The hematocrit, the hemoglobin concentration, and the erythrocyte count all assess the same basic biologic variable. *Anemia* refers to a pathologic reduction in this variable, to the point where oxygen demands of tissues are not adequately met. However, none of these three laboratory tests actually assess whether oxygen demands of tissues are being adequately met. Therefore, as a practical matter, anemia is generally defined by a hematocrit, hemoglobin concentration, or erythrocyte count below a lower limit of “normal.” The precise definition of which values are normal, and therefore which values signify anemia, becomes somewhat complex for a pregnant woman, a fetus, and for a neonate, because the normal values for hematocrit, hemoglobin concentration, and erythrocyte count vary considerably during pregnancy and with fetal and neonatal age.

ANEMIAS UNIQUE TO PREGNANT WOMEN

Physiologic Anemia of Pregnancy

Expansion of the plasma volume is the cause of the physiologic anemia of pregnancy (Table 48.1). Expanding the plasma volume reduces the hematocrit, the blood hemoglobin concentration, and the circulating erythrocyte count but does not reduce the absolute amounts of hemoglobin or number of erythrocytes in the entire circulation. The mechanisms underlying these changes are obscure. It has been speculated that the physiologic anemia of pregnancy serves the purpose of reducing maternal blood viscosity, thereby enhancing placental perfusion and facilitating oxygen and nutrient delivery to the fetus. Beginning approximately the sixth week of pregnancy, the plasma volume increases disproportionately to the red cell mass. It generally reaches a maximum value at approximately 24 weeks' gestation ([1]) but can continue increasing until as late as the 37th week ([2]). At its peak, the plasma volume is about 40% higher among pregnant women than among nonpregnant women ([3], [4]). A reduction in the hematocrit, hemoglobin concentration, and circulating erythrocyte count are usually evident by the seventh to eighth week of pregnancy ([1], [4], [5]), and the reduction continues until the 16th to 22nd week when a new equilibrium is established ([3], [6]). It has been suggested that a hemoglobin concentration less than 11 g/dl in the late first trimester and less than 10 g/dl in the second and third trimesters are lower limits below which a cause other than the physiologic anemia of pregnancy should be sought. Similar values were reported by Milman et al., studying only iron replete women, where the lowest hemoglobin values in pregnant women were 11.0 g/dl in the fist trimester and 10.5 g/dl in the second and third trimesters ([7]).

TABLE 48.1. Features of the Physiologic Anemia of Pregnancy

Plasma volume begins to increase during 6th week of pregnancy
No significant increase in erythrocyte production during the 1st trimester
Dilutional anemia is first apparent by 7th to 8th week
Increase in erythrocyte production apparent during 2nd trimester
Lowest hemoglobin explainable by dilutional effect (the physiologic anemia of pregnancy) is 11 g/dl in 1st trimester; 10 g/dl in 2nd and 3rd trimesters
Physiologic anemia of pregnancy is normochromic, normocytic, does not worsen during the 3rd trimester, and does not require additional evaluation or specific treatment

During pregnancy, a 15 to 25% increase in the red cell mass generally occurs but is masked by the dilutional effect of the increase in plasma volume ([2], [3], [5]). A greater increase in red cell mass generally occurs if iron supplements are taken ([8]). Results of ferrokinetic studies demonstrated accelerated erythropoiesis during pregnancy, supporting the concept of an increase in red cell mass ([9], [10]). Choi and Pai investigated erythropoiesis during pregnancy among 342 women by examining reticulocyte subpopulations using flow cytometry and also by measuring serum transferrin receptor concentrations ([11]). They found no differences between prepregnancy and those during the first and second trimesters. However, during the third trimester of pregnancy, reticulocyte maturity index and serum transferrin receptor concentrations increased twofold. After delivery these values decreased, falling to nonpregnant values about 5 weeks after delivery. They concluded that maternal erythropoiesis increases late in gestation and returns to normal by about 1 month after delivery.

Maternal plasma volume generally decreases during the final weeks of pregnancy, and consequently the hematocrit, hemoglobin, and circulating erythrocyte count increase ([12], [13]). Measurements of plasma volume made during late pregnancy with the patient supine, as contrasted to the decubitus position, have been criticized because of variable effects of interference with the circulation imposed by the gravid uterus ([2]). With this potential pitfall in mind, conflicting reports regarding changes in plasma volume near term may represent only variations within the error of measurement or random occurrences ([5], [12], [13]). The maternal blood volume generally returns to prepregnancy levels within 1 to 3 weeks after delivery ([14], [15], [16] and [17]), in part reflecting blood loss at delivery ([10]).

Erythropoietin Biology in the Mother and Fetus

Much remains to be learned about maternal/fetal erythropoietin biology. It is clear that erythropoietin acts as a physiologic stimulator of maternal erythropoiesis during pregnancy, but erythropoietin also has nonerythropoietic actions in the fetus. The increase in maternal erythropoiesis during the third trimester is preceded by an increase in serum erythropoietin concentrations, presumably on the basis of reduced oxygen delivery to maternal renal tissues during the late second and early third trimesters ([18]). Similarly, serum erythropoietin concentrations are elevated in fetuses with anemia, and correlate with hypoxemia ([19]).

Erythropoietin has certain critical nonerythropoietic effects during human fetal development (Table 48.2) ([20]). It is an important growth and development factor for intestinal villi ([20], [21] and [22]). It also plays a role in fetal central nervous system (CNS) development ([23]). Erythropoietin is a constituent of amniotic fluid, in concentrations of 25 to 40 mU/ml. A normal human fetus swallows 200 to 300 ml of amniotic fluid per kilogram body weight per day, and thus swallows 10 to 15 U of erythropoietin/kg/day ([20], [21]). In humans, erythropoietin does not cross the placenta from maternal to fetal circulations, thus the source of the erythropoietin in

amniotic fluid is not the maternal circulation. In the second and third trimesters, amniotic fluid is largely derived from fetal urine, with minor constituents from fetal tracheal effluent and the placenta and fetal membranes. However, erythropoietin in amniotic fluid does not appear to come from fetal urine. The fetal kidney makes little erythropoietin before delivery, and the first-voided urine of neonates has no detectable erythropoietin ([24]). Studies using *in situ* hybridization and immunohistochemistry indicate that the source of erythropoietin in amniotic fluid is largely maternal: from mesenchymal and endothelial cells in the deciduae and from the amnion ([21]).

TABLE 48.2. Actions of Erythropoietin in the Human Fetus

Site of Erythropoietin Production	Mechanism of Erythropoietin Delivery to Target Cells	Actions at Target Cells
Hepatocyte/hepatic macrophages	Paracrine	Erythropoiesis/angiogenesis
Glia	Paracrine	Neural migration
Glia	Paracrine	Neural protection from hypoxia
Decidua and amniotic membranes (amniotic fluid)	Swallowed by fetus	Small bowel villous development
Mammary epithelia (breast milk)	Swallowed by neonate	Small bowel villous development

Erythropoietin is also present in human colostrum and breast milk in concentrations of 10 to 20 mU/ml; essentially the same as in amniotic fluid ([25]). Erythropoietin concentrations in mother's milk do not correlate with erythropoietin concentrations in her blood ([25]). In fact, over the first weeks of lactation, maternal serum erythropoietin concentrations fall, whereas milk erythropoietin concentrations increase, reaching the highest concentrations in women breast-feeding for a year or more. The source of erythropoietin in breast milk appears to be mammary gland epithelium ([25]).

Erythropoietin in human amniotic fluid, colostrum, and breast milk is relatively protected from proteolytic digestion in the fetal and neonatal gastrointestinal tract ([25]). However, rather than being absorbed into the blood, the erythropoietin swallowed by the fetus from amniotic fluid and by the neonate from colostrum and breast milk binds to erythropoietin receptors on the luminal surface of villous enterocytes, where it serves as a growth and development factor. Indeed, experimental animals artificially fed formulas devoid of erythropoietin have retarded villous development, a condition that can be treated by enteral recombinant erythropoietin and is blocked by antierythropoietin antibody ([21]).

Erythropoietin is produced by cells in the developing CNS and is present in relatively high concentrations in fetal cerebrospinal fluid (CSF) ([26] , [27]). Among newborn infants, the highest concentrations of erythropoietin in the CSF are seen in the most premature neonates, and by several years of age, CSF erythropoietin concentrations are generally below 1 mU/ml ([26]). Erythropoietin receptors are expressed on human fetal neurons ([28] , [29] , [30] and [31]). It has been speculated that erythropoietin in the CNS is a natural neuroprotectant from hypoxia. CNS erythropoietin production increases rapidly during hypoxia, and when erythropoietin binds to receptors on neurons, antiapoptotic activity is induced. Cell culture systems and whole animal models illustrate a marked neuroprotective effect of erythropoietin ([32]). The clinical utility of recombinant erythropoietin as a neuroprotectant is a topic of current studies.

The liver is the primary site of erythropoietin production in the fetus. The kidney does not become the primary site until after birth, probably by several months of age. In the human fetus, the kidney produces about 5% of the total erythropoietin during midgestation ([33]). The developmental mechanisms regulating the switch in erythropoietin production from the liver to the kidney are not completely known but may involve developmental expression of transcription activators such as hypoxia inducible factor and hepatic nuclear factor 4 ([34]), or developmental methylation of promoter and enhancer regions around the gene. Alternatively, the switch might involve the GATA transcription factors, particularly GATA-2 and GATA-3, which are negative regulators of erythropoietin gene transcription. Studies are ongoing to determine the biologic mechanisms involved in erythropoietin gene expression during fetal and neonatal development.

Iron Deficiency during Pregnancy

The physiologic anemia of pregnancy is normochromic and normocytic. Therefore, if a pregnant woman has a microcytic hypochromic anemia, nonphysiologic causes must be considered. Iron deficiency is common in pregnancy and is certainly the most common cause of nonphysiologic anemia during pregnancy ([8]). It is particularly common in lower economic groups ([35]). The prevalence of iron deficiency ranges from 16 to 55% in pregnant women during the third trimester.

In a Cochrane review, Milman et al observed that among fertile women, 20% have iron reserves of less than 500 mg, which is stated as the required minimum during pregnancy; 40% have iron stores of 100 to 500 mg, and 40% have undetectable iron stores ([36]). The demand for absorbed iron increases from 0.8 mg/day in early pregnancy to 7.5 mg/day in late pregnancy. An iron supplement of 65 mg/day beginning at or before 20 weeks' gestation generally is adequate to prevent iron deficiency during pregnancy.

The fetus acts as an effective parasite for the nutrients required for hemoglobin synthesis. Thus, the hemoglobin concentration of infants born to mothers with severe iron deficiency anemia is normal ([37] , [38] , [39] , [40] , [41] and [42]), and the serum iron, transferrin saturation, and serum ferritin levels are unrelated to maternal iron status ([39] , [40] , [43] , [44] and [45]).

Iron balance in pregnancy is discussed in Chapter 28. Limited iron reserves before pregnancy are common ([35] , [46]), and the additional iron requirements of pregnancy impose a negative iron balance unless supplemental iron is provided ([8]).

Pregnant women who are iron deficient sometimes experience unique manifestations. There is evidence that the risks of premature delivery, low birth weight, and infant death are increased by severe iron deficiency. However, it is difficult to distinguish the effects of the iron deficiency itself from the conditions that produced the deficiency. A large case-control study from Venezuela indicated that maternal iron deficiency was associated with increased odds of premature delivery [odds ratio (OR), 1.70; 95% confidence interval (CI), 1.18 to 2.57] ([47]). However, when Mahomed reviewed 20 trials evaluating the issue of iron supplementation in pregnancy for the Cochrane database, he concluded that iron supplementation during pregnancy resulted in a substantial reduction in women with anemia (a hemoglobin below 10 g/dl late in pregnancy) but had no detectable effect on maternal or fetal outcome ([48]). Thus, whether maternal iron deficiency adversely influences pregnancy is controversial. In fact, it is not entirely clear whether maternal iron deficiency reduces the fetal iron supply. Harthoorn-Lasthuizen et al found no significant differences in iron status of neonates born to iron-deficient versus iron-sufficient women and concluded that the fetal iron supply is not negatively influenced by iron deficiency in the mother ([49]). In contrast, Turgeon O'Brien et al reviewed medical records of 202 pregnant women to examine the association of low and high ferritin levels and anemia with pregnancy outcome ([50]). They observed an inverse relationship between first trimester anemia and birth weight, but they observed no relationship in the second and third trimesters. They suggested that maternal iron deficiency in early pregnancy was associated with poor fetal weight gain but that maternal iron deficiency later in pregnancy was not.

Sifakis et al sought to determine whether recombinant erythropoietin administration, combined with parenteral iron, was an effective treatment for moderate and severe iron deficiency anemia during pregnancy ([51]). They studied 26 pregnant women with evidence of iron deficiency and with a hemoglobin less than 8.5 g/dl despite at least 8 weeks of iron supplementation. They administered recombinant erythropoietin, 150 U/kg SC three times/week plus 100 mg parenteral iron daily for 4 weeks. Nineteen (73%) of the women responded with a hemoglobin increase of less than 3 g/dl within 4 weeks. However, seven (27%) had no response.

During iron deficiency, the placenta becomes hypertrophied, a possible cause of maternal hypertension. A special type of pica, namely, ingestion of baking powder, can lead to symptoms suggesting preeclampsia ([52]).

The usual criteria for diagnosing iron deficiency are valid during pregnancy (see Chapter 28), including a reduced mean corpuscular volume (MCV), a reduced serum transferrin saturation to less than 16%, and a reduced serum ferritin concentration. Measurement of serum transferrin receptors may be useful in complicated situations in which inflammatory disease makes the serum ferritin value less reliable ([53]). Interpretation of serum iron values can be complicated during pregnancy:

Even in apparently iron-replete women, serum iron levels progressively decline, and values for serum total iron-binding capacity and free erythrocyte protoporphyrin increase ([8], [54]), findings that usually indicate iron deficiency.

Dietary supplementation with 78 mg of elemental ferrous iron daily during pregnancy increased the hematocrit, hemoglobin concentration, and red cell mass, the red cell mass rising to nearly twice that found in similar, apparently healthy women not supplemented ([8]). At term, the mean hemoglobin concentration averaged 12.4 g/dl in those who received the supplement and 10.9 g/dl in those who did not. In Bantu women, whose diet is habitually high in iron, a significant change in serum iron does not occur, and iron deficiency anemia does not develop during pregnancy ([55]). Some have recommended that all pregnant women receive iron supplements beginning at 18 to 20 weeks' gestation in doses ranging from 30 to 60 mg/day ([35]). The recommendation of the U.S. Institute of Medicine is that iron supplementation be provided selectively to those with a serum ferritin level less than 20 ng/dl in the first and second trimester and that all pregnant women receive a supplement of 30 mg/day in the third trimester.

For treatment of established iron deficiency, the oral regimen described in Chapter 28 should be used. Constipation may be an especially problematic side effect in pregnant women; therefore, gradual increases in dose until fully therapeutic levels are achieved, along with emphasis on taking medication with meals are particularly important precautions. Rarely, parenteral treatment may be necessary.

Deficiency of Folate and Other Nutrients during Pregnancy

Macrocytic anemia of pregnancy is often megaloblastic and in most cases results from deficiency of folic acid ([56], [57], [58] and [59]). Megaloblastic anemia during pregnancy begins most often in either the third trimester or shortly after delivery ([60]). Folate requirements increase during pregnancy, and the diets of many pregnant patients are insufficient to meet the increased need ([61], [62]). Although folate deficiency occurs most often in economically deprived patients, this consequence of inadequate eating habits is not confined to the poor ([60], [61], [62] and [63]). Particularly in pregnant adolescents, the diet may provide an inadequate source of folate, regardless of the economic class ([62]). In uncomplicated pregnancies, the gastrointestinal absorption of dietary folate (polyglutamate) and of folic acid (monoglutamate) is normal ([64]). Folate deficiency during pregnancy is relatively common, although its frequency depends on the population studied. The prevalence varies from 1 to 50% of pregnant patients ([58], [60], [63], [65]). In North America, the prevalence is 1 to 4% ([66]). Not all patients in whom the serum concentration of folate is low develop megaloblastic anemia. Of those who do, often the serum folate concentration was low earlier in pregnancy ([60]).

Pregnant women often have no symptoms with folate deficiency anemia and are found to have blood hemoglobin levels of 6 to 9 g/dl in the third trimester or postpartum. Folate deficiency is clearly associated with fetal neural tube defects and cleft palate, but these defects are established very early in fetal development, long before maternal megaloblastic anemia is detected ([66]). The association between low serum folate during the first trimester of pregnancy and fetal neural tube defects has been known for over 25 years ([67]). Randomized, double-blind, controlled clinical trials, indicating that prenatal folate administration reduces neural-tube defects, date back 20 years ([68]). Lumley reviewed this issue for the Cochrane database, examining four trials involving 6425 women treated with folate or placebo ([69]). Preconceptional folate supplementation reduced the incidence of neural tube defects to a relative risk of 0.28 (95% CI, 0.13 to 0.58). Folate did not increase miscarriage, ectopic pregnancy, or still birth. Multivitamins without folate did not prevent neural tube defects, and adding multivitamins to folate did not produce additional preventive effects. Thompson et al. reported an unexpected but significant reduction in childhood acute lymphoblastic leukemia (ALL) among offspring of women supplemented with folate during pregnancy ([70]). They performed a case-control study of 83 children with ALL and 166 controls. Mothers who reported taking the combination of iron and folate during pregnancy had a risk of ALL in their child of 0.37 (95% CI, 0.21 to 0.65). For iron alone, the OR was 0.75 (0.37 to 1.51). This protective effect requires validation and mechanistic investigation.

An association between bacteriuria and folate deficiency was noted in pregnant patients. In experimental systems, infection may induce folate-deficient megaloblastic anemia. Malabsorption (see Chapter 43) may be associated with megaloblastic anemia of pregnancy, even in nontropical areas ([55]).

Rarely, folate-deficient pregnant patients develop erythroblastopenia and bone marrow changes closely simulating acute leukemia. In one case, the findings suggesting leukemia were so convincing that 6-mercaptopurine was prescribed for 4 months ([71]). With full awareness of the confusion between these diagnoses and the application of current tools for diagnosing leukemia, this difficulty should be avoided.

Megaloblastic anemia during pregnancy, as in the nonpregnant patient, is suggested by an increased MCV with oval macrocytes and hypersegmented granulocytes on blood smear, but a bone marrow examination can be done if doubt exists. Folate deficiency must be distinguished from vitamin B_{12} deficiency. The latter is rare in pregnancy, and the distinction can often be made on clinical grounds, especially on the basis of a careful nutritional history.

Folate is transported across the placenta against a concentration gradient. Infants born to mothers with the megaloblastic anemia of pregnancy have no anemia and no biochemical evidence of folate deficiency ([43], [72]). The concentration of vitamin B_{12} also is two to three times higher in cord blood than in maternal blood ([73]). Nevertheless, this nutritional advantage is insufficient to protect the infant if the mother is vitamin B_{12} deficient and if the sole source of nutrition is the mother's milk. Megaloblastic anemia accompanied by irreversible neurologic damage has been documented in breast-fed infants of vegetarian mothers ([74], [75]) and in breast-fed infants of mothers with subclinical pernicious anemia ([76], [77]).

Dietary supplementation with approximately 0.3 mg of folic acid daily during pregnancy reduces the occurrence of megaloblastic anemia to approximately 0.7% of all pregnant women ([59], [78], [79]), whereas a supplement of only 0.1 to 0.2 mg/day is not adequate to maintain serum folic acid concentration at normal levels ([80], [81]). A supplement of 0.45 mg/day results in supranormal values for serum folate ([79], [81]), but, even with this amount of supplementation, megaloblastic anemia may occur in a pregnant patient in whom the course is complicated by urinary tract infection or hemolysis hemorrhage ([79]). Nevertheless, because true pernicious anemia caused by a lack of intrinsic factor and vitamin B_{12} does occur in pregnant patients ([82]), the considerations regarding masking of pernicious anemia with folate doses of 0.40 mg/day or more, apply (Chapter 43). Accordingly, daily supplements of 0.4 mg of folic acid, but not more, are generally prescribed for most pregnant women. In high-risk patients, such as those with disorders or chronic hemolytic anemia, the supplement may be increased to 1 mg/day ([66]).

For established deficiencies, the regimen described in Chapter 43 should be followed. If the possibility of vitamin B_{12} deficiency cannot be excluded, vitamin B_{12} injections should be added to the regimen.

Zinc deficiency has been associated in some studies with fetal growth restriction, congenital abnormalities, and neurodevelopmental delay. Iodine deficiency during pregnancy is very uncommon in developed countries but can result in fetal wastage, preterm delivery, and neonatal hypothyroidism. Deficiency of magnesium, selenium, copper, and calcium have also been associated with complications of pregnancy and fetal development ([83]). In a study in Nepal, vitamin A supplementation reduced maternal mortality ([84]). It was suggested that vitamin A influenced the synthesis of erythropoietin. To determine whether daily vitamin A supplementation increased plasma erythropoietin concentrations in humans, a randomized, double-blind, controlled clinical trial was performed in 203 women in Malawi, Africa, using a daily vitamin A dose of 3000 µg (retinol equivalent), iron (30 mg), and folate (400 µg) versus iron and folate without vitamin A. There were no differences in any parameter between vitamin A and control mothers or neonates. Thus, vitamin A supplementations did not appear to have any benefit in this population. In contrast, Burns et al. quantified vitamin A levels in plasma of 449 women enrolled in a multicenter cohort study of mother to infant transmission of human immunodeficiency virus (HIV) type 1 ([85]). Women with low vitamin A levels before the third trimester were more likely to deliver infants of low birth weight (OR, 4.58; 95% CI, 1.57 to 13.40).

Maternal Anemia Associated with Prenatal Infections

Most clinically significant infections of the fetus are viral or protozoal, but generally these conditions result in minimal evidence of infection in the mother. Specifically, women carrying a fetus infected with cytomegalovirus, toxoplasmosis, rubella, herpes simplex, or parvovirus B19 generally have no anemia related to the infection. However, certain infectious diseases during pregnancy do result in maternal anemia. For example, intestinal helminth infections, common in certain parts of the world, produce or exacerbate iron deficiency during pregnancy, resulting in anemia. Nurdia et al reported that 70% of 442 pregnant women from Central Java, Indonesia, had either *Trichuris trichiura*, *Necator americanus*, or *Ascaris lumbricoides* detected during pregnancy ([86]). They observed a significant negative association between hookworm infection and serum ferritin in the first trimester and suggested that anthelminthic therapy should be given to infected women before conception as a means of improving their iron status. Similarly, Torlesse and Hodges reported that anthelminthics were useful in Sierra Leone, reducing the decline in hemoglobin

concentration during pregnancy by more than 6.5 g/L ([87]).

Syphilis generally does not result in maternal anemia. Mavrov and Goubenko, from the Ukraine, reported on 155 pregnant women with syphilis. They observed that 78% of the women remained asymptomatic throughout pregnancy, although placental and fetal/neonatal pathology were found in about half of cases ([88]).

Malaria can cause maternal and fetal anemia ([89]). The anemia is mild in most neonates with malaria, but with a marked placental accumulation of parasites, intrauterine growth retardation can be significant ([90]). Steketee et al reviewed studies between 1985 and 2000 and summarized the risk neonatal anemia, low birth weight, and infant mortality associated with maternal malaria ([91]). Indeed, maternal malaria was associated with substantial risks for anemia (population attributable risk, 3 to 15% increased), low birth weight (8 to 14% increased risk), and infant mortality (3 to 8% increased risk). They estimated that each year 75,000 to 200,000 infant deaths are associated with maternal malaria.

HIV-1 infection during pregnancy remains a major world-wide medical issue ([92]). The rate of maternal to fetal HIV transmission can be markedly reduced by complying with protocols of antiretroviral treatment during pregnancy and labor, coupled with postpartum treatment of neonates ([93]). Maternal HIV infection does not cause significant fetal anemia. However, progressive anemia develops in neonates after vertical HIV transmission. Before routine antiretroviral therapy of HIV-exposed neonates, Galli et al observed a progressive anemia among 22 neonates with perinatal HIV infection ([94]). Beginning in the second month of life, hemoglobin concentrations, hematocrits, and circulating erythrocyte counts were lower in infected than in uninfected infants born to HIV-infected mothers. They reported that anemia at 2 months of age was a good predictor of those neonates born to HIV-positive women who acquired vertical HIV transmission.

Some fraction of the anemia observed among neonates delivered to HIV-positive women can be ascribed to the antiretroviral treatment. Zidovudine has a more pronounced suppressive effect on erythroid progenitors of fetal origin than it does on progenitors of maternal origin, possibly due to the more rapid cycling rate of fetal progenitors ([95]). This is consistent with the findings of zidovudine toxicity among nonhuman primates (*Macaca nemestrina*) treated with zidovudine throughout pregnancy, where the infants at birth were mildly anemic ([96]). The *in vitro* experiments and the animal studies support clinical reports, such as those of Ferrazin et al., who reported that zidovudine given to pregnant women leads to a mild macrocytic anemia in neonates, resolving by 2 months of life ([97]). Silverman et al found similar results from a six-centered treatment trial of 39 HIV-infected pregnant women ([98]). In that study, zidovudine was instituted at a mean of 13 weeks' gestation with lamivudine added in 85% of cases at a mean of 17.6 weeks. No changes in maternal hematocrit, hemoglobin, or erythrocyte count were observed. However, anemia in the neonatal period (hematocrit <0.50 L/L) was seen in 62% of the 40 neonates, with no children needing transfusions. Mild anemia, sometimes slightly macrocytic, among neonates delivered after maternal zidovudine treatment was also reported from U.S. centers by Sperling et al ([99]), and from a European collaborative study ([100]).

Pregnancy-Induced Hemolytic Anemia

Diverse hemolytic anemias can occur in pregnant women just as well as in nonpregnant women. In fact, pregnancy can exacerbate underlying autoimmune hemolytic anemia ([101]). Thus, hemolytic anemia is not particularly uncommon in obstetric practice. However, a rare entity has been described (approximately 25 cases reported), in which an idiopathic hemolytic anemia occurs during pregnancy, resolves completely after pregnancy, and recurs during subsequent pregnancy (Table 48.3). The pathogenesis of this anemia is not known. Terms for the condition include *idiopathic autoimmune hemolytic anemia of pregnancy*, *unexplained hemolytic anemia associated with pregnancy*, and *pregnancy-induced hemolytic anemia*. The condition is not homogeneous. In the cases reported by Ng et al from Kuala Lumpur ([102]) and Benraad et al from The Netherlands ([103]), women had immunoglobulin G warm antibodies and were successfully treated with glucocorticoids. In contrast, the majority of cases have no identifiable immune mechanisms and have a variable response to glucocorticoids ([104] , [105] , [106] , [107] , [108] , [109] , [110] , [111] and [112]).

TABLE 48.3. Features of Idiopathic Pregnancy-Induced Hemolytic Anemia

No identifiable mechanism
Anemia becomes apparent in the 3rd trimester
Remits completely within 2 mo of delivery
Generally recurs in subsequent pregnancies
Anemia is usually severe, even life-threatening
Corticosteroids and intravenous immunoglobulin sometimes helpful
Erythrocyte transfusions mainstay treatment for severe anemia
Donor cells have a shortened survival
Neonates generally have transient, nonsevere hemolysis

This pregnancy-induced hemolytic anemia becomes apparent in the third trimester of pregnancy and in most cases remits completely within 2 months of delivery, sometimes taking as long as 4 or 5 months. The anemia is usually very severe, even life-threatening to mother and fetus. Corticosteroids and intravenous immunoglobulin (IVIG) have been reported to be successful in some cases, but many of the women have been treated with repeated packed erythrocyte transfusions. Generally, the transfused donor cells have a shortened survival. Neonates born to women with pregnancy-induced hemolytic anemia generally have transient hemolysis, lasting 1 to 2 months; severe jaundice requiring neonatal exchange transfusion has not been reported.

