*, have been described but do not have significant complement-induced lysis *in vivo* ([113]). Tc [a], Tc [b], and Tc [c] are antithetical antigens, as are WES [a] and WES [b]. Tc [b], Tc [c], and WES [a] are low-incidence antigens, whereas the rest are high-incidence antigens (Table 23.8).

Antibodies and Clinical Significance Antibodies to Cromer antigens do not cause HDN, perhaps because DAF is strongly expressed on the apical surface of trophoblasts and, therefore, absorbs antibodies from the maternal serum ([1]).

KNOPS BLOOD GROUP SYSTEM (ISBT 022)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)

Kn [a]	No	IgG	No	No	Very rare (<1%)
Kn [b]	No	IgG	No	No	Very common (>99.9%)

The Knops blood group system was established in 1991. It is named after Mrs. Knops, the first antibody producer ([32]).

Genes and Antigens The Knops system consists of seven antigens: Kn [a], Kn [b], McC [a], Sl [a], Yk [a], McC [b], and Vil (Table 23.1). Most of the antigens are common, occurring with a prevalence of greater than 90% in most populations (Table 23.8). The Sl [a] antigen occurs with a much greater prevalence in white populations (98%) than in black populations (60%) ([1]). Kn [b] occurs at a low incidence. The antigens in the Knops blood group system are encoded by the *KN* gene found at chromosome 1q32 ([17]). The antigens are found on a gp called *complement receptor 1* (CR1). The gene is located within the regulation of the complement activation cluster at 1q32. CR1 is a member of the complement control family. It inhibits both the classic and alternate pathways of complement activation by cleavage of C4b and C3b, thus protecting the red cells from hemolysis. It is hypothesized that low levels of CR1 on red cells may increase deposition of immune complexes on blood vessel walls, resulting in damage to the blood vessels ([114]). Some antigens in the Knops blood group system (CR1 and S1 [a]) may act as a binding site for *P. falciparum*.

Antibodies and Clinical Significance Antibodies in the Knops blood group system are usually IgG and do not bind complement ([32]). They have not been implicated in HDN or HTR.

INDIAN BLOOD GROUP SYSTEM (ISBT 023)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
In [a]	No	IgG	No	No	Very common (>99%)
In [b]	Seldom	IgG	No	Rare	Very rare (<1%)

The Indian blood group was so named because 4% of Indians from Bombay express the antigen ([32]).

Genes and Antigens The Indian blood group system consists of two antigens: In [a] and In [b] (Table 23.1). The antigens of the Indian blood group system are encoded by the *IN* gene located at chromosome 11p13. The gene contains at least 19 exons and is distributed over 50 kbp ([17]). The gene product is CD44. CD44 is thought to be the major human hyaluron receptor and also may bind fibrinogen, laminin, collagen, and osteopontin ([1]). The interaction between CD44 and hyaluron is likely required for the adhesion of lymphoid and erythroid cells to the bone marrow stroma during lymphopoiesis and erythropoiesis. A patient with a novel form of congenital dyserythropoietic anemia and CD44 deficiency was noted to have the In(a–b–) phenotype ([115]). The principal phenotypes of the Indian blood group system and their frequencies are outlined in Table 23.8.

Antibodies and Clinical Significance Antibodies in the Indian system are usually IgG and do not activate complement ([32]). These antibodies have not been associated with HDN, but anti-In [b] has been implicated in one immediate HTR ([116]).

OK BLOOD GROUP SYSTEM (ISBT 024)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
Ok [a]	No	IgG	No	No	Very rare (<0.1%)

The Ok blood group system consists of one antigen: Ok [a] (Table 23.1). Antibodies against the Ok [a] antigen were initially identified in 1979 in the serum of a Japanese woman, Mrs. Okbutso ([32]).

Genes and Antigens The Ok [a] antigen is encoded by the *OK* gene, which is located at 19p13.3-p13.2. The *OK* gene contains seven exons distributed over 1.8 kbp ([17]). The gene encodes for CD147, an extracellular matrix metalloproteinase inducer. The function of CD147 is unknown, but it is speculated that it may be involved in lymphocyte inactivation and the function of the blood–brain barrier ([117] , [118]). The Ok [a] antigen is resistant to treatment with proteases, sialidase, DTT, and acid ([76]).

Antibodies and Clinical Significance Antibodies in the initial patient with anti-Ok [a] were IgG and did not activate complement. Anti-Ok [a] has not been associated with HTR or HDN, but it has been demonstrated to cause decreased red cell survival.

RAPH BLOOD GROUP SYSTEM (ISBT 025)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
MER2	No	IgG	No	No	Rare (8%)

The RAPH blood group system consists of one antigen: MER2 (Table 23.1). The RAPH blood group system is named after the first patient known to have antibodies against the antigen. The MER2 antigen was given system status in 1999.

Genes and Antigens The gene, *MER2*, is found on chromosome 11p15. Although the function of MER2 is unknown, anti-MER2 was found in three individuals with renal failure, suggesting that MER2 is possibly required for normal renal function ([1] , [119]). Ninety-two percent of English blood donors are positive for MER2 (Table 23.8) ([32]).

Antibodies and Clinical Significance Antibodies against MER2 are IgG. They have not been documented to cause HDN or HTR.

JOHN MILTON HAGEN BLOOD GROUP SYSTEM (ISBT 026)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
JMH1	No	IgG	No	No	Very rare (<0.1%)

The John Milton Hagen blood group system consists of one antigen: JMH1 (Table 23.1). The antigen was previously listed as 901007 but was recognized as a system by the ISBT Working Party in July 2000 ([2]).

Genes and Antigens The JMH antigen is located on CDw108 gp. It is encoded by *SEMA7A*, which is located on chromosome 15q23-24.

Antibodies and Clinical Significance Antibodies against JMH are usually autoimmune and do not tend to be clinically significant. Individuals producing allo-anti-JMH have been reported ([120]). The antibodies tend to be IgG. They have not been documented to cause HDN or HTR.

Low-Incidence Antigens

An antigen is considered to be a low-incidence antigen if (a) it occurs in less than 1% of a population tested; (b) it is not part of an existing blood group system or related closely enough to another antigen to merit collection status; and (c) it is serologically distinct from other low-incidence antigens. Furthermore, to allow identification of further examples, red cells containing the antigen and antibody must be available. Table 23.3 lists the low-incidence antigens. These antigens comprise the 700 series of the ISBT terminology ([121]).

Typically, these antibodies arise as a result of no known stimulus. Occasionally, antibodies to these antigens may be discovered in mothers of neonates with HDN.

Because of the low frequency of these antigens, initial screening against a standard red cell panel is negative; however, the serum is positive when tested against paternal cells. Family studies often detect other individuals with the antigen.

High-Incidence Antigens

An antigen is considered to be a high-incidence antigen if it is found on more than 90% of individuals in populations tested. Antigens that are found in more than 99% of the population are termed *public antigens*. As noted previously, high-incidence antigens were initially included in the 900 series but are now contained in the 901 series. The 901 series currently contains 11 antigens (Table 23.4).

The significance of high-incidence antigens is that the rare individual lacking a high-incidence antigen may experience severe HTRs when transfused with antigen-positive blood. Because by definition the majority of the population expresses the antigen, it is very difficult to find compatible blood for such a patient.

Collections of Antigens

In the ISBT terminology, related sets of antigens (genetically, biochemically, or serologically) that cannot correctly be classified as systems, as they have not been shown to be genetically distinct from all existing systems, are designated as collections. Five collections are currently recognized: Cost, Ii, Er, GLOB, and Le ^{c}/Le ^{d} (Table 23.2).

II COLLECTION (ISBT 207)

Summary of Important Characteristics

Antibody Specificity	Clinically Significant	Antibody Class	HDN	HTR	Frequency of Antigen-Negative Blood (White Population)
I	Seldom	IgM	No	No	Very uncommon (adults)
i	Seldom	IgM	No	No	Very common (adults)

The I antigen was described in 1956 by Weiner et al. ([122]). The antigen was named I for *individuality*.
Genes and Antigens The Ii antigens are synthesized on red blood cells and are located on the same carbohydrate chains on which the ABH antigens are located (Fig. 23.2). The I antigens are located below the ABH antigens. The synthesis of the antigens requires the actions of ß-3- *N*-acetylglucosaminyl-transferase and ß-4-galactosyl-transferase ([101]). The i antigen consists of the disac-charides, galactose- *N*-acetyl-glucosamine, linked in a straight, nonbranched chain. The I antigen consists of the linear chains modified into branched chains ([123]). Adult red blood cells express predominantly the I antigen. Conversely, fetal cells predominantly express the i antigen with little or no I expression. However, during the first 18 months of life, the infant's red cells gradually express more I and less i. Very rarely, adult red blood cells express predominantly the i antigen. The gene involved is most likely *IGnt*, which is found on chromosome 6p24; however, other genes at different locations have been found to code for I branch-forming enzymes ([124]). *IGnt* encodes ß([1], [2], [3], [4], [5] and [6])- *N*-acetylglucosaminyl-transferase.
Antibodies and Clinical Significance The anti-I antibody is found as an IgM autoantibody in most normal individuals. The antibody is generally reactive at low temperatures and is not clinically significant. Anti-I cold agglutinins increase in titer after infection with *Mycoplasma pneumoniae* and tend to be polyclonal in nature ([125]). Monoclonal anti-I autoantibodies are found in high titers in cold hemolytic agglutinin disease. These antibodies are clinically significant and cause hemolysis. Anti-I alloantibodies are rare because the i phenotype is very uncommon. When they occur in adults with the i phenotype, they are clinically significant and can cause hemolysis. The anti-i autoantibody may be found in individuals commonly with lymphoproliferative disorders such as chronic lymphocytic leukemia, lymphoma, and Hodgkin disease. Patients with mononucleosis secondary to Epstein-Barr virus infection may have transient anti-i, which causes hemolysis.
GLOB COLLECTION (ISBT 209) The GLOB or globoside collection of antigens includes P, Pk, and LKE antigens (Table 23.2). The antigens of the GLOB collection were initially considered to be part of the P blood group system, and they are related to the P1 antigen. The P antigen, also known as *globoside*, has been demonstrated to be on almost all human red blood cells ([16]).
Antibodies and Clinical Significance Autoantibodies against the P antigen are uncommon and may be idiopathic or secondary to other disorders such as syphilis and infections with various agents (e.g., measles, mumps, Epstein-Barr virus, cytomegalovirus, varicella-zoster virus, adenovirus, influenza A, *M. pneumoniae*, *Haemophilus influenzae*, and *E. coli*) ([126]). Anti-P has been implicated in paroxysmal cold hemoglobinuria and is known as the *Donath-Landsteiner antibody*. This antibody is IgG and has biphasic activity in that it binds to red blood cells and fixes complement component C1 at low temperatures (0° to 4°C) and causes hemolysis at higher temperatures. Please see Chapter 34 and Chapter 35 for a more complete discussion of paroxysmal cold hemoglobinuria.

PLATELET ANTIGENS

Alloantibodies directed against platelet surface antigens can cause isolated thrombocytopenia. The antibodies most commonly play a role in neonatal alloimmune thrombocytopenia (NAT) and posttransfusion purpura (PTP), but they also mediate the destruction of platelets in passive alloimmune throm-bocytopenia (PAT), posttransfusion refractoriness (PTR), and transplantation-associated thrombocytopenia (TAT) ([127]). Although the mechanisms of platelet clearance are understood in some disorders (e.g., NAT), the platelet–antibody interaction and resulting thrombocytopenia are less well understood in others (e.g., PTP). Limiting factors have been the lack of appropriate investigational technology and the rarity of some of the disorders. Until recently, the identification of incompatible antigens has relied on serologic methods that require well-characterized antisera. After the identification of the genetic basis for the major platelet alloantigens, a number of different genotyping techniques were developed over the past decade. This advance has made it possible for more laboratories to perform platelet alloantigen investigations based on DNA methodology rather than relying on the requirements for sufficient platelets and appropriate typing antisera for serologic studies.

Immunization to platelet alloantigens can occur in normal individuals when exposed during pregnancy, transfusion, or transplantation to alloantigens they lack. Unlike red cell alloantibodies, it is uncommon for alloantibodies against platelets to form spontaneously.

Platelet Glycoprotein Polymorphisms

Alloantigens are expressed on platelet proteins, glycoproteins, and carbohydrates. Many of these proteins are found exclusively on platelets as complexes containing two or more different polypeptide chains and are termed *platelet-specific proteins*. Most of these platelet glycoproteins also function as cell receptors. These receptors play a major role in the interaction of platelets with the damaged vessel wall (adhesion) and with other platelets (aggregation).

On platelets, most alloantigens are caused by a structural change in a protein due to an altered amino acid that is encoded by a polymorphism in the gene. Many of these polymorphisms arise from single base pair mutations within the gene. To date, all the polymorphisms on platelets have been diallelic, with only a single mutation recorded at each respective locus (Fig. 23.4).

Figure 23.4. Schematic representation of amino acid substitutions that determine human platelet antigens (HPAs). The relative locations of the various amino acid substitutions encoded by single nucleotide polymorphisms are indicated on the respective platelet glycoprotein (GP). One antigen (HPA-14bw) results from an in-frame deletion of three nucleotides on the HPA-1b allele of the ßIIIa gene. Immunization to the alloantigens determined by the highly polymorphic gene for GPIIIa accounts for the majority of clinically significant alloimmune thrombocytopenias.

Because of the tremendous variability in the human genome among individuals, a typical person can be heterozygous for 24,000 to 40,000 substitutions, each encoding a different amino acid ([128], [129] and [130]). Thus, it is likely that there are many polymorphisms that encode variant forms of platelet proteins that have yet to be identified.

NOMENCLATURE Like red cells, the initial platelet alloantigens were described and characterized based on the binding of alloantibodies from immunized individuals to platelet proteins. Before the advent of gp-specific assays, the rate of identifying novel alloantigens was low, and the practice of identifying the antigen by the first few letters of the proband surname was sufficient. Alleles were noted with a superscript *a* or *b* and were assigned in the temporal order in which they were identified with serum from alloimmunized patients (e.g., Ko ^{a} Ko ^{b}; Bak ^{a} Bak ^{b}). However, a rapid increase in the detection rate of new antigens also coincided with confusing reports when the same alloantigen was discovered more than once by different investigators and given more than one designation. This prompted a reconsideration and standardization of the nomenclature in the form of the human platelet antigen (HPA) system ([131]). The system was based on organizing the antigens based on their recognition by specific alloantisera. HPA designations were assigned to antigens at a certain locus as they were reported chronologically in the literature. However, to establish consistency in the terminology, the high- and low-frequency alleles were assigned *a* and *b*, respectively. Thus, the PL ^{A1}/PL ^{A2} antigens became HPA-1a/-1b, and the Bak ^{a}/Bak ^{b} antigens became HPA-3a/-3b. For a few loci, alloantibodies to the low-frequency antigen had been reported first, which resulted in the reversal of a/b allele assignments (e.g., HPA-2a/-2b = Ko ^{b}/Ko ^{a}; HPA-5a/-5b = Br ^{b}/Br ^{a}). It was proposed that the Platelet Nomenclature Committee, a joint panel of the ISBT and the International Society of Thrombosis and Haemostasis, be charged with ensuring the orderly assignment of new HPA designations after confirmation of the alloantibody reactivity and specificity. A list of HPA assignments based on the 2002 platelet workshop describes 16 HPA systems and antigens (Table 23.9). Some alloantibodies have been reported that recognize only the low-frequency antigens at certain loci, mainly on gpIIIa. Thus, their HPA designations are not considered at present to be true antigen systems, because there is, as yet, no evidence that the antithetical high-frequency polymorphism induces structural changes that would be immunogenic in an individual homozygous for the low-frequency allele. Only HPA-1 to HPA-5 and HPA-15 alloantigens constitute complete systems in which alloantibodies to both alleles have been reported.

TABLE 23.9. Human Platelet Alloantigens

HPA System	Antigen	Original Designation	Amino Acid Substitution	Glycoprotein	Reference
1	HPA-1a	Zw ^{a}, PL ^{A1}	Leu33	ßIIIa	168
	HPA-1b	Zw ^{b}, PL ^{A2}	Pro33		
2	HPA-2a	Ko ^{b}	Thr145	Iba	385
	HPA-2b	Ko ^{a}, Sib ^{a}	Met145		
3	HPA-3a	Bak ^{a}, Lek ^{a}	Ile843	aIIb	182
	HPA-3b	Bak ^{b}	Ser843		
4	HPA-4a	Yuk ^{b}, Pen ^{a}	Arg143	ßIIIa	195
	HPA-4b	Yuk ^{a}, Pen ^{b}	Gln143

	HPA-16bw	Duv ^{a}	Ile140	ßIIIa	211
			Thr140		

HPA, human platelet antigen.

The HPA system is useful when considering the alloimmune thrombocytopenias, especially for the simple identification of the relevant pathologic alloantibody and the zygosity of the patient for that allele. However, it should be noted that the HPA system is misleading from a genetic point of view ([132]). Many polymorphisms evolved

at different loci on the PL ^{A1} variant of the gpIIIa gene. Thus, there are two HPA designations (i.e., HPA-1a and HPA-4a) for the single gpIIIa gene encoding Leu33 and Arg143. Furthermore, Newman et al. noted that if alloantibodies were found to all the high-frequency alleles on gpIIIa, then the designations PL ^{A1}, Pen ^{a}, Mo ^{b}, Ca ^{b}, and Sr ^{b} all would refer to the same molecular entity. However, although a description of the gene by its haplotype would be of benefit when considering the concept that combinations of polymorphisms could have different effects on protein function, at present, there is no nomenclature that can efficiently describe haplotypes.

PLATELET-SPECIFIC ALLOANTIGENS: BIOCHEMISTRY AND GENETICS

Glycoprotein IIb/IIIa (aIIbß3) Glycoproteins IIb and IIIa form a heterodimer complex that is a member of the integrin family of integral membrane proteins, a superfamily of noncovalently associated a and ß subunits involved in cell–cell and cell–vessel contact. Of these, gpIIb/IIIa, with 50,000 to 80,000 surface copies, is by far expressed most abundantly on platelets ([133]). Activated gpIIb/IIIa mediates platelet aggregation through binding to fibrinogen and vWF. A complex of the a and ß subunits is required for expression of the gpIIb and gpIIIa subunits on the surface. A deficiency of gpIIb/IIIa results in Glanzmann thrombasthenia, an inherited bleeding disorder ([134] , [135]). The gene for gpIIIa, located on chromosome 17, may be the most polymorphic of the human integrin subunits ([136] , [137] , [138] , [139] and [140]). Hence, a large number of platelet alloantigens, including PL ^{A}, Pen, Ca/Tu, Mo, Sr, La, Gro, Oe, and Duv determinants, are located on gpIIIa. Polymorphisms of the gene on chromosome 17 encoding the a subunit, gpIIb, are responsible for the Bak and Max alloantigens. gpIIb is synthesized exclusively by megakaryocytes; thus, gpIIb/IIIa is unique to platelets. However, the gpIIIa subunit also is expressed on endothelial cells in association with the subunit av to form the vitronectin receptor, also expressed in low numbers on the platelet surface.

Glycoprotein Ia/IIa (a2ß1) The collagen receptor, gpIa/IIa, is a member of the integrin family of cell-surface receptors. These membrane gp heterodimers consist of noncovalently associated a and ß subunits ([141] , [142] , [143] , [144] and [145]). Patients in whom deficiencies of gpIa/IIa are reported demonstrate chronic mucocutaneous bleeding associated with prolonged bleeding times ([146] , [147]). Three or more alleles of the a2 gene regulate the level of expression of gpIa/IIa on platelets ([148] , [149] and [150]). Quantitative binding of platelets to type I or III collagens correlates with the number of gpIa/IIa molecules expressed on the platelet surface ([149]). Alloantibodies to the Br and Sit determinants are expressed on gpIa.

Glycoprotein CD109 CD109 is a monomeric 175-kd gp that is anchored to the platelet membrane by GPI ([151]). The precise function for the GPI-anchored protein is not known. However, the recent determination of the cDNA sequence for CD109 indicates that it is a novel member of the a2M/C3, C4, C5 family of thioester-containing proteins and thus may mediate covalent cell–substrate and cell–cell interactions ([152]). Although CD109 expression has been reported to be activation-dependent on platelets, this has not been established. It is possible that the protein is constitutively expressed on the resting platelet and undergoes structural changes after activation that expose epitopes for certain monoclonal antibodies ([151] , [153] , [154]). The Gov ^{a} and Gov ^{b} alloantigens are expressed on CD109 ([151] , [153]).

Glycoprotein Ib/IX/V gpIb consists of two disulfide-linked proteins (gpIba and gpIbß) and is found on the platelet surface in association with gpIX and gpV ([155]). The four polypeptides share similar structural features, including a region in each of leucine-rich gp repeats, and are encoded by four separate genes. The short arm of chromosome 22 contains the gene for gpIba; the long arm contains the gene for gpIbß ([156] , [157]). The genes for gpIX and gpV are located on chromosome 3 ([158]). The gpIb-IX-V complex resides on the platelet surface as a heptamer, with one molecule of gpV flanked by two molecules each of gpIX, gpIba, and gpIbß ([155] , [159]). A region within the amino-terminal domain of gpIba functions as the major receptor for vWF, which mediates platelet contact and adhesion to damaged endothelium ([160] , [161] and [162]). A deficiency or lack of gpIb-IX-V is associated with the Bernard-Soulier syndrome, an inherited bleeding disorder ([163] , [164] and [165]). Platelets express approximately 25,000 copies of the gpIb-IX-V complex ([166]). Alloantibodies have been reported that recognize the Ko and Iy determinants on gpIba and gpIbß, respectively.

CLINICALLY SIGNIFICANT PLATELET ALLOANTIGENS

Pl ^{A} Polymorphism: HPA-1

Summary: HPA-1 Antigens

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-1a	Yes	Yes	Yes	Yes	Yes	Yes	Associated with severe thrombocytopenia
HPA-1b	Seldom	Yes	Yes	No	Yes	No	

The PL $^{A1/A2}$ (Zw $^{a/b}$) alloantigen system has been associated with all of the alloimmune thrombocytopenic syndromes and is the primary cause of NAT and PTP in whites ([167]). Alloimmunization to the PL ^{A} antigens is important both for the frequency (>75%) and for the severity of thrombocytopenia, which often is greater for syndromes involving the gpIIb/IIIa complex ([127]). A Leu (PL ^{A1}) to Pro (PL ^{A2}) change at residue 33 is encoded by a T to C substitution at position 196 of gpIIIa cDNA ([168]). The gene frequencies in the white population are 0.85 and 0.15 for PL ^{A1} and PL ^{A2}, respectively. A second substitution, Leu to Arg at residue 40, of less than 3% of PL ^{A2} alleles, has no known clinical significance ([169] , [170]). Alloimmunization to PL ^{A1} is associated with the immune response genes HLA-DRB3*0101 or -DQB1*02. Heterogeneity in the binding of anti-PL ^{A1} antibodies to platelets may be a consequence of a complex and disulfide-bonded structure in the amino-terminal portion of gpIIIa that imposes a three-dimensional structural constraint on the PL ^{A1} antigen ([171] , [172] , [173] and [174]). Further evidence for structural factors distant to the Leu33Pro substitution in the control over the expression of the PL ^{A1} epitope was recently reported in 1 of 6000 individuals tested for antigen status using phenotyping and genotyping. An Arg93Gln substitution on the Leu33 allele disrupted the formation of the PL ^{A1} antigen phenotype in an individual who had been typed positive for PL ^{A1} using genotyping ([175]). Alloantibodies to PL ^{A1} inhibit clot retraction and platelet aggregation, possibly by blocking fibrinogen binding ([176] , [177]).

Br Polymorphism: HPA-5

Summary: HPA-5 Antigens

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-5a	Yes	Yes	Yes	No	Yes	No	Usually causes moderate thrombocytopenia
HPA-5b	Yes	Yes	Yes	Yes	Yes	Yes	

The Br $^{a/b}$ (Zav $^{a/b}$, Hc ^{a}) alloantigens have been associated with all of the alloimmune thrombocytopenic syndromes and are the second most common cause of NAT in whites ([167]). A Glu (Br ^{b}) to Lys (Br ^{a}) change at residue 505 is encoded by a G to A substitution at position 1648 of gpIa cDNA ([178]). The gene frequencies in the white population are 0.89 and 0.11 for Br ^{b} and Br ^{a}, respectively. The Br ^{a} allele is in linkage disequilibrium with the -52T polymorphism associated with lower levels of surface gpIaIIa ([148] , [150]). However, platelets from Br $^{a/a}$ and Br $^{b/b}$ homozygous donors do not demonstrate differences in their static adhesion to collagen ([178]).

Gov Polymorphism: HPA-15

Summary: HPA-15 Antigens

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-15a	Yes	Yes	No	No	Yes	No	Usually causes moderate thrombocytopenia
HPA-15b	Yes	Yes	?	No	Yes	No	

The Gov $^{a/b}$ alloantigens have been associated with NAT, PTP, and PTR ([151] , [153] , [179]). Large studies on the frequency of the Gov $^{a/b}$ alloantibodies have recently been made possible by the adaptation of the monoclonal antibody immobilization of platelet antigens (MAIPA) technology to include monoclonal capture antibodies for CD109. These studies indicate that immunization to the Gov alloantigens is second only to the PL ^{A1} antigen, occurring as often as Br $^{a/b}$ antibodies ([180]). The Gov $^{a/b}$ antigens are the result of a Ser (Gov ^{b}) to Tyr (Gov ^{a}) change at residue 703 encoded by a C to A substitution at position 2108 of CD109 cDNA ([181]). Large European studies indicate that the gene frequencies for the Gov ^{a} and Gov ^{b} antigens are 0.41 and 0.59, respectively. The Gov $^{a/b}$ alloantigens are unique because they can be removed from the platelet surface by the action of phospholipase on the membrane anchor ([151]).

Bak Polymorphism: HPA-3

Summary: HPA-3 Antigens

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-3a	Yes	Yes	Yes	No	No	No	Can cause severe thrombocytopenia
HPA-3b	Seldom	?	Yes	No	Yes	No	

The Bak $^{a/b}$ (Lek ^{a}) alloantigens have been associated with NAT and PTP. Although less common, anti-Bak antibodies can occasionally cause thrombocytopenia as severe as the PL ^{A1}-mediated disease. An Ile (Bak ^{a}) to Ser (Bak ^{b}) change at residue 843 is encoded by a T to G substitution at position 2622 of gpIIb cDNA ([182]), creating the Bak epitopes on the heavy chain of the integrin subunit. The gene frequencies in the white population are 0.61 and 0.39 for Bak ^{a} and Bak ^{b}, respectively. Unlike other platelet-specific alloantigens, posttranslational glycosylation modifications may contribute to the expression of the Bak $^{a/b}$ epitopes ([182], [183] and [184]).

Ko Polymorphism: HPA-2

Summary: HPA-2 Antigens

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-2a	Yes	?	No	No	?	No	Usually causes moderate thrombocytopenia
HPA-2b	Yes	Yes	No	No	Yes	No	

The Ko $^{a/b}$ (Sib $^{a/b}$) antigens have been associated with NAT and PTR and are expressed on gpIba ([185], [186], [187], [188] and [189]). A Thr (Ko ^{b}) to Met (Ko ^{a}) change at residue 145 is encoded by a G to A substitution at position 524 of gpIba cDNA. The gene frequencies in the white population are 0.911 and 0.089 for Ko ^{b} and Ko ^{a}, respectively ([187]). Some evidence has been reported that shows anti-Ko alloantibodies prevent ristocetin-induced agglutination ([187]); however, this has not been confirmed in other studies ([190], [191]). The Ko antigens may be in linkage disequilibrium with a variable numbers of tandem repeat (VNTR) polymorphism that is responsible for four different molecular weights for the gpIba molecule. A tandem of 13 amino acids in the mucin-rich domain can be expressed with one to four repeats, thus encoding polypeptides of different lengths (VNTR-A, -B, -C, and -D alleles have 4, 3, 2, and 1 repeats, respectively) ([192]). The Ko ^{a} allele may have originated on the VNTR-B allele, from which the VNTR-A allele was derived. Because less than 1000 base pairs separate the Ko and VNTR loci, the rate of crossover during meiosis would be low, and, in most populations, the Ko ^{a} antigen is expressed on the VNTR-A and -B alleles ([186], [193]). However, there is evidence that crossover may have occurred ([194]).

Pen Polymorphism: HPA-4

Summary: HPA-4 Antigens

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-4a	Yes [a]	Yes	Yes	No	No	No	Usually causes moderate thrombocytopenia
HPA-4b	Yes [a]	Yes	No	No	No	No	

[a] Anti–HPA-4 alloantibodies are important in the Asian population due to the higher frequency of the HPA-4b allele.

The Pen $^{a/b}$ (Yuk $^{b/a}$) alloantigens have been associated with NAT and PTP. An Arg (Pen ^{a}) to Gln (Pen ^{b}) change at residue 143 is encoded by a G to A substitution at position 525 of gpIIIa cDNA ([195]). Because the gene frequencies in the white population are greater than 0.99 and less than 0.01 for Pen ^{a} and Pen ^{b}, respectively, this alloantigen system is of little consequence clinically in North America and Europe. However, Pen ^{b} is expressed in approximately 1% of Asians and contributes significantly to platelet alloimmunization. Anti-Pen ^{a} antibodies can inhibit platelet aggregation, consistent with the proximity of the epitope to the RGD binding domain ([176]).

LOW-FREQUENCY ANTIGENS Genetic variations of the gpIIb and gpIIIa genes that entered the human genome after the PL $^{A1/A2}$ and Bak $^{a/b}$ polymorphisms have been reported in association with alloimmunization causing NAT. The majority of the low-frequency antigens on gpIIIa have occurred as mutations on the Leu33 form of the ß3 gene. The low-frequency antigen reported on gpIIb is a result of a mutation on the Ser843 form of the aIIb gene. Until alloimmunization to the antithetical antigen is demonstrated in an individual homozygous for the low-frequency antigen, these polymorphisms are not considered true alloantigen systems within the HPA nomenclature. Alloimmunization to low-frequency antigens on gpIa and gpIbß also have been reported.

Ca/Tu Polymorphism: HPA-6w The Ca ^{a} (Tu ^{a}) platelet alloantigen is the result of an Arg to Gln (Ca ^{a}) change at residue 489 encoded by a G to A substitution at position 1564 of gpIIIa cDNA ([196], [197] and [198]). The gene frequency for the Ca ^{a} allele is approximately 0.003 in the white population and has been detected in a few unrelated families distributed across three ethnic groups ([199]).

Mo Polymorphism: HPA-7w The Mo ^{a} antigen results from a Pro to Ala (Mo ^{a}) replacement at residue 407 encoded by a C to G substitution at position 1317 of gpIIIa cDNA ([200]). This low-frequency antigen has been found in one other individual outside the proband family.

Sr Polymorphism: HPA-8w A C to T substitution at position 2004 of the Leu33 form of the ß3 cDNA encodes an Arg to Cys (Sr ^{a}) change at residue 636 ([201]). This private alloantigen system has been found only in one family in the white population. The polymorphism results in the creation of an unpaired cysteine that does not appear to compromise the integrity or function of gpIIb/IIIa in these individuals.

Max Polymorphism: HPA-9w The Max ^{a} platelet alloantigen results from of a Val to Met (Max ^{a}) change at residue 837 encoded by a G to A substitution at position 2603 of gpIIb cDNA ([202]). The mutation for the Max ^{a} antigen is found only in Bak ^{b} individuals.

La Polymorphism: HPA-10w The La ^{a} platelet alloantigen is the result of an Arg to Gln (La ^{a}) change at residue 62 encoded by a G to A substitution at position 281 of gpIIIa cDNA ([203]).

Gro Polymorphism: HPA-11w The Gro ^{a} alloantigen results from an Arg to His (Gro ^{a}) change at residue 633 encoded by a G to A substitution at position 1996 of gpIIIa cDNA ([204], [205]).

Iy Polymorphism: HPA-12w A low-frequency platelet allo-antigen called Iy ^{a} located on gpIbß has been associated with NAT ([206]). A Gly to Glu (Iy ^{a}) change at residue 15 is encoded by a G to A substitution at position 141 of gpIbß cDNA ([207]). This polymorphism is rare, found with a gene frequency less than 0.0016 in Asians and in only 1 of 249 German subjects ([208]).

Sit Polymorphism: HPA-13w The low-frequency platelet alloantigen called Sit ^{a} located on gpIa has been associated with NAT. A Met to Thr (Sit ^{a}) change at residue 799 is encoded by a T to C substitution at position 2531 of gpIa cDNA. This rare polymorphism has a gene frequency of 0.0025 ([209]).

Oe Polymorphism: HPA-14w The Oe ^{a} antigen is unique because it appears to be induced by tertiary structure changes that result from the deletion of the amino acid lysine at residue 611 of the gpIIIA cDNA ([210]). The “in-frame” deletion of the codon AAG1929-1931 occurred on the Pro33 form of the ß3 gene. Thus, all individuals who express Oe ^{a} are also PL ^{A2} positive. There is no apparent effect on receptor function due to the deletion of the amino acid.

Duv Polymorphism: HPA-16w The Duv ^{a} antigen is the result of a Thr to Ile (Duv ^{a}) change at residue 140 due to a C to T substitution at position 517 of gpIIIa cDNA ([211]). The antigen has been found only in one family to date. Antibodies to the Duv ^{a} antigen may inhibit platelet function due to the proximity of the polymorphism to the RGD binding site.

OTHER PLATELET ANTIGENS Some platelet alloantibodies have been localized to epitopes on platelet glycoproteins, but their genetic basis has not yet been reported. Va ^{a} is a low-frequency antigen on gpIIb/IIIa that is associated with NAT ([212]). The Nak ^{a} antibody originally was reported in a multitransfused Japanese patient ([213]). The antibody bound to gpIV on approximately 90% of donor platelets. However, further studies demonstrated that individuals who formed the anti-Nak ^{a} antibodies actually lacked gpIV on their platelets ([214], [215]). The antibody bound to epitopes on gpIV that were not encoded by polymorphisms; thus, anti-Nak ^{a} is more correctly called an *isoantibody*, similar to the anti-gpIIb/IIIa antibodies induced in transfused individuals who lack gpIIb/IIIa on their platelets (Glanzmann

thrombasthenia).
PLATELET NONSPECIFIC ALLOANTIGENS Alloantigens that are not restricted to the megakaryocyte lineage can also be expressed on platelets. These include the ABH blood determinants and MHC class I molecules.
ABH Blood Group Antigens It is now known that most of the membrane proteins on the surface of platelets can express determinants of the ABH blood groups. These include the gpIb/IX/V, gpIIb/IIIa, gpIV, gpV, CD31, and CD109 molecules ([216], [217] and [218]). Approximately 25% of platelets mismatched for the A or B blood groups are immediately cleared when transfused to an incompatible recipient. The remaining ABO-incompatible platelets have a normal survival, possibly explained by the platelet-to-platelet variability in the number of A and B antigens ([219], [220] and [221]).
HLAs The class I HLAs are expressed on the surface of platelets. These highly polymorphic antigens are the major cause of refractoriness to platelet transfusion. In contrast to the relatively constant numbers of molecules on lymphocytes, the level of expression of the HLA molecule on platelets can vary tremendously (up to 35-fold) among different individuals ([222], [223]). Because the HLA-C antigen levels are very low on platelets, only the HLA-A and -B antigens are a consideration when crossmatching for transfusion ([224]).

Alloimmune Thrombocytopenic Disorders

Platelet-specific alloantibodies play a major role in the immunopathology and thrombocytopenia observed in NAT and PTP. Alloantibodies also mediate platelet clearance in two less common syndromes: PAT and TAT. In addition, antiplatelet antibodies may play a role in refractoriness to platelet transfusions. However, more commonly in these patients, the thrombocytopenia is complicated by septicemia or by HLA antibodies.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA NAT is caused by maternal IgG alloantibodies that cross the placenta and cause the destruction of fetal platelets. Maternal alloimmunization to paternally derived alloantigens on the fetal platelets can occur early, often within the first trimester of the first pregnancy. Although analogous to HDN, alloimmunization to inherited paternal platelet antigens and the destruction of fetal platelets can occur during the first pregnancy with an antigen-incompatible fetus. Thus, NAT often presents as unexpected isolated severe thrombocytopenia in an otherwise healthy neonate. Thrombocytopenia can be severe, with the platelet count falling to less than 10×10^9/L within the first few days after birth, and may take several weeks to return to normal. Clinical findings include petechiae in 90%; gastrointestinal tract hemorrhage in 30%; and hemoptysis, hematuria, and retinal bleeding in less than 10% of patients. Intracranial hemorrhage is found in 10 to 20% of neonates and can occur early during pregnancy. Hydrocephalus, porencephalic cysts, and epilepsy can complicate recovery from fetal and neonatal intracranial bleeding. Anemia and hyperbilirubinemia can occur from extravasation and resorption of blood. Although more than 16 different platelet alloantigen systems have been established, most cases of NAT are caused by alloantibodies to HPA-1a (PL^{A1}, Zw^{a}) (78%), HPA-5b (Br^{a}, Zav^{a}), and HPA-15b (Gov^{a}). Recent evidence suggests that alloimmunization to Gov$^{a/b}$ antigens in NAT can occur more often than thought previously and can be as frequent as immunization to Br$^{a/b}$ antigens. Other alloantigens implicated in NAT include PL^{A2}, Ko^{a}, Bak^{a}, Bak^{b}, Pen^{a}, Pen^{b}, Br^{b}, and Gov^{b}. However, it is now clear that immunization to "private" alloantigens also can cause NAT. The majority of these have been found as rare polymorphisms on paternal ßIIIa. The mother carries the common form of the gene and becomes immunized to alloantigens expressed only in the fetus and on platelets from the father and his immediate family (e.g., Sr^{a}). In some cases, a polymorphism has also been detected in a few unrelated individuals in the general population and is termed a *low-frequency antigen* (e.g., Ca/Tu). These rare alloantigens have been, to date, reported only in NAT, which requires only one exposure to paternal alloantigens during pregnancy. This is in contrast to the other classic alloimmune syndrome, PTP, which is associated with two temporally distinct exposures to the immunizing antigen. The PTP patient is usually immunized initially via pregnancy and is later reexposed via transfusion. This requirement for two exposure events would exclude the rare platelet alloantigens from a role in PTP. However, it is possible that a selection bias could eventually increase the relative frequency of the rare antigens in the general population and allow for their participation in PTP and other transfusion and transplantation-mediated alloimmune disorders. In theory, directed donations of blood, organs, or bone marrow to family members could cause alloimmunization involving a rare alloantigen. In large studies, antibodies to the PL^{A1} alloantigen are found in the majority (78%) of serologically confirmed cases of NAT, with antibodies to Br$^{a/b}$ and Gov$^{a/b}$ antigens identified in approximately 20%. All other specificities account for the remaining small percentage of alloantibodies found. However, up to 60% of clinically identified cases of NAT lack serologic evidence of antiplatelet alloantibodies ([167]). In some cases, a portion of clinically identified NAT may be reported antibody-negative due to a lack of assay sensitivity or specificity. The first report of platelet alloantibodies in 1969 was followed by almost 20 years in which only three additional alloantibody specificities were detected using then-current methodology, including the platelet suspension immunofluorescence test and direct binding enzyme immunoassays. When the use of gp-specific assays for antiplatelet antibody studies became established in some laboratories, the rate of detection of new alloantibodies and antigens increased significantly ([127]). By measuring the binding of maternal IgG to specific platelet glycoproteins, the MAIPA and radioimmunoprecipitation assays are able to detect specific antiplatelet alloantibodies binding to proteins expressed in low numbers on the platelet surface (e.g., IaIIa) and discriminate this from background binding of IgG to non–platelet-specific epitopes (e.g., anti-HLA). Although the sensitive and specific MAIPA assay is used widely in reference laboratories to screen for alloantibodies, it too is limited by the requirement for specific monoclonal antibodies to various platelet glycoproteins to detect antiplatelet antibodies. Thus, some clinical NAT cases may not be corroborated with a positive laboratory test for alloantibodies because the maternal immunization is directed against epitopes on platelet proteins to which monoclonal antibodies are unavailable. This was demonstrated by the report of alloimmunization to epitopes on a novel platelet protein, CD109. Although no alloantibodies were detected using the routine MAIPA assay with capture monoclonal antibodies to glycoproteins Ia/IIa, Ib/IX, and IIb/IIIa, anti-Gov$^{a/b}$ reactivity was readily identified using radioimmunoprecipitation. Until monoclonal antibodies to CD109 are used routinely in the MAIPA, the radioimmunoprecipitation assay may be used to detect Gov$^{a/b}$ alloantibodies. The enhanced sensitivity imparted by radiolabeling the majority of platelet proteins, including those expressed in low numbers on the platelet surface, has established the radioimmunoprecipitation assay as a universal screening method for platelet alloantibodies in NAT. NAT is estimated to occur in 1 in 1000 to 2500 births. The alloantibodies most often involved are directed against PL^{A1}. Because the PL^{A1}-negative phenotype is approximately 2% in the North American population, the theoretical risk for NAT in newborns is approximately 1 in 50 births, which is much higher than observed cases. Although it is possible that limitations in recognition and technical issues in testing for alloantibodies might play a role in the underdiagnosis of some cases of NAT, the lower-than-expected responsiveness to the PL^{A1} antigen in susceptible women demonstrates that additional factors play a role in alloimmunization ([225]). Maternal immunization to PL^{A1} shows an HLA restriction, wherein PL^{A1}-negative women who produce alloantibodies are almost exclusively HLA-DRB3*0101 or -DQB1*02. The risk factor in the case of -DQB1*02 is 141, similar to that for the HLA-B27 restriction in the autoimmune disease ankylosing spondylitis ([226]). In one case of NAT, T cells were shown to play a role in the HLA restriction. Peptides that contain the same Leu33 polymorphism that is recognized by anti-PL^{A1} antibodies were able to stimulate T cells sharing CDR3 motifs ([227]). However, alloimmunization to the PL^{A2} antigen is not associated with a specific HLA type and has a much lower incidence in NAT ([228], [229]). This may explain the observation that although phenotype frequencies for PL^{A1} and PL^{A2} predict that anti-PL^{A2} should be observed six times more frequently than anti-PL^{A1}, alloimmunization to PL^{A1} accounts for far more cases of NAT than anti-PL^{A2} ([127]). In a large study of clinically suspected NAT, alloantibodies to PL^{A1} were found more frequently by a ratio greater than 100:1 when compared with anti-PL^{A2} ([167]). Immunization to the Br$^{a/b}$ alloantigens also has been associated with specific class II genes ([230], [231]). However, unlike the reversed relative risk versus the expected rates of immunization reported for the PL$^{A1/A2}$ system, the theoretical ratio of alloimmunization against Br^{a} versus Br^{b} is similar to the observed ratio ([127], [232]). The differences in the rate of immunization to platelet alloantigens also vary between different racial or ethnic populations. The distribution and frequency of platelet alloantigen genes in the worldwide population is a major factor in determining which alloantigens are most important in the investigation of NAT in different countries (Table 23.10). Although studies have shown that the PL^{A1} antigen accounts for the majority of NAT cases in the white population, it has rarely been shown to play a role in the Japanese. This may be explained by the lower gene frequency for PL^{A2} in the Japanese population compared with whites (0.02 vs. 0.15). Without accounting for differences in the frequency of immune response genes, alloimmunization to PL^{A1} should be at least 50 times less in the Japanese population. Antibodies to Pen^{a} and Pen^{b} are most frequently reported in Japanese cases of alloimmunization. This may be related directly to the higher gene frequency for Pen^{a} in the Japanese population compared with whites (0.0083 vs. <0.001), which would increase the number of individuals homozygous for the rare allele who may be susceptible to alloimmunization to Pen^{b}.

TABLE 23.10. Human Platelet Antigen (HPA) Frequency by Ethnic Group

Antigen	Gene Frequency			References
	White	Black	Asian	
HPA-1a	0.85–0.89	0.92	0.99–1.00	199, 385, 386, 387, 388 and 389
HPA-1b	0.11–0.15	0.08	0.00–0.01	
HPA-2a	0.91–0.93	0.82–0.88	0.87–0.92	194, 386, 387, 389, 390
HPA-2b	0.07–0.09	0.11–0.18	0.08–0.13	
HPA-4a	1.00	1.00	0.99–1.00	199, 387, 388, 389 and 390
HPA-4b	0.00	0.00	0.00–0.01	

HPA-5a	0.87–0.95	0.79	0.95–0.97 [386], [387], [388], [389] and [390]
HPA-5b	0.05–0.13	0.21	0.03–0.05

Immunization to platelet nonspecific alloantigens such as ABO and HLA is more likely to play a role in transfusion- and transplantation-associated thrombocytopenia rather than NAT. As these antibodies pass from the mother into the fetal circulation, they are likely to be targeted to the larger population of HLA and ABO-bearing cells rather than to platelets. In cases in which only ABO or HLA antibodies are observed in NAT, it is possible that platelet-specific alloantibodies are present but go undetected due to the technical limitations of current assays. Diagnostic tests for NAT should be designed to determine the maternal and paternal platelet alloantigen haplotypes to assess the presence of antigen incompatibilities. Genotyping should be used to determine the alloantigen status because few laboratories have adequate typing sera available to perform immunophenotyping for all the relevant alloantigens. Because this uses very little sample, genotyping also allows for the determination of fetal platelet antigens directly, rather than inferring them from the paternal platelet typing. To detect platelet-specific alloantibodies in maternal serum, a specific and sensitive assay should be used that can discriminate the presence of coexisting platelet nonspecific antibodies (e.g., anti-HLA). Due to the possibility of maternal alloimmunization to relatively low-frequency alloantigens, including Br ^{a}, it is preferable to test for antiplatelet antibodies using the father's platelets as a target. Although it is important to assess the risk for NAT in future pregnancies, this can be complicated by the presence of both alleles in a heterozygous father. In such cases, the fetal platelet alloantigens can be determined by genotyping fetal amniocytes obtained between 16 to 20 weeks' gestation.

POSTTRANSFUSION PURPURA PTP typically presents as severe thrombocytopenia resulting within 7 to 10 days after an immunogenic blood transfusion. It usually affects elderly women who have been sensitized to the platelet alloantigen during previous pregnancy ([127], [233]). Because prior transfusion also has been reported as the initial immunizing event, occasionally males can develop PTP. As in NAT, the most common alloantibody implicated in PTP is directed against PL ^{A1} and follows transfusion of antigen-positive blood to PL ^{A1}-negative/HLA-DR3–positive individuals. Thrombocytopenia can follow the transfusion of any blood product—not only platelets—and is most commonly seen after the infusion of packed red cells. Fever and chills are often observed during the transfusion; this is followed by petechiae and ecchymoses once thrombocytopenia develops. It is important to recognize this rare disorder because the severe thrombocytopenia can cause mucosal surface bleeding and subsequent anemia, with fatal intracranial hemorrhage observed in approximately 10% of patients. Therapy using high-dose intravenous ?-globulin has been shown to be effective and may be augmented with transfusion of antigen-negative platelets. Because PTP often presents in postoperative patients, the differential diagnosis of PTP includes other common thrombocytopenic syndromes such as heparin-induced thrombocytopenia and bacteremia. However, unlike PTP, these other disorders do not commonly present with severe thrombocytopenia (<10 × 10 ^{9}/L). In addition, heparin-induced thrombocytopenia is often associated with thrombotic complications rather than the overt bleeding that characterizes PTP. The major challenge of PTP is to understand the mechanism underlying the destruction of autologous platelets that follows the exposure and sensitization to immunizing blood product. A number of theories have been proposed to explain the clearance of the antigen-negative (PL $^{A2/A2}$) platelets in the presence of anti-PL ^{A1} antibodies. The mechanisms proposed include the adsorption of alloantigen-alloantibody immune complexes to receptors on recipient platelets with subsequent clearance mediated by complement or by the reticuloendothelial system (innocent bystander syndrome); the binding to autologous platelets of soluble or microparticle-associated alloantigen derived from the destruction of transfused blood product, thus making the recipient platelets a target for the alloantibodies; or, finally, the presence of pseudospecific alloantibodies that are produced in the early phase of the anamnestic response and can bind to determinants on autologous platelets, leading to their destruction ([127], [233]). As in NAT, platelet typing and antiplatelet antibody testing are necessary to identify the pathogenic alloantibodies. However, because of the severe thrombocytopenia in the acute stages of PTP, genotyping is required to assess the risk for alloimmunization. Although anti-PL ^{A1} is most often implicated, PTP also is reported in association with alloimmunization to other platelet-specific antigens, including PL ^{A2}, Bak ^{a}, Bak ^{b}, Pen ^{a}, Br ^{a}, Br ^{b}, Ko ^{a}, and Gov ^{a}. Some of these antigens are distributed with relatively low frequencies in the population, and screening for antiplatelet antibodies should therefore use sensitive and specific assays and an informative panel of target platelets.

PASSIVE ALLOIMMUNE THROMBOCYTOPENIA The abrupt onset of thrombocytopenia within a few hours after transfusion of a blood product is a hallmark of PAT. Platelet-specific alloantibodies in the blood product (usually plasma) rapidly clear the recipient's antigen-positive platelets. Although similar to PTP, this syndrome manifests within hours of transfusion and has a shorter duration of thrombocytopenia, which is mediated by the amount and specificity of the transfused alloantibody. Testing for PAT has shown that it is difficult to measure alloantibody in the recipient's plasma, suggesting that the transfused antibodies are limited and bind to the incompatible platelets soon after transfusion. However, the alloantibody can be detected in the donor plasma, and in one case, sensitization of recipient platelets by the transfused alloantibody *in vivo* was demonstrated using direct radioimmunoprecipitation to measure IgG bound to platelet gpIaIIa directly on the patient's platelets ([234]). Alloantibodies against the PL ^{A1} and Br ^{a} antigens have been implicated in passive alloimmune thrombocytopenia ([127], [233]). Severe thrombocytopenia is found in association with the transfusion of blood products containing alloantibodies to the PL ^{A1} antigen. The finding that even red blood cell concentrates can cause PAT due to anti-PL ^{A1} antibodies correlates with reports that as little as 10 ml of plasma containing alloantibodies can cause thrombocytopenia in transfused volunteers ([235]). Because thrombocytopenia can occur in multiple transfusion recipients, it is important to investigate cases of suspect PAT to ensure that the alloimmunized blood donor does not donate blood in the future ([236]).

TRANSPLANTATION-ASSOCIATED ALLOIMMUNE THROMBOCYTOPENIA Alloimmune mechanisms can explain the rare syndrome of transplantation-associated alloimmune thrombocytopenia that can complicate transplantation either with a solid organ or with allogeneic bone marrow ([127]). Both anti-PL ^{A1} and anti-Br ^{a} alloantibodies can cause thrombocytopenia that may develop very soon or very long after transplantation. In one case, a man with Ph1 chromosome–positive chronic myelogenous leukemia developed severe thrombocytopenia (17 × 10 ^{9}/L) 18 months after receiving an allogeneic bone marrow transplant from his HLA-matched sister ([237]). An immune mechanism was suggested by the repeated platelet count increase after treatment with high-dose intravenous ?-globulin and remission after splenectomy. Anti-PL ^{A1} antibodies were detected in Ig eluted from the patient's platelets. Although chromosome analysis of the patient's marrow demonstrated a normal Ph1-negative female karyotype, sensitive Southern blot analysis of splenic cell DNA identified a small amount (3%) of residual male cells. The patient's sister was PL ^{A1}-positive, and another brother was PL ^{A1}-negative. Although pretransplant platelet alloantigen studies were not done, it was deduced that the patient was likely PL ^{A1}-negative and that the thrombocytopenia was mediated by a host-versus-donor alloimmune thrombocytopenia in which the patient's residual lymphoid cells developed an anti-PL ^{A1} alloimmune response to PL ^{A1}-positive platelets derived from the engrafted bone marrow. Alloimmune-mediated platelet destruction due to a bone marrow transplant recipient's preexisting anti-Br ^{a} antibodies was suggested by a rapid transient increase in platelet count from 43 to 108 × 10 ^{9}/L after administration of intravenous ?-globulins ([238]). The patient received the allogeneic marrow from her HLA-matched brother who typed positive for Br ^{a}. The detection of a small amount of group A (<5%) blood cells in the recipient after transplantation with her brother's group O marrow indicated that a chimeric state existed in this patient. The thrombocytopenia eventually improved as the level of circulating antibody decreased. Thrombocytopenia that may also have an alloimmune mechanism was reported in patients after autologous peripheral blood cell transplantation for metastatic breast carcinoma ([239]). Both patients had preexisting anti-PL ^{A1} antibodies that rose in titer after transplantation. Because moderate to severe thrombocytopenia is expected soon after transplantation due to marrow ablative treatment, variable rate of engraftment of donor marrow–derived megakaryocyte precursors, and fever and other comorbid clinical factors, it is difficult to determine the pathogenic mechanism in these patients. Although the thrombocytopenia may have resulted from a refractory state caused by the rapid clearance of transfused platelets by alloantibodies, it is also possible that platelets derived from engrafted autologous marrow were destroyed in a PTP-like syndrome. Solid organ transplants rarely can lead to alloimmune thrombocytopenia. Donor-derived immunocompetent lymphoid cells contained within the organs transplanted from a single donor to three recipients (two kidneys, one liver) are suspected to be the cause of severe thrombocytopenia (platelet count nadirs: 2, 2, and 12 × 10 ^{9}/L) that developed within 5 to 8 days ([240]). The severe thrombocytopenia in the renal transplant patients was refractory to intravenous ?-globulins and platelet transfusions. One patient recovered after splenectomy 50 days after transplantation, and the other died due to multiorgan failure associated with bacteremia and severe thrombocytopenia. The thrombocytopenia resolved in the liver transplant recipient after receiving a new liver after rejection of the first transplant. Serum from the multiparous female organ donor was shown to contain anti-PL ^{A1} alloantibodies. Platelet typing and antibody studies of the transplant recipients showed that although they typed PL ^{A1}-positive, anti-PL ^{A1} antibodies were detected in their posttransplant, but not pretransplant, sera. These observations suggest that anti-PL ^{A1} antibodies derived from transplanted immunocompetent lymphoid cells were responsible for the severe thrombocytopenia in these patients. A similar case of donor lymphocyte-induced thrombocytopenia was caused by a liver transplant obtained from a donor who died of bleeding related to severe autoimmune thrombocytopenia. Anti-gpIIb/IIIa antibodies without allospecificity were detected in both the organ donor and the posttransplant recipient serum ([241]).

PLATELET TRANSFUSION REFRACTORINESS Nonimmune patient-dependent factors usually are involved when unexpectedly poor platelet count increments are observed after transfusion. Although ABO or HLA incompatibility and platelet storage can contribute to reduced platelet count recovery ([217], [242], [243] and [244]), more often septicemia, drugs, and increased platelet consumption in severely thrombocytopenic patients are responsible for platelet transfusion refractoriness. Although there is only anecdotal evidence that platelet-specific alloantibodies can cause platelet transfusion refractoriness ([189], [245]), some refractory patients do benefit from transfusion with platelets that are HLA- and platelet alloantigen–compatible ([246]). However, in a prospective study, platelet-specific alloantibodies accounted for, at most, 5% of the patients with platelet transfusion refractoriness ([247]).

Platelet Polymorphisms as Risk Factors for Cardiovascular Disease

There is increasing evidence that ischemic vascular disease may result from interactions between environmental factors (e.g., smoking), genetic susceptibility, and concurrent diseases (e.g., diabetes). There is good evidence to show that platelets can play a major role in the formation of an occlusive thrombus at the site of a ruptured atherosclerotic plaque ([248]). The rate of formation or the susceptibility for platelets to participate in thrombus formation may depend partly on factors that include certain polymorphisms on the platelet glycoproteins.

Measures of platelet reactivity using *in vitro* assays demonstrate heterogeneous results, indicating that there is a range of platelet reactivity among individuals. For example, some individuals' platelets may be considered hyperreactive based on the lower epinephrine dose threshold that induces platelet aggregation. The major platelet glycoproteins that function as receptors and mediate aggregation and adhesion can also differ antigenically and structurally between individuals. Recent evidence suggests that certain polymorphisms on glycoproteins IIb/IIIa, Ib/IX/V, and Ia/IIa may be associated with enhanced platelet function *in vivo*.

Platelet aggregation is mediated by gpIIb/IIIa, the major receptor for fibrinogen and vWF. GpIIb/IIIa is highly polymorphic, having four known alleles of the aIIb subunit and eight alleles of the ß3 subunit ([249]). The Leu33Pro alleles on ß3 are the most clinically important. The Leu33 allele encodes the PL ^{A1} alloantigen, which is highly immunogenic to some Pro33 (PL ^{A1}-negative) individuals. Although these alleles are distributed within the general white population with gene frequencies of 0.85 (PL ^{A1}) and 0.15 (PL ^{A2}), the gene frequency for PL ^{A2} was found to be almost four times higher among younger patients with myocardial infarction or unstable angina ([250]). Since that first report, numerous studies have not been able either to establish or to exclude PL ^{A2} as a risk factor for ischemic vascular disease ([251]).

However, *in vitro* studies indicate that gpIIb/IIIa-mediated functions such as aggregation, adhesion, spreading, and clot retraction demonstrate heterogeneity and that the PL ^{A2} phenotype was associated with a lower activity threshold ([252] , [253]). Interactions between platelet integrins and the extracellular matrix are important for cell migration, which is directly involved in restenosis after angioplasty. Recent studies using the PL ^{A1} or PL ^{A2} forms of gpIIIa transfected into Chinese hamster ovary cells demonstrated enhanced migration activity when the PL ^{A2} form of the protein was a constituent of the integrin complex, as either aIIbß3 or avß3 ([254]). Further, a reduced affinity of the platelet function inhibitor abciximab for platelets with the PL ^{A2} phenotype suggested that patients with this allele may have a less favorable outcome to treatment after percutaneous coronary intervention ([255]). Other studies involving the Ile843Ser polymorphism responsible for the Bak alloantigens on aIIb have not established an association with cardiovascular disease. Although small studies have reported a link with both the Bak ^{a} and Bak ^{b} antigens with either stroke or myocardial infarction, larger studies have not reported a similar association ([256] , [257] , [258] and [259]).

Three dimorphisms of gpIba have potential relevance in thrombotic risk. The Thr145Met alleles encode the Ko alloantigens, which are in linkage disequilibrium with a VNTR polymorphism in the macroglycopeptide region of gpIba. This results in a duplication of the 13–amino acid sequence one to four times (VNTR D to VNTR A) and would result in an increasingly longer polypeptide. However, the few studies that report an association between any of the variable polymorphisms and the risk for coronary artery disease have not been supported in others ([260] , [261] and [262]). An additional polymorphism in the Kozak region of the molecule may be important for regulating the efficiency of translation of gpIba, thus affecting the number of receptors expressed ([263] , [264]). However, an association between this dimorphism and a risk for arterial thrombosis could not be demonstrated in subsequent studies ([265] , [266] and [267]). One study from Australia did report an association between the Kozak polymorphism and ischemic stroke, suggesting that further studies may be warranted ([268]).

The level of expression of a major collagen receptor, gpIa/IIa, can vary up to threefold depending on the inheritance of linked, allelic polymorphisms in the a2 (gpIa) gene. The 807-T/C/G polymorphism segregates independently of the alleles encoding the Br ^{a}/Br ^{b} and Sit ^{a} alloantigens. Although some studies suggested an association of the 807T allele (high receptor density) with myocardial infarction or stroke, other studies were unable to confirm this observation ([269] , [270] , [271] and [272]). However, in a large study of 2237 male patients, an association between younger patients with the 807T allele and myocardial infarction was reported ([273]).

WHITE CELL ANTIGENS

Antigens expressed on granulocytes, monocytes, and lymphocytes are traditionally known as the *self-antigens*. These include the MHC genes, as well as other antigens expressed on subsets of white cells, including those expressed primarily on neutrophils and monocytes. The MHC has several subloci, including genes encoding the HLA class I and II antigens. The class I antigens are present on every cell and tissue in the body, except for red cells, sperm, and some placental cells. The class II antigens are expressed mainly on select cells of the immune system (e.g., T and B cells and macrophages). In addition, the white cells express some antigens that are shared with other cells of the body, including red cells and platelets.

The white cell antigens can play a pivotal role in host defense, self-recognition, and autoimmunity. They have been implicated in graft rejection and graft-versus-host disease (GVHD) after transplantation and are responsible for transfusion reactions and fetal neutropenia due to expression of incompatible alloantigens. Because of their high polymorphism, these antigens are used in forensic medicine, paternity testing, and anthropologic studies.

Finally, many white cell antigens are recognized by monoclonal antibodies. The majority of these antibodies identify proteins that are markers of differentiation, cell adhesion molecules, and various phagocytic, complement, and chemotactic receptors.

Granulocyte Antigens

GRANULOCYTE-SPECIFIC ANTIGENS The antigens on granulocytes were initially defined using human alloantisera, most often through the diagnosis and investigation of infants with alloimmune neonatal neutropenia (ANN), but are also implicated in autoimmune neutropenia of childhood, febrile transfusion reactions (FTRs), and transfusion-related acute lung injury. The NA and NB antigens are most often implicated in alloimmune neutropenia, and the availability of monoclonal antibodies to the target proteins has facilitated the characterization of these alloantigens. Alloantibodies to the 5b, Ond ^{a}, and Mart ^{a} antigens are much less common. Alloimmunization to these antigens has been recorded in FTRs, ANN, and transfusion-related acute lung injury (5b), as well as in the sera of multiparous women (Mart ^{a}) and in a multitransfused male with aplastic anemia (Ond ^{a}).

Nomenclature Standardization of the nomenclature for the neutrophil antigens has modified the original *N* designations to *HNA* (human neutrophil antigen) ([274] , [275]). The Granulocyte Working Party of the ISBT is charged with the allocation of new antibody/antigen specificities after confirmation of their reactivity and biochemical and molecular characterization. Unlike the HPA nomenclature system for platelet alloantigens, the neutrophil alloantigen nomenclature assigns different antigens on the same gp to the same HNA antigen system, with alleles distinguished by lowercase letters (Table 23.11). Thus, the NA1, NA2, and SH antigens are all expressed on Fc?RIIIb and are, therefore, designated as alleles of the gene for Fc?RIIIb (HNA-1a, -1b, and -1c, respectively), with the base modifications encoding the alleles at distinct locations ([276]). Seven alloantigens have been assigned HNA designations on five glycoproteins (HNA-1 to HNA-5). However, other specificities, including ND1, 5a, 9a, and NB2, have been reported but cannot be confirmed due to a lack of available antisera.

TABLE 23.11. Human Neutrophil Alloantigens

HNA System	Antigen	Original Designation	Glycoprotein
1	HNA-1a	NA1	Fc?RIIIb	CD16
	HNA-1b	NA2	
	HNA-1c	SH	
2	HNA-2a	NB1	CD177
3	HNA-3a	5b	Unknown
4	HNA-4a	Mart ^{a}	CR3/CD11b
5	HNA-5a	Ond ^{a}	Leukocyte function antigen-1/CD11a

HNA, human neutrophil antigen.

Modified from Stronek D. Neutrophil alloantigens. Trans Med Rev 2002;16:67–75.

The HNA system has improved the nomenclature for the neutrophil antigens; however, it does not account for the different haplotypes possible for certain genes (e.g.,

Fc?RIIIB). The nomenclature works best for antigen systems with two alleles but has the same problems as the HPA system used to designate the platelet alloantigens. These systems are not able to completely define the haplotypes due to the possibility of crossover between alleles. Thus, although the majority of base substitutions at position 266 of Fc?RIIIB encoding the SH antigen have been found on the NA2 form of the gene, SH can also occur with variants of NA2. Modifications to the nomenclature may be required in the future to clarify these issues and to address the NB antigen system after its molecular characterization.

HNA-1a, -1b, and -1c (NA1, NA2, and SH) The most clinically important of granulocyte-specific antigens are the HNA-1a and -1b alleles, which are most commonly associated with ANN. This antigen system was first described in 1960 by Lalezari ([277]). It consists of gene products for two antithetical antigens, NA1 and NA2, which are expressed on the low-affinity Fc? receptor, Fc?RIIIb. Monoclonal antibodies to this gp are specific for CD16. Fc?RIIIb is a 233–amino acid gp secured to the membrane via a GPI anchor ([278] , [279] , [280] and [281]). The NA1 gene on chromosome 1 differs from the NA2 gene by five nucleotide bases at positions 141, 147, 227, 277, and 349. Four of these changes encode a different amino acid, two of which result in a different glycosylation pattern because of the changes at bases 227 and 277. Thus, NA2-Fc?RIIIb has two additional glycosylation sites, which accounts for the larger molecular mass of this form of the gene product (65- to 80-kd gp) compared with the NA1-Fc?RIIIb product (50- to 65-kd gp). The soluble Fc?RIIIb found in plasma has the same NA antigens as those found on neutrophils, which have been shown to be the source of the soluble gp ([282]). The gene frequencies for NA1 and NA2 demonstrate marked differences among different racial groups. The NA1 gene frequency in whites ranges from 0.30 to 0.37, and that of NA2 ranges from 0.63 to 0.70. However, in the Asian population, the frequency of NA1 ranges between 0.60 and 0.66, whereas NA2 ranges from 0.30 to 0.33 ([283] , [284] , [285] , [286] and [287]). The gene for Fc?RIIIb shares homology with the gene for the Fc?RIIIa receptor, differing only by four nucleotides. A C to T change at position 733 creates a stop codon in the gene for Fc?RIIIb, resulting in a GPI-anchored protein that is 21 amino acids shorter than Fc?RIIIa, which is a transmembrane protein. However, the genes for the two forms of Fc receptor share similarities, and special care is required when using polymerase chain reaction and restriction enzymes for genotyping the NA antigens. The Fc?RIIIA gene shares partial homology with both the NA1 and NA2 forms of Fc?RIIIB. At positions 227 and 349, Fc?RIIIA is the same as the NA1 form of Fc?RIIIB but is homologous to NA2-Fc?RIIIB at positions 141, 147, and 277. Neither anti-NA1 nor anti-NA2 antibodies recognize Fc?RIIIa, which suggests that these alloantigens, like platelet alloantigens, depend on tertiary conformations. The conformational changes, in turn, are induced by the amino acid polymorphisms. However, genotyping procedures with genomic DNA require multisite analysis to ensure differentiation of the NA1 and NA2 partial polymorphisms on Fc?RIIIA from those on the actual gene of interest, Fc?RIIIB ([284] , [286] , [288]). Alternate alleles of the NA1 and NA2 genes have been described ([286]). These are single nucleotide substitutions at one of the five NA-Fc?RIIIB polymorphic sites. They have been detected only by genotyping, because the changes have not been reported to induce an immune response. However, changes at certain sites can directly affect the level of expression of Fc?RIIIb and the NA1/NA2 antigens. This has been confirmed using studies on cells transfected with variants of the Fc?RIIIB gene ([281]). The SH polymorphism (HNA-1c) results from an alanine to aspartate amino acid change at position 78 due to a C to A substitution at nucleotide 266 in Fc?RIIIB ([289]). SH is expressed on neutrophils in 4 to 5% of whites, but it is expressed much more frequently (25 to 38%) on neutrophils from black individuals ([289] , [290] and [291]). In many individuals with the SH polymorphism, the Fc?RIIIB gene is duplicated on the same chromosome ([292] , [293]). In most cases, SH is expressed on the NA2 form of Fc?RIIIB, suggesting that the mutation at nucleotide 266 occurred after those encoding the NA2 allele. However, reports of some cases of SH-positive individuals having an NA1 phenotype suggest that crossover between NA1-Fc?RIIIB and NA2-Fc?RIIIB, or NA2-Fc?RIIIB and Fc?RIIIA, may have taken place ([286]).

HNA-2a (NB1) The neutrophil NB1 alloantigen has been implicated in ANN, FTRs, autoimmune neutropenia, and transfusion-related lung injury ([294] , [295]). It is expressed on a 58- to 64-kd GPI-anchored gp (CD177) on neutrophils in 97% of individuals in the white population ([275] , [296]). The NB1 gene on chromosome 19q13.2 has been sequenced and has been determined to belong to the Ly-6 gene family ([297]). Proteins encoded by Ly-6 family genes are characterized by repeating cysteine-rich domains and include the urokinase-type plasminogen activator, the reactive inhibitor of lysis receptor (CD59), and polycythemia rubra vera-1 ([298]). A genetic polymorphism associated with the NB1 antigen has not been identified. This may have implications for the genetic basis of the anti-NB1 antibodies. The putative antithetical antigen to NB1, NB2, has not been reliably characterized due to a lack of alloantisera. Polyclonal antibodies that react to the NB1 gp do not recognize a gp determinant on individuals lacking the NB1 antigen ([299]), suggesting that NB1-negative individuals may lack CD177. This would indicate that the anti-NB1 antibodies may not result from an immune response to the gp product of a polymorphism in the NB1 gene. The antibodies may be more similar to the isoantibodies reported in patients who lack specific surface glycoproteins and who are exposed to these polypeptides through transfusion or pregnancy (e.g., gpIIb/IIIa in Glanzmann thrombasthenia and gpIV in Nak ^{a}-negative individuals). Similarly, in some individuals with paroxysmal nocturnal hemoglobinuria and in families with individuals who lack the Fc?RIIIB gene, a deficiency of Fc?RIIIb is associated with an absence of the NA1 and NA2 antigens ([300] , [301] and [302]). Unlike other neutrophil polymorphisms, the NB1 antigen is expressed only on a subpopulation of cells (56 to 64%) and has a higher level of expression on neutrophils from women compared with men ([286] , [296] , [302]). The level of NB1 antigen declines with age in women but remains constant in men.

HNA-3a (5b) The 5b antigen is located on a 70- to 95-kd protein on neutrophils but has also been reported on lymphocytes, platelets, and endothelial cells ([303]). However, the biochemical and molecular nature of the gp carrying the 5b antigen has not been reported. Alloimmunization to 5b has been associated with FTRs, alloimmune NAT, and transfusion-related lung injury ([304]).

HNA-4a (Mart^{a}) Mart ^{a} is recognized by antibodies in sera from nontransfused multiparous women ([305]). The alloantigen is located on the aM-chain of the C3bi receptor (CR3, CD11b) and is expressed on granulocytes, monocytes, and lymphocytes in 99% of the white population. A single nucleotide substitution of G to A at position 302 encodes an Arg to His polymorphism at amino acid 61 that is associated with the Mart ^{a} antigen ([306]). The clinical significance of immunization to Mart ^{a} is unknown because none of the infants of the women with anti-Mart ^{a} was reported to have evidence of neutropenia.

HNA-5a (Ond^{a}) Antibodies to the Ond ^{a} antigen were discovered in the serum from a multiply transfused male with aplastic anemia. Biochemical and molecular analysis has demonstrated that Ond ^{a} is expressed on the aL integrin unit (leukocyte function antigen-1, CD11a) and is associated with a G to C nucleotide substitution at position 2446, which encodes an Arg to Thr amino acid change at 766 ([306]).

Detecting Antibodies to Granulocyte Antigens

The study of antibodies to granulocytes uses techniques evolved from leukoagglutinin assays with reactive antisera. The two most commonly used tests are the granulocyte agglutination test (GAT) and the granulocyte immunofluorescence test (GIFT) for investigation of granulocyte-specific antibodies. GAT currently is used in modified form using a microtechnique with purified granulocyte suspensions in microtest plates. However, the basis of this test is unlike that of red cell agglutination. The granulocyte agglutination measures the response of the cells after interaction with antibody. The GIFT assay is performed in microtiter plates in which antibodies bound to the cells are detected with fluorescein-conjugated antihuman Ig.

Problems are associated with the GAT and GIFT assays, primarily due to coexisting antibodies to HLA and other granulocyte-specific antigens. These may mask or confuse the reactivity of interest. Even with the use of well-characterized test sera and procedures to eliminate HLA reactivity using absorption techniques or chloroquine stripping, the GAT and GIFT assays have limited sensitivity and specificity.

Biochemical characterization of granulocyte antigens has facilitated the development of more specific methods for investigation of granulocyte-specific antibodies. These include antigen capture (e.g., the monoclonal antibody-specific immobilization of granulocyte antigens assay), immunoblot, and immunoprecipitation assays, similar to the assays used to study platelets.

SHARED ANTIGENS Granulocytes also express antigens that are associated with other peripheral blood cells and tissues. The class I (HLA-A, -B, and -C) antigens can be demonstrated on granulocytes, but not using cytotoxicity tests as used for lymphocytes. The concentration of HLA on granulocytes is lower than on lymphocytes. Although granulocyte precursors also carry HLA, it is not known if the HLAs on mature granulocytes are intrinsic or adsorbed from the plasma. Although no class II can be detected on mature granulocytes, they are present on immature cells. Various blood group antigens have been reported on neutrophils. Initially ABO antigens were reported on granulocytes; however, more specific and sensitive assays failed to confirm the presence of ABH on granulocytes. There is evidence for the expression of the Ii, Lex, and P system antigens on granulocytes, but there is no evidence of MN, Rh, Kidd, Duffy, or Kell antigens on the surface of normal granulocytes.

Clinical Significance of Granulocyte Antigens

Alloantibodies Alloantibodies specific for the HNA-1 antigens on Fc?RIIIb are most commonly implicated in ANN ([307] , [308]). They have also been identified in FTRs and transfusion-related lung injury. The HNA-2a and HNA-3a antigens are also associated with these diseases. ANN can occur in the fetus and in newborns born to mothers who lack the respective antigen. The mother becomes immunized during pregnancy to the incompatible fetal-paternal alloantigen. The resulting maternal alloantibodies can cross the placenta and mediate the destruction of fetal neutrophils, similar to the mechanism of cell clearance seen in NAT and HDN. The neutropenia is self-limiting and transient, and most infants recover spontaneously within 2 weeks to 6 months ([275]). Although it is common for the neutropenic infants to contract mild infections, overwhelming sepsis can occur, with a mortality rate of approximately 5%. FTRs are associated with granulocyte-specific antibodies in the recipient that mediate destruction of the transfused cells. It can be associated with transfusion-related lung injury, resulting in acute respiratory distress and pulmonary edema. The syndrome is most commonly associated with transfusion of plasma containing HLA or neutrophil-specific antibodies. Bone marrow transplantation can result in immune-mediated granulopenia. It is common to match donor and recipient for HLAs but not for granulocyte-specific antigens, and the presence of granulocyte-specific antibody can delay neutrophil engraftment.

Autoantibodies Granulocyte-specific antibodies are observed in primary and secondary autoimmune neutropenia. Unlike alloantibodies, these autoantibodies are directed to epitopes expressed on protein and carbohydrates present on all normal granulocytes. Primary autoimmune neutropenia is seen most often in children 3 to 30 months of age and usually resolves spontaneously after 1 to 2 years. In some cases, NA1 and NA2 antibodies are found in children with autoimmune neutropenia ([309]). In the majority of patients, granulocyte-specific antibodies can be detected. Secondary autoimmune neutropenia is most often associated with another autoimmune disease such as Felty syndrome, systemic lupus erythematosus, or malignancy (e.g., lymphoma). Unlike primary autoimmune neutropenia, granulocyte-specific antibodies are not detected as readily in autoimmune neutropenia secondary to other autoimmune diseases.

Monocyte Antigens Monocytes express both class I and II HLAs, as well as some shared antigens discussed previously, including HNA-4a.

Lymphocyte Antigens Numerous monoclonal antibodies recognize a number of molecules associated with various aspects of lymphocyte function and differentiation. These antibodies and antigens have been well characterized and are assigned to cluster designation (CD) antigens based on their patterns of reactivity. These antigens are discussed elsewhere (see Chapter 10). Lymphocytes also express a number of shared antigens, including HNA-3a, HNA-4a, and HNA-5a. Some ABH and Lewis antigens can be adsorbed to the lymphocyte surface from the plasma. Ii and P1 and P antigens are also expressed on lymphocytes; however, the major antigens associated with lymphocytes are the HLAs.

HLAs The HLAs are encoded by the MHC, a cluster of genes encompassing approximately one-thousandth of the human genome. The MHC is located on the short arm of chromosome 6 (band 6p 21.3) and was defined initially by investigation of antibodies to HLAs in individuals immunized through pregnancy or transfusion ([310]). These antigens are distributed on many types of cells and tissues and are important in the regulation of the immune response. They play a primary role in graft rejection and GVHD in transplantation and transfusion. The immune response to specific antigens is controlled by immune response genes (Ir), also located in the MHC (for discussion elsewhere, see Chapter 18).

MOLECULAR STRUCTURE OF HLAS The HLA complex on chromosome 6 has over 200 genes, more than 40 of which encode leukocyte antigens (Fig. 23.5). Of the three coding regions in the MHC, only the class I and II antigens are involved in the immune response. The class I genes encode HLA-A, -B, -C, -E, -F, and -G, and the class II genes encode HLA-DP, -DQ, -DR, -DN, and -DO. These class I and II gene products are both structurally and functionally different. The class III genes encode complement components C2, C4A, C4B, Bf, 21-hydroxylase, and tumor necrosis factor-a and -ß ([311]).

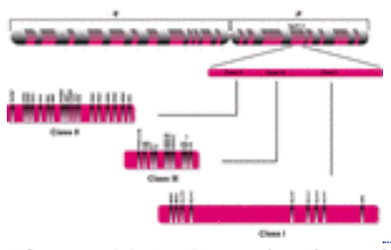

Figure 23.5. Organization of the major histocompatibility complex on chromosome 6. A partial gene map of the HLA complex is shown. The major loci of the genes expressed in the HLA class I and class II regions are depicted, as well as the unrelated class III genes. The following genes are shown in order, but not to scale: BF (complement factor B), C2 (complement component 2), C21B (cytochrome P-450, subfamily 21), C4A/C4B (complement components C4A/C4B), HSP (heat shock protein), LMP (large multifunctional protease), LTA/LTB (lymphotoxins A and B), MICA/MICB (MHC class I chains A and B), P450 (cytochrome P-450), PSMB8 and 9 (proteasome beta 8 and 9), TAP1/TAP2 (transporter proteins associated with antigen processing), TAPBP (TAP-binding protein, tapasin), TNF-a (tumor necrosis factor-a), and HSPA1A/HSPA1B/HSPA1L (heat shock proteins 1A A-type/1A B-type/1A-like).

The class I molecule consists of two polypeptide chains, a and ß, each encoded by different genes ([312] , [313] , [314] , [315] and [316]) (Fig. 23.6). The HLA-A, -B, and -C genes encode the larger a-chain, a 45-kd transmembrane protein with three amino acid domains. Two of these, a1 and 2, account for most of the variation in the molecule. Polymorphisms of the HLA genes are found in these parts of the molecule. A constant region, similar to those found in Ig molecules, is in the a3 region close to the cell membrane. The class I a-chain is noncovalently associated with a smaller molecule, ß $_2$-microglobulin. No polymorphisms have been reported on this 12-kd extracellular protein encoded by a gene on chromosome 15.

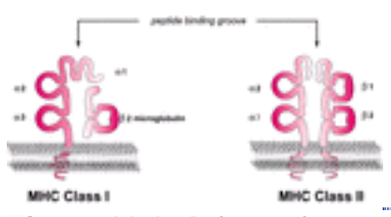

Figure 23.6. Schematic representation of the HLA class I and class II molecules. The class I and class II molecules are each composed of two polypeptide chains that are manufactured separately in the endoplasmic reticulum. A peptide-binding groove is created by the a1 and a2 peptide-binding domains of the class I molecule. A similar peptide-binding structure is created in the class II molecule by the association of the a1 and ß1 peptide-binding domains. The HLA class I and II molecules also have immunoglobulin-like domains (a3: class I; a1 and ß1: class II) proximal to a transmembrane domain and cytoplasmic tail.

X-ray crystallography demonstrates further similarities to Ig molecules. The membrane-proximal a3 and ß $_2$-microglobulin portions of the HLA molecule have Ig-like folds, in contrast with the a1 and 2 portions, which form a platform topped by a helices. A groove between these helices is the binding site for a peptide fragment from a processed antigen. Class II molecules also share similarities with Igs. Like the class I molecules, they also consist of a heavy and a light chain (Fig. 23.6). The heavy a-chain has a molecular weight of 34 kd, and the smaller ß-chain has a molecular weight of 29 kd. Both chains are transmembrane molecules, each with two structural domains. Similar to the class I molecule, the class II molecule has a functional antigen-binding groove formed by the distal a1 and ß1 domains ([317]). The a2 and ß2 constant regions share homology with Ig constant regions, ß $_2$-microglobulin, T-cell receptors, and class I heavy chains. This homology may account for similarity in the crystallographic structure of the class I and class II antigens ([318]).

NOMENCLATURE The nomenclature of the HLAs has been standardized by the World Health Organization nomenclature committee, which regularly reviews newly reported specificities and genetic loci to determine the nomenclature for the HLAs, partly defined by the results of International Histocompatibility Testing Workshops ([319] , [320] and [321]) (Table 23.12).

TABLE 23.12. Serologic Antigens and DNA Polymorphisms of the HLA System

Locus	Serologic Antigens (Number of Antigens)	DNA Polymorphisms (Number of Alleles)
Class I		
HLA-A	A1 to A80 (20)	A*0101 to A*8001 (59)
HLA-B	B7 to B81 (30)	B*0701 to B*8201 (118)
HLA-C	Cw1 to Cw11 (8)	Cw*0101 to Cw*1802 (36)
Class II		
HLA-DR	None	DRA*0101, DRA*0102 (2)
	DR1 to DR8 (18)	DRB1*0101… (184)
	DRw52 (1)	DRB3*01011… (11)
	DRw53 (1)	DRB4*01… (9)
	DR51 (1)	DRB5*01011… (12)
HLA-DQ	None	DQA1*0101… (18)
	DQw1 to DQw9	DQB1*0101… (31)
HLA-DP	None	DPA1*0101… (10)
	None	DPB1*0101… (77)

Modified from Troup GM, Williams TM. HLA: the molecular age. In: Rossi EC, Simon TK, Moss GS, et al., eds. Principles of transfusion medicine, 2nd ed. Baltimore: Williams & Wilkins, 1996:817.

The nomenclature for the class I and class II antigens is similar, consisting of the region of the gene (e.g., HLA-A) and a number. A *w* is assigned to antigens that await confirmation of their reproducibility and specificity. A *w* is assigned to the Bw4 and Bw6 antigens and to the DW and DP specificities defined by cellular techniques. However, the HLA-C antigens are also recorded with a *w* to avoid confusion with the complement components. Because the antigens are originally defined by the reactivity of antisera, some early specificities have been further defined with more restricted antisera. These subspecificities are called *splits* and usually are written to incorporate the parent antigen in parentheses [e.g., HLA-A9 is split to HLA-23(9) and HLA-24(9)]. It is also common among the HLA-A and -B

alleles to find specific antisera that cross-react with more than one antigen. Antisera that react with one specificity in these cross-reactive groups may demonstrate reactions with other antigens in the same group [e.g., HLA-A2 and -A28, or -A19 (consisting of A29 to A33)] ([322], [323] and [324]). The Bw4 and Bw6 antigens are public antigens expressed on the HLA-B molecule. The HLA-B specificity includes both this public antigen (Bw4 or B7 and Bw6) and a private specificity [e.g., B44(12)], written as B7(Bw6). Those HLA regions and genes that have been defined using molecular techniques are identified using a unique nomenclature. The nomenclature for the class I antigens consists of the locus name, a star (*), and a four-digit number (e.g., HLAA*0101). The first two digits of the number refer to the serologic specificity. Because both the a and ß (A and B) genes are polymorphic for the class II antigens, the chain also must be specified (e.g., HLA-DRB1*0101 or HLA-DQA1*0101) (Table 23.12).

CLASS I HLAS The class I (class I-a) antigens are expressed on all nucleated cells and on the anucleate platelets. In addition, soluble HLA-A and -B antigens can be found in plasma where they circulate in association with high-density lipoproteins (released from cell membranes) ([325], [326], [327] and [328]). Adsorption of these vesicles into other cell membranes may explain why red cells also carry these antigens. The class I antigens are products of the highly polymorphic HLA-A, -B, and -C genes ([313], [316], [329]). A description and list of the class I antigens can be found in the review by Bodmer et al. ([330]). Molecular techniques have increased the number of HLA-A specificities to more than 80 from the 20 defined serologically. Similarly, HLA-B and -C loci have 30 and 8 serologically defined antigens and more than 118 and 36 specificities, respectively, identified using molecular techniques. It may not be appropriate to designate the molecularly defined polymorphisms as antigens, because the resulting proteins do not initiate alloantibody formation. Hence, these alleles are more correctly referred to as *genetic polymorphisms*. The HLA-E, -F, and -G molecules (class I-b) are similar in structure to the class I-a molecules but have a different tissue distribution ([331], [332] and [333]).

Methods of Detecting Class I HLAs and Antibodies

Antigen Typing Both serologic and molecular techniques have been used to identify polymorphisms of the class I genes. Serologic methods use lymphocytotoxic (functional) assays, in which sera with known anti–HLA-A, -B, and -C specificities are incubated with test cells. Cell viability is monitored after the addition of complement, which damages the cell membrane of antibody-sensitized lymphocytes, allowing the uptake of dye such as eosin ([334], [335]). Because of the requirement for a relatively large and informative number of specific typing sera, commercial kits are generally used for serotyping. Molecular methods are used to detect polymorphisms, and sequencing is used to identify changes at each locus.

Antibody Detection and Identification Testing for anti-HLA antibodies uses lymphocytotoxic techniques similar to those used for HLA typing. For these assays, patient serum is screened against a panel of typed cells. Generally, 30 to 60 different target cell phenotypes are required to identify the antibody specificities. These methods are used to select potentially compatible platelets for patients who are refractory to platelet transfusions.

CLASS II HLAS The class II HLAs are found on lymphocytes, monocytes, macrophages, endothelial cells, activated T cells, and Langerhans cells ([311], [317]). Many of these cells play an important role in initiating the immune response. The class II genes are proximal to the centromere on the short arm of chromosome 6 and consist of one a-chain (DRA) and one or two ß-chain (DRB) genes. Therefore, one DRA- and one DRB1-encoded polypeptide are expressed by all individuals. The other DRB genes (DRB2 to DRB9) do not always encode a polypeptide that is coexpressed with the DRB1 product. Only the DRB3, 4, and 5 gene products are associated with a DRB1-encoded polypeptide. Although two a-chain genes and two ß-chain genes are found for the DQ and DP regions, only one product (a + ß) is expressed ([336]). A list of class II antigens can be found in the review by Bodmer et al. ([330]).

Methods of Detecting Class II HLAs and Antibodies The class II antigens have been detected using both serologic and cellular assays. The International Histocompatibility Workshop in 1977 initially defined the class II antigens identified using serologic techniques ([337]). Serologic typing for the class II antigens is performed using a method similar to that used for the class I antigens. However, instead of using unfractionated lymphocytes, the typing of class II antigens uses only B lymphocytes. These are first isolated from peripheral blood and incubated with specific anti-DR/-DQ sera to determine the class II phenotype. To date, 21 HLA-DR and 9 HLA-DQ antigens have been serologically identified. It is now known that a single gene does not exist for HLA-D; however, the term continues to be applied to functional assays such as the mixed lymphocyte culture, the primed lymphocyte typing test, and T-cell clones ([338]). Because of the limitations of the functional assays, molecular methods have replaced the cellular assays for HLA class II typing. This typing is used for the identification of compatible bone marrow donors and recipients. More than 180 alleles at the HLA-DRB locus and more than 30 alleles at the HLA-DQB1 locus have been identified ([339]).

CLASS III HLAS A cluster of genes located between HLA-B and HLA-DR in the class III region of the MHC encode some components of the complement system, including C4A, C4B, C2, and properdin factor B (Bf). The C4A and C4B loci encode C4 variants. These polymorphic genes also are responsible for the Rodgers (C4A) and the Chido (C4B) red cell phenotypes ([340], [341] and [342]). This area of the MHC also encodes other proteins, including 21-hydroxylase and tumor necrosis factor-a and -ß. Other genes on chromosome 6 linked to the HLA complex include sulfoxide dismutase, phosphoglucomutase-3, neuraminidase, glyoxalase, and coagulation factor XIIIA ([343]).

INHERITANCE OF HLAS Closely linked genes on one chromosome, such as those of the MHC, are often inherited as a unit cluster or haplotype. Thus, a child inherits one haplotype from each parent, resulting in four possible phenotypes. In some cases, an individual exhibits only two or three of the four HLA-A and -B antigens. This has been attributed to homozygosity or chromosome deletions. However, the limitations of serologic methods are demonstrated by molecular studies showing that some individuals are heterozygous at certain loci (e.g., HLA-A*0201/HLA-A*0202) who previously serotyped as homozygous HLA-A2. The chance that any two of the children are completely identical is 25%. However, crossover can occur during meiosis, thus creating a new haplotype. For the MHC, there is a crossover rate of 0.8% between the A and B loci and approximately 0.5% between the B and DR loci. Because of linkage disequilibrium, alleles at linked loci are associated more frequently than would be expected. Thus, HLA-A1 (13.8%) and HLA-B8 (9%) are in linkage disequilibrium because their actual haplotype frequency (6%) is much higher than would be expected (1.3%) if they were independently inherited. Linkage disequilibrium contributes to the observation that different racial groups have wide variations in their haplotypes. Antigen frequencies vary considerably between populations, such that some alleles are seen rarely (e.g., HLA-A1, -B8 in Orientals), whereas others are found almost exclusively within a certain race (e.g., HLA-A34 in blacks). Inheritance of the class III gene cluster as a closely linked unit, referred to as a *complotype*, is associated with certain disease states ([340], [344]).

CLINICAL SIGNIFICANCE OF THE MAJOR HISTOCOMPATIBILITY COMPLEX Studies of the MHC and inheritance of specific alleles and haplotypes demonstrate a role in transplantation and transfusion and an association with certain diseases. The highly polymorphic antigens of the MHC also provide markers for use in forensic medicine and paternity testing and for anthropologic studies ([345], [346] and [347]).

Transplantation Histocompatibility testing is used to identify compatible donors for the transplantation of solid organs and bone marrow. For solid organ transplants, HLA matching has reduced graft rejection and demonstrated better graft survival, with closer matches (6/6 for HLA-A, -B, and -DR) associated with more beneficial outcomes. This effect is in addition to the benefits of using immunosuppressants (e.g., cyclosporin or tacrolimus) and ABO compatibility matching. The benefit of HLA-A, -B, and -DR matching on graft survival has been demonstrated, especially for second kidney transplants ([348], [349], [350], [351] and [352]). Although blood transfusion before kidney transplantation may be beneficial due to immunosuppressive mechanisms, leukocyte-depleted blood does not demonstrate the same effect, which suggests an immunosuppressive effect of the transfused white cells ([353], [354] and [355]). ABO compatibility does not play a major role in bone marrow transplantation compatibility. This contrasts with solid organ transplantation. However, HLA compatibility has a significant benefit. Transplant success relates directly to the HLA compatibility of the donor and recipient. Transplants with marrow donated from HLA-identical siblings shows lower incidences of delayed engraftment or rejection and GVHD than transplants with marrow from non–HLA-identical relatives ([356], [357], [358] and [359]). However, it is now clear that other genetic factors contribute to transplant success. The increased use of bone marrow transplantation for the treatment of certain hematologic diseases has required an increase in the number of unrelated marrow donors. Donor registries provide access to compatible donors for those patients without HLA-identical siblings. The use of marrow from unrelated HLA-A, -B, and -DR–identical donors has not eliminated the risk of acute GVHD and graft rejection ([360], [361] and [362]). More precise matching using molecular techniques has demonstrated that although HLA-DP may not play a major role, DRB1, DQB, and HLA-C matching can result in decreased risk of graft failure and GVHD ([363], [364] and [365]).

Association with Disease Many diseases have been associated with specific HLA-A, -B, -C, and -DR antigens and with complement allotypes and HLA haplotypes (Table 23.13) ([366], [367], [368], [369], [370], [371] and [372]). The first of these associations was reported for Hodgkin disease, with HLA typing demonstrating a higher frequency of A1, B5, and B18 in these patients. However, the A1, B8 haplotype is prevalent in long-term survivors, suggesting that it may have a protective effect ([373]). Many of the early associations with disease states were with the HLA-B antigens, such as ankylosing spondylitis and HLA-B27 ([374], [375]). However, the use of molecular techniques has now demonstrated strong associations of some class II molecules with certain diseases, including those with an autoimmune mechanism. Three loci, DQB1, DQA1, and DRB1, may be associated with susceptibility or resistance to insulin-dependent diabetes mellitus. Patients with DRB1*0405, 0401, or 0402 are susceptible to insulin-dependent diabetes mellitus, whereas those with DRB1*0404, 0403, or 0406 are resistant to the disease ([376], [377]). Whereas 95% of patients with insulin-dependent diabetes mellitus express HLA-DR3 or -DR4, those individuals heterozygous for both antigens have an increased risk of developing the disease ([378]). There is the possibility that the a- and ß-chains from each haplotype might form pairs of molecules with modified peptide-binding properties in concert with dosage effects that may play a role in accelerating the disease. The importance of specific peptide-binding grooves, possibly controlled by amino acids at key positions, is also demonstrated in celiac disease and rheumatoid arthritis ([379]).

TABLE 23.13. Associations between Certain HLA Markers and Disease

Disease	Associated HLA Antigens and Alleles	Relative Risk
Birdshot retinochoroidopathy	A29	109.0
Ankylosing spondylitis	B27	87.4
Reactive arthropathy, including Reiter syndrome	B27	37.0

Dermatitis herpetiformis	DR3	15.9
Idiopathic membranous glomerulonephritis	DR3	12.0
Celiac disease	DR3	10.8
	DR7, DR11	6.0–10.0
	DR7, DQB1*0201	Not assessed
	DR11, DQA1*0501	
	DQA1*0501	
	DQB1*0201	
Sicca syndrome	DR3	9.7
Idiopathic Addison disease	DR3	6.3
Systemic lupus erythematosus	DR3	5.8
Grave disease	DR3	3.7
Myasthenia gravis	DR3	2.5
	B8	3.4
Type 1 diabetes mellitus (insulin dependent)	DR3	3.3
	DR4	6.4
	DR2	0.19
	DQB1*0302	9.5
	DQB1*0201	2.4
	DQB1*0602	0.15
	DRB*0101	Not assessed
	DRB*0101	
Goodpasture syndrome	DR2	15.9
Multiple sclerosis	DR2	4.1
	DRB1*1501	Not assessed
	DRB5*0101	
	DQB1*0602	
Pemphigus vulgaris (Ashkenazi Jews)	DR4	14.1
Postpartum thyroiditis	DR4	5.3
Rheumatoid arthritis	DR4	4.2
Behçet syndrome	B51	3.8
Psoriasis vulgaris	Cw6	13.3
Hashimoto disease	DR11	3.2

Modified from Klein J, Sato A. The HLA system. N Engl J Med 2000;343:782–786.

A specific HLA or haplotype is generally associated with susceptibility or resistance to a disease and does not directly play a role in the disease itself. Sometimes, the disease gene may be linked to HLA, probably due to linkage disequilibrium ([380], [381] and [382]). This is supported by observations of diseases associated with certain HLAs or haplotypes only within a family, but not in the general population. These associations may play a role in diseases such as leprosy and in MHC-linked immune response genes in PL ^{A1}-negative/HLA-B8-DR3–positive individuals who develop PTP ([383], [384]). Although a number of mechanisms have been proposed to explain the association between certain diseases and specific HLAs, including cross-reactive antibody responses, linkage of an HLA locus with a non-HLA disease-associated gene, regulation of T-cell development, thymic selection of T-cell receptor repertoire on HLA molecules with self-peptides, and interaction of class II HLA molecules with superantigens (cross-reactive), the exact mechanisms are unknown.

Transfusion Medicine

Until Harvey's doctrine of the circulation of blood was proposed in 1616, the concept of blood transfusion had no rationale. The concept of transfusion therapy

developed once it had been accepted that blood circulated and that the intravascular space might be replenished with fluids introduced from outside the body. The first transfusion of blood in humans occurred in 1667 ([1]). Progress was slow thereafter because of the complexities of transfusion, which we now recognize, particularly the incompatibility of interspecies transfusions ([2]). By the early twentieth century, transfusion as a therapeutic measure was still cumbersome and risky, but during and shortly after World War I, technical progress permitted the rapid expansion of blood banking and of blood transfusion as a therapeutic modality ([3]).

The understanding of genetic differences between individuals, pioneered by Landsteiner in 1901, was most important. The development of anticoagulants, blood preservatives, and sterile techniques allowed the collection and preservation of donor blood for later use. More recently, component therapy has broadened the application of transfusion therapy from blood volume support to the specific replacement of most blood cells and many plasma proteins. Technical advances continue, particularly in the more efficient use of components and fractions of donor blood, improvement of donor screening techniques, development of methods of pathogen inactivation, improved immunologic matching of donor blood products with the recipient, and development of recombinant products.

Transfusion medicine has recently been recognized as a specialty of its own. The acquired immunodeficiency syndrome (AIDS) epidemic and the transmission of other infectious agents through blood transfusion have revolutionized the practice of transfusion medicine. Increasing public awareness of the risks of transfusion has resulted in a more stringent approach to donor selection and testing and preparation of blood and its components, and it has led to an increase in the use of autologous blood. Blood centers are licensed in accordance with the manufacturing guidelines of the Food and Drug Administration (FDA) in the United States or its counterparts in other countries. Additional professional standards are set by the American Association of Blood Banks (AABB) ([4]). Blood centers must follow good manufacturing practices and must maintain uniform standards to maintain their licenses. Improved donor screening has resulted in a dramatic improvement in the safety of blood components. However, prudent use of these agents requires an understanding of their indications, limitations, potential benefits, and hazards ([5], [6], [7], [8] and [9]).

BLOOD DONATION AND COLLECTION

Donor Selection

In the United States, donor eligibility criteria are established and strictly enforced by the FDA. Donor selection is undertaken with two goals in mind: to protect the health of the donor by ensuring that a donation does not place the donor at risk, and to protect the recipient by ensuring that the donor meets all health and screening criteria so that the risk of transmitting infectious agents or causing other adverse events is minimized ([4], [8], [10]).

In the United States, the majority of fresh blood products are collected from unpaid volunteers. The paying of donors for fresh blood products for transfusion was discontinued after studies in the early 1970s demonstrated that paid donors had a substantially higher prevalence of hepatitis ([11], [12] and [13]). However, commercial fractionators continued to pay plasma donors.

Donor Identification and Registration

Donor registration must be done in a way that permits accurate identification of the potential donor, including full name, date of birth, address, and telephone number, so that the donor can be traced if required. Records must be sufficient to link a donor to all previous donations and all prior test results. These records must be kept for a minimum of 10 years.

Donor Information

The donor must be given educational material that describes the signs and symptoms of AIDS and the activities associated with an increased risk of acquiring human immunodeficiency virus (HIV). The donor must be informed that donor testing may not detect all infections, and that individuals who have engaged in risk behavior should not donate ([10]).

Donor Health History

Information to be elicited is defined by the FDA and the AABB. Donors are screened by appropriately trained personnel who administer a standardized questionnaire to each donor before each donation. The history includes a review of current health status to ensure that the donor is free of current signs of infection and that the donor's cardiovascular status is sufficient to tolerate an acute blood volume loss of 10 to 15%. The donor is questioned about recent exposures to blood, potential exposures to HIV or hepatitis, sexual contact with individuals at risk for HIV, a history of needle sharing by the donor or sexual partners, a history of travel to or residence in areas endemic for malaria or variant Creutzfeldt-Jakob disease, medications, and immunizations. The donor must be medically fit and must not have any identifiable risk factors that could result in an adverse outcome in either the donor or the recipient.

The donor must meet certain requirements of age and vital signs. The hemoglobin must be at least 125 g/L. Donor weight must be sufficient so that the donation constitutes no more than a 15% loss of blood volume. There must be no evidence on examination of the arms that the donor has ever used parenteral drugs other than those prescribed by a physician ([4]).

Confidential unit exclusion allowing donors to privately designate that their blood not be used for transfusion was initiated as a result of the AIDS epidemic. Although initially mandated by the FDA, confidential unit exclusion is now a voluntary option for blood centers ([4], [10]).

Informed Consent

The donor must sign the health history form indicating that the questions have been answered truthfully, that the donation process is understood, and that the donor consents to testing for infectious agents that can be transmitted by blood transfusion including HIV and hepatitis ([8], [10]).

Blood Collection Process

Phlebotomy and collection of blood proceed only if the donor appears suitable after predonation screening. Blood is collected from the donor in accordance with established standards ([4]). Blood may be collected either manually or using automated collection devices.

Whole Blood (Manual) Collection

The phlebotomy site is swabbed with a disinfectant ([14]). Using a large bore needle to allow rapid flow of blood into the anticoagulant, blood is collected into a primary sterile plastic collection bag containing a measured volume of anticoagulant. The volume of blood drawn is standardized for the collection bag used (either 450 or 500 ml); the amount collected is controlled by scales that discontinue flow when the desired weight of blood is collected. The blood and anticoagulant are mixed gently during the collection process. At the beginning or end of the collection process, specimen tubes for testing of the donor are filled. Because most whole blood units will be separated into components, the primary bag has one to three satellite bags attached to allow separation of components while maintaining a sterile closed system. The collection tubing is heat-sealed into segments that are left attached to provide samples for crossmatching. The whole blood is transported to a laboratory where it can be separated into its components (red cells, plasma, platelets) by centrifugation.

Blood Component Separation

Whole blood is centrifuged to sediment the red blood cells (RBCs) (Fig. 24.1). Most of the supernatant “platelet-rich plasma” is pushed off through integrally attached tubing into a sterile satellite bag. The bag containing platelet-rich plasma may be centrifuged at a higher rate to sediment the platelets. All but 50 ml of plasma is then removed into a third satellite bag. The platelet pellet is resuspended in the residual 50 ml of plasma, called a *platelet concentrate*. The plasma is frozen at -18°C or lower. If frozen within 8 hours of collection, it is called *fresh frozen plasma* (FFP). FFP may be further processed into cryoprecipitated antihemophilic factor (AHF) (“cryo”) by subsequently thawing the FFP at 1° to 6°C, removing the supernatant, and refreezing the cold, insoluble cryoprecipitate ([8]). The supernatant from the

cryoprecipitate preparation, depleted in factor VIII and fibrinogen, may be labeled as plasma, cryoprecipitate reduced ([8]).

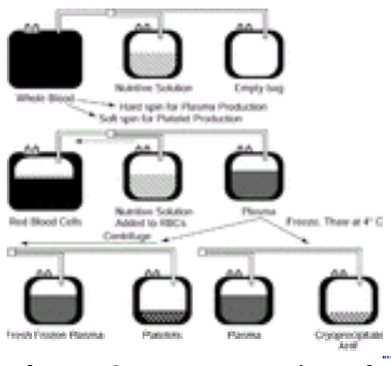

Figure 24.1. Preparation of components from a whole blood donation. AHF, antihemophilic factor; RBC, red blood cell. (Reprinted from Jeter EK, Spivey MA. Blood components and their use. In: Introduction to transfusion medicine: a case study approach. Bethesda, MD: American Association of Blood Banks Press, 1996:5, with permission.)

Terminology

The 450 or 500 ml of whole blood in the original collection bag is referred to as *one whole blood unit*, and each component made from that unit is defined as one “unit” of that component. Because each whole blood unit constituted approximately 10% of a donor's blood volume, each component can be considered roughly 10% replacement therapy for an adult patient.