In cases of autoimmune hemolytic anemia during pregnancy, whether idiopathic or of an identified variety, the degree of hemolysis is generally more severe in the mother than that in the fetus ([113]). However, therapy that ameliorates the maternal disease (such as corticosteroids or IVIG) often does not protect the fetus. This is in contrast to autoimmune thrombocytopenia during pregnancy, in which maternal and fetal platelet counts are likely to be concordant.

Postpartum Anemia

Postpartum anemia is common, particularly among low-income women. Studying nearly 60,000 women who were enrolled in the Special Supplemental Nutrition Program for Women, Infants, and Children, Bodnar et al reported an overall incidence of postpartum anemia of 27% ([114]). However, rates reached 48% among non-Hispanic black women. Prenatal anemia was the best predictor of postpartum anemia. Maternal obesity, multiple births, and formula feeding also predicted postpartum anemia.

Peripartum hemorrhage is an obvious and common cause of postpartum anemia. An estimated blood loss at delivery in excess of 500 ml is claimed to be a good predictor of postpartum anemia ([115]). Unsuccessful vacuum extraction can cause peripartum hemorrhage and subsequent postpartum maternal anemia. Shoham-Vardi et al. evaluated over 2100 cases of delivery by vacuum extraction in Israel between 1990 and 1998 ([116]) and reported that 5.4% of all deliveries were complicated by unsuccessful extraction, with a subsequent cesarean section. Postpartum anemia was much more common in the women following unsuccessful vacuum extraction than in those in whom cesarean sections were not preceded by attempts at vacuum extraction. Maternal blood loss during and after the unsuccessful vacuum extraction procedures was suggested as the cause.

Hemorrhage occurring a week or more after delivery, so-called secondary postpartum hemorrhage, has a high morbidity rate. Hoveyda and MacKenzie analyzed 132 consecutive women presenting with secondary postpartum hemorrhage over a 3-year period at Barrett Maternity Hospital, Northampton, United Kingdom ([117]). They observed this complication in just under 1% of women and found that that most presented in the second week after delivery. Histories of either primary postpartum hemorrhage or manual removal of the placenta were the only significant risk factors identified. Eighty-four percent of these women were rehospitalized, 63% required surgery, and 17% received blood transfusions.

Peripartum hemolysis is another cause of postpartum anemia. Hemolytic reactions have been described in women receiving second- and third-generation cephalosporins, such as cefotetan, administered prophylactically for caesarian section ([118]). Garratty et al noted that 10 of 35 cases of cefotetan-induced hemolytic

anemia occurred in patients who had received cefotetan prophylactically for obstetric and gynecologic procedures ([119]).

Several studies have tested the effect of recombinant erythropoietin administration for treating postpartum anemia ([120], [121], [122], [123] and [124]). As shown in Table 48.4, the studies suggest efficacy, with a reduction in postpartum transfusions. These conclusions require verification by randomized, placebo-controlled trials appropriately powered to detect a significant difference in postpartum transfusions.

TABLE 48.4. Reports of Recombinant Erythropoietin (rEpo) Administration to Women with Postpartum Anemia

Author (Reference No.)	Year	Country	Design	Number Subjects	Results	Adverse Effects
Huch (120)	1992	Switzerland	Randomized, not placebo controlled. 4000 U IV × 1, then SC for 4 d.	37 rEpo treated; 37 controls	Treated = higher reticulocytes, hemoglobin, and hematocrit by day 5	None
Zimmermann (121, 122)	1994	Switzerland	Randomized into 4 groups: 1) 150 U SC × 2 d; 2) 150 U IV × 2 d; 3) 300 U SC × 1 d; 4) 300 U IV × 1 d.	95 subjects: 1) 26; 2) 25; 3) 22; 4) 22	No difference between groups	None
Meyer (123)	1995	Switzerland	“Blues Questionnaire” of women receiving vs. not receiving postpartum rEpo.	71 rEpo treated; 274 controls	Anemia on postpartum day 5 correlates with “blues,” but rEpo treatment does not reduce this	None
Breymann	1996	Switzerland	Randomized into 3 groups; 1) rEpo 300 U/kg × 1 SC + iron; 2) 300 U/kg × 1 IV + iron vs. rEpo + iron; 3) iron only.	90 (30/group)	Combination of rEpo + iron was more effective than iron alone in treating postpartum anemia	None
Makrydimas	1998	Greece	Not randomized, not placebo controlled. rEpo SC + oral iron vs. iron alone for 15 d.	10 rEpo treated; 10 controls	No transfusions in rEpo group vs. 2 in control group	None
Malinova	1999	Bulgaria	Not controlled. rEpo SC + oral iron × 5 d.	5	Higher reticulocytes, blood pressure	None
Breymann	2000	Switzerland	Randomized, 3 groups (treated 4 d): 1) rEpo + IV iron; 2) placebo + IV iron; 3) oral iron.	60	Higher reticulocytes and hemoglobin in rEpo than other groups	None

ANEMIA IN THE FETUS AND NEONATE

Normal Erythrocyte Values during Human Fetal Development

The erythron at birth reflects the relative hypoxic nature of the fetal environment. Bone marrow cavities are fully used by the erythroid marrow, and circulating red cells have all the features associated with stress erythropoiesis: increased variation in size and shape, macrocytosis, and shortened survival. Many of the characteristics of the erythron at birth are related to the disproportionate number of young cells.

Marrow cellularity in the fetus approaches 100%, and all cell lines are represented by 30 weeks' gestation. Because the available marrow space is fully cellular, the fetus and newborn infant have no marrow reserve on which to call. This limitation undoubtedly contributes to the persistence of hepatic and splenic erythropoiesis in congenital hemolytic anemias. Erythroid precursors account for 30 to 65% and myeloid cells 45 to 75% of nucleated marrow cells at birth ([125]). The myeloid to erythroid ratio at birth is approximately 1.5:1. Marrow cellularity decreases after birth, attaining a density that is normal for adults by 1 to 3 months ([125]). Initially, this decrease in cellularity results from a rapid decline in red cell precursors. At 1 week of age, erythroid elements account for only 8 to 12% of nucleated cells, and the myeloid to erythroid ratio exceeds 6:1. The normal adult proportion of myeloid to erythroid precursors is not established until the third month. Both the percentage and absolute number of lymphocytes increase during the first 2 months, so that by 3 months of age, they constitute nearly 50% of marrow nucleated cells. Differential counts of bone marrow aspirates from preterm infants are the same as those for term infants ([126]).

Normal values for the hemoglobin concentration and packed cell volumes (Table 48.5) are influenced strongly by the site of blood sampling. Perfusion of small vessels in the infant's extremities is poor, resulting in increased transudation of fluid and hemoconcentration. Consequently, the hemoglobin concentration and packed cell volume of capillary blood are 5 to 10% higher than those of venous blood ([127]). The difference between capillary and venous values is greatest at birth but disappears by 3 months of age. The discrepancy is greatest in preterm infants and in those with hypotension, hypovolemia, and acidosis ([128]). Differences can be minimized but not fully resolved by warming the extremity before sampling, obtaining freely flowing blood, and discarding the first few drops. The interpretation of serial observations necessitates the consistent use of one site of blood sampling.

TABLE 48.5. Normal Mean Values Relative to the Erythron for Term Infants during the First Week

	Cord Blood	Day 1	Day 3	Day 7
Hb (g/dl)	16.8	19	18.5	17.0
PCV (L/L)	53.0	58	55.0	54.0
MCV (fl)	106.0	107	99.0	98.0
MCH (pg)	34.0	35	33.0	33.0
MCHC (g/dl)	31.7	32	33.0	33.0
Reticulocytes (%)	5.3	4	3.0	0.5
Normoblasts (%)	500.0	200	0.5	0.0

Hb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; PCV, packed cell volume.

The normal mean value for hemoglobin concentration in blood obtained from the umbilical vein is 16.8 g/dl, with CI 95% limits of 13.7 and 20.1 g/dl ([129]). Hemoglobin values from the umbilical artery are approximately 0.5 g/dl higher. The packed cell volume of umbilical venous blood averages 0.53 L/L, with CI 95% limits of 0.47 to 0.57 L/L ([129]). Hemoglobin concentration and the packed cell volume increase during the first hours to mean levels of 18.4 g/dl and 58%, respectively ([127]). This increase is attributed in part to a shift of fluid from the intravascular compartment but also, more important, to the transfusion of red cells from placenta via umbilical vessels at the time of birth ([130]). After the first day, the packed cell volume slowly decreases, reaching levels seen in cord blood by 7 days ([131]). A drop in the concentration of hemoglobin below the cord blood concentration during the first week of life is indicative of either hemorrhage or hemolysis. The MCV at birth is 106.4 fl (standard deviation ± 5.7 fl) ([132]). Values of 94 fl or less are seen in infants with a-thalassemia trait or iron deficiency. Iron deficiency can result from *in utero* hemorrhage, as is seen with chronic fetomaternal hemorrhage (FMH) or twin-to-twin transfusion syndrome (TTS).

The mean corpuscular hemoglobin is increased at birth, with values ranging from 33.5 to 41.4 pg. The mean corpuscular hemoglobin concentration is within the normal adult range but can be slightly elevated in the presence of increased numbers of spherocytes, commonly seen on newborn peripheral smears.

Reticulocytosis and normoblastosis reflect the accelerated nature of erythropoiesis. The mean number of reticulocytes at birth is approximately 5.3%, with a range of 4 to 7% ([133]). Reticulocytes remain elevated for the first 1 to 3 days of life, dropping abruptly to 0 to 1% by day 7. Nucleated red cells are seen regularly on blood

smears during the first day of life. When quantified, they constitute about 0.1% of the red cell population (500 normoblasts/mm ^{3}) ([134]). Normoblasts are cleared rapidly from the circulation during the first 3 days of life.

Red cell morphology is characterized by macrocytosis and poikilocytosis. Target cells and irregularly shaped cells are particularly prominent. A high proportion of stomatocytes is noted when viewed by phase contrast microscopy ([135]). Decreased splenic function compared to adults results in increased number of siderocytes (3.16% vs. normal male adult mean of 0.09%) ([136]). Differential staining of red cells for fetal hemoglobin (HbF) provides a nice demonstration of the switch in hemoglobin synthesis that precedes birth: The younger macrocytes contain a minimal amount of HbF, whereas the smaller, older cells are rich in HbF ([137]).

Differences in hematologic values for preterm and term infants reflect the dynamic nature of the erythron in late fetal development ([138]). The hemoglobin concentration rises slowly from approximately 14.5 g/dl at 28 weeks' gestation to 15.0 g/dl at 34 weeks to 16.8 g/dl at 40 weeks ([129]). The relationship between cord hemoglobin concentration and duration of pregnancy is linear for normal weight for date infants. The MCV is higher in preterm infants than in term infants. In one group of preterm infants with an average birthweight of 1300 g, the average MCV on the first day of life was 115 fl, 8 fl above the mean for term infants ([139]).

Reticulocyte counts in preterm infants are slightly higher, averaging 6 to 10%. Nucleated red cells number 1000 to 1500/mm ^{3}. There is an inverse relationship between numbers of nucleated red cells and gestational age. As in the term infant, normoblasts are cleared rapidly from the circulation during the first postnatal days, although a few may still be observed in small preterm infants as late as 7 days. Variations in red cell size and shape are somewhat greater than those observed in term infants, and cytoplasmic vacuoles are evident in nearly one-half of all cells when viewed by using interference-contrast microscopy. Red cell survival is considerably shorter than in term infants. For infants who undergo exchange transfusion or multiple transfusions, both erythropoietin concentrations and reticulocyte counts are lower at any given hemoglobin concentration ([140]). It is often assumed that oxygen delivery is decreased in newborns because of the presence of a high-affinity hemoglobin. In fact, a leftward shift in the hemoglobin-oxygen dissociation curve due to high levels of HbF might actually better maintain oxygen delivery during episodes of severe hypoxemia.

Precise quantification of red cell survival is made difficult by the disproportionate number of young cells at birth and by a higher rate of chromium elution from HbF compared with HbA ([141]). Nevertheless, data from most studies indicate a substantially shorter rate of red cell survival in neonates relative to that in children and adults, regardless of the techniques used. The life span of red cells from term infants is estimated to be 60 to 80 days with use of the ^{51}Cr method ([142]) and 45 to 70 days when using methods involving ^{59}Fe ([142]). Fetal studies using [14C]cyanate-labeled red cells in sheep revealed an average red cell life span of 63.6 ± 5.8 days ([143]). The mean red cell life span increased linearly from 35 to 107 days as the fetal age increased from 97 days (midgestation) to 136 days (term).

Cells of the newborn have a similarly short survival in normal, compatible adults ([144]), indicating that factors intrinsic to the newborn red cell are responsible. This conclusion gains further support by the demonstration that adult red cells survive normally in newborn recipients ([145]). The life span frequency function is not parametrically distributed, in that most cells are destroyed before the mean survival is reached. Shortened red cell survival as well as demands imposed by an expanding red cell mass account for erythropoietic rates at birth that are three to five times greater than those of normal adults.

The abrupt transition from the relative hypoxia of the uterus to an oxygen-rich environment triggers responses that have a profound effect on erythropoiesis. During the first 2 months of life, the infant experiences both the highest and lowest hemoglobin concentrations occurring at any time in development. Although quite variable, erythropoietin levels at birth usually are well above the normal adult range. Erythropoietin levels fall in the immediate postnatal period, with a half-life of no more than 4 hours: 2.6 ± 0.5 hours in infants with polycythemia and 3.7 ± 0.9 hours in infants of the preeclampsia group ([146]). By 24 hours, the erythropoietin value is below the normal adult range, where it remains throughout the first month of life. The decrease in erythropoietin is followed by a decline in the number of bone marrow precursors ([125] , [147]) and a fall in the reticulocyte count.

The combination of shortened cell survival, decreased production, and growth-related expansion of the blood volume is responsible for a progressive fall of the hemoglobin concentration to a mean of approximately 11 g/dl at 2 months of age ([148]). The lower range of normal for infants of this age is approximately 9 g/dl. This nadir is called *physiologic anemia*, in that it is not associated with apparent distress and is not prevented with nutritional supplements. Stabilization of the hemoglobin concentration is heralded by an increase in reticulocytes at 4 to 8 weeks ([147]). Thereafter, the hemoglobin concentration rises to a mean level of 12.5 g/dl, where it remains throughout infancy and early childhood ([149]).

The placenta and umbilical cord contain 75 to 125 ml of blood at term, or approximately one-fourth to one-third of the fetal blood volume. Umbilical arteries constrict shortly after birth, but the umbilical vein remains dilated, and blood flows in the direction of gravity. Infants held below the level of the placenta can receive half of the placental blood volume (30 to 50 ml) in 1 minute. Conversely, infants held above the placenta can lose 20 to 30 ml of blood back into the placenta per minute ([150]). The blood volume of infants with early cord clamping averages 72 ml/kg, whereas the volume of infants with delayed cord clamping averages 93 ml/kg. Linderkamp et al. compared postnatal alterations in blood viscosity, hematocrit, plasma viscosity, red cell aggregation, and red cell deformability in the first 5 days of postnatal life in full-term neonates with early (less than 10 seconds) and late (3 minutes) cord clamping ([151]). The residual placental blood volume decreased from 52 ± 8 ml/kg of neonatal body weight after early cord clamping to 15 ± 4 ml/kg after late cord clamping. The neonatal blood volume was 50% higher in the late cord-clamped infants than in the early cord-clamped infants. Intrauterine asphyxia appears to have little effect on blood volume, whereas intrapartum asphyxia and nuchal cords are associated with a reduced blood volume ([152]).

Preterm infants have slightly larger blood volumes (89 to 105 ml/kg) owing to an increased plasma volume. At 30 weeks' gestation, half of the approximately 120 ml/kg total blood volume of the fetoplacental circulation is in the fetus ([149]). Preterm infants commonly experience rapid cord clamping, resulting in a decreased blood volume. Postnatally, blood volume decreases rapidly, so that by 1 to 2 months of age, it approximates the normal adult volume of 77 ml/kg.

Fetal and Neonatal Erythrocyte Membrane and Metabolism

The different morphologic variants seen by using phase contrast microscopy suggest that the red cell membrane of the newborn differs from that of the adult. Protein patterns obtained with two-dimensional polyacrylamide gel electrophoresis isoelectric focusing show only minor variations from patterns obtained with adult cells ([153]). Although a-spectrin is extracted less easily from neonatal red cell ghosts ([154]), the percentage of spectrin dimers and the spectrin tryptic peptide pattern are the same as in adult cells ([155]). An increase in the amount of immunoreactive myosin in the red cell membrane has been observed ([156]).

The quantity and distribution of lipids in neonatal red cells differ in several respects from adult red cells. Total values of lipid, phospholipid, and cholesterol are increased out of proportion to the surface area of newborn red cells ([157] , [158]). Neonatal cells also exhibit increased endocytosis in response to membrane-active agents, suggesting that the membranes of neonatal cells are less stable and are capable of greater reorganization ([158]). The distribution of phospholipid is altered, with an increased level of sphingomyelin and a decreased amount of phosphatidylcholine. Phosphatidylinositol values may also be increased ([159]). Unsaturated fatty acids are diminished in concentration, producing a relative increase in saturated fatty acids. These changes appear not to affect membrane viscosity ([158]).

Antigen expression differs from that of adult cells. The A, B, S, and Lutheran antigens are present in decreased amounts ([160]). Replacement of the i antigen with its adult counterpart I requires its conversion from a linear polylactosamine to a branched polylactosamine ([161]). Reduced A and B antigenicity may result in part from decreased branching and increased stimulation of glycoproteins on neonatal red cells ([162]).

The number of membrane receptors for digoxin is 2.5 times that in adult red cells ([163]). The red cell to plasma ratio of digoxin in infants on maintenance digoxin therapy is three times that of adults. Sequestration of digoxin by red cell receptors undoubtedly contributes to the greater digoxin tolerance of infants. An increase in insulin receptors is explained by the young mean age of newborn red cells and by their larger surface area ([164]).

Red cell deformability and viscoelastic properties are normal ([165]). Nevertheless, the passage of newborn red cells through small pore filters is impaired. This difficulty probably results from the greater size and therefore the greater minimal cylindrical diameter of neonatal red cells ([165]). One theory is that this property of neonatal cells may restrict their passage through the spleen, thereby contributing to their shortened life span.

In addition to distinctive membrane and hemoglobin characteristics, neonatal red cells also exhibit metabolic characteristics that differ from those of adult red cells (

Table 48.6) ([129], [141], [157], [166], [167]). To some extent, differences are explained by the young mean age of red cells at birth. The increase in activity of many of the glycolytic enzymes is comparable in magnitude to that observed in high-reticulocyte adult blood ([168], [169]). Increased glycolytic enzyme activity, in turn, is responsible for increased consumption of glucose and galactose and increased levels of adenosine triphosphate (ATP) ([170]). Glucose consumption, although increased, may be less than that observed in age-matched cells from adults ([171]).

TABLE 48.6. Metabolic Characteristics of Neonatal Red Blood Cells

Metabolic characteristics explained by young mean cell age
Increased enzyme activity
Hexokinase
Aldolase
Triosephosphate isomerase
Phosphoglycerate mutase
Pyruvate kinase
Lactate dehydrogenase
Glucose-6-phosphate dehydrogenase
6-Phosphogluconate dehydrogenase
Glutathione reductase
Glyoxalase I and II
Galactokinase
Galactose-1-phosphate uridyl transferase
Increased glucose and galactose consumption
Increased levels of ATP
Metabolic characteristics distinctive for neonatal red cells
Embden-Meyerhof pathway
Increased activity of phosphoglycerate kinase, enolase, glucose phosphate isomerase, and glyceraldehyde-3-phosphate dehydrogenase
Decreased activity of phosphofructokinase
2,3-Diphosphoglycerate instability
Pentose phosphate pathway and glutathione metabolism
Decreased glutathione peroxidase and glutathione synthetase
Glutathione instability
ATP and phosphate metabolism
ATP instability
Decreased phosphate uptake, slower incorporation of phosphate into ATP and 2,3-diphosphoglycerate
Nonglycolytic enzymes
Decreased enzyme activity
Carbonic anhydrase
Catalase
Cholinesterase
Adenylate kinase
Phosphoribosyl transferase
Cytochrome b_5 reductase

ATP, adenosine triphosphate.

Certain characteristics of neonatal red cells reflect fundamental metabolic differences. The activities of four enzymes in the Embden-Meyerhof pathway—phosphoglycerate kinase, enolase, glucose phosphate isomerase, and glyceraldehyde-3-phosphate dehydrogenase—are increased out of proportion to cell age ([169], [170], [172]). The activity of phosphofructokinase, a rate-controlling enzyme in glycolysis, is only 40 to 70% of that in adult red cells of comparable age ([169], [170], [172]). Low levels of phosphofructokinase may produce a block in glycolysis, resulting in the accumulation of glucose-6-phosphate and fructose-6-phosphate and a decrease in the amounts of 2,3-diphosphoglycerate (2,3-DPG) and phosphoenolpyruvate ([173]). Decreased activity of phospho-fructokinase is probably explained by accelerated decay of a less stable fetal isoenzyme ([174]). Neonatal red cells contain a homotetramer of liver-type phosphofructokinase subunits rather than the heterotetramer of liver and muscle subunits present in adult cells ([175]). Differences in the relative proportions of isoenzymes have also been described for hexokinase and enolase ([176]). The concentration of 2,3-DPG falls rapidly during short periods of incubation ([170]), apparently because of accelerated breakdown. Preterm infants have lower 2,3-DPG concentrations than term infants. These concentrations gradually increase with gestation ([177], [178]). Concentrations can be increased with the use of erythropoietin, thereby shifting the oxygen dissociation curve to the right ([179]).

The activities of two key enzymes of the pentose phosphate pathway, glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, are increased by virtue of a young mean red cell age ([169], [170]). The response of the pentose phosphate pathway to oxidant stimuli is normal, and the level of reduced glutathione is equal to or greater than that found in adults ([171]). Yet newborn cells exhibit glutathione instability, increased Heinz body formation, and a propensity to increased methemoglobin generation, all indicative of greater susceptibility to oxidant-induced injury ([157], [168]). The basis for this oxidant vulnerability is not known. Although red cells of the newborn infant have low levels of activities of both glutathione peroxidase ([180]) and glutathione synthetase ([181]), no apparent relationship exists between these deficiencies and oxidant vulnerability ([182]). Other factors that have been implicated in attempts to explain metabolic differences include deficient catalase activity, decreased numbers of membrane sulfhydryl groups ([183]), greater residual membrane hemoglobin ([184]), and other plasma factors ([185], [186]). Studies evaluating the antioxidant capacity of preterm red cells and plasma from infants with respiratory distress syndrome reported no difference in activity between sick and well preterm infants, and antioxidant activity appeared intact. The study did not provide convincing evidence of oxidative damage and diminished antioxidant defenses in preterm infants with neonatal respiratory distress syndrome ([187]).

Although elevated at birth, the red cell ATP level falls rapidly during short periods of incubation. The uptake of labeled orthophosphate by cord blood cells is slower than that by adult cells, resulting in delayed incorporation of phosphate into ATP and 2,3-DPG ([188]). This disturbance in energy metabolism has been held responsible for accelerated potassium loss during incubation. Neonatal erythrocytes have increased rates of endocytosis compared to adult erythrocytes; these rates gradually decrease to adult levels with prolonged incubation ([189]). In septic neonates, ATP concentration in red blood cells was significantly lower than in neonates with respiratory distress syndrome and controls, whereas the 2,3-DPG concentration was increased ([190]).

The activity of a number of nonglycolytic enzymes also is different in neonatal red cells. Carbonic anhydrase ([188]), catalase ([191]), acetylcholinesterase ([192]), adenylate kinase ([192]), hypoxanthine-guanine-phosphoribosyl transferase ([193]), and cytochrome b_5 reductase ([194]) are all less active than in adult red cells. Differences in carbonic anhydrase activity have been exploited by using this enzyme to lyse selectively any contaminating maternal cells from samples of mixed fetal and maternal cells obtained for the prenatal diagnosis of hemoglobinopathies ([195]). Reduced activity of cytochrome b_5 reductase, the enzyme responsible for methemoglobin reduction, contributes to the infant's vulnerability to methemoglobinemia. This enzyme exists in both soluble and membrane-bound forms. The membrane-bound form is the precursor enzyme that is posttranslationally processed to a smaller, soluble form, probably by a calmodulin-dependent endogenous

protease ([196]). Neonatal red cells have membrane-bound cytochrome *b* $_5$ reductase activity comparable to that of adult cells but are limited in their ability to convert membrane-bound enzyme to the soluble form.

Cord blood contains three types of hemoglobin: HbF (a $_2$, ? $_2$), HbA (a $_2$, ß $_2$), and HbA2 (a $_2$, d $_2$). HbF constitutes the major fraction (50 to 85%) ([5]). Because of this, hemoglobinopathies involving ß-chain synthesis, such as sickle cell disease and ß-thalassemia, do not present in the neonatal period. The G-? to A-? ratio at birth is approximately 3:1, in contrast to a ratio of 2:3 in adults ([197] , [198]). HbA accounts for 15 to 40% of the hemoglobin. HbA2 is present in only trace amounts (mean, 0.3%) at birth ([199]), but it increases slowly after birth, reaching the normal adult level (2 to 3%) by 5 months of age. Relative to values in adults, that of free erythrocyte protoporphyrin is high at birth and remains elevated through the first 6 months of age ([200]).

The level of HbF at birth is influenced by a number of variables, the most significant of which is gestational age. Premature infants have more HbF and postmature infants less (Fig. 48.1) ([201]). Neonates who have survived chronic intrauterine hypoxia, such as occurs with maternal heart and lung disease, have higher levels of HbF ([202]). Hemolytic disease is associated with lower levels of HbF. This association does not result from a difference in the synthetic ratios of ß- and d-globin chains ([203]), but rather relates to a younger population of red cells produced late in fetal life ([204]). The switch from ?-chain synthesis to ß-chain synthesis is insensitive to environmental variables and appears to be developmentally programmed. Neither intrauterine transfusion nor neonatal exchange transfusion affects the synthetic rates of ß- and d-chains ([202]). Studies quantifying the specific gamma globin messenger RNAs (mRNAs) report that (G)gamma globin mRNA to total gamma globin mRNAs remains around 66% until the 44 week of postconceptual age, when a change in the (G)gamma and (A)gamma globin mRNA proportions occurred. Immature red cells of adults have a range of (G)gamma globin mRNA to total gamma globin mRNAs varying from 20 to 74% ([205]). Lower levels of HbF are associated with trisomy 21 ([206]); higher levels are associated with trisomy 13 ([207]).

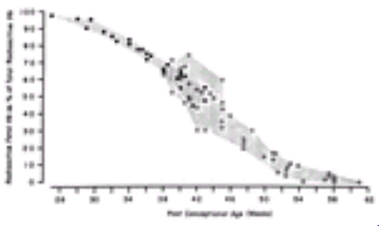

Figure 48.1. Decline in fetal hemoglobin (Hb) synthesis as a function of gestational age. Solid dots cord blood samples from preterm infants; open circles samples from infants considered to have been delivered at term. (From Bard H. The postnatal decline of hemoglobin F synthesis in normal full-term infants. J Clin Invest 1975;55:395, with permission.)

HbF has an affinity for oxygen that is greater than that of HbA ([208]). The oxygen tension at which the hemoglobin of cord blood is 50% saturated is 19 to 21 mm Hg, 6 to 8 mm Hg lower than that of normal adult blood. This shift to the left of the hemoglobin-oxygen dissociation curve results from poor binding of 2,3-DPG by HbF ([209]). The position of the oxygen dissociation curve is determined by both the percentage of HbA and the red cell content of 2,3-DPG ([210]). As the relative proportion of HbA increases, the oxygen dissociation curve shifts by approximately 4 to 6 months of age to a position that is normal for the adult (Fig. 48.2). The increased oxygen affinity of HbF confers a physiologic advantage to the fetus in facilitating the transfer of oxygen from mother to fetus. Postnatally, however, it imposes a potential hazard in that oxygen unloading is constrained.