“Closed” versus “Open” Systems

If blood component manipulation is performed without opening the system to air, all blood components may be stored to the limit of their viability. If the blood bag or tubing is entered, however, the system is considered potentially open to bacteria, and the product is assigned a 4-hour outdate if stored at room temperature or 24 hours if kept refrigerated. Devices are now available that use high-temperature welds to attach additional containers or tubing to the original container in a way that prevents entry of bacteria. With these “sterile connection devices,” blood components may be split into aliquots, filtered, or otherwise manipulated without loss of shelf life ([8]).

Automated Blood Collection and Separation Devices: Apheresis

The word *apheresis* is derived from a Greek word that means to separate or to take away. Initially, it referred to a manual process in which whole blood was withdrawn from the donor, centrifuged, plasma retained, and red cells returned to the donor. In 1914, Abel experimentally removed plasma from anephric dogs, and replaced it with crystalloid ([15]). It was not until the advent of plastic bags that manual apheresis could be used routinely in humans. Between 1950 and 1980, manual apheresis was the primary source of plasma for fractionation.

The development in the 1970s and 1980s of automated cell separator devices has changed the approach to apheresis and has resulted in the routine application of this methodology to the collection of blood components for transfusion, as well as the treatment of certain diseases ([8] , [16]).

In discontinuous centrifugal devices, anticoagulated blood is collected into a disposable bowl. When the bowl is spun, centrifugal force causes the red cells to move to the outside of the bowl, platelet-rich plasma to move to the inside, and white blood cells (WBCs) (buffy coat) to move in between. Using optical detectors, the desired component can be pumped into an attached plastic blood bag, and the remaining components can be reinfused into the donor.

There are now continuous flow devices in which incoming blood is continuously subjected to a centrifugal force. A standing cell gradient is established. The fraction(s) to be removed is pumped into a bag, and the rest is reinfused continuously. The volume of blood in the extracorporeal circuit is lower than with the discontinuous technique, and the procedure is faster. An increasing proportion of blood components are being collected using automated cell separation. These devices can collect multiple unit-equivalents of platelets or plasma from one donation. Apheresis is the primary source of plasma for fractionation because multiple units of plasma may be obtained without causing iron deficiency in the donor. Apheresis technology is commonly used to collect platelets because a full therapeutic dose of platelets (equivalent to six whole blood–derived platelet units) or even as many as three therapeutic doses (equivalent to 18 whole blood–derived units) can be obtained from one apheresis donation. If a donor is large enough, it may be possible to obtain two RBC unit-equivalents from one apheresis donation, returning plasma, platelets, and saline to the donor to minimize volume loss. Some apheresis devices can be programmed to collect any desired combination of red cells, plasma, or platelet products from the same donation. Apheresis technology is also used for therapeutic plasma exchange (TPE) and for collection of peripheral blood hematopoietic progenitor cells (HPCs), as discussed later in this chapter.

Membrane filtration can be combined with apheresis to collect plasma. Blood is pumped over a membrane with a specific pore size that permits passage of plasma but not cells. Such devices have been used to collect plasma for fractionation or to perform TPE.

Complications of Donation

The most common complication of donation is a hematoma, which may be striking but resolves spontaneously. Most individuals tolerate whole blood donations well, compensating for the acute volume loss by increasing heart rate and increasing vascular resistance. Approximately 2 to 5% of donors, however, experience vasovagal reactions, with syncope occurring in 0.1 to 0.3% ([17]). Apheresis donors face the additional potential complication of transient hypocalcemia from the citrate infused when anticoagulated blood components are returned to them from the apheresis device. Symptoms consist of tingling or muscle cramps. Citrate symptoms are treated by slowing the flow of the device or giving the donor oral calcium supplements ([16]). Intravenous calcium infusions are needed only during prolonged apheresis procedures such as those for HPC collection.

Donor Testing

Every blood donation undergoes a series of tests to determine its suitability for transfusion. In the United States, the following tests must be performed on every unit collected: ABO group and Rh type, red cell antibody screen, tests for infectious markers including hepatitis B surface antigen (HBsAg) and antibodies to hepatitis B core (HBc) antigen, hepatitis C, HIV-1 and -2, human T-cell lymphotropic virus (HTLV)-I and -II, and a serologic test for syphilis. Tests for hepatitis C virus (HCV) and HIV nucleic acid were implemented under investigational protocols and will be required when licensed. These tests are performed on pools of 16 to 24 donor specimens, as nucleic acid detection methods remain too laborious to apply to individual donations. Nucleic acid testing for other viruses is likely to be implemented in the future.

Blood and its components are not released for transfusion unless all the tests for infectious markers are negative ([4]). Because of the extent of testing, there is typically a delay of 24 to 48 hours from the time of collection until a component can be released for transfusion.

RED BLOOD CELL PRESERVATION AND STORAGE

Blood cells are isolated and preserved in such a way that they remain functional after transfusion. This involves three distinct but interrelated processes: anticoagulation, preservation of cell viability so that survival after transfusion is satisfactory, and preservation of cell function.

Anticoagulant/Preservative Solutions

Blood banking and transfusion did not become practical until the development of anticoagulant and preservative solutions capable of preserving red cells in viable form.

The anticoagulant used for essentially all transfusable blood components today is citrate, which chelates ionized calcium in donor blood, making it unavailable to the calcium-dependent stages of coagulation. After transfusion, citrate is readily metabolized into bicarbonate by the liver of the recipient ([18]).

During World War I, a solution of sodium citrate and glucose was developed in which blood could be stored for several days, and this citrated blood was used to treat shock in British and American soldiers ([18]). During World War II, it was found that the addition of citric acid [acid citrate dextrose (ACD)] permitted preservation of red cell viability for up to 21 days. Continuing efforts were made to prolong red cell viability. Citrate phosphate dextrose (CPD) solution ([19]) is a modified ACD, with added NaH_2PO_4 and a higher pH. Stored in CPD, red cell phosphate and 2,3-diphosphoglycerate (2,3-DPG) are maintained at a higher concentration than in ACD. However, red cell viability remains limited to 21 days.

In the 1950s, it was noted that red cells that had lost their adenosine triphosphate (ATP) did not survive well during storage ([20]). Nakao ([21]) demonstrated that the ATP content and posttransfusion viability of aged red cells could be regenerated by the addition of adenine, which allows the red cells to maintain the adenine nucleotide pool. Simon et al. ([22]) described the maintenance of red cell ATP levels using preservatives containing glucose and low concentrations of adenine. These studies eventually led to the adenine-supplemented anticoagulant preservatives now in use ([18], [23]).

CPDA-1 is CPD supplemented with adenine. It was made available in the United States in 1978, although it had been used extensively in Europe for several years before then. Initial concerns about potential toxicity of adenine in humans have proved to be unfounded. CPDA-1 is now one of the standard anticoagulant-preservative solutions in clinical use. The shelf life of RBC concentrates in CPDA-1 is 35 days ([4]).

Packed Red Cells versus Red Cells in Additive Solutions

After whole blood is collected into CPD or CPDA-1, the red cells may be concentrated by centrifugation and removal of most of the plasma (“packed RBCs”). Approximately 20% of the anticoagulant-containing plasma must be left with the red cells to provide metabolic substrate for the red cells during storage. Another approach to red cell preservation involves virtually complete removal of the anticoagulated plasma from the red cells (“dry pack”), followed by resuspension of the red cells in 100 ml of an additive solution. Such additive solutions contain saline, adenine, and glucose, with or without mannitol to decrease hemolysis. The duration of red cell storage in additive solutions is extended to 42 days ([8], [18]). Red cells in additive solution are now the most common preparations available for transfusion.

Red cells collected in any of the anticoagulants and preservatives must be stored at 1° to 6°C to maintain optimum function ([4]).

Changes in Red Cells during Storage

When blood is stored in liquid medium, the red cells undergo a series of biochemical and structural changes that have major influences on their viability and function after transfusion ([18], [24], [25] and [26]).

STRUCTURAL CHANGES A number of red cell changes contribute to decreased cell viability after storage ([24], [25] and [26]). Soon after storage begins, red cells, which normally have a disc shape, become spherical with surface projections (spheroechinocytosis). Later defects include loss of membrane lipids and a small amount of protein, as well as other alterations in the structural proteins. Loss of membrane deformability correlates closely with viability ([24]). The more severe membrane changes are irreversible and probably contribute to the decrease in posttransfusion survival of red cells ([25]). The blood bag plasticizer appears to influence membrane stability. Red cells are currently stored in polyvinyl chloride (PVC) bags that contain di-2-ethylhexylphthalate (DEHP) as a plasticizer. Morphologic deterioration is greater in red cells stored in containers that do not contain DEHP, with increased red cell hemolysis and increased loss of deformability, suggesting that DEHP has a direct stabilizing effect on the membrane ([27], [28]). Adding DEHP can prevent deterioration of stored red cells, with many of the spherical cells reverting to normal discoid morphology ([29]). Concerns, however, have been raised about potential toxic effects of DEHP, and efforts are being made to identify alternative containers with equivalent red cell storage capabilities ([30]).

BIOCHEMICAL CHANGES During storage, red cells metabolize glucose and produce lactic and pyruvic acid. This results in a drop in pH and a decrease in the rate of glycolysis. As glycolysis slows, the red cells become depleted of ATP. Because human red cells contain no enzymes with which to synthesize adenine or other purines *de novo*, the nucleotide pool gradually becomes exhausted. In the presence of adenine, ATP may be regenerated. Understanding this has led to methods for prolonging red cell storage by the addition of exogenous adenine and inorganic phosphate, both of which improve the cells' ability to regenerate ATP ([18]). Red cells lose potassium and gain sodium during storage. This is because the Na^+-K^+ gradient is normally maintained by a Na^+-K^+ ATPase that does not function well at 4°C. Gamma irradiation of red cells to prevent graft-versus-host disease (GVHD) (see section Graft-Versus-Host Disease) doubles the rate of potassium leakage ([31], [32]). Red cells reabsorb potassium after transfusion ([33]).

RED CELL 2,3-DIPHOSPHOGLYCERATE One of the significant changes in stored red cells is 2,3-DPG depletion, which is not related to red cell viability but to the ability of the red cells to deliver oxygen ([18], [34], [35]). When blood is preserved in ACD, 2,3-DPG drops to below 50% within 48 hours. In CPD-, CPDA-1–, and additive solution–stored red cells, 2,3-DPG is better maintained but is essentially depleted after approximately 2 weeks. 2,3-DPG levels improve rapidly within the first 6 hours after transfusion, with return to near-normal levels by 24 hours after transfusion ([33], [36]). The clinical implications of transfusion of blood with decreased 2,3-DPG content remain controversial ([18], [37], [38] and [39]). The oxygen dissociation curve of cells that are 2,3-DPG–depleted is shifted to the left, resulting in increased hemoglobin oxygen affinity and decreased tissue oxygenation. These changes are thought to be of limited clinical significance because the stored red cells rapidly regain their 2,3-DPG in the circulation. They may be relevant only in a select group of patients such as those in shock. However, the acidosis that may be present in such patients shifts the oxygen dissociation curve to the right. Because of such compensatory mechanisms, the need for blood specifically altered to preserve or reconstitute red cell 2,3-DPG has not been demonstrated.

Rejuvenating Solutions

A number of chemical agents—dihydroxyacetone ([40]), pyruvate ([41]), phosphoenolpyruvate ([42]), and inosine ([43])—are capable of maintaining near-normal red cell 2,3-DPG content during storage or of replenishing 2,3-DPG after storage. Although none of these chemicals are likely to be used in transfusion because of their side effects, studies with these agents have resulted in the development of rejuvenating solutions.

Rejuvenating solutions contain pyruvate, inosine, glucose, phosphate, and adenine and may be added to red cells up to 3 days after the expiration date. Treatment with rejuvenating solutions corrects the metabolic defects of the red cell, with a return to normal levels of ATP and 2,3-DPG. These rejuvenated red cells may either be washed and transfused within 24 hours or frozen for later use ([8]). Such rejuvenated red cells have a normal survival and oxygen affinity ([44], [45]).

In Vivo Recovery of Stored Red Cells

After transfusion of stored blood, red cells that have developed lethal degrees of damage are removed promptly from the circulation of the recipient. Red cells that survive the first 24 hours after transfusion have normal survival thereafter ([46], [47], [48] and [49]). Therefore, the criterion by which the adequacy for transfusion of banked blood is assessed is the proportion of transfused red cells that remain in circulation at 24 hours after transfusion. Generally, 75% survival at 24 hours is considered evidence of adequate viability; the anticoagulant systems in current use readily achieve this goal. Work to develop optimal additive solutions capable of maintaining red cell ATP and 2,3-DPG levels and to prolong red cell storage time continues.

Frozen Red Cells

Red cell freezing is a labor-intensive process that is used primarily for storing rare blood types or prolonged storage of autologous red cells in the event of planned or postponed surgery. Glycerol is gradually added to the red cells as a cryoprotectant to a final concentration of 40% (weight/volume). The cells are then frozen at -65°C or colder for up to 10 years. Immediately after thawing, an automated cell processor must be used to wash the glycerol from the cells. The washed cells are resuspended in isotonic saline and glucose. In most cases, postthaw storage is limited to 24 hours because an open system is used to process the cells ([8]).

Recently, a closed cell processing system that maintains sterility was developed; cells glycerolized and deglycerolized with this system can be sterilely resuspended in an additive solution and stored in the refrigerator for up to 2 weeks after thawing ([50]).

BLOOD COMPONENT MODIFICATION

Leukocyte Reduction

When whole blood is separated by centrifugation, WBCs sediment at the interface between red cells and platelet-rich plasma. Therefore, WBCs typically contaminate both red cell and platelet components, with concentrations of WBCs approximately 10^9/product. WBCs in blood components can mediate febrile transfusion reactions and stimulate HLA alloimmunization in transfusion recipients ([51]). Therefore, it may be desirable to remove the WBCs from transfusable blood components.

Historically, several methods have been used to reduce the number of WBCs in transfusable blood components. Relatively nonspecific methods were used initially, including saline washing of red cells or physical separation of RBCs from the WBC layer (buffy coat) ([51]). Later, a microaggregate filter was used to remove WBCs after centrifugation ([52]). These methods resulted in white cell reduction of 70 to 90% and were effective in preventing most febrile reactions to red cells. Freezing and deglycerolization of red cells have also been used to remove WBCs and result in approximately 2-log WBC removal. Most recently, selective leukoreduction filters have been developed that can remove 3-logs or more WBCs from blood components. These synthetic fiber filters remove WBCs by a combination of mesh density, chemical attraction, and active adhesion ([51]). All leukocyte-reduced red cells are now produced using these special filters and, by FDA criteria, contain fewer than 5×10^6 WBCs/unit and at least 85% of the original RBC component.

Leukofiltration of RBC components may be performed at the blood collection center, in the hospital transfusion service, or at the bedside. In practice, most filtration is currently performed by the blood collection center. This provides a high level of assurance that the filtration is performed properly. The clinical importance of leukoreducing RBCs before storage, as opposed to after storage, is not well established. Although WBCs can produce cytokines in blood products that are stored at room temperature (i.e., platelets), the levels of cytokines in refrigerated RBC products are probably too low to cause febrile transfusion reactions ([53] , [54]). Removal of WBCs from red cell products before storage provides a theoretical benefit in that WBC breakdown products in the blood component are reduced, and there is some evidence that red cell viability is better preserved if leukoreduction is performed before storage ([51]). However, there has been no demonstrated *clinical* benefit from the removal of WBCs from red cell products before storage, compared to poststorage or bedside filtration.

Leukoreduction filters are also available for platelet components. Whole blood–derived platelet concentrates contain fairly large numbers of WBCs, and it appears that many of the febrile transfusion reactions to these products are due to cytokines produced by the WBCs in these products during room temperature storage ([55] , [56] , [57] and [58]). Therefore, removal of WBCs from whole blood–derived platelet concentrates *before* storage would be ideal. In the United States, the FDA does not permit pooling of platelet concentrates before storage; therefore, each platelet concentrate would have to be leukofiltered individually. In other countries, platelet concentrates may be pooled, leukofiltered, and then stored. It should be noted that apheresis platelets usually contain very few WBCs and usually qualify as leukoreduced ($<5 \times 10^6$ WBCs) without need for filtration.

Leukoreduced products are indicated for patients with a history of febrile, nonhemolytic transfusion reactions to reduce the risk of HLA alloimmunization and as an alternative to cytomeg-alovirus (CMV) antibody screening of donors to reduce the risk of transfusion-transmitted CMV. Although the use of leukoreduced products is becoming increasingly widespread, the medical necessity of universal leukoreduction remains controversial ([59]).

Washed Products

Saline washing can be used to reduce the amount of plasma in cellular blood products. Automated cell washers similar to aphe-resis machines are the most efficient method, capable of removing approximately 99% of plasma proteins from red cell products ([8]). Although cell washing was previously used also as a means of leukocyte reduction, it is no longer the most effective method for this purpose. Today, washing is primarily used to prevent severe allergic reactions, which are thought to be triggered by donor plasma proteins. Washing on an automated cell processor takes 30 to 45 minutes/unit. Because the washing procedure is usually performed in an “open” system, the red cells have only a 24-hour shelf life after washing. A closed processing system has been developed that may permit longer storage of washed cells ([50]). Although many facilities perform red cell washing, few offer washed platelets. Use of automated cell washers to wash platelets has been described ([8]). However, in practice, it may be difficult to ensure adequate platelet recovery and viability after washing.

Irradiation of Blood Products

Gamma irradiation of cellular blood components is used to prevent transfusion-related GVHD by impairing the proliferative capacity of lymphocytes in the blood component. The recommended dose for the irradiation of blood and blood products is 2500 cGy at the center of the irradiation field, with a minimum dose of 1500 cGy at any point in the field ([4] , [60]). This dose of radiation has no significant adverse effect on red cell, platelet, or granulocyte function. However, there are changes in the red cell membrane that result in an increased loss of potassium from the cell, limiting the storage time of red cell concentrates to 28 days ([31] , [32]). The amount of accumulated free potassium in the supernatant of irradiated red cells may be clinically important in massive transfusion, especially in the neonate ([61]). It may be reasonable to consider performing irradiation just before transfusion, or washing stored irradiated products, if massive transfusion of irradiated products is required for a patient at risk for hyperkalemia.

It should be noted that the dose of irradiation used for cellular blood components is not sufficient to inactivate pathogens ([62]). The irradiation doses required for pathogen inactivation would irreparably damage blood components.

USE OF BLOOD COMPONENTS

Table 24.1 lists the blood components available for clinical use and briefly summarizes the indications for use of each. The use of each component is discussed in detail below.

TABLE 24.1. Blood Components and Indications for Use

Component	Composition	Volume	Indications and Expected Benefit
Whole blood	RBC and plasma (approx. Hct, 40%); WBCs; platelets [a]	500 ml	To increase red cell mass and plasma volume (plasma deficient in labile clotting factors V and VIII); for hypovolemic anemia, massive transfusion, or exchange transfusion in neonates
Packed RBCs	RBC and reduced plasma (approx. Hct, 75%); WBCs; platelets [a]	250 ml	To increase red cell mass in symptomatic anemia; 10 ml/kg raises Hct by 10%
RBCs, adenine-saline added	RBC and 100 ml of additive solution (approx. Hct, 60%); WBCs; platelets [a]; little plasma	330 ml	To increase red cell mass in symptomatic anemia; 10 ml/kg raises Hct by 8%
RBCs, leukocytes reduced (prepared by filtration)	>85% original volume of RBCs; $<5 \times 10^6$ WBCs	>85% of original volume	To increase red cell mass; $<5 \times 10^6$ WBCs to decrease the likelihood of febrile reactions, immunization to leukocytes (HLA antigens), or CMV transmission
RBCs, washed	RBCs (approx. Hct, 75%); reduced WBCs; no plasma	225 ml	To increase red cell mass; reduce risk of allergic reactions to plasma proteins; or reduce free potassium dose
RBCs, frozen; RBCs, deglycerolized	RBCs (approx. Hct, 75%); $<5 \times 10^6$ WBCs; no platelets; no plasma	225 ml	To increase red cell mass; minimize febrile or allergic transfusion reactions; use for prolonged RBC blood storage

Granulocytes, pheresis	Granulocytes (>1.0 × 10^{10} polymorphonuclear cells/unit); lymphocytes; platelets (>2.0 × 10^{11}/unit); some RBCs	220 ml	To provide granulocytes for selected patients with sepsis and severe neutropenia (<0.5 × 10^{9}/L)
Platelet concentrates	Platelets (>5.5 × 10^{10}/unit); RBCs; WBCs; plasma	50 ml	Bleeding due to thrombocytopenia or thrombocytopathy; 1 unit/10 kg raises platelet count by 17–50 × 10^{9}/L
Platelets, pheresis	Platelets (>3 × 10^{11}/unit); RBCs; WBCs; plasma	300 ml	Same as platelets; sometimes HLA matched; benefit is equivalent to 6 platelet concentrates
Platelets, leukocytes reduced	Platelets (as above); <5 × 10^{6} WBCs/final dose of pooled or pheresis platelets	300 ml	Same as platelets; <5 × 10^{6} WBCs to decrease the likelihood of febrile reactions, alloimmunization to leukocytes (HLA antigens), or CMV transmission
FFP; thawed plasma	FFP: all coagulation factors; thawed plasma: reduced factors V and VIII	200 ml	Treatment of some coagulation disorders; 10 ml/kg of FFP raises factor levels by a maximum of 25%[b]
Cryoprecipitated antihemophilic factor	Fibrinogen; factors VIII and XIII; von Willebrand factor	15 ml	Deficiency of fibrinogen, 1 unit/5 kg raises fibrinogen 70 mg/dl; also used for factor XIII replacement; not first choice therapy for hemophilia A, von Willebrand disease, topical fibrin sealant

approx., approximate; CMV, cytomegalovirus; FFP, fresh frozen plasma; Hct, hematocrit; RBC, red blood cell; WBC, white blood cell.

[a] WBCs and platelets are nonfunctional.

[b] Lower recovery of some factors because of diffusion from the vascular space.

Modified from Triulzi DJ, ed. Blood transfusion therapy: a physician's handbook, 7th ed. Bethesda: American Association of Blood Banks, 2002.

ALTERNATIVES TO ALLOGENEIC DONOR BLOOD

Allogeneic blood donation is blood donated by one individual that is intended for transfusion into a different individual. This blood represents the majority of blood transfused in the United States. Directed (or designated) donation is a donation made by a friend or family member of a patient, intended for transfusion specifically into that patient. Autologous blood donation is blood donated by a patient, intended for transfusion back into the same patient.

Autologous Blood Transfusion

Blood for autologous transfusion may be collected pre- or perioperatively. In the 1980s and early 1990s, interest in and requests for autologous collections increased significantly. This was a result of the AIDS epidemic and the awareness that transfusion-transmitted infections cannot be totally eliminated by donor screening and testing. However, interest in autologous blood donation decreased in the late 1990s and early 2000s, possibly due to the substantial increase in safety of the blood supply ([63]).

Preoperative Autologous Blood Donation

Preoperative autologous blood donation is most often used for patients who are likely to require transfusion during elective surgery and when there is minimal risk to the patient by undergoing this procedure ([64], [65] and [66]). It is also used in patients for whom crossmatch-compatible blood cannot otherwise be made available, as in patients with rare blood groups or with multiple alloantibodies. For autologous collections, the donor selection criteria are not as stringent as for allogeneic donors. However, patients with advanced age or significant cerebral or cardiac disease such as arrhythmias or unstable angina must be evaluated before they are enrolled in an autologous donation program. Children are also eligible for autologous blood donation, but the volume of blood collected and anticoagulant used must be adjusted to body weight. The eligibility of each patient must be carefully assessed.

Autologous blood for transfusion during elective surgery can be obtained by collecting blood units from the patient on several occasions preoperatively. The hemoglobin concentration must be at least 110 g/L before the collection of each unit, and if not contraindicated, the patient/donor should receive iron supplements ([65]). An autologous donor may donate blood every 3 days as long as the donor's hemoglobin remains at or above 110 g/L. This “aggressive” donation schedule stimulates a more substantial endogenous erythropoietin response, resulting in more autologous units collected or a higher patient hemoglobin at surgery ([67]).

Some of the limitations of a preoperative autologous collection program are the condition of the patient, the storage interval, and the erythropoietic response, as well as socioeconomic, cultural, ethnic, and gender issues ([64], [65], [66] and [67]). In most instances, units of blood are stored in the liquid state for 35 to 42 days. They may be frozen if a longer interval between donation and surgery is required, but this significantly increases the cost and is not routinely recommended ([68], [69]).

All autologous collections must be tested for ABO group and Rh type. The units must be labeled *For Autologous Use Only*. There must also be a method of confirming identity and compatibility of the autologous unit with the recipient ([4]). If autologous blood is to be transfused at an institution that is not the collecting facility, the blood unit must be tested for transfusion-transmitted infectious diseases ([4]). Medical institutions vary in their policies and procedures concerning the receipt, storage, and transfusion of autologous blood with positive infectious disease markers. Although the presence of a positive infectious marker does not preclude the patient from being in an autologous program, some institutions do not release such units because of the risk to health care workers or the risk of accidental transfusion of the unit to the wrong patient. Patients with positive infectious markers are thereby excluded from an autologous program in these hospitals.

If units with positive infectious markers are released for transfusion, a biohazard label must be attached, and the units must be properly disposed of if they are not used. Proper labeling minimizes the risk of an infectious unit accidentally being transfused to the wrong patient.

Disadvantages of Autologous Donation

Autologous transfusions cannot be considered risk-free. Some of the disadvantages of an autologous program include the logistics involved in organizing the procedure, collection of autologous blood for questionable indications, the underuse of predeposited autologous blood, and overtransfusion because of availability ([70]). Because the stringent donor criteria used in the selection of volunteer allogeneic blood donors do not apply, there are increased numbers of adverse reactions including hospitalization in this group of donors. There is a reported 12-fold increase in the number of autologous donors hospitalized after a donation as compared to allogeneic donors, with an increased risk in the elderly ([71]). Another disadvantage is the development of anemia as a result of repeated phlebotomy, especially if the last unit of autologous blood is collected fewer than 15 days preoperatively. The requirement for both autologous and allogeneic blood increases in such patients ([66], [72]). It may be preferable to leave the blood *in vivo*.

Transfusion reactions such as bacterial contamination, febrile nonhemolytic transfusion reactions (FNHTRs), allergic reactions, and volume overload can occur with autologous transfusion ([73]). The possibility of an accident or error such as the transfusion of the wrong unit or an allogeneic unit to the autologous donor/patient has been reported to be as high as 1.2% ([74]). The costs and benefits of this program must be addressed, especially at a time when the risks of allogeneic blood transfusion are so low ([75]). The indications for autologous transfusion should be better defined to provide this important service appropriately. Autologous transfusions are not without complications and are not risk-free. They do play an important role, however, especially in the younger patient.

Crossover of Autologous Units

Autologous blood drawn from a patient/donor can be released for another patient but only under certain exceptional circumstances: The patient/donor does not need the unit; the blood meets all medical and laboratory criteria for a volunteer blood donor; and the blood tests negative for infectious markers. Situations that meet these conditions must be approved by the medical director on a case-by-case basis ([4]). Most facilities do not permit crossover because of concern about the safety of the

unit of blood for allogeneic purposes and also for logistic and clerical reasons. The practice is not widely used ([65]).

Erythropoietin

Erythropoietin has been used to stimulate red cell production, either to increase the number of units that can be collected preoperatively ([67], [76]) or as an alternative to preoperative collection ([67], [77], [78]). Its routine use has not been recommended because of the high cost and the waste of autologous blood.

Acute Normovolemic Hemodilution

A second approach to autologous blood transfusion involves the withdrawal of blood immediately before the surgical procedure and replacing the blood with crystalloid, colloid, or both, thereby acutely hemodiluting the patient and creating a normovolemic anemia ([66], [79]). This procedure is performed in the operating room under controlled conditions. Patients who might not be eligible for preoperative autologous donation may benefit from acute normovolemic hemodilution (ANH). The blood collected is transfused during surgery as required, depending on the intraoperative blood loss. Patients most likely to benefit from ANH are those with anticipated large surgical blood losses who can tolerate low intraoperative hematocrits ([80], [81]).

Units collected by ANH can be stored at room temperature for up to 8 hours or at 1° to 6°C for up to 24 hours ([4]); the blood so collected does not undergo any storage-related changes. The cost of such a program is significantly less than that of a preoperative autologous donation program ([82]).

Intraoperative Salvage

A third approach to autologous transfusion is the collection and retransfusion of blood lost during intraoperative hemorrhage ([8], [83]). This method has become popular with the development of technical devices to facilitate the procedure. There are two basic techniques available. The most common is the use of an anticoagulated vacuum suction device, which delivers blood shed from the surgical field into a centrifugelike device that washes the shed blood with saline before it is reinfused. The other technique involves collection of shed blood into special collection devices equipped with filters and reinfusion either directly or after further processing (e.g., washing). The salvaged blood contains red cell stroma, free hemoglobin, activated clotting factors, and fibrin degradation products. The reinfused blood does not appear to cause problems in the recipients, but the exact risk is difficult to define. It also appears that the risk is not increased with unwashed blood if the volume of blood reinfused is limited to approximately 1 L.

There are contraindications to the use of salvaged blood. These include the possibility of bacterial or tumor cell contamination of the operative field and, therefore, the reinfused salvaged blood. Topical substances used during the surgical procedure can be aspirated into the salvaged blood and inadvertently reinfused into the patient (e.g., hemostatic materials, irrigation solutions with added antibiotics). During procedures using such products, care should be taken to minimize the aspiration of these materials.

Postoperative Salvage

Blood can also be collected postoperatively for reinfusion. In the majority of instances, such blood is collected after cardiac or orthopedic surgery. The transfusion of such shed blood must begin within 6 hours of collection ([4]). Shed blood contains activated coagulation factors, complement, and factors derived from the fibrinolytic system. The blood must be filtered before transfusion to remove fat particles and any particulate matter that may be present. The volume of fluid collected may be small and generally has a hematocrit of less than 20%. Because the procedure is associated with a number of inherent difficulties, returns a very small number of RBCs to the patient, and is expensive, patient selection is important ([84]).

Directed Donations

In comparison to preoperative autologous donation, the practice of directed blood donations is more controversial ([85], [86]). Directed donation programs exist primarily for emotional reasons, although these programs are required to be offered in certain states. In these programs, patients anticipating the need for blood can determine who their donors will be. Usually, friends or relatives are selected on the supposition of a decreased risk of infectious diseases in familiar donors. There is no scientific evidence of their increased safety in a setting in which volunteer blood donors are used ([86]). On the contrary, blood from donors coerced to give blood for a friend may be less safe, as the social pressure to donate may make donors with risk factors reluctant to self-exclude. Also, directed donors are more likely to be first-time donors, who have a higher incidence of positive tests for infectious markers ([87]).

An additional problem of a directed donor program is logistic: Collections from directed donors must be made with enough time so that they can be processed, tested, shipped, and received at the patient's hospital before the day of surgery. Often, hospital blood banks are unaware that patients have arranged for directed donations, and if these are not received in advance of surgery, standard blood units are made available. Disappointments can be avoided only if an elaborate tracking system is in place ([88]).

There is no scientific evidence to support the use of directed donors such as parents for infants and children. In fact, the use of directed donations from family members is associated with an increased risk of certain complications. Use of a parent for blood support of a neonate may be associated with increased risks because of potential maternal-paternal-neonatal incompatibilities ([85]). The transfusion to a woman of childbearing age of blood from her husband or his relatives increases the risk of hemolytic disease of the newborn in future pregnancies ([89]). Because of an increased risk of GVHD, all blood that has been collected from a blood relative must be irradiated before transfusion ([4]).

Blood Substitutes

Because blood can be in short supply or not readily available (e.g., at the location of accidents or on the battlefield), research into the development of a blood substitute has produced several substances that are in clinical trials. In South Africa, a stroma-free bovine hemoglobin product was approved for human use April 2001.

Currently, two main groups of oxygen-carrying substances exist. One group is based on cell-free hemoglobin from either bovine or human sources and is referred to as *hemoglobin-based oxygen carriers*, or HBOCs. The other group is a family of chemicals called *perfluorocarbons*, or PFCs.

PFCs are substances with high oxygen-carrying capacity. Although immiscible with blood, they can be emulsified and transfused, with a short survival in the circulation. The oxygen dissociation curve is linear, so useful oxygen transport requires that the patient be exposed to a high concentration of inspired oxygen. PFCs have a number of potential adverse effects, including flulike symptoms after infusion, possible complement activation, and immunologic effects caused by reticuloendothelial system blockade ([90], [91] and [92]).

Stroma-free hemoglobin is prepared by controlled lysis of red cells in such a way as to avoid red cell membrane contamination. Because cell membranes are not present, blood group antigens are not expressed; therefore, HBOCs can be given to anyone regardless of blood type. They are capable of carrying oxygen, although with an altered P_{50}. When given intravenously, HBOCs have significant osmotic activity and a short half-life in comparison to intact RBCs, limiting their clinical effectiveness. The oxygen-carrying capacity and half-life of all HBOCs have been improved by cross-linking, polymerization treatments, or both. Some side effects of HBOCs include vasoconstriction, interference with macrophage function, gastrointestinal distress, possible neurotoxicity, generation of free radicals in tissue, and interference with numerous laboratory tests ([90], [91]). Both HBOCs and PFCs are in phase II and III clinical trials. Studies have shown efficacy in decreasing the number of allogeneic RBCs transfused to patients undergoing various surgical procedures ([90], [91]). How useful and cost-effective these products will be when available for general medical use remains to be established.

RED CELL TRANSFUSION

Red cell transfusion should be based on a careful assessment of each patient's unique clinical situation. Many guidelines for red cell transfusion have been

published, but it must be remembered that they are *guidelines*—not absolutes. The treating physician must understand the limitations, risks, and benefits of red cell transfusion.

The main indication for RBC transfusion is inadequate oxygen delivery due to anemia and, in some cases, hypovolemia. Wound healing is not impaired in the presence of anemia, and transfusion does not improve wound healing. Patients with chronic diseases should never be transfused simply because of mild asymptomatic anemia or as part of supportive care.

Considering that approximately 12 million units of RBCs are transfused in the United States each year, it is somewhat unsettling to realize that their efficacy has never been demonstrated in well-designed trials. Some recent studies show an increase in mortality in specific groups of transfused intensive care unit patients when compared to untransfused matched controls ([93], [94]). In contrast, a study of elderly patients with anemia and myocardial infarction showed a transfusion-associated decrease in short-term mortality ([95]). The clinician must be aware that not all is known about blood transfusion and its potential to affect, both positively and negatively, a patient's health.

Indications for Red Cell Transfusion

HYPOVOLEMIA DUE TO HEMORRHAGE One of the major indications for blood transfusion is the restoration of an adequate blood volume after the loss of large amounts of blood ([96]). In such situations, the rapid restoration of circulating blood volume is more important than maintaining a normal red cell mass; fluid resuscitation is accomplished initially by the infusion of a crystalloid solution such as saline or Ringer's lactate. The use of colloids such as albumin, hydroxyethyl starch, or low-molecular-weight dextran does not appear to be of any clinical advantage over crystalloids ([97], [98]). In general, adults losing less than 20% of their blood volume (or approximately 1 L) do well without red cell transfusion, providing that fluid resuscitation is adequate to maintain the circulating blood volume and that further blood loss is avoided. Young healthy patients can sustain losses of up to 30 to 40% of blood volume as long as intravascular blood volume is adequately maintained with IV fluids. When red cells are necessary, whole blood (if available) or red cell units may be transfused. In the resuscitation of hypotensive patients after hemorrhage, hemoglobin and hematocrit measurements are unreliable (Fig. 24.2). Clinical assessment of circulatory status (Table 24.2), including monitoring of pulse, blood pressure, respiratory rate, urinary output, and mental status, is essential. Measurements such as whole-body oxygen consumption, oxygen extraction ratio, and oxygen delivery are more reliable in judging the need for transfusion and may be indicated depending on the clinical status of the patient ([99], [100] and [101]).

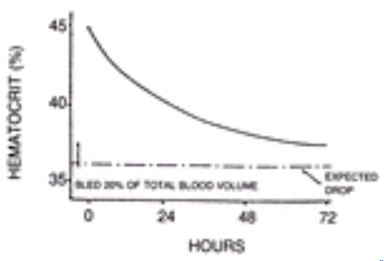

Figure 24.2. After acute hemorrhage, the hematocrit may not reflect true red cell losses for up to 72 hours.

TABLE 24.2. Clinical Signs of Blood Loss

Volume Lost		
ml	**% of Blood Volume**	**Clinical Signs**
500	10	None; occasionally vasovagal syncope
1000	20	At rest, there may be no clinical evidence of volume loss; a slight postural drop in blood pressure may be seen; tachycardia with exercise
1500	30	Resting supine blood pressure and pulse may be normal; neck veins flat when supine; postural hypotension
2000	40	Central venous pressure, cardiac output, systolic blood pressure below normal even when supine and at rest; air hunger, cold clammy skin; tachycardia
2500	50	Signs of shock; tachycardia, hypotension, oliguria, drowsiness, or coma

SURGERY There is no rationale for the routine preoperative transfusion of patients with mild anemia. The optimal pre- and postoperative hemoglobin depends on the patient's clinical condition. The belief that a hemoglobin value of less than 100 g/L, or a hematocrit of less than 0.30 L/L, indicates a need for red cell transfusion preoperatively has been discarded. Each case must be considered individually, taking into account such variables as duration of anemia, the time of the surgical procedure, the probability of blood loss, and any coexistent clinical features such as underlying cardiovascular disease that may contribute to morbidity. An arbitrary threshold for transfusion cannot be defined ([102], [103] and [104]). The use of blood during and after surgery depends on the judgment of the surgeon and anesthesiologist. Patients should not be transfused simply to replace small amounts of blood lost during surgery. Surgery may often be performed with reasonable safety in patients refusing blood transfusions ([105]), and even cardiopulmonary bypass surgery may be performed without the need for homologous transfusions and, sometimes, with small volumes of autologous blood only ([106], [107]). Below a certain critical level, patients do require transfusion. Approximately 17 clinical practice guidelines have been published, none as exhaustively researched as the American Society of Anesthesiologists Task Force on Blood Component Therapy. This task force rejected the adoption of a single “transfusion trigger” but did advise clinicians that transfusion is rarely indicated if the hemoglobin is above 100 g/L, and transfusion is almost always indicated if the hemoglobin is below 60 g/L ([103]). Preoperative requests for blood should be in accordance with standard operating procedures that are predetermined on the likelihood of a procedure requiring a blood transfusion. Such maximum surgical blood order schedules represent transfusion practice guidelines for pretransfusion assessment, including the number of units that should be crossmatched for a variety of procedures ([108], [109]). A pretransfusion sample should be sent to the blood bank if it is likely that blood will be required for a specific surgical procedure. The request could be for a type and screen if it is unlikely that the patient will require blood, or for crossmatch for a specific number of units if it is likely.

ANEMIA RBCs are often transfused in the management of various types of anemia. The blood hemoglobin concentration or hematocrit alone should not determine the need for transfusion. Patients should be transfused only on the basis of clinical indications. Physiologic adaptations to anemia, including elevated red cell 2,3-DPG content and increased cardiac output, compensate to a significant extent for chronic anemia. Functional impairment is unusual, and transfusion is rarely required in anemic patients with a hemoglobin concentration above l00 g/L. Even when hemoglobin concentration is below 100 g/L, tissue oxygenation is usually maintained as long as the cardiac output is adequately increased, the perfusion of critical organs is not constrained, and oxygen consumption is not excessive (e.g., patient is not engaging in vigorous physical activity). When the hemoglobin is less than 60 to 70 g/L, transfusion is often required to prevent or treat symptoms of anemia (syncope, dyspnea, postural hypotension, tachycardia, angina, transient ischemic attacks). When hemoglobin is between 60 and 100 g/L, the decision to transfuse should be based on a consideration of the patient's age, cardiovascular and respiratory status, activity level, symptoms, underlying diagnosis, and state of bone marrow activity. Many anemic patients with a stable hemoglobin concentration at the lower end of this range do not need transfusion. Children may tolerate even lower levels. In all patients, physiologic adjustments to chronic or acute anemia ultimately have a limit. In patients with limited ability to increase cardiac output or with impaired perfusion of vital organs, such as elderly patients with myocardial or vascular disease, anemia is poorly tolerated. Many types of anemia can be treated with medical therapy, and patients with chronic anemia are often well adapted. In such situations, it is usually possible to withhold blood transfusion and to await recovery of the patient's marrow function after specific replacement therapy (iron, folate, B_{12}, erythropoietin).

INDICATIONS FOR TRANSFUSION OF ANEMIC PATIENTS

Deficiency States Patients who are anemic solely because of deficiency of iron, folate, or B_{12} rarely require transfusion. Elderly patients who present with pernicious or severe iron deficiency anemia may require a limited number of red cell transfusions, particularly when angina or congestive heart failure has been the cause of the patient seeking medical attention. More often, iron-deficient patients who are also bleeding actively from the gastrointestinal tract or other sites require red cell transfusions. In such situations, the goal of transfusion is not to correct the patient's hemoglobin concentration, but to raise it sufficiently to stabilize the patient; thereafter, the marrow should be permitted to correct the deficiency.

Hemolytic Anemias Patients with acute or chronic hemolytic anemias may require red cell transfusion; often, this need arises at the time of a hemolytic or aplastic crisis. Such patients are often critically ill, and safe transfusion requires careful clinical attention. In autoimmune hemolytic anemia ([110], [111]), the clinician may be faced with a severely anemic patient for whom crossmatch-compatible blood cannot be obtained. These patients produce an antibody that reacts with all RBCs including their own, and the cautious transfusion of “incompatible” red cells may be necessary. In these cases, withholding transfusion hoping to find “compatible”

RBCs places the patient in needless danger. Consultation with a transfusion medicine specialist should allay the clinician's fears.

Hypoproliferative Anemias In aplastic and sideroblastic anemias, myelodysplastic states, and myelofibrosis, patients often depend on regular transfusion of red cells and may die of transfusion-induced iron overload after several years of such support unless precautions are taken to remove iron. The development and use of recombinant human erythropoietin have eliminated the need for transfusion in some patients with hypoproliferative anemia, such as those with end-stage renal disease ([67]). Patients with malignant diseases often require transfusions for relief of symptoms of anemia. In this situation, the marrow function may be severely depressed by chemotherapy or radiotherapy. Infections and thrombocytopenic bleeding may be present, and recovery of marrow function is delayed. Transfusions are indicated to ameliorate symptoms and many clinicians maintain hemoglobin levels above 80 to 90 g/L during ongoing marrow suppressive therapy.

Hereditary Red Cell Disorders In children with thalassemia (see Chapter 42), bone marrow hyperplasia with its undesirable effects on the skeleton may be ameliorated, and iron absorption may be decreased, by regular transfusions to maintain a near-normal hemoglobin concentration ([112]). Such a program is possible only in conjunction with an aggressive iron chelation program, as the predictable iron load otherwise leads to fatal hemosiderosis. In sickle cell disease (see Chapter 40), the adverse microvascular effects of sickle cells can be relieved temporarily by transfusion of normal red cells, thereby reducing the proportion of sickle cells in circulating blood. Red cell exchange may be indicated to reduce the proportion of sickle cells without increasing the hematocrit to unacceptable levels.

Pretransfusion Testing of Red Cells

COMPATIBILITY TESTING PROCESS The process of selecting red cells for transfusion involves three stages. Blood grouping involves determination of the ABO group and Rh type of both recipient and donor specimens. The recipient's serum or plasma is screened for the presence of unexpected red cell antibodies. Crossmatching either *in vitro* or electronically after selection of a donor unit of the appropriate group and type determines whether the donor cells are compatible with the recipient's plasma. Properly selected blood products will be compatible with the recipient, indicating that transfusion should not result in hemolysis of donor red cells. Because only the ABO and Rh(D) red cell antigens are prophylactically matched in routine transfusion practice, there are always significant antigenic differences between donor and recipient, both for red cells and the accompanying leukocytes, platelets, and plasma. Repeated exposure to foreign antigens with chronic transfusion or pregnancy may result in antibody formation in the recipient. There is no room for error in the provision of blood for transfusion. If clerical or laboratory error results in donor and recipient being mismatched for the ABO group, transfusion of even a few milliliters of red cells may lead to a life-threatening transfusion reaction with shock, intravascular coagulation, and acute renal failure. Such reactions are rare because of rigid adherence to a routine designed to maximize safety at all levels of the transfusion process. Careful identification of the patient for whom the blood is ordered, including complete labeling of the specimen at the bedside of that patient, is essential. Careful ABO blood grouping along with comparing results of ABO testing with historical records for each patient adds to the level of safety. Ensuring positive identification of crossmatched units of blood and verifying that the information identifying the unit with the intended recipient is reviewed in the presence of that recipient before the administration of the blood are crucial ([4], [8]).

BLOOD GROUPING The presence of ABO antigens is determined by testing the unknown RBCs with anti-A and anti-B sera by one of a variety of methods including slide, tube, gel, or microplate tests ([8]). Identifying which ABO antigens are on the surface of an individual's RBCs is called the *forward grouping* or *forward type*. Cells agglutinated only with anti-A serum are group A; those reacting only with anti-B are group B. Those reacting with both antisera are group AB, and red cells that fail to agglutinate with either anti-A or anti-B are group O. “Reverse grouping” or “reverse typing” should be performed to confirm the reaction obtained by the forward grouping test. This involves testing the reactions of the serum or plasma from the person of unknown type with the red cells of known A and B type. Agglutination of the red cells indicates the presence of anti-A or anti-B in the individual's serum. The conclusions of forward and reverse tests should agree as shown in Table 24.3.

TABLE 24.3. ABO Grouping

	Expected Reactions of			
	Patient's Cells with		Patient's Serum with	
Patient Blood Group	**Anti-A**	**Anti-B**	**A Cells**	**B Cells**
O	None	None	+	+
A	+	None	None	+
B	None	+	+	None
AB	+	+	None	None

The antisera used in blood group antigen detection can be obtained from donors with naturally occurring high levels of antibodies, from people or animals specifically stimulated to produce antibodies against blood groups, or from monoclonal antibodies of mouse or human origin. The advantages of monoclonal antibodies include their high quality and stability and their ease of production in large quantities. Antisera must be of known specificity and potency, and control testing must be done on a routine basis ([8]). The Rh type of red cells is determined by examining the cells' reaction with anti-D serum from commercial sources. Commercial antisera may be modified by the manufacturer with the addition of high concentrations of protein or by chemically altering the immunoglobulin (Ig) G molecules in such a way that they perform as direct agglutinins in the laboratory. This permits rapid, reliable testing to determine the D antigen status of the cells. However, these high-protein reagents may cause false-positive reactions because of spontaneous aggregation of the red cells in their presence. If this happens, an Rh-negative patient could be typed as Rh positive if the recommended Rh control is not simultaneously tested. This has resulted in the development of low-protein, saline-reactive monoclonal reagents. Monoclonal anti-D reagents contain both human IgM and polyclonal IgG antibodies and are currently most widely used. They can also be used in the antiglobulin test for weak D. As with all reagents, manufacturers' instructions must be followed ([8]).

Weak D Some red cells react weakly with anti-D reagents. If donor blood is being tested, the presence or absence of D must be confirmed. If the initial test for D is negative, a second test must be performed using a method that detects weak D. If D is detected by either method, the unit is labeled Rh positive. In recipients, it is not necessary to confirm the presence of D. Patients who type as Rh negative even though they are weak D–positive are not adversely affected by the transfusion of Rh-negative products. If the patient is known to be weak D–positive, Rh-positive donor blood may be administered. Before labeling a patient weak D–positive, care must be taken to ensure that the patient has not recently been transfused with Rh-positive red cells.

TESTING FOR RED CELL ANTIBODIES Antibodies in potential blood recipients fall into several categories. The most common blood group antibodies that are clinically significant and may be implicated in hemolytic transfusion reactions or hemolytic disease of the newborn are shown in Table 24.4.

TABLE 24.4. Significance of Certain Blood Group Antibodies

			Clinical Significance	
Blood Group System	**Antibody**	**Relative Frequency in Antibody Screening**	**Hemolytic Transfusion Reaction**	**Hemolytic Disease of the Newborn**
ABO	Anti-A	All group B and O	Yes	Yes
	Anti-B	All group A and O	Yes	Yes
Rhesus	Anti-D	Common	Yes	Yes
	Anti-c	Common	Yes	Yes
	Anti-E	Common	Yes	Yes
	Anti-C	Common	Yes	Yes
	Anti-e	Uncommon	Yes	Yes
Kell	Anti-K	Common	Yes	Yes
	Anti-k	Rare	Yes	Yes
Kidd	Anti-Jka	Common	Yes	Yes
	Anti-Jkb	Rare	Yes	Yes
Duffy	Anti-Fya	Common	Yes	Yes
	Anti-Fyb	Rare	Yes	Yes
MN	Anti-M	Common	Occasional	Occasional
	Anti-N	Rare	Rare	Rare
SsU	Anti-S	Uncommon	Yes	Yes
	Anti-s	Rare	Yes	Yes

Lewis	Anti-Lea	Common	Yes	No
	Anti-Leb	Uncommon	No	No
P	Anti-P1	Uncommon	Rare	No
Ii	Anti-I	Uncommon	No	No

All human plasmas contain naturally occurring antibodies that react with the complementary antigens of the ABH system. These are of great importance in transfusion, as they are complement-fixing IgM antibodies; transfusion of incompatible red cells leads to immediate hemolytic reactions. Many people also have naturally occurring antibodies (usually low-titer IgM antibodies reacting at or below room temperature) reacting with some antigens of the Lewis, P, Ii, MN, or other systems; these are rarely active above room temperature and are only occasionally important in transfusion. Finally, people exposed to foreign red cells by prior transfusion or pregnancy may produce IgG antibodies to antigens of certain other systems, primarily Rh (C, c, D, E, e), Kell, Duffy, Kidd, and Ss, but many less common possibilities exist. These red cell antibodies are clinically significant. They do not often lead to intravascular hemolytic reactions, but transfused incompatible red cells may exhibit decreased survival caused by increased clearance in the reticuloendothelial system. Many of these IgG antibodies can also cause hemolytic disease of the newborn ([6], [8]). There are two major classes of antibodies that react with red cells. Complete or saline antibodies agglutinate red cells suspended in saline solution; these are usually IgM. Those that do not react visibly in saline and are capable of producing agglutination reactions only with special techniques to make their interaction with red cells detectable are called *incomplete agglutinins*; these are generally IgG antibodies. The best example of a room-temperature saline agglutination test is that used in ABO grouping. Other red cell antibodies readily detected in saline suspension are those belonging to the Lewis, MN, P, and Ii blood group systems. With the important exception of ABO system antibodies, many of the others detected with this test are of no clinical significance, as they are not reactive at 37°C. The best examples of incomplete agglutinins, or IgG antibodies, are those reacting with antigens of the Rh system. If such antibodies are not detected in the recipient, immediate hemolysis of transfused, incompatible red cells is extremely rare. However, their presence may lead to a significantly decreased survival of transfused cells and the development of an extravascular hemolytic syndrome [delayed hemolytic transfusion reaction (DHTR)].

ANTIGLOBULIN TEST The antiglobulin (Coombs) test (Fig. 24.3 and Fig. 24.4) is based on the reaction between an antihuman globulin (AHG) reagent and antibody- or complement-coated red cells. AHG reagents are commercially available and are prepared either by the injection of an animal with human globulin or through hybridoma technology. AHG reagents may be polyspecific or monospecific. The polyspecific reagents contain antibodies with both anti–human IgG and anticomplement activity. Monospecific AHG reagents, anti-IgG, anti-C3b, and anti-C3d, are used to determine which protein is responsible for a positive direct antiglobulin test ([8]).

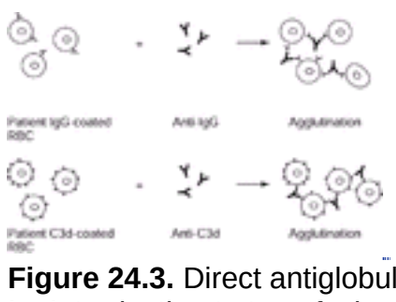

Figure 24.3. Direct antiglobulin test with anti–immunoglobulin G (IgG) and anti-C3d. RBC, red blood cell. (Reprinted from Jeter EK, Spivey MA. Pretransfusion testing. In: Introduction to transfusion medicine: a case study approach. Bethesda, MD: American Association of Blood Banks Press, 1996;56, with permission.)

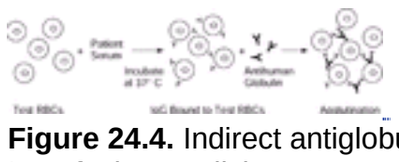

Figure 24.4. Indirect antiglobulin test. IgG, immunoglobulin G; RBC, red blood cell. (Reprinted from Jeter EK, Spivey MA. Pretransfusion testing. In: Introduction to transfusion medicine: a case study approach. Bethesda, MD: American Association of Blood Banks Press, 1996;56, with permission.)

The *direct* antiglobulin test is performed by washing the test cells with saline, adding polyspecific AHG, and observing for agglutination (Fig. 24.3). Positive reactions (agglutination) suggest the presence of IgG antibodies or complement bound to the red cell ([8]). The *indirect* antiglobulin test is used to determine the presence of red cell antibodies in serum or plasma (Fig. 24.4). Reagent red cells are washed, incubated with the patient's serum or plasma, washed again to remove unbound immunoglobulins, mixed with AHG (usually monospecific anti-IgG), and then centrifuged briefly. The cell button is gently resuspended and examined for agglutination. A positive reaction suggests that IgG antibodies in the patient's plasma have bound to the reagent cells. A positive indirect antiglobulin test therefore indicates the presence of antibodies capable of reacting with red cells and capable of possibly hemolyzing such cells if they were transfused. Direct and indirect antiglobulin tests (Coombs test) are the simplest approaches to the detection of IgG anti–red cell antibodies. Because many of these serologic reactions are rather weak, the addition of various media has been used to enhance the agglutination reaction. These tests involve procedures that diminish the mutually repulsive electrostatic forces between red cells, permitting visible agglutination by IgG antibodies ([8]). Antigens that often require such enhancing tests include those of the Kidd (Jk ^{a} and Jk ^{b}), Rh (D, C, E, c, e), Kell, and Duffy (Fy ^{a} and Fy ^{b}) systems.

MEDIA THAT ENHANCE AGGLUTINATION

Albumin Mixing red cells with serum or plasma in the presence of albumin makes certain weak reactions (e.g., those involving Rh system antibodies) more easily detected. Although long thought to be the effect of albumin itself, the enhancement of reactions is most likely due to albumin's low ionic strength buffer ([8]).

Enzymes Pretreatment of the test red cells with various proteolytic enzymes, such as trypsin, papain, ficin, or bromelin, increases the sensitivity of the test for some antibodies, particularly those reacting with antigens of the Kidd and Rh systems. The M and N, Fy ^{a} and Fy ^{b}, and, in some cases, S and s antigens are destroyed or weakened by such treatment. Enzymes remove sialic acid from the red cell membrane, thereby diminishing the negative charge of the cell. Enzyme-treated cells should be used as an investigative tool in antibody investigation, not for antibody screening ([8]).

Reduced Ionic Strength Performance of serologic reactions in a solution of fixed low ionic strength also potentiates certain agglutination reactions and shortens the incubation period required for the detection of most antibodies ([8]).

Polyethylene Glycol Use of polyethylene glycol in the antiglobulin test has been reported to be superior to albumin for detection of clinically significant antibodies. Polyethylene glycol enhances antibody binding by excluding water molecules in the diluent, allowing for closer interaction between antibody and antigen. It has been shown to increase the detection of clinically significant red cell antibodies while decreasing the detection of insignificant ones ([8]).

OTHER ANTIBODY IDENTIFICATION TESTS Sera containing several antibodies may be analyzed by absorbing with one or more selected red cells ([6], [8]). Antibodies so adsorbed may be eluted from the cells, and their specificity may be determined. When necessary, the identity of certain antibodies may be confirmed by their inhibition by soluble antigens, such as A, B, and Lewis substances present in the saliva of secretors. Neonatal (cord) red cells exhibit a number of antigens very weakly and may be used to investigate antibody specificity.

PRETRANSFUSION COMPATIBILITY TESTING The purpose of compatibility testing is to detect antibodies in the recipient's serum that react with donor red cells and have the potential to destroy the transfused cells. Reactions examining this possibility are called *major crossmatches*. Serologic crossmatching of donor plasma with recipient red cells (minor crossmatch) is generally not performed. Donor antibodies directed at recipient ABO antigens are excluded by the selection of group-compatible plasma products. Donor plasma is screened for red cell antibodies other than ABO ([4]). Antibodies of other specificities are rare in donors, with an incidence of 0.32 to 0.34% ([113], [114]), the most common ones being anti-D, -E, and -K. Plasma containing antibodies other than ABO is generally not transfused. Even if transfused, these antibodies would be unlikely to cause recipient hemolysis because they would be diluted greatly in the recipient's circulation ([113], [115], [116] and [117]).

Selection of Red Cells for Transfusion

A series of serologic tests is used to select donor blood for patients. Although individual transfusion services prefer different specific methods, the general principles of compatibility testing are the same.

A properly labeled, fresh sample of patient blood must be provided. If the patient has been transfused or has been pregnant within the preceding 3 months, the specimen must be obtained within 3 days of the anticipated transfusion ([4]).

DONOR The ABO group of the donor unit must be confirmed. The Rh typing must be repeated if the unit is labeled as Rh negative. These tests are performed to confirm the blood group and to ensure that the unit has not been mislabeled.

RECIPIENT The recipient's ABO group and Rh type must be determined. The recipient's serum is screened for the presence of antibodies that may have been

induced by prior pregnancy or transfusion. A set of commercially prepared group O red cells, expressing 18 clinically relevant antigens, is used in this test in accordance with FDA rules. The use of group O red cells avoids agglutination by anti-A or anti-B. The antigens expressed must include D, C, E, c, e, M, N, S, s, P_1, Le^a, Le^b, K, k, Fy^a, Fy^b, Jk^a, and Jk^b. These cells are incubated with the patient's serum and tested with the indirect antiglobulin test for reactions indicating the presence of antibody in the serum ([8]). If such screening reactions are positive, the antibody specificity can be determined by reaction of the serum with a commercially prepared panel of reagent red cells of known antigenic composition. If an antibody has been found on the screen, it is best to withhold transfusion, if the patient's clinical status allows, until identification is complete. The incidence of unexpected RBC antibodies in patients requiring transfusion is low.

TYPE AND SCREEN If it is unlikely that blood will be required, for example, for a surgical procedure, a “type and screen” rather than a crossmatch should be requested. In this instance, the blood bank types the patient's blood and screens for unexpected antibodies; if antibodies are not found, the blood bank ensures that blood of the appropriate group is available for transfusion if necessary. In such an event, a telephone call can trigger a rapid crossmatch test and blood will be available with minimal delay. The appropriate use of type and screen improves the efficiency of the blood bank. It assists in inventory control by not segregating blood for patients who are unlikely to require it and is therefore cost-effective.

CROSSMATCH If no antibody has been detected on the screen and there is no record of the previous presence of a clinically significant antibody, only verification of ABO compatibility between the donor unit and recipient is required before transfusion. This can be done either by an immediate spin crossmatch or a computer crossmatch. The immediate spin crossmatch consists of mixing the patient's serum with donor saline-suspended red cells at room temperature, spinning the tube, and reading the results immediately. The purpose of this test is to detect ABO incompatibility due to the presence of anti-A, anti-B, or both in the patient's serum ([8]). The conditions for computer crossmatch are outlined in the AABB standards ([4]). Briefly, the computer system must be validated to prevent release of ABO-incompatible blood. This computer crossmatch can be used only for patients who do not have a record of clinically significant antibodies. The recipient's ABO blood group must have been determined on at least two separate tests. The system must contain complete information on the donor unit and the recipient, including ABO group and Rh type. Data entered must be verified as correct before the release of blood. The system must contain logic to alert the user to discrepancies for either the donor unit or the recipient, including unit labeling, blood grouping, and ABO incompatibilities. If a clinically significant antibody has been found, antibody identification should be performed. Donor units lacking the specific antigen should be selected, and a major crossmatch using an indirect antiglobulin test should be performed on each unit to ensure compatibility. The physician should also be advised about the nature of the problem, as well as the potential for delays if further units are required. Once a unit of blood is crossmatched for a patient, there must be positive identification of the patient and the unit. Before every transfusion, the requisition, the label on the unit, and the patient's identification must be checked. This aspect of patient and unit identification is critical and must be documented.

CROSSMATCHING PROBLEMS

Pseudoagglutination *Pseudoagglutination* refers to red cell clumping (rouleaux formation) that typically occurs when the sedimentation rate is elevated, in the presence of dysproteinemias, or after the administration of dextran or hydroxyethyl starch. Dilution in saline abolishes the reaction ([6], [8]).

Autoagglutination *Autoagglutination* refers to red cell agglutination by the patient's own serum or plasma and often indicates the presence of a cold agglutinin. This artifact persists after dilution but is removed by washing the red cells and repeating the serologic test at 37°C. A positive indirect antiglobulin test against all screening and donor red cells often indicates the presence of an IgG, warm-reacting autoantibody. The patient's direct antiglobulin test is also positive. Often, such autoantibodies preclude the identification of any compatible donor units. If red cells must be transfused, it is essential that ABO compatibility be ensured. The patient's serum should be screened for alloantibodies that might be masked by the autoantibody ([8], [118], [119]). Such screening requires the removal of the autoantibody from the patient's serum, so that any alloantibodies present can be identified. If the patient has not been transfused within 4 months, this can be done by absorbing autoantibody from the serum with autologous red cells, from which already attached antibody has been removed by enzyme or chemical treatment. Alternatively, autoantibody may be removed by absorption with a panel of cells selected to lack the antigens to which the patient may become alloimmunized. The autoantibody-depleted serum can then be examined for the presence of residual alloantibodies, and a major crossmatch can be done. If only the autoreactive antibody is present, transfusion of red cells is generally well tolerated.

Alloantibody to High-Incidence Antigens Occasionally, a patient may have a red cell antibody that does not react with the patient's own cells but reacts with all donor red cells. In many of these cases, it is not clear whether the antibody is likely to cause significant hemolysis. In such patients, if a transfusion is considered essential, a small amount (=5 ml) of ^{51}Cr-labeled, crossmatch-incompatible red cells may be transfused, and their survival may be determined over 24 hours. Survival of more than 70% of labeled cells at 24 hours indicates that the recipient's antibody is not likely to cause significant destruction of transfused cells ([120], [121]). *In vitro* assays such as the monocyte monolayer assay may also be useful in this regard ([122]). These tests may also be used to evaluate apparent *in vivo* incompatibility of red cells that are crossmatch compatible in the laboratory ([123], [124]).

Drugs Drugs may cause the formation of antibodies and are one of the possible causes of serologic incompatibility. Incompatibility in a crossmatch may be due to the presence of a drug-induced antibody coating the donor cells. The situation of one positive crossmatch among other negative crossmatches in a patient with a negative antibody screen directs an investigation into the possibility of a positive direct antiglobulin test in the suspect donor unit. Some drugs may stimulate an autoantibody in the patient that reacts with all reagent cells tested as well as donor red cell units crossmatched. Drugs implicated include a-methyldopa and procainamide. In some cases, the *in vitro* findings may be identical to those found in autoimmune hemolytic anemias. The presence of these antibodies may or may not be clinically significant but may result in a delay if a transfusion is required. In most cases, however, drug-induced antibodies are associated with a positive direct antiglobulin test that is not part of the standard pretransfusion or crossmatch testing, and the indirect antiglobulin test is negative. The mechanisms of drug-induced hemolytic anemias are discussed in Chapter 36.

Polyagglutination Polyagglutination is the phenomenon in which a patient's red cells are agglutinated by most or all group-compatible sera. It is caused by alteration of antigenic structures on the red cell membrane with exposure of previously hidden red cell antigens ([6]). T (and, more rarely, Tn) antigens are in these cases exposed during bacterial or viral infection by enzymes associated with the infecting organism. Most adult sera contain naturally acquired antibodies capable of reacting with these determinants. The situation may be elucidated by testing the patient's red cells with cord serum, which lacks the antibodies necessary for this reaction, and by examining for reactions with lectins of plant origin that have specific activity with the antigens involved in polyagglutination ([125], [126]).

Transfusions in the Newborn Period

PRETRANSFUSION TESTING The so-called naturally occurring IgM ABO antibodies do not begin to appear until approximately 3 to 6 months of age. However, IgG antibodies of maternal origin, including maternal anti-A or anti-B, may be passively transferred to the fetus. Thus, pretransfusion testing in the newborn consists of ABO and Rh typing of the infant's cells and an antibody screen for passively transferred maternal IgG antibodies, including anti-A or anti-B. If the initial antibody screen is negative, the infant may be transfused with products compatible with the patient's ABO/Rh type, and no further compatibility testing is required for the first 4 months of life. If a clinically significant antibody of maternal origin is detected, units that are antigen negative or crossmatch compatible must be issued until the antibody is no longer detectable in the infant's serum ([4]).

SELECTION OF PRODUCTS FOR TRANSFUSION Preterm infants may require multiple transfusions to replace blood drawn for laboratory tests. It has become common practice to limit donor exposure by reserving one unit or one-half of a unit for a single preterm infant. Serial aliquots may be obtained using a sterile connection device up to the outdate of the unit ([127], [128] and [129]). Blood products for low-birth-weight infants should be irradiated to prevent transfusion-related GVHD and should be CMV safe. Either CPDA-1 or additive red cells may be used for aliquot transfusions. However, the safety of additive solutions has not been demonstrated in the setting of massive transfusion of infants (i.e., one unit or more in a neonate). The amount of free potassium in the supernatant of the irradiated blood may also become clinically important in the setting of massive transfusion ([61]). For massively transfused infants at increased risk of hyperkalemia, the dose of free potassium in the transfused product may be decreased by delaying irradiation until just before issue or by washing the RBCs.

EXCHANGE TRANSFUSION The most common indication for exchange transfusion in the neonate is hyperbilirubinemia that has not responded adequately to phototherapy, particularly that associated with hemolytic disease of the newborn. Other indications may include disseminated intravascular coagulation or the removal of toxins. Usually, one to two blood volumes are exchanged. Red cells collected in CPD or CPDA-1 that are less than 1 week old are preferred. Because several clotting factors in newborns are at the low end of hemostatic levels, many centers perform exchanges using whole blood, or red cells reconstituted with FFP, to prevent further lowering of factor levels by the exchange. Red cells used for the exchange transfusion should be irradiated to prevent transfusion-related GVHD ([8]).

Selection of Blood for Emergency Transfusion

For patients in hemorrhagic shock, it is necessary to transfuse blood immediately, and no blood bank testing should be attempted before emergency transfusion. The risk of transfusing group O cells is extremely low and is certainly much lower than the risk of the patient's death if blood transfusion is delayed. For patients given uncrossmatched blood, a specimen of the patient's blood should be sent to the blood bank for an antibody screen and crossmatch, as the transfusion is proceeding.

If the patient's blood group is known, uncrossmatched blood of the same group may be used; otherwise, group O red cells should be chosen ([4]). Patients of blood group AB may be given either group A or group B cells. Such uncrossmatched blood should be Rh(D) negative when used in women of childbearing age in whom sensitization to D would be undesirable. As Rh-negative blood is often in limited supply, Rh-positive blood is often used for the emergent transfusion of older females and of males of unknown blood group. In such cases, sensitization may occur, but the risk of an immediate hemolytic reaction is low ([6]).

Despite the lack of a crossmatch, transfusion of group O blood under emergency situations is safe. The incidence of red cell alloantibodies in healthy people is low,

and most such antibodies do not cause dangerous acute intravascular hemolytic transfusion reactions even if incompatible blood is given. However, the decision to use uncrossmatched blood is the responsibility of the attending physician, who must weigh the risks against the expected benefits and document in the patient's record the need for the uncrossmatched blood.

Table 24.5 outlines the selection of blood and plasma by ABO type. If the blood group is known, group-compatible red cells and FFP can be selected. If the blood group is not known, group O red cells should be used; if plasma is required, group AB FFP should be used because it contains no anti-A or anti-B.

TABLE 24.5. Selection of Blood and Plasma by ABO Type

Component	Recipient ABO Type	Selection of Blood Component

Modified from Jeter EK, Spivey MA. Introduction to transfusion medicine: a case study approach. Bethesda, MD: American Association of Blood Banks Press, 1996.

Administration of Blood

The first step before the administration of blood or of a blood product is to obtain consent for the transfusion from the patient. Every hospital should set its own policy. A note in the chart indicating that the risks of transfusion as well as the indications have been discussed with the patient and that the patient has accepted this form of therapy is adequate. There must be a written order for the administration of the product ([4]).

All blood products should be given through an appropriate administration set containing a filter; careful aseptic technique should be practiced at all times. There must be confirmation and documentation that the information identifying the unit of blood with the patient has been verified in the presence of the patient ([4]).

Vital signs should be documented before and after transfusion and as clinically required. For the first 15 minutes after the infusion has begun, the patient should be kept under close observation to detect any signs of a serious transfusion reaction. If none is observed, the infusion rate may be increased. One unit of red cells is often given in 1 to 4 hours, depending on the amount to be transfused and on the patient's cardiovascular status. Infusion of a unit for longer than 4 hours is not recommended, as there is a risk of bacterial proliferation because the opened unit is at room temperature. Drugs or medications should not be injected into the blood. Normal (0.9%) saline, 5% albumin, or ABO-compatible plasma may be added to the red cell concentrate. No other solution and no medication should be added to or infused through the same tubing as blood unless there is documentation of compatibility and FDA approval ([4]). Dextrose causes red cells to agglutinate or hemolyze; hypotonic saline causes hemolysis. Ringer's lactate or other solutions containing calcium must never be added to blood because the calcium present leads to coagulation. After the transfusion has been completed, the transfusion tag or record should become part of the patient's chart.

When the patient being transfused is in severe congestive heart failure, additional measures should be taken. Administration of diuretics before or during the transfusion may not be adequate to prevent aggravation of heart failure by volume overload. In the presence of heart failure, transfusion should proceed slowly (e.g., 1 ml/kg/hour) with careful observation and additional diuretics given if clinically indicated. If slower rates than this are needed, the blood component may be divided by the blood bank into two or more parts and each part transfused over 4 hours. The unused portions should be kept in the blood bank until needed for transfusion. Alternatively, blood may be given safely by exchange transfusion, which can be accomplished by the simple means of removing blood from one vein while infusing concentrated red cells into another on the opposite limb. Removal of 500 ml of blood with a hematocrit of, for example, 0.15 L/L, accompanied by the infusion of two units of concentrated red cells, results in a significant increase in the patient's hemoglobin concentration.

PLATELET TRANSFUSION

Platelet transfusion is often life-saving when hemorrhage is caused by thrombocytopenia. Modern chemotherapy for hematologic malignancies would not be possible without the ability to prevent or treat thrombocytopenic bleeding. Similarly, many open-heart surgical procedures would not be feasible without platelet transfusions. Whether this therapeutic modality is effective depends on recipient factors, such as the presence of sepsis, azotemia, drugs, and platelet antibodies, and on the ability of the blood bank to provide functional platelets in sufficient numbers ([130], [131] and [132]).

Preparation of Platelet Concentrates

Platelets, like erythrocytes, are actively metabolizing cells and require specific conditions for their preparation and storage in a viable, functional form ([133], [134]). They are prepared for transfusion either as platelet concentrates from whole blood or buffy coat or by apheresis from single donors. Although the method of preparation differs, both products are stored under the same conditions.

Platelet concentrates may be prepared from whole blood collected into bags with satellites (Fig. 24.1). The anticoagulants in current use, CPD and CPDA-1, are satisfactory for preparation of platelet concentrates. The whole blood is kept at room temperature and must be processed within 8 hours of collection. The unit of whole blood is centrifuged at low speed at room temperature, and the supernatant, platelet-rich plasma, is expressed into a satellite bag. The supernatant is centrifuged again to further concentrate the platelets. Most of the supernatant platelet-poor plasma is expressed, and after 1 hour, the platelets are gently resuspended in the remaining plasma (50 to 60 ml). Approximately 60 to 75% of the donor platelets, or a minimum of 5.5×10^{10} platelets/unit, are recovered ([135]).

In Europe, platelet concentrates are prepared from the buffy coat. Briefly, the whole blood unit is spun inverted at high speed, and the platelet-poor plasma and the buffy coat are withdrawn, each into its own satellite bag. The buffy coat is then centrifuged at low speed to separate the platelets from the red and white cells. The functional quality of these platelets is comparable to those prepared by the American method ([135]). Platelet concentrates prepared from buffy coat contain fewer white cells than those prepared from platelet-rich plasma, although filtration is necessary to meet the European standards for leukoreduced products. In some European countries, platelet concentrates are pooled, resuspended in an additive solution, and filtered before storage ([136]). In the United States, the pooling of platelets before storage is prohibited.

Apheresis (Pheresis) Platelets

An alternative approach involves the collection of single donor platelets by apheresis using one of the automated collection devices described earlier ([16]). Platelets collected in this way contain at least 3×10^{11} platelets in approximately 300 ml of plasma, the approximate equivalent of six units of random donor platelets. Many pheresis platelets are leukocyte-reduced by the collection technology. Because the procedure is carried out in a closed system, the platelets can be stored for 5 days in the appropriate plastic bag ([4], [8]). Apheresis platelets are collected either from HLA-compatible donors to support alloimmunized patients or from random donors to supplement the platelet inventory. In some centers, apheresis products are the routine source of platelets. There is no significant functional difference between platelets collected by apheresis and those concentrated from whole blood donations ([137]). However, pheresis platelets typically contain fewer WBCs and, therefore,

are less likely to cause febrile transfusion reactions than whole blood–derived platelet concentrates ([138], [139]). The use of apheresis platelets also results in fewer donor exposures for recipients.

Platelet Storage

Platelet products must be kept under specific conditions to ensure optimal recovery and function after transfusion. Unlike red cells, platelets stored at 4°C undergo shape changes and lose their viability; platelet survival and function are optimized by storage at room temperature (20° to 24°C) ([140], [141]). During storage, the platelets metabolize glucose to lactate and hydrogen, which is buffered by bicarbonate present in the plasma, resulting in a release of CO_2. The nature of the bag in which platelet concentrates are stored is important. The plastics used in the early era of platelet transfusion were made of PVC and plasticizers and were not permeable to O_2 and CO_2. In these bags, stored platelets become depleted of oxygen, resulting in a shift from oxidative to glycolytic metabolism, with increased lactate generation, decreased pH, and decreased platelet viability. As the pH decreases below 6.2, platelets undergo shape change, are damaged, and show reduced *in vivo* recovery. The platelets could not be stored for longer than 72 hours in the PVC bags. The plastic materials currently in use in the manufacture of blood bags are more permeable to gases. This permits continued oxidative metabolism and prolongation of storage time ([142], [143] and [144]). Although platelet viability is maintained for up to 7 days in the new plastic containers ([145]), storage of platelet concentrates at room temperature is recommended for only 5 days because of the risks of bacterial growth ([146], [147]). Viability is best preserved if the platelets are gently agitated during storage. Platelets must be stored in sufficient plasma to maintain a pH greater than 6.2 ([4]).

PLATELET STORAGE AND FUNCTIONAL INTEGRITY Even under optimum storage conditions, platelets, like red cells, develop a storage lesion ([148]). After storage at room temperature, the changes that occur in the platelets include decreased aggregation in response to single platelet agonists such as adenosine diphosphate and reduction in adenosine diphosphate and ATP content both in granules and in the metabolic pool. ß-Thromboglobulin and platelet factor-4 are released, and both dense and a-granules are depleted ([149]). There is increased surface expression of P-selectin (CD62), a molecule derived from the a-granule membrane of the resting platelet. Platelets may develop morphologic changes and impaired responses to hypotonic shock. It has been difficult, however, to correlate the clinical response to platelet transfusions with specific *in vitro* findings. The *in vivo* effectiveness of stored platelets is dependent on the recovery of transfused platelets in the circulation of recipients. This has been assessed through platelet recovery and survival studies in normal volunteers using autologous radiolabeled platelets ([150]). Platelet recovery is the percentage of transfused platelets that are found in circulation immediately after transfusion. Even when fresh platelets are transfused, only approximately two-thirds of the transfused platelets are recovered in the circulation ([132]); the remaining 30 to 40% are pooled in the spleen ([151]). At the end of storage, mean platelet recovery is approximately 40 to 50% ([144], [152]). After the initial recovery, there is little difference in survival of fresh versus stored platelets; both show a half-life of 3 to 5 days in healthy adults ([141]). In patients, however, the observed recovery and survival of transfused platelets are often substantially lower than these figures (as discussed in the section Dosage and Expected Response). The *in vivo* hemostatic efficacy of transfused platelets is difficult to assess. The use of bleeding times in thrombocytopenic patients as an indicator of function is not of value because of great variability in technique and lack of reproducibility of results ([153]). Function is best assessed through clinical assessment of hemostasis ([154]). The clinical response generally correlates with the posttransfusion platelet increment.

PLATELET ADDITIVE SOLUTIONS Recently, synthetic storage solutions for platelets have been studied. These solutions contain acetate, which functions both as a metabolic substrate and as a buffer. Platelets stored in one of these solutions (Platelet Additive Solution-2) showed increased P-selectin expression and decreased *in vivo* recovery compared to platelets stored in plasma ([136], [155]). Another solution, Platelet Additive Solution-3, however, appears to show suitable preservation of platelet function for 7 days. This latter solution is a component of the platelet pathogen inactivation system recently approved in Europe ([156]).

FROZEN PLATELETS Frozen storage of platelets has been investigated. The role of such preparations has been established only for patients with alloantibodies for whom satisfactory donors cannot be found. Autologous platelets may be frozen using dimethyl sulfoxide as the cryoprotective agent. *In vitro* recovery of frozen and thawed platelets and posttransfusion increments may be satisfactory for clinical use, although only approximately half of the platelets survive the freeze-thaw process ([157], [158]). A recent report suggests that recovery may be improved by combining a platelet additive solution with a reduced concentration of dimethyl sulfoxide ([159]). Theoretically, autologous frozen platelet transfusions may permit support of highly alloimmunized patients through periods of chemotherapy-induced myelosuppression ([158], [160]). In practice, however, frozen platelets are not generally available.

Selection of Platelet Donors

ABO GROUP The clinical importance of ABO compatibility in platelet transfusion is controversial. Platelets bear both intrinsic ([161]) and adsorbed ([162]) antigens of the ABH system. Transfusion of ABO-incompatible platelets may be associated with decreased posttransfusion platelet recovery and normal survival ([163], [164], [165] and [166]). The reduction in recovery is variable and may be related to the isohemagglutinin titer of the recipient. Rarely, a high titer of anti-A or anti-B may cause frank refractoriness to ABO-incompatible platelets ([167], [168] and [169]). Platelet products contain a significant amount of donor plasma. Rarely, high-titered donor isoagglutinins in platelet products may cause intravascular hemolysis of recipient red cells ([170]). Some investigators have suggested that patients who receive platelets mismatched for ABO develop refractoriness at a higher rate than patients who receive ABO-compatible products ([169], [171], [172]). However, these studies were small, did not control for the presence of HLA antibodies, and differed in their observations as to whether it was cell or plasma compatibility that was important. Most important, patients who developed refractoriness to ABO-incompatible products did not show better responses when given ABO-identical products, suggesting that ABO may not have been the cause of refractoriness ([172]). In practice, it is difficult to ensure availability of ABO-identical platelet products, and many centers simply limit the volume of incompatible plasma transfused.

RH TYPE Platelets do not carry Rh antigens, and the donor's Rh type is important only because the red cells present in the platelet concentrate may immunize Rh-negative recipients. Although early studies found that as many as 19% of D-negative recipients of platelets from D-positive donors developed anti-D, several recent studies in hematology/oncology patients found that immunization did not occur ([173]). It is possible that the difference in observations is related both to an increase in intensity of chemotherapy as well as to a substantial improvement in the purity of platelet products. The red cell content of most apheresis platelets currently is below the dose thought to be immunizing. For most platelet recipients, anti-D prophylaxis would be of little benefit. For recipients with future childbearing potential, however, it may be reasonable to consider administration of intravenous anti-D Ig to prevent D immunization ([174]).

ASPIRIN AND OTHER NONSTEROIDAL ANTIINFLAMMATORY DRUGS Acetylsalicylic acid (ASA) irreversibly acetylates platelet cyclooxygenase and inhibits platelet aggregation. Platelet-mediated hemostasis is restored, however, if ASA-inhibited platelets are mixed with untreated platelets ([175]). After a single dose of aspirin, ASA-exposed platelets are inhibited for the rest of their lifespan, but platelets produced after clearance of the drug restore hemostatic function. Therefore, platelets from donors who have taken ASA are acceptable as long as 36 hours have elapsed from the last dose. Platelets donated within 36 hours of ASA ingestion are acceptable for use if mixed with platelets from unexposed donors ([4]). Other nonsteroidal antiinflammatory drugs may impair platelet function, but the effects are reversible—that is, platelet function is restored once the platelets are removed from the offending drug ([176]). Therefore, platelets from donors taking nonaspirin antiinflammatory drugs are acceptable for transfusion.

Administration of Platelets

Platelet concentrates may be provided by the blood bank in their individual plastic bags or pooled before transfusion. Once the blood bag is opened by puncturing one of the sealed ports, the platelets must be administered within 4 hours ([4]). Platelets must be administered through a filter approved for platelet use, either a standard 170-µm filter or a leukoreduction platelet filter.

Dosage and Expected Response

The usual dose of platelets is one unit for each 10 kg body weight or approximately six units (or one apheresis platelet) for a typical adult dose ([177]). The *in vivo* recovery of transfused platelets should be assessed by a platelet count obtained 10 minutes to 1 hour posttransfusion ([178], [179]).

As noted above, even under ideal circumstances, only two-thirds of transfused platelets are expected to be found in the circulation of the recipient. One can estimate the maximum expected increase in circulating platelet count after transfusion of one apheresis platelet product containing the minimum of 3×10^{11} platelets into a 70-kg adult with a blood volume of 5 L as follows: Maximum increase in count = $2/3 \times 3 \times 10^{11}$ platelets distributed in 5 L blood volume = 40×10^{9}/L.

In practice, the observed posttransfusion platelet recovery in patients is often much lower than ideal. A recovery as low as 30% of the ideal is generally considered “acceptable” ([180]). This would correspond to an increase in platelet count of approximately 13×10^{9}/L after transfusion of one apheresis platelet product to a 70-kg

adult. The expected and “acceptable” increases in platelet count would be proportionately lower in a larger adult and higher with transfusion of a larger dose of platelets.

Many investigators have assessed the acceptability of a posttransfusion platelet increment by calculating a corrected count increment (CCI). With the CCI, the measured increment in circulating platelet count is corrected for the patient's size and for the dose of platelets given as follows: CCI = (posttransfusion count – pretransfusion count) × body surface area (m^2)/number of platelets administered (10^{11}).

The maximum achievable CCI is approximately 25 × 10^9/L. The typical CCI in patients is approximately one-half of this, and the lowest “acceptable” CCI is considered to be approximately 7.5 × 10^9/L ([178], [180]). Patients with *in vivo* recoveries or CCIs lower than acceptable values should be evaluated for causes of platelet refractoriness such as an enlarged spleen or alloimmunization (as discussed in the section Platelet Refractoriness and Alloimmunization).

In healthy adults, the half-life of transfused platelets is 3 to 5 days ([141]). In thrombocytopenic patients, however, platelet survival is reduced. A fixed rate of platelet consumption of 7.1 × 10^9/L/day has been measured in otherwise stable patients with severe thrombocytopenia ([181]). It is assumed that this platelet consumption is associated with maintenance of vascular integrity. The rate of consumption may be higher in critically ill patients.

Given the limited absolute increase in platelet count achieved with the standard dose of platelets and the presence of ongoing platelet consumption, many patients return to their baseline platelet count within 1 to 2 days of platelet transfusion. In stable patients, the transfusion-free interval may be increased by administering larger doses of platelets with each transfusion ([182], [183]). Mathematic modeling suggests, however, that the total number of platelets transfused may be increased by this strategy ([184]).

Indications for Platelet Transfusion

The risks of posttraumatic and spontaneous bleeding increase as the platelet count falls. In general, assuming that platelet function is normal, there is minimal risk of spontaneous bleeding due to thrombocytopenia at platelet counts above 50 × 10^9/L, and this level is usually sufficient to permit surgical procedures ([185]). As the count falls below this level, there is an increasing risk of microvascular bleeding, characterized by petechiae, ecchymoses, oozing at venipuncture and incision sites, epistaxis, menorrhagia, gastrointestinal bleeding, or intracranial hemorrhage.

The precise degree of bleeding risk at any given platelet count is difficult to determine, as many other clinical variables have important effects. These include the cause of thrombocytopenia, the duration of thrombocytopenia, the nature of concurrent disease processes including sepsis, uremia, vasculitis, or malignant processes invading blood vessels or other organs; the coexistence of coagulopathies, such as liver disease, vitamin K deficiency, intravascular coagulation, or heparin treatment; and the presence of drugs such as ASA or semisynthetic penicillins that interfere with platelet function.

In general, the risk of significant spontaneous hemorrhage increases gradually as the platelet count drops below 50 ×10^9/L ([186]) and is high at counts below 5 × 10^9/L ([130], [131]) (Fig. 24.5 and Fig. 24.6).

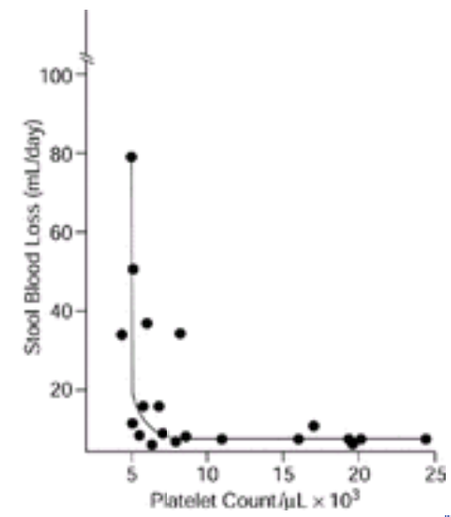

Figure 24.5. Stool blood loss as a measure of thrombocytopenic bleeding. When stool blood loss was determined in 20 aplastic thrombocytopenic patients, blood loss was less than 5 ml/day at platelet counts greater than 10 × 10^9/L. At platelet counts between 5 and 10 × 10^9/L, blood loss averaged 9 ± 7 ml/day. At levels less than 5 × 10^9/L, blood loss was markedly elevated at 50 ± 20 ml/day). (From Slichter SJ. Several clinical practice guidelines for platelet transfusion have been published ([137], [177], [185]), and the conclusions are summarized below.

PROPHYLACTIC PLATELET TRANSFUSION Prophylactic platelet transfusion in the management of acute leukemia prevents major bleeding episodes, except perhaps during the terminal phase of the patient's illness ([187], [188]). However, no difference in mortality has been demonstrated between patients transfused prophylactically and those transfused only when bleeding occurred ([188]). Despite lack of such proof, it is common practice to attempt to prevent bleeding problems by administering prophylactic transfusions to thrombocytopenic patients. The indications for prophylactic transfusion remain controversial. Until recently, it was common practice to transfuse platelets when the count was below 20 × 10^9/L. This level was chosen arbitrarily and has recently been challenged ([189]). Several recent studies have reevaluated the platelet transfusion trigger in patients with acute leukemia and in recipients of hematopoietic cell transplants ([190], [191], [192], [193] and [194]). These studies all demonstrated that reducing the trigger for prophylactic platelet transfusion from 20 × 10^9 to 10 × 10^9/L resulted in decreased platelet transfusion without an increased frequency of significant hemorrhage. In these studies, however, the trigger for transfusion was liberalized in the presence of clinical factors suspected to increase the risk of hemorrhage, such as fever, an increased WBC count, coagulopathy, bleeding, or invasive procedures. When significant hemorrhagic events occurred, they were often in patients with morning platelet counts above 20 × 10^9/L ([192], [193], [195]). Infection, vascular lesions, or prolonged duration of thrombocytopenia may contribute to the risk of significant hemorrhage ([193], [195]). Thus, it appears that a prophylactic transfusion trigger of 10 × 10^9/L is as safe as 20 × 10^9 in most patients with acute leukemia or after myeloablative hematopoietic cell transplant. However, an assessment of individual clinical risk factors is appropriate. Prophylactic platelet transfusion is usually recommended before major surgical procedures in patients with platelet count less than 50 × 10^9/L ([103], [137],

[177]). The safety of performing surgical procedures at counts below this level has not been formally evaluated. It has been demonstrated that bone marrow aspirations and biopsies, bronchoscopies, and lumbar punctures may be safely performed in patients with platelet counts of less than 20 to 25 × 10^9/L ([137]). However, the minimum safe platelet level for specific invasive procedures remains to be defined. Prophylactic transfusion of platelets is generally *not* recommended in patients with platelet consumption disorders, such as idiopathic thrombocytopenic purpura (ITP) and thrombotic thrombocytopenic purpura (TTP). In ITP, there is reduced recovery and survival of transfused platelets; transfusion usually does not result in a measurable increase in platelet count. There is some evidence that platelet transfusion may be harmful in patients with TTP ([196], [197]). However, platelet transfusion may be used to treat life-threatening bleeding in patients with these disorders.

THERAPEUTIC PLATELET TRANSFUSION Rapid massive bleeding is unlikely to be due solely to throm-bocytopenia and suggests the presence of a vascular injury. Rapid massive bleeding in the postoperative setting is usually surgical in nature and, therefore, not correctable by platelet transfusion. However, bypass-induced platelet dysfunction may contribute to bleeding after cardiac surgery ([198]); platelet transfusion may improve hemostasis in such situations. Platelet transfusion is most useful in thrombocytopenic patients with microvascular bleeding (e.g., oozing or mucous membrane or gastrointestinal bleeding). Transfusion to achieve a platelet count of 50 × 10^9/L is generally recommended ([103], [177], [185]) for bleeding patients. However, hemostasis may be achieved through repeated platelet transfusion even in the absence of a demonstrable rise in platelet count. Transfusion is indicated in bleeding patients with platelet dysfunction regardless of the platelet count. Dilutional thrombocytopenia may occur after massive transfusion of red cells and plasma volume expanders. However, a platelet count of less than 50 × 10^9/L is not generally seen unless more than two blood volumes (20 red cell units in an adult) have been replaced ([199], [200]). In this setting, the decision to administer platelets should be based on clinical assessment for evidence of microvascular bleeding and measured platelet counts ([201]); platelet transfusions should not be given routinely for a predetermined number of units of blood transfused. In all situations, the clinical decision regarding platelet transfusions requires consideration of several variables, including an estimation of platelet count and function, cause of thrombocytopenia, and state of the coagulation system; the presence or likelihood of bleeding (the development of petechiae, spontaneous mucous membrane oozing, and retinal hemorrhages are often danger signals indicating hemostatic incompetence); and the hazards of transfusion, which include all those encountered with the transfusion of any blood product.

Platelet Refractoriness and Alloimmunization

Refractoriness to platelet transfusions is a clinical state that can be defined as an unacceptable recovery of transfused platelets on two or more occasions. As noted above, a CCI of less than 7500 measured at 10 minutes to 1 hour after the transfusion is a commonly used definition of an unacceptable response or, as a general rule of thumb, an absolute increment of less than 13 × 10^9/L after transfusion of six units of platelets to a 70-kg adult. Clinical factors reported to be associated with refractoriness to platelet transfusion are listed in Table 24.6 ([132], [180], [202], [203] and [204]).

TABLE 24.6. Factors Reported to Be Associated with Platelet Refractoriness

Immune factors
Alloantibodies
Anti-HLA
Antiplatelet glycoprotein
ABO
Autoantibodies
Idiopathic thrombocytopenic purpura
Drug-related
Nonimmune factors
Splenomegaly
Fever, infection
Disseminated intravascular coagulation
Immune complexes
Bone marrow transplantation
Amphotericin

IMMUNE CAUSES OF REFRACTORINESS The major immune cause of refractoriness is the presence of anti-HLA antibodies. These antibodies are stimulated by pregnancy or by transfusion of WBC-containing blood products. Platelets bear HLA class I antigens on their surface. Anti-HLA antibodies are produced by 30 to 50% of recipients of WBC-containing blood products (Table 24.7) ([51]). They are found in up to 30% of untransfused women with a history of pregnancy ([205], [206]). After exposure to blood products, up to two-thirds of women with a history of pregnancy produce HLA antibodies ([207]). Transfusion of platelets that are serologically incompatible with a preexisting HLA antibody typically results in no increase in platelet counts ([208], [209]).

TABLE 24.7. Efficacy of Leukocyte-Reduced Products in Preventing Transfusion-Induced HLA Alloimmunization

	Type of Blood Products Received	
Author	**Control**	**Leukoreduced**
Elghouzzi	26/93 (0.28)	10/67 (0.15)
Schiffer	13/31 (0.42)	5/25 (0.20)
Andreu	11/35 (0.31)	4/34 (0.12)
Sniecinski	10/20 (0.50)	3/20 (0.15)
Rebulla	5/15 (0.33)	4/16 (0.25)
Van Marwijk	11/26 (0.42)	2/27 (0.07)
Oksanen	3/15 (0.20)	2/16 (0.12)
Handa	9/23 (0.39)	4/49 (0.08)
Lane	7/20 (0.35)	3/26 (0.11)
Williamson	21/56 (0.37)	15/67 (0.22)
TRAP	59/131 (0.45)	25/137 (0.18)

NOTE: This is a summary of prospective controlled trials in hematology and oncology patients. Each numerator indicates the number of patients developing HLA antibodies; the denominator indicates the number of patients transfused with that type of blood product. The number in parentheses represents the calculated proportion of patients making antibodies.

Modified from Dzik WH. Leukoreduced blood components: laboratory and clinical aspects. In: Simon TL, Dzik WH, Snyder EL, et al., eds. Rossi's principles of transfusion medicine, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2002:270–287.

The incidence of clinically significant alloantibodies to platelet-specific glycoproteins in transfusion recipients is unclear. Antibodies to platelet glycoproteins have been detected almost exclusively in patients who also have broadly reactive anti-HLA antibodies. Using the sensitive MAIPA (*m*onoclonal *a*ntibody *i*mmobilization of *p*latelet *a*ntigen) assays, investigators have reported detection of antibodies to platelet glycoproteins in as many as 25% of HLA-alloimmunized transfusion recipients ([210], [211] and [212]). A significant proportion of the antibodies detected have ill-defined specificity, and the contribution of such antibodies to platelet refractoriness is unclear. The presence of platelet-specific antibodies in patients who are broadly sensitized to HLA presents an enormous transfusion support challenge. Although many blood centers maintain HLA-typed donor registries, at present, very few of these donors are typed for platelet antigens. The solid-phase red cell adherence or recently developed MAIPA-based platelet crossmatching assays could theoretically be used to test HLA-selected products for compatibility with a patient's antiplatelet antibodies, although it has not yet been established whether these assays have adequate sensitivity and specificity for this application. As discussed above, high-titered ABO antibodies have been implicated in platelet refractoriness. Many investigators recommend a trial of ABO-compatible products in refractory patients,

although studies have not demonstrated a high likelihood of improvement. Antiplatelet autoantibodies are usually associated with absolute refractoriness to platelet transfusion. However, in the event of life-threatening bleeding, patients with ITP may benefit clinically from repeated infusions of platelets even in the absence of a demonstrable rise in platelet count.

NONIMMUNE CAUSES OF REFRACTORINESS Of the nonimmune factors implicated in refractoriness, splenomegaly is the most potent. Transfused platelets pool in the enlarged spleen; increasing the dose of platelets does not necessarily improve the posttransfusion increment. Each of the other nonimmune factors listed in Table 24.6 has been reported to be associated with refractoriness, although the importance of each factor has not been demonstrated consistently ([132], [180], [202], [203], [213]).

PREVENTION OF HLA ALLOIMMUNIZATION Although platelets express HLA class I molecules on their surface, purified platelets do not appear to induce primary immunization to HLA antigens. It appears that the presence of WBCs is necessary, presumably because of their dual expression of both HLA class I and class II antigens ([214]). Multiple studies have demonstrated that the prophylactic use of leukoreduced blood products significantly decreases the incidence of HLA immunization in transfusion recipients (Table 24.7) ([51], [215], [216]). Use of leukoreduced blood products is recommended for patients who are likely to require intensive platelet transfusion support, because the development of anti-HLA antibodies would complicate such support. Purified platelets can stimulate a secondary immune response to HLA ([214]). Patients with prior pregnancy are highly likely to produce HLA antibodies after transfusion. HLA alloimmunization has been observed in up to two-thirds of such patients. The use of leukoreduced products appears to be of limited benefit in such patients, with HLA antibodies produced by 33 to 44% of patients with a history of pregnancy despite the use of leukoreduced products ([207], [215], [217]). As an alternative to removing WBCs from blood products, *in vitro* studies indicate that ultraviolet (UV) irradiation of WBCs abrogates their ability to present HLA antigens in mixed lymphocyte culture ([218], [219]). *In vivo* studies demonstrate that UV irradiation of blood products is as effective as leukocyte reduction in preventing primary HLA alloimmunization ([207]). UV irradiation of platelet products requires special blood containers and equipment and is not currently available in the United States. A pathogen inactivation system involving psoralen and UV light has recently been approved in Europe ([156]). In the United States, however, this system will most likely be applied to apheresis platelets, which are already leukoreduced. Early studies suggested that HLA alloimmunization in platelet transfusion recipients could be reduced by minimizing donor exposure through the use of pheresis platelets rather than pooled platelet concentrates ([220], [221]). Recently, however, it has been shown that if all products are leukoreduced, there is no incremental benefit to the use of pheresis products ([207]).

DIAGNOSIS AND MANAGEMENT OF ALLOIMMUNIZATION Historically, anti-HLA antibodies have been detected by lymphocytotoxicity assays. Newer methods of testing for HLA antibodies include an enzyme immunoassay in which HLA glycoproteins are immobilized on a plastic plate using monoclonal antibody ([222]). A commercially available solid-phase red cell adherence assay permits screening for serologic reactivity against platelets selected from inventory ([223]). Early studies demonstrated that thrombocytopenic patients with lymphocytoxic antibodies could be successfully supported with platelets obtained from donors who were HLA identical to the patient or donors who were partially HLA matched and whose lymphocytes were serologically compatible with the patient's antibody ([208], [224]). These observations led to the practice of providing apheresis platelets from “HLA-matched” donors for patients with lymphocytoxic antibodies. Depending on the availability of family members, the rarity of the patient's HLA type, and the size of the HLA-typed donor registry, it may be difficult or impossible to locate platelet donors who are HLA identical to the patient. Therefore, many platelets provided as HLA matched bear one or more antigens that are foreign to the recipient. Serologic crossmatching of partially mismatched products can be used to identify those that are more likely to result in a good posttransfusion increment ([208], [209], [225]). In most HLA-alloimmunized patients, the specificity of the antibody can be defined ([213], [226], [227]). Patients can be successfully supported with products that lack the HLA antigens(s) to which the antibodies are directed ([213], [226]). If the platelet inventory is HLA typed, products lacking the offending antigen(s) can usually be found in inventory; thus, many patients can be supported with products on the shelf without the need for special donor recruitment or serologic crossmatching. Alternatively, serologic crossmatching of HLA-untyped products may be used to support patients whose antibodies are not broadly reactive. For many alloimmunized patients, it is possible to identify serologically compatible platelets among HLA-untyped products in the blood center inventory using the solid-phase red cell adherence crossmatching assay ([223]). However, compatible products are unlikely to be found in inventory for patients who have broadly reactive antibodies; such patients require specific recruitment of HLA-selected donors. In summary, HLA-alloimmunized patients may be supported with (a) products from donors who are HLA identical to the patient or who lack HLA antigens foreign to the recipient; (b) products that are partially HLA matched and serologically compatible; (c) by identifying the specificity of the patient's HLA antibody and avoiding products bearing the offending antigen(s); or (d) by serologic crossmatching of products in inventory. These methods are equally effective clinically ([213]). The first method is often limited by the inadequate availability of donors. The last method is not applicable to patients with broadly reactive antibodies, who comprise approximately 10 to 15% of alloimmunized patients ([223], [227]). It should be noted that HLA antibodies may appear or disappear over the course of a patient's treatment ([132], [213]). It is important to monitor patients' responses to platelet transfusion and to reevaluate them serologically if they do not respond to products that were previously acceptable.

PLATELET TRANSFUSIONS FOR REFRACTORY PATIENTS A recent guideline suggests withholding prophylactic transfusion for nonbleeding patients who do not achieve acceptable posttransfusion increments in platelet counts ([137]). However, many clinicians arbitrarily transfuse one dose of platelets daily based on the assumption that some platelets are necessary for maintaining vascular integrity ([181]). For bleeding patients, many practitioners recommend infusion of larger or more frequent doses of platelets ([180], [228]).

ROLE OF PHARMACOLOGIC AGENTS IN MANAGING THROMBOCYTOPENIC PATIENTS In situations in which HLA-compatible products could not be obtained, some investigators have reported that intravenous Ig infusions improved responses to incompatible products. However, some authors found no improvement, improved responses to compatible products only, or improved 1-hour but not 24-hour posttransfusion increments ([132], [180], [229], [230], [231] and [232]). Recent anecdotal reports suggest that recombinant factor VIIa may stop bleeding in severely thrombocytopenic patients ([233], [234]). The indications for use of this agent in thrombocytopenic patients remain to be defined. The antifibrinolytic agents aminocaproic acid and tranexamic acid have been reported to reduce bleeding in thrombocytopenic oncology patients ([235], [236] and [237]), although a beneficial effect has not been demonstrated consistently by all investigators. The use of these agents is contraindicated in patients with disseminated intravascular coagulation. The discovery of thrombopoietin (TPO) in 1994 initially caused optimism that this agent could be used clinically to prevent thrombocytopenia or enhance platelet recovery after myelosuppressive therapy. Two recombinant forms of TPO have been evaluated in clinical trials. One of these, a pegylated nonglycosylated form of the molecule, was found to be associated with the production of anti-TPO antibodies and throm-bocytopenia ([238]); this agent is no longer in clinical development. In clinical trials, TPO did not improve the time to platelet recovery in patients undergoing chemotherapy for acute myelogenous leukemia or after myeloablative HPC transplants. However, TPO has been reported to improve the nadir platelet count and to reduce the duration of thrombocytopenia in patients receiving less myelosuppressive therapy. TPO was reported to increase platelet counts in patients with HIV-related thrombocytopenia, ITP, and the myelodysplastic syndrome ([239], [240]). TPO administration can improve platelet yield in apheresis donors, including autologous platelets being collected for freezing ([159]). The clinical safety of and appropriate indications for TPO remain to be defined; the agent is not yet FDA approved for clinical use.

GRANULOCYTE TRANSFUSIONS

Severe bacterial and fungal infections in the setting of prolonged chemotherapy-associated neutropenia continue to be a significant source of morbidity and mortality in the modern treatment of malignancy. The risk of serious bacterial infection first appears as the neutrophil count falls below 1.0×10^9/L and increases rapidly below 0.5×10^9/L. Fungal infections occur with much higher frequency as the neutrophil count falls below 0.2×10^9/L ([241]). Other risk factors include the duration of neutropenia and the rate of fall of the neutrophil count ([242]). Although the use of growth factors [granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor] has reduced the severity and duration of neutropenia, many patients still experience prolonged periods of poor granulocyte production, often lasting 2 to 3 weeks or longer ([243], [244] and [245]). Although the concept of augmenting host defenses with granulocyte infusions dates back 60 years, difficulty in obtaining adequate yields of granulocytes as well as safety concerns stifled the initial interest generated after early clinical successes in the 1970s ([246], [247]). The introduction of modern apheresis techniques, the use of growth factors to increase donor granulocyte yields, and a number of positive results from clinical trials have led to renewed interest in applying this cellular therapy to a wider range of patients ([248], [249]).