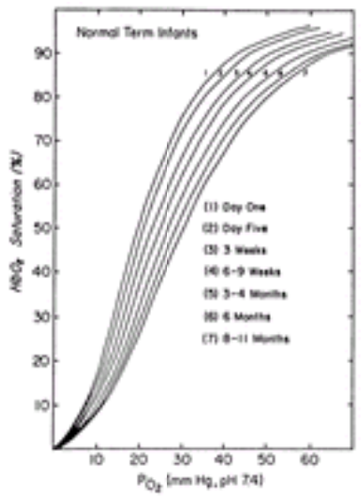

Figure 48.2. Oxygen dissociation curves of blood from term infants at different ages. The P $_{50}$ at birth is 19.4 ± 1.8 mm Hg; by 11 months of age, P $_{50}$ is 30.3 ± 0.7. Hb, hemoglobin. (From Oski FA, Delivoria-Papadopoulos M. The red cell, 2,3-diphosphoglycerate, and tissue oxygen release. J Pediatr 1970;77:941, with permission.)

HbF is resistant to alkali denaturation, a property that is the basis for its chemical quantitation ([211]). Unlike HbA, HbF is not eluted from fixed blood smears immersed in an acid buffer ([212]). This property permits the differential staining of HbF and HbA, a technique used widely to study the distribution of HbF in red cells and to detect fetal cells in the maternal circulation.

Fetal and Neonatal Anemia due to Hemolysis

Hemolytic anemia in neonates is generally associated with serum bilirubin levels above 10 mg/dl. The exaggerated bilirubin response to shortened red cell survival reflects the unique nature of bilirubin metabolism in the newborn period ([213]). During intrauterine life, bilirubin is cleared effectively by the placenta and is metabolized by the maternal liver ([214]). As a result, fetal hemolytic disease never presents as jaundice at birth, and the bilirubin concentration of cord blood is normal or is elevated only modestly. After birth, however, the products of heme catabolism must be processed by the liver. The neonatal liver is limited in its ability to metabolize bilirubin efficiently, in part because of a deficiency of the cytoplasmic acceptor protein ligandin ([215]), and in part because of decreased activity of uridine diphosphoglucuronyl transferase ([216]). As a result, hepatic binding and transport are compromised, conjugation of bilirubin is limited, and biliary excretion is reduced.

Causes of hemolytic disease in the newborn are noted in Table 48.7. Worldwide, isoimmunization caused by maternal-fetal blood group incompatibility is the most common cause of hemolytic anemia. The pathophysiology, diagnosis, prevention, and treatment of erythroblastosis fetalis are discussed in Chapter 36. Descriptions of the neonatal expressions of hemolysis resulting from congenital defects of the red cell are provided in subsequent chapters: hereditary spherocytosis, hereditary elliptocytosis, and hereditary pyropoikilocytosis in Chapter 32; pyruvate kinase deficiency and glucose-6-phosphate dehydrogenase deficiency in Chapter 33; and hemoglobin H disease in Chapter 42.

TABLE 48.7. Causes of Hemolytic Disease in Newborns

Immune-mediated
Rh incompatibility (anti-D antibody)
ABO, c, C, e, E, G incompatibility
Minor blood group incompatibility:
Fya (Duffy), Kell group, Jka, MNS, Vw

	Drug-induced (penicillin, a-methyldopa, cephalosporins)
	Maternal autoimmune hemolytic anemia
Congenital erythrocyte enzyme defects	
	Glucose-6-phosphate dehydrogenase deficiency
	Pyruvate kinase deficiency
	Hexokinase deficiency
	Glucose phosphate isomerase deficiency
	Pyrimidine 5' nucleotidase deficiency
Hereditary erythrocyte membrane disorders	
	Spherocytosis
	Elliptocytosis
	Stomatocytosis
	Pyropoikilocytosis
	Other membrane disorders
Infection	
	Bacterial sepsis (*Escherichia coli*, group B streptococcus)
	Parvovirus B19 (can present with hydrops fetalis)
	Congenital syphilis
	Congenital malaria
	Congenital TORCH infections (*to*xoplasmosis, *r*ubella, *c*ytomegalovirus, disseminated *h*erpes)
	Other congenital viral infections
Hemoglobin defects	
	a-thalassemia syndromes
	?-thalassemia syndromes
	a- and ?-chain structural anomalies
Macro- and microangiopathic hemolysis	
	Cavernous hemangiomas
	Arteriovenous malformations
	Renal artery stenosis or thrombosis
	Other large vessel thrombi
	Severe coarctation of the aorta
	Severe valvular stenoses
Other causes	
	Disseminated intravascular coagulation
	Hypothyroidism
	Galactosemia
	Lysosomal storage diseases
	Prolonged metabolic acidosis from metabolic disease (amino acid and organic acid disorders)

Antigens in the ABO, MN, Rh, Kell, Duffy, and Vel systems are well developed on fetal red cells during early intrauterine life ([217]). They are present in the fifth to seventh gestational week and remain constant through the remainder of intrauterine development. Other antigens, such as the Lutheran and XgA systems, develop more slowly but are present at birth, unlike Lewis antigens, which develop after birth. By 2 years of age, red cell and plasma antigens have developed a pattern that is seen throughout the remainder of life ([218]).

Although A and B antigens are present early *in utero*, A and B isoagglutinin production occurs later during the second and third trimester ([219]). By 30 to 34 weeks' gestation, about one-half of all fetuses have some measurable anti-A or anti-B antibodies. The fetal production of such antibodies is not related to maternal blood type, rather, intrauterine exposure to gram-negative organisms whose antigens are chemically related to those of blood groups A and B act as a potent stimulus for antibody development.

Isoimmunization due to Rh or ABO incompatibility is the most common cause of hemolytic disease in the newborn period. ABO incompatibility represents a spectrum of hemolytic disease in newborns.

To determine the frequency of red blood cell antigen alloimmunization that is capable of causing hemolytic disease, a study group in Syracuse, New York, identified 452 women who had a positive antibody screen during a 30-month screening period ([221]). The frequencies of specific alloimmunization were: anti-D, 18.4%; anti-E, 14%; anti-c, 5.8%; anti-C, 4.7%; Kell group, 22%; anti-MNS, 4.7%; anti-Fya (Duffy), 5.4%; and anti-Jka, 1.5%. The study group concluded that anti-D was still a common antibody, despite the use of RHo (D) immune globulin (Rhogam).

Rhesus and Kell antigen status can be determined by DNA studies, and molecular biology techniques, such as polymerase chain reaction, have been used recently to determine fetal blood type. These methods may represent an advance in the clinical management of alloimmunization in the future ([222]).

Anti-Kell anemic fetuses have lower reticulocyte counts and total serum bilirubin levels than comparable anti-D anemic fetuses ([223]). The level of hemolysis caused by anti-Kell antibodies is less than that caused by anti-D antibodies, but fetal erythropoiesis is blunted. It appears that Kell sensitization results in both suppression of fetal erythropoiesis and hemolysis. Vaughan and co-workers evaluated the effects of anti-Kell antibodies on erythroid progenitors ([224]). The growth of Kell-positive erythroid progenitor cells from cord blood was markedly inhibited by anti-Kell antibodies in a dose-dependent fashion. Anti-D antibodies had no effect on erythroid progenitor growth. They concluded that anti-Kell antibodies cause fetal anemia by suppressing erythropoiesis at the level of erythroid progenitors. Fetuses with anti-Kell hemolytic anemia may therefore benefit from fetal blood sampling rather than amniotic fluid analysis, which might underestimate the degree of anemia ([223]).

Extremely high titers of anti-C antibody have been associated with neonatal hemolytic disease ([225]). However, routine screening of titers is not warranted, because antibody titers do not accurately reflect the severity of hemolytic disease ([226]). Blood type is sufficient to screen for possible anti-D antibody.

Fetal and Neonatal Anemia due to Hemorrhage

Hemorrhage can occur at any time during the prenatal, perinatal, and postnatal periods (Table 48.8).

TABLE 48.8. Causes of Hemorrhage in the Fetus and Neonate

Prenatal	
	Chronic and/or acute twin-to-twin transfusion syndrome
	Chronic and/or acute fetal-maternal hemorrhage
	Hemorrhage into amniotic fluid after periumbilical blood sampling

- Traumatic amniocentesis
- Maternal trauma
- Trauma after external cephalic version

Perinatal
- Placental abruption
- Placenta previa
- Vasa previa
- Trauma or incision of placenta during cesarean section
- Ruptured normal or abnormal (varices, aneurysms, hematoma) umbilical cord
- Placental hematoma
- Velamentous insertion of the cord
- Nuchal cord

Postnatal
- Subgaleal hemorrhage
- Cephalohematoma
- Hemorrhage associated with disseminated intravascular coagulation/sepsis
- Intraventricular/intracranial hemorrhage (prematurity, trauma, isoimmune thrombocytopenia)
- Organ trauma (liver, spleen, adrenal, renal, gonadal)
- Pulmonary hemorrhage
- Iatrogenic blood loss (phlebotomy, central line accidents)

PRENATAL HEMORRHAGE Maternal and fetal circulating cells may cross the placental barrier at varying times during the pregnancy. Fetal red cells can be found in the maternal circulation before delivery, as evidenced by studies of maternal blood group immunization. Approximately 50 to 75% of pregnancies are associated with some degree of FMH. This event is uncommon in the first trimester. Approximately 1 pregnancy in 400 is associated with a fetal transplacental bleed of 30 ml or greater, and approximately 1 pregnancy in 2000 is associated with a potential fetal transplacental hemorrhage of 100 ml or more ([227]). More commonly, the volume of fetal blood transferred into the maternal circulation is relatively small, usually on the order of 0.01 to 0.10 ml. The overall risk of Rh immunization occurring with FMH in an Rh-incompatible pregnancy is 16% if the fetus is Rh positive and ABO compatible with its mother. This risk decreases to 1.5% if the fetus is Rh positive but ABO incompatible, due to the destruction of ABO incompatible cells early during transfer. Fetal transfer of cells to the mother occurs during abortions as well (approximately a 2% incidence of such transfer with spontaneous abortion and a 4 to 5% rate if induced) ([228]). The Kleihauer Betke stain of maternal blood evaluates the acid elution of hemoglobin from red cells ([212]). HbF resists acid elution to a greater degree than adult hemoglobin. Maternal cells appear clear (termed *ghost cells*), whereas the contaminating fetal cells appear pink. Results from mothers with increased HbF synthesis (i.e., sickle cell disease, thalassemia, and hereditary persistence of HbF) are not reliable; in these cases, other measures should be taken to detect FMH. Diagnosis of FMH may also be difficult to detect when the mother and infant are ABO incompatible, because fetal cells are rapidly cleared from the maternal circulation by maternal anti-A or anti-B antibodies. Severe FMH occurs in 1 in 1000 deliveries and has been associated with decreased fetal movements and a fetal sinusoidal heart rate pattern ([229]). Giacoia reviewed these variables to determine if they correlated with the severity of FMH ([230]). Fetal movements for a period ranging between 24 hours and 7 days were absent in 17 of 134 cases evaluated. In this group, six infants survived, five were stillborn, and five died in the neonatal period. A sinusoidal heart rate pattern was reported in 21 cases, and was associated with decreased fetal movement in 40% of the cases. No significant difference was found between the cases with a FMH of less than 200 ml and those less than 200 ml. Decreased neonatal blood volumes are associated with a maternal history of vaginal bleeding, placenta previa or abruption, nonelective cesarean section, and deliveries associated with cord compression ([231]). Significant FMH has been described following trauma ([232]), and fetal hemorrhage into the placenta has been associated with placental chorioangioma ([233]). Infants need rapid evaluation and treatment if a significant hemorrhage is suspected. The infant with massive hemorrhage presents with pallor and tachypnea but generally with minimal to no oxygen requirement. Hemoglobin concentrations can be extremely low at birth, between 4 and 6 g/dl. A significant metabolic acidosis is often present as a result of poor perfusion. Other causes of pallor in the newborn period do occur and can be ruled out once the infant is stable. Infants with asphyxia and infants with chronic anemia due to hemolysis can also present with pallor. These diagnoses can be distinguished from acute hemorrhage based on differences in clinical signs and symptoms. The clinical picture with chronic blood loss is usually mild, and infants respond to conservative therapy with iron alone. Asphyxiated infants will be pale, floppy, and may have poor peripheral circulation. The hemoglobin will be stable, but may decrease if disseminated intravascular coagulation (DIC) and internal bleeding occur. TTS is a complication of monochorionic twin gestations, occurring in 5 to 30% of these pregnancies ([234]). TTS involves placental anastomoses, which allow transfer of blood from one twin to the other. The perinatal mortality rate can be as high as 70 to 100%, depending on severity and timing of presentation. Approximately 70% of monozygous twin pregnancies have monochorionic placentas ([235]). Although vascular anastomoses are present in almost all instances of monochorionic placentas, not all of those develop TTS. Acute TTS generally results in twins of similar size but with hemoglobin concentrations that vary by more than 5 g/dl ([236]). In chronic TTS, the donor twin becomes progressively anemic and growth retarded, whereas the recipient twin becomes polycythemic, macrosomic, and sometimes hypertensive. Both infants can develop hydrops fetalis; the donor twin becomes hydropic from profound anemia, whereas the recipient twin becomes hydropic from congestive heart failure and hypervolemia. The donor twin often has low amniotic fluid volumes, whereas the recipient twin has increased amniotic fluid, due to significant differences in blood volume, renal blood flow, and urine output. Chronic TTS can be diagnosed by serial prenatal ultrasounds measuring cardiomegaly, discordant amniotic fluid production, and fetal growth discrepancy of >20%. Percutaneous umbilical blood sampling can determine if hemoglobin concentration differences of greater than 5 gm/dl exist between the two fetuses ([236]). After birth, the donor twin may require transfusions and can also experience neutropenia, hydrops from severe anemia, growth retardation, congestive heart failure, and hypoglycemia. The recipient twin is often the sicker of the two. Problems include hypertrophic cardiomyopathy, congestive heart failure, polycythemia, hyperviscosity, respiratory difficulties, hypocalcemia, and hypoglycemia. Neurologic evaluation and imaging are imperative because the risk of antenatally acquired neurologic cerebral lesions is 20 to 30% in both twins ([236]). The incidence of neurologic morbidity following the intrauterine death of one of the fetuses averages 20 to 25%. Morbidities include multiple cerebral infarctions, hypoperfusion syndromes from hypotension, and periventricular leukomalacia. Long-term neurologic follow-up is indicated for all TTS survivors. Treatment for TTS consists of close monitoring and reduction amniocenteses to decrease uterine stretch and prolong the pregnancy. The average survival rates with serial reduction amniocenteses range from 40 to 70% ([237]). Selective feticide of the hydropic twin has also resulted in the survival of the healthier twin in some studies ([238]). Treatment *in utero* has occurred during some pregnancies using laser surgery to ablate bridging vessels, resulting in improved survival rates up to around 50%, with approximately 70% of the pregnancies having at least one survivor ([239] , [240]). However, the survival rate without morbidity in the surviving twin is approximately 50% ([241]). Supski et al. performed a metaanalysis of 140 cases to correlate types of treatment with outcome ([242]). They found no differences in outcome between amnioreduction, fetoscopy, septostomy, or close observation. Although the number of cases was small, the results of the analysis showed that a definitive form of treatment has not been established for severe TTS.

PERINATAL HEMORRHAGE Obstetric complications, such as placenta previa, placental abruption, incision or tearing of the placenta during cesarean section, and cord evulsion of normal or abnormal umbilical cords, can result in significant neonatal blood loss. Newborns may also undergo significant blood loss back into the placenta, termed a *fetoplacental hemorrhage*. Finally, placental anomalies, such as a multilobed placenta and placental chorioangiomas, may be a source of hemorrhage during the perinatal period ([233]). Placental abruption involves premature separation of the placenta from the uterus and occurs in 3 to 6 per 1000 live births. Prolonged rupture of the membranes, severe fetal growth restriction, chorioamnionitis, hypertension (before pregnancy and pregnancy-induced), cigarette smoking, advanced maternal age, and male fetal gender are potential risk factors for placental abruption ([243]). The incidence of abruption increases with lower gestational age. Mortality ranges from 0.8 to 2.0 per thousand births ([244]), or 15 to 20% of the deliveries in which significant abruption occurs. Women with a history of a previous cesarean birth and increased parity are at increased risk of having a pregnancy complicated by placenta previa ([245]), a condition where part or all of the placenta overlies the cervical os. Cigarette smoking is associated with a 2.6- to 4.4-fold increased risk of placenta previa ([246]). Prenatal diagnosis of vasa previa (anomalous vessels overlying the internal os of the cervix) can be made with transvaginal color Doppler, and should be suspected in any case of antepartum or intrapartum hemorrhage. Although uncommon (1 in 3000 deliveries), the perinatal death rate is high, ranging from 33 to 100% when undetected before delivery. Infants are often stillborn ([247]). Infants born after placental abruption may be anemic but may also present with signs of hypoxia. In these infants, it is important to monitor changes in hematocrit and neurologic signs. Infants born to mothers with placenta previa can also be anemic. The need for postnatal transfusions in the infants is generally associated with the volume of maternal hemorrhage. The infant's hemoglobin should be measured at birth and again at 12 to 24 hours whenever there is evidence of placental abruption, placenta previa, or unusual vaginal bleeding. A Kleihauer Betke stain can be performed on maternal blood to determine if fetal hemorrhage occurred. Monitoring mothers with a history of second or third trimester bleeding with Doppler flow ultrasound may detect placental abnormalities and thereby decrease the incidence of anemia and fetal loss in newborns ([247]). Cord rupture due to excess traction on a shortened or abnormal umbilical cord usually occurs on the fetal side. Cord aneurysms, varices, and cysts can all lead to formation of a weakened cord. Cord infections (funisitis) can also weaken the cord and increase the risk of rupture. Infants born precipitously may be at increased risk for hemorrhage due to a ruptured cord. Hematomas of the cord occur infrequently (1 in

5000 to 6000 deliveries) but can also be a cause of fetal blood loss, and may be associated with significant perinatal mortality. Intrauterine death may occur due to compression of the umbilical vein and arteries by the hematoma. Cord hematomas can result from trauma due to percutaneous umbilical blood sampling and can also be associated with a high maternal a-fetoprotein. Hematomas of the cord can be accurately diagnosed *in utero* by ultrasound and differentiated from other lesions of the placenta and cord ([248]). The lesion can be associated with poor fetal growth and FMH. Subamniotic hematomas can occur when chorionic vessels rupture near the cord insertion. Most subamniotic hematomas are the result of excessive traction on a normal or shortened umbilical cord and are not noted until after delivery. Velamentous insertion of the umbilical cord occurs when the umbilical cord enters the membranes distant from the placenta and is present in approximately 0.5 to 2.0% of pregnancies ([249]). Blood vessels left unprotected by Wharton jelly are more likely to tear. Rupture of anomalous vessels in the absence of traction or trauma can occur even if the cord itself attaches centrally or paracentrally. The fetal mortality remains very high in this condition, often because detection by routine ultrasound is rare. Eddleman and co-workers noted that targeted sonographic examination of the placental site of umbilical cord insertion could reveal abnormal placental cord insertions. However, distinguishing the specific type of abnormal insertion would likely require the use of color Doppler imaging ([250]).

POSTNATAL HEMORRHAGE Blood loss into the placenta is one of the most common etiologies for a low birth hematocrit in a neonate. Of the 120 ml/kg of blood in the fetoplacental unit, a large residual volume remains in the placenta, and blood continues to flow in the direction of gravity after birth. Fetoplacental hemorrhage occurs when the infant is held above the placenta after birth. In addition, infants can lose 10 to 20% of their total blood volume when born with a tight nuchal cord that allows blood to be pumped through umbilical arteries while constricting flow through the umbilical vein ([251]). Blood loss into the subgaleal space can occur during difficult deliveries requiring vacuum or forceps assistance, such as face presentation, occiput posterior presentations, and shoulder dystocias. Subgaleal hematomas are potentially life-threatening events and must be recognized as early as possible to prevent significant morbidity or mortality. The hematomas occur when emissary or “bridging” veins are torn, allowing blood to accumulate in the large potential space between the galea aponeurotica (the epicranial aponeurosis) and the periosteum of the skull. The subgaleal space extends from the orbital ridge to the base of the skull and can accommodate an infant's entire blood volume (>85 ml/kg of blood). Subgaleal hematomas may form because of preexisting risk factors (such as coagulopathy or asphyxia), but vacuum extraction itself is a risk factor for the development of subgaleal bleeding. The diagnosis should be considered in the presence of a ballotable fluid collection in dependent regions of the infant's head, coupled with signs of hypovolemia ([252]). Treatment requires restoration of blood volume and control of bleeding. Exsanguination due to subgaleal hemorrhage has been reported; the mortality is high if the hemorrhage goes unrecognized. A rule of thumb for estimating the volume of blood lost is: 38 ml of blood has been lost for every 1 cm increase in head circumference that occurs ([253]). Of 134 infants undergoing vacuum extraction, 28 had scalp trauma, and only one infant had subgaleal, subdural, and subarachnoid hemorrhage ([254]). The duration of vacuum application is thought to be the best predictor of scalp injury, followed by duration of second stage of labor and paramedian cup placement. Of those infants with reported subgaleal hemorrhages, 80 to 90% had some history of vacuum or instrument-assisted delivery ([255]). It is important to remember that a cesarean delivery does not preclude the use of vacuum or forceps, and significant hemorrhage can still occur via this route of delivery. Therefore, limiting the frequency and duration of vacuum assistance in high-risk infants may decrease the incidence of subgaleal hematomas. Anemia appearing after the first 24 hours of life in a nonjaundiced infant may result from occult hemorrhage. In addition to birth trauma causing visible hemorrhages, such as a cephalohematoma, internal hemorrhage can occur. Breech deliveries may be associated with renal, adrenal, or splenic hemorrhage into the retroperitoneal space. Delivery of macrosomic infants, such as infants born to diabetic mothers, may also result in organ damage and hemorrhage. Infants with overwhelming sepsis may develop DIC and bleed into soft tissue and organs, such as liver, adrenal glands, and lungs. In addition to causing anemia, adrenal hemorrhage may result in circulatory collapse due to the loss of organ function. The incidence of adrenal hemorrhage is 1.7 per 1000 births ([256]). Adrenal hemorrhage can also affect surrounding organs. Intestinal obstruction and kidney dysfunction have been reported in infants with adrenal hemorrhage ([257]). Diagnosis can be made using ultrasonography, during which calcifications or cystic masses are noted. Adrenal hemorrhage can be distinguished from renal vein thrombosis (RVT) by ultrasound, in that RVT generally results in a solid mass. Occasionally, both entities may coexist in the same patient ([258]). Infants with RVT may have gross or microscopic hematuria and may go on to develop renal failure and hypertension. Infectious etiologies resulting in DIC and hemorrhage are also a cause of adrenal hemorrhage. Mostoufizadeh and colleagues reported five cases of echovirus type 11 diagnosed in neonates born in the Boston area during a single season ([259]). Four of the mothers experienced symptomatic gastroenteritis late in the third trimester of pregnancy. Affected infants experienced jaundice, hepatosplenomegaly, hypotonia, and progressive hepatic failure. At autopsy, investigators found massive hepatic and adrenal hemorrhage and necrosis, with evidence of a consumptive coagulopathy. Echovirus type 11 was isolated from various sites before and after death. The newborn liver is very prone to iatrogenic rupture, resulting in a high morbidity and mortality ([260]). Infants may appear asymptomatic until the liver ruptures and hemoperitoneum occurs. This can occur in both term and preterm infants ([261]) and has been associated with chest compressions during cardiopulmonary resuscitation. Surgical intervention involving vascular tamponade has been reported to save some infants; however, the mortality remains high ([262]). Splenic rupture can result from birth trauma or as a result of distention caused by extramedullary hematopoiesis, such as that seen in erythroblastosis fetalis. Abdominal distension and discoloration, scrotal swelling, and pallor are clinical signs of splenic rupture; these signs may also be seen with adrenal hemorrhage or hepatic rupture ([261]). Other rare causes of hemorrhage in the newborn include hemangiomas of the gastrointestinal tract ([263]), vascular malformations of the skin, and hemorrhage into soft tumors, such as giant sacrococcygeal teratomas. Occult intraabdominal hemorrhage can occur with fetal ovarian cysts, which are usually benign and resolve spontaneously. One case of fetal anemia was diagnosed by a spontaneous hemorrhage into a fetal ovarian cyst and was managed by intrauterine blood transfusions ([264]).

Fetal and Neonatal Anemia due to Congenital Infection

Neonatal sepsis due to group B streptococcus, *Escherichia coli*, and other perinatal organisms may result in hemolysis, DIC, and hemorrhage. Infants are often jaundiced and have hepatosplenomegaly, although the degree of hyperbilirubinemia does not always reflect the degree of anemia. Infants may have an elevated direct bilirubin as well, possibly due to infectious involvement with the liver. Bacteria, such as *E. coli*, produce hemolytic endotoxins, which result in increased red cell destruction, often associated with a microangiopathic process ([265]).

Congenital viral infections due to cytomegalovirus, toxoplasmosis, rubella, and herpes simplex may also be associated with a hemolytic anemia. Congenital syphilis may present with hemolytic anemia despite negative testing in the mother. Initial maternal screening for syphilis may be negative despite overwhelming infection, a condition termed the *prozone effect* ([266]). This occurs when a higher than optimal amount of antibody in the tested sera prevents the flocculation reaction seen in positive reagin test results. Serum dilution is necessary to make the correct diagnosis. In cases of nonimmune hydrops, nontreponemal testing should be repeated using serum dilutions to prevent a missed diagnosis of syphilis in women with negative syphilis serologic results.

Fetal and neonatal infection with parvovirus B19 can cause severe anemia, hydrops, and fetal demise ([267] , [268]). The infant generally presents with a hypoplastic anemia ([269]), but hemolysis can occur as well. The virus replicates in erythroid progenitor cells and shuts down erythropoiesis, resulting in red cell aplasia. *In utero* transfusions for hydropic fetuses have been investigated but are not successful in all patients. Treatment with IVIG during aplastic crises leads to resolution of the anemia.

Other infections associated with neonatal anemia include malaria and HIV. Congenital malaria may occur in areas, such as New York City ([270]), where imported cases of malaria are increasing. Congenital HIV infection can be asymptomatic in newborns. Infants born to mothers on zidovudine may have a hypoplastic anemia due to side effects of the drug ([97]).

Anemia of Prematurity and Other Hypoproliferative Disorders

Impaired erythrocyte production can result from a variety of reasons. Lack of an appropriate or sufficient marrow environment for growth (as seen in osteopetrosis) can cause decreased red cell production. Lack of specific substrates or their carriers (e.g., iron, folate, vitamin B_{12}, or transcobalamin II deficiency) can lead to deficient production. Lack of specific growth factors stimulating erythropoiesis (e.g., decreased erythropoietin production or abnormalities in Epo receptors) can also lead to hypoproliferative anemia, such as the anemia of prematurity.

ANEMIA OF PREMATURITY In preterm infants, adaptive mechanisms to the extrauterine environment are incomplete. Erythropoietin concentrations in anemic preterm infants are still significantly lower than those found in adults, given the degree of their anemia ([140]). This normocytic, normochromic anemia, termed the *anemia of prematurity*, commonly affects infants at less than or equal to 32 weeks' gestation. The anemia of prematurity is not responsive to the addition of iron, folate, or vitamin E. Some infants may be asymptomatic, whereas others demonstrate signs of anemia that are alleviated by transfusion. These signs traditionally include tachycardia, increased episodes of apnea and bradycardia, poor weight gain, an increased oxygen requirement, and elevated serum lactate concentrations that decrease following transfusion. Infants with the anemia of prematurity have a decreased ability to increase serum erythropoietin concentrations, despite diminished available oxygen to tissues ([271]) and the appearance of signs of anemia. However, erythroid progenitors are highly sensitive to erythropoietin ([272] , [273]), and concentrations of other erythropoietic growth factors appear to be normal ([274]) (Figure 48.3).

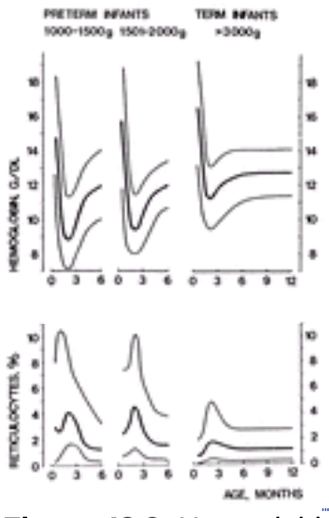

Figure 48.3. Hemoglobin concentration and reticulocyte counts in preterm and term infants. Curves describe median values and 95% confidence limits for infants of three different weight categories. (From Dallman PR. Anemia of prematurity. Annu Rev Med 1981;32:143, with permission.)

The molecular and cellular mechanisms responsible for the anemia of prematurity remain undefined. Some explanations include the transition from fetal to adult hemoglobin, shortened erythrocyte survival, and hemodilution associated with a rapidly increasing body mass ([144], [275]). It is unknown whether preterm infants rely on erythropoietin produced by the liver (the source of erythropoietin *in utero*), or that produced by the kidney, or a combination of the two. Regardless of the mechanism responsible for the anemia of prematurity, exogenous erythropoietin administered to preterm infants activates erythropoiesis ([276]). A review of studies evaluating the use of erythropoietin to prevent and treat the anemia of prematurity reveals a positive effect on decreasing transfusion requirements in preterm infants ([277]).

OTHER HYPOPROLIFERATIVE ANEMIAS With the exception of the anemia of prematurity, anemia in the newborn period is rarely the result of impaired red cell production (Table 48.9). Although classified as a congenital anemia, the Diamond-Blackfan syndrome characteristically is not recognized until after 2 to 3 months of age. However, it is estimated that 10 to 25% of affected infants have a mild anemia at birth ([278]). Rarely, hydrops fetalis has been reported in conjunction with this syndrome. This disorder is discussed in Chapter 45. Aase syndrome, another congenital hypoplastic anemia syndrome involving marrow and skeletal anomalies ([279]), is likely a variant of Diamond-Blackfan syndrome. Congenital dyserythropoietic anemia is a rare disorder marked by ineffective erythropoiesis, megaloblastic anemia, and characteristic abnormalities of the nuclear membrane and cytoplasm seen on electron microscopy. This disorder is reviewed in Chapter 46.

TABLE 48.9. Syndromes Associated with Anemia

Genetic Syndrome	Phenotypic Features	Genotypic Features
Adenosine deaminase deficiency	Autoimmune hemolytic anemia, reduced erythrocyte adenosine deaminase activity.	AR, 20q13.11
Congenital dyserythropoietic anemias	Type I (rare): megaloblastoid erythroid hyperplasia and nuclear chromatin bridges between nuclei; type II (most common): “hereditary erythroblastic multinuclearity, positive acidified serum (HEMPAS) test, increased lysis to anti-i; type III: erythroblastic multinuclearity (“gigantoblasts”), macrocytosis.	Type I: 15q15.1-q15.3; type II: 20q11.2; type III: 15q21
Diamond-Blackfan syndrome	Steroid-responsive hypoplastic anemia, often macrocytic after 5 mo of age.	AR; sporadic mutations and AD inheritance described; 19q13.2, 8p23.3-p22
Dyskeratosis congenita	Hypoproliferative anemia usually presenting between 5 to 15 yr of age.	X-linked recessive, locus on Xq28; some cases with AD inheritance
Fanconi pancytopenia	Steroid-responsive hypoplastic anemia, reticulocytopenia, some macrocytic RBCs, shortened RBC lifespan. Cells are hypersensitive to DNA cross-linking agents.	AR, multiple genes: complementation; group A: 16q24.3; B:; C: 9q22.3; D2: 3p25.3; E: 6p22-p21; F: 11p15; G: 9p13
Osler hemorrhagictelangiectasia syndrome	Hemorrhagic anemia.	AD, 9q34.1
Osteopetrosis	Hypoplastic anemia from marrow compression; extramedullary erythropoiesis.	AR: 16p13, 11q13.4-q13.5; AD: 1p21; lethal: reduced osteoclasts
Pearson syndrome	Hypoplastic sideroblastic anemia, marrow cell vacuolization.	Pleioplasmatic rearrangement of mitochondrial DNA; X-linked or AR
Peutz-Jeghers syndrome	Iron deficiency anemia from chronic blood loss.	AD, 19p13.3
X-linked a-thalassemia/mental retardation (ATR-X and ATR-16) syndromes	ATR-X: hypochromic, microcytic anemia; mild form of hemoglobin H disease ATR-16: more significant hemoglobin H disease and anemia are present.	ATR-X: X-linked recessive, Xq13.3; ATR-16: 16p13.3, deletions of a-globin locus

AD, autosomal dominant; AR, autosomal recessive; RBC, red blood cell.

Fanconi pancytopenia is an autosomal-recessive disorder characterized by marrow failure and congenital anomalies, including abnormalities in skin pigmentation, gastrointestinal anomalies, renal anomalies, and upper limb anomalies ([280]). Approximately one-third of patients have no obvious congenital anomalies, and anemia is less common than thrombocytopenia and leukopenia. Five genetic phenotypes of Fanconi pancytopenia have been reported, and two of the genes have been cloned ([281]). Cells are hypersensitive to DNA cross-linking agents such as diepoxybutane and mitomycin C. The diepoxybutane test represents a sensitive and specific diagnostic test. Most patients with Fanconi anemia present in early childhood, but newborns have been reported, usually when obvious congenital anomalies are present ([282]). Patients generally have an androgen-responsive hypoplastic anemia, reticulocytopenia, and macrocytic erythrocytes on the peripheral smear. Erythropoietin concentrations are usually elevated, and HbF production is increased. A significant percentage of patients develop myelodysplastic syndrome or acute myelogenous leukemia later in life. Treatment of Fanconi pancytopenia includes androgen therapy, and, in many cases, bone marrow transplantation has been successful (Chapter 44). Osteopetrosis is a rare autosomal-recessive disorder characterized by defects in osteoclastic function, resulting in a decreased bone marrow space. Developmental delay, ocular involvement, and neurodegenerative findings occur in association with hypoplastic anemia, although patients may also present with hemolytic anemia. Longitudinal studies in the United States and Europe have shown variability in outcome, although survival rates beyond 5 to 6 years are less than 30% ([283], [284]). Patients presenting with early hematologic and visual impairment had an even shorter life expectancy. Limited treatment options for this disorder include marrow transplantation and administration of calcitriol and interferon-? ([284]). Pearson marrow-pancreas syndrome is a disorder involving the hematopoietic system, exocrine pancreas, liver, and kidneys ([285]). Patients present in infancy with macrocytic anemia, which is sometimes associated with neutropenia and thrombocytopenia. Marrows have normal cellularity, but abnormalities including vacuolization of erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts are present. The disorder appears to involve defects in oxidative phosphorylation due to mitochondrial DNA abnormalities ([286], [287]). The anemia is unresponsive to pyridoxine supplementation. Bone marrow transplantation has not been reported in these patients, and the disorder is considered fatal.

Hemoglobins Associated with Cyanosis: Methemoglobinemia and Low-Affinity Hemoglobins

This chapter is concerned with disorders of hemoglobin (Hb) characterized by cyanosis. These conditions are associated with decreased arterial oxygen saturation in the absence of pulmonary or cardiac disease. The most common of these relatively rare causes of cyanosis is methemoglobinemia. Accumulation of methemoglobin in the red cell occurs when the rate of heme oxidation is increased (*acquired methemoglobinemia*), when methemoglobin reduction is limited by deficient reducing capacity [*nicotinamide adenine dinucleotide* (*reduced form*) (*NADH*)– *cytochrome* b $_5$ *reductase deficiency*], or when a structural abnormality in the globin moiety stabilizes Hb in the oxidized state (*HbM disorders*). Cyanosis unrelated to methemoglobinemia is also characteristic of the Hb variants that have a low affinity for oxygen.

CYANOSIS

The term *cyanosis* refers to a bluish discoloration of the skin and mucous membranes resulting from excessive amounts of reduced Hb. It is usually most marked in the lips, nail beds, ears, and malar eminences. As a rule, cyanosis becomes apparent when the mean capillary concentration of reduced Hb exceeds 5 g/dl. It is the absolute rather than the relative amount of reduced Hb, however, that is important in producing cyanosis. For this reason, if the same proportion of Hb is reduced, cyanosis will be more evident when the total Hb level is high, as in polycythemia, and less evident if there is an associated anemia. In contrast to reduced Hb, methemoglobin produces detectable cyanosis at concentrations as low as 2.0 g/dl.

Long-standing cyanosis dating from birth and unaccompanied by obvious cardiac and pulmonary disease was first reported by Francois in 1845 ([1]). Although it was appreciated that cyanosis could be induced by “blood poisons,” not until 1891 did Dittrich ([1]) emphasize that methemoglobinemia tended to disappear spontaneously without any alteration in the concentration of circulating erythrocytes, thereby suggesting the existence of a reducing mechanism in erythrocytes. At the turn of the century, a new concept was introduced—that of “autotoxic enterogenous cyanosis,” a disorder attributed to the formation of intracellular methemoglobin or sulfhemoglobin by toxic substances, possibly of bacterial origin absorbed from the gastrointestinal tract. Ultimately, it was recognized that met-hemoglobinemia could be observed in the absence of exposure to drugs, chemicals, or gastrointestinal disease. In 1948, a hereditary form of methemoglobinemia was described, and not long thereafter, the abnormality in the globin moiety of infected individuals was described ([2]). Subsequently, Scott and Hoskins ([3]) noted a high incidence of hereditary methemoglobinemia in Alaskan Eskimos and Native Americans, and Scott with Griffith, in the following year, reported the absence of an enzyme, later called (*NADH*)– *cytochrome* b $_5$ *reductase* (*diaphorase*), in the erythrocytes of those affected.

“Enterogenous cyanosis” is no longer considered to be an entity. Cases reported as such can best be explained by exposure to chemicals or drugs capable of increasing the rate of Hb oxidation. It remains possible, however, that erythrocytes are made more susceptible to the action of oxidant drugs by products of bacterial overgrowth in the intestinal tract ([4], [5]).

METHEMOGLOBINEMIA

Methemoglobin is an oxidation product of Hb in which the sixth coordination position of ferric iron is bound to a water molecule (acid form, having absorption peaks at 631 and 500 nm) or to a hydroxyl group (alkaline form, having absorption peaks at 575 and 540 nm). Acid methemoglobin is the predominant species at physiologic pH. Methemoglobin is produced at a slow, predictable rate *in vivo* by the escape of an electron from heme to released oxygen. After loss of an electron, binding of oxygen by the oxidized (ferric) heme cannot occur unless an electron is regained by means of reducing mechanisms within the cell. Because the capacity of red cells to reduce oxidized heme exceeds the spontaneous rate of heme oxidation by several hundredfold, less than 1% of the total Hb is normally in the ferric or methemoglobin form. The most important pathway of methemoglobin reduction uses NADH–cytochrome b_5 reductase for the transfer of an electron from NADH to heme. The reaction appears to proceed in two steps: (a) enzymatic reduction of cytochrome b_5, followed by (b) nonenzymatic transfer of an electron from reduced cytochrome b_5 to methemoglobin (Fig. 49.1). Another mechanism for methemoglobin reduction involves the direct transfer of electrons from ascorbic acid and glutathione to heme. The nicotinamide adenine dinucleotide phosphate (NADPH)–dependent methemoglobin reductase (dehydrogenase) lacks an endogenous electron acceptor and therefore is physiologically inert. It can be “activated,” however, by an exogenous electron acceptor, such as methylene blue or riboflavin ([6]). The NADPH-dependent enzyme reduces methylene blue to leukomethylene blue, which rapidly reduces methemoglobin nonenzymatically (Fig. 49.1).

Figure 49.1. Metabolic pathways for the reduction of methemoglobin (MetHb) to hemoglobin (Hb). **A:** Nicotinamide adenine dinucleotide (reduced form) (NADH)–dependent cytochrome b_5 reductase pathway. **B:** Nicotinamide adenine dinucleotide phosphate (NADPH)–dependent dehydrogenase pathway. The latter pathway requires an exogenous electron acceptor, such as methylene blue. NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate.

Acquired (Toxic) Methemoglobinemia

Various chemical compounds used in the home or in industry and several therapeutic agents are capable of increasing the rate of heme oxidation 100- to 1000-fold, thereby overwhelming the capacity of erythrocytes to maintain Hb in the reduced state. Infants are especially vulnerable. To some extent, the vulnerability of infants can be attributed to a greater susceptibility of fetal Hb (HbF) to oxidation compared with that of adult Hb (HbA). Of probably greater significance is reduced capacity for methemoglobin reduction during the first months of life ([7]). In the red cells of adults, NADH–cytochrome b_5 reductase is approximately equally distributed between a soluble form and a form tightly bound to the inner surface of the membrane ([8]). The membrane-bound enzyme is believed to be the primary gene product. It is posttranslationally processed, probably by a calmodulin-dependent protease, to a smaller, soluble form. Although membrane-bound enzyme activity in neonatal red cells is the same as that of adult cells, that of the soluble enzyme is 50% less ([9]). The relative deficiency of the soluble form of the enzyme appears to be related to impairment of the proteolytic processing of the membrane precursor. The ability of cells of infants to solubilize membrane-bound enzyme increases with age, reaching adult capacity by 6 months of age.

PATHOGENESIS A number of substances are capable of oxidizing Hb directly and do so *in vitro* (Table 49.1). These include nitrites, nitrates, chlorates, and quinones. The mechanism of Hb oxidation by most of these substances is not well defined. Nitrates, when ingested, are reduced to nitrites in the intestinal tract. Poisoning, sometimes fatal, is observed in infants given well water high in nitrates or powdered milk reconstituted with water containing nitrates ([10], [11]).

Nitrate-contaminated well water used in dialysis equipment has also been incriminated as a cause of methemoglobinemia in patients receiving home dialysis treatment ([12]). Nitrates may be absorbed from burn sites after the topical application of bismuth subnitrate or ammonium, potassium, or silver nitrate ([13]). Foods high in nitrates or accidentally contaminated with nitrites are a well-recognized cause of met-hemoglobinemia ([14], [15], [16] and [17]), as is the direct administration of nitrite as a folk remedy ([18]). The use of butyl and isobutyl nitrate, substances used by the gay community and drug abusers, can cause potentially fatal methemoglobinemia ([19]).

TABLE 49.1. Agents Implicated in Acquired Methemoglobinemia

Direct oxidants	Indirect agents	Aminobenzenes
Therapeutic agents	Sulfonamides	Aminophenol
Amyl nitrite	Dapsone	Benzocaine
Ethyl nitrite	Sulfamethizole	Lidocaine
Sodium nitrite	Sulfanilamide	Nitrobenzene
Ammonium nitrate	Sulfapyridine	Nitroethane
Silver nitrate	Sulfathiazole	Nitrofurans
Bismuth subnitrate	Prontosil	Nitrotoluenes
Nitroglycerin	Aniline dyes	Phenacetin
Quinones	Diaper-marking ink	Phenazopyridine (Pyridium)
Domestic and industrial agents	Dyed blankets	Phenylenediamine
Well water high in nitrates	Laundry markings	Prilocaine
Food high in nitrates	Freshly dyed shoes	Primaquine
Nitrous gases (arc welders, silo fillers)	Red wax crayons	Procaine
Corning extract	Miscellaneous compounds	Resorcin
Butyl nitrite (“room odorizers”)	Acetanilid	Toluenediamine
Potassium chlorate	Acetylphenylhydrazine	Trinitrotoluene

An indirect effect is postulated for certain aromatic amino and nitro compounds, including acetanilid (Bromo-Seltzer), phenacetin (APC, Empirin, Anacin, Stanback), sulfonamides, phenazopyridine (Pyridium) ([20]), and aniline dyes. Because most of these agents do not produce methemoglobin *in vitro*, active intermediate compounds are presumed responsible. The ingestion of deodorant containing naphthalene and aniline ([21]) or red wax crayons containing p-nitroaniline ([22]); contact with marking ink ([23]), dyed blankets, or laundry marks on diapers ([24]); and benzocaine ([25]), prilocaine, resorcinol ([26]), aniline dyes, nitrobenzene ([27]), or other aromatic compounds absorbed orally, rectally, or percutaneously have led to methemoglobinemia. Exposure to such compounds industrially also has been reported to produce methemoglobinemia. Exposure to naphthalene has been associated with met-hemoglobinemia in glucose-6-phosphate dehydrogenase (G6PD)–deficient infants, and malaria prophylaxis has been reported as provoking methemoglobinemia in unsuspected heterozygotes deficient in NADH–cytochrome b_5 reductase. Dapsone given for the prophylaxis and treatment of *Pneumocystis carinii* pneumonia in immunocompromised patients is a well-documented cause for methemoglobin ([28], [29], [30], [31] and [32]). Cimetidine is reported to ameliorate the degree of methemoglobinemia in patients for whom dapsone therapy is essential ([33]). Methemoglobinemia that follows the ingestion of nitroethane artificial fingernail remover may be delayed and recurrent ([34]). The inhalation of nitric oxide as premedication for endoscopy or for the treatment of pulmonary edema has been implicated as a cause of severe methemoglobinemia ([35], [36]). Endogenous overproduction of nitric oxide may be responsible for methemoglobinemia in children with septic shock ([37]). Transient methemoglobinemia unassociated with apparent oxidant or drug exposure has been described in young infants with gastroenteritis and metabolic acidosis ([38], [39] and [40]). Methemoglobin levels as high as 67% have been observed. Some infants have had transient organic aciduria ([41]). The basis for met-hemoglobinemia in sick infants is likely multifactorial, involving enteric colonization by nitrate-generating bacteria and accelerated autooxidation of oxyhemoglobin by acidosis and hyperchloremia ([42]) as well as limited capacity for methemoglobin reduction. Colonic inflammatory changes induced by cow milk or soy-milk protein appear to be operative in some infants with diarrhea-associated methemoglobinemia ([43]). The rapidity of methemoglobin production depends on several factors: (a) the extent and rate of entry of the compound into the circulation and erythrocytes, (b) the metabolism of the offending chemical compounds within the body, (c) the extent to which the compound is converted to intermediates with either increased or decreased oxidizing potential, (d) the excretion of the compound, and (e) the rate at which erythrocytes reduce methemoglobin to Hb. Thus, the effect of nitrite introduced intravenously is expended within 1 hour, whereas the peak effect of nitrobenzene is not reached until 12 to 15 hours after exposure ([44]). The extent to which these factors are influential in different persons may vary, and this variation may explain why some seem to be more likely to develop methemoglobinemia than others.

CLINICAL FEATURES Symptoms vary in intensity, but they often are mild or absent altogether. Concentrations of 10 to 25% methemoglobin, although producing cyanosis, are tolerated without ill effects; at 35 to 40%, slight exertional dyspnea and headaches, as well as fatigue, tachycardia, and dizziness, may be experienced. Lethargy and stupor may appear with concentrations of approximately 60%; the lethal concentration for adults probably is greater than 70%. With the exception of infants, methemoglobin concentrations rarely approach lethal levels. Toxic methemoglobinemia may be associated with hemolytic anemia caused by the precipitation of Hb to form Heinz bodies ([20]). Signs of toxicity in patients with acquired methemoglobinemia are greater than would be expected from a comparable decrement in the red cell mass. This observation is explained by the tendency of oxidized heme to increase the oxygen affinity of the remaining functional heme groups in the Hb tetramer ([45]). As a result, tissue hypoxia resulting from loss of the oxygen-carrying capacity of blood is compounded by less efficient unloading of oxygen from Hb.

TREATMENT In the absence of symptoms, simple avoidance of the offending oxidant is sufficient to permit conversion of methemoglobin to Hb by physiologic mechanisms. Patients who are symptomatic or in whom a rapid increase in methemoglobin concentration has occurred are best given methylene blue intravenously. As noted previously, this substance is an effective electron donor for NADPH-methemoglobin reductase. In the presence of this enzyme and NADPH, methylene blue is rapidly reduced to leukomethylene blue, which in turn reduces methemoglobin nonenzymatically (Fig. 49.1). The initial dose is 1 mg/kg body weight in a 1-g/dl solution given over 5 minutes. Twice this amount is used for symptomatic infants. A second dose of 2 mg/kg body weight may be given if cyanosis has not cleared within 1 hour. Cumulative doses in excess of 7 mg/kg cause dyspnea, precordial pain, restlessness, apprehension, a sense of oppression, fibrillar tremors, persisting cyanosis, and hemolytic anemia ([46]). In patients with more than 70% methemoglobin, automated red cell exchange has been used to achieve a rapid restoration of red cell oxygenation ([47]). Reduction of methylene blue to leukomethylene blue requires an intact pentose phosphate pathway for regeneration of NADPH. Consequently, methylene blue has no effect on methemoglobin levels in patients with G6PD deficiency. Because of its oxidant properties, methylene blue may trigger hemolytic episodes in G6PD-deficient individuals ([48]). Such subjects are best managed with exchange transfusions to restore reduced Hb ([49]). Because of the slow rate at which it reduces methemoglobin, ascorbic acid has no place in the treatment of toxic methemoglobinemia.

Hereditary Methemoglobinemia

In contrast to acquired methemoglobinemia, the hereditary forms are rare. An autosomal-recessive mode of transmission characterizes familial methemoglobinemia due to NADH–cytochrome b_5 reductase deficiency, and an autosomal-dominant mode is characteristic of the Hb variants that stabilize iron in the oxidized state. Congenital deficiency of NADPH–cytochrome b_5 reductase is not associated with methemoglobinemia ([50]).

NICOTINAMIDE ADENINE DINUCLEOTIDE (REDUCED FORM)–CYTOCHROME b_5 REDUCTASE (NICOTINAMIDE ADENINE DINUCLEOTIDE–METHEMOGLOBIN REDUCTASE, DIAPHORASE) DEFICIENCY ([51])

Hereditary methemoglobinemia responsive to the administration of methylene blue or ascorbic acid was described initially in cases involving persons of European extraction. After the demonstration that these individuals were deficient in NADH-dependent cytochrome b_5 reductase, a near-global distribution of the disorder was recognized. Congenital deficiency of NADH–cytochrome b_5 reductase has been recognized as the cause of methemoglobinemia among Navajo and Alaskan Indians ([9]), Cubans, Puerto Ricans ([52]), North Africans, Arabs ([53]), Hindu, Chinese ([54], [55]), Japanese ([56]), Siberians, and blacks ([57], [58]). Most reports are descriptions of sibships derived from inbred populations. Most affected subjects are homozygous for a rare, functionally abnormal allele of the enzyme ([57]), although double heterozygosity for two different variants is well documented ([59], [60]). The carrier or heterozygous state is characterized by intermediate levels of enzyme activity together with a greater than normal susceptibility to methemoglobin formation after exposure to oxidant drugs and chemicals ([61]). Two clinically distinct syndromes are recognized. They are due to deficient activity of two different forms of the enzyme. Type I NADH–cytochrome b_5 reductase deficiency is characterized by isolated methemoglobinemia and enzyme deficiency limited to red cells. Type II NADH–cytochrome b_5 reductase deficiency is characterized by mental retardation, spasticity, microcephaly, and growth retardation ([62], [63]). The enzyme defect is generalized and involves both soluble and membrane-bound forms of the enzyme. The membrane-bound enzyme, which is localized in the endoplasmic reticulum of

all somatic cells, participates in the destruction and elongation of fatty acids as well as in cholesterol synthesis and drug metabolism. Multiple variants of NADH–cytochrome *b* $_5$ reductase activity have been identified by electrophoretic, functional, and immunologic techniques ([54], [55], [58], [64], [65]). At least 14 different mutations have been described in families with type I enzyme deficiency, and 11 different mutations in families with type II disease ([55], [62], [65]). In addition, several electrophoretically distinct variants with normal catalytic activity have been described. The overall prevalence of these clinically silent variants is approximately 1 in 100 ([66]). The mutants responsible for type I enzyme deficiency have relatively normal enzyme activity but are unstable ([58], [67]), whereas the type II mutant enzymes have deficient catalytic efficiency ([68], [69] and [70]). Variants with distinctive physical and functional properties include Boston slow ([64], [71]), Duarte ([71]), Princeton ([71]), Gaza ([53]), Beni Messous, La Tronche, Grenoble, Puerto Rico ([52], [71]), and m $_S$ ([60]). Deficient enzyme activity is the result of exaggerated enzyme lability in at least some of the variants (Boston slow, Puerto Rico, Beni Messous, and La Tronche). Consequently, the distribution of methemoglobin is heterogeneous in peripheral blood cells, being greatest in the older, more dense population ([52], [59]). The sole clinical expression of erythrocyte enzyme deficiency is cyanosis, often dating from birth, in the absence of associated signs or symptoms. No digital clubbing or evidence of cardiopulmonary disease is apparent. Pregnancies are not compromised, and life expectancy is normal. Affected individuals are “more blue than sick.” The contrast is especially striking if cyanosis is pronounced. The hue may be slate-gray, gray-brown, or violet. Cyanosis is apparent over the entire body, but it is particularly noticeable in the lips, the mucous membranes of the mouth, the tongue, the palate, the nose, over the cheekbones, on the ears, and in the nail beds. Erythrocytosis, if present, is mild. A variant of unusual severity was described in patients from the Yakut region of Siberia, where erythrocytosis (red cell count as high as 7.0×10^{12}/L), reticulocytosis, and hyperbilirubinemia are associated features ([72]). Hereditary deficiency of NADH–cytochrome *b* $_5$ reductase involving all cells is phenotypically similar to the disorder caused by isolated red cell enzyme deficiency except for associated mental retardation, spasticity, opisthotonos, microcephaly, and growth retardation ([63], [73]). Evidence of neurologic disease is apparent by 2 to 3 months of age, and death may occur as early as 1 year of age. Because cytochrome *b* $_5$ reductase plays an important role in lipid metabolism by brain microsomes, the neurologic disorder presumably is a consequence of defective myelin production. Untreated individuals generally maintain levels of met-hemo-globin between 15 and 30%. Most of the methemoglobin is segregated in older cells. Oxidation of one heme group in the Hb tetramer increases the oxygen affinity of the remaining ferrohemes ([45]). As a result, the oxygen dissociation curve may be shifted slightly to the left, and mild compensatory erythrocytosis may be noted ([54]). Red cell survival is normal ([72]). Screening tests for the detection of deficient red cell NADH–cytochrome *b* $_5$ reductase have been described. One requires the addition of nitrited blood to a reaction mixture freshly prepared from stable stock reagents ([74]). It is based on disappearance of fluorescence because of NADH consumption, a principle used in the detection of other red cell enzyme deficiencies. Another screening test takes advantage of the brown color that results from the addition of ferricyanide to blood and its failure to change to red when NADH is added ([75]). Assay of enzyme is required for confirmation of the diagnosis ([76]). Measurement of enzyme activity in amniotic fluid cells has been used to identify affected fetuses in families with type II cytochrome *b* $_5$ reductase deficiency ([77]). Treatment is rarely necessary except for cosmetic purposes. Methylene blue in oral daily doses of 100 to 300 mg and ascorbic acid (500 mg daily) are usually sufficient to maintain the methemoglobin level below 10% in both type I and type II NADH-dependent cytochrome *b* $_5$ reductase deficiency. When used for protracted periods, methylene blue may cause urinary tract irritation, and ascorbic acid may induce renal stones due to hyperoxaluria ([78]). Riboflavin in daily oral doses of 20 to 60 mg may be as effective as ascorbic acid ([79]). Methemoglobin is reduced after the intravenous injection of methylene blue (1 mg/kg). Thereafter, it increases gradually, reaching pretreatment levels after 10 to 14 days.