Donor Preparation/Selection

As early granulocyte transfusion studies used granulocytes prepared from patients with chronic myelogenous leukemia who had high granulocyte counts, the concept of patients receiving a very high granulocyte dose became a desirable goal in subsequent trials ([250]). This led to the development of methods to collect large quantities of granulocytes from normal donors. Centrifugal apheresis, using either continuous or discontinuous cell separators, became the standard method for the production of granulocyte concentrates ([242], [251], [252]). The quantity and quality of granulocytes obtained depend on the apheresis collection technique as well as on the level of circulating neutrophils present in the donor. Infusion of hydroxyethyl starch or dextran to improve the sedimentation of donor red cells during centrifugation improves the efficiency of apheresis, but the granulocyte yield remains low ([242]). It has been suggested that a daily granulocyte dose in the order of 10×10^{10} cells would be necessary to achieve clear-cut benefit ([253]). Administration of oral corticosteroids produces a transient neutrophilia in the donor, but the collection yields remain in the range of 2 to 3×10^{10} ([254]). A number of clinical studies have shown the utility of G-CSF in increasing the dose/collection ([255], [256], [257], [258] and [259]). Donors treated with varying doses of G-CSF with or without cortico-steroids produce yields ranging from 2.4 to 9.9×10^{10} granulocytes. Although adverse effects occur in 30 to 69% of donors, most consist of mild to moderate degrees of bone pain, headache, myalgias, and fatigue. Data from the bone marrow transplant

literature support the short-term safety of G-CSF administration in healthy donors, although rare serious adverse events have been reported; long-term follow-up data are limited and deserve further attention ([260]). G-CSF administration to healthy donors is generally performed under institutional review board–reviewed protocols. Based on available evidence, donor pretreatment with a single dose of G-CSF (300 to 600 µg subcutaneously) with dexamethasone (8 mg orally) 12 hours before collection may allow reliable yields in a well-tolerated and cost-effective manner. Although repeated daily G-CSF stimulation and granulocyte collection have been reported ([261], [262]), standard practice is to perform a second collection no sooner than 7 days after the initial cytapheresis ([263]).

Prospective granulocyte donors should meet all FDA and AABB standards for donation. Because granulocyte products must usually be transfused before completion of donor infectious disease testing, donors who have been tested recently are strongly preferred. Donors should also be free of disorders that might be exacerbated by the administration of dexamethasone (e.g., diabetes) or G-CSF (e.g., arthritis, vasculitis, splenomeg-aly, gout, thrombocytopenia). Donor/recipient pairs should be ABO compatible due to the large number of RBCs contained in the product. RBC compatibility must be verified for each granulocyte product. CMV infections are a significant risk when seropositive donors are used for immunocompromised sero-negative patients; therefore, CMV-negative patients should receive CMV-negative products ([264]).

Patients requiring granulocyte transfusions may have become alloimmunized to HLA, RBC, or both antigens during the course of prior transfusion support or pregnancy. Studies suggest decreased recovery and survival as well as failure of granulocytes to localize at the site of inflammation in patients who have lymphocytotoxic or granulocyte-specific antibodies ([265], [266]). Recipients should, therefore, be screened for the presence of HLA antibodies. In alloimmunized patients, HLA-compatible random donors or family members should be used; random donors may be preferred over family members if related allogeneic transplantation is anticipated as part of treatment for the underlying disease. If laboratory tests for alloimmunization are not readily available, the likelihood of sensitization may be estimated by reviewing the patient's record for a history of platelet refractoriness or febrile transfusion reactions.

Granulocyte Collection/Storage

Once an appropriate donor has been selected and prepared, centrifugal leukapheresis is performed by processing 7 to 10 L of blood over 3 to 4 hours using an agent such as hydroxyethyl starch to reduce the amount of contaminating RBCs by sedimentation. According to AABB standards, there should be at least 1×10^{10} granulocytes/unit collected ([4]); yields with current techniques achieve mean yields of 2 to 3×10^{10}/leukapheresis. Products contain 200 to 400 ml of plasma, 10 to 30 ml of RBCs, and 1 to 6×10^{11} platelets. Although granulocyte storage is permitted for up to 24 hours at room temperature, transfusion within 8 hours of collection is recommended. Biochemical assessments of the effects of storage on subsequent function (e.g., nicotinamide adenine dinucleotide phosphate oxidase activity, adhesion protein expression, respiratory burst activity, and bactericidal activity) reveal that effective storage may be possible for up to 48 hours at 10°C ([267]).

Administration of Granulocytes

Granulocytes should be administered on a daily basis until the patient's endogenous neutrophil count rises to 0.5×10^{9}/L or until the infection clears. Granulocyte concentrates should be given through a standard filter set to ensure that aggregates are not administered. The concentrate should be given slowly (over 1 to 2 hours) with the patient under constant observation, including the use of pulse oximetry. Transfusion reactions occur in 10 to 50% of patients but are usually mild, consisting of fever and chills. Premedication with antihistamines, acetaminophen, or steroids is common practice before infusion. More severe reactions occur in 1 to 5% of patients and tend to be pulmonary in nature. A serious potential interaction between granulocyte transfusions and amphotericin B has been reported ([268]), but this association has not been substantiated by others ([269], [270]). Nevertheless, many physicians administer granulocytes and amphotericin at least 8 hours apart to limit the potential for increased pulmonary toxicity. If there are any signs or symptoms of respiratory distress, the transfusion should be discontinued immediately, the recipient should be examined for hypoxemia or pulmonary edema, and a chest radiograph should be done and assessed for pulmonary infiltrates. If major adverse effects do occur, the recipient should be studied for the presence of antibodies that react with neutrophils. Granulocyte products contain a large number of lymphocytes and are, therefore, potentially capable of causing transfusion-associated GVHD (TA-GVHD). The current practice of irradiating all granulocyte products with 1500 to 3000 cGy should prevent transfusion-related GVHD without significantly impairing granulocyte function ([267]). Pre- and posttransfusion neutrophil counts should be determined to guide therapy. With large doses (>8×10^{10}), neutrophil increments may exceed 2×10^{9}/L immediately after infusion and may last for 24 to 48 hours ([271]).

Clinical Indications and Efficacy

Prior clinical trials conducted on the use of granulocyte transfusions in the setting of neutropenia give some insight into the patient populations that may benefit from this therapy. A review of 32 papers ([272]) revealed that most studies have been uncontrolled, involved small heterogeneous populations of patients, and had different treatment approaches. Approximately 62% of the 206 patients with bacterial sepsis were reported to have benefited from granulocyte transfusion; conversely, 71% of 63 patients with invasive fungal infection did not respond to the infusions. Seven controlled trials were completed between 1972 and 1982: Three showed a positive effect, two showed benefit in specific patient populations, and two demonstrated no benefit. Some of the studies were likely limited by the cytapheresis techniques used and the low cell yields obtained, as most donors were pretreated with corticosteroids only. Further analysis confirmed the importance of higher neutrophil doses as well as leukocyte compatibility in the three positive trials. Recent trials ([258], [273]) provide additional evidence to support the use of granulocyte transfusions in critically ill neutropenic patients with bacterial as well as candidal sepsis. Based on this information, granulocyte therapy may warrant consideration in severely neutropenic patients with bacterial infections unresponsive to typical antimicrobial therapy.

The applicability of granulocyte infusions in the setting of invasive fungal infections remains unclear. No study has shown clear efficacy in patients with active aspergillosis, although often the neutrophil dose was not known or was suboptimal. Limited clinical and animal model data give some indication of usefulness in the setting of candidal and noninvasive fungal infections ([258], [274]). As the overall data are limited, a brief trial of granulocyte infusions may be warranted in patients with self-limited neutropenia and documented fungal infection who are refractory to standard antifungal therapy.

The effect of the prophylactic use of granulocyte transfusions to diminish the risk of serious infections in severely neutropenic patients during therapy of hematologic malignancies and after bone marrow transplantation has been investigated in a number of controlled trials ([249]). Although prophylactic granulocyte transfusion may decrease the risk of septicemia, the increased incidence of adverse effects observed with this therapy may outweigh the beneficial effects ([264], [275], [276], [277], [278], [279] and [280]). As no clinical efficacy has been observed, prophylactic transfusions are not recommended.

Granulocyte transfusions may also be indicated in infected patients with severe neutrophil dysfunction (e.g., chronic granulomatous disease and leukocyte adhesion deficiency) who are not responding to appropriate antimicrobial therapy. Although controlled trials have not been performed, transfused granulocytes do migrate within recipients and appear to be of therapeutic benefit ([281], [282] and [283]). Because of the adverse effects associated with the transfusion of granulocytes, they should be used judiciously in the patient with severe documented infections, as the infusions may result in alloimmunization of the recipient and render him or her unresponsive to granulocyte transfusion therapy at a later date.

Neonatal bacterial sepsis continues to be a major cause of morbidity and mortality. The function of the neutrophil in the neonate is impaired, with diminished chemotaxis and abnormal adhesion properties ([284]). Infection may result in neutropenia and depletion of the neutrophil storage pool ([285], [286] and [287]). Granulocyte transfusions have been used in the treatment of neonatal sepsis with varying results ([285], [288], [289] and [290]). The efficacy of this approach has been evaluated in six controlled trials with four studies demonstrating a survival benefit. Analysis of the overall data does not establish a clear benefit when other available therapies are considered ([246]). When compared with standard therapy of intravenous Ig, neonates with group B *Streptococcus* may experience increased survival after receiving granulocyte support ([291]). Although conflicting data exist, centers that experience a high mortality rate in septic infants with neutropenia and ongoing neutrophil storage pool depletion may consider a trial of granulocyte therapy. The recommended dose is 1×10^{9} granulocytes/kg of body weight ([249]).

HEMATOPOIETIC STEM CELLS

Peripheral blood stem (progenitor) cells (PBPCs) collected by cytapheresis have become the standard source of hematopoietic cells for autologous transplantation ([292]). Grafts are collected after mobilization of the patient's PBPCs with chemotherapy or growth factor (G-CSF or granulocyte-macrophage colony-stimulating factor) administration ([293], [294], [295] and [296]). When autologous transplants are performed with mobilized progenitor cells, significant decreases are seen in the duration of neutropenia and thrombocytopenia. Extension of this practice into the area of allogeneic transplantation is rapidly gaining acceptance. Collecting PBPCs from

matched related donors has been shown to yield adequate numbers of cells for engraftment with minimal toxicity to the donor. A number of randomized trials comparing peripheral blood progenitor cells to bone marrow show that PBPCs are associated with faster engraftment of neutrophils and platelets ([297]). Despite a 1-log greater content of T cells in progenitor cells obtained from the peripheral blood, initial studies have not shown an overall increase in the incidence or severity of acute GVHD. However, the long-term risk for chronic GVHD may, in fact, be higher with PBPCs when compared to bone marrow–derived grafts ([298]). Similar findings are seen in studies comparing the source of progenitor cells in matched-unrelated donor transplantation ([299]). Although the data with regard to allogeneic PBPCs are encouraging, long-term follow-up is still needed to determine the impact of this therapeutic modality on relapse and overall survival.

PBPCs are collected using technology (cytapheresis) similar to that used for platelet collection ([16]). The mononuclear cells are collected until an adequate number have been obtained, often by daily pheresis via peripheral veins or an indwelling catheter for 1 to 3 days. The minimum target dose is 2 to 5 × 10^{6} $CD34^{+}$ cells/kg and 20 to 50 × 10^{4} colony-forming units granulocyte-monocyte/kg ([300] , [301]). The cells are collected and frozen for later use in autologous transplantation; allogeneic cells are most often infused fresh within 24 hours. After the recipient receives the appropriate preparative regimen (myeloablative or nonmyeloablative chemotherapy with or without radiotherapy), the stem cells are thawed, prepared, and infused, with successful marrow reconstitution over a period of 3 to 4 weeks ([302] , [303] and [304]).

The newest source of HPCs to be used in transplantation is umbilical cord blood (UCB). The blood can be collected from the umbilical vein and placenta immediately after birth using a collection bag and an appropriate volume of CPD anticoagulant. Although not found in large numbers, hematopoietic cells in UCB have proliferative advantages over traditional sources. Initial clinical studies were carried out in the related transplant setting where it was demonstrated that engraftment does occur with a relatively low incidence of GVHD ([305]). Similar results were seen with UCB transplants performed in the matched-unrelated setting, driving the subsequent development of cryopreserved cord blood banks. An increasing number of UCB transplants over recent years has allowed data to be collected on long-term survival. Patients who received related UCB had a 1-year survival of 63% compared with 29% in the unrelated setting ([306]). Because a strong association exists between cell dose and survival, the majority (>80%) of UCB transplants are performed in children. Despite limiting this approach primarily to children, a report by the Placental Blood Program at the New York Blood Center on a group of 562 unrelated UCB transplants showed a relatively high rate of incomplete/nonengraftment and increased 100-day mortality due to infectious complications ([307]). Further data on relapse and long-term survival must be collected to determine the utility of this source of HPCs. Unresolved questions include the need for *in vitro* expansion before infusion in adult patients as well as many ethical issues that surround the collection, storage, and use of UCB.

TRANSFUSION OF PLASMA AND COMMERCIAL PROTEIN CONCENTRATES

The large-scale use of plasma dates from World War II, when plasma became invaluable as a volume expander in the treatment of hemorrhagic shock under field conditions. In current medical practice, plasma and products prepared from it have found numerous other roles. Plasma comes from two sources: whole blood donations and apheresis collections. Plasma may be used for transfusion, further processed by the blood center into cryoprecipitate, or sent to commercial facilities for manufacturing into plasma derivatives. Recombinant protein products can be used in place of some plasma derivatives.

The therapeutic effectiveness of each plasma product can be estimated on the basis of the factor content of the product and its expected distribution into the plasma volume of the recipient (usually, approximately 40 ml/kg). However, the *in vivo* recovery of individual factors varies significantly.

Noncommercial Plasma Components for Transfusion

These components, such as FFP, are produced from individual volunteer blood donors and are briefly described below.

FRESH FROZEN PLASMA FFP is prepared by separating citrated plasma from whole blood and freezing it within 8 hours of collection or by freezing citrated apheresis plasma within 6 hours of collection. FFP may be stored at -18°C or below for up to 1 year. Under these conditions, there is minimal loss of activity of the labile coagulation factors V and VIII. One ml of FFP contains approximately one unit of coagulation factor activity. After thawing, FFP may be stored in the refrigerator for up to 24 hours before use. FFP is indicated for use in patients who are bleeding or having an invasive procedure *and* who are deficient in multiple coagulation factors or in a single factor for which there is no specific factor concentrate available. It is also indicated for replacement of clotting factors during massive transfusion, for reversal of warfarin (if immediate reversal is necessary), and as the replacement fluid for plasma exchange procedures in patients with TTP ([9] , [177]). It should not be used as a volume expander, because alternative products with lower risk of infectious diseases and allergic reactions are available for this purpose (e.g., crystalloid, albumin, starch). Each unit of FFP prepared from whole blood contains approximately 200 ml of plasma. Apheresis plasma may be packaged into 200- or 400-ml bags. A typical dose of 10 to 15 ml/kg would constitute approximately 25 to 30% replacement therapy for coagulation factors (although there is lower recovery of some factors because of their diffusion into the extravascular space). FFP must be ABO compatible with the recipient's red cells.
PLASMA FROZEN WITHIN 24 HOURS This is plasma that has been stored in the refrigerator for up to 24 hours before freezing. The content of this product is similar to FFP except that factor VIII activity is reduced to 75% of normal ([308]). If used immediately after thawing, the factor VIII content of this product would be similar to that of an FFP unit that had been stored for 24 hours after thawing.
LIQUID PLASMA, THAWED PLASMA *Liquid plasma* is a term for plasma separated from refrigerated whole blood up to 5 days after its expiration date. It may be stored at l° to 6°C or frozen at or below -18°C. *Thawed plasma* is a term for FFP that has been stored in the refrigerator for more than 24 hours after thawing. The only significant difference between these products and FFP is the content of the labile coagulation factors (V and VIII). When plasma is stored at 1° to 6°C, factor VIII activity decreases by approximately 50% within the first few days of storage but falls only slowly thereafter. By the end of 40 days' storage, factor VIII activity remains approximately 30% of normal. Factor V levels decline steadily and reach approximately 30% of normal after 3 weeks of storage. Other coagulation factors, including fibrinogen and factors II, VII, IX, X, and XIII, are generally stable under refrigerated storage conditions ([309] , [310]). Liquid plasma or thawed plasma should not be used for clotting factor replacement in patients who are deficient in factors V or VIII. However, it may be reasonable to use these products for plasma replacement in massively bleeding patients, as use of these products would still permit maintenance of clinically hemostatic factor levels (i.e., 30% of normal).
PLASMA, CRYOPRECIPITATE-REDUCED This is the supernatant remaining after removal of cryoprecipitate from FFP (see the section Cryoprecipitated Antihemophilic Factor). Storage conditions are the same as for liquid plasma. This product is deficient in fibrinogen, factor VIII, von Willebrand factor (vWF), and factor XIII. It may be used for the same indications as liquid plasma. It is also useful in the treatment of TTP, because it is deficient in high-molecular-weight vWF multimers.
CRYOPRECIPITATED ANTIHEMOPHILIC FACTOR *Cryoprecipitated AHF*, or *cryoprecipitate*, is an extract of FFP that is enriched in high-molecular-weight plasma proteins. It is prepared by thawing one unit of FFP at 1° to 6°C. Under these conditions, the high-molecular-weight proteins remain as a precipitate. The precipitated protein is concentrated by centrifugation, and all except approximately 15 ml of supernatant is removed. The remaining 15 ml and the precipitate are refrozen. Each unit of this cryoprecipitate contains approximately 80 to 120 units of factor VIII and at least 150 mg of fibrinogen. It also contains factor XIII and the high-molecular-weight multimers of vWF. Cryoprecipitate was originally developed for the treatment of hemophilia A. It is no longer the treatment of choice for that disorder because less infectious alternatives are available. At the present time, cryoprecipitate is most often used for correction of hypofibrinogenemia (<100 mg/dl), particularly in patients with disseminated intravascular coagulation or in those whose fibrinogen is depleted from prolonged exposure to cardiopulmonary bypass circuits. Cryoprecipitate has also been used topically, along with thrombin and calcium, as a “fibrin glue.” However, commercial products that are much more effective as topical hemostatic or sealant agents are now available. The typical dose of cryoprecipitate of one unit/5 kg would be expected to raise the recipient's fibrinogen level by approximately 70 mg/dl ([9] , [177]). Multiple units of cryoprecipitate may be pooled before issue.

Commercial Plasma Derivatives

Commercial plasma derivatives are made from pooled plasma derived from thousands of donors. In the United States, paid plasmapheresis donors provide most of the plasma derivatives, but excess (“recovered”) plasma from volunteer whole blood donations is also used. Thousands of plasma units are pooled and fractionated into a number of purified proteins. The usual fractionation procedure is based on Cohn's cold ethanol fractionation process, developed in the 1940s ([311] , [312]). As the temperature, ionic strength, pH, and ethanol concentration are varied, plasma can be separated into several fractions. Fraction I contains factor VIII and fibrinogen, fraction II contains the immunoglobulins, and fraction V contains albumin. Fractions III and IV contain a number of other coagulation factors and proteins. Although other approaches such as ion exchange chromatography have been applied to the preparation of certain plasma products, Cohn's method still remains the standard. More recent advances have introduced affinity chromatography steps, using monoclonal antibodies, to obtain more highly purified preparations.

Because thousands of donors are represented in the plasma pools used for the production of plasma derivatives, contamination with infectious agents is common. Remarkably, albumin and intramuscular immune globulin preparations have not been associated with disease transmissions. Clotting factor concentrates, however, were highly infectious before the implementation of specific pathogen inactivation processes. Thus, most recipients of the early factor VIII concentrates produced in the 1970s developed evidence of exposure to hepatitis B, and 90% of recipients between 1979 and 1984 were exposed to HIV ([313] , [314]). Methods of heat treatment

developed in the early to mid-1980s reduced the risk of HIV—but not of hepatitis C. Today, almost all plasma derivatives are treated by methods demonstrated to inactivate HIV, HCV, and hepatitis B virus (HBV), such as prolonged heat and treatment with organic solvents and detergents, that inactivate lipid-coated viruses. Pooled plasma products, however, could still transmit infectious agents that lack a lipid coat and that are resistant to heat. Most recently, concerns have been raised about the potential for prion transmission through blood products, although available evidence suggests that these agents, if present in blood, would likely be removed from plasma products during the manufacturing process ([315]). Because the possibility of infectious disease transmission cannot be completely eliminated, proteins produced through recombinant DNA techniques are generally considered preferable to derivatives from pooled plasma. Many recombinant products, however, contain albumin derived from pooled plasma.

There are many commercial plasma derivatives available. Some examples are described below.

ALBUMIN Albumin ([316] , [317]) may be prepared by a variety of fractionation procedures, but the standard is cold ethanol (Cohn) fractionation; albumin so prepared is approximately 95% pure. A less complex preparative method yields plasma protein fraction that is approximately 85% albumin. Both products are heat treated to eliminate the risk of transmission of viral hepatitis and HIV. They are available as 4% or 5% solutions; albumin is also available at a 25% concentration. These products are generally pure and free of most of the side effects of plasma.
SOLVENT DETERGENT–TREATED PLASMA Solvent detergent–treated plasma is made from thousands of units of FFP that have been thawed, pooled, subjected to treatment with organic solvents and detergents, filtered, and refrozen. The product was developed to reduce the risk of transmitting enveloped viruses, such as HIV, HCV, and HBV. It is therapeutically equivalent to FFP and attractive for treatment of TTP in that it is deficient in the highest-molecular-weight vWF multimers ([318] , [319]). Because it is a pooled product, however, it carries an increased risk of transmitting infectious agents that are not destroyed by solvent/detergent treatment, including nonenveloped viruses such as parvovirus B19 ([320] , [321]). This product is no longer distributed in the United States.
COAGULATION FACTOR CONCENTRATES The coagulation factor concentrates, both the recombinant products and those made from plasma, are discussed in detail elsewhere as part of the management of hemophilia (see Chapter 59). Factor concentrates made from human plasma are treated by methods such as pasteurization or solvent detergent sterilization that inactivate lipid-enveloped viruses such as HIV and most of the hepatitis viruses.
FACTOR VIII Several plasma-derived factor VIII preparations are available, each prepared in a slightly different way. Only some contain therapeutic amounts of von Willebrand's factor. Recombinant factor VIII concentrates are available and may be the treatment of choice for hemophilia A but do not contain vWF. These products are reviewed in detail in Chapter 59.
FACTOR IX Prothrombin complex concentrates contain variable concentrations of the vitamin K–dependent factors II, VII, IX, and X. Such concentrates have variable degrees of thrombogenic activity and are now used mainly in the treatment of patients with coagulation inhibitors. Activated factor IX complex concentrates such as Autoplex and FEIBA are prepared in such a way that factor VIII is bypassed in the coagulation cascade. They are used in the management of patients with factor VIII inhibitors ([322] , [323]). A recombinant factor VIIa product is also available for use in patients with factor VIII inhibitors (see Chapter 59). More purified factor IX concentrates that do not appear to have thrombogenic activity have been developed using affinity chromatography. Among the plasma-derived factor IX preparations, these purified products are the most appropriate for the treatment of hemophilia B. However, recombinant factor IX products are also available (see Chapter 59).
ANTITHROMBIN III Antithrombin III is a plasma protease inhibitor that circulates in plasma at a concentration of 180 to 300 mg/L ([324]). Antithrombin-deficient patients with thrombosis or in situations with a high risk of thrombosis have been managed by transfusion of antithrombin III ([325]). Antithrombin III deficiency may be treated by infusion of plasma ([326]). Antithrombin III concentrates are available, prepared from pooled plasma by affinity chromatography with heparin agarose ([324]).
PROTEINS C AND S There are no plasma-derived concentrates of proteins C or S available in the United States. However, a recombinant activated protein C product is available, which appears useful in the treatment of patients with sepsis ([327]).
INTRAMUSCULAR IMMUNOGLOBULINS Intramuscular immune globulin preparations are prepared from pooled plasma by cold ethanol fractionation. They are provided as 16.5% protein solutions, containing approximately 95% IgG and small amounts of IgA and IgM. They contain dimeric and polymeric IgG, artifacts of the fractionation procedure, which are capable of nonspecifically activating complement by both the classic and alternate pathways. This mechanism probably explains the major adverse effects that occur if these products are administered intravenously. Products labeled for intramuscular use must therefore not be given intravenously. Intramuscular immune globulins have not been associated with infectious disease transmission. Some, but not all, are solvent detergent–treated. Nonspecific immune globulin preparations contain a broad spectrum of antibodies naturally present in the donor population. They are most often used for passive immunization (e.g., to hepatitis A). Immune globulins against a particular agent are derived from the plasma of donors selected for high concentrations of antibodies to that agent. Such preparations include Rh immune globulin, hepatitis B immune globulin, and varicella zoster immune globulin.
INTRAVENOUS IMMUNE GLOBULINS A number of modified Ig products that permit intravenous administration are available. These are produced by various chemical modifications designed to decrease the aggregation of IgG. Nonspecific complement activation is reduced, whereas the ability of the Ig molecules to interact with pathogenic organisms and complement is retained ([328]). Intravenous immune globulin (IVIG) preparations are supplied as 3 to 12% protein solutions or powders that have to be reconstituted. Slow administration is necessary, however, to help prevent adverse reactions. The ability to administer IVIG in high doses has led to its use as an immune suppressant or immune modulator ([329] , [330] and [331]). As is the case with the intramuscular immune globulins, nonspecific IVIG preparations contain a broad spectrum of antibodies naturally present in the donor population. These preparations are indicated for the prophylaxis of infections in patients with primary immunodeficiencies. Other FDA-approved indications include prophylaxis of infection in patients with B-cell chronic lymphocytic leukemia, treatment of Kawasaki syndrome, treatment of patients with ITP, the prevention of infections after bone marrow transplantation, and the treatment of pediatric HIV infections. There are many off-label uses for these products, with varying levels of evidence for benefit. Some applications with established clinical benefit include treatment of Guillain-Barré syndrome, dermatomyositis, red cell aplasia due to parvovirus B19 infection, and prenatal treatment of pregnant women with antiplatelet alloantibodies ([9] , [332]). Compared to intramuscular immune globulins, there are fewer IVIG preparations targeted against specific agents. One preparation commonly available is intravenous Rh immune globulin, which may be used to suppress Rh immunization or for treatment of ITP in Rh-positive individuals. Unlike the intramuscular immunoglobulins, intravenous immunoglobulins have been associated with transmission of hepatitis C in the past ([333] , [334] , [335] and [336]). Today, these products are solvent detergent–treated and, therefore, unlikely to transmit lipid-enveloped viruses. IVIGs have been associated with some adverse reactions, including renal failure and thrombotic events. They should be used with caution in patients with IgA deficiency, because they may contain small quantities of IgA.

ADVERSE EFFECTS OF BLOOD TRANSFUSION

The potential complications of blood transfusion therapy are many, but most present problems only in patients requiring repeated or large numbers of transfusions. The risks associated with the transfusion of any specific unit of blood are low. However, the risks must be weighed against the benefits at the time each transfusion is ordered.

Transfusion complications can be classified as immunologic and nonimmunologic (Table 24.8). Many of the immune reactions are caused by the stimulation of antibody production by foreign alloantigens present on transfused red cells, leukocytes, platelets, or plasma proteins. Such alloimmunization may lead to immunologically mediated reactions when transfusions carrying these antigens are administered in the future. These include hemolytic reactions caused by red cell incompatibility; febrile or pulmonary reactions caused by leukocytes and platelet antigens; allergic or anaphylactic reactions caused by antibodies reacting with soluble antigens, usually plasma proteins, in the transfused material; and GVHD caused by engraftment of transfused lymphocytes in immunosuppressed recipients.

TABLE 24.8. Adverse Effects of Transfusion

Immunologic
Alloimmunization
Red cell antigens
HLA antigens
Platelet-specific antigens
Neutrophil-specific antigens
Plasma proteins
Hemolytic transfusion reactions
Immediate
Delayed
Febrile transfusion reactions
Transfusion-related acute lung injury
Allergic transfusion reactions

- Posttransfusion purpura
- Immunosuppressive effects
- Graft-versus-host disease

Nonimmunologic
- Volume overload
- Massive transfusion
  - Metabolic
  - Hypothermia
  - Dilutional
  - Pulmonary microembolization
- Miscellaneous
  - Plasticizers
  - Transfusion hemosiderosis

Infectious
- Hepatitis: A, B, C, delta, other
- Human immunodeficiency virus-1/-2
- Human T-lymphotropic virus-I/-II
- Cytomegalovirus
- Epstein-Barr virus
- Bacterial contamination
- Syphilis
- Parasites: malaria, *Babesia*, trypanosomes
- Other organisms

The nonimmune reactions are caused by the physical or chemical properties of the transfused blood products, as well as contaminating infectious agents. Nonimmune reactions include circulatory overload and certain adverse effects encountered specifically when large numbers of transfusions are given.

Immunologic Transfusion Reactions

ALLOIMMUNIZATION TO TRANSFUSED ANTIGENS

Alloantibodies Reacting with Red Cell Antigens Although the antigenic composition of transfused red cells always differs from that of the recipient, only a minority of multitransfused recipients develop red cell alloantibodies. The risk of red cell alloimmunization has been estimated at 1.0 to 1.4%/unit transfused ([337], [338]); in multitransfused patients, the incidence of such antibodies ranges from 5 to 30% ([339], [340] and [341]). The majority of patients who produce antibodies do so early, generally after the first ten or fewer transfusions. Multiple red cell antibodies may be encountered. Antibodies to Rh system antigens and to Kell (K) are most often detected. Antibodies to antigens of the Duffy (Fy) and Kidd (Jk) systems also occur, but transfusion-induced antibodies to other red cell antigens are less commonly found. The production of such antibodies is a property of both the recipient's immune response and the immunogenicity of the different red cell antigens. The incidence of antibodies does not appear to be related to the patient diagnosis. For example, patients with hemoglobinopathies, thalassemia, and leukemia and those undergoing surgery requiring multiple transfusions produce antibodies with approximately the same frequency ([339], [340]). However, a group of hyperresponders has been found who make alloantibodies after a small number of transfusions. The majority of patients are nonresponders. The reported incidence of alloimmunization of thalassemics is 5 to 10%, whereas the overall risk of patients with sickle cell anemia is 20 to 30%. The increased incidence of alloimmunization in sickle cell patients has been attributed to the difference in race between the blood donor pool and the patient population, in that most of the donors are white ([342]). As a result, there is a greater likelihood of minor antigen incompatibility between donor and recipient. The differing immunogenicity of various red cell antigens also plays a role. Some blood banks select donors for sickle cell patients according to red cell phenotype. Others do not preselect because only a portion of transfused patients become alloimmunized and because of the cost involved ([343]).

Alloantibodies Reacting with Leukocyte Antigens Alloimmunization to HLA and other leukocyte-associated antigens has been discussed earlier with respect to problems encountered in granulocyte and platelet transfusion. These antibodies occur mainly in multiparous women ([206], [344]) and multitransfused patients. For example, after cardiac surgery, antibodies were detectable in 33% of males and 64% of females ([345]). In patients receiving transfusion support for aplastic anemia or acute leukemia, 20 to 70% become immunized to HLA antigens ([346]). As discussed in the section Platelet Transfusion and shown in Table 24.7, the prophylactic use of leukocyte-reduced products reduces the incidence of HLA alloimmunization in transfusion recipients that have not been previously exposed to foreign HLA. However, the prevalence of HLA alloimmunization remains high in patients with a history of pregnancy.

Alloantibodies Reacting with Plasma Proteins Although antibodies to soluble plasma proteins such as lipoproteins and to Gm and Inv determinants on IgG are often detectable in multitransfused patients, transfusion reactions have rarely been attributed to such antibodies ([347], [348] and [349]). Some anaphylactic reactions are attributed to anti-IgA antibodies ([350], [351] and [352]), especially in patients who are IgA deficient, although the presence of antibodies reacting with IgA is not always clearly correlated with the occurrence of this type of transfusion reaction ([353]).

HEMOLYTIC TRANSFUSION REACTIONS The development of antibodies capable of reacting with red cell antigens may lead to red cell destruction, usually involving transfused rather than recipient cells. The clinical significance of such reactions ranges from life-threatening to trivial. Whether hemolysis occurs immediately within the circulation, more slowly within the reticuloendothelial system, or not at all depends on the antigen and antibody involved ([354], [355], [356] and [357]). The incidence of such reactions is variably reported. Several studies from the Mayo Clinic document a hemolytic reaction rate, both immediate and delayed, of between 1 in 6200 and 1 in 1400 red cell transfusions. In these reports, reactions caused by clerical error and ABO mismatching were virtually nonexistent, but some reactions were attributed to weak atypical antibodies missed in pretransfusion testing ([354], [358], [359]). The high reaction rate was related in part to a high index of suspicion and in part to the use of sensitive tests for serologic evidence of minor DHTRs. In contrast, in a review of fatal hemolytic reactions reported to the U.S. Bureau of Biologics, 86% were caused by ABO incompatibility, and of these 89% were caused by simple clerical error ([360], [361]).

Immediate (Intravascular) Hemolytic Transfusion Reactions Immediate hemolytic transfusion reactions (IHTRs) are most typically associated with ABO incompatibility because anti-A and anti-B antibodies are predominantly IgM and are capable of binding complement and causing immediate destruction of red cells. An IHTR caused by ABO incompatibility is rare and is usually related to clerical error. Other red cell antigens such as Jk^a, K, and Fy^a (which may bind complement) may also lead to such reactions. Infrequently, hemolytic transfusion reactions may be caused by destruction of recipient red cells after the transfusion of plasma containing antibodies ([362], [363]). For example, anti-A_1 occurring naturally in group A donors of subgroup A_2 has been reported to cause hemolytic transfusion reactions ([364]). Hemolytic reactions caused by the transfusion of plasma containing other antibodies are extremely rare, as blood donors are screened for red cell antibodies other than ABO.

Signs and Symptoms IHTRs occur soon after the incompatible transfusion has begun. Occasionally, they are mild; more typically, there is a sudden change clinically. Fever with or without chills is one of the most common manifestations of such reactions. Other signs and symptoms include anxiety, chest or back pain, flushing, dyspnea, tachycardia, and hypotension. If the patient is under general anesthesia, these symptoms may not be recognized; only severe hypotension and evidence of oozing or hemoglobinuria serve as clues to the presence of a hemolytic reaction. Such reactions are life-threatening and include acute renal failure, shock, and intravascular coagulation. It has been estimated that a fatal immediate hemolytic reaction occurs in approximately 1/600,000 red transfusions ([357]). The mortality of a severe IHTR increases with the amount of blood transfused, with a 44% mortality rate in patients receiving more than 1 L of incompatible blood.

Pathophysiology The primary event in IHTRs is the interaction between the antibody and the red cell membrane resulting in the development of immune complexes, the activation of the complement cascade (leading to the release of C3a and C5a with anaphylatoxic activity), and the coagulation mechanism via cytokines and factor XII (leading to both consumptive coagu-lopathy and generation of bradykinin). Vasomotor mediators implicated in the transfusion reaction include histamine, serotonin, and cytokines. Shock results from release of such vasoactive substances ([356], [357]). The renal failure that may occur in this setting is of complex and poorly understood etiology but appears to be primarily ischemic, caused by a combination of hypotension, vasoconstriction, and intravascular coagulation. The free hemoglobin circulating in such patients was once thought to be the major cause of renal failure by precipitating in and obstructing the renal tubules, but there is adequate evidence to discount this hypothesis. Infusion of incompatible red cell stroma, free of hemoglobin, is sufficient to produce acute renal failure ([355]).

Management A transfusion must be discontinued immediately on any suspicion of a hemolytic transfusion reaction. A posttransfusion blood sample and the discontinued bag of blood should be sent to the blood bank for investigation of the cause of the reaction. The severity of the reaction is related to the volume of red

cells infused. Although as few as 30 ml of incompatible blood may be lethal, most severe reactions require more than 200 ml. Hydration must be begun immediately to prevent renal failure. An infusion of normal saline is given to maintain the blood pressure and increase the urine flow rate to 100 ml/hour. Mannitol or furosemide may be used to maintain urine output. If oliguric renal failure develops, fluid challenges must be restricted. Vasoactive drugs such as dopamine may be effective against hypotension and impaired renal perfusion. Once renal failure is established, the usual supportive measures including fluid restriction, management of electrolyte balance, and dialysis are required. The coagulopathy may also require specific management. Some recommend early heparinization at moderate dose if no specific contraindication exists; its use remains controversial. The patient may require support of the defective hemostatic mechanisms with platelets and cryoprecipitate or FFP. In massive intravascular hemolytic transfusion reactions, exchange transfusion has been performed ([365]), but most reactions can be managed more conservatively.

Investigation of Immediate Transfusion Reactions The following steps must be carried out in the investigation of patients with immediate transfusion reactions. The patient's identity must be confirmed and all the records on the patient and the donor blood label must be checked for clerical errors. A new, properly labeled sample of blood must be drawn from the patient and sent to the blood bank with the discontinued unit of blood. The posttransfusion sample must be visually checked for hemolysis. In intravascular reactions, free plasma hemoglobin can be detected most quickly by centrifuging a tube of blood anticoagulated with ethylenediaminetetraacetic acid or heparin; pink plasma indicates intravascular hemolysis—that is, evidence of red cell destruction. There must be an investigation for possible alloantibodies. A direct antiglobulin test must be performed on the specimen submitted at the time of the reaction. If the test is positive, the pretransfusion sample should also be tested because the patient may have had a positive direct antiglobulin test before transfusion. Red cell typing should be repeated on all specimens. If the posttransfusion ABO and Rh type does not agree with pretransfusion results, there has been an error in patient identification or typing. Antibody detection tests should be repeated on the pre- and postreaction samples. The direct antiglobulin test on the postreaction specimen may reveal sensitization of red cells in the patient only if the antibody or complement-coated transfused incompatible cells have not been immediately destroyed. A repeat crossmatch should be positive, although the antibody may not be readily demonstrable in serum at the time the reaction is suspected clinically. The antibody specificity is identified by its reactions with a panel of red cells of known phenotype. It may be necessary to elute the offending antibody from the patient's red cells before it can be identified ([8]). In a minority of patients in whom there is a high clinical suspicion of a hemolytic transfusion reaction, no immunologic abnormality may be identified. In some, repeated examination for antibodies over a prolonged period of time may eventually reveal the cause; in others, results may be persistently negative. In such patients, ^{51}Cr red cell survival testing may be of value in documenting hemolysis caused by incompatibility ([120], [121], [123], [124]). Patients with major hemolytic transfusion reactions should be assessed for the possible presence of intravascular coagulation, and their renal function should be monitored closely. Urinary hemosiderin or free hemoglobin in the urine may also be detected; wine-colored urine is typical of intravascular hemolysis. The laboratory can confirm the identity of the pigment. Demonstration of methemalbuminemia, reduced serum haptoglobin, or hyperbilirubinemia may provide supportive evidence.

Prevention Most IHTRs are preventable. The most likely cause is human error, such as mislabeling of the patient sample, drawing the sample from the wrong patient, transcription errors, and improper identification of the unit with the recipient. Mechanisms to ensure positive identification of the patient (recipient), the blood sample, and the transfusion component must be in place to prevent IHTRs ([4]).

Delayed Hemolytic Transfusion Reactions DHTRs generally are much milder than those occurring immediately, and red cell destruction is predominantly extravascular ([354], [359], [366], [367]). The transfused red cells are destroyed beginning 2 to 10 days after a transfusion. Investigation may reveal the presence of a red cell antibody not detected in the pretransfusion blood sample. The direct antiglobulin test is often positive, but the reaction is transient and may be missed if performed too late. The test reverts to negative as the incompatible red cells are removed from the circulation. DHTRs almost always represent secondary, or anamnestic, antibody responses. On first exposure to an immunogenic red cell antigen, a primary antibody response generally is delayed in onset and slow to reach its peak. For example, anti-D appears a minimum of 4 to 8 weeks after transfusion and may not develop for up to 5 months, after most or all the donor red cells have been removed by the aging process ([354]). The antibody level gradually declines, and antibody screening and crossmatch tests may be negative. After a subsequent transfusion, the previously sensitized recipient manifests a much more brisk immune response, with high concentrations of IgG antibody developing within days. Donor cells remaining in the circulation may become coated with antibody and removed by the reticuloendothelial system. Rarely, primary immunization after transfusion may lead to a DHTR ([368]). In delayed hemolytic reactions, destruction of the sensitized red cells is extravascular; that is, the IgG-coated red cells are removed by the reticuloendothelial system. Often, there are no symptoms, with a new red cell antibody and positive direct antiglobulin test detected incidentally ([369]). If present, symptoms and signs may include fever, falling hematocrit, jaundice, and, infrequently, hemoglobinemia and hemoglobinuria. Rarely, the reactions may be dramatic; renal failure is uncommon, but fatalities have been reported. The antibodies responsible for DHTRs are well defined. Antibodies to Kidd (Jk) antigens and to antigens of the Rh system are the major offenders, with anti-Kell and anti-Duffy (Fy) implicated in most other delayed reactions. Ten to twenty-five percent of patients have more than one alloantibody. Anti-Kidd antibodies are particularly troublesome because the plasma concentration of these antibodies declines more rapidly than others, so that pretransfusion tests are more commonly negative in patients who are in fact sensitized ([6]).

Investigation of Delayed Hemolytic Transfusion Reaction If a DHTR is suspected, a fresh blood sample should be obtained from the patient. This sample should be screened for the presence of previously undetectable red cell antibodies. A direct antiglobulin test should be done. If it is positive, the antibodies should be eluted from the red cells and identified. If the transfused cells have already been destroyed, the direct antiglobulin test will not be positive, but an antibody should be detectable in the patient's serum. The physician must be advised and the patient given a card indicating the presence of the antibody. The blood bank must retain a permanent record of clinically significant antibodies because the antibody may again become undetectable.

Management In most instances, no specific therapy is necessary. The few patients who experience severe reactions should be treated with adequate hydration. If clinically indicated, crossmatch-compatible blood negative for the offending antigen(s) should be administered. The physician and patient should be informed about the antibody so that transfusions may be administered safely in the future.

Pseudohemolytic Transfusion Reactions In patients manifesting a clinical syndrome consistent with intravascular hemolysis, but in whom no blood group incompatibility can be identified, other explanations should be considered. Conditions that mimic hemolytic transfusion reactions are called *pseudohemolytic transfusion reactions* ([356]). These include bacterial contamination with organisms such as *Yersinia*, resorption of large hematomas, and hemolysis caused by drug reactions or vascular prostheses. Pretransfusion hemolysis of donor blood caused by mechanical trauma, freezing, heat, hypotonic solutions, or outdated red cells should always be considered a potential cause of such a reaction ([356]).

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS FNHTRs ([370], [371] and [372]) have been reported in a variable proportion of patients receiving transfusions, ranging between 0.5% and 3.0%; they are more common in multiply transfused patients. The typical reaction consists of a chill followed by fever, usually during or within a few hours of the transfusion. Headache, nausea, and vomiting may occur. Occasionally, the reaction may be severe, including pulmonary symptoms, but usually these reactions are mild. Whatever their degree, febrile transfusion reactions usually run their course within a few hours. Some causes of FNHTRs are as follows. Alloimmunization to antigens on leukocytes and platelets is one of the most common causes of nonhemolytic febrile reactions. Early studies detected the presence of leukoagglutinins in such patients ([373], [374]). HLA antibodies are most commonly found, followed by platelet-specific antibodies; granulocyte-specific antibodies are detected in only a minority of patients ([375], [376] and [377]). Another cause of FNHTRs is the transfusion of cytokines that have developed *in vitro*, especially in whole blood–derived platelet concentrates stored at room temperature ([378]). Recent studies have shown that during storage, the leukocytes in platelet concentrates release cytokines that may be responsible for the febrile reaction ([55]). The causative role of accumulated cytokines is supported by the observation that leukoreduction filtration after storage does not eliminate many of the FNHTRs to platelet concentrates ([56]). The incidence of FNHTRs to platelet concentrates increases with the age of the platelet concentrate and the leukocyte concentration in the product. The reactions appear to be mediated by the plasma supernatant of the platelet products ([55], [56], [57] and [58], [379]). The concentration of cyto-kines in platelet concentrates can be reduced by leukoreducing the products soon after collection. Cytokine levels are reduced in apheresis platelets, most of which are leukoreduced by the collection technology ([380]). The possibility of bacterial contamination of the product must be considered as a possible cause of FNHTR. Symptoms caused by transfusion of bacteria or their toxins can be mild or may be fatal. Platelet components are involved more often because they are stored at room temperature. However, certain organisms such as *Yersinia enterocolitica* proliferate in red cells at storage temperatures of 1° to 6°C. Bacterial contamination is often not considered as a cause of a febrile reaction; it may be more prevalent than reported because of underinvestigation ([381], [382] and [383]).

Management of Febrile Reactions The approach to management of febrile transfusion reactions must be based on an understanding of all the possible causes. Although many such reactions are caused by WBC alloimmunization or cytokines, fever may also be an indication of an unsuspected hemolytic transfusion reaction or contamination of the donor blood by bacteria or endotoxin. For these reasons, every transfusion complicated by a febrile transfusion reaction should be discontinued. The only exception to this rule may be some frequently transfused patients who predictably develop fever with most transfusions; in such cases, the physician, after very carefully assessing the patient, may elect to persist with the transfusion. The possibility of a hemolytic reaction should be considered when fever occurs. The donor unit, along with a patient serum specimen, should be returned to the blood bank for investigation. Other tests for hemolysis should be done as discussed previously, if clinically indicated. The donor unit and patient blood should be cultured if there is any suspicion of bacterial contamination. The symptoms of a febrile transfusion reaction may often be ameliorated with an antipyretic such as acetaminophen or hydrocortisone in patients who develop severe reactions. Meperidine may be used to decrease or stop severe shaking chills. Antihistamines are indicated only if the patient also has allergic symptoms such as hives.

Prevention of Febrile Transfusion Reactions Febrile transfusion reactions to red cells occur most commonly in patients who have been sensitized to WBC antigens by previous transfusions or pregnancies. In such patients, the risk of a febrile transfusion reaction varies with the leukocyte content of the donor unit. Use of leukoreduced red cells may decrease the incidence of FNHTRs ([384], [385] and [386]). Every patient who experiences a reaction does not routinely need specific preventive measures because only a minority will have a second reaction. It is, therefore, common practice for blood banks to provide leukoreduced products only after two febrile reactions have been documented ([387], [388]). When whole blood–derived platelets are given, febrile reactions are common. Removal of leukocytes from these components at the time of transfusion often fails to prevent FNHTR because of the high level of cytokines in these products ([55], [56], [57] and [58]). Reduction

of the level of cytokines by using platelet concentrates stored for a shorter time, prestorage leukoreduction of platelet concentrates, or use of apheresis platelets reduces the incidence of FNHTR to platelet products ([139], [389]). If reactions persist, premedication with antipyretics or corticosteroids may be required. Because granulocyte concentrates cannot be modified by leukoreduction, premedication should be routine in patients who receive these products.

TRANSFUSION-RELATED ACUTE LUNG INJURY Transfusion-related acute lung injury most commonly presents as severe respiratory distress of sudden onset, caused by a syndrome of noncardiogenic pulmonary edema resembling the adult respiratory distress syndrome ([390], [391]). Chills, fever, chest pain, hypotension, and cyanosis, as well as the usual manifestations of pulmonary edema, may be seen. The chest radiograph shows florid pulmonary edema. The reaction may occur within several hours of the transfusion; it may be severe initially but generally subsides within 48 to 96 hours with appropriate respiratory support, without residual effects. Transfusion-related acute lung injury occurs much less often than FNHTR, with a reported incidence of approximately 1 in 5000 transfusions ([390]), but it may be underdiagnosed. These reactions are thought to be caused by the transfusion of antibodies in donor plasma that are reactive with recipient granulocytes. Such antibodies may react with HLA- or granulocyte-specific antigens. Based on studies of adult respiratory distress syndrome, which has similar pulmonary manifestations, it has been suggested that agglutination of granulocytes and complement activation occur in the pulmonary vascular bed, leading to capillary endothelial damage with consequent fluid leak into the alveoli ([390], [392]). Management involves supportive measures for the pulmonary edema and hypoxia, including ventilatory support if required. Hemodynamic monitoring may be required to determine whether fluid overload is a factor; if not, diuretics are of no proven value ([393]). Very high doses of corticosteroids may be of benefit in transfusion-related acute lung injury ([392]), probably by blocking granulocyte aggregation and consequent vascular damage. Donors whose plasma is implicated in such reactions should be examined for the presence of granulocyte-specific and HLA antibodies reacting with recipient leukocytes. Many of the donors involved in such reactions have been multiparous females. It would be reasonable to avoid further transfusion of plasma-containing products from donors who are found to have anti-HLA or antigranulocyte antibodies.

ALLERGIC REACTIONS Allergic reactions are also common in transfusion recipients, with an estimated incidence of 1 to 3% ([371]), but their actual incidence may be higher because they are often not reported. They range from urticarial lesions (hives), other skin rashes, bronchospasm, and angioedema to anaphylactic shock. Minor reactions are dose related, with an incidence related to the volume of plasma transfused. Whole blood and plasma are more likely than concentrated red cells to cause such reactions; washed red cells or albumin are rarely implicated. Minor urticarial reactions are the only transfusion reactions that do not necessitate immediate discontinuation of the transfusion. Fortunately, the incidence of severe anaphylactic transfusion reactions is very low, as such reactions can be life-threatening. Most allergic reactions are thought to be mediated by recipient IgE to proteins or other soluble substances in donor plasma. The interaction between the antigen and IgE stimulates the release of histamine from mast cells and basophils. Most patients do not have repeated allergic reactions, but those with a history of atopy are at higher risk for additional reactions. For patients with repeated allergic reactions, premedication with an H_1-blocking antihistamine is usually sufficient for prevention. If maximal premedication fails to control the allergic response, reducing the plasma content of the transfused blood product is another option. This can be accomplished by centrifuging the product and removing almost all the plasma or by red cell washing. In patients with severe anaphylactoid or anaphylactic reactions, antibodies reacting with IgA in donor plasma should be considered. The incidence of genetically determined IgA deficiency in the otherwise normal population is high, ranging from 1 in 400 to 1 in 500 ([394]). Without necessarily having prior transfusion exposure, approximately 20 to 25% of such patients produce antibodies to IgA, generally class specific (i.e., reacting with all IgA molecules). In patients with anti-IgA titers of 1 in 256 or higher, there is a high likelihood of a major anaphylactic reaction after transfusion ([395]), often after administration of only a few milliliters of plasma. Such patients should be transfused, when necessary, with washed red cells ([396]) or with IgA-deficient blood products. In addition, many patients with normal IgA levels have antibodies that react with some, but not all, IgA molecules; the incidence of such limited-specificity antibodies has been reported at 2% of normal adults ([397]), but the incidence may be as high as 21% in multiply transfused patients ([370]). The concentration of such limited-specificity antibodies generally is low, and the resulting reactions are usually milder, but the possibility of a major reaction exists ([352]).

POSTTRANSFUSION PURPURA Posttransfusion purpura ([398], [399], [400], [401] and [402]) is the development of life-threatening thrombocytopenia 5 to 10 days after transfusion. This rare complication is caused by the development of alloantibodies directed against platelet-specific antigens; anti–HPA-1a is usually implicated, although antibodies with other specificities have also been reported (see Chapter 53). Posttransfusion purpura is thought to occur as a result of a secondary immunologic response to the platelet-specific antigen, most patients having been sensitized by prior pregnancy or transfusion. The mechanism of destruction of the patient's own platelets is uncertain. Management includes high-dose IVIG ([403]); corticosteroids may be of value ([404]). Posttransfusion thrombocytopenia may also be associated with the passive administration of a platelet-specific antibody ([405], [406] and [407]). Both anti–HPA-1a and anti–HPA-5a have been implicated; these cases can be defined as passive posttransfusion purpura, and the resulting thrombocytopenia occurs within hours of the transfusion. It is important to identify the donors of these blood products to prevent further infusion of plasma-containing products from such donors.