CYTOCHROME *b* $_5$ DEFICIENCY Congenital deficiency of cytochrome *b* $_5$ was implicated as the cause of life-long methemoglobinemia in a Yemenite Jew ([80]). Although red cell cytochrome *b* $_5$ reductase activity was normal, red cells and red cell hemolysates failed to reduce methemoglobin normally. The addition of the purified reductase was without effect, whereas the addition of cytochrome *b* $_5$ normalized methemoglobin reduction. This case illustrates the importance of the cofactor cytochrome *b* $_5$ for methemoglobin reduction *in vivo*. Elevated levels of methemoglobin (15 to 19%) were effectively reduced with methylene blue.

HEMOGLOBIN M DISORDERS Hbs designated *M* are characterized by amino acid substitutions that create an abnormal environment for the heme residue, displacing the equilibrium toward the oxidized (ferric) state. Familial cyanosis having an autosomal-dominant inheritance pattern was recognized in Japan as early as 1800. This condition, originally described as *hereditary nigremia*, was restricted to the Iwate district of Honshu. The Hb variant now known to be responsible for this disorder is referred to as *HbM Iwate*. In recent years, HbM variants have been recognized in a variety of ethnic groups in North America, Europe, and Africa. Seven HbM variants have been identified and characterized (Table 49.2). In six of the seven, tyrosine is substituted for histidine in the heme pocket of the globin chain. The affected moiety is the proximal a-chain histidine (E7) in HbM Boston, the distal a-chain histidine (F8) in HbM Iwate ([81]), the proximal ß-chain histidine (E7) in HbM Saskatoon, the distal ß-chain histidine (F8) in HbM Hyde Park ([82]), the proximal ^{G}?-chain histidine (E7) in HbF M Osaka ([83]), and the distal ^{G}?-chain histidine (F8) in HbF M Fort Ripley ([84]). In each of these variants, the phenolic group of tyrosine forms covalent bonds with heme iron, thus stabilizing iron in the oxidized form ([81], [85]). The substitution in HbM Milwaukee (ß67 Val?Glu) also involves the heme pocket. The carboxylic group of the substituted glutamate is of sufficient length to form a bond with iron ([86], [87]). Other Hb variants, such as Hb St. Louis ([88]), also oxidize abnormally rapidly. Because of their instability, however, they are characterized by hemolytic anemia (see Chapter 41) rather than by methemoglobinemia. The oxygen affinity of HbM Boston, HbM Iwate, and HbM Milwaukee is decreased, and that of Hb Saskatoon and Hb Hyde Park is normal ([82], [85]). The a-chain variants have nearly absent Bohr effect in contrast to preserved Bohr effect in the ß-chain variants.

TABLE 49.2. Hemoglobin (Hb) M Disorders

Hb	Substitution	Oxygen Affinity	Bohr Effect
HbM Boston [a]	a58(E7)His?Tyr	Decreased	Decreased
HbM Iwate [b]	a87(F8)His?Tyr	Decreased	Decreased
HbM Saskatoon [c]	ß63(E7)His?Tyr	Normal	Normal
HbM Hyde Park [d]	ß92(F8)His?Tyr	Normal	Normal
HbM Milwaukee	ß67(E11)Val?Glu	Decreased	Normal
HbFM Osaka	^{G}?63(E7)His?Tyr	Unknown	Unknown
HbFM Fort Ripley	^{G}?92(F8)His?Tyr	Unknown	Unknown

[a] HbM Boston is identical to HbM Kiskunhalas and HbM Osaka.

[b] HbM Iwate is identical to HbM Kankakee and HbM Oldenburg.

[c] HbM Saskatoon is identical to HbM Arhus, HbM Chicago, HbM Emory, HbM Erlangen, HbM Hida, HbM Kurume, and HbM Radom.

[d] HbM Hyde Park is identical to HbM Akita.

Clinically, the HbM disorders are characterized by cyanosis without dyspnea, clubbing, or other signs or symptoms of disease. Individuals with HbM Boston and HbM Iwate are cyanotic from birth, because the a-chains of HbF are also affected by the mutation. Cyanosis is not apparent in infants with the ß-chain variants until they are 3 to 6 months of age. The two ?-chain variants are characterized by transient cyanosis in the first weeks of life ([83], [84]). The cyanosis resulting from methemoglobinemia may be compounded by Hb desaturation in variants associated with low oxygen affinity. Mild hemolytic anemia has been observed in some individuals with ß-chain variants ([85], [89], [90]). Methemoglobin is distributed uniformly among peripheral blood erythrocytes. HbM can be distinguished from other forms of methemoglobinemia by the spectroscopic examination of an acid methemoglobin hemolysate. Instead of the normal absorption maxima at 502 and 632 nm, wavelengths lower than 632 nm are found. In addition, slight variations in the absorption spectra permit differentiation of the HbM variants. The M Hbs can also be identified by electrophoresis under appropriate conditions, which include an agar gel medium and a neutral pH. HbA is the major component, and HbM accounts for 15 to 30% of the total pigment in the a-chain HbM disorders and for 40 to 50% in the ß-chain HbM variants. The homozygous state for the M Hbs is presumably incompatible with fetal survival. Treatment is neither indicated nor possible. Methemoglobin levels are unaffected by methylene blue or ascorbic acid. The most important reason for confirming the diagnosis is the avoidance of unnecessary restrictions on activity and inappropriate diagnostic pursuits.

LOW-AFFINITY HEMOGLOBINS

The stable Hb variants that have reduced affinity for oxygen are listed in Table 49.3. Unstable mutants that exhibit a low oxygen affinity are characterized by hemolytic anemia rather than by cyanosis; these are discussed in Chapter 41.

TABLE 49.3. Low-Affinity Hemoglobin Variants

Hemoglobin	Substitution	Bohr Effect
Kansas	ß102(G4)Asn?Thr	Normal
Beth Israel	ß102(G4)Asn?Ser	Normal
Yoshizuka	ß108(G10)Asn?Asp	—
Agenogi	ß90(F6)Glu?Lys	—
Titusville	a94(G1)Asp?Asn	Decreased

Low-affinity Hbs have in common a right shift of the oxygen dissociation curve. At any given oxygen tension, the Hb is less saturated with oxygen than HbA. If the shift is of sufficient magnitude, arterial desaturation results in clinically apparent cyanosis ([91], [92]). The amino acid substitution in both Hb Kansas and Hb Beth Israel involves the ß102 residue, which is at the $a_1ß_2$ interface of the Hb molecule. The substituted amino acid prevents the formation of a stabilized bond between a_1 and $ß_2$ in the oxyhemoglobin or R (relaxed) conformation ([93]). Destabilization of oxyhemoglobin is sufficient to increase the partial pressure at which whole blood is half saturated from a normal value of 26 mm Hg to 70 mm Hg in Hb Kansas and 88 mm Hg in Hb Beth Israel ([92]). The mutation at ß108 in Hb Yoshizuka involves the $a_1ß_1$ contact, disrupting the overall conformation of Hb to favor the deoxyhemoglobin or T (tant) state. The exact mechanisms responsible for the low oxygen affinity of Hb Agenogi, Hb Yoshizuka, and Hb Titusville ([94]) are not as well defined.

Both Hb Kansas and Hb Beth Israel are characterized clinically by cyanosis unassociated with symptoms or apparent exercise intolerance. Arterial blood is approximately 50% saturated with oxygen despite normal oxygen tension. The inheritance pattern for most of the Hb variants with altered oxygen affinity is autosomal dominant. Hb Beth Israel, however, appears to have arisen as a spontaneous mutation ([92]). Tissue oxygenation is normal, and, as a result, erythrocytosis does not occur. Mild anemia, noted in many individuals with low-affinity Hbs, is related to improved oxygen delivery, hemolysis, or both.

Unexplained cyanosis in association with normal arterial oxygen tension should prompt a search for a low-affinity Hb. Most, but not all, variants are detected by starch gel electrophoresis at an alkaline pH. Hb Kansas, Hb Beth Israel, and Hb Agenogi move slightly more slowly, and Hb Yoshizuka slightly faster than HbA.

Robert T. Means, Jr.

Erythrocytosis

DEFINITIONS AND TERMINOLOGY

The terms *polycythemia* and *erythrocytosis* are often used as if they are interchangeable; in fact, they describe related but distinct findings that usually, but not always, coexist. *Polycythemia* ("many cells") describes an increase in the total quantity or volume (mass) of red blood cells in the body without any implication regarding leukocytes or platelets. An increase in the *concentration* of erythrocytes, however, whether measured as number of cells, hemoglobin (Hb), or packed cell volume (hematocrit), is more correctly designated *erythrocytosis*. Erythrocytosis may be the result of an increase in the red cell volume or mass (polycythemia; also called *absolute erythrocytosis*) or the result of a reduced plasma volume (called *relative* or *spurious* polycythemia or erythrocytosis), which produces an increase in red cell concentration that does not reflect an increase in the quantity of red cells in the body.

Despite the precision with which these terms are defined, opportunities for confusion abound. *Polycythemia vera* (also called *polycythemia rubra vera*) is a myeloproliferative disorder associated with trilineage marrow hyperplasia and characterized by an increased red cell mass, usually in association with leukocytosis and thrombocytosis. The outdated term *erythremia* refers to this disease (see Chapter 85). Some patients who do not have this myeloproliferative disease are described as having polycythemia vera simply because they have an elevated red cell mass [i.e., their polycythemia is "true" ("vera")]. Such errors are frequently encountered in consultative practice.

PATHOLOGIC PHYSIOLOGY

Red cell survival in polycythemic states is typically normal, implying that increased red cell mass reflects increased erythropoiesis. As the red cell mass rises, the total blood volume typically increases: The variability of changes in plasma volume means that the degree of increase is unpredictable ([1]).

The clinical manifestations of erythrocytosis are related in part to the disorder responsible for erythrocytosis [e.g., thrombosis in patients with polycythemia vera ([2]), hypertension in relative polycythemia ([3]), and so on]. In addition, the increased blood volume and increased blood viscosity that occur in association with polycythemia themselves produce certain symptoms and signs; these are related to the degree of the increase and the resulting effects on blood flow and oxygen transport ([4]). Thus, the "ruddy cyanosis" seen in patients with polycythemia vera is a consequence of dilatation of cutaneous vessels by expanded blood volume and sluggish local circulation caused by increased blood viscosity ([5] , [6]). Headache, dizziness, tinnitus, a full feeling in the head, and a bleeding tendency may develop in patients with erythrocytosis and expanded blood volume regardless of the basic cause ([7]). These symptoms usually are relieved by normalization of the hematocrit.

Blood Viscosity and Oxygen Transport

Viscosity is an intrinsic characteristic of a liquid and represents the tendency of that liquid to resist changes in shape. The viscosity of blood is a result of the interaction of several factors, including the red cell concentration [referred to in this section as the *volume of packed red cells* (VPRC)], the physical characteristics (deformability, aggregability, and size) of red cells, the plasma volume, plasma proteins, platelet count, and leukocyte number and character ([8]). As discussed below, the blood viscosity affects the oxygen content and delivery. This section focuses primarily on the contribution of red cell concentration to viscosity and oxygen transport; more complete discussions are available elsewhere ([8]).

The rate of flow of a liquid through a tube of fixed length is directly related to the pressure gradient across that length of tube and to the radius raised to the fourth power (r^4) and inversely related to the viscosity of that liquid (Poiseuille law) ([9] , [10]). Determinations of the effects of erythrocytosis on blood viscosity were largely made by determining the flow rate of venous blood through an 18-gauge needle under known pressure and thus calculating viscosity ([9]). The values thus determined are only an approximation. Poiseuille law is strictly applicable only to fluids that maintain constant viscosity under differing flow rates; this is not the case with blood (Fig. 50.1) ([6] , [10]). As the velocity of flow (indicated by the shear rate) increases, the viscosity at any given VPRC decreases ([10]). Other factors that interact with the VPRC to contribute to viscosity are the mean erythrocyte corpuscular volume (MCV) and mean corpuscular Hb (MCH) ([11] , [12] and [13]). At any given VPRC, decreased MCV or MCH (or both) is associated with increased viscosity, especially at low flow rates ([12] , [13]). This is a clinically significant observation, because iron deficiency with a normal Hb or hematocrit is a common endpoint of the treatment of polycythemia by phlebotomy.

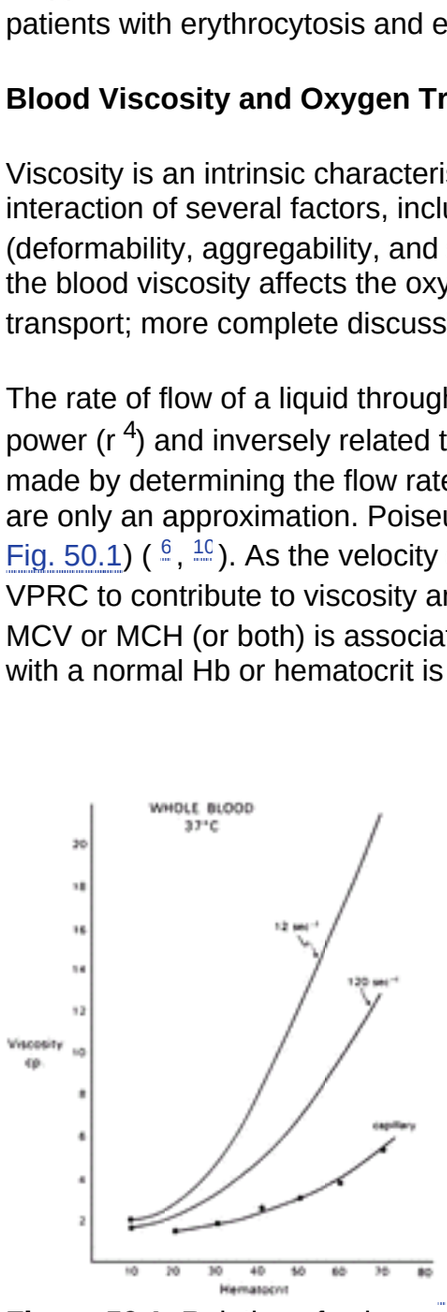

Figure 50.1. Relation of volume of packed red cells (hematocrit) to blood viscosity in centipoise (cp) as measured in a capillary viscosimeter compared with that calculated for shear rates of 120 sec^{-1} (ascending aorta) and 12 sec^{-1} (medium arteriole). (From Wells RE Jr, Merrill EW. The variability of blood viscosity. Am J Med 1961;31:505, with permission.)

It is noted above that the model for determining blood viscosity represents a somewhat artificial system: Calculated values probably exceed those existing *in vivo* ([10]). However, studies of cerebral blood flow in patients with erythrocytosis of various etiologies have demonstrated the clinical effects of an elevated hematocrit on *in vivo* blood flow ([14] , [15] , [16] and [17]). Cerebral blood flow in patients with erythrocytosis due to an elevated red cell mass ([14]), due to reduced plasma volume ([16] , [17]), or of

unknown etiology ([15]) was significantly reduced compared to controls (Table 50.1). Hematocrit reduction, either by venesection ([14], [15], [16] and [17]) or by volume expansion ([17]), improved cerebral blood flow.

TABLE 50.1. Effect of Erythrocytosis on Cerebral Blood Flow (CBF)

Etiology of Erythrocytosis (No. Patients)	Reference	CBF (ml/100 g/min)	Percent Normal CBF
Polycythemia (16)	14	37.9 ± 11.2	54.8 ± 16.2
Mixed (38)	15	41.4 ± 10.5	63.6 ± 16.2
Relative polycythemia	16		
High-normal red blood cell mass (21)		45.8 ± 10.9	66.8 ± 15.9
Low plasma volume (18)		48.8 ± 12.9	71.1 ± 18.8
Relative polycythemia (5)	17	40.7 ± 5.4	59.9 ± 7.8

NOTE: Values expressed as mean ± standard deviation.

The determination of blood viscosity values at different VPRC allows the estimation of blood flow rates under different conditions. As Poiseuille law predicts (and the data in Table 50.1 imply), blood flow decreases linearly with increasing viscosity ([18]). The rate of oxygen transport can then be calculated from the blood flow rate and oxygen content. At a given vessel size and pressure gradient, the predicted relation of oxygen transport to VPRC is expressed by an arch-shaped curve (Fig. 50.2A) ([9], [18], [19]). At low VPRC, the reduced Hb content of blood translates into reduced oxygen content. At elevated VPRC (>0.5 to 0.6), increased viscosity reduces oxygen transport despite increased blood oxygen content. Optimal oxygen transport would be predicted to occur in the normal hematocrit range ([18], [19], [20] and [21]). Experiments in normovolemic dogs (Fig. 50.2B, dashed line) support this prediction ([19]).

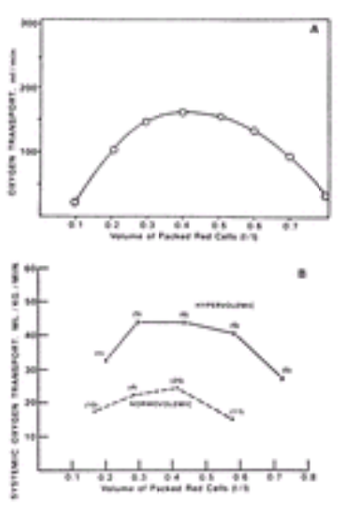

Figure 50.2. Arterial oxygen transport at different volumes of packed red cells and thus different viscosity values. **A:** Values in curve were calculated from blood viscosity values as measured by Pirofsky ([9]). **B:** Systemic oxygen transport as calculated from cardiac output measured in normo-volemic and hypervolemic dogs. (From Murray JF, Gold P, Johnson BL Jr. The circulatory effects of hematocrit variations in normovolemic and hypovolemic dogs. J Clin Invest 1963;42:1150–1159, with permission.)

The differences in oxygen transport observed between normovolemic and hypervolemic dogs at different VPRC (Fig. 50.2B) reflect the probable situation occurring in patients with erythrocytosis due to an expanded red cell mass (polycythemia). In polycythemia, the associated hypervolemia permits an oxygen transport curve that is similar to that of normovolemic patients but which is elevated and shifted to the right ([19], [22]). Therefore, in patients with tissue hypoxia, polycythemia is beneficial because it leads to hypervolemia and increases oxygen transport (compare oxygen transport at VPRC 0.6 on the hypervolemic and normovolemic curves in Fig. 50.2B). In contrast, in patients who have a normal or decreased total blood volume (as in relative or spurious polycythemia), erythrocytosis has an adverse effect on oxygen transport.

RELATION TO TREATMENT OF POLYCYTHEMIA The considerations noted above are of interest in understanding not only the pathophysiology of the different etiologies of erythrocytosis but also their treatment. Patients with polycythemia vera have no need for increased tissue oxygen transport. In some areas where fixed vessel diameter (from arteriosclerosis) limits increased blood flow, however, the additional impeding effect of increased blood viscosity may limit oxygen transport and result in local tissue ischemia. Phlebotomy can bring about a significant clinical benefit (see Chapter 93). When treating by phlebotomy, however, blood volume should not be reduced too greatly at any one bleeding, especially in patients with known symptoms of cardiovascular disease (angina pectoris, transient ischemic attacks). This is particularly true early in the course of therapy, when hematocrit (and consequently viscosity) is highest ([23]). Rather, time should be allowed for hemodilution to occur between phlebotomies; in emergencies, the blood volume should be maintained by infusing saline or some other plasma expander ([24]). A concern is that the patient not suddenly be shifted from the hypervolemic, erythrocytosis-beneficial curve to the normo-volemic, erythrocytosis-adverse curve. Another concern is that a sudden fall in blood volume from any cause, such as dehydration or acute hemorrhage, may result in local ischemia because increased cardiac output cannot compensate immediately for the effects of high viscosity. In patients with congestive heart failure, the need for reduction of blood viscosity may be urgent, because the ability to increase cardiac output to compensate for the increased blood viscosity has been compromised. The oxygen-Hb dissociation curve is shifted to the right in such patients ([25]). In contrast to polycythemia vera, patients with polycythemia due to tissue hypoxia may benefit from increased VPRC. Reduced arterial oxygen saturation means that blood oxygen transport is less efficient at particular Hb or hematocrit levels. Therefore, the curves for oxygen transport would be shifted closer to the origin than those noted in situations in which Hb oxygenation is normal (Fig. 50.2B). In the presence of decreased arterial oxygen saturation, tissue hypoxia may persist even when erythrocytosis is marked. The main advantage to decreasing blood viscosity and blood volume in hypoxic (secondary) polycythemia is to decrease the cardiac workload. One would predict that in such situations an increase in tissue oxygen transport and clinical improvement should result from phlebotomy; results show that this is the case ([26]). Again, especially early in the course, phlebotomy with preservation of an expanded blood volume may be beneficial ([23], [24]). To achieve the best balance between increased cardiac work and decreased tissue hypoxia in patients with hypoxemic erythrocytosis, some authors suggest that the hematocrit be maintained between 0.50 and 0.55 ([24], [26]); however, the subjective symptomatology of the patient is usually the best guide ([18]).

CLASSIFICATION AND APPROACH TO THE PATIENT WITH ERYTHROCYTOSIS

As stated previously, erythrocytosis (an increase in red cell *concentration*) may result from decreased plasma volume or from *polycythemia*, which is an increase in the absolute quantity of red cells or red cell mass. The various forms of erythrocytosis are listed in Table 50.2. They are classified according to red cell mass (relative erythrocytosis or polycythemia vs. actual polycythemia). Polycythemia, in turn, is divided into primary polycythemia (*polycythemia vera* and *familial primary polycythemia*) and polycythemia driven by erythropoietin production (*secondary polycythemia*). The secondary polycythemic syndromes are divided into those that represent a response to tissue hypoxia (physiologically appropriate) and those driven by erythropoietin not produced in response to tissue hypoxia (physiologically inappropriate).

TABLE 50.2. Classification of Erythrocytosis

Relative erythrocytosis or polycythemia (pseudoerythrocytosis)
  Hemoconcentration
  Spurious polycythemia (Gaisböck syndrome)
Polycythemia (absolute erythrocytosis)
  Primary polycythemia
    Polycythemia vera
    Primary familial polycythemia
  Secondary polycythemia
    Secondary to decreased tissue oxygenation (physiologically appropriate polycythemia or hypoxic erythrocytosis)
      High-altitude erythrocytosis (Monge disease)
      Pulmonary disease
        Chronic cor pulmonale
        Ayerza syndrome
      Cyanotic congenital heart disease
      Hypoventilation syndromes
        Primary alveolar hypoventilation
        Pickwickian syndrome, Ondine curse
        Positional desaturation
        Sleep apnea
      Abnormal hemoglobins
        Inherited
        Acquired: drugs and chemicals, carboxyhemoglobin
      Familial polycythemia
    Secondary to aberrant erythropoietin production or response (physiologically inappropriate polycythemia)
      Tumors, cysts, hemangiomas, and so forth
      Androgen abuse
      Erythropoietin abuse
      Familial polycythemia
  Idiopathic polycythemia

An approach to the evaluation of the patient with erythrocytosis is outlined in Figure 50.3. Although polycythemia can usually be differentiated from relative erythrocytosis on clinical grounds (as described below), the measurement of red cell mass and blood volume is recommended as the initial step in evaluation. Normal values are presented in Table 50.3, but considerable variation exists from one subject to another in red cell, plasma, and total blood volume, even when expressed as milliliters per kilogram (ml/kg) body weight. This variation results, in part, from differences in body fat content ([27], [28], [29], [30] and [31]); blood volume is more closely related to lean body mass ([29]) than to weight or surface area. It has been proposed that a red cell mass of at least 125% of that predicted should be considered as indicating polycythemia ([32]). It is a common practice to measure either plasma volume or red cell volume and, from one of these determinations, to calculate total blood volume on the basis of the relative amounts as indicated by a hematocrit determination. In the view of most ([33], [34] and [35]), but not all ([11]), investigators, this practice is associated with an increased chance of error; measuring red cell mass and plasma volume separately is preferable. It must be emphasized that blood volume measurements do not differentiate between secondary polycythemia and polycythemia vera; they are useful only in distinguishing absolute from relative erythrocytosis. In men with a hematocrit greater than 60% or women with a hematocrit greater than 55%, there is reported to be greater than 99% likelihood that the red cell mass is elevated ([36]); although this is probably correct, it should be remembered that in certain circumstances of severe hemoconcentration [e.g., in the systemic capillary leak syndrome ([37])], hematocrits in this range may be observed in patients with a normal red cell mass. Such patients typically exhibit physical findings suggestive of severe intravascular volume depletion and redistribution of intravascular volume.

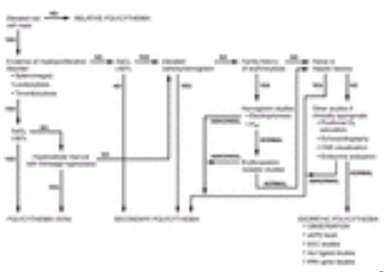

Figure 50.3. Approach to patients with erythrocytosis. CNS, central nervous system; EEC, endogenous erythroid colonies; SaO_2, arterial oxygen saturation; sEPO, serum erythropoietin.

TABLE 50.3. Normal Values for Red Blood Cell, Plasma, and Total Blood Volume (ml/kg ± 1 Standard Deviation [a])

	No.	Red Blood Cells	Plasma	Total Blood Volume
Women				
Sea level				
Wennesland, et al. (30)	97	25.4 ± 2.6	36.8 ± 3.7	—
Huff and Feller (27)	20	24.4 ± 2.6	34.8 ± 3.2	58.9 ± 4.9
Men				
Sea level				
Wennesland, et al. (30)	199	28.3 ± 2.8	34.4 ± 4.0	—
Huff and Feller (27)	42	28.3 ± 4.1	33.5 ± 5.2	61.5 ± 8.6
Weil, et al. (39)	16	27.1 ± 3.7	33.0 ± 5.3	60.0 ± 8.6
1600 m [b]				
Weil, et al. (39)	19	26.8 ± 3.2	31.9 ± 3.6	58.7 ± 5.8
3100 m [b]				
Weil, et al. (39)	39	31.8 ± 6.7	35.2 ± 5.3	66.8 ± 8.5

[a] Red blood cell volume measured by ^{51}Cr method. Other values calculated without correction for trapped plasma.

[b] Only values of which we are aware at altitudes significantly above sea level. They may be somewhat low for unknown reasons; the packed cell volumes at 1600 m were the same as at sea level, a finding that contradicts our own large experience.

The goal of the approach outlined in Figure 50.3 is initially to distinguish spurious (relative) polycythemia from actual polycythemia; then to distinguish polycythemia

vera from secondary polycythemia and primary proliferative polycythemia; to rule out other primary polycythemia; and finally to identify the etiology of secondary polycythemia. The characteristics of polycythemia vera are outlined in Chapter 85; the other polycythemic syndromes are discussed below. A certain number of patients are not readily classified as having either polycythemia vera or secondary polycythemia. These patients fall into a category called (for want of a more physiologic term) *idiopathic polycythemia* and appear to represent a heterogeneous group of disorders (see below).

Two tests that do not appear in the routine evaluation of erythrocytosis described in Figure 50.3 are the serum erythropoietin level and the formation of erythroid colonies *in vitro* in the absence of added erythropoietin ["endogenous erythroid colonies" (EEC)]. The role of serum erythropoietin levels in the evaluation of erythrocytosis has been well evaluated in a number of studies (Table 50.4) ([38], [39] and [40]). Although mean serum erythropoietin concentration in the subset of patients with polycythemia vera is significantly lower than that observed in secondary polycythemia, there is considerable overlap, making it less useful for individual cases. This would be expected physiologically. A patient with secondary polycythemia due to tissue hypoxia would have an elevated serum erythropoietin level until the hematocrit was sufficiently high to adequately oxygenate tissue; then the erythropoietin concentration would be expected to decrease. The intermittent nature of detection of an elevated serum erythropoietin concentration in secondary polycythemia has been described ([41]), as has the failure of serum erythropoietin concentrations to predict clinical course in idiopathic erythrocytosis ([42]). Studies have been reported demonstrating that polycythemia vera and secondary polycythemia can be distinguished based on the serum erythropoietin response to phlebotomy: After phlebotomy, serum erythropoietin levels increase in secondary polycythemia but remain stable in polycythemia vera ([43]). Methods for detecting low serum erythropoietin concentrations are probably not sufficiently sensitive that a low serum erythropoietin can be considered as ruling out secondary polycythemia ([44]).

TABLE 50.4. Serum Erythropoietin Levels in Erythrocytosis

	Mean Serum Erythropoietin Concentration (U/L)		
Normal	6.7 (3.3–13.5)	15 ± 4	25 (18–35)
Polycythemia vera	2.1 ± 1.0	17 ± 8	16 (8–22)
Secondary polycythemia	121.7 ± 242.0	94 ± 101	30 (14–23)
Relative polycythemia	7.0 ± 2.5	—	23 (17–39)
Reference	38	40	39

NOTE: Values expressed as mean ± standard deviation or as mean (range).

EEC are described as a hallmark of myeloproliferative disorders ([45], [46]); however, they do not absolutely distinguish polycythemia vera and secondary polycythemia nor are they observed in all polycythemia vera patients. EEC corresponding to erythroid burst-forming units were observed in 12 of 17 polycythemia vera patients, 3 of 11 secondary polycythemics, 1 of 6 relative polycythemics, and 1 of 11 normal individuals in one series ([47]). EEC corresponding to erythroid colony-forming units (CFU-E) have also been described and represented of total CFU-E in polycythemia vera patients, 3.6 ± 2.8% of total CFU-E in secondary polycythemics and patients with elevated endogenous erythropoietin levels, and 0.2 ± 0.3% of total CFU-E in normal persons ([48]). Flow cytometry–based techniques for detecting EEC have been described that may make this diagnostic technique (now primarily available through research laboratories) available on a more routine basis ([49]).

Soluble transferrin receptors are typically elevated in all forms of polycythemia and thus do not distinguish polycythemia vera and secondary polycythemia ([50]).

RELATIVE POLYCYTHEMIA

Lowered fluid intake, marked loss of body fluids, or a combination of both causes a decrease in plasma volume and may produce a relative erythrocytosis. The decrease in plasma volume may result from any cause of intravascular fluid loss, insensible fluid loss, persistent vomiting, severe diarrhea, copious sweating, postoperative complications, or shift of fluid into the extravascular space ("third-spacing") ([37], [51], [52]) or may be an effect of high altitude ([53]). In severe burns, plasma loss leads to hemoconcentration.

Chronic relative polycythemia or erythrocytosis has been variously referred to as *Gaisböck syndrome* ([48], [54]), *"stress" erythrocytosis* ([3]), *benign polycythemia* ([52]), *benign erythrocytosis* ([55]), *spurious polycythemia* ([56], [57]), *pseudopolycythemia* ([58]), and *apparent polycythemia* ([59]). The last three terms are the most accurate: In the absence of an elevated red cell mass, there is no polycythemia. In one series of 215 patients referred with a diagnosis of polycythemia vera ([60]), 18 (8.3%) were believed to have chronic relative erythrocytosis, possibly caused by "stress" ([3]). Patients with relative polycythemia or erythrocytosis are typically male; the mean age at diagnosis is less than is seen in patients with polycythemia vera ([59]). Obesity is typically described as an associated feature ([3]), although not all studies support this association ([61]). Other features reported to be strongly associated with relative polycythemia are hypertension and smoking ([59], [61], [62]); associations with alcohol abuse and renal disease are occasionally reported ([59], [60]). It is probable that this syndrome is not a true clinical entity ([57], [63]). The red cell mass values generally accepted as normal at sea level, or at any given altitude, represent the mean ± 2 standard deviations. Thus, on the basis of the normal frequency distribution curve for this physiologic parameter, the values in 2.5% of the population are above this range. The individuals in this group should not be regarded as necessarily abnormal ([63]).

The optimal management of relative polycythemia is unknown. As noted previously, phlebotomy increases cerebral blood flow even in patients with relative polycythemia; whether it is of symptomatic benefit is less clear ([16], [17]). It should probably be avoided. Theoretic arguments can be made that contracting the blood volume further in these patients who already are normovolemic or slightly hypovolemic may impair tissue perfusion. Satisfactory control of hematocrit can be obtained in at least two-thirds of patients by reduction of excess weight, improved hypertension control, avoidance of diuretics, and reduction if not cessation of smoking ([61]). Potentially leukemogenic cytoreductive therapy, such as radioactive phosphorus or oral chemotherapeutic agents, is probably never indicated.

POLYCYTHEMIA (ABSOLUTE ERYTHROCYTOSIS)

Primary Polycythemia

POLYCYTHEMIA VERA Polycythemia vera is discussed in Chapter 85.

PRIMARY FAMILIAL POLYCYTHEMIA ("CHUVASH POLYCYTHEMIA") *Familial erythrocytosis* or *polycythemia* is a term used to describe instances in which two or more members of a family have polycythemia, do not have polycythemia vera, and have no identifiable "secondary" causes ([62], [64]). This finding can result from a constellation of pathophysiologic mechanisms, including abnormalities of oxygen-Hb interaction, or idiopathic constitutive erythropoietin secretion. These syndromes are discussed under etiologies of secondary polycythemia, below. *Primary familial polycythemia* is a term used to describe a syndrome observed in families with abnormalities of the erythropoietin receptor, resulting in hypersensitivity to erythropoietin and consequent erythrocytosis ([65], [66] and [67]). This particular autosomal-dominant trait does not necessarily confer an adverse prognosis early in life: The propositus of the first such family described was an Olympic gold medallist in cross-country skiing ([65]). However, these individuals are at increased risk for thrombotic and vascular mortality later on ([68], [69]). A variant of this syndrome occurs with high frequency among the people of the Chuvashia region of the former Soviet Union. These individuals appear to have a mutation in the oxygen-sensing pathway regulating erythropoietin production and also in the response of erythroid progenitors to erythropoietin ([70], [71] and [72]).

Secondary Polycythemia [Physiologically Appropriate (Hypoxic)]

Insufficient oxygen supply to the tissues may result from any of the following, alone or in combination: (a) decreased ambient oxygen pressure (e.g., high altitude); (b) pulmonary diffusion or mixing abnormalities; (c) right-to-left cardiopulmonary shunts, as in cyanotic congenital heart disease; (d) hypoventilation; or (e) altered oxygen-carrying affinity of Hb. In all of these disorders, insufficient tissue oxygenation leads to increased erythropoietin production and a consequent increase in red cell mass (see Chapter 7).

HIGH-ALTITUDE ERYTHROCYTOSIS In 1890, Viault showed that erythrocytosis develops during sojourn at high altitude ([73]). He found erythrocyte counts of 7.5 to 8.0 × 10^{12} cells/L not only in natives of the Peruvian Andes working in a mine at an altitude of 4392 m above sea level, but also in himself and in a traveling companion, although his blood count in Lima (160 m above sea level) had been normal. On a Mt. Everest expedition, researchers demonstrated that red cell volume and values of total Hb rose progressively as higher altitudes were attained; at 19,000 feet (5800 m), mean values were 49% above those at sea level. The increase in total blood volume was partially masked by reductions in plasma volume ([74]). Recent investigations of the control of erythropoiesis at high altitudes indicate that a sharp increase in erythropoietin production occurs within the first week of high-altitude exposure and is associated with mobilization of iron stores and evidence of iron-deficient erythropoiesis ([75]). Mechanisms of adaptation to living at high altitude apparently are multiple and differ between ethnic groups ([76] , [77]). The rapid ascent to high altitude is accompanied by symptoms of fatigue, dizziness, pulsating headache, anorexia, nausea, vomiting, insomnia, and irritability—a syndrome well known to mountain climbers and residents of high altitudes and referred to as *acute mountain sickness* ([78] , [79] and [80]). The symptoms first appear some 4 to 6 hours after reaching a high altitude but may be delayed for as many as 96 hours, suggesting that the pathogenesis represents more than simple hypoxia. The incidence is greatest in younger persons, in those flying to high altitude, or in those who climb fast and spend few nights acclimatizing. Gender, the weight of the load carried, and recent respiratory infection do not appear to affect the incidence ([81]). Severity is greatest in the young and correlates with the speed of ascent and the altitude reached ([81]). Thus, all persons develop symptoms if they are suddenly transported from sea level to 15,000 feet (4570 m) or higher, whereas a few develop symptoms at 8000 to 10,000 feet (2400 to 3000 m) ([74]). After 4 to 8 days, acclimatization usually occurs, and symptoms remit spontaneously ([78] , [81]). In some individuals, however, symptoms may progress to cerebral confusion, coma, and even death related to pulmonary edema unless the subject is returned to low altitude ([79] , [82]). The pathogenesis of acute mountain sickness may involve hypoxia and subsequent excessive secretion of antidiuretic hormone and adrenal steroids with resulting fluid retention, increased blood volume, and finally cerebral edema, pulmonary congestion, or both ([79] , [83]). The incidence and severity of symptoms can be considerably reduced by administering diuretics, such as acetazolamide or furosemide ([79] , [80] and [81]). The administration of dexamethasone has also proven effective in the prevention and treatment of this disorder ([84]). The events associated with acclimatization after arrival at high altitude are not understood completely but probably include the following: An increase in erythrocyte 2,3-diphosphoglycerate (DPG) levels and a shift to the right in the oxygen-Hb dissociation curve, thus allowing better tissue delivery of oxygen despite decreased arterial oxygen saturation ([77] , [82] , [85]). The increase in 2,3-DPG appears to compensate for the left shift in the curve that results from the initial hypocapnia and increase in arterial pH ([79] , [82]). Increased erythropoietin production with subsequent increase in iron mobilization (discussed above), reticulocytosis ([86]), and increase in red cell mass and blood volume. Correction of the initial excessive antidiuretic hormone and adrenal steroid secretion and return to the normal diurnal variation of plasma steroid levels ([79]). The final result is a new equilibrium at decreased oxygen saturation and carbon dioxide tension with increases in alveolar ventilation, respiratory frequency, and red cell mass ([78] , [84]). These manifestations of acclimatization are quickly lost on descent to sea level, even after many years of residence at high altitude. At an altitude of 15,000 feet, well-acclimated individuals had hematocrit values of approximately 0.60 and, although cyanotic, had no significant limitations of physical activity ([87]). This physiologic state is accomplished by hematologic adjustments and alterations in ventilatory rate, the diffusing capacity of the lungs, and the anatomic relation of capillaries to muscles ([76]), as well as increased levels of myoglobin ([76]) and altered enzymes within the muscle cell ([88]). Cardiac output remains normal despite the increase in blood viscosity imposed by polycythemia. In some individuals, however, after a few or many years of good adaptation, excessive erythrocytosis develops, and arterial oxygen saturation may fall to as low as 60% (normal, 81%). An incapacitating illness characterized by alveolar hypoventilation develops. This entity is known as *chronic mountain sickness* or *Monge disease* ([88]). Diminished mental acuity, headaches, dyspnea, fatigue, reduced physical fitness, nausea, vomiting, diminution of visual acuity, dizziness, tinnitus, vague or even excruciating pains in the extremities, paresthesias, and cough are characteristic symptoms. If the condition advances, symptoms include incessant dyspnea, aphonia, profound lethargy, and even coma. The face is bluish violet or almost black, the eyelids are edematous and bluish, the sclerae are intensely colored by distended capillaries, the tongue is thick, the hands are enlarged and turgid, the fingers are clubbed, and dependent edema may be observed. The thorax is more barrel shaped than in healthy inhabitants of the same region and altitude. Hypotension is often present. The spleen and the liver are infrequently enlarged, unless cardiac failure ensues. Erythrocytosis is more marked than in normal residents of high altitudes, with VPRC up to 0.84 L/L and Hb values as high as 28.0 g/dl. MCV is normal or slightly increased, and the mean corpuscular Hb concentration (MCHC) is normal ([87]). Normal reticulocyte and leukocyte counts are usually observed ([88] , [89]). Hyperbilirubinemia owing to unconjugated bilirubin may be pronounced. Red cell turnover is greater in these individuals than in normal residents of high altitudes ([90]). Platelet counts usually are normal or high, yet epistaxis is common, and hemoptysis, bleeding of the gums, and purpura may occur. Red cell volume is greatly increased (88 to 95 ml/kg body weight) ([90]). Affected individuals usually are in the fourth to sixth decade of life. Remissions and relapses are described. Ascent to still higher altitudes aggravates symptoms, whereas descent to sea level relieves them. Cardiac impairment does not appear until late in the disease course, and death occurs more often from hemorrhage, pulmonary tuberculosis, or bronchopneumonia than from cardiac insufficiency. At first, the disease was considered a distinct entity. It has been suggested that the disease is an exaggeration of the process of acclimatization and aging, because patients with chronic mountain sickness had Hb concentrations within the normally distributed values for large groups of native residents. Support for this suggestion comes from the observation that chronic lung disease increases the likelihood of chronic mountain sickness ([91]). Chronic mountain sickness has not been reported to occur in natives of the Himalayas ([92] , [93]). This may reflect in part occupational differences, namely mining, and a consequently high incidence of chronic lung disease in the Andes as compared with the pastoral occupation of the Sherpas. Differentiation of chronic mountain sickness from other causes of hypoxic polycythemia should not be difficult. Cases of congenital or acquired cyanotic heart disease can be distinguished by the cardiac findings. Polycythemia vera is not altered by increased ambient oxygen tension, whereas in Monge disease, descent to sea level produces complete relief of symptoms, together with a pronounced reduction in the blood volume and restoration of normal blood counts ([87]). Medroxyprogesterone also produces clinical and laboratory improvement, apparently by decreasing the frequency of periods of sleep apnea and accompanying arterial oxygen desaturation ([94] , [95]).

PULMONARY DISEASE A variety of diseases, such as chronic obstructive pulmonary disease, diffuse pulmonary infiltrates (fibrous or granulomatous), kyphoscoliosis, and multiple pulmonary emboli, lead to erythrocytosis as the result of inadequate oxygenation of the blood circulating through the lungs. Not all patients with lung disease and decreased arterial oxygen saturation, however, have elevated Hb or hematocrit levels ([96] , [97]), and only in approximately 50% is an increase in red cell mass noted ([98]). The reason for this suboptimal response to hypoxia is not clear, but it does not appear to result from a decrease in erythropoietin production or the presence of chronic infection ([96] , [97] and [98]). When polycythemia occurs, it usually is associated with increased MCV, reduced MCHC ([99]), and normal MCH ([96]) values. The red cell changes have been attributed to increased water uptake by the cell, which in turn may result from carbon dioxide retention ([96]). It has been suggested that carbon dioxide retention may inhibit the marrow response, but no confirmatory evidence is available ([96]). If polycythemia is present, it is corrected by chronic oxygen administration ([100]). Cavernous hemangiomas of the lung may be associated with erythrocytosis ([101]). Pulmonary arteriovenous fistulae should be suspected when a murmur is heard in a lung field in association with erythrocytosis, cyanosis, and other symptoms suggestive of a pulmonary disorder ([102] , [103] and [104]).

Chronic Cor Pulmonale The clinical picture of chronic cor pulmonale varies, but oxygen deficiency with arterial desaturation and elevated pulmonary artery pressure are of central importance ([105] , [106]). Polycythemia with its associated increase in blood viscosity and volume appears to be the physiologic price of a compensatory mechanism progressively extended to the point at which it is more injurious than beneficial ([107]). As in less severe pulmonary disease, the MCV of the red cells tends to be elevated, whereas the MCHC generally is decreased ([108]).

Ayerza syndrome (Primary Pulmonary Hypertension) Ayerza syndrome, characterized clinically by slowly developing asthma, bronchitis, dyspnea, and cyanosis (“black cardiacs”) with associated polycythemia, was described by Ayerza in 1901. The syndrome probably represents right-sided heart failure consequent to primary pulmonary hypertension ([109] , [110] and [111]).

CYANOTIC HEART DISEASE Red cell counts of 7.0 to 8.5 × 10^{12}/L are common in persons with congenital heart disease; counts as high as 10.0 to 13.9 × 10^{12}/L have been reported ([112]). Polycythemia occurs in patients with a partial shunt of the blood from the pulmonary circuit. The most common defects producing such polycythemia are pulmonary stenosis (usually with defective ventricular or atrial septum, patent foramen ovale, or patent ductus arteriosus), persistent truncus arteriosus, complete transposition of the great vessels, and the tetralogy of Fallot (pulmonary stenosis, defective ventricular septum, dextroposition of the aorta, right ventricular hypertrophy). Individuals with such defects exhibit evidence of disturbed cardiorespiratory function, marked cyanosis, clubbing of the fingers and toes, and sometimes stunted growth. The total plasma volume may be reduced to below normal levels, but the increase in the size of the red cell mass is so great that the total blood volume usually is higher than normal ([113] , [114]). Erythroid hyperplasia is observed in the marrow ([112] , [115]). The general consensus is that low oxygen tension resulting from shunting of unoxygenated blood through or around the lungs with consequent desaturation of the arterial blood stimulates erythropoietin production. The arterial oxygen saturation often is as low as 30 to 35%. With successful operative intervention, this value may be significantly corrected, with resolution of polycythemia.

ACQUIRED HEART DISEASE In acquired heart disease, such erythrocytosis as may develop is of minor degree and is correlated to some extent with the degree of cardiopulmonary decompensation. Polycythemia is reportedly accompanied by evidence of intensified erythropoiesis in the bone marrow, an increase in red cell mass, and some macrocytosis ([116]).

HYPOVENTILATION SYNDROMES Polycythemia is found occasionally in patients who exhibit no evidence of pulmonary disease or cardiovascular shunts. The primary defect in at least some of this group appears to be an inadequate ventilatory drive from the respiratory center in the brain ([105] , [117]). Such a defect has been reported in patients with the *Pickwickian syndrome*, so called because of the description of Joe, the hypersomnolent fat boy, in Dickens's *The Pickwick Papers* ([118]). In the setting of extreme obesity, these patients exhibit somnolence, cyanosis, and hypercapnia and may develop periodic respiration, ultimately with right ventricular failure. Voluntary hyperventilation alleviates the hypercapnia, and in many patients, loss of weight restores normal alveolar ventilation and reverses the syndrome ([105]

). Alveolar hypoventilation and erythrocytosis, however, do not develop in all obese individuals; it appears that only in the presence of an insensitive respiratory center does a massive panniculus limit respiratory function and result in alveolar hypoventilation, hypoxemia, and hypercapnia ([119]). In some patients, the decreased ventilatory drive is of unknown cause or is a result of idiopathic disease of the medullary respiratory center (Ondine curse) ([117] , [120]); other etiologies include bulbar poliomyelitis, vascular thrombosis, or previous encephalitis ([105] , [117]). In any case, the consequent hypoxemia results in elevated levels of erythropoietin and erythrocytosis, with hematocrits reported as high as 0.75 ([121]). Medroxyprogesterone acetate has been reported to be an effective treatment for the Pickwickian syndrome ([122]). Patients with polycythemia and positional arterial oxygen desaturation have also been reported ([123]). Whether this results from alveolar hypoventilation while supine or from shunting through an arteriovenous malformation while upright ([124]) is unclear. Obstructive sleep apnea has been associated with polycythemia (presumably due to episodic erythropoietin secretion during apneic episodes) in some ([125]) but not all ([126]) reports.

ABNORMAL HEMOGLOBINS

Inherited Abnormalities of Hemoglobin Certain mutant Hbs are characterized by increased oxygen, and patients who carry such Hbs tend to develop erythrocytosis ([127] , [128] , [129] , [130] and [131]). Oxygen-Hb dissociation curves are shifted dramatically to the left in individuals carrying these abnormal Hbs. The degree of left shift can be quantified by determining the P_{50} (i.e., the oxygen pressure at which Hb is half-saturated). The normal value in whole blood is 23 to 29 mm Hg at standard pH, temperature, CO_2 content, and barometric pressure. The whole-blood P_{50} is almost invariably decreased in patients with a high-affinity Hb; most values fall between 9 and 21 mm Hg. In a few instances, the P_{50} has been normal, or nearly so, in whole blood (e.g., HbG Norfolk), necessitating the measurement of the oxygen dissociation curve of the purified Hb to demonstrate the defect. The most important physiologic consequence of increased oxygen affinity is that release of oxygen is impaired at partial pressure of oxygen values normally found in tissues. Uptake of oxygen in the lungs is enhanced, but this effect is relatively unimportant, because normal Hb is nearly completely saturated in the lungs under the usual physiologic circumstances. As previously noted, however, the increased affinity may confer some advantages when environmental oxygen is low, such as at high altitudes. The first described high-affinity Hb, Hb Chesapeake, was reported in 1966 ([132]). By 2000, more than 115 high-affinity Hbs had been characterized. Most result from amino acid substitutions in the ß-chain. Some unstable Hbs (see Chapter 41) and M Hbs (see Chapter 49) also have increased affinity for oxygen but do not cause erythrocytosis. Most of the high-affinity Hb variants associated with erythrocytosis are found in single subjects or in small family clusters. However, studies of the few large kindreds available suggest that the inheritance pattern is autosomal-dominant ([132] , [133]). No apparent predilections for any racial group or geographic area have been observed. The severity of reported erythrocytosis varies considerably. With some of the variants (particularly those involving the a-chain), the associated blood Hb levels were within normal limits. In other variants (e.g., Hb British Columbia), the abnormality in oxygen binding was relatively mild and was demonstrable only by careful laboratory studies. In most patients, a mild, stable erythrocytosis (Hb, 17 to 20 g/dl) is found. The finding of erythrocytosis is often incidental. Patients may have noticed that their complexions are ruddy, but they usually have no other symptoms, and the clinical course is benign. Somewhat more severe erythrocytosis has been noted with a few variants: Hb Vanderbilt, Hb Malmö, Hb Wood, Hb Kempsey, Hb Yakima, Hb Heathrow, Hb Little Rock, Hb Syracuse, Hb Osler, and Hb Villaverde. Many of these patients were symptomatic, but some complained of the nonspecific symptoms of expanded blood volume and erythrocytosis: headaches, dizziness, a feeling of “fullness” in the head, and fatigue. Leukocyte and platelet counts were rarely abnormal ([131]). Individuals with high-affinity Hbs are not at a disadvantage under hypoxic conditions. They tolerate ascent to high altitudes as well as or better than normal subjects and thus appear to be preadapted to hypoxic stresses. Under such conditions, the enhanced oxygen loading seems more important than the impaired delivery. Similarly, exercise tolerance appears unimpaired ([134]). There is no evidence that oxygen delivery to the heart is defective in patients with high-affinity Hbs. Although myocardial infarctions and other findings of atherosclerotic cardiovascular disease are reported in these patients, it is unclear whether this is an actual association or simply reflects the high frequency of atherosclerosis in the general population ([135] , [136] , [137] and [138]). High-affinity Hbs appear to exert no adverse effects on fetal development *in utero*. Theoretically, oxygen delivery to a developing, noncarrier fetus might be impaired when the mother is a carrier, because the normal differential in oxygen affinity between fetal and adult Hb (which is in favor of the developing fetus) would be narrowed. However, only in the family with Hb Yakima was there a suggestion that spontaneous abortions occurred at an increased rate ([139]). In contrast, normal pregnancy outcomes were recorded for mothers carrying the severe high-affinity variants Hb Bethesda, Hb Osler, and Hb Little Rock ([140] , [141]). Evidently, maternal and fetal polycythemia and increased uterine and fetal blood flow compensate for the theoretic deficit in placental oxygen transport. There are no data addressing whether carrier fetuses have a developmental advantage over noncarriers born to these mothers; however, in dizygotic twins born to a mother with Hb Osler, the carrier twin developed more fully than the noncarrier as measured by the ponderal index (weight/length ^{3}) ([140]). It has been suggested that the homozygous state for high-affinity Hbs would be incompatible with life because of insufficient oxygen release to tissue. This may be true; however, at least four patients with abnormal Hb levels approximating those that would be observed in homozygotes have been described with no apparent ill effects [Hb Abruzzo ([142]), Hb Crete ([143]), and Hb Headlington ([144])]. The unusually high proportion of abnormal Hb was clearly due to concurrent ß-thalassemia in two cases ([144]) and probably in the others as well. Routine electrophoresis at alkaline pH on cellulose acetate detects approximately one-half of the stable high-affinity Hbs. An additional 10 to 15% can be detected by electrophoresis on citrate agar at acidic pH, and a further 10% are detectable by isoelectric focusing. This leaves 20 to 25% electrophoretically silent. The detection of an abnormal Hb in these circumstances requires determination of P_{50} under conditions controlled for pH and DPG concentration. The steps used to identify Hbs with altered oxygen affinity have been outlined ([129]). Some high-affinity Hbs interfere with detection of glycated Hb and lead to falsely elevated HbA_{1c} levels in diabetics ([145]). Most patients fully compensate for the reduced tissue oxygen delivery by developing erythrocytosis. Levels of serum erythropoietin and erythrocyte 2,3-DPG are typically normal, indicating that compensation is complete. It may be assumed that a new homeostatic equilibrium has been achieved by the mechanism reviewed in the discussion on erythropoietin levels in the classification of polycythemia. The situation is precisely analogous ([146]). No treatment is indicated for most patients with high-affinity Hbs. Their erythrocytosis is a compensation for a physiologic state and should be regarded as “normal for them.” In the rare patient with erythrocytosis and associated symptoms, phlebotomy may be used, but caution must be used to avoid lowering the hematocrit to a point at which oxygen delivery is impaired. A reasonable approach is probably to phlebotomize the individual patient to the highest hematocrit at which he or she is no longer symptomatic rather than to a specific number ([129] , [134] , [136] , [147]). Certainly, reducing blood Hb concentrations to normal levels would be undesirable. Under no circumstances should cytoreductive agents be used for treatment. A partial listing of high-affinity Hbs associated with erythrocytosis is shown in Table 50.5.

D, decreased; DPG, diphosphoglycerate; f, migrating faster than hemoglobin A; IF, demonstrable only by isoelectric focusing; N, normal; NS, not separable; s, migrating slower than hemoglobin A.

NOTE: Variants are grouped by a-chain and ß-chain abnormalities. Within each group, they are listed in order of the position in the polypeptide chain at which amino acid substitution has occurred. See Chapter 35 for an explanation of the notation for structure.

[a] Hill *n* is a measure of subunit interaction. Normal range, 27 to 31.

[b] Value for pH at which separation was detected.

[c] High values probably occurring in individuals with coexisting thalassemia.

Molecular Pathology Most of the changes in the oxygen affinity of Hb can be accounted for by effects on the equilibrium between a low-affinity molecular configuration, designated *T*, and a high-affinity configuration, designated *R* (see Chapter 7). Normally, the Hb molecule shifts from T to R as oxygen is bound, accounting for the phenomenon of subunit interaction. The usual measure of subunit interaction is the value *n* in Hill's equation. With no subunit interaction, *n* is 1.0; the value for HbA is 2.7 to 3.1. Most high oxygen-affinity variants are characterized by a reduced value for *n*; 16 of the 29 variants in Table 50.5 with reported *n* values are 1.5 or less. Biphasic Hill plots are observed when Hbs of different oxygen affinities are mixed. The high oxygen-affinity variants result from molecular alterations that either stabilize the R form or destabilize the T form. The most common known sites for amino acid substitutions involve the a $_1$ß $_2$ interface, which destabilize the T form. Substitutions at 2,3-DPG binding sites or at residues involving intrachain salt bridges also destabilize the T form. In contrast, certain Hbs result from amino acid substitutions that stabilize the R form, such as Hb Little Rock (172), Hb Chesapeake (186), and Hb Creteil (159). The mechanisms by which several other substitutions produce altered oxygen affinity are unclear.