TRANSFUSION-RELATED IMMUNOMODULATION Allogeneic blood transfusion results in the transfer of not only RBCs, but also significant amounts of potential immune effector cells, their products (e.g., cytokines), and various substances that may be seen by the host immune system as foreign antigens. A large body of literature exists that substantiates the modulation of host immune systems by transfused substances, raising the possibility of the development of clinical syndromes generally referred to as *transfusion-related immunomodulation* (TRIM) ([408]). Although possible beneficial immunomodulatory effects have been reported in renal transplant patients receiving transfusion before surgery by mechanisms that are not well understood ([409], [410], [411], [412] and [413]), TRIM is generally considered to have a number of deleterious effects ([408], [409]). A large number (>150) of clinical studies have been performed over the last two decades specifically addressing two potential harmful TRIM-associated effects: cancer recurrence and postoperative bacterial infections. The aim of the studies has been to document TRIM and to ascertain the effect, if any, that removal of immune effector cells (leukoreduction) might have. Many observational cohort studies have been reported along with a number of randomized clinical trials attempting to measure the possible TRIM effect; still, contradictory findings exist today. Despite some reports of a transfusion-associated increased risk of cancer recurrence or postoperative infections, most studies include potential confounders or sources of bias. To date, no definitive association or causal relationship has been proven in a rigorous fashion. Randomized trials have not definitively established an increase in cancer-related death or relapse, nor have they clearly identified a reproducible increase in the rate of infection ([414], [415], [416], [417], [418], [419], [420], [421] and [422]). Some investigators have argued for prophylactic leukoreduction of blood products for all patients based on observations that white cells in blood products mediate a TRIM effect in animal models ([409]). This recommendation has been questioned, however, in the face of randomized trials in humans that disagree regarding the existence of a clinically measurable TRIM effect and that fail to establish the reduction of this effect by leukoreduction ([59]). Similarly, arguments have been made that HIV-positive patients should receive leukoreduced blood because of *in vitro* studies suggesting that exposure to allogeneic leukocytes would induce HIV activation ([423]). However, a recent multicenter study in HIV-infected patients failed to demonstrate the activation of HIV or CMV by transfusion. Furthermore, this study revealed a tendency toward reduced, rather than improved, survival among the patients who received blood products that were leukoreduced, although this trend was not statistically significant ([424]). Thus, although the practice of using leukoreduced blood products for all patients is becoming increasingly widespread, current evidence does not establish the efficacy of this blood product modification in reducing TRIM.

GRAFT-VERSUS-HOST DISEASE Most cellular blood products, including red cell, platelet, and granulocyte products, contain viable, immunocompetent T lymphocytes ([425]). When transfused into immunoincompetent recipients, these donor lymphocytes may proliferate in the patient and lead to the clinical syndrome of TA-GVHD ([426], [427]). TA-GVHD has also been reported in immunocompetent patients, especially those who receive transfusions from family members or from random donors who share HLA antigens, as is the case when the donor is homozygous for an HLA haplotype ([428], [429]). In these cases, the recipient does not recognize the donor cells as foreign, allowing the transfused lymphocytes to proliferate and cause TA-GVHD. A higher incidence has been reported in countries such as Japan whose populations are genetically similar. Transfusion of leukocyte or platelet concentrates or fresh blood has been responsible for most cases of posttransfusion GVHD. Frozen-thawed plasma products (FFP, cryoprecipitate) have not been definitively associated with TA-GVHD. TA-GVHD occurs earlier than that seen after bone marrow transplantation, usually within 1 to 2 weeks, but is otherwise similar ([430]). Fever is the most common symptom, followed by a typical erythematous, maculopapular skin rash that begins centrally and spreads peripherally to the hands and feet. Abnormalities of hepatic function, nausea, and bloody diarrhea often occur as the process progresses. Leukopenia followed by pancytopenia due to marrow failure is quite common in TA-GVHD and is seen most often 2 to 3 weeks after the onset of symptoms. The diagnosis is based on the clinical picture and can be confirmed histologically with a skin biopsy. Laboratory confirmation that the GVHD is transfusion induced can be obtained by demonstrating the presence of donor lymphocytes in the patient. This can be done by HLA typing of patient and donor cells by DNA methods for class I and II antigens, by cytogenetic analysis, or by analysis of DNA microsatellite polymorphisms or variable number tandem repeats ([425]). Severe systemic infections are the most common cause of death, which often occurs within 3 to 4 weeks from the time of the implicated transfusion. Despite aggressive treatment, the fatality rate in TA-GVHD is significantly higher than that associated with bone marrow transplantation and has been reported to be greater than 90% ([430]). Corticosteroids, antithymocyte globulin, cyclosporine, and growth factors have all been used with minimal success in the treatment of TA-GVHD. Although a few reports of spontaneous resolution have been reported, current treatment approaches have used combinations of immunosuppressant medications with lymphocyte-directed antibody therapy (anti-CD3, anti–interleukin-2 receptor, antithymocyte globulin). Because of the lack of effective treatment regimens, TA-GVHD should be prevented by pretransfusion irradiation of all blood products administered to patients at risk. Irradiation inhibits proliferation of donor lymphocytes but has no significant adverse effect on red cell, platelet, or granulocyte function. Changes in the red cell membrane do occur that result in an increased loss of potassium from the cell, limiting the storage time of irradiated red cells to 28 days. This may be important in neonates, as the dose of free potassium may be high in a relatively large-volume transfusion, necessitating the use of freshly irradiated or washed RBCs. The recommended dose for the irradiation of blood and blood products is 2500 cGy at the center of the irradiation field, with a minimum dose of 1500 cGy at any point in the field ([4], [60]). Based primarily on case reports and reviews, a number of immunosuppressed and immunocompetent patient groups can be stratified according to risk for developing TA-GVHD ([430]) (Table 24.9).

TABLE 24.9. Patients at Increased Risk for Transfusion-Associated Graft-Versus-Host Disease

High risk
Bone marrow transplant (allogeneic and autologous)
Intrauterine transfusions
HLA-matched platelet transfusions
Transfusions from blood relatives
Severe congenital immunodeficiency
Hodgkin disease
Moderate risk
Hematologic malignancy (acute myelogenous leukemia/acute lymphocytic leukemia/non-Hodgkin lymphoma)
Patients treated with purine analog drugs (e.g., chronic lymphocytic leukemia)
Malignancies treated with intensive chemo-/radiotherapy
Solid organ transplant recipients
Preterm infants
Newborns receiving exchange transfusion
Low/theoretical risk
Human immunodeficiency virus/acquired immunodeficiency syndrome
Healthy term newborns

Modified from Schroeder ML. Transfusion-associated graft-versus-host disease. Br J Haematol 2002;117:275–287.

Nonimmunologic Adverse Effects of Blood Transfusion

VOLUME OVERLOAD Transfusion of red cell preparations or plasma products may result in circulatory overload. In chronically anemic patients, the plasma volume expands so that the blood volume is normal. Virtually the entire volume of the blood product infused remains in the circulation; in elderly patients with limited cardiac reserve or in severely anemic patients in congestive heart failure, transfusion may lead to fatal pulmonary edema. Diuretic therapy and other measures to manage heart failure may be of some benefit; partial exchange transfusion may be indicated. Prevention of these reactions is most important. Transfusions should be administered slowly at a rate of 1 to 2 ml of blood/kg of body weight/hour, with the patient under close observation. Manipulation of the blood product as described above can be helpful in managing the most difficult cases.

MASSIVE TRANSFUSION

Metabolic Effects Stored blood differs in its composition from that circulating in the body. If large amounts of stored blood are infused rapidly, one may observe adverse effects related to such differences. The elevated K^+ content of stored red cells rarely leads to hyperkalemia, but it is a risk in the presence of renal failure, shock with acidosis, or of hemolysis. Plasma contains a significant amount of citrate as anticoagulant; recipients with normal circulatory status promptly metabolize this in the liver, but during plasma exchange or in patients in shock or severe liver failure, citrate excess may lead to hypocalcemia. Hypocalcemic reactions caused by citrate may be treated by intravenous calcium injection (431).

Hypothermia Hypothermia may occur if a large volume of cold blood is infused rapidly. Hypothermia is one of the most common complications of massive transfusion and contributes to the associated coagulopathy. Neonates and the elderly are particularly sensitive to this reaction. Hypothermia affects the way the liver metabolizes citrate, resulting in an increased risk of hypocalcemia. Rapid infusions of citrated blood products in such patients, especially through central venous lines, may lead to arrhythmias. Hypothermia interferes with platelet function and clotting, both of which are improved when the patient is warmed (431). One way of approaching this problem is with the use of warmed intravenous fluids or blood. Blood-warming devices are available that can warm adequately the blood administered even during a rapid and massive transfusion. All patients who are receiving large amounts of red cells and plasma should have those products administered through blood-warming devices. Blood warmers must be checked regularly to ensure that they maintain their temperature. If the blood is overheated, hemolysis and the associated complications of transfusing hemolyzed blood may result. Any one of these potential problems alone is rarely significant. However, in the critically ill patient who requires massive transfusion, acidosis, hypoxemia, hypothermia, hypocalcemia, and hypo- or hyperkalemia often coexist, with a consequent risk of induction of cardiac arrhythmias. Neonates receiving exchange transfusions are particularly susceptible to such physical and metabolic effects (61 , 432).

Dilutional Effects Transfusion of large volumes of blood products in patients requiring replacement of one or more blood volumes results in dilution of platelets and labile coagulation factors. Such patients are often affected by sepsis, shock, and intravascular coagulation, which may aggravate the dilutional hemostatic defects. In practice, most patients tolerate otherwise uncomplicated dilutional coagulopathy well. Factor VIII activity may rise as a response to stress; factor V falls, but rarely to dangerous levels. Moderately severe thrombocytopenia, accompanied in some cases by a significant degree of platelet dysfunction, may be a more significant problem. Transfusion therapy of such patients is best guided by laboratory measurements and clinical assessment. Most authors recommend against the routine transfusion, according to predetermined formulas, of platelets, FFP, or cryoprecipitate. Transfusion of platelets and coagulation factors is rarely necessary before the replacement of one to two blood volumes (199 , 200).

Microaggregates and Pulmonary Microembolization Microaggregates form during storage of red cells; they are composed of platelets, leukocytes, and fibrin. All blood products are routinely administered through a filter with a pore size of 170 µm, but these devices do not remove microaggregates, which are therefore transfused with the blood. A number of microaggregate filters with a pore size of 40 µm have been devised to remove such debris from blood (388 , 433). An extensive literature deals with the clinical significance of microaggregates and the utility of 40-µm filters. In patients receiving large volumes of stored blood, a syndrome of pulmonary dysfunction with hypoxemia was thought to be caused by widespread pulmonary microvascular obstruction by such microaggregates. In patients transfused while on cardiopulmonary bypass, exclusion of the pulmonary vascular bed from the circulation was thought to permit transfused microaggregates to embolize to the cerebral, retinal, and renal circulation. Currently, the role of microaggregates in the genesis of these syndromes is in doubt; the numerous clinical variables that coexist in such patients make it difficult to be certain of the relationship between microaggregates and the observed problems. Studies have shown no benefit in the microaggregate filtration of up to six units of blood in surgical patients. The use of microaggregate filters has therefore decreased significantly.

MISCELLANEOUS Air embolism was a potential hazard when glass bottles, which had to be vented, were used; modern collapsible plastic bags have essentially eliminated this problem as long as the infusing system remains securely closed. Fat embolism may occur in the rare situation in which blood products are transfused via the bone marrow.

Plasticizers Some blood bags are made from plastic materials, such as PVC, that contain phthalates (DEHP), which maintain the flexibility of the bag. This substance is lipophilic and can be demonstrated to be eluted into the bag's contents, depending on the time and temperature of storage. In human recipients, no adverse effects have been demonstrated to date (30). However, because of concerns raised about potential toxicities, attempts are being made to identify different plasticizers that are less likely to leach into stored products. As these become available and are shown to be safe and suitable for storage of red cells and platelets, they will replace the bags currently in use.

Iron Overload: Transfusion Hemosiderosis Iron overload is a major problem in patients requiring long-term red cell transfusion support for chronic anemias due to bone marrow failure (434 , 435). Each unit of red cells contains approximately 0.25 g of iron. After a large number of red cell transfusions, in the absence of blood loss, the recipient develops the stigmata of transfusion siderosis: impaired growth, failure of sexual maturation, myocardial and hepatic dysfunction, hyperpigmentation, and, often, diabetes. Patients such as those with thalassemia who are at risk of this complication should receive prophylactic aggressive iron chelation therapy.

INFECTIOUS COMPLICATIONS OF BLOOD TRANSFUSION

Overview of Blood Donor Screening for Infectious Diseases

In the 1960s, transfusion-associated hepatitis (TAH) occurred in more than 30% of multiply transfused patients. The development and implementation of a screening test for HBsAg and the switch to an all-volunteer blood supply resulted in a dramatic reduction in the incidence of both B and non-A, non-B (NANB) TAH (Fig. 24.7) (436). However, a significant risk of NANB hepatitis persisted.

Figure 24.7. Annualized incidence of posttransfusion hepatitis B and non-A, non-B at the National Institutes of Health, 1964 to 1986. First-, second-, and third-generation tests refer to tests for hepatitis B surface antigen. ALT, alanine aminotransferase. (Reprinted from Alter HJ. You'll wonder where the yellow went: a 15-year retrospective of posttransfusion hepatitis. In: Moore SB, ed. Transfusion-transmitted viral diseases. Arlington, VA: American Association of Blood Banks, 1987, with permission.)

In the early 1980s, the blood banking industry was further challenged with the appearance of AIDS. In the early and mid-1980s, before the identification of the causative agents of AIDS or NANB hepatitis, the idea of using surrogate tests to identify donations at increased risk of transmitting one of these infections was introduced. Proposed tests included those that would detect the consequences of an infection [e.g., elevated alanine aminotransferase (ALT) in the case of NANB hepatitis or inverted helper to suppressor T-cell ratio in the case of AIDS] or those likely to be positive in individuals who engaged in high-risk sexual activity or needle sharing (e.g., antibody to HBc antigen) ([437], [438], [439] and [440]). Before the availability of a specific test for HIV, some blood suppliers implemented HBc antibody testing or donor T-cell testing in an attempt to reduce the risk of transmitting AIDS through blood transfusion.

After the development and implementation of a test for HIV antibody in 1985, it became clear that there is a delay between the onset of infection and the development of detectable antibody. A blood donation made during this “window period” could pass infectious disease screening tests but transmit infection. The FDA required blood centers to inform prospective donors about the window period and to directly question them about specific risk behaviors. Gradually, improvements in the sensitivity of the HIV antibody test led to shortening the HIV window period from 45 days to 22 to 25 days ([441], [442]).

During the mid-1980s, surrogate tests for NANB hepatitis and risk activity (ALT and HBc antibody) became required in the United States. A donor screening test for the retrovirus HTLV-I was implemented in 1988. The first donor screening test for antibodies to hepatitis C became available in 1990, and an improved test became available in 1992. In 1996, a donor screening test for HIV-1 p24 antigen was implemented because available information suggested that this test could shorten the HIV window period by an additional 6 days ([442]). By this time, the risks of transfusion-transmitted HIV and hepatitis were too low to measure prospectively and could only be estimated with the aid of mathematic modeling (Fig. 24.8) ([443], [444]).

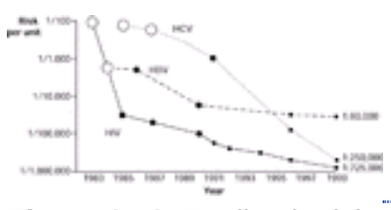

Figure 24.8. Decline in risk of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) transmission by transfusion, 1983 to 1999. Estimates indicated by solid circles are based on recipient follow-up studies; estimates indicated by open circles are based on donor prevalence measurements; estimates indicated by solid squares represent projections based on mathematic modeling. (Reprinted from Busch MP. Closing the windows on viral transmission by blood transfusion. In: Stramer SL, ed. Blood safety in the new millennium. Bethesda, MD: American Association of Blood Banks, 2001, with permission; and modified from Kleinman SH, Busch MP. The risks of transfusion transmitted infection: direct estimation and mathematical modeling. Baillieres Best Pract Res Clin Haematol 2000;13:631–649.)

Despite the extremely low risk of transfusion-transmitted HIV and hepatitis, there continued to be immense public pressure to further improve transfusion safety. Most recently, efforts have turned to the development of donor screening tests that detect viral nucleic acid, which is theoretically detectable before antigen or antibody. Nucleic acid test systems that are presently available are labor intensive and not readily applicable to the rapid screening of large numbers of blood donations. Testing pools of specimens improves the feasibility of testing large numbers of samples. Recently, blood centers in the United States implemented the testing of minipools of 16 to 24 donor specimens for HIV and HCV nucleic acid. Because minipool nucleic acid testing detects HIV infection earlier than p24 antigen testing, the FDA has permitted discontinuation of the p24 antigen test.

Table 24.10 lists the tests currently performed on all volunteer blood donations in the United States. It is thought that the residual risk of transmitting these agents by transfusion is related mainly to window period donations. The probability that a donation was made in the window period can be calculated from the observed incidence of new infections in blood donors and the length of the window period ([87], [445]). As indicated in Table 24.11, the incidence of new infections in repeat blood donors is extremely low. Recently, the use of nucleic acid testing, which detects donors in the process of seroconversion, revealed that first-time donors are two to three times more likely than repeat blood donors to be in the process of acquiring a new infection at the time of donation ([87]). Thus, the overall probability that a unit will transmit infection is also a function of the relative proportions of units from first-time versus repeat donors. Table 24.11 indicates current overall risk estimates of window period donations based on these considerations.

TABLE 24.10. Infectious Disease Testing Currently Performed on United States Blood Donations

Infection	Tests Designed to Detect
Hepatitis B	Hepatitis B surface antigen
	IgM and IgG antibody to hepatitis B core antigen
Hepatitis C	IgG antibody to hepatitis C peptides
	Hepatitis C virus nucleic acid [a]
HIV-1/-2	IgM and IgG antibody to HIV-1/-2
	HIV-1 nucleic acid [a]
HTLV-I/-II	IgG antibody to HTLV-I/-II
Syphilis	IgM and IgG antibody to treponemal antigens
	Or nontreponemal serologic reactivity (e.g., rapid plasma reagin)

HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; Ig, immunoglobulin.

[a] Nucleic acid testing is performed on minipools of 16 to 24 donor samples.

TABLE 24.11. Current Estimated Risks of Transfusion-Transmitted Infection Based on Window Period/Incidence Estimates [a]

Agent	Window Period (Days) [b]	Incidence of New Infections in Repeat Donors (per 100,000 Person-Years)	Estimated Risk/Unit Transfused [c]
Hepatitis B	59	3.016	1:171,000
Hepatitis C	10	1.889	1:1,613,000
Human immuno-deficiency virus	11	1.554	1:1,779,000

Human T-cell lymphotropic virus [d]	51	1.392	1:428,000

[a] Estimates are based on figures from Dodd RY, Notari EP IV, Stramer SL. Current prevalence and incidence of infectious disease markers and estimated window-period risk in the American Red Cross blood donor population. Transfusion 2002;42:975–979.

[b] Window period estimates are for the combinations of tests listed in Table 24.10.

[c] Estimated risk/unit transfused is calculated based on the assumption that 20% of donations are from first-time donors with a twofold higher incidence of new infections compared to repeat donors, as recommended by Glynn SA, Kleinman SH, Wright DJ, et al. International application of the incidence rate/window period model. Transfusion 2002;42:966–972.

[d] For human T-cell lymphotropic virus, incidence figures for 1998 to 1999 were used because of potential underestimates during later observation periods.

Because the current risks of transmitting HIV and hepatitis are so low, the absolute benefit gained from further incremental improvements in blood donor testing for these infections would be very small. The implementation of individual unit nucleic acid testing, for example, would be associated with extremely high cost with very little incremental improvement in blood safety ([446]). Similarly, the cost-effectiveness of implementing processes that would inactivate residual pathogens in blood products has also been questioned ([447]). However, pathogen inactivation systems might represent a reasonable approach toward reducing the risk of blood contamination by other infectious agents for which there is currently no testing, such as bacteria and parasites. At present, it appears that the public desire is to require implementation of any process that could potentially improve blood safety without regard to cost-effectiveness.

Transfusion-Associated Hepatitis

Before the development of serologic tests capable of determining the cause of TAH, all TAH was thought to be due to the “serum hepatitis” agent, later called the *hepatitis B virus.* As sensitive tests for HBsAg were applied to the study of TAH, however, it became clear that only 25 to 30% of cases were caused by this virus ([448] , [449]). Subsequent studies excluded hepatitis A virus (HAV), CMV, and the Epstein-Barr virus (EBV) as common causes of TAH. The designation *NANB hepatitis* was created to describe the majority of cases ([450]). In 1988, the major causative agent of NANB hepatitis was identified as HCV ([451] , [452]). Widespread testing of all blood donations for this virus was implemented in 1990. An improved test for hepatitis C became available in 1992. Since then, TAH has become rare. A small number of cases of TAH that are negative for all serologic markers have been identified and can be called *non-ABC hepatitis* ([453]).

HEPATITIS B VIRUS HBV ([454] , [455] and [456]) is a DNA virus with a lipoprotein shell, in which the HBsAg is found, and an inner core. The inner core contains DNA, DNA polymerase, and protein kinases, and it expresses the antigenic determinant known as the *hepatitis B core* (HBc) antigen. The intact virus can be visualized with the electron microscope as a 42-nm double-shelled particle. The viral envelope material (HBsAg) circulates in the plasma, both as intact virions and as incomplete spheres and tubules. The HBsAg in serum can be identified by serologic methods. Hepatitis B infection is transmitted by people who have acute viral hepatitis or who are HBsAg carriers. HBV is transmitted parenterally, sexually, or perinatally from infected mothers to their infants. The incubation period ranges from 1 to 6 months. Only approximately 25 to 40% of hepatitis B infections are associated with jaundice. Fulminant infection, with a high mortality rate, occurs in 0.2 to 0.5% of cases. Most individuals, however, experience transient subclinical hepatitis detectable only by laboratory tests. Although it is often stated that 5 to 10% of infected adults go on to become chronic HBsAg carriers, more recent studies suggest that the development of chronic infection is far less common, approximately 1% ([457]). Of these, approximately 25% develop chronic hepatitis that may resolve after many years or may lead eventually to fatal cirrhosis or hepatocellular carcinoma. The infection pattern is different in the Far East and in Africa in that the disease is acquired primarily perinatally. Chronicity is more common in this population, as is the development of cirrhosis and hepatocellular carcinoma. In the West, the infection is more commonly sexually or parenterally acquired, mainly in young adults ([456]). Treatment of chronically infected patients with nucleoside analogs suppresses viral replication in some patients; however, long-term treatment is associated with the emergence of drug-resistant variants ([458]). Routine vaccination of infants and children with recombinant HBsAg is now recommended in the United States and should reduce the incidence of this infection. During the course of symptomatic infection, a well-defined sequence of serologically detectable changes occurs ([453]). The HBsAg is detectable during the late incubation period, an average of 59 days after exposure, and often before the development of symptoms. IgM antibody to HBc is almost always detectable at the time of illness and persists for 6 to 12 months, with IgG anti-HBc persisting indefinitely. HBsAg usually becomes undetectable by 12 weeks after the onset of illness, followed by the appearance of anti-HBs. Patients developing the chronic carrier state usually exhibit high levels of HBsAg and anti-HBc, but no anti-HBs. Hepatitis Be antigen (HBeAg) is related to a core subcomponent; it is a soluble protein not associated with any visible structure that is detected in acute hepatitis and in patients who are in the process of becoming chronic HBsAg carriers. Its presence correlates with high levels of virus. It, therefore, indicates recent or ongoing infection and infectivity. HBeAg generally disappears from the serum before HBsAg and is followed by the development of anti-HBe. All people carrying HBsAg must be considered infectious, but they vary in degree of infectivity. In an HBsAg-positive person, the presence of HBeAg correlates with high infectivity, whereas the HBeAg-negative state is less infectious.

Donor Screening for Hepatitis B The discovery of HBsAg and development of serologic tests for this marker led to a dramatic reduction in the risk of hepatitis B transmission by transfusion (Fig. 24.7) ([459]). Screening of all blood products for HBsAg began in 1970 in the United States with low-sensitivity tests and was made mandatory in 1972. The high-sensitivity third-generation test in current use becomes positive an average of 59 days after exposure and detects most but not all donors infectious for hepatitis B. Residual infectivity has been associated largely with individuals who appear to clear HBsAg and who make anti-HBc antibody but who do not make anti-HBs antibody ([460]). Units from such individuals are currently interdicted in the United States by donor screening for anti-HBc, originally implemented in an effort to reduce the risk of NANB hepatitis ([439] , [440] , [461]). Recently, sensitive polymerase chain reaction assays have confirmed the presence of HBV DNA in some individuals with high-titered anti-HBc and absent anti-HBs ([462]). A recent study of anti-HBc–positive U.S. blood donations suggests that approximately 1 in 50,000 of these contains HBV DNA at low levels that would be detectable only by individual unit nucleic acid testing ([463]). Anti-HBc–positive donations therefore remain excluded from the U.S. blood supply, although testing for this marker is not performed in many other countries. Anti-HBc–positive donations are permitted to be included in pooled plasma products in the United States. However, HBV infectivity should be reliably eradicated by the pathogen inactivation processes to which these products are subjected. Circulating HBV DNA can also be detected in early HBV infection before the development of detectable HBsAg. More sensitive HBsAg assays or minipool HBV nucleic acid testing would detect some of these individuals ([464] , [465]). Based on currently implemented donor screening tests for HBV (i.e., HBsAg and anti-HBc), the current estimated risk of HBV transmission in the United States is 1 in 171,000 units (Table 24.11).

HEPATITIS C VIRUS HCV is now known to be the cause of approximately 90% of cases of NANB hepatitis ([444] , [466] , [467] , [468] , [469] and [470]). Before the identification of the causative agent, NANB hepatitis was defined clinically on the basis of elevated ALT levels in the absence of serologic evidence of other infections (HAV, HBV, CMV, and EBV). In 1988, the genome of HCV was cloned. Serologic studies using recombinant peptides produced from the cloned genome confirmed that this agent was the cause of the majority of cases of NANB hepatitis. HCV is now known to be a lipid-enveloped RNA virus in the Flaviviridae family. Today, the diagnosis of HCV infection can be made either serologically by the detection of antibodies to HCV (anti-HCV) or by the identification of viral genomic material using nucleic acid testing technology ([469]). The prevalence of HCV infection in the general population of the United States is estimated to be 1.8% ([471]). Just under one-half of cases are related to parenteral drug use, but the mode of transmission for the remainder of cases remains largely unknown ([472]). Although some studies have suggested that sexual exposure is a risk factor for HCV, most studies of long-term sexual partners have indicated very low rates of transmission by this route ([473]). Similarly, the rate of perinatal transmission of HCV is low (average, 5 to 6%) but is higher in the presence of co-infection with HIV ([471]). The average incubation period for HCV is 6 to 7 weeks. Sixty to seventy percent of infections are asymptomatic. Ten to twenty percent of cases are associated with nonspecific symptoms, and jaundice occurs in only 20 to 30% of cases. Even icteric patients usually have a mild acute illness, although immunocompromised patients may develop severe infections. Fulminant hepatitis is rare. The most important aspect of HCV infection is its chronicity. Only 15 to 25% of individuals clear the virus; the rest remain chronically infected. Sixty to seventy percent of chronically infected patients show biochemical evidence of chronic hepatitis. Over a period of 20 to 30 years, it is estimated that cirrhosis develops in 10 to 20% of chronically infected patients, and hepatocellular carcinoma develops in 1 to 5% ([471]). Treatment with interferon and ribavirin suppresses viral replication in some patients, although only a minority achieves a sustained response ([474]).

Donor Screening for Hepatitis C Virus Before the discovery of and testing for HCV, the reported incidence of NANB hepatitis ranged between 7 and 10% of all patients receiving blood transfusions ([461]). This high incidence of TAH stimulated attempts to identify surrogate tests that would correlate with the NANB carrier state. The Transfusion-Transmitted Viruses Study reported in 1981 ([438]) that assay of donor blood for serum ALT levels was of value in predicting NANB infectivity. Patients receiving donor blood containing elevated serum ALT had an increased chance of developing TAH; this effect was demonstrable in recipients of both single and multiple units of blood and correlated with the degree of elevation of donor ALT level. Screening for anti-HBc was also found to be of predictive value for NANB infectivity; donor units positive for anti-HBc (but not anti-HBs) were associated with a high incidence of NANB transmission ([439] , [440] , [461]). Anti-HBc and ALT testing were, therefore, instituted as surrogate tests for the NANB ([475]). These tests, as well as changes in donor deferral policies related to HIV, resulted in more than a 50% decrease in the risk of transmitting NANB hepatitis ([476]). In 1990, the first donor screening test for anti-HCV became available. This test detected antibodies to

the C100-3 recombinant peptide that represented only a small part of the viral genome. Although most patients with HCV infection ultimately made antibodies to this peptide, the detection of such antibodies was delayed for up to 26 weeks or longer, and some infected patients did not make antibodies to this peptide. The second-generation antibody test, which became available in 1992, contained additional peptides representing the core and NS3 regions of the genome, resulting in improved sensitivity, specificity, and earlier detection. Version 3 antibody tests, which contain NS5 peptides as well as improved sensitivity for antibodies to NS3, have been available since 1996, but implementation of these tests was not required because the improvement in sensitivity was thought to be marginal. Even with third-generation tests, however, antibodies are not reliably detected until an average of 10 weeks after infection. In 1999, testing of 16- to 24-member minipools of donor specimens for HCV nucleic acid was implemented in large nationwide trials. These trials detected HCV nucleic acid in approximately 1/300,000 units that passed all other testing ([87], [477]). Minipool testing for HCV nucleic acid is now required by the FDA. The window period for HCV is now estimated to be approximately 10 days, and the risk of HCV transmission by transfusion of fresh blood products is now estimated to be approximately 1 in 1.6 million (Table 24.11). Because HCV is lipid enveloped, HCV infectivity of pooled plasma products should be reliably removed by the solvent detergent treatment to which most of these products are subjected. After the discovery of HCV and testing for anti-HCV, there was little value in the continued use of ALT testing, and this testing is no longer required ([478]). However, anti-HBc testing has been retained for the foreseeable future because of its value in reducing the risk of HBV transmission and also its perceived value as a surrogate marker of high-risk sexual activity and intravenous drug use.

HEPATITIS D VIRUS The hepatitis D virus (HDV) ([479], [480], [481] and [482]) has a hybrid structure, consisting of HBs antigen enclosing a minute RNA genome that is incomplete and, therefore, incapable of survival without helper functions provided by HBV. Thus, it is found only in association with HBV. It is endemic in some areas. This agent may be transmitted with blood products in association with HBV, resulting in an episode of acute viral hepatitis similar to hepatitis B infection, although with an increased risk of fulminant or chronic disease. In HDV infections in people who are already hepatitis B carriers, the resulting illness is particularly severe, as the helper virus, HBV, is well established at the time of infection. Transfusion of blood products containing HDV may in this way transform a benign HBsAg carrier state to fulminant hepatitis or to severe progressive liver disease. Chronic hepatitis B carriers requiring repeated transfusion are at risk of this infection, especially if they are recipients of pooled products that may contain HDV ([483]). Because HDV can be transmitted only with HBV, the testing of all blood donations for the presence of hepatitis B excludes virtually all transmission of HDV. HDV is not an independent risk factor, so specific testing for it alone is not warranted.

HEPATITIS A VIRUS HAV is much less significant than other hepatitis viruses in blood transfusion practice. HAV is a small, nonenveloped virus with a single positive-stranded RNA genome that belongs to the picornavirus family. HAV is spread by person-to-person contact, usually by the fecal-oral route; epidemics are associated with poor sanitation and contaminated water and food. The fatality rate is very low, and chronic hepatitis and carrier states do not occur. The incubation period for HAV is 25 to 30 days, with a range of approximately 15 to 45 days. Starting in the prodromal phase, during which time there may also be a viremia, HAV is shed almost exclusively in the feces. The viremia lasts for only a few days before symptoms appear. The diagnostic test is the appearance of anti-HAV IgM, which is followed by anti-HAV IgG. The presence of anti-HAV IgG is not of diagnostic importance, unless there is an increasing titer, because it persists indefinitely after HAV infection ([484], [485]). Transfusion-transmitted infection occurs only if blood is collected during the brief asymptomatic viremic phase. Transfusion transmission of HAV by fresh blood products is rare. However, transmission of HAV has been associated with pooled plasma products ([486]). Because HAV is not lipid enveloped, infectivity is not eliminated by solvent detergent treatment. Therefore, immunization to HAV is recommended for patients who are expected to receive pooled plasma products, such as patients with clotting disorders. The FDA does not require donor screening for this agent. Some plasma derivative manufacturers, however, test plasma pools for HAV nucleic acid in an effort to reduce the risk of transmitting this agent.

HEPATITIS E VIRUS The hepatitis E virus is responsible for waterborne outbreaks; its spread is similar to HAV in that it is enterically transmitted. To date, there is no evidence of a chronic carrier state. It, therefore, does not appear to present a risk of transmission by transfusion ([487]).

NON-A-E HEPATITIS Approximately 10% of cases of chronic NANB hepatitis are not accounted for by HCV. Despite much effort, the cause of most of these cases remains unidentified. Attempts to isolate viruses from the blood of individuals with chronic NANB hepatitis led to the discovery of several new agents including GB virus/hepatitis G virus, SEN virus, and TT virus ([488]). Infection with each of these three agents is relatively common, and all three are transmissible by transfusion. TT virus and SEN virus are nonenveloped viruses and, therefore, would not be inactivated by solvent detergent treatment. However, there is currently no convincing evidence that any of these agents causes hepatitis.

Human Immunodeficiency Virus Type 1 and Type 2

AIDS was first reported in 1981. In late 1982, the first cases of AIDS-like illness were reported in transfused patients ([489], [490]). By early 1984, the responsible virus, HIV-1, initially called *HTLV-III*, was identified ([491], [492], [493] and [494]). HIV-1 is a retrovirus in the lentivirus family. It is a lipid-coated RNA virus with a reverse transcriptase. The immunogenic components include an envelope (gp41/gp120) and core (p24) proteins. HIV-2 is a closely related virus (>50% homology) identified initially in West Africa that bears a high degree of antigenic similarity to HIV-1 and causes a similar clinical disease.

Like HBV, HIV is transmitted parenterally, sexually, or peri-natally from infected mothers to their infants. Early reported cases of AIDS in the United States were clustered in men who had sex with men and intravenous drug users. Later, heterosexual transmission became more prevalent ([437]). Although heterosexual spread is responsible for an increasing percentage of HIV cases in the United States, as of the year 2000, men who had sex with men and intravenous drug users continued to account for the majority of new HIV diagnoses ([495]). The majority of HIV infections in the United States are caused by HIV-1; HIV-2 infection is very rare.

Two to three weeks after exposure to HIV, the patient often develops an acute flu- or mononucleosis-like illness. The infection then enters a clinically latent stage during which viral replication continues. Untreated individuals, however, remain asymptomatic for an average of 10 years. Ultimately, the patient's $CD4^+$ T cells become depleted, and the patient develops severe immunodeficiency, resulting in opportunistic infections, neoplasms, or both, and death. Treatment of infected individuals with “highly active antiretroviral therapy” has dramatically reduced HIV-related morbidity and mortality in the United States, although the development of drug resistance and side effects limits the effectiveness of therapy ([496]).

DONOR SCREENING FOR HUMAN IMMUNODEFICIENCY VIRUS It is now known that in some parts of the United States, as many as 1% of units were infected with HIV in the early 1980s ([497]). After the first reports of transfusion-related AIDS and before the availability of a specific test for the causative agent, some U.S. blood centers implemented surrogate testing for markers of HIV infection or of risk activity, such as testing for inverted CD4 to CD8 ratio or anti-HBc ([437]). Retrospective testing of retained donor samples indicates that just before the implementation of the first HIV antibody test, the overall prevalence of HIV in U.S. blood donations was approximately 1/600 ([498]). A test for HIV-1 antibody became available in 1985 and was rapidly implemented. The sensitivity of the antibody test was improved over the years, with progressive shortening of the time to antibody detection from the initial 45 to 55 days to an average of 22 to 25 days ([441], [442]). The initial donor screening tests were designed to detect antibody to HIV-1 but would have detected the majority of HIV-2 infections as well because of the high degree of cross-reactivity. In 1992, the FDA required implementation of specific screening for antibodies to HIV-2 in addition to HIV-1. In 1996, testing for HIV-1 p24 antigen was implemented because available information suggested that this test could shorten the HIV window period by an additional 6 days ([442]). Minipool testing for HIV-1 nucleic acid was implemented in the United States in nationwide clinical trials in 1999 and became required in 2003. With the implementation of minipool nucleic acid testing, the requirement for HIV-1 p24 antigen testing was eliminated because minipool nucleic acid testing detects infections earlier than the antigen test. The window period for HIV, based on minipool nucleic acid screening, is currently estimated at 11 days ([87]). Along with improvements in donor testing, improvements in donor education and questioning processes have led to the selection of a blood donor population with an incidence of new HIV infections that is tenfold lower than that of the general population ([499]). The progressive improvement in donor selection and testing processes has resulted in the progressive lowering of the risk of HIV transmission by transfusion to the current low estimate of approximately 1/1.8 million units (Table 24.11).

Human T-Lymphotropic Virus I and II

HTLV-I was the first human retrovirus discovered. It was isolated in 1978 from an individual with adult T-cell lymphoma ([500]). HTLV-II, a closely related retrovirus, was isolated in 1982 from a patient with hairy cell leukemia ([501]). Both viruses infect lymphocytes and cause lifelong infections. HTLV-I has been associated with adult T-cell leukemia/lymphoma as well as a neurologic disease called *HTLV-I–associated myelopathy* (HAM) or *tropical spastic paraparesis* (TSP). HTLV-II has been associated with neurologic symptoms similar to HAM/TSP. Rarely, HTLV-II has been associated with lymphoid neoplasms. The likelihood of clinical disease in HTLV-II–infected individuals is not yet clearly defined ([502]).

HTLV-I infection is endemic in certain parts of Japan, the Caribbean, Brazil, Melanesia, and Africa. HTLV-II is endemic in some Native American populations. Infection is spread sexually, through breast-feeding, and through needle sharing. It is transmitted by transfusion of cellular blood components but not by frozen plasma components or plasma derivatives. In the United States, infections with these viruses are found primarily in immigrants from endemic areas, their sexual contacts, individuals who received transfusions before effective screening, and intravenous drug users. At least one-half of the infections in the United States are caused by HTLV-II.

The majority of individuals with HTLV-I or -II infections never develop any symptoms of infection. In endemic areas, the lifetime risk of adult T-cell lymphoma in

HTLV-I–infected individuals is estimated at 2 to 4% ([503]). Adult T-cell lymphoma typically appears between the ages of 40 to 60 years, suggesting a long latent period of infection before the onset of disease. HAM/TSP develops in approximately 2% of HTLV-I–infected individuals. Although HAM/TSP develops after a long latency in endemic areas, in transfusion-transmitted infection, HAM/TSP symptoms may appear within only months or a few years of the implicated transfusion.

The diagnosis of HTLV-I and -II infection is based on detection of antibody by enzyme immunoassay tests. Confirmation is somewhat problematic in that there is no FDA-approved confirmatory assay. However, nonapproved supplemental assays are available and are useful for counseling patients. Some of these assays can differentiate between HTLV-I and -II infection ([502] , [503]).

DONOR SCREENING FOR HUMAN T-LYMPHOTROPIC VIRUS The first blood donor test for HTLV-I became available in 1988. This test detected antibodies to HTLV-I in approximately 1/4000 blood donors. It was noted that the screening tests for HTLV-I antibody did not reliably detect antibodies to HTLV-II, and, in 1997, the FDA required the addition of specific testing for HTLV-II antibody. The current tests detect only IgG and, therefore, have a relatively long window period of 51 days. As of 2002, the risk of transmitting HTLV-I/-II by transfusion is estimated at 1 in 428,000 units (Table 24.11).

Syphilis

During the first half of the twentieth century before the availability of effective treatment for syphilis, more than 100 cases of transfusion-transmitted syphilis were described. With the advent of penicillin and the implementation of donor screening with a serologic test for syphilis in the 1940s, transfusion-transmitted syphilis became rare. There have been no documented cases of transfusion-transmitted syphilis in the United States in the last 35 years ([504]).

It is thought that *Treponema pallidum* circulates briefly early in primary disease. It circulates again during the secondary phase of infection, at which time the patient is typically symptomatic. Antibody tests are often negative in early syphilis, with antibodies becoming detectable approximately 3 to 5 weeks after exposure and 1 week after development of the primary chancre. There are two types of antibody tests for syphilis: nontreponemal tests, such as rapid plasma reagin, which detect antibodies to cardiolipin, and specific antitreponemal antibody tests. The former tests become nonreactive after successful treatment of infection, but the latter tests remain positive for life. Initially, nontreponemal tests were used for blood donor screening, although recently most laboratories have switched to antitreponemal assays because these are more specific and are available in an automated format.

The necessity of screening blood donors for syphilis has been questioned recently ([504] , [505] and [506]). The viability of *T. pallidum* in blood components as they are currently stored is unclear. Even though spirochetes may be present in the blood of donors with syphilis, they appear to survive very poorly during cold storage. In experimental animals inoculated with spirochetes, infectivity is generally absent by 96 hours of storage, although infectivity may persist somewhat longer if large numbers of organisms are present ([507] , [508]). There is no information regarding the viability of spirochetes in platelet components. The major argument for retaining syphilis antibody testing, however, has been the claim that it has value as a surrogate marker for risk activity.

Cytomegalovirus

CMV is a DNA virus in the herpesvirus family ([509]). Like other herpesviruses, it remains latent after acute infection, with the potential for reactivation. It is thought that CMV is spread primarily through oral secretions and sexual contact. It can also be spread transplacentally, through blood transfusion, and through organ transplantation. Observed seroprevalence rates in adults range from 40% upward with evidence of ongoing exposure and seroconversion throughout adulthood.

In immunologically normal adults, disease manifestations range from none to a mononucleosis-like syndrome. In immu-nosuppressed or immunodeficient patients, however, both primary and reactivation disease may be associated with overwhelming manifestations including thrombocytopenia, hemolytic anemia, pneumonitis, colitis, hepatitis, meningoencephalitis, and death. Effective antiviral treatment is available. The incidence of severe disease can be reduced by prophylactic treatment of high-risk patients with antiviral drugs or by careful monitoring of such patients and initiation of therapy with the first evidence of infection ([509]).

The occurrence of CMV infection after transfusion was first noted in the 1960s as a postpump syndrome after open-heart surgery. Patients who received large quantities of fresh blood developed a syndrome of fever, rash, lymphadenopathy, and splenomegaly, associated with an atypical lymphocytosis 8 to 12 weeks after surgery. It was later confirmed that this syndrome was associated with serologic evidence of CMV infection that had been transmitted by transfusion ([510]). Today, with use of stored blood components, the incidence of transmission of CMV by transfusion appears to be low (<1%) in immunologically normal recipients ([511]). The likelihood of CMV transmission by transfusion of unscreened blood is higher in immunodeficient patients, with observed transmission rates of 5 to 13% in low-birth-weight infants, 20% in seronegative recipients of seronegative solid organs, and 25 to 65% in seronegative recipients of seronegative bone marrow transplants. The risk of CMV transmission to these patients can be greatly reduced by restricting their transfusions to products obtained from CMV seronegative donors ([512] , [513]).

CMV is transmitted only through cellular blood components. As an alternative to screening blood donations for CMV antibody, many studies have demonstrated that the transmission of CMV can be greatly reduced by processes that remove the majority (2 to 3 logs) of WBCs from blood products ([513] , [514] and [515]). Most investigators have observed no transmission of CMV by leukoreduced blood components, although most studies involved small numbers of patients. The largest study evaluated the incidence of CMV infection and CMV disease in 502 bone marrow transplant recipients randomized to receive either leukoreduced (i.e., leukofiltered) or antibody-screened blood components ([516]). CMV infection was observed in 1.3% of recipients of seronegative components and in 2.4% of recipients of leukoreduced components (difference not statistically significant). However, in the leukoreduced arm, all CMV-infected patients developed disease, and five out of six died; in the serologically screened arm, there were no cases of CMV-related disease or death. Despite these findings, most organizations have concluded that it is acceptable to use leukoreduced blood components in lieu of CMV antibody-screened blood components to reduce the risk of transfusion-related CMV ([517]).

It is generally recommended that cellular products with a reduced risk of transmitted CMV (i.e., antibody-screened or leukoreduced) be used for patients at high risk of severe primary CMV disease, including unborn babies (i.e., intrauterine transfusion), low-birth-weight infants of seronegative mothers, seronegative recipients of seronegative solid organ or HPC transplants, and seronegative patients with severe cellular immunodeficiency (e.g., HIV-infected patients). Products with reduced CMV risk are often provided also for seronegative patients who are likely to be treated with transplantation in the future to reduce their future risk of CMV reactivation disease. There is no demonstrated clinical benefit to providing products of reduced CMV risk to seropositive patients. Such patients are already at risk of reactivation disease. Although second-strain infections may occur, the clinical significance of these has not been demonstrated. Seronegative recipients of seropositive transplants are at high risk of CMV disease and are likely to be monitored closely, treated prophylactically, or both. It is unclear whether providing blood products with reduced CMV risk to such patients is of clinical benefit ([513] , [514]).

Epstein-Barr Virus

EBV is even more ubiquitous than CMV; 90% of blood donors have antibodies against EBV. Because most blood recipients are also immune, posttransfusion EBV infection is rare but has been reported ([518]). Because EBV is cell associated, it has been suggested that the risk of transfusion-transmitted EBV may be reduced by the use of leukoreduced blood components.

Parvovirus B19

Parvovirus B19 is a small nonenveloped DNA virus that is extremely resistant to physical inactivation. Infection is common; by age 15, approximately 50% of children have detectable antibody. Ongoing exposure occurs in adults, with an annual seroconversion rate of 1.5% found in women of childbearing age ([519]). The virus is spread chiefly though respiratory secretions. Disease manifestations include “fifth disease” (erythema infectiosum) and poly-arthropathy. In immunologically normal individuals, B19 causes an acute, self-limited (4 to 8 days) cessation of RBC production. In individuals with diseases involving increased RBC destruction, this can lead to an acute aplastic crisis. Immunosuppressed or immunodeficient patients may develop chronic anemia, which may be reversible by treatment with exogenous Ig. Intra-uterine infection can result in hydrops fetalis.

Individual blood donations are not currently screened for B19 infection. Transfusion transmission of B19 has been documented, particularly by pooled plasma products ([320] , [321]). B19 DNA is detectable in the majority of pooled plasma products ([520]). B19 is resistant to the viral inactivation processes usually applied to plasma derivatives, such as solvent detergent treatment and heat. Recently, many plasma derivative manufacturers have implemented processes to reduce the level

of B19 virus in pooled products by removing plasma units that contain high-titered B19 DNA ([521]).

Infections Transmitted by Arthropods

Historically, it was thought that the risk of transfusion transmission of these diseases in the United States was rare. However, recent studies suggest that, with the exception of malaria, these infections may be vastly underrecognized.

Malaria is a common infection globally. However, transfusion-transmitted malaria is rare in the United States, with only zero to three cases/year occurring during the last decade ([522]). This degree of safety is remarkable considering that there is no donor screening test for malaria. Screening is accomplished entirely by donor questioning. According to current FDA guidelines, individuals are deferred from donation for 1 year after travel to a malarious area and for 3 years after living in a malarious area. Almost 3% of otherwise eligible donors are excluded on the basis of this questioning. Of the donors implicated in the recent cases of transfusion-transmitted malaria in the United States, approximately 60% (including the majority of *Plasmodium falciparum* infections) should have been excluded by donor deferral criteria. The remaining cases are largely related to chronic asymptomatic infections in donors who are beyond the deferral period ([522]).

Babesiosis is caused by a protozoan parasite that infects human RBCs. It is transmitted by the *Ixodes* tick, the same vector that transmits the causative agents of Lyme disease and human granulocytic ehrlichiosis. U.S. cases of babesiosis were first identified in the northeast United States but have now also been identified in Minnesota, Wisconsin, and California. Incubation ranges from 1 to 9 weeks or longer. Symptoms range from none to mild flulike symptoms to a malaria-type illness with hemolytic anemia. Rarely, infection can be fatal. The disease can be successfully treated with quinine and clindamycin ([523]). It is thought that many or most cases of human *Babesia* infection are subclinical. Using unlicensed tests, antibodies to *Babesia* have been found in 0.3 to 8.9% of the population in endemic areas ([524]). Asymptomatic individuals may remain infective for months or years ([525]). More than 40 cases of transfusion-transmitted babesiosis have been reported, including one cluster of cases in which an asymptomatic donor transmitted infection on four different occasions over a 6-month period ([526]). It appears likely that transfusion-transmitted babesiosis is vastly underrecognized. There is currently no donor screening test for this infection. Theoretically, infectious donations could be detected through antibody or nucleic acid testing, or the infectivity of these donations could be reduced through pathogen inactivation.

Lyme disease is caused by the spirochete *Borrelia burgdorferi*. It is transmitted by the same tick vector that transmits babesiosis. *B. burgdorferi* may be found in the blood during early infection. The organism has been found to survive the storage conditions of RBC and platelet components. However, there have been no documented cases of transfusion-transmitted Lyme disease ([527]).

Trypanosoma cruzi, the protozoan parasite that causes Chagas disease, is endemic in portions of Mexico, Central America, and South America. It is transmitted to humans by the reduviid bug. The parasite enters through the skin or mucosa, multiplies near the site of entry, and then disseminates. Acute infection is usually self-limited, although rarely it may involve myocarditis or meningoencephalitis and may be fatal, particularly in immunocompromised patients. In most cases, however, the acute infection goes undiagnosed, and the infection becomes chronic. After decades, 10 to 30% of chronically infected individuals develop cardiac or intestinal dysfunction that can be fatal. The transmission of *T. cruzi* by transfusion is well documented in endemic areas, and many of these countries screen blood donations for *T. cruzi* antibody ([528]). In the United States, there is no test licensed for this purpose. Seroprevalence surveys have been performed in U.S. blood donor populations using unlicensed assays. Antibodies to *T. cruzi* have been found in 1/7500 donors in areas of the country with relatively large populations of immigrants from endemic areas (e.g., Los Angeles), with lower prevalence rates in other parts of the United States ([529]). The infectivity of antibody-positive donors in the United States remains the subject of investigation. To date, there have been only five cases of transfusion-transmitted *T. cruzi* documented in the United States and one in Canada. The most recent case, however, was recognized only because the unit was identified during a seroprevalence study ([530]). It is likely that the majority of *T. cruzi* transmissions are unrecognized. Recently documented transmissions of *T. cruzi* infection by organ transplantation in the United States have led to heightened concern about this agent ([531]). As is the case with babesiosis, potential mechanisms for reducing the risk of *T. cruzi* transmission by transfusion include screening donors for *T. cruzi* antibody or nucleic acid or subjecting blood components to pathogen inactivation processes.