Acquired Abnormalities of Hemoglobin Moderate elevations of carboxyhemoglobin in erythrocytes shift the oxygen dissociation curve. In heavy smokers, carboxyhemoglobin concentration may reach sufficiently high levels (4.0 to 6.8%) to produce polycythemia (187). In the older literature, polycythemia in association with phosphorus poisoning has been described, although it may have been merely relative erythrocytosis resulting from acute liver damage. Although certain drugs and chemicals (e.g., nitrites, nitrates, aniline dyes, sulfonamides, and nitrobenzene) produce toxic levels of methemoglobin, sulfhemoglobin, or both in the blood of even normal persons (188, 189, 190 and 191), erythrocytosis apparently has not been described in patients with toxic methemoglobinemia.

FAMILIAL POLYCYTHEMIA (PHYSIOLOGICALLY APPROPRIATE) Familial defects in 2,3-DPG metabolism [e.g., DPG mutase deficiency (192) or elevated erythrocyte adenosine triphosphate (193)], which would have the effect of shifting the oxygen dissociation curve, provide other physiologically appropriate (tissue hypoxia) reasons for polycythemia.

Secondary Polycythemia [Physiologically Inappropriate (Normoxic)]

ABERRANT ERYTHROPOIETIN SECRETION Erythrocytosis has been described in association with a variety of neoplasms, cysts, vascular abnormalities, and endocrinologic disorders. In the syndromes discussed in the preceding section, erythrocytosis was secondary (i.e., driven by increased erythropoietin); however, this erythropoietin secretion and the consequent erythrocytosis were physiologic responses to tissue hypoxia. In this section, disorders in which erythropoietin-driven erythrocytosis bears no relation to physiologic requirements are reviewed (Table 50.6).

TABLE 50.6. Disorders Associated with Normoxic Secondary Polycythemia

Renal disease	Other neoplasms
Renal cell carcinoma	Uterine leiomyomata
Renal sarcoma [a]	Uterine fibroid tumors [a]
Renal adenoma [a]	Cutaneous leiomyomata [a]
Renal hemangioma [a]	Meningioma [a]
Wilms tumor [a]	Placental trophoblastic tumors [a]
Solitary renal cysts	Chronic lymphocytic leukemia [a]
Polycystic kidney disease	Systemic amyloidosis [a]
Hydronephrosis	Atrial myxoma [a]
Horseshoe kidney [a]	Endocrine disorders
Renal artery stenosis [a]	Cushing syndrome
Postrenal transplantation	Primary aldosteronism
Hepatic disease	Virilizing ovarian tumors
Hepatocellular carcinoma	Bartter syndrome [a]
Hepatic hamartoma [a]	Pheochromocytoma [a]
Hepatic metastases [a]	Other
Hepatic angiosarcoma [a]	Human immunodeficiency virus infection [a]
Hepatic angioma [a]	
Viral hepatitis [a]	
Vascular cerebellar tumors	

[a] Polycythemia infrequently reported.

Renal Disorders *Renal cell carcinoma* (hypernephroma) is one of the disorders most frequently associated with erythrocytosis. Erythrocytosis is observed in 0.9 to 1.6% of patients with renal cell carcinoma (approximately one-fourth as frequent a finding as anemia) (194). Elevated serum erythropoietin levels, however, are observed in more than 60% of patients (195). Erythrocytosis also has been reported in patients with renal sarcoma, hemangioma, adenoma (196), Wilms tumor (197), renal cysts, hydronephrosis (198, 199), horseshoe kidney (199), and polycystic kidneys (196). Renal artery stenosis has also been reported in association with erythrocytosis (200). Erythrocytosis in renal cell carcinoma is attributed to constitutive erythropoietin production by the tumor. Erythropoietin messenger RNA can be demonstrated in renal carcinoma cells (201). It is assumed that this is also the mechanism by which other parenchymal renal diseases produce erythrocytosis.

Hydronephrosis and anatomic abnormalities probably produce erythrocytosis by increasing pressure on erythropoietin-producing cells in the renal parenchyma ([202]). Significant and measurable concentrations of erythropoietin (sometimes >100 mU/ml) can be detected in fluid aspirated from renal cysts associated with polycythemia. Production of erythropoietin in renal cell carcinoma is said to predict a good response to therapy ([203]). Management of erythrocytosis in these patients should be directed at treatment of the responsible renal lesion with phlebotomy as an adjunct, when necessary. Erythrocytosis is also observed in patients after renal transplantation ([204]). This phenomenon is associated with elevated serum erythropoietin; the source of erythropoietin is presumed to be the transplant recipient's native kidneys ([205] , [206]). Effective therapeutic modalities include phlebotomy, angiotensin-converting enzyme inhibitors, and theophylline ([207] , [208] and [209]).

Liver Diseases During fetal development, the liver contributes to erythropoietin production (Chapter 6); hepatic disease, like renal disease, may be associated with erythropoietin production and polycythemia. Erythrocytosis has been identified in persons with hepatocellular carcinoma with incidence 2.5 to 10.0% ([210] , [211] , [212] and [213]). When measured, red cell mass has been shown to be increased ([211]), and elevated serum erythropoietin levels have also been described ([213]). As with renal cell carcinoma, erythropoietin production by the tumor has been demonstrated ([214] , [215] and [216]). Remission of erythrocytosis may be observed after successful tumor treatment ([215] , [216]). Erythrocytosis has also been reported with hepatic hamartomas and tumors metastatic to liver ([196]), as well as hepatic angiomas ([217]) and hemangiosarcomas ([218]). Polycythemia has been reported in the early stages of viral hepatitis ([219] , [220]). Cirrhosis is occasionally listed in texts as associated with erythrocytosis, but this apparently does not occur except in the setting of another disease, such as cirrhosis with hepatocellular carcinoma.

Cerebellar Vascular Tumors The association of erythrocytosis with vascular tumors of the cerebellum is well established ([196] , [221]). Elevated serum erythropoietin levels and tumor production of erythropoietin have been demonstrated ([222] , [223]). Correction of erythrocytosis may be observed after effective therapy and erythrocytosis may return with recurrence of the tumor ([196]).

Leiomyoma and Fibroid Tumors of the Uterus Several cases in which large leiomyomas and fibroid tumors of the uterus were associated with erythrocytosis have been reported ([224] , [225]). Erythrocytosis tends to subside after effective therapy and is also associated with production of erythropoietin by tumor ([226] , [227]). Cutaneous leiomyomata have also been associated with erythrocytosis ([228]).

Other Neoplasms Rare instances of erythrocytosis in association with a variety of other tumors have been reported, but some of these associations may be coincidental ([196]). However, erythropoietin synthesis by tumor cells has been clearly demonstrated in a patient with meningioma ([229]). Erythrocytosis has also been reported in rare patients with chronic lymphocytic leukemia ([230]), systemic amyloidosis ([231]), placental trophoblastic tumors ([232]), and atrial myxomas ([233]).

Endocrinologic and Other Disorders Erythrocytosis has been reported in association with a number of endocrinologic disorders, including Cushing syndrome, primary aldosteronism ([234]), virilizing ovarian tumors ([235]), Bartter syndrome ([236]), and pheochromocytoma ([237]). In the latter disorder, tumor erythropoietin production has been reported ([237]). There have been a number of reports describing small numbers of patients with human immunodeficiency virus infection and polycythemia ([238] , [239] , [240] , [241] , [242] and [243]). It is unclear if there is an actual pathophysiologic association or if this is coincidental.

DRUG-INDUCED ERYTHROCYTOSIS Anabolic and androgenic steroids may be abused by both recreational and professional athletes for purposes of improving performance ([244] , [245]). A consequence of androgen administration, either medicinal or extralegal, may be erythrocytosis ([246]). In some cases, the degree of erythrocytosis may be severe. Recombinant human erythropoietin has also been abused by athletes (particularly those in endurance sports) to increase the red cell mass and thus oxygen-carrying capacity ([244] , [247] , [248]). As indicated earlier, this may backfire if the athlete becomes hypovolemic as a result of exertion. Cases of surreptitious erythropoietin self-administration resulting in accelerated hypertension and unstable angina have been reported ([249]). A perceived advantage of erythropoietin over androgens for this purpose is the inability to distinguish endogenous from exogenous erythropoietin as well as the lack of hepatic toxicity. More recently developed techniques that allow discrimination between exogenous recombinant erythropoietin and endogenous erythropoietin may make this practice less frequent ([250]).

FAMILIAL POLYCYTHEMIA (PHYSIOLOGICALLY INAPPROPRIATE) Kindreds that exhibit an autosomal-recessive erythrocytosis associated with increased erythropoietin production have been described ([251]).

Idiopathic Polycythemia

The term *idiopathic polycythemia* (or *erythrocytosis*) refers to patients who have an elevated red cell mass of unknown etiology after appropriate investigation. It would include most of the patients formerly categorized as “benign erythrocytosis.” The existence of this group, which is estimated to contain 20 to 30% of patients evaluated for polycythemia ([125]), essentially represents a failure to correctly categorize all polycythemic patients.

Of 25 patients reported in one series, 12 were found to have elevated erythropoietin levels and were therefore assumed to represent patients with secondary polycythemia; these patients tended to be younger than the patients with normal erythropoietin levels ([123]). Progenitor culture studies were not helpful in subcategorizing the group in this particular study ([123]). Some studies have reported endogenous colony-formation studies to be useful and serum erythropoietin levels not helpful ([42]), whereas others have reported the opposite ([252]).

Kiladjian and colleagues treated 39 patients with idiopathic erythrocytosis with pipbroman and compared their clinical course to 140 concurrently treated polycythemia vera patients ([253]). The risk of leukemia, thrombosis, and myelofibrosis was the same in the two groups. This study confirms that the idiopathic erythrocytosis group contains a certain number of polycythemia vera patients; however, it does not provide a way to identify individuals who do not have a myeloproliferative disorder and therefore should not be exposed to leukemogenic agents ([253]).

Because this category probably represents a mixed bag, including early polycythemia vera, mild secondary polycythemia, and normal individuals at the higher end of the bell-shaped curve for red cell mass ([61]), a cautious approach is warranted. Observation may be the most reasonable intervention; this may be the patient subset in whom otherwise low-yield studies, such as erythropoietin levels, and erythroid progenitor studies are likely to be useful.

Diagnostic Approach to the Bleeding Disorders

Except for that which occurs during menstruation, spontaneous bleeding is abnormal. Surprisingly, little blood is lost, even after large injuries, because of the efficiency with which vascular integrity is normally maintained and the rapidity with which it is restored after injury. In general, these phenomena reflect the functional effectiveness of normal hemostasis (see Chapter 19, Chapter 20, Chapter 21 and Chapter 22). It must be recognized, however, that the adequacy of hemostasis is only relative, and despite the presence of normal vessels, platelets, and coagulation factors, bleeding can occur as the result of localized pathologic processes.

The 11 chapters in Part V deal with disorders that result from abnormalities of the hemostatic process. Chapter 51 is a summary of the diagnostic approach to these disorders and includes a brief discussion of laboratory methods for their study. In subsequent chapters, individual disorders are considered in six categories: thrombocytopenia (Chapter 52, Chapter 53, Chapter 54 and Chapter 55), bleeding disorders caused by vascular abnormalities (Chapter 56), thrombocytosis (Chapter 57), disorders of platelet function (Chapter 58), inherited coagulation disorders (Chapter 59), and acquired coagulation disorders (Chapter 60). The pathophysiology of thrombosis and the principles of antithrombotic therapy are summarized in Chapter 61.

CLINICAL EVALUATION OF THE BLEEDING PATIENT

A careful evaluation of the patient presenting with a bleeding disorder can often provide valuable clues as to whether the abnormality resides in the vessels, platelets, or the process of blood coagulation; a carefully obtained history can usually establish whether the disorder is inherited or acquired; and the physical examination may reveal findings such as the characteristic skin lesions of hereditary hemorrhagic telangiectasia, which alone may provide the diagnosis of a previously perplexing bleeding problem. Results of the clinical evaluation should lead to a rational and efficient laboratory investigation. If laboratory studies are to be used to maximal advantage in terms of time and expense, they should supplement and not supersede a careful review of the history and the physical examination.

It is important to ask specific questions about bleeding because people with normal hemostasis may believe they bleed excessively ([1]). Certain questions may discriminate between those with normal and abnormal hemostasis, including whether excessive bleeding occurs after tooth extraction or small cuts, whether spontaneous bruising or muscle bleeding occurs, or whether the patient has ever been transfused or treated with blood products ([1]).

MANIFESTATIONS OF DISORDERED HEMOSTASIS

Certain signs and symptoms are virtually diagnostic of disordered hemostasis. They can be divided arbitrarily into two groups: those seen more often in disorders of blood coagulation and those most commonly noted in disorders of the vessels and platelets. The latter group is often called *purpuric disorders* because cutaneous and mucosal bleeding usually are prominent. The clinical findings that are most valuable in distinguishing between these two broad categories are summarized in Table 51.1. Although these criteria are relative, they provide valuable clues to the probable diagnosis if they are applied to the predominant clinical features in a given patient.

TABLE 51.1. Clinical Distinction between Disorders of Vessels and Platelets and Disorders of Blood Coagulation

Finding	Disorders of Coagulation	Disorders of Platelets or Vessels
Petechiae	Rare	Characteristic
Deep dissecting hematomas	Characteristic	Rare
Superficial ecchymoses	Common; usually large and solitary	Characteristic; usually small and multiple
Hemarthrosis	Characteristic	Rare
Delayed bleeding	Common	Rare
Bleeding from superficial cuts and scratches	Minimal	Persistent; often profuse
Sex of patient	80–90% of inherited forms occur only in male patients	Relatively more common in females
Positive family history	Common	Rare (except von Willebrand disease and hereditary hemorrhagic telangiectasia)

Bleeding into Skin and Soft Tissues

Petechiae are characteristic of an abnormality of the vessels or the platelets, such as thrombocytopenia, and are exceedingly rare in the coagulation disorders. These lesions are small capillary hemorrhages ranging from the size of a pinhead to much larger (Fig. 51.1). They characteristically develop and regress in crops and are most conspicuous in areas of increased venous pressure, such as the dependent parts of the body and areas subjected to pressure or constriction from girdles or stockings. In patients with scurvy, petechiae may be distributed around hair follicles in the “saddle area” of the thighs and buttocks (see Fig. 56.6). Petechiae must be distinguished from small telangiectasias and angiomas. Vascular structures such as telangiectasias or angiomas blanch with pressure, whereas petechiae do not.

Figure 51.1. Diffuse petechial rash induced by a tourniquet in a patient with chronic idiopathic thrombocytopenic purpura (platelet count = 40×10^9/L).

In the purpuric disorders, petechiae commonly are associated with multiple superficial ecchymoses, which usually develop without perceptible trauma but seldom spread into deeper tissues. Small isolated ecchymoses are commonly noted in apparently normal women, especially on the legs, and in small children.

Although large superficial ecchymoses may be seen in association with the coagulation disorders, the most characteristic lesion is the large spreading hematoma (Fig. 51.2). Such hematomas may arise spontaneously or after trivial trauma and often spread to involve an entire limb by dissecting within muscles and deep fascial spaces, often with minimal discoloration of the overlying skin.

Figure 51.2. Large dissecting hematoma of thigh in a patient with hemophilia A. The lesion resulted from a slight bump to the inguinal area and spread to involve the entire thigh. See Color Plate. (Courtesy of Dr. John Lukens.)

Hemarthrosis

Hemorrhage into synovial joints is virtually diagnostic of a severe inherited coagulation disorder, most commonly hemophilia A or hemophilia B, and is rare in disorders of the vessels and platelets or in acquired coagulation disorders. This disabling problem often develops with pain and swelling as chief symptoms but without discoloration or other external evidence of bleeding (Fig. 51.3). Subperiosteal hemorrhages in children with scurvy and swollen painful joints that may develop in some patients with allergic purpura occasionally may be confused with hemarthrosis.

Figure 51.3. Acute hemarthrosis and its sequelae in a patient with hemophilia B. Note the periarticular swelling in the left leg and the marked atrophy of the thigh muscles as a result of recurrent hemarthrosis. (Courtesy of Dr. John Lukens.)

Traumatic Bleeding

The unavoidable traumas of daily life and even minor surgical procedures are a greater challenge to hemostasis than any test yet developed in the laboratory. In contrast to “spontaneous” bleeding manifestations, bleeding after trauma in a person with a hemorrhagic diathesis differs in a quantitative way from that which would normally be expected in terms of the amount, duration, and magnitude of the inciting trauma. Such variables are extremely difficult to assess accurately by taking the patient's history. The amount of blood lost may be exaggerated by the patient. The need for transfusions and the number administered may serve as a rough guide. The patient's statement concerning the duration of bleeding is more reliable. Detailed inquiry as to past injuries and operations must be made because the patient is likely to forget procedures or injuries that were uncomplicated and to dwell on those in which bleeding was a problem. Whether reoperation was required for prolonged bleeding after tooth extraction or other minor surgical procedures may be helpful in identifying a patient with abnormal hemostasis.

In individuals with a coagulation disorder, the onset of bleeding after trauma often is delayed. For example, bleeding after a tooth extraction may stop completely, only to recur in a matter of hours and to persist despite the use of styptics, vasoconstrictors, and packing. The temporary hemostatic adequacy of the platelet plug despite defective blood coagulation may explain this phenomenon of delayed bleeding, as well as the fact that patients with coagulation disorders seldom bleed abnormally

from small superficial cuts such as razor nicks. In contrast, posttraumatic or postoperative surgical bleeding in thrombocytopenic patients usually is immediate in onset, as a rule responds to local measures, and rarely is as rapid or voluminous as that encountered in patients with coagulation disorders. However, it may persist for hours or days after surprisingly small injuries.

Valuable information often is obtained from a careful review of dental procedures, because most patients have had one or more teeth extracted at some time during their lives. Inquiry should clarify whether the extractions were single or multiple, the size and location of the tooth or teeth, any treatment given, and the amount, if any, of direct operative trauma. The amount of bleeding normally encountered varies greatly, but as a rough guide, uncomplicated extraction of a single molar tooth may result in brisk bleeding for up to 1 hour and slight oozing for up to 2 days in normal persons ([2]). Typically, bleeding is more profuse from upper than from lower sockets and is more extensive after extraction of molar teeth, particularly impacted third molars, than after removal of other teeth. In patients with inherited coagulation disorders, the shedding of deciduous teeth often is uncomplicated.

The response to trauma is an excellent screening test for the presence of an inherited hemorrhagic disorder, and a history of surgical procedures or significant injury without abnormal bleeding is equally good evidence against the presence of such a disorder. The removal of molar teeth is a major challenge to hemostasis, as is a tonsillectomy, and it is a rare hemophiliac, however mildly affected, who can withstand these procedures without excessive bleeding.

Miscellaneous Bleeding Manifestations

Despite the fact that structural causes for bleeding (such as polyps, varices, and tumors) are commonly seen in patients with hematuria, hematemesis, and melena, bleeding from these sites may also be associated with both purpuric and coagulation disorders. Severe menorrhagia may be the sole symptom of women with von WillebrandWillebrand disease (vWD), mild thrombocytopenia, or autosomally inherited coagulation disorders. Recurrent gastrointestinal bleeding or epistaxis in the absence of other bleeding manifestations is common in hereditary hemorrhagic telangiectasia. A coagulation disorder or a disorder of platelet function should be considered if protracted hematuria is the only symptom.

Bleeding into serous cavities and internal fascial spaces often occurs in patients with inherited coagulation disorders and may create serious diagnostic problems. In hemophilia, retroperitoneal hemorrhage or bleeding into the psoas sheath may mimic appendicitis, and hemorrhage into the bowel wall may be confused with intestinal obstruction. Signs and symptoms simulating a variety of acute intraabdominal disorders also may be seen in association with allergic purpura. Bleeding into the central nervous system may complicate thrombocytopenia and may occur after minor trauma in patients with coagulation disorders. Multiple small retinal hemorrhages are common in patients with thrombocytopenia and other purpuric disorders but are uncommon in those with inherited coagulation disorders; large hematomas of the orbit may be seen in the latter group. The coexistence of bleeding and thromboembolic phenomena or bleeding from previously intact venipuncture sites is suggestive of diffuse intravascular coagulation (DIC). Protracted wound healing, wound dehiscence, and abnormal scar formation have been described in inherited afibrinogenemia, the dysfibrinogenemias, and in factor XIII deficiency ([3]). Hemoptysis rarely is associated with hemorrhagic disorders.

CLINICAL FEATURES OF INHERITED BLEEDING DISORDERS

An inherited bleeding disorder is suggested by the onset of bleeding symptoms in infancy and childhood, a positive family history (particularly if it reveals a consistent genetic pattern), and laboratory evidence of a single or isolated abnormality, most commonly the deficiency or aberrance of a single coagulation factor.

Age at Onset: Bleeding in the Neonate

Birth and the neonatal period provide unique challenges to the hemostatic mechanism ([4]), and bleeding during the first month of life often is the first evidence of an inherited disorder of hemostasis. Small cephalohematomas and petechiae are common in the newborn as a result of the trauma of delivery. Large cephalohematomas that progressively increase in size may result from hemophilia but are more common in association with acquired bleeding disorders such as hemorrhagic disease of the newborn (see Chapter 60). Bleeding from the umbilical stump and after circumcision is common in the acquired coagulation disorders, and it also occurs in the inherited coagulation disorders ([5]) with the exception of hypofibrinogenemia, dysfibrinogenemia, and factor XIII deficiency. The onset of bleeding from the umbilical cord may be delayed in these latter disorders. In the evaluation of bleeding in the neonate, the clinician should remember that hematochezia and hematemesis may originate from swallowed blood of maternal origin. Simple tests to distinguish such maternal blood from fetal blood have been described ([5]).

Many infants with inherited coagulation disorders do not bleed significantly in the neonatal period. Less than one-third of patients with hemophilia A and B and only 10% of those with other inherited coagulation disorders have hemorrhagic symptoms during the first week of life. In such patients, the disorder may become clinically silent for a time. Hematomas may first be seen only when the child becomes active. Hemarthrosis commonly does not develop until a child is 3 or 4 years of age.

A mild inherited hemorrhagic disorder may be difficult to distinguish from the insidious onset of an acquired defect. Patients with mild inherited coagulation disorders may enter adult life before characteristic bleeding manifestations occur. These patients and those with some forms of inherited throm-bocytopenia and disordered platelet function often describe a history of posttraumatic bruising and hematoma formation that they have come to accept as normal. In hereditary hemorrhagic telangiectasia, the lesions become more prominent with advancing age and may not be symptomatic until middle age. Similarly, in patients with Ehlers-Danlos syndrome, bleeding may not be a problem until adult life.

Family History

The family history is of great importance in the evaluation of bleeding disorders. In disorders inherited as autosomal-dominant traits with characteristic symptoms and high penetrance, such as hereditary hemorrhagic telangiectasia, an accurate pedigree spanning several generations can often be obtained. The presence of typical bleeding manifestations in male siblings and maternal uncles is virtually diagnostic of X-linked recessive inheritance, which characterizes hemophilia A and hemophilia B. In such X-linked traits, the family history also may be helpful in a negative sense—that is, it may clearly exclude the disorder in certain offspring, such as the sons of a known hemophiliac. Details of the various genetic patterns that may be encountered are discussed in the chapters that deal with these conditions.

The limitations of the family history, however, are greater than is commonly realized. Hearsay history is difficult to evaluate, and it is often impossible to assess the significance of easy bruising or to differentiate between manifestations of a generalized bleeding disorder and more common localized lesions, such as peptic ulcer and uterine leiomyomas. In affected families, a bewildering variety of unrelated symptoms is often attributed to bleeding. A negative family history is of no value in excluding an inherited coagulation disorder in an individual patient. As many as 30 to 40% of patients with hemophilia A have a negative family history ([6]). The family history usually is negative in the autosomal-recessive traits, and consanguinity, which is commonly present in these kindreds, is notoriously difficult to document or exclude.

CLINICAL FEATURES OF ACQUIRED BLEEDING DISORDERS

Generalized bleeding may be a prominent feature of a wide variety of acquired disorders that encompass virtually the entire field of medicine. Bleeding manifestations usually are less severe than in the inherited forms, and the clinical picture often is dominated by evidence of the underlying disorder rather than by bleeding alone. In the neonate, for example, DIC usually is associated with significant complications such as sepsis, hypoxia, acidosis, or problems related to prematurity. The physician should suspect sepsis or occult thrombosis in any sick neonate with unexplained thrombocytopenia ([5]). Multiple hemostatic defects commonly are present in patients with acquired hemorrhagic diseases, which often include throm-bocytopenia and significant coagulation abnormalities. In contrast, a single abnormality usually is found in patients with inherited hemorrhagic disorders.

In general, the emphasis of the study of the acquired bleeding disorders should be on the patient, not on the laboratory. A thorough history and the physical examination often reveal the cause of thrombocytopenia, such as a drug or acute leukemia. In most vascular disorders, including senile purpura, allergic purpura, scurvy, and amyloidosis, the history and physical examination are of primary diagnostic importance, and the laboratory has little to offer.

Drug History

The importance of exhaustive interrogation regarding drug use and chemical exposure cannot be overemphasized. The list of drugs associated with thrombocytopenia (see Table 53.5) or vascular purpura grows longer each year. Less common but more serious is drug-induced aplastic anemia, which may present initially with

bleeding (see Chapter 44). Many commonly used drugs (see Table 58.4), notably aspirin, impair platelet function and produce abnormal findings on laboratory tests that often lead to expensive and unnecessary additional laboratory studies. The same drugs may provoke bleeding when administered to patients with preexisting hemostatic defects such as hemophilia A.

Drug ingestion also may produce coagulation abnormalities, and drugs that potentiate or antagonize the anticoagulant effects of coumarin derivatives may lead to bleeding or erratic laboratory control. The surreptitious ingestion of such agents is not uncommon.

Results of various coagulation tests may be abnormal in a surprisingly large percentage of hospitalized patients because of heparin that is administered therapeutically or is used in small amounts to maintain the patency of indwelling venous catheters, venous pressure lines, arteriovenous shunts, and various pumps and infusion machines. The partial thromboplastin time (PTT), in particular, may be greatly prolonged in patients who have received even a minute amount of this anticoagulant. Such coagulation abnormalities often are confused with DIC, inhibitors of factor VIII, and other serious coagulation disorders, and they commonly lead to repeated, often detailed, and usually useless coagulation studies. A thorough bedside inventory often is required to find out that heparin is indeed responsible. Prolongation of the thrombin time associated with a normal reptilase time or direct assay of heparin provides laboratory evidence of heparin contamination.

LABORATORY METHODS FOR STUDY OF HEMOSTASIS AND BLOOD COAGULATION

No single test is suitable for the laboratory evaluation of the overall process of hemostasis and blood coagulation, but methods of varying complexity and use are available for assessing various components and functions individually. The emphasis of the following discussion is on methods that are simple and widely available in most laboratories. The interpretation of the most commonly used tests and the range of values obtained in normal subjects with representative techniques are summarized in Table 51.2. Definitive methods usually require a specially equipped laboratory and trained personnel, and are discussed here from a general standpoint only. Additional comments concerning the use and limitations of the various methods are included in chapters dealing with individual disorders. For details concerning such definitive methods, the reader is referred to more comprehensive works devoted entirely to this subject ([7]).