West Nile virus (WNV) is a flavivirus that is transmitted to humans by the bite of an infected mosquito. Previously identified in other countries, WNV was first recognized in the northeast United States in 1999. By 2002, infections had been identified throughout the continental United States. Most WNV infections are subclinical. Approximately 20% of infected individuals develop fever. In approximately 1/150 cases, severe symptoms develop, such as meningitis, encephalitis, or flaccid paralysis. Severe infection may be fatal ([532]). There is preliminary evidence that WNV is transmissible by transfusion and by organ transplantation ([533] , [534]). It is likely that only nucleic acid testing will detect infections in blood donors before the onset of symptoms. Donor screening with investigational WNV nucleic acid tests was implemented in 2003.

Transmissible Spongiform Encephalopathies: Creutzfeldt-Jakob Disease and Variant Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) is a rapidly progressive fatal infection of the nervous system caused by an agent called a *prion* ([535]). Sporadic cases occur in approximately 1/million population. CJD has also been transmitted iatrogenically through contact with infected tissues such as pituitary-derived human growth hormone and dura mater transplants. There is also a familial form of CJD. Although individuals at increased risk for CJD are currently excluded from blood donation in the United States, there is good evidence that CJD is not transmissible by transfusion ([315]).

A transmissible spongiform encephalopathy with different clinical features was first recognized in the United Kingdom (UK) in 1996. This disease, called *variant CJD* (vCJD), is now known to be caused by the same prion that causes bovine spongiform encephalopathy (BSE), or “mad cow disease.” A BSE epidemic occurred in the UK between 1980 to 1996, linked to the feeding of cattle with meat-and-bone meal, a practice that has since been discontinued. BSE has subsequently appeared, to a lesser extent, in other countries. The risk of human vCJD is thought to be proportional to exposure to BSE-contaminated beef products. As of the end of 2001, more than 100 cases of vCJD had been confirmed. Because the length of the incubation period is not known, it is not known how far the human epidemic has progressed. Concerns about the potential for secondary vCJD transmission by transfusion were triggered by the finding of prions in lymphatic tissues and further heightened when animal experiments demonstrated transmission of BSE by the blood of two asymptomatic cows ([536] , [537]). Worldwide, steps have been taken in an effort to minimize the theoretical risk of vCJD transmission by blood products in the absence of a screening test for the infection. In the United States, individuals are currently excluded from donating blood if they lived in the UK for 3 months or more between 1980 and 1996, if they lived in Europe for 5 years or more since 1980, or if they received a transfusion in the UK since 1980 ([315]). Because of the pathologic evidence that the vCJD prion accumulates in lymphoid tissue, the UK has implemented leukoreduction of all transfusable blood components. However, there is no evidence that the risk of vCJD transmission would be reduced by leukoreduction of blood components ([536]). Because prions lack lipid coats and nucleic acid, the causative agent of vCJD would not be inactivated by any of the pathogen inactivation processes currently in use or under development.

Bacterial Contamination

Bacterial contamination is a major cause of transfusion-related fatalities ([361] , [538]). The majority of blood components are not currently screened for bacterial contamination.

Sources of contamination include the collection system (bags), a donor with asymptomatic bacteremia, inadequately cleaned skin, or a skin core from the collection needles. Bacteria can be cultured from 1/300 to 1/3000 cellular blood components ([381] , [539]). Initially, levels of bacteria in the blood components are extremely low. The likelihood that the bacteria will multiply to levels that cause symptoms in recipients is higher for platelet components, which are stored at room temperature, compared to red cell products, which are refrigerated. The frequency of febrile reactions due to bacterial contamination has been estimated at 1/4000 to 1/15,000 platelet units and 1/30,000 RBC units ([540] , [541]). Based on voluntarily reported cases, the likelihood of a fatal reaction due to bacterial contamination was estimated at 1/500,000 platelet units and 1/8 million RBC units ([542]). However, it is assumed that morbidity and mortality related to bacterial contamination are underrecognized and, therefore, underestimated and underreported.

The organisms most often implicated in fatal cases of red cell contamination are *Yersinia*, *Pseudomonas, Enterobacter*, and *Serratia* species ([538]). The organisms involved in fatal platelet contamination are more varied and include *Staphylococcus, Streptococcus, Klebsiella, Serratia*, and *Salmonella* species.

Symptoms in recipients of bacterially contaminated products range from none to symptoms indistinguishable from those of a nonhemolytic febrile reaction, to acute sepsis with fever, hypotension, and death. Severe symptoms are often associated with endotoxin-producing organisms. The transfusion should be discontinued, and

cultures should be performed on both the blood product and the recipient. Suspected cases of bacterial contamination should be reported immediately to the blood supplier so that other components made from the same donation can be retrieved and quarantined pending the results of cultures. Treatment is the same as for sepsis of other etiologies. Treatment with recombinant activated protein C [drotrecogin alpha (activated)] may be of benefit ([327]). In some cases, the onset of symptoms may be delayed, even for days, and the linkage of the infection to the transfusion may go unrecognized ([543]).

The frequency of bacterial contamination can be minimized by careful questioning of donors for evidence of bacterial infection and careful attention to preparation of the venipuncture site. It has been suggested that the frequency of bacterial contamination could be reduced by diverting the first few milliliters of the blood collection. Although this might reduce the prevalence of skin flora, it has not been established that this would reduce the frequency of clinically relevant contamination. The risk of transfusion-related complications related to bacteria could also be reduced by systems that would detect pathogenic levels of bacteria in blood components or by processes that would inhibit the growth of bacteria in blood products. Both of these approaches have been investigated. Detection systems evaluated include gram staining of older platelets before issue, bacterial culture of platelet products on the day after collection (for which commercial systems have been recently developed), and detection of metabolic changes induced by bacterial proliferation ([538]). The pathogen inactivation systems in development for cellular blood components all appear likely to inhibit the growth of bacteria ([544]).

Pathogen Inactivation Technologies

Donor screening and testing cannot completely eliminate the possibility of transfusion-transmitted infection or blood product contamination. The ideal pathogen inactivation technology (PIT) would effectively inactivate residual pathogens without adversely affecting the function, toxicity, or immunogenicity of the blood component. Cellular blood components cannot withstand the heat- and solvent/detergent-PITs that are used in the production of plasma derivatives. Most of the PITs in development for cellular products consist of blood product additives that bind to and damage DNA and thereby prevent residual pathogens from proliferating in the blood component or in the recipient. These agents would theoretically also prevent transfusion-related GVHD because the DNA of WBCs in the blood product would also be affected. The efficacy of these agents is dependent on the agent's ability to penetrate cellular membranes or viral envelopes and reach the target nucleic acid. Because of concern that DNA-altering agents could cause long-term toxicity in transfusion recipients, many of these PITs include processes that remove the DNA-binding agent or inactivate it. Examples of PITs in development have been recently reviewed ([544] , [545]) and are described briefly below.

PATHOGEN INACTIVATION TECHNOLOGIES FOR PLATELETS AND PLASMA S-59 is synthetic psoralen that causes irreversible DNA cross-linking on exposure to UV light. Clinical trials of S-59/UV-treated platelets and FFP have been carried out. S-59/UV treatment does not appear to adversely affect the therapeutic effectiveness of FFP. However, treatment of platelets appears to cause some reduction in posttransfusion increments and *in vivo* platelet survival ([546] , [547]). An S-59/UV platelet treatment system has been approved for use in Europe. Methylene blue, when exposed to light, causes oxidation of nucleic acid guanosine residues. This treatment is ineffective against intracellular pathogens and is therefore applicable only to cell-free plasma products. Methylene blue/light-treated plasma has been used in parts of Europe. Riboflavin, on exposure to light, causes guanine oxidation and nucleic acid adducts. This system is being evaluated as a potential treatment for platelet products.
PATHOGEN INACTIVATION TECHNOLOGIES FOR RED BLOOD CELLS S-303 is a compound referred to as a *frangible anchor linker effector*. It consists of a nucleic acid binding ligand, an alkylating agent, and an alkyl chain. The “frangible” linker breaks down on exposure to blood, leading to inactivation of unreacted compound. S-303–treated red cells are in clinical trials. PEN110 (Inactine) is an aziridine compound. This compound is very small and can permeate tight virus capsids such as those of the parvovirus family. PEN110 inactivates DNA by binding covalently to guanine. PEN110 does not require activation by light; it is mixed with the RBCs for 6 to 24 hours at room temperature and then removed by washing. The shelf life of the RBCs can be preserved by processing the cells in a closed system and resuspending them in an additive solution. Clinical trials of this product are under way.

THERAPEUTIC APHERESIS

Therapeutic apheresis is an important modality of therapy in the management of several diseases ([16] , [548] , [549] , [550] , [551] , [552] , [553] and [554]). The term *plasmapheresis* refers to the selective removal of plasma. This includes the collection of plasma from normal donors. A *therapeutic plasma exchange*, on the other hand, refers to the removal of a large proportion of a patient's plasma and replacement with crystalloid or colloid fluids. These terms are often used interchangeably. Therapeutic cytapheresis, the removal of leukocytes or platelets, is used infrequently in the management of patients with leukostasis or thrombocytosis.

Therapeutic Plasma Exchange

INDICATIONS The therapeutic goal of TPE is to remove plasma components such as monoclonal proteins and cryoglobulins ([552]), immune complexes ([550]), lipoproteins, or toxins ([552]) responsible for physical or metabolic problems. This may include removal of autoantibodies, as in myasthenia gravis ([553]) and Goodpasture syndrome ([552]), and alloantibodies in posttransfusion purpura or in patients with factor VIII inhibitors ([551]). The existence and pathogenic role of antibodies or immune complexes are presumed in several situations often treated with TPE, including neurologic disorders such as Guillain-Barré syndrome ([548] , [553] , [555] , [556]), polyneuropathy ([553]), and various nephritides ([552] , [557]). In TTP, TPE using cryoprecipitate-reduced plasma ([558]) or FFP as the replacement fluid serves to replace the missing vWF-cleaving metalloprotease as well as to remove autoantibodies to this protein ([559]). TPE or plasma transfusion ([560] , [561]) may be life-saving in this disease. Guidelines for clinical practice have been developed by the American Society for Apheresis. The disorders for which TPE has been used are divided into four categories: category I, TPE is standard and acceptable; category II, TPE is generally accepted but as a supportive rather than first-line therapy; category III, there is insufficient evidence to establish the efficacy of TPE; category IV, a lack of efficacy has been demonstrated through controlled trials ([549]). Some of the indications for TPE (categories I and II) are listed in Table 24.12.

TABLE 24.12. Some Indications for Therapeutic Plasma Exchange

Accepted as therapy (category I)
Thrombotic thrombocytopenic purpura
Posttransfusion purpura
Guillain-Barré syndrome
Myasthenia gravis
Chronic inflammatory demyelinating polyneuropathy
Goodpasture syndrome
Refsum disease
Accepted as supportive therapy (category II)
Cold agglutinin hemolytic anemia
ABO-incompatible marrow transplant
Cryoglobulinemia
Lambert-Eaton myasthenic syndrome
Rapidly progressive glomerulonephritis
Autoimmune thrombocytopenia
Myeloma and paraproteinemias with renal failure or hyperviscosity
Coagulation factor inhibitors
Familial hypercholesterolemia

TECHNICAL CONSIDERATIONS The amount of plasma to be removed from the patient is determined by the physician, depending on the clinical situation. A patient's plasma volume may be estimated at 40 ml/kg, determined from a nomogram based on the patient's sex, height, weight, and hematocrit ([562]), or estimated according to the weight and hematocrit by the following formula:

$$\text{Circulating blood volume} = \text{patient weight (kg)} \times 70 \text{ ml/kg}$$

$$\text{Circulating plasma volume} = \text{circulating blood volume} \times [1.0 - \text{hematocrit (expressed as a decimal)}]$$

TPE is typically performed with 1.0 to 1.5 plasma volume exchanges or approximately 3000 to 4500 ml. If less than 1000 ml is removed from an adult, it may be possible to replace the loss with crystalloid alone; if a more extensive plasma exchange is performed, use of a colloid is necessary. Albumin (5%) is the replacement fluid most commonly used in the United States. FFP is indicated in certain instances, such as TTP or as a component of the replacement fluid in the setting of a coagulopathy. After exchange of one plasma volume, approximately 62% of the original plasma has been removed. The efficiency of plasma exchange decreases with further exchange (Table 24.13).

TABLE 24.13. Plasma Exchange: Theoretical Efficiency

Number of Plasma Volumes Exchanged	Percent (%) of Original Plasma Remaining
0.5	60
1.0	38
1.5	22
2.0	15

In practice, measurement of plasma protein concentrations after exchange has confirmed the approximate validity of these estimates. However, efficacy varies with the plasma factor to be removed. IgM and fibrinogen, which are largely confined to the intravascular space, are removed most efficiently ([563], [564] and [565]). IgG is removed less efficiently by plasma exchange because only 45 to 50% of the body's IgG is located in the intravascular space, although IgG levels can be reduced by repeated TPE. Patients receiving plasma exchange for immunologic diseases generally have 1.0 to 1.5 plasma volumes exchanged at each procedure; this is often repeated, for a total of 5 to 7 exchanges over a period of 7 to 10 days. Such plasma exchange schedules have been determined empirically; the optimal exchange regimens for different diseases are unknown.

Therapeutic Cytapheresis

Therapeutic leukapheresis is used in the treatment of patients with leukostasis as a result of extremely high circulating concentrations of immature cells ([551], [566], [567]). At blast counts above 100 × 10^9/L, there is an increasing risk of cerebral and pulmonary leukostasis, resulting in impaired capillary blood flow due to obstruction of small vessels. This situation may be encountered in the acute leukemias but rarely in chronic lymphocytic leukemia or chronic myelogenous leukemia. Therapeutic leukapheresis decreases the circulating blast count more rapidly than chemotherapy alone; chemotherapy must be instituted promptly once the patient is stabilized to prevent rebound leukocytosis. The only exception is in pregnancy, in which leukapheresis may be indicated until after the delivery of the fetus, thereby protecting the fetus from the teratogenic effects of chemotherapy.

Therapeutic leukapheresis has also been used in the treatment of patients with other leukemic diseases, such as chronic lymphocytic leukemia resistant to drugs, Sézary syndrome, and hairy cell leukemia, and as maintenance therapy in chronic myelogenous leukemia. However, it has not found a distinct role in such conditions ([551], [567], [568]). Collection of leukocytes by apheresis, followed by *ex vivo* exposure of the leukocytes to UV light in the presence of a psoralen, and reinfusion of the treated leukocytes (“photopheresis”) has become standard therapy for cutaneous T-cell lymphoma. This procedure may be useful in the treatment of other disorders such as GVHD ([567]).

Therapeutic plateletpheresis ([551], [569], [570]) is performed very rarely and is not considered to be first-line therapy. It is indicated in patients with very high platelet counts, usually above 1.0 to 1.5 × 10^{12}/L, in whom the high count is directly responsible for serious thrombotic or hemorrhagic problems, or in whom other urgent clinical situations necessitate immediate lowering of the platelet count. Therapeutic plateletpheresis must be followed by cytotoxic therapy to prevent rebound after the procedure, or its effect is very short lived.

Erythrocytapheresis (red cell exchange) is used in sickle cell disease to dilute sickled cells with normal erythrocytes and thereby prevent thromboses or improve capillary circulation. Stroke, acute chest syndrome, priapism, and retinal infarction are some of the indications for red cell exchange, although good studies are lacking to prove its effectiveness ([551]).

Therapeutic Absorption of Plasma Constituents

Apheresis technology may be used to selectively remove constituents of plasma implicated in disease processes. In these procedures, a patient's plasma is withdrawn and separated by apheresis technology, passed over a selective absorption column, and reinfused into the patient. This technique has been used to selectively remove IgG (staphylococcal protein A columns) or low-density-lipoprotein cholesterol ([567]).

Adverse Effects

Adverse reactions to therapeutic apheresis are common but usually mild ([571], [572] and [573]). In a 1-year period in Canada, there were side effects in 12% of more than 5235 procedures in 627 patients ([572]). They included vasovagal reactions, fluid imbalance with hypovolemia or overload, fever, chills, and hypocalcemic citrate reactions ranging from paresthesias to arrhythmias. If plasma is used as the replacement fluid, urticarial reactions may be encountered. Mild dilutional coagulopathy and thrombocytopenia occur but are rarely significant ([574], [575]). Problems related to venous access are common. The possibility of immunologic rebound after plasma exchange has been suggested but has not been observed clinically ([576], [577]), perhaps because many patients so treated are also receiving immunosuppressive agents for the underlying diseases. Infections related to indwelling venous lines are not uncommon. Deaths have been reported with therapeutic apheresis ([571], [573], [578]). It is important that patients be carefully assessed and the indications reviewed before implementing this form of therapy.

SUMMARY

Blood transfusion is an essential component of therapy for a wide variety of disorders. The menu of blood components and technologies for collecting, processing, and screening blood are constantly changing. Collaboration between transfusion medicine professionals and patient care teams ensures the most appropriate application of blood transfusion therapies.

ACKNOWLEDGMENTS

The authors wish to thank Marlis Schroeder, MD, FRCPC, for the excellent previous editions of this chapter, on which this work was built. We are extremely grateful to Michelle Perkins Harmon for providing the technical and organizational expertise that was essential to the preparation of this manuscript.

Hematopoietic Stem Cell Transplantation

Pluripotent hematopoietic stem cells (HSCs) have the ability to reconstitute immunohematopoiesis after myeloablative therapy and transplantation ([1]). There are many potential sources for HSCs, which may be used for transplantation, including both the marrow and peripheral blood from the patient (autologous), family members, or volunteer unrelated donors. Umbilical cord blood has also been identified as a potential source of HSCs. HSC transplantation (HSCT) is done for a variety of therapeutic indications: (a) to support hematopoiesis after myeloablative doses of total body irradiation (TBI) and chemotherapy used in the treatment of hematologic malignancies, (b) to establish a graft-versus-leukemia (GVL) reaction, or (c) to replace diseased tissues of hematologic or immunologic origins. The advances in supportive care after transplantation have resulted in HSCT being a therapeutic modality that is highly successful in otherwise fatal diseases ([2], [3]). The focus of this chapter is on the general indications for HSCT, sources of stem cells, conditioning regimens, transplant biology issues, and complications of HSCT; other chapters provide detailed discussions of the indications and results of HSCT in relation to specific diseases (Table 25.1).

TABLE 25.1. Disorders Treated by Bone Marrow or Stem Cell Transplantation

Disease	Chapter
Nonmalignant	
Aplastic anemia	44
Fanconi anemia	45
Diamond-Blackfan syndrome	45
Sickle cell disease	40
Thalassemia	42
Paroxysmal nocturnal hemoglobinuria	37
Myelofibrosis	86

Non-Hodgkin lymphoma	90
Multiple myeloma	98
Solid tumors	—

HISTORICAL PERSPECTIVE

Early Preclinical Studies

After the effects of radiation on hematopoiesis became evident during World War II, Jacobson and colleagues reported in 1949 that mice could survive an otherwise lethal exposure to TBI if the spleen was shielded ([4]). Radiation protection could also be conferred by infusion of bone marrow ([5] , [6]). A runting syndrome developed after recovery of hematopoiesis when the infused marrow was from a donor of a different strain ([7]). This syndrome was due to graft-versus-host (GVH) disease (GVHD), a complication that was soon recognized to limit the use of allogeneic marrow transplantation in humans. In further studies in mice, methotrexate (MTX) and 6-mercaptopurine were found to be effective in inducing immune tolerance or ameliorating the GVH reaction ([8] , [9] and [10]).

The dog served as a random-bred model for studies of principles and techniques of bone marrow transplantation applicable to humans. The dog was the first random-bred species in which it was demonstrated that the results of *in vitro* histocompatibility typing could predict the outcome of marrow transplantation ([11] , [12]). Littermates genotypically identical to their donors for the major histocompatibility complex (MHC) survived longer after marrow transplantation than did those transplanted with marrow from MHC-nonidentical siblings. However, despite the MHC genotypic identity, GVHD was still potentially severe in many but not all dogs. This indicated that other factors, identified as minor histocompatibility antigens (mHC), were involved in the development of GVHD. Pharmacologic immunosuppression with cyclosporine (CSP) or MTX, given for prevention of GVHD, improved survival after allogeneic marrow grafting ([13] , [14]). It was then established that these two drugs in combination were more effective than either used alone ([15]). This observation led to the use of the combination of MTX and CSP in human patients in 1981, and this remains the standard in many transplant programs ([16] , [17] and [18]).

Early Clinical Studies

Bone marrow was the first commonly used source of HSCs for transplantation. Bone marrow transplantation from HLA-identical donors was first successfully used by two groups in 1968 to treat patients with immunologic deficiencies ([19] , [20]). After extensive preclinical studies of GVHD, the first report of a successful marrow transplant for aplastic anemia from an HLA-identical sibling donor was published in 1972 ([21]). A report of 100 patients with end-stage leukemia treated with marrow transplantation was presented by a Seattle group in 1977 ([22]). Allogeneic HSCT from HLA-matched related or unrelated donors is now considered standard therapy for many malignant and nonmalignant hematologic diseases.

HEMATOPOIETIC STEM CELLS

The *HSC* is defined as a cell with the ability to achieve long-term reconstitution of both myeloid and lymphoid lineages. To fulfill these criteria, HSCs must be able to self-renew and to be pluripotent. Colony-forming units (CFU) (e.g., CFU granulocyte-monocyte, CFU megakaryocyte, CFU erythroid, burst-forming unit erythroid) and long-term culture-initiating cells are progenitor cells that cannot reconstitute hematopoiesis ([23] , [24]). No universally accepted *in vitro* assays for HSCs are currently available. A population of small mononuclear cells containing HSC can be identified by (a) a repertoire of cell-surface antigen expression, including the presence of the CD34 antigen and the absence of lineage-specific antigens; and (b) the exclusion of fluorescent vital dyes including Rhodamine 123 and Hoechst 33342.

A small population of CD34-negative HSCs has been identified in mice ([25] , [26] and [27]). These HSCs may be in a resting or activated self-renewing state in which CD34 is reversibly expressed on only those cells that are activated ([28]). However, successful transplantation of this CD34-negative subset of HSCs into lethally irradiated mice also requires the presence of the CD34-positive subset ([29]). In humans and other species, successful sustained engraftment was achieved with the CD34-positive subset of cells, confirming their true “stem cell” nature ([30] , [31] , [32] and [33]).

Marrow-derived pluripotent HSCs may include nonhematopoietic cell lineages, as some studies have shown or suggested that the transplantation of HSCs may result in the regeneration of muscle, endothelial cells, osteoblasts, hepatocytes, and neuronal and nonneuronal cells of the brain ([34] , [35] , [36] , [37] , [38] , [39] , [40] , [41] and [42]). However, some of the experimental observations may have resulted from cell fusion, changes of the cells in culture before transplantation, or mistakenly identifying a cell from a nonhematopoietic lineage as hematopoietic. If “transdifferentiation” of circulating HSCs occurs, it is likely a rare event ([43]).

Identification of Cell Populations Enriched for Hematopoietic Stem Cells

The CD34 antigen is a cell surface type 1 transmembrane protein that is highly O-glycosylated and expressed primarily on hematopoietic progenitor cells and vascular endothelium derived from many tissues ([44] , [45] and [46]). Cell-surface expression of CD34 is developmentally regulated in hematopoiesis and is inversely related to the stage of differentiation, as CD34 expression is lost beyond the committed progenitor stage. The functional significance of CD34 expression on hematopoietic progenitor cells and developing blood vessels is unknown, except that CD34 on vascular endothelial cells binds to L-selectin ([47]). The CD34 knock-out mouse has a decreased number of embryonic hematopoietic progenitors, however, development is otherwise normal. In the grown CD34 knock-out mice, reduced colony-forming activity of hematopoietic progenitors was found, but recovery of hematopoiesis after sublethal irradiation was indistinguishable from that seen in wild-type mice ([48]).

The CD34 antigen is expressed on 1 to 5% of normal human adult marrow cells, up to 1% of mobilized peripheral blood cells, and by 2 to 10% of normal fetal liver and marrow cells ([44] , [49]). Approximately 90 to 95% of the CD34-positive cells express antigens indicating commitment to the lymphoid or myeloid lineages ([50] , [51]). Purified populations of HSCs can be obtained with strategies that lineage-deplete a CD34-positive population of cells using monoclonal antibodies (MAb) directed against DR, CD33, CD38, CD71, and B- and T-cell markers (Table 25.2). In addition, human HSCs appear to be Thy-1 ^{low}, c-kit ^{low}, Rhodamine 123 ^{low}, and CD133-positive ([52] , [53] , [54] , [55] , [56] and [57]). *In vivo* preclinical models for studying populations of purified human HSCs based on the previously mentioned characteristics include transplantation into severe combined immunodeficiency syndrome (SCID)–Hu mice or into fetal sheep ([56] , [58]).

TABLE 25.2. Characteristics of Human Hematopoietic Stem Cells

Cell-surface antigen expression
Positive

Dye exclusion
Rhodamine 123, Hoechst 33342

[a] CD34-negative hematopoietic stem cells have been identified in mice.

In both animal and human studies, enriched populations of autologous CD34-positive marrow cells or blood cells have been shown to protect against myeloablative doses of radiation or chemotherapy ([31] , [59] , [60]). Conversely, the CD34-negative subset of the marrow was not protective ([61]). An evaluation of the contributions of the CD34-positive cells to long-term hematopoiesis in these studies was obscured initially by the lack of a marker to distinguish the transplanted autologous cells from endogenous reconstitution. Later, allogeneic CD34-enriched populations of marrow cells depleted of T cells and B cells were demonstrated to reconstitute stable

lymphopoiesis and myelopoiesis in lethally irradiated dogs and baboons ([31], [62]). Complete and stable donor hematopoietic chimerism was also shown in humans after transplantation with allogeneic CD34-enriched cells from the peripheral blood ([33], [63], [64] and [65]). These studies have confirmed that CD34-positive hematopoietic cells are capable of producing long-term stable hematopoiesis and reconstituting multiple hematopoietic lineages.

Sites of Hematopoiesis and Sources of Hematopoietic Stem Cells

In the developing human embryo, the production of hematopoietic cells shifts to the liver from the yolk sac after 6 weeks of gestation. At 16 weeks of gestation, the most active site of hematopoiesis is the fetal liver. At the end of gestation, essentially all hematopoietic production derives from the marrow with only small contributions from the liver and spleen. Umbilical cord blood is enriched for hematopoietic progenitor cells. Similar numbers of progenitors were found in a single collection of cord blood as in the volume of adult marrow normally required for successful engraftment ([66]). Eventually, it was shown that there were also sufficient numbers of long-term reconstituting cells in a collection of cord blood to successfully engraft recipients after myeloablative chemoradiotherapy ([67], [68] and [69]).

Because almost all hematopoietic production in normal adults occurs in the bone marrow, this was historically the site from which HSCs were routinely collected ([1]). This site was clinically reliable and provided an easily accessible source of long-term reconstituting cells. The presence of HSCs in peripheral blood was first documented in preclinical studies ([70], [71]). In early clinical studies, transplantation of autologous peripheral blood stem cells collected without the prior administration of chemotherapy or cytokines resulted in protection from myeloablative chemotherapy or chemoradiotherapy ([72]). However, obtaining sufficient cell numbers required a prolonged period of collection.

Mobilization of HSCs into the peripheral blood overcame the practical problem of collecting sufficient stem cells from this site. The number of CD34-positive cells collected from the peripheral blood after mobilization with granulocyte colony-stimulating factor (G-CSF) alone was similar or greater than that collected from a marrow harvest ([73], [74]). Combined chemotherapy and G-CSF resulted in even higher CD34-positive cell collection than with G-CSF alone, but sufficient numbers of CD34-positive cells in either graft resulted in rapid engraftment regardless of how the HSCs were collected ([75]). Cytokines used in combination [e.g., G-CSF and stem cell factor] were synergistic in the mobilization of HSCs into peripheral blood ([76], [77] and [78]). Among other cytokines that have been demonstrated to mobilize HSC into peripheral blood are granulocyte-macrophage colony-stimulating factor, interleukin (IL)-6, IL-8, and flt-3 ligand ([79], [80]). Mobilization strategies including chemotherapy are now routinely used for the collection of autologous HSCs from the peripheral blood ([81], [82] and [83]). Normal donors receive only G-CSF for the mobilization of HSCs to be used in allogeneic transplants. In addition to cytokines and chemotherapy, MAb specific to the adhesion molecule VLA-4 (very late antigen-4) can also mobilize hematopoietic progenitors in nonhuman primates ([84]). Infusion of MAb specific for the VLA-4 ligand and VCAM-1 (vascular cell adhesion molecule-1) gave similar results. An essential step contributing to the release of hematopoietic progenitors from the marrow may be the cleavage of VCAM-1 expressed on stromal cells by neutrophil proteinases after the administration of G-CSF ([85]). Hematopoietic progenitors reversibly down-regulate a4ß1 integrin expression and adhere significantly less to stroma and fibronectin during mobilization ([86]). a4ß1 integrin expression is restored after progenitors are removed from the *in vivo* mobilizing milieu, which may account for their homing properties after transplantation. The ability of MAb specific for certain adhesion molecules to mobilize HSCs suggests that cytokines may be effecting mobilization or homing by modulating the expression of adhesion molecules in the marrow microenvironment or on the HSCs.

COLLECTION OF HEMATOPOIETIC STEM CELLS FOR TRANSPLANTATION

Marrow

Marrow is obtained by multiple aspirations from the posterior iliac crest under general or epidural anesthesia ([87]). The anterior iliac crest or the sternum may also be harvested if larger quantities of marrow are required. The target volume of marrow for transplant is 10 to 15 ml/kg of recipient or donor weight, whichever is the smaller individual. Marrow is collected with heparinized syringes through large-bore needles and placed into small amounts of culture medium. The collected marrow must be filtered before intravenous transfusion into the recipient to remove small particles or clots. If the patient and donor are ABO-incompatible and there are high anti-A or -B titers, the marrow can be red blood cell–depleted or plasma-depleted depending on whether it is a major or minor ABO mismatch ([88]). In some cases of a major ABO mismatch, plasmapheresis of the recipient may be effective in reducing the high anti-A or -B titers so that red blood cell depletion of marrow is not required. Marrow is usually infused immediately after harvesting, but delays of 24 hours may occur without adverse consequences. These delays occur not infrequently when marrow is shipped from distant sites, usually after harvest from unrelated donors. In an analysis of marrow characteristics harvested from 1549 donors, the median total nucleated cell count was 2.5 (range, 0.3 to 12.0) × 10^8/kg recipient weight ([89]). Life-threatening complications from marrow harvesting, usually related to the administration of anesthesia, were reported as 0.4% in this study population. Similar complication rates have been cited in other studies ([90]).

Peripheral Blood

HSCs circulate in the peripheral blood, but the concentration is very low and therefore multiple aphereses are required to collect adequate numbers of HSCs. The number of leukaphereses may be reduced to one or two when HSCs are mobilized to the peripheral blood after the administration of cytokines alone or in combination with chemotherapy. An effective mobilization strategy for patients with malignancy is cyclophosphamide (CY)-based chemotherapy and G-CSF, 6 µg/kg/day ([83]). After chemotherapy, leukapheresis is started when the total white blood cell count has recovered to 1 × 10^9/L. Patients who do not require chemotherapy and normal allogeneic donors can be mobilized with G-CSF alone ([63], [64], [91]). Administration of G-CSF (5 to 16 µg/kg) is by daily subcutaneous injections for 5 to 8 days and is generally well tolerated. Bone pains, myalgias, and flulike symptoms may occur. Leukapheresis is performed as early as day 4 using a continuous blood flow separation technique. Pheresed products may be cryopreserved in 5% dimethylsulfoxide for use after thawing on the day of transplant. A more rapid sustained hematopoietic recovery of both neutrophil and platelet counts occurs with increasing numbers of CD34-positive peripheral blood stem cells (up to 5 × 10^6/kg). Some investigators consider 2.5 × 10^6/kg of recipient weight a minimum dose of CD34-positive cells from the peripheral blood to achieve complete autologous recovery. Platelet recovery also is more rapid at higher CD34-positive cell doses ([82], [83]). Because this cell dose yields consistent and prompt engraftment after autologous infusion, it could be considered an appropriate target for collection of allogeneic HSCs from the peripheral blood. Donors of peripheral blood avoid general anesthesia and other complications of marrow harvesting. If peripheral veins are inadequate, vascular access by a large-bore double-lumen catheter may be required.

Cord Blood

Experience with the collection and transplantation of umbilical cord blood cells is still limited. However, umbilical cord blood cells are now being collected routinely and cryopreserved at the National Marrow Donor Program Network of Cord Blood Banks ([92], [93]). After the separation of the placenta, umbilical cord blood cells are collected into a closed system, which uses a sterile donor blood collection set. The placenta and umbilical cord can be suspended on a frame and the blood drained as a “standard gravity phlebotomy” into CPD (citrate, phosphate, dextrose) anticoagulant. The median volume of umbilical cord blood collected in one study of 44 patients was 100 ml (range, 42 to 282 ml) ([68]). The median number of nucleated cells per kilogram of recipient weight was 5.2 × 10^7 (range, 1 to 33).

SELECTION OF STEM CELL SOURCE

There are three general categories of HSC—autologous, syngeneic, and allogeneic—that may be used to reconstitute hematopoiesis after high-dose myeloablative chemoradiotherapy (Table 25.3). In general, the selection of the source of the stem cells to be used for any individual patient is based on (a) the availability and (b) the type of disease for which the patient is being transplanted. Availability is often the critical determinant of the type of stem cell selected. Although autologous HSCs should be available for most patients, extensive prior cytotoxic therapy or heavy involvement of marrow or peripheral blood with malignant cells may preclude the use of this source of HSCs. Although the preferred allogeneic donor is an HLA-matched sibling, not more than 30% of patients have access to this source. There are even fewer HLA-matched sibling donors for pediatric patients because of the smaller family size now compared to previous generations. Syngeneic donors are available in less than 1% of cases, and phenotypically HLA-matched or one-antigen–mismatched haploidentical family donors are available in less than 5% of cases ([94], [95]). Approximately 30 to 40% of patients may find a phenotypically HLA-matched unrelated donor on volunteer registries ([96]). The availability of unrelated or related umbilical cord blood grafts increases the chance of success for the identification of an allogeneic donor for both pediatric and adult patients, but the experience is still very limited for adults ([67], [68] and [69]).

TABLE 25.3. Sources of Hematopoietic Stem Cells [a]

	Relationship of Donor	Major Histocompatibility Complex (HLA) Matching	Genetically Identical Haplotype	Minor Histocompatibility Complex Matching [b]	Site of Hematopoietic Stem Cell Collection
Syngeneic	Sibling	Identical	2	Identical	Marrow or peripheral blood
Allogeneic	Sibling	Identical	2	Shared	Marrow or peripheral blood
	Sibling, parent, child	Zero- or one-antigen mismatch [c]	1	Shared	Marrow
	Sibling	Identical	2	Shared	Umbilical cord blood
	Sibling	Zero- or one-antigen mismatch	1	Shared	Umbilical cord blood
	Unrelated	Identical or one-antigen mismatch	0	Divergent	Marrow
	Unrelated	Zero- to three-antigen mismatch	0	Divergent	Umbilical cord blood
Autologous	Self	—	—	—	Marrow or peripheral blood

[a] Potential sources of hematopoietic stem cells to reconstitute patients after myeloablative therapy. Umbilical cord blood as a site of hematopoietic stem cells for transplantation is being investigated.

[b] *Shared* indicates a higher probability of sharing minor histocompatibility complex antigens within the family. *Divergent* indicates that the probability of sharing minor histocompatibility complex antigens is no better than that expected by matching two unrelated individuals who were randomly chosen. There is currently no routine testing for minor histocompatibility complex compatibility.

[c] Two- or three-antigen–mismatched transplants of unmanipulated marrow grafts from adult or pediatric family donors have, in general, a high transplant-related mortality.

The patient's disease requiring stem cell transplantation is another important determinant. Autologous, syngeneic, or allogeneic HSCs can support hematopoietic recovery after myeloablative chemoradiotherapy for malignant hematologic and nonhematologic diseases. For acquired disorders of marrow function (e.g., aplastic anemia), syngeneic or allogeneic HSCs are needed ([2]). Patients with congenital hematopoietic or immunologic defects (e.g., thalassemia, SCID) ([97], [98]) require transplantation with allogeneic stem cells.

Autologous Source of Stem Cells

Depending on the disease type, autologous marrow or peripheral blood stem cell grafts may be used when other donors are not available and may indeed be the stem cell of choice. Autologous stem cell support is now most commonly derived from “mobilized” peripheral blood stem cells instead of marrow because of faster hematopoietic recovery in the recipient ([81], [82]). Peripheral blood stem cell transplants have decreased the time required for hospitalization. Before cryopreservation, autologous HSC graft may be treated with MAb, chemotherapeutic agents, or long-term culture to purge malignant cells from the graft. Autologous stem cell support after myeloablative therapy has been successful for treatment of acute myelogenous leukemia (AML), non-Hodgkin lymphoma, and Hodgkin disease ([99], [100], [101], [102], [103] and [104]). Disease-free survival was prolonged in patients with multiple myeloma ([105], [106]). Significant transplant-related complications encountered most frequently include liver or lung toxicity, caused in large part by high-dose myeloablative cytotoxic therapy. A GVHD-like syndrome involving the skin and gastrointestinal tract has been described, but it is generally not frequent or severe ([107]).

Allogeneic Source of Stem Cells

TRANSPLANTATION FROM RELATED DONORS The preferred allogeneic donor is a genotypically HLA-identical sibling. A genetic match at the HLA loci between siblings is confirmed by the genotyping of five HLA loci including HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1. If an HLA-identical sibling is available, patients with hematologic malignancies should be transplanted with peripheral blood stem cells rather than marrow. Two phase 3 studies have now shown an improved disease-free and overall survival with transplantation of peripheral blood stem cells (Fig. 25.1) ([108], [109]). A third study concluded that peripheral blood was an equivalent source of HSCs compared with marrow if administered to patients with standard-risk leukemia because a significant difference in survival could not be demonstrated ([110]). All three studies showed an accelerated recovery of neutrophil counts in the group receiving peripheral blood stem cells. Although most studies have not shown a significant increase in the incidence of acute GVHD in the peripheral blood stem cell group, the incidence of chronic GVHD is significantly greater ([108], [109], [110] and [111]). After longer follow-up in one study, a significant difference was not observed in the incidence of chronic GVHD between the two groups, but it was concluded that chronic GVHD may be more protracted and less responsive to treatment in those transplanted with peripheral blood HSCs ([112]). There was no difference in late transplant-related mortality or in the frequency of complications. Higher doses of CD34-positive cells in the peripheral blood stem cell graft (>8 × 10^6/kg) were associated significantly with the development of chronic GVHD ([113]). Because outcome is unlikely to be improved if peripheral blood stem cells result in an increased risk of chronic GVHD compared to marrow, patients with nonmalignant disorders should be transplanted with marrow. Survival of patients with aplastic anemia transplanted with marrow was 88% with a median follow-up of 6 years (Fig. 25.2) ([114]). Similar results have been reported in patients transplanted with marrow for hemoglobinopathies ([115], [116]).

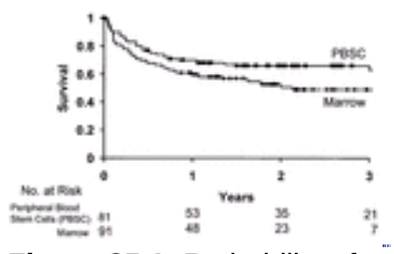

Figure 25.1. Probability of overall survival after myeloablative conditioning and transplantation with either peripheral blood stem cells or marrow. Survival at 2 years was improved in the peripheral blood stem cell group as compared to marrow (66% vs. 54%; $p = .006$). Disease-free survival was also improved in the peripheral blood stem cell group ($p = .003$). (From Bensinger WI, Martin PJ, Storer B, et al. Transplantation of bone marrow as compared with peripheral-blood cells from HLA-identical relatives in patients with hematologic cancers. N Engl J Med 2001;344:175–181, with permission.)

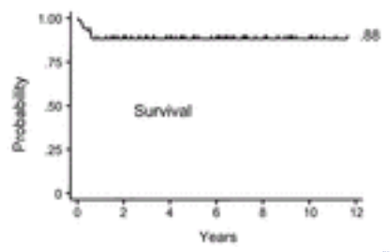

Figure 25.2. Overall survival among the 94 patients with aplastic anemia who underwent transplantation from HLA-identical siblings after conditioning with cyclophosphamide and antithymocyte globulin. With a median follow-up of 6.0 (0.5 to 11.6) years, the Kaplan-Meier estimate of survival was 88%. Cyclosporine and methotrexate were administered after transplantation for graft-versus-host disease prophylaxis. (From Storb R, Blume KG, O'Donnell MR, et al. Cyclophosphamide and antithymocyte globulin to condition patients with aplastic anemia for allogeneic marrow transplantations: the experience in four centers. Biol Blood Marrow Transplant 2001;7:39–44, with permission.)

An HLA-haploidentical donor (parent, sibling, child) is available for almost all patients, but full haplotype differences (genotypically identical at one HLA haplotype but nonidentical at the other HLA haplotype) are associated with a high risk of severe GVHD, graft rejection, and increased mortality. However, transplants for hematologic malignancies from HLA-haploidentical family members mismatched for only one HLA antigen in the nonidentical HLA haplotype may have a similar overall survival to those transplanted with HSCs from HLA-identical siblings ([117]). In this situation, although the higher incidence of GVHD results in an increased

transplant-related mortality, relapse is less frequent, resulting in no overall difference in long-term survival compared to transplants from HLA-matched siblings. Patients transplanted from HLA-haploidentical family members mismatched for two or more HLA loci had significantly lower overall survivals compared to patients transplanted from phenotypically matched unrelated donors ([118]). Transplantation of patients with advanced leukemia with high-dose CD34-positive cell grafts, which are highly T-cell depleted, resulted in 12 of 43 patients being alive and disease-free at 18 months ([119]). However, immune reconstitution after transplantation has been poor. Patients who lack a closely matched family donor should be offered a phenotypically matched unrelated donor before other investigational approaches are considered.

TRANSPLANTATION FROM UNRELATED DONORS After the initial success with transplantation of marrow from matched unrelated volunteers, large databanks were established around the world, including the National Marrow Donor Program in the United States. The worldwide registries, including the National Marrow Donor Program, contain more than 7 million volunteer donors who have been typed for HLA-A and -B antigens, and more than half of these are also typed for HLA-DR ([96]). The incidence of grade II to IV GVHD is approximately 70% after transplantation from matched unrelated donors, which is higher than the reported incidence of 35 to 40% for GVHD after transplants from HLA-matched siblings ([95] , [120]). However, disease-free survival for patients with chronic myelogenous leukemia (CML) in chronic phase after transplantation from a matched unrelated volunteer within 1 year of diagnosis is comparable to that observed after HLA-matched sibling transplants ([121]). The Kaplan-Meier estimate of survival at 5 years is 57%. Survival at 5 years is 74% for patients who were 50 years of age or younger and who received a transplant from an HLA-matched donor within 1 year after diagnosis. More precise genotyping of the HLA loci improves outcome after transplantation from HLA-matched unrelated donors. DNA typing can identify unique alleles encoded by the same serologic specificity ([122] , [123]). Unrelated individuals, matched for HLA-A, -B, and -DR, may differ at other HLA loci ([124] , [125]). Based on the availability of matched A, B, and DR donors listed in the Bone Marrow Worldwide Registry, a highly compatible donor (an allelic match for HLA-A/B/Cw/DRB1/DRB3/DRB5/DQB1 loci) was identified for 38.4% of the patients from whom at least a single blood sample could be obtained. If an HLA-DRB3, -DQB1, or -Cw mismatch was accepted, a potential donor would have been identified for 68.6% of patients. A single class I HLA antigen mismatch or two allelic mismatches without a single class I allelic mismatch were associated with a higher risk of graft failure ([126]). The presence of DRB1 mismatching correlated with a significantly worse survival and an increased incidence of grade III to IV acute GVHD ([127]). These results confirmed the importance of precise matching to improve outcome. Because of the higher risk of acute GVHD, studies of peripheral blood stem cell transplantation from unrelated donors started later than those done from HLA-identical donors. The rate of neutrophil and platelet recovery was increased with the use of peripheral blood stem cells, compared to what might have been expected with a marrow transplant ([128] , [129]). The incidence of both acute and chronic GVHD appeared comparable between the two types of stem cell grafts. In one report, patients with CML in chronic phase had a better survival with peripheral blood stem cells than with marrow transplants ([129]). Prospective phase 3 studies are required to confirm the observations in these early reports.

TRANSPLANTATION WITH UMBILICAL CORD BLOOD GRAFTS The first successful cord blood cell transplant was done in 1988 ([67]). Two studies were then conducted of cord blood transplantation from HLA-matched or HLA-haploidentical allogeneic siblings (44 patients) and partially HLA-mismatched unrelated donors (25 patients) ([68] , [69]). In the first report of a large experience in 562 recipients after transplantation with umbilical cord blood grafts from unrelated donors, the probability of engraftment at 42 days and grade III to IV GVHD was 81% and 23%, respectively ([130]). It was concluded from this study that stem cells derived from umbilical cord blood engraft regularly, cause a low rate of GVHD relative to the number of HLA mismatches, and produce survival rates comparable to those of transplantation of marrow from unrelated donors. This experience was confirmed in a retrospective analysis of 541 children with leukemia transplanted with stem cell grafts from unrelated donors of which 99 were from umbilical cord blood. Recipients of cord blood had an increased number of HLA mismatches but a significantly lower risk of both acute and chronic GVHD compared to recipients of unmanipulated marrow from unrelated donors. However, the day 100 mortality was higher in the cord blood group, possibly related to the significantly delayed recovery of hematopoiesis after transplantation ([131]). These results were later confirmed by another group ([132]). It was concluded that the use of umbilical cord blood was an option for children with acute leukemia lacking an acceptably matched unrelated marrow donor. In children who had received umbilical cord blood or bone marrow grafts from HLA-identical siblings, the umbilical cord blood group had a lower risk of acute and chronic GVHD, with a relative risk of 0.41 ($p = .001$) and 0.35 ($p = .02$), respectively ([133]). Survival was similar in both groups. The progenitor cell and CD34-positive cell content of the umbilical cord blood graft predicted the rate of neutrophil recovery after transplantation ([134] , [135]). Recovery of neutrophil and platelet counts after transplantation may be improved with the use of multiple cord blood units ([136]). After the infusion of two umbilical cord blood grafts into adult patients, the median day to neutrophil recovery was 24 (range, 12 to 28) in 23 adult patients compared to 27 (range, 13 to 59) in another study of 68 adult patients who received only a single cord blood graft ([137]). Shortening the time to engraftment with the infusion of multiple cord blood units may improve outcome early after transplantation, but this experience needs to be confirmed with a larger study. The reported low incidence of severe GVHD after the transplantation of umbilical cord blood cells from unrelated donors (relative to the degree of HLA disparity) may be related to the decreased immunocompetence of the fetal blood cells compared to adult cells ([138]). Two years after transplantation, T-cell receptor rearrangement excision circles (TRECs) were greater in recipients of umbilical cord blood than in recipients of marrow grafts, suggesting complete immune recovery despite the low number of cells infused ([139]). Recipients of umbilical cord blood cell transplants to date have been children predominantly, but recent studies in adults ([140]) suggest that results obtained are comparable to those reported in children, even though the numbers of cells infused per kg of body weight were lower ([137]). In 68 adult patients with life-threatening hematologic disorders, 48 (71%) had umbilical cord blood grafts that were mismatched for two or more HLA antigens. There were five cases of primary graft failure with a median of 27 (range, 13 to 59) days to neutrophil engraftment. The incidence of grade III to IV GVHD was 20%, and 18 of 68 patients were surviving disease-free at 40 months after transplantation. Umbilical cord blood grafts should therefore be considered for both pediatric and adult patients lacking a suitably matched unrelated donor or who are unable to wait for a search for an unrelated donor to be completed.

ABO INCOMPATIBILITY

ABO incompatibility between the donor and the recipient occurs in approximately 30% of cases. A major ABO incompatibility is considered to occur when the isohemagglutinins in the recipient plasma are directed against the donor red blood cell antigens. A minor ABO incompatibility occurs when the isohemagglutinins in the donor plasma are directed against recipient red blood cell antigens. ABO incompatibility between the donor and the recipient has no significant effect on the incidence of graft rejection, GVHD, or survival ([141] , [142]). However, these ABO incompatibilities may result in severe hemolytic episodes after transplantation. In major ABO incompatibilities with high isohemagglutinin titers in the recipient plasma, an acute hemolytic event can be prevented by red cell depletion of the graft. Conversely, plasmapheresis may be effective in reducing the antidonor isohemagglutinin in the recipient plasma. If the latter approach is chosen, the goal should be to reduce the isohemagglutinin titer to 1:16 or lower ([143]). If there is continued production of antidonor isohemagglutinins in the recipient plasma after transplantation, delayed erythropoiesis or even pure red cell aplasia and persistent hemolysis may result ([144]). Although plasmapheresis and erythropoietin may be of some benefit, the delayed hemolytic episode may persist for months after transplantation. If there are no contraindications, early withdrawal of immunosuppression may result in a more rapid resolution of the delayed hemolytic event, possibly because of a GVH reaction against the isohemagglutinin-producing cells of the recipient ([145]). To prevent hemolytic events related to minor ABO incompatibilities, the isohemagglutinins can be removed from the stem cell graft if the antirecipient titers are high. The risk of hemolysis from a minor ABO mismatch appears to be increased after peripheral blood stem cell transplantation, possibly related to the higher content of lymphoid B cells in the graft. The development of severe hemolysis may be prevented with the administration of MTX after transplantation ([146]).

CONDITIONING REGIMENS

Myeloablative

Effective myeloablative conditioning regimens are necessary for successful treatment of hematologic malignancies and the achievement of allogeneic HSC engraftment. The ideal myeloablative conditioning regimen should (a) eliminate or reduce the tumor load, (b) suppress the host immune system to prevent graft rejection (this does not apply to hematopoietic support with autologous cells), and (c) have tolerable nonhematopoietic toxicity. The first conditioning regimens consisted of TBI alone or in combination with CY ([1]). TBI was an effective antineoplastic modality that was not cell cycle–specific and was also immunosuppressive. CY was a chemotherapeutic agent with immunosuppressive properties that had few nonhematopoietic toxicities that were similar to TBI and therefore could be used in combination. Other conditioning regimens that have since been developed include (a) the replacement of CY with other chemotherapeutic agents (e.g., etoposide, cytarabine, and melphalan) in combination with TBI ([147] , [148]); (b) other chemotherapeutic agents in combination with both CY and TBI ([149] , [150]); and (c) chemotherapeutic agents used in combination with CY but without TBI, including busulfan (BU)/CY and carmustine-CY-etoposide ([151] , [152]). In one study, carmustine-CY-etoposide was associated with a significant incidence of transplant-related complications and mortality ([153]). Other high-dose cytotoxic regimens have been used, especially with autologous stem cell support ([154] , [155] and [156]).

Most preparative regimens used for the treatment of malignant diseases have not been tested in phase 3 studies, so it is unclear if any one regimen represents an improvement over those previously used. Two phase 3 studies in allogeneic marrow transplantation have compared differing intensities of TBI (1200 cGy vs. 1575 cGy) ([157] , [158]). The relapse rate was reduced in the group of patients receiving the higher dose of TBI, but there was an increase in complications in this same group from regimen-related toxicity and GVHD, which negated any improvement in disease-free survival compared to the group receiving the lower dose of TBI. In several

studies, the combination of BU and CY was determined to be an acceptable alternative to CY/TBI for patients with leukemia ([3], [159], [160]). However, in one study, patients in the BU/CY group had an increased risk of venoocclusive disease (VOD) of the liver, hemorrhagic cystitis, chronic GVHD, bronchiolitis obliterans, and alopecia ([161]). Since this last study, it has been demonstrated that targeting of BU levels in the plasma may decrease the risk of relapse and severe regimen-related toxicities, contributing to an improved disease-free survival ([162]) (Fig. 25.3). Monitoring of CY levels may also be important because increased exposure to its toxic metabolites may lead to increased liver toxicity and nonrelapse mortality ([163]).

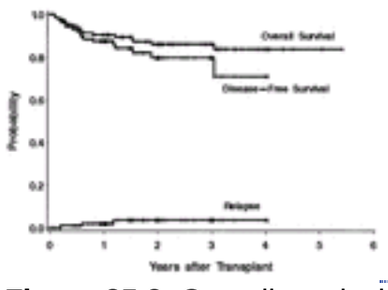

Figure 25.3. Overall survival among 101 patients after hematopoietic stem cell transplantation from HLA-identical siblings for chronic myelogenous leukemia in chronic phase. The conditioning regimen included targeted busulfan (900 ng/ml) and cyclophosphamide. Graft-versus-host disease prophylaxis consisted of the combination of cyclosporine and methotrexate. Patients were transplanted between September 1995 and December 1999. The probability of survival was 85% at 5 years. (From unpublished data from the Fred Hutchinson Cancer Research Center.)

In patients suffering from SCID, engraftment of allogeneic stem cells from matched related siblings may occur without conditioning therapy ([98]). High-dose CY in combination with antithymocyte globulin (ATG) as a preparative regimen for patients with aplastic anemia was associated with graft rejection in less than 5% of cases ([114]). The actuarial survival rate was 88% at 6 years after transplantation (Fig. 25.2). For transplantation of patients with thalassemia or sickle cell disease, a myeloablative conditioning regimen, usually consisting of the combination of BU and CY, is necessary to prevent a high incidence of graft rejection because most patients with these disorders have received multiple blood transfusions and are potentially sensitized to donor mHCs ([97], [164]).

Although HSC engraftment may be achieved after transplantation and some patients are cured, relapse remains an important problem in patients with advanced hematologic malignancies. Because further intensification of the conditioning regimen using current modalities is unlikely to improve overall survival because of the associated increase in toxicity, other strategies will be required to achieve a cure. Radiolabeled MAb specific for certain tissues or sites from which the malignancy originates might enhance the efficacy of the conditioning regimen and decrease the rates of relapse ([165], [166]).

Nonmyeloablative

Myeloablative conditioning regimens are associated with the development of regimen-related toxicities resulting in prolonged periods of hospitalization and the development of significant morbidity and potential mortality including VOD of the liver and idiopathic interstitial pneumonitis. The development of nonmyeloablative regimens permits the application of this potentially curative treatment to a large number of patients, including older patients and patients with contraindications to intensive cytotoxic regimens. The success of the nonmyeloablative conditioning regimens in preclinical and clinical studies established new biologic principles, which formed the basis of our understanding of the engraftment process after allogeneic HSCT. The findings in these studies were consistent with the following conclusions regarding successful engraftment:

- Intensive cytotoxic myeloablative therapy is not needed to “create marrow space.”
- Stem cell grafts can “create their own marrow space” with a GVH effect.
- Engraftment is promoted by posttransplant suppression of the host-versus-graft reaction.

Many different nonmyeloablative conditioning regimens have been piloted. These fall into two broad categories: (a) reduced-intensity regimens and (b) minimally myelosuppressive regimens ([167], [168], [169], [170], [171], [172], [173], [174] and [175]). The reduced-intensity regimens still require the use of the cytotoxic therapies pretransplant to prevent graft rejection. The recipients usually become aplastic from the regimen, and complete chimerism is established early after transplantation. Because of the intensity of the regimen, a substantial antitumor effect may still be associated with the regimen, resulting in a tumor response early after transplantation. The reduced-intensity regimen is, however, still associated with myelosuppression and some significant regimen-related toxicities. The minimally myelosuppressive regimens rely on pretransplant and posttransplant immunosuppression to prevent graft rejection. After transplantation, a mixed chimeric state may persist for months before converting to full donor hematopoietic chimerism (Table 25.4) ([174]). The regimen is only mildly myelosuppressive, resulting in lower requirements for blood product (Fig. 25.4) ([176]). In some cases of a major ABO incompatibility, however, there may be delayed development of donor red cell chimerism resulting in an increased need for red blood cell products due to the persistence of antidonor isohemagglutinins. This may be prevented by adding an antimetabolite (MTX, mycophenolate mofetil) to the GVHD prophylaxis. If this approach is ineffective, withdrawal of CSP may induce a graft-mediated immune reaction against recipient isohemagglutinin-producing cells resulting in a decrease in isohemagglutinin levels and improvement in donor red blood cell chimerism ([145]). The onset of cytomegalovirus (CMV) infections is significantly delayed after nonmyeloablative transplantation ([177]). After nonmyeloablative conditioning with a minimally myelosuppressive regimen, patients can generally be managed on an outpatient basis.

TABLE 25.4. Median Percentage of Donor Cells and Chimerism Status after Stem Cell Transplant

	Median Percentage on Day 28 [a] (range)	Median Percentage on Day 56 [b] (range)
Donor cells		
T cells	60 (10–100)	91 (5–100)
Peripheral blood neutrophils	91 (0–100)	99 (4–100)
Bone marrow	87 (0–100)	95 (2–100)
Chimerism		
Mixed [c]	86	79
Full donor [d]	14	21

[a] 44 evaluable patients. One additional patient-donor pair had no identifiable DNA polymorphism, and evidence of donor cell engraftment was based on red blood cell polymorphisms.

[b] 41 evaluable patients.

[c] =1% and =5% T cells of donor origin.

[d] >95% T cells of donor origin.

From McSweeney PA, Niederwieser D, Shizuru JA, et al. Hematopoietic cell transplantation in older patients with hematologic malignancies: replacing high-dose cytotoxic therapy with graft-versus-tumor effects. Blood 2001;97:3390–3400, with permission.

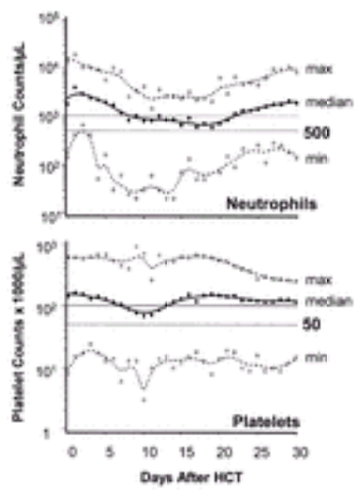

Figure 25.4. Engraftment after nonmyeloablative hematopoietic stem cell transplantation (HCT). Engraftment profile showing neutrophil and platelet changes after HCT. Graphs show the median (*solid lines*) and range (*broken lines*) of neutrophil and platelet counts of all 45 patients on days 0 through 30. Circles represent the minimum (min) and maximum (max) values on each day. (From McSweeney PA, Niederwieser D, Shizuru JA, et al. Hematopoietic cell transplantation in older patients with hematologic malignancies: replacing high-dose cytotoxic therapy with graft-versus-tumor effects. Blood 2001;97:3390–3400, with permission.)

Early studies of nonmyeloablative transplantation focused on patients whose donors were HLA-identical siblings, because the risk of graft rejection and GVHD is less compared to alternative donors. When TBI, 200 cGy, was given for the conditioning regimen only, graft rejection was associated with a lack of prior intensive chemotherapy and a diagnosis of CML ([174]). When fludarabine was added to low-dose TBI, graft rejection was no longer observed as a significant problem. Nonmyeloablative conditioning regimens have also been effective for transplantation with alternative sources such as unrelated donors and umbilical cord blood ([178], [179] and [180]).

Allogeneic HSC grafts can induce a GVL or graft-versus-tumor (GVT) effect. The effectiveness of the GVT effect can best be seen in the responses patients have had with minimally myelosuppressive regimens (Fig. 25.5) ([174], [181]). In patients not otherwise eligible for a myeloablative conditioning regimen, sustained responses have been noted in AML, the chronic leukemias, lymphoma, and myeloma. A minimally myelosuppressive conditioning regimen may be more appropriate for indolent hematologic malignancies including CML, chronic lymphocytic leukemia, agnogenic myeloid metaplasia, and low-grade lymphomas ([174], [175], [182], [183] and [184]). In diseases requiring cytoreduction, reduced-intensity regimens may be of more benefit. Another strategy that appears promising is high-dose cytotoxic therapy and autologous transplantation to debulk the disease or induce a clinical remission, followed by allogeneic nonmyeloablative transplantation ([185], [186] and [187]). The objective of this tandem approach is to consolidate the remission with a GVT reaction. The effect of the GVT reaction on solid tumors is also being explored, and significant responses have been seen in some patients with renal cell carcinoma ([188]). Careful assessment of the patient, the disease type, and the disease status are required to determine the optimal approach.

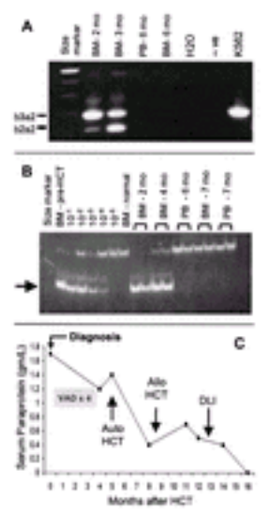

Figure 25.5. Complete disease responses after hematopoietic stem cell transplantation (HCT). **A:** Example of molecular remission of chronic myelogenous leukemia induced by nonmyeloablative HCT without donor lymphoid infusion, as documented by failure of reverse transcription–polymerase chain reaction to detect bcr-abl transcripts. The lane described "–ve" is negative control of normal bone marrow (BM). K562 is a positive control for bcr-abl. **B:** Example of molecular remission of chronic lymphocytic leukemia induced by HCT without donor lymphocyte infusion as documented by polymerase chain reaction to detect a tumor-specific immunoglobulin heavy-chain gene arrangement (*arrow*). Each posttransplantation sample was amplified in duplicate. The lanes designated 10^{-1} to 10^{-5} show a dilution series of the patient's pretransplantation sample (more than 90% tumor cells) into normal bone marrow. **C:** Example of complete remission of multiple myeloma after allogeneic HCT. The patient was initially treated with four cycles of vincristine, adriamycin, and dexamethasone (VAD). High-dose cytoreduction with melphalan, 200 mg/m^2, and autologous transplantation (Auto HCT) were performed 3 months before allogeneic HCT (Allo HCT). Donor lymphocyte infusion (DLI) was given 4 months after HCT because of persistent tumor. After complete remission was achieved, trace levels of serum monoclonal paraprotein detected by immunofixation were present intermittently in follow-up testing. PB, peripheral blood. (From McSweeney PA, Niederwieser D, Shizuru JA, et al. Hematopoietic cell transplantation in older patients with hematologic malignancies: replacing high-dose cytotoxic therapy with graft-versus-tumor effects. Blood 2001;97:3390–3400, with permission.)

GVHD and infections are the major reasons for transplant-related treatment failures after nonmyeloablative transplantation. Because these patients, in general, are older and face a poor outcome because of preexisting complications, nonmyeloablative transplantation has been well-tolerated and effective compared to what could have been expected after myeloablative conditioning. Treatment-related mortality after nonmyelo-ablative transplantation was 22% in one study of 192 patients treated for a variety of hematologic diseases ([175]). The day 100 treatment-related mortality was only 6%. Because the disease response is related to the development of a GVT response, early studies relied on short courses of immunosuppressive therapy or the early administration of donor lymphocyte infusions. GVHD tended to develop later than expected, in many cases at 3 to 6 months after transplantation. Because GVHD developed in many patients and full donor chimerism was being achieved as late as 6 to 12 months after transplantation (indicating an active GVH reaction during this period), immunosuppressive therapy for GVHD prophylaxis was administered for a longer period and donor lymphocyte infusions were delayed in later studies. Further follow-up is required to assess if this will reduce the incidence of transplant-related complications in this patient group. Strategies for the optimal management of GVHD are required so that complications are reduced. Although some patients have durable tumor responses after nonmyeloablative transplantation, further studies are required to determine whether outcomes will be comparable to those achieved in patients who had received myeloablative conditioning.

ENGRAFTMENT

Successful engraftment results from the circulation, homing, and growth of HSCs. After autologous HSCT, a minimal number of CD34-positive cells is required to prevent delayed recovery of neutrophil and platelet counts. After allogeneic HSCT, adequate suppression of the host immune system is necessary to prevent graft rejection. Immunosuppression may be achieved by the use of myeloablative or nonmyeloablative conditioning regimens. The early establishment of donor T cells is important in the prevention of graft rejection even when substantial numbers of CD34-positive cells are administered ([189]). A single stem cell may substantially reconstitute hematopoiesis (clonal dominance), but this occurs only infrequently in humans ([190], [191]). However, this demonstrates the considerable proliferative potential of a normal HSC. In many studies of HSCT, engraftment has generally been defined as the achievement of a peripheral blood neutrophil count greater than 0.5×10^9/L. The rate of engraftment is dependent on the number of HSCs, especially the CD34-positive cell content, the purging strategies for autologous marrow, the use of growth factors, and the use of MTX for GVHD prophylaxis ([16], [83], [192]). Graft failure may result from an infusion of inadequate numbers of HSCs, drug toxicity, infection (CMV), or, in the case of allogeneic marrow transplantation, from graft rejection. Graft function may be restored when incriminating drugs are

discontinued or when recovery from infection occurs.

Graft rejection is infrequent (<1 to 2% incidence) after HSCT from HLA-matched siblings ([193], [194] and [195]). When grafts are rejected, as indicated by low blood counts, chimerism studies also demonstrate the loss of donor cells in the peripheral blood and marrow ([195], [196]). Factors that influence the risk of graft rejection include T-cell depletion of marrow grafts, increased HLA disparity, the intensity of the conditioning regimen and posttransplant immu-nosuppression, pretransplant immunization of the host against donor alloantigens, and the number of HSCs in the graft ([194], [197], [198], [199] and [200]). Hematopoietic growth factors have not been shown to be effective in preventing graft rejection. Historically, graft rejection after a myeloablative conditioning regimen and an allogeneic HSCT has almost always been fatal. The use of noncytotoxic immunosuppressive conditioning regimens and the infusion of donor peripheral blood stem cells may salvage patients after graft rejection ([201]). Aggressive medical management during the prolonged neutropenic period is required to prevent infectious deaths after transplantation of the second stem cell graft. Although the transplant-related mortality has been high in the pilot studies of nonmyeloablative transplantation, graft rejection has not been associated with a significant morbidity or mortality because the duration of the pancytopenic period has in general been short ([174]).

REGIMEN-RELATED TOXICITIES

The severity of regimen-related toxicities is related to the intensity of the myeloablative therapy used, the type of cytotoxic therapy, the medical condition of the patient before transplantation, and the presence of posttransplant factors, including the use of MTX, CSP, and amphotericin B. Although many groups are investigating the potential benefits of nonmyeloablative transplantation, which reduces the severity of regimen-related toxicities, outcomes may still be better in good-risk patients undergoing myeloablative conditioning ([202]).

Oral mucositis occurs in more than 90% of patients, and many require pain relief with continuous intravenous infusions of narcotic drugs. Improvement occurs when the marrow recovers, approximately 2 to 3 weeks after transplantation. The severity of the oral mucositis depends on the intensity of myeloablative therapy and the use of MTX. Severe mucositis may result in upper airway obstruction or aspiration pneumonitis. Gastroenteritis induced by chemotherapy and irradiation results in nausea, vomiting, and diarrhea, which may persist for up to 2 to 3 weeks after transplantation. Central lines are placed before transplant for administration of fluids, drugs, and hyperalimentation during this period of therapy-induced mucositis and gastroenteritis.

Renal dysfunction is common after HSCT ([203]). Some factors associated with the development of severe renal failure requiring dialysis are hyperbilirubinemia, significant fluid retention after transplantation, amphotericin B administration, and pretransplant serum creatinine levels greater than 0.7 mg/dl. CSP may also contribute directly to renal dysfunction.

Lung and liver are the two organs that limit further escalation of myeloablative therapy. Idiopathic interstitial pneumonitis occurs in 8 to 18% of patients after marrow transplantation ([204], [205] and [206]). Clinical manifestations include dyspnea, nonproductive cough, hypoxemia, and diffuse pulmonary infiltrates. This toxicity is most likely due to TBI, but high doses of chemotherapeutic agents like CY, BU, and bischloroethyl-nitrosourea, if part of the preparative regimens, may also be directly toxic to the lungs. Pulmonary VOD must be considered in patients with diffuse pulmonary infiltrates because VOD may have a favorable response to corticosteroids ([207], [208]). Treatment for idiopathic interstitial pneumonitis consists of supplemental oxygen and ventilatory support. Survival is poor (3%) for patients requiring intubation and mechanical ventilation for longer than 24 hours ([209]).

VOD of the liver is the most frequent cause of hyperbilirubinemia within 20 days after HSCT ([210]). This event is characterized by damage to vascular endothelial cells and to hepatocytes in zone 3 of the liver acinus. The overall incidence of VOD is 53%, and 15% of patients have severe disease. Risk factors for the development of severe VOD are pretransplant hepatitis with elevated serum levels of hepatocellular enzymes, the intensity of the conditioning regimen (TBI >13 Gy), and the use of BU. Targeting strategies for BU and CY may reduce the incidence of severe VOD. In uncontrolled studies, favorable responses to the administration of tissue plasminogen activator have been reported ([211], [212]). However, the risk of bleeding must be weighed against the potential benefit of this agent. Responses were also observed in patients treated with defibrotide, a single-stranded polydeoxyribonucleotide with fibrinolytic and antithrombotic activity ([213]).

Delayed complications related to myeloablative therapy include secondary malignancies, sterility, hypothyroidism, and cataracts ([214], [215], [216], [217], [218], [219] and [220]). After autologous HSCT, there is an increased risk of developing a myelodysplastic syndrome ([221], [222], [223] and [224]). Children may experience delays in growth and development ([225]).

GRAFT-VERSUS-HOST DISEASE

GVHD occurs when genetically disparate lymphocytes are transferred into an immunologically compromised recipient incapable of rejecting the donor graft ([226]). The initial stages of a GVH reaction involve the recognition of the host's disparate minor and major histocompatibility antigens by T cells in the donor graft. There are two primary classes of major histocompatibility antigens (MHC): HLA class I antigens have a broad distribution and are expressed on all cells, whereas HLA class II antigens are expressed on antigen-presenting cells, including macrophages, dendritic cells, B cells, and activated T cells. mHCs represent genetic polymorphisms of endogenous cellular proteins that are presented to T cells as small peptides bound in the grooves of the major histocompatibility antigens. Some mHCs identified in humans as being associated with GVHD include CD31, HA-1, and the DBY (male-specific mHA) gene ([227], [228], [229], [230] and [231]). The association between the polymorphism within the adhesion molecule CD31 and the development of GVHD was not observed by other groups ([232], [233]).

In murine studies, the CD8-positive T cells react more specifically with class I molecules and CD4-positive T cells react more specifically with class II molecules ([234], [235] and [236]). The induction and release of cytokines (e.g., IL-1, IL-2, tumor necrosis factor) might be important in the development and maintenance of the GVHD reaction ([237]). Epithelial cells of the skin, bile ducts, and gastrointestinal tract are the primary tissues damaged by a GVH reaction. Target cells for the GVH reaction are epithelial stem cells, which are located in the rete ridges of the skin, the crypt cells of the gut, and the parafollicular bulge of the hair follicle ([238]). In the liver, the small interlobular and marginal bile ducts on the periphery of the portal spaces are damaged by the GVH reaction ([239]). In tissues involved with GVHD, a lymphoid infiltrate is present, and cell death occurs by apoptosis. Lymph nodes lack germinal centers, and these may not recover for many months after HSCT. Abnormal CD4:CD8 ratios can be found in the lymph node as well as in the peripheral blood ([240]).

Acute Graft-Versus-Host Disease

CLINICAL EVALUATION Acute GVHD involves three organ systems primarily—the skin, the gastrointestinal tract, and the liver. A maculopapular rash is often present and can be pruritic or painful. It may involve the palms and the soles. In severe cases, bullae and epidermal separation may occur, which resembles toxic epidermal necrolysis. Gastrointestinal GVHD involves the small and large intestine, which may result in nausea or vomiting, crampy abdominal pain, diarrhea, intestinal bleeding, and ileus. Lesions of the mouth may also occur. Patients may present only with symptoms of persistent anorexia, nausea, and vomiting as a manifestation of GVHD in the gastrointestinal tract ([241], [242] and [243]). If severe GVHD of the gastrointestinal tract occurs, the bowel may be scarred permanently, and mucosal regeneration may not be possible ([244]). Cholestatic jaundice is common in GVHD involving the liver, but hepatic failure due solely to GVHD is unusual unless the GVHD is long-standing. A biopsy of these organs is useful in confirming the diagnosis of GVHD, although direct cytotoxic effects from the conditioning regimen can produce tissue damage that may confound the histopathologic diagnosis of GVHD in the first 3 weeks after marrow transplantation. Risk factors for the development of acute GVHD include the degree of the HLA match, a sex mismatch with the donor, a prior history of donor parity, an increased dose of TBI, and the type of acute GVHD prophylaxis used ([120], [245]). The CD34-positive cell dose is an independent risk factor for acute GVHD after peripheral blood stem cell transplantation ([246]). The degree of HLA match is of primary importance in determining the risk of acute GVHD. After marrow transplantation from HLA-haploidentical (MHC-mismatched) siblings, the incidence of acute GVHD was greater than 70% compared with 42% in patients transplanted from HLA-matched siblings ([117]). The increased incidence of acute GVHD in patients transplanted from fully HLA-matched unrelated donors (=70%) is likely related to an increased disparity in mHC antigens or unrecognized disparities of the phenotypically matched major histocompatibility loci. To facilitate the study and prognostication of acute GVHD, a clinical staging and grading system (Glucksberg) was developed ([1], [247]). The staging and grading system has since been updated (Table 25.5) ([248]). Grade I or very limited acute GVHD has a favorable prognosis and does not require treatment. Therapy is usually required for grade II GVHD because it is moderately severe and usually consists of multiorgan disease. Because patients who have anorexia, nausea and vomiting, and positive biopsies for GVHD from the upper gastrointestinal tract usually require therapy, they have been included under grade II. Grade III to IV disease is severe multiorgan GVHD and is associated with a decreased patient survival ([120]). An acute GVHD Severity Index has also been developed, grouping patients with patterns of organ involvement associated with similar risks of treatment-related mortality and treatment failure ([249]). The International Bone Marrow Transplant Registry (IBMTR) Severity Index was designed to avoid the need for

subjective assessment of the performance status, which was included in the Glucksberg system. Another difference is that patients with a rash covering 25 to 50% of their skin (overall grade I, Glucksberg) would be placed in the IBMTR Index B group. Some HSCT programs are now using the IBMTR Severity Index for the grading of acute GVHD. Other approaches for assessing acute GVHD have also been described in which the overall clinical course across time is described rather than focusing on the peak grade achieved ([250]).

TABLE 25.5. Recommended Staging and Grading of Acute Graft-Versus-Host Disease

	Extent of Organ Involvement		
	Skin	**Liver**	**Gut**
Stage			
1	Rash on <25% of skin [a]	Bilirubin 2–3 mg/dl [b]	Diarrhea >500 ml/day [c] or persistent nausea [d]
2	Rash on 25–50% of skin	Bilirubin 3–6 mg/dl	Diarrhea >1000 ml/day
3	Rash on >50% of skin	Bilirubin 6–15 mg/dl	Diarrhea >1500 ml/day
4	Generalized erythroderma with bullous formation	Bilirubin >15 mg/dl	Severe abdominal pain with or without ileus
Grade [e]			
I	Stage 1–2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III	—	Stage 2–3 or	Stage 2–4
IV [f]	Stage 4 or	Stage 4	—

[a] Use “rule of nines” or burn chart to determine extent of rash.

[b] Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin has been documented.

[c] Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area. Gut staging criteria for pediatric patients were not discussed at the Consensus Conference. Downgrade one stage if an additional cause of diarrhea has been documented.

[d] Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.

[e] Criteria for grading given as minimum degree of organ involvement required to confer that grade.

[f] Grade IV may also include lesser organ involvement with extreme decrease in performance status.

From Prezepiorka D, et al. Consensus conference on acute GVHD grading. Bone Marrow Transplant 1995;15:825–828, with permission.

PREVENTION There are two major approaches to the prevention of acute GVHD after allogeneic marrow transplantation: pharmacologic immunosuppression, T-cell depletion, or both. Agents for pharmacologic immunosuppression are generally more effective when used in combination ([16] , [17] , [251]). CSP (a calcineurin inhibitor) and MTX in combination are the agents used most commonly by transplant centers. The addition of prophylactic corticosteroids to the combination of CSP and MTX or to CSP alone provides a limited additional benefit, if any, and, in one study, a paradoxical increase in GVHD was observed in the corticosteroid arm ([252] , [253] and [254]). CSP should be continued to day 180, especially in patients who have previously had acute GVHD, because patients who stopped at day 60 had a higher transplant-related mortality. Even for patients without GVHD by day 60 after transplantation and in whom CSP may be stopped safely, the practice has been to maintain immunosuppression on a tapering schedule until day 180. All three agents have significant adverse effects. MTX delays, but does not prevent, hematopoietic engraftment, and the severity of oral mucositis may be increased. Nephrotoxicity and neurotoxicity are complications associated with the administration of CSP, and microangiopathic hemolytic anemia has been described in association with this agent. Metabolic complications and aseptic necrosis are associated with the administration of corticosteroids. Another calcineurin inhibitor, tacrolimus, in combination with MTX was compared with CSP and MTX in phase 3 studies for the prevention of GVHD. The incidence of acute GVHD was lower in the tacrolimus group when using HLA-identical sibling donors or unrelated donors (Fig. 25.6) ([255] , [256]). The incidence of chronic GVHD was similar in both groups. The patients in the CSP arm of the matched sibling study had a better disease-free and overall survival, largely as a result of imbalance in the underlying risk factors for death in the two groups, especially among patients in the advanced disease category ([257]). Disease-free and overall survival were similar between the two groups in the unrelated donor study ([256]). Some transplant programs now prefer tacrolimus in combination with MTX as their standard for GVHD prophylaxis because of the improved control of acute GVHD. Mycophenolate mofetil is a reversible inhibitor of inosine monophosphate dehydrogenase and is being studied after both myeloablative and nonmyeloablative transplantation in combination with either CSP or tacrolimus and without MTX ([258]).

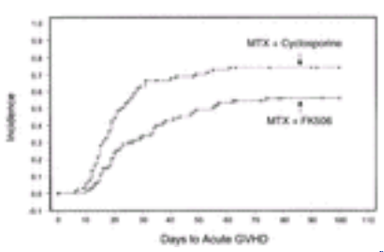

Figure 25.6. Kaplan-Meier estimate of acute graft-versus-host disease (GVHD). The combination of tacrolimus (FK506) and methotrexate was compared to cyclosporine and methotrexate as GVHD prophylaxis after a myeloablative conditioning regimen and hematopoietic stem cell transplantation from an HLA-matched unrelated donor. There was less acute GVHD in the tacrolimus group at 100 days after hematopoietic stem cell transplantation than in the cyclosporine group (56% vs. 74%, respectively; $p = .0002$). (From Nash RA, Antin JH, Karanes C, et al. Phase 3 study comparing methotrexate and tacrolimus with methotrexate and cyclosporine for prophylaxis of acute graft-versus-host disease after marrow transplantation from unrelated donors. Blood 2000;96:2062–2068, with permission.)

An alternative method of GVHD prophylaxis is T-cell depletion of the marrow. Strategies for T-cell depletion include the use of MAb, which are specific for T cells, selective agglutination to soybean lectin, and counter-flow centrifugation elutriation ([259] , [260] , [261] and [262]). Although reduction in acute and chronic GVHD has been observed with transplantation of T-cell depleted marrow, there was also an associated increase in graft rejection, the occurrence of lymphoproliferative disorders, and relapse ([197]). As a result, there was no improvement in overall survival. Many of the early T-cell depletion studies used techniques that targeted the total T-cell population ([198]). More recently, studies of T-cell subset depletion using MAb specific for CD6, CD8, or T-cell receptor-aß epitopes on T lymphocytes have not observed a high incidence of graft rejection ([199] , [200] , [263] , [264]).

TREATMENT The most common agents used to treat acute GVHD are corticosteroids and ATG. In many marrow transplant centers, the administration of corticosteroids (methylprednisolone or prednisone, 2 mg/kg/day) is the standard treatment for acute GVHD ([265] , [266] and [267]). High doses of methylprednisolone (10 mg/kg/day) did not prevent evolution to grade III to IV acute GVHD ([268]). Because complete remission of GVHD is only seen in 40% of cases after primary treatment, other immunosuppressive agents have been investigated in combination with prednisone. When a CD5-specific immunotoxin was added to prednisone at the start of treatment, GVHD manifestations were more effectively controlled during the first 5 weeks only, when compared to prednisone alone ([269]). Similarly, no long-term benefit was observed when ATG was added to prednisone as primary therapy ([270]). More effective treatment strategies are required to improve the outcome of acute GVHD. Other immunosuppressive agents have been studied in patients with steroid-refractory GVHD, including ATG, daclizumab, rapamycin, mycophenolate mofetil, ABX-CBL (CD147-specific mAb), and visilizumab. Outcomes at 6 to 12 months after salvage therapy for steroid-resistant GVHD have been poor with a high transplant-related mortality ([271] , [272] , [273] , [274] and [275]). In a multivariate analysis designed to identify factors associated with the likelihood of complete response to therapy, the combination of CSP and MTX as GVHD prophylaxis was better than CSP and MTX as single agents ([265]). In an analysis to identify covariates associated with failure of initial therapy or death not due to relapse of malignancy, treatment with ATG had a higher risk of failure than corticosteroids. Other factors associated with an unfavorable outcome were recipient HLA disparity with the donor, presence of a liver complication other than GVHD, and early onset of GVHD. Other therapies being investigated to improve local control of GVHD, which may permit a decrease in systemic immunosuppression, include psoralen and ultraviolet A irradiation therapy for the skin and oral nonadsorbable beclomethasone therapy for the gastrointestinal tract ([276] , [277] and [278]). The massive secretory diarrhea of acute GVHD has been controlled in some cases with a somatostatin analog, octreotide acetate ([279] , [280]).

Chronic Graft-Versus-Host Disease

CLINICAL EVALUATION Chronic GVHD is a syndrome that may develop as early as 50 to 60 days or as late as 400 days after transplantation. The incidence of chronic GVHD is dependent on the degree of disparity in the major histocompatibility antigens. It was observed in 33% of HLA-identical sibling transplants, in 49% of HLA-nonidentical related transplants, and in 64% of matched-unrelated transplants ([281]). A prior history of acute GVHD is a significant risk factor for the development of chronic GVHD. Among patients without a history of acute GVHD, factors that were associated with an increased risk of *de novo* chronic GVHD were increasing patient age, the infusion of buffy coat cells in addition to marrow, and corticosteroid therapy before transplantation ([282] , [283]). Corticosteroid use for GVHD prophylaxis may also increase the risk of development of chronic GVHD ([252] , [254]). Clinical features of chronic GVHD include skin lesions that may initially resemble lichen planus and that may progress to generalized scleroderma, keratoconjunctivitis, buccal mucositis, esophageal and vaginal strictures, intestinal abnormalities, chronic liver disease, pulmonary insufficiency secondary to bronchiolitis obliterans, and a wasting syndrome ([284]). If generalized scleroderma occurs, it may lead to joint contractures and debility; however, this feature of chronic GVHD has not been seen as commonly in recent years. Elevations in alkaline phosphatase and serum bilirubin are often the first indication of hepatic involvement with chronic GVHD. Damage to the bile ducts has a similar histopathology to that seen in primary biliary cirrhosis. Liver biopsies are often helpful in establishing a diagnosis. Onset of bronchiolitis obliterans may occur at less than 150 days (40%) or more than 150 days (60%) after HSCT ([285]). Response to immunosuppressive treatment has been observed but is often incomplete. Prognosis is poor except for those patients with mild to moderate disease occurring more than 150 days after HSCT. Keratoconjunctivitis sicca is a common complication and is generally irreversible. This is managed by frequent eye drops and tear duct ligation. Screening studies and clinical manifestations of chronic GVHD are used in a clinical classification of chronic GVHD. Based on a retrospective clinical and pathologic review published in 1980, a staging system was developed in which chronic GVHD was classified into limited and extensive categories. Extensive disease was associated with more frequent infections ([284]). The utilization of this classification system was difficult because many patients were not classifiable by strict organ criteria, and other significant prognostic factors have since been identified. Poor prognostic factors are extensive skin involvement, thrombocytopenia, and progressive-type onset ([286] , [287]). To clarify the ambiguities of the original classification, the group in Seattle revised the clinical criteria for limited and extensive chronic GVHD (Table 25.6) ([288]). Prolonged immunosuppressive treatment is indicated for patients with clinically extensive chronic GVHD or other high-risk features, including platelet counts of less than 100 × 10^9/L, progressive onset, or corticosteroid treatment at the time of diagnosis of chronic GVHD.

TABLE 25.6. Revised Seattle Classification for Limited and Extensive Chronic Graft-Versus-Host Disease (GVHD)

Clinically limited
Oral abnormalities consistent with chronic GVHD, a positive skin or lip biopsy, and no other manifestations of chronic GVHD
Mild liver test abnormalities (alkaline phosphatase =2 × upper limit of normal, AST or ALT =3 × upper limit of normal, and total bilirubin =1.6), positive skin or lip biopsy, and no other manifestations of chronic GVHD
Less than six papulosquamous plaques, macular-papular or lichenoid rash involving <20% of BSA, dyspigmentation involving <20% BSA, or erythema involving <50% BSA, positive skin biopsy, and no other manifestations of chronic GVHD
Ocular sicca (Schirmer test =5 mm with no more than minimal ocular symptoms), positive skin or lip biopsy, and no other manifestations of chronic GVHD
Vaginal or vulvar abnormalities, positive biopsy, and no other manifestations of chronic GVHD
Clinically extensive
Involvement of two or more organs with symptoms or signs of chronic GVHD with biopsy documentation of chronic GVHD in any organ
Karnofsky or Lansky Clinical Performance scores <60%, =15% weight loss, and recurrent infections not due to other causes, with biopsy documentation of chronic GVHD in any organ
Skin involvement more extensive than defined for clinically limited chronic GVHD, confirmed by biopsy
Scleroderma or morphea
Onycholysis or onychodystrophy believed to represent chronic GVHD with documentation of chronic GVHD in any organ
Decreased range of motion in wrist or ankle extension due to fasciitis caused by chronic GVHD
Contractures believed to represent chronic GVHD
Bronchiolitis obliterans not due to other causes
Positive liver biopsy or abnormal liver function tests not due to other causes with alkaline phosphatase >2 × upper limit of normal, AST or ALT >3 × upper limit of normal, or total bilirubin >1.6, and documentation of chronic GVHD in any organ
Positive upper or lower gastrointestinal biopsy
Fasciitis or serositis believed to represent chronic GVHD and not due to other causes

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BSA, body surface area.

In an attempt to prevent the development of chronic GVHD, patients without GVHD at day 80 after transplantation were given a 24-month course of CSP and compared with a group receiving CSP for 6 months ([289]). There were no significant differences between the groups in the incidence of chronic GVHD, transplant-related survival, or overall survival ([289]). It was concluded that patients without GVHD at day 80 would have a standard taper of CSP with discontinuation at 6 months.

TREATMENT Extensive chronic GVHD that is left untreated has a poor prognosis. In an original report of chronic GVHD, only 2 of 13 patients survived and there was significant morbidity ([284]). Prednisone given for 9 to 12 months reversed many of the signs and symptoms of disease. The mortality in the group treated with prednisone was 21% ([290]). Patient survival was worse with the combination of azathioprine and prednisone compared to prednisone alone ([287]). The combination of CSP and prednisone was first used in patients with high-risk chronic GVHD who had a platelet count less than 100,000. The results of this study appeared promising compared to historical controls ([291]). In a randomized control study of patients with standard-risk chronic GVHD who had a platelet count greater than or equal to 100 × 10^9/L at diagnosis, in which prednisone alone was compared with a combination of CSP and prednisone, an early analysis suggested decreased morbidity and improved survival in the combination therapy arm ([214]). However, as the study matured, a trend toward improved survival was seen with prednisone alone ([292]). This study of combination therapy for standard-risk chronic GVHD suggested that more intense immunosuppression is not beneficial if manifestations of chronic GVHD are otherwise well controlled. A study of patients with high-risk chronic GVHD who had a platelet count of less than 100 × 10^9/L at diagnosis, in which patients were randomized between CSP alone and the combination of CSP and prednisone, indicated a trend toward improved survival and decreased morbidity in the combination therapy arm. Patients with clinically extensive chronic GVHD are treated for a period of 9 to 12 months. At the end of this time, they are reevaluated and, if there is no evidence of active chronic GVHD, the immunosuppressive agents are tapered. Other therapies that have been reported to have some limited efficacy for treatment of chronic GVHD include psoralen and ultraviolet A irradiation, extracorporeal photopheresis, and ursodeoxycholic acid treatment for GVHD of the liver ([293] , [294] and [295]). Treatment with thalidomide, although initially believed to be promising, was found in other studies to be ineffective or too toxic for patients to maintain compliance ([296] , [297] and [298]). By 3 to 5 years after initiation of therapy, many patients have inactive chronic GVHD, and immunosuppressive therapy has been discontinued ([1] , [114] , [214]) (Fig. 25.7). Approximately 75% of patients treated for extensive chronic GVHD survive with Karnofsky scores of greater than 80%. Infections are the major cause of excess mortality in patients with clinically extensive chronic GVHD.

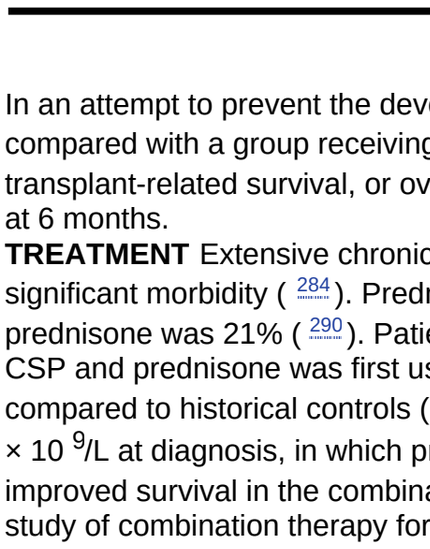

Figure 25.7. A: Prevalence of chronic graft-versus-host disease (GVHD) after allogeneic marrow transplantation from HLA-identical sibling for aplastic anemia (*AA*). The prevalence curve accounts for the time of onset of chronic GVHD and the time of its resolution in response to therapy. **B:** Probability of survival among the 29 patients with chronic GVHD (83%) and probability of discontinuing immunosuppression given for chronic GVHD (73%). ATG, antithymocyte globulin; CSP,

cyclosporine; CY, cyclophosphamide; MTX, methotrexate. (Modified from Storb R, Blume KG, O'Donnell MR, et al. Cyclophosphamide and antithymocyte globulin to condition patients with aplastic anemia for allogeneic marrow transplantations: the experience in four centers. Biol Blood Marrow Transplant 2001;7:39–44.)

GRAFT-VERSUS-TUMOR EFFECT

The first clinical report of a GVT effect after allogeneic marrow transplantation was published in 1979 ([299]). The term *GVT* is used to refer to the graft-versus-leukemia/lymphoma effect and the graft-versus-myeloma effect, as well as the antitumor effects of the graft on solid tumors such as renal cell carcinoma. It was observed that patients who developed GVHD had a lower risk of relapse after transplantation. These observations were confirmed in a subsequent study, but early attempts at inducing a GVT effect to reduce the relapse rate and improve survival were not successful ([300] , [301]). In 1990, Kolb and colleagues successfully treated three patients with CML who relapsed after marrow transplantation with donor lymphocyte infusions from the original HLA-identical sibling marrow donor ([302]). These early observations were expanded in a subsequent report of 135 patients, including 84 patients with CML ([303]). Complete remissions were achieved in 54 of 84 (72%) CML patients, 5 of 23 (29%) patients with AML, one of five (20%) patients with myelodysplastic syndrome, and 0 of 22 patients with acute lymphoblastic leukemia. GVHD developed in 41% of patients, and 34% showed signs of myelosuppression after donor lymphocyte infusions. Fourteen (10%) of patients died from complications related to GVHD or myelosuppression. This was confirmed in another large study of 140 patients with relapsed malignancy after marrow transplantation ([304]). Complete remissions were observed for patients with CML, AML, and myelodysplastic syndrome at a comparable rate to that described by Kolb et al. However, in patients with acute lymphoblastic leukemia, 18.2% of patients achieved a complete remission compared to none of these patients in the original study. Acute and chronic GVHD after the donor lymphocyte infusions correlated with disease response. Donor lymphocyte infusions may also be effective in patients with multiple myeloma who have relapsed after transplantation ([304] , [305]). The durability of the responses was confirmed with longer follow-up of patients who had achieved a complete remission after donor lymphocyte infusions ([306]). Twenty-five of 39 evaluable CML patients and 11 of 27 patients with other diseases had sustained remissions with a median follow-up of 32 months. Survival for patients with CML and other diseases was 61% at 3 years and 65% at 2 years, respectively. The number of CD3-positive cells infused into patients with relapse after T-depleted marrow transplant is likely an important parameter in determining clinical response and the risk for the development of GVHD ([307]). Patients with CML had a lower risk of GVHD, and efficacy of treatment was maintained with a strategy of escalating the dose of donor lymphocytes based on response of disease and GVHD ([308]). Comparable results of lymphocyte infusions from unrelated donors have now been demonstrated. The response, severity of GVHD, and the degree of myelosuppression were similar to those observed after lymphocyte infusions from HLA-matched sibling donors ([309]). Although patients may have an excellent response to infusions of donor lymphocytes, better strategies are required to minimize the severe complications of GVHD and myelosuppression associated with allogeneic cell therapy.

Many long-term remissions after transplantation are largely the result of a GVT effect directed at MHC and mHC molecules. Because mHC molecules may be expressed at varying levels in different host tissues, it may be possible to separate the syndrome of GVHD from GVT. Disparities of hematopoiesis-associated mHC molecules or the presence of leukemia-associated antigens on the patient's leukemia cells might be targeted specifically. The tissue or tumor-restricted antigens could serve as targets for T-cell immunotherapy to enhance GVT activity without inducing GVHD. Peptides identified as minor histocompatibility molecules have been isolated and sequenced ([231] , [310] , [311] and [312]). Cytotoxic T-lymphocyte (CTL) clones specific for hematopoietic system–restricted mHC have been generated *ex vivo* ([312] , [313]). These CTLs efficiently lyse leukemic cells from patients with AML and acute lymphoblastic leukemia and, in a NOD/SCID mouse model, inhibit the engraftment of human AML cells by direct CTL recognition of the SCID leukemia-initiating cells. The contribution of natural killer cells to the antitumor effect after allogeneic HSCT is still being investigated ([314]).

IMMUNE RECONSTITUTION

After myeloablative therapy and autologous or allogeneic transplants, the patient's immune system may be impaired for 4 to 5 months. Immune reconstitution is most thoroughly studied after allogeneic transplantation. Recovery of the immune system due to cells derived from the donor graft occurs in phases over a period of 1 to 2 years in patients who do not develop GVHD. The first phase of recovery is defined by the increase in neutrophil counts that occurs 2 to 3 weeks after transplantation. Although the function of neutrophils is largely intact, they have impaired chemotaxis for a period up to 4 months ([315] , [316]). Monocyte numbers in the peripheral blood return to normal within 3 to 4 weeks after transplantation. Monocyte counts in the peripheral blood were inversely correlated with infection rates between days 100 and 365 ([317]). Monocytes have been shown to be of donor origin within 41 days, and their function is generally normal ([318] , [319]). Macrophages in the liver and lung have been shown to be of donor type by day 80 ([320] , [321]). Natural killer cells and cells capable of mediating antibody-dependent cytotoxicity have recovered to normal levels by 30 days after transplantation ([322]). Natural killer cells produce lymphokines, including IL-2, which may contribute to the recovery of the T-cell population in T-depleted grafts ([323]). The recovery of the immune system from donor origin is important in understanding the GVL effect and the complications after HSCT, including graft rejection, GVHD, and infections.

B Cells

There are defects in serum immunoglobulin (Ig) production initially after the transplant. Serum antibody responses to different antigens, including FX174, keyhole limpet hemocyanin, pneumococcal, and meningococcal antigen, are lower than normal ([324] , [325] and [326]). The defect in antibody production occurs in both T-dependent and T-independent systems. B lymphocytes respond to mitogenic stimulation, including staphylococcal aureus and cross-linked anti-IgM antibodies, after 2 months. By 3 months after transplantation, B lymphocytes with surface Ig have recovered to normal levels ([327]). Persistent deficiencies in B lymphopoiesis have been described in association with both acute and chronic GVHD or its treatment ([328]). The number of B-cell precursors in the marrow is not related to CD34-cell dose, type of transplant, donor age, or recipient age. Low B-cell counts on day 80 are associated with high infection rates from day 100 to 365 after transplantation ([317]).

Serum IgG and IgM achieve normal levels by 1 year after transplantation ([324]). Serum IgA may remain low for a period of 2 years. If serum IgG levels are below 4 g/L, patients are generally treated with intravenous Ig. Routine early administration of intravenous Ig has been demonstrated to decrease the rate of infections during the first 100 days after transplantation, as well as the incidence of acute GVHD ([329]).

T Cells

Repopulation of donor T cells is poor initially in all recipients and remains defective in patients with chronic GVHD. A reversed CD4:CD8 ratio with low levels of CD4-positive cells and normal or high levels of CD8-positive cells has been demonstrated ([330]). If patients remain healthy and without chronic GVHD, the ratio of CD4 to CD8 cells normalizes eventually. In some patients, there can be an outgrowth of T cells with ?/d receptors, which are CD45 RO-positive ([331]). *In vivo* cellular immunity determined by skin testing to the recall antigens *Candida*, mumps, and trichophyton and the neoantigen dinitrochlorobenzene is diminished and may be prolonged if chronic GVHD develops ([332]).

T cells have a decreased proliferation in response to mitogenic stimuli such as phytohemagglutinin and CD3-specific antibody. After 3 months, the addition of exogenous IL-2 can normalize the proliferative response to phytohemagglutinin stimulation ([333] , [334]). By 6 months, the response to phytohemagglutinin stimulation has normalized without the requirement for exogenous IL-2. T-cell immunity to herpes simplex virus (HSV) can be detected by day 40 ([335] , [336]). CTL function against varicella-zoster virus (VZV) and CMV is acquired at a later time (=3 months). Acquisition of T-cell immunity to herpes virus may be delayed by prophylaxis of viral infections with antiviral agents ([335] , [337]).

After myeloablative conditioning and allogeneic transplantation, immunity may be restored by the adoptive transfer of mature T cells; this is important for establishing cellular immunity to infectious agents including the herpes viruses ([337] , [338] and [339]). Vaccination protocols may enhance this infectious disease–specific cellular immunity. An inactivated varicella vaccine given before and during the first 90 days after transplantation significantly reduces the risk of developing VZV infections ([340]). CD4 T-cell proliferation in response to VZV is greater in patients who receive the vaccine. T-depleted HSCT or the development of GVHD requiring therapy may significantly delay the recovery of cellular immunity, resulting in an increased risk of infections. After transplantation with a peripheral blood stem cell graft, the rate of definite infections was significantly decreased compared to marrow ([341]). The counts of most lymphocyte subsets, especially CD4 T cells, were higher in the peripheral blood stem cell group. The thymus contributes to late immune reconstitution; it exports newly generated T cells to the periphery. Quantification of a DNA excision circle, generated during T-cell receptor rearrangement, can be used as a measure of thymic function. As these TRECs are lost on further cell division, cells in which they are present can be identified as recent thymic emigrants, and thymic output can thereby be quantitated. Increased thymic output (high TREC levels) was

associated with an increased number of naïve T cells and a broader T-cell repertoire ([342], [343]). Younger patients had a more rapid recovery and higher TREC levels after HSCT. Low TREC levels correlated with the presence of chronic GVHD and severe opportunistic infections. The extent of the thymic rebound correlates with the patient's capacity to respond to vaccinations ([344]). Measures to enhance thymic output after transplantation, especially in older patients, may enhance immune reconstitution and decrease the risk of infections.

Evaluation of Hematopoiesis and Immunity in Patients Surviving More Than 20 Years after Transplantation

It has now been more than 30 years since the first patients were transplanted with allogeneic HSCs after myeloablative conditioning. Donor-derived hematopoiesis and immunity were assessed in long-term survivors. All evaluable patients had normal complete blood counts (except one with concomitant liver disease) and polyclonal hematopoiesis and remained complete donor chimeras with greater than 97% donor-derived hematopoiesis ([345]). Some shortening of telomere length was demonstrated, but it was concluded (within the limits of follow-up) that the stem cell proliferative potential was not compromised during hematopoietic reconstitution. Immunity of the recipients in long-term follow-up was normal or near-normal in comparison to the stem cell donor ([346]). The one exception was the observation that the number of TREC-positive CD4 cells was lower in transplant recipients who were age 18 years or older at the time of transplantation. The posttransplantation insufficiency of the thymus in older patients at the time of transplantation may not be fully reversible; however, this was not considered to be clinically significant.

Adoptive Transfer of Immunity

It has been demonstrated that the adoptive transfer of *ex vivo* cloned donor T cells specific for CMV may restore CMV-specific T-cell immunity in the early posttransplant period, preventing complications arising from these diseases ([347]). The development of GVHD and the need for immunosuppressive therapy limit the potential of this approach. The ability to transfer specific immune responses from the donor to the recipient has been shown for tetanus, diphtheria, and measles antigens without vaccination boosts after transplant. Specific serum antibody was noted within the first 3 months after transplant, as well as after 1 year ([348], [349] and [350]).

Transfer of donor immunity causing disease in the recipient has also been reported. Allergen-specific IgE-mediated hypersensitivities of donors, including allergic rhinitis and asthma, were observed in recipients ([351]). Transfer of other immunologic conditions by HSCT, including myasthenia gravis, psoriasis, vitiligo, and autoimmune thyroiditis, has been reported ([352], [353], [354] and [355]). Serologic markers for systemic lupus erythematosus were adoptively transferred from the donor in one case report, but the recipient had not developed clinical disease by 3 years after transplantation ([356]). In another case report, a recipient transplanted from a donor with rheumatoid arthritis had not developed any manifestations of an autoimmune disease at 4 years after transplantation ([357]). There is a risk of adoptively transferring autoimmune diseases from stem cell donors, but the degree of that risk is not defined. Therefore, potential donors with autoimmune diseases should not be excluded solely on this basis. The decision to proceed should be based on the availability of other therapeutic options and a consent from the patient after being informed of the possible transmission of the autoimmune disease with the stem cell graft.

INFECTIOUS COMPLICATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

One of the most essential tasks in the care of patients after HSCT is to prevent or expeditiously treat opportunistic infections. There are periods after HSCT during which patients may be at greater risk from certain types of opportunistic pathogens (Fig. 25.8). Although the principles for preventing and managing infections in an immunosuppressed patient are widely accepted, the strategies for achieving these practices may vary from center to center. Two of the most important measures for reducing the risks of infection are an effective hand-washing policy and a strategy for preventing transmission of respiratory infections including respiratory syncytial virus, parainfluenza, and influenza. Effective screening of the blood supply has reduced the incidence of transfusion-related infections, especially hepatitis C. Risk factors for development of infection before engraftment are neutropenia and oral and gastrointestinal mucosal damage from the myeloablative therapy. After engraftment, a profound deficiency of both B-cell– and T-cell–mediated immunity persists. The integrity of mucosal barriers may be compromised by GVHD, the conditioning regimen, or viral infections. The degree of immunodeficiency in this period is influenced by the type of immunosuppressive therapy and the severity of GVHD, if present. Recovery from the immu-nodeficiency state is faster after autologous stem cell support than after allogeneic HSCT. In 3 months, most patients have recovery of T-cell immunity specific for herpes viruses including CMV ([358]). If chronic GVHD develops, B-cell and T-cell immunodeficiencies may persist for years, and Ig production and reticuloendothelial function may also be impaired.