TABLE 51.2. Interpretation of Common Tests of Hemostasis and Blood Coagulation

Test	Normal Range [a] (±2 SD) and Reference	Common Causes of Abnormalities
Platelet count		
Phase microscopy	140,000–440,000/µl	Thrombocytopenia, thrombocytosis
Automated	177,000–406,000/µl	
Partial thromboplastin time (activated) [b]	26–37 sec; (51) [c]	Deficiencies or inhibitors of prekallikrein; high-molecular-weight kininogen; factors XII, XI, IX, VIII, X, and V; prothrombin or fibrinogen; lupus inhibitors; heparin
Prothrombin time [b]	12.0–15.5 sec; (62) [c]	Deficiencies or inhibitors of factors VII, X, and V; prothrombin or fibrinogen; dysfibrinogenemia; lupus inhibitors; heparin
Thrombin time [b]	18–22 sec; (7)	Afibrinogenemia, dysfibrinogenemia, hypofibrinogenemia, and hyperfibrinogenemia; inhibitors of thrombin (heparin) or fibrin polymerization (fibrin degradation products, paraproteins)
Fibrinogen assay [b]	150–430 mg/dl; (68)	Afibrinogenemia, dysfibrinogenemia, and hypofibrinogenemia; inhibitors of thrombin or fibrin polymerization
Factor VIII assay [b]	50–150 U/dl; (7)	Hemophilia A and von Willebrand disease; acquired antibodies to factor VIII
Fibrin degradation product assay	0–5 µg/ml; (77)	Disseminated intravascular coagulation; fibrinogenolysis; thrombolytic drugs, liver disease; dysfibrinogenemia

[b] Tests affected by heparin.

[c] Significant variations depending on reagents and technique.

Tests of Vascular and Platelet Phases

BLEEDING TIME Hemostasis in a small superficial wound, such as that produced when measuring the bleeding time, depends on the rate at which a stable platelet plug is formed and, thus, provides a measure of the efficiency of the vascular and platelet phases. However, it does not discriminate between vascular defects, thrombocytopenia, and platelet dysfunction. The bleeding time leaves much to be desired in terms of reproducibility because no two skin areas are exactly the same and it is impossible to produce a truly standard wound ([8]). Older studies using the bleeding time test supported the view that this test might be helpful in predicting bleeding in individual patients ([9]). More recent studies suggest that a bleeding time result is determined not only by platelet number and function, but also by hematocrit ([10]), certain components of the coagulation mechanism ([11], [12]), skin quality ([13]), and technique ([14]). A careful analysis of this literature indicates that there is no correlation between a skin template bleeding time and certain visceral bleeding times ([14], [15]), and that no correlation exists between preoperative bleeding time results and surgical blood loss or transfusion requirements ([16]). A clinical outcomes study reported that discontinuation of the bleeding time in a major academic medical center had no detectable adverse clinical impact ([17]). A position paper of the College of American Pathologists and the American Society of Clinical Pathologists concluded that the bleeding time was not effective as a screening test, and that a normal bleeding time does not exclude a bleeding disorder ([18]). Patients thought to have a platelet-type bleeding disorder based on their personal or family history (or both) should be evaluated for vWD and the inherited qualitative platelet disorders using assays discussed in the section Platelet Function Assays. Newer assays that may be useful in screening patients for platelet dysfunction are also discussed in the section New Assays of Platelet Function.

PLATELET ENUMERATION Platelets are considerably more difficult to count than erythrocytes or leukocytes. This difficulty is to be expected in view of the small size of these cells and their tendency to adhere to foreign surfaces and to aggregate when activated. In general, techniques for platelet counting may be classified into three groups: hemacytometer or direct methods, in which whole blood is diluted and the platelets are counted in much the same way as leukocytes or erythrocytes; semiautomated methods, in which the number of platelets in plasma prepared by sedimentation or centrifugation is determined in an electronic particle counter; and fully automated electronic methods. Virtually identical values for the normal range of the platelet count have been obtained with modern methods, as summarized in Table 51.2. An estimate of platelet numbers in a well-prepared blood smear by an experienced observer is a valuable check on the platelet count as determined by any method. In general, when a blood smear is examined at l00× power, each platelet seen/field represents approximately l0,000 platelets × l0 ^{9}/L. Consequently, a normal blood smear should demonstrate, on average, at least l4 platelets/high-power field. Instruments for totally automated platelet counting are widely used. Details of automated cell counters are discussed in Chapter 1. When automated methods are used, various nontechnical factors may produce falsely low platelet counts ([19]). These factors include platelet agglutinins ([20]), abnormal amounts of plasma proteins in various paraproteinemias, previous contact of platelets with foreign surfaces such as dialysis membranes ([21]), giant platelets, platelet satellitism ([22]), lipemia ([23]), and ethy-lenediaminetetraacetic acid–induced platelet clumping ([24]), a phenomenon that may produce platelet clumps of sufficient size to artifactually increase the leukocyte count ([25]). Spuriously high platelet counts may result from the presence of microspherocytes ([26]), fragments of leukemic cells ([27]), and Pappenheimer bodies ([28]). Special technical modifications and the use of careful manual counting methods may be required to eliminate these artifacts and to obtain accurate platelet counts.

PLATELET VOLUME MEASUREMENTS The widespread availability of particle counters in the clinical laboratory now permits the accurate measurement of platelet volume on a routine basis. Mean platelet volume (MPV) is increased in disorders associated with accelerated platelet turnover as the result of large numbers of megathrombocytes ([29]) or in patients with Bernard-Soulier syndrome. Normal or decreased values for MPV usually are obtained in patients with disorders associated with deficient platelet production, in some patients with sepsis ([30]), and in people with certain big-spleen syndromes ([31]). Some authors suggest that increased MPV provides evidence of accelerated platelet production and may be interpreted in the same way as the reticulocyte count. The method is difficult to standardize, however, and when determined on routinely collected specimens by automated counters, it is affected by numerous variables pertaining to specimen collection, anticoagulant, temperature, and duration of storage ([32]). In view of these problems and the difficulty in interpreting platelet size heterogeneity under normal and

abnormal conditions ([33]), these measurements should be interpreted with caution. Nevertheless, this method is potentially valuable, and estimates of MPV are obtained with currently available instruments at essentially no additional cost. The presence of microcytic platelets in patients with some inherited thrombocytopenias such as Wiskott-Aldrich syndrome is reliably reflected by MPV measurements. On the other hand, giant platelets associated with Bernard-Soulier syndrome may be counted as leukocytes or erythrocytes and may not be reflected in the MPV.

PLATELET FUNCTION ASSAYS Since the 1960s, platelet aggregation using platelet-rich plasma has been the standard method to assess platelet function. This method uses aggregometers, which are modified nephelometers that permit measurement of changes in optical density of a platelet suspension under conditions of constant temperature and continuous agitation (Fig. 51.4; also see Fig. 58.3). Most instruments measure a combination of light scatter and absorption. Instruments have been developed that permit both nephelometric and photometric measurements and the simultaneous measurement of aggregation and nucleotide release ([34]).

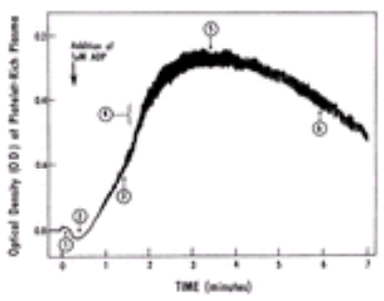

Figure 51.4. The interpretation of aggregometer tracings. Tracing of platelet aggregation produced by a low concentration of adenosine diphosphate (ADP), illustrating normal changes in optical density (OD)—that is, (*1*) a slight decrease caused by dilution with aggregating agent; (*2*) a transient increase caused by initial platelet swelling or shape change; (*3*) a rapid progressive decrease as platelet aggregates form, the size of which is roughly proportional to the amplitude of the oscillations in the tracing (*4*). The OD then reaches a nadir (*5*) from which maximal aggregation as a percentage of the initial OD may be calculated as follows: maximal aggregation (%) = OD at T0 – minimum OD/OD at T0. After this (*6*), a slow increase in OD caused by disaggregation occurs under some conditions.

Platelet aggregation usually is studied in suspensions of citrated platelet-rich plasma, in which the size and dimensions of the stirring bar, variations in plasma citrate concentration attributable to variations in hematocrit, the pH, and the nature of the buffers are important variables. Platelet suspensions usually are prepared by differential centrifugation, but methods that use albumin density–gradient centrifugation and gel filtration have also been described ([35]). Although harvesting platelets from the blood of thrombocytopenic patients is difficult, testing such platelets in the aggregometer is reproducible in suspensions containing as few as 50,000 platelets/µl. Methods for the study of platelet aggregation in whole blood ([36] , [37]) also have been described. Interphased computer systems have been developed for calculating and expressing platelet function data ([38]). Adaptation of microplate technology to platelet aggregation has been reported, permitting more samples to be more rapidly analyzed ([39]). Adenosine diphosphate (ADP) in concentrations of 5 µmol/L or higher produces platelet aggregation directly that is independent of the release of platelet-contained ADP ([40]). Various other aggregating agents act mainly by inducing the release reaction, such as a suspension of connective tissue particles (collagen), epinephrine and norepinephrine, and thrombin. With epinephrine (5 µmol/L), a weak primary aggregating effect usually can be clearly distinguished from the subsequent release reaction, which produces a secondary wave of aggregation. Such primary and secondary waves of aggregation also may be seen with carefully titrated amounts of ADP (0.2 to 1.5 µmol/L) ([40]). *Ristocetin* is an antibiotic that induces platelet agglutination (platelet metabolic activity not required) in the presence of von Willebrand factor (vWF). Patients deficient in vWF (vWD) or in the receptor for vWF (Bernard-Soulier syndrome) have an abnormal ristocetin response. Ristocetin is tested in concentrations of 0.6 to l.2 mg/ml; the lower concentrations are helpful in identifying specific variants of vWD, type IIB and platelet-type vWD (see Chapter 58 and Chapter 59). The release reaction is measured only indirectly by routine aggregometry—that is, the aggregation associated with the release of ADP from the platelets (release-induced aggregation or secondary aggregation). Methods for the quantitation of various substances released from platelets have been described. For example, the amounts of ADP or serotonin released/unit of time serve as indices of dense body release ([41]); the amount of various hydrolytic enzymes or platelet factor 4 released is a measure of the extent of a-granule release ([42]). Sensitive methods have been developed for the determination of platelet-derived substances in plasma that may serve as markers of intravascular platelet activation ([43]), including platelet factor 4, ß-thromboglobulin, stable prostaglandins (6-keto prostaglandin F_{1} a and thromboxane A_{2}), and leukotrienes ([43]). These measurements may have diagnostic value in thromboembolic disorders and syndromes characterized by intravascular platelet aggregation.

Clot Retraction Clot retraction usually is deficient when the platelet count is below 50,000/µl and in a rare disorder of platelet function (Glanzmann thrombasthenia) ([44]). It is normal in most other disorders of platelet function. Qualitative estimates of clot retraction can be made by incubating a tube of clotted blood, in which retraction normally is apparent within 2 hours. This test is primarily of historical interest; Glanzmann thrombasthenia is typically diagnosed using platelet aggregation methods or flow cytometry.

New Assays of Platelet Function Recently appreciated limitations of the bleeding time test have led to the development of newer assays to evaluate platelet function ([45]). Some of these are point-of-care tests. The clinical use and predictive value of these tests to identify patients with hemostatic disorders remain to be established. One assay, the platelet function analyzer (PFA-100), has been investigated for several years, and many published reports using this assay are available. In this method, citrated blood samples are exposed to high shear rates in a capillary flowing through an aperture within a membrane coated with collagen and either ADP or epinephrine ([46]). The closure time to hemostatic plug formation within the aperture is the endpoint of the test. A large study using the PFA-100 found that prolonged closure times could be attributed to specific quantitative or qualitative abnormalities in platelet function or vWF (or both) in 93% of patients tested ([47]). It was suggested that optimal use of the PFA-100 in evaluation of hemostasis would use an algorithmic approach, evaluating not only PFA-100 closure times, but also a complete blood count, blood smear, and assays for vWD and platelet aggregation to further evaluate abnormal closure times ([47]).

Tests of Coagulation Phase

It is doubtful whether any of the innumerable minor technical variations that have found their way into methods for the study of blood coagulation have significantly improved the specificity or reproducibility of the commonly used tests. Because of the lack of standardization of techniques and reagents, however, the normal range of almost every test varies depending on the technique used, and the physician must be aware of the normal range for the specific method used in a particular laboratory.

In general, meticulous performance of coagulation tests is more important than the exact technique chosen. Blood samples obtained by traumatic venipunctures or from indwelling catheters often are inadequate for coagulation studies ([48]). A poorly collected blood sample is a far more common cause of inaccurate results than is technical error. Confusion and delay usually result when coagulation tests are performed on inadequate specimens.

With the exception of testing for fibrin degradation products (FDPs), all coagulation tests are performed on citrated plasma, most commonly obtained using blue-top Vacutainer tubes. These tubes contain either 3.2% or 3.8% buffered sodium citrate and a vacuum that pulls in nine parts of blood to one part citrate. The International Society for Thrombosis and Haemostasis recommends the routine use of 3.2% sodium citrate. A pool of freshly frozen citrated plasma from several normal donors is a suitable control for screening procedures in most laboratories. Lyophilized control plasma and borderline abnormal control plasmas are available commercially to standardize coagulation assays and to provide reference standards.

The citrate ion does not enter the erythrocyte. Consequently, the plasma citrate concentration is abnormally high when blood with a high hematocrit is collected in usual concentrations of this anticoagulant. This may produce artifactual prolongation of one-stage screening tests of coagulation, such as the PTT ([49]). To obtain interpretable data on such samples, special tubes containing citrate concentrations appropriate for the hematocrit must be prepared, or citrate must be added to the control plasma so the citrate concentration equals that of the patient's plasma.

PARTIAL THROMBOPLASTIN TIME The PTT is a simple test of the intrinsic and common pathways of coagulation. When a mixture of plasma and a phospholipid platelet substitute is recalcified, fibrin forms at a normal rate only if the factors involved in the intrinsic pathway (prekallikrein, high-molecular-weight kininogen, and factors XII, XI, IX, and VIII) and in the common pathway (factors X and V, prothrombin, and fibrinogen) are present in normal amounts (Fig. 51.5). Platelet substitutes of various kinds may be used, such as chloroform extract of brain ([50]) and other crude cephalin fractions as well as soybean phosphatides (inosithin). In the PTT, such platelet substitutes are provided in excess, and the test is unaffected by the number of platelets remaining in the plasma (unless the sample contains antiphospholipid antibodies). Platelet substitutes are only partial thromboplastins, however, and they are incapable of activating the extrinsic pathway, which requires complete tissue thromboplastin (tissue factor). Thus, the PTT bypasses the extrinsic pathway and is unaffected by deficiency of factor VII. The PTT assay is used to detect factor deficiency, screen for the lupus anticoagulant, and monitor heparin anticoagulation.

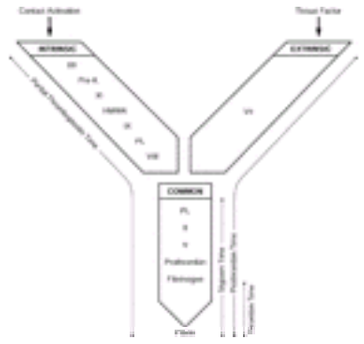

Figure 51.5. The interpretation of common screening tests of blood coagulation. Coagulation factors are indicated within arrow-shaped blocks, which represent the major pathways of coagulation. Screening tests are indicated at the side of these blocks in relation to pathways and coagulation factors measured by each. HMWK, high-molecular-weight kininogen; PL, phospholipid; Pre-K, prekallikrein.

The PTT is somewhat more sensitive to deficiencies of factors VIII and IX than to deficiencies of factors XI and XII or factors involved in the common pathway ([51], [52]), but with most techniques, the test usually yields abnormal results if the plasma level of any of the essential factors is below 15 to 30% of the normal value. The PTT thus detects some mild coagulation disorders. However, the ability to detect mild factor deficiency is reagent dependent, and certain PTT reagents may not detect factor deficiency as low as 5 to 10% ([53]). As is the case with all one-stage tests, the PTT may be shortened by high levels of a single factor, most commonly factor VIII. Thus, a short PTT may signify any of the various hypercoagulable states (see Chapter 61), and high levels of any of the factors involved in the intrinsic or common pathways of coagulation may mask deficiencies of other factors ([54]). In the original method, contact activation was provided by the glass tube, but the addition of activators, such as ellagic acid, or particulate silicates, such as Celite or kaolin, provides more optimal and standardized contact activation and represents a significant improvement over the original nonactivated test ([55], [56]). The activated PTT (aPTT) is the routine assay currently used to evaluate intrinsic coagulation. The aPTT of plasma deficient in prekallikrein (Fletcher factor) is abnormal when it is determined by standard methods using particulate activators such as Celite or kaolin ([57]). This abnormality is minimized or abolished by protracted contact activation [15 minutes ([58])], as compared with 2 to 3 minutes used in the standard technique. The aPTT may yield normal results in prekallikrein deficiency when soluble activators such as ellagic acid are used ([58]). Because of physiologic abnormalities in the contact phase of the intrinsic pathway, the aPTT often is prolonged in normal newborn infants when it is performed with particulate activators. These abnormalities are abolished when preformed activation product is used as the activator ([59]). Prolonged aPTT values that are observed in healthy children are not due to a single deficiency or inhibitor to a coagulation protein, but rather from the combination of mild decreases of several coagulation proteins ([60]). Whereas increased PTT values may suggest a bleeding disorder, shortened PTT values have been found to be independent predictors of an increased risk of death, thrombosis, bleeding, and morbidity ([61]). The use of the aPTT in the control of heparin therapy and in detection of the lupus anticoagulant is discussed in Chapter 61 and Chapter 60, respectively.

PROTHROMBIN TIME The production of fibrin by means of the extrinsic and common pathways (Fig. 51.5) requires tissue factor and factor VII, in addition to factors X and V, prothrombin, and fibrinogen. These pathways are measured by the prothrombin time (PT) ([62]), in which plasma is recalcified in the presence of excess tissue factor. This test does not require contact activation and bypasses the intrinsic pathway and the factors involved therein. Because tissue thromboplastins contain phospholipids that act as platelet substitutes, the test is unaffected by platelet numbers. Of the five coagulation factors measured by the PT (factors V, VII, and X, prothrombin, and fibrinogen), three (prothrombin and factors VII and X) are vitamin K–dependent and are depressed by coumarinlike drugs. As a result, the PT is the test used most widely for controlling oral anticoagulant therapy. The PT usually is prolonged if the plasma levels of any of the requisite factors are below 10% of normal, and it is more sensitive to deficiencies of factors VII and X than to deficiencies of fibrinogen and prothrombin. The PT also is prolonged by inhibitors of any of the essential factors and by heparin, but it is less sensitive to the anticoagulant action of heparin than is the aPTT. Various modified techniques and thromboplastins ([63]), including recombinant human thromboplastins ([64]), have been developed to improve the use of the PT in the control of coumarin anticoagulant therapy (see Chapter 61). The expression of the PT as a percentage of normal may be misleading and is not recommended because the dilution curves used to arrive at this figure often have little quantitative meaning ([65]). Use of the international normalized ratio in monitoring oral anticoagulation therapy is the recommended format (discussed in Chapter 61). The PT performed with bovine brain thromboplastin is abnormal in patients with certain genetic variants of factor IX deficiency but is normal in patients with the more common form of this disorder. The venom of Russell viper contains an enzyme that initiates coagulation by the direct activation of factor X and does not require factor VII. The one-stage "prothrombin time" performed with this venom (the Stypven time) thus distinguishes between deficiency of factor VII and deficiency of factor X (Fig. 51.5).

THROMBOPLASTIN GENERATION TEST The thromboplastin generation test is important for historical reasons. This two-stage test measures the amount and rate of prothrombinase formation by way of the intrinsic pathway ([66]). The thromboplastin generation test has been supplanted by specific factor assays in most coagulation laboratories.

ASSAY OF PLASMA FIBRINOGEN Several accurate methods are available for the quantitative assay of plasma fibrinogen, a measurement of great clinical importance that should be available in all laboratories. Fibrinogen may be converted into fibrin, which is quantitated by gravimetric, nephelometric ([67]), or chemical ([68]) methods. An immunologic ([69]) method has also been described. Kinetic techniques based on the thrombin time, however, are simple to perform, and they have been widely adopted ([70]). Both gravimetric methods and those based on the thrombin time underestimate fibrinogen in the presence of high concentrations of FDPs; technical modifications designed to avoid these problems have been proposed ([71]). Some nephelometric methods appear to be minimally affected by FDP. Modified methods that eliminate interference by heparin ([72]), as well as automated techniques, have been described. Marked differences in fibrinogen levels obtained by gravimetric and immunologic methods and those obtained by functional techniques are found in patients with the inherited dysfibrinogenemias. Reference values to identify patients with dysfibrinogenemia have been reported ([73]).

THROMBIN TIME AND RELATED TECHNIQUES When thrombin is added to plasma, the time required for clot formation is a measure of the rate at which fibrin forms (Fig. 51.5). This test (thrombin time) yields abnormal results when the fibrinogen level is below 70 to 100 mg/dl, but it is unaffected by the levels of any of the other coagulation factors ([74]); it is greatly prolonged by heparin. The thrombin time may also be prolonged by a qualitatively abnormal fibrinogen, elevated levels of fibrin (fibrinogen)-degradation products, certain paraproteins, and hyperfibrinogenemia. The thrombin time and modifications thereof are technically simple, can be performed quickly, and are valuable, particularly in the diagnosis of DIC. The reptilase clotting time is similar to the thrombin time in principle, but coagulation induced by this enzyme, which is prepared from snake venom, is unaffected by the presence of heparin.

Tests for Fibrin (Fibrinogen)-Degradation Products and D-Dimer

Fibrin (fibrinogen)-degradation products (FDPs) are protein fragments of varying sizes that result from the proteolytic action of plasmin on fibrin or fibrinogen (see Chapter 21) ([75]). Plasma levels of these fragments are commonly increased in association with DIC and fibrinogenolysis, disorders in which their presence is of considerable diagnostic significance. Quantitative assays for FDP are based on several principles, such as staphylococcal clumping ([76]), the agglutination of latex particles coated with antifibrinogen antibody ([77]), immunodiffusion ([78]), and red cell hemagglutination inhibition ([79]). Serum containing rheumatoid factor ([80]) or residual fibrinogen may yield false-positive results in some assays. Reagents needed for most of these methods are available commercially.

None of the aforementioned methods distinguishes between fibrin degradation products and fibrinogen degradation products; to make this distinction, measurement of the DD-dimer or even more sophisticated methods are required ([81]). Extremely sensitive methods for the measurement of fibrinopeptides and specific FDP, such as the DD-dimer ([82]), DDE-trimer, or B-ß 15-42–related peptide, are useful as indices of DIC and as markers of subtle activation of coagulation *in vivo* (see Chapter 60).

Unpolymerized fibrin monomer is commonly present in the blood of patients with DIC. Various techniques (paracoagulation techniques) for demonstrating such monomers have been described; these range from the ethanol gelation test ([83]) and modifications thereof ([84]), which are insensitive, to various protamine gelation techniques ([85]), which are highly sensitive but nonspecific. Cryofibrinogen, which may be demonstrated in some cases of DIC, also may signify the presence of fibrin monomers. All of these assays to diagnose DIC have been supplanted by the D-dimer test ([82]). The use of D-dimer tests to exclude venous thromboembolism is discussed in Chapter 61.

Tests for Factor XIII Activity

The principle of the factor XIII screening test is that clots cross-linked by factor XIII resist denaturation by high concentrations of urea or acid. Deficiency of factor XIII results in premature clot lysis ([3]). Patient plasma is recalcified to induce a clot; the clot is then suspended in 5 mol/L urea (or 1% monochloracetic acid) for 24 hours. Clot stability is visually examined after 24 hours of incubation. Because this assay is a screening test, abnormal results should be repeated and confirmed using a

quantitative factor XIII method, such as measuring factor XIII–dependent incorporation of labeled amines into substances such as fibrinogen or casein ([86]).

Tests for Fibrinolysis

The plasma euglobulin fraction contains plasminogen activators and fibrinogen. Most of the major antiplasmins are removed in the pseudoglobulin supernatant fluid. The rate of lysis of a fibrin clot prepared from the euglobulin fraction (the euglobulin clot lysis time) thus provides a measure of fibrinolysis in the absence of major inhibitors and is a measure of the activity of plasminogen activators ([87]). This test has been adapted to allow measurement of endothelial cell plasminogen activators released *in vivo* after vascular occlusion ([88]).

Tests for fibrinogenolysis and assays for individual components of the fibrinolytic enzyme system, including plasminogen ([89]), free plasmin ([90]), and antiplasmins, are available. Routine coagulation assays for plasminogen activators and plasminogen activator inhibitors typically involve enzyme-linked immunosorbent assay methods ([91] , [92]). These tests are most useful in evaluating patients with recurrent thrombosis who may have abnormal fibrinolysis. Blood collection methods, timing, processing, and determination of assay-specific reference ranges are critically important in accurate evaluation of fibrinolysis parameters ([91] , [92] and [93]).

Moderate concentrations of e-aminocaproic acid (4×10^{-4} mol/L) inhibit plasminogen activators but not free plasmin. Thus, a shortened euglobulin lysis time in the presence of such concentrations of e-aminocaproic acid indicates the presence of free plasmin, as in association with fibrinogenolysis (see Chapter 60). Fibrinolysis in heated fibrin plates also measures free plasmin ([94]) because plasminogen activators are thermolabile.

The rate of whole blood clot lysis is a gross measurement of fibrinolysis, and its determination requires only the incubation and observation of a blood clot, such as one of the samples obtained for a clotting time. If rapid, whole blood clot lysis may be of diagnostic significance; otherwise, the time required for lysis, which normally is more than 24 hours, is usually too long to be of diagnostic help. Neither the euglobulin clot lysis time nor the whole blood clot lysis time is interpretable in the presence of severe hypofibrinogenemia. The results of both tests may be normal, despite the presence of plasminogen activators, as the result of plasminogen depletion. The whole blood and euglobulin clot lysis times have been supplanted by specific assays of fibrinolytic components, as discussed earlier in this section.

Bioassays for Coagulation Factors

Bioassays for coagulation factors are usually based on the familiar screening tests, such as the PT and aPTT. In principle, the extent to which an unknown sample corrects the abnormality in plasma with a known deficiency is assumed to be proportional to the content of the deficient factor in the sample.

The results of coagulation assays may be expressed in terms of units, which equal the amount of a given factor that is present in 1 ml of normal pooled or reference plasma. Alternatively, plasma levels of various factors may be expressed as a percentage of normal. Thus, plasma levels of various coagulation factors typically range from 50 to 150 U/dl, or 50 to 150% of normal.

One-stage methods for factors VIII and IX, which are based on the aPTT and use substrate plasma from patients with severe inherited deficiencies (<1% of normal) of these factors, have proved satisfactory in most laboratories and are somewhat simpler to perform than comparable two-stage methods. However, two-stage methods are more specific than one-stage methods, particularly in patients with intravascular coagulation and liver disease ([95]), presumably because the two-stage methods are less affected by the presence of activated coagulation factors or traces of thrombin that increase the activity of factors V and VIII. Plasmas deficient in specific factors are available commercially. Modifications that do not depend on natural substrates have been developed, including techniques for the assay of prothrombin ([96]); factors V ([97]), VII, and X combined ([65]); and factors VIII ([98]), IX ([99]), X ([100]), and XI ([101]). Details of coagulation assay methodology have been reported ([102]).

Tests for Inhibitors of Coagulation

Abnormalities in any test of coagulation, if caused by deficiency of an essential factor, are corrected by the addition of small amounts of normal plasma. If the abnormality is caused by the presence of one of the various inhibitors of coagulation rather than a deficiency of an essential factor, the opposite is true: Small amounts of the patient's plasma impair coagulation in normal samples. These tests are called *mixing studies* or *inhibitor screens*. This phenomenon is the essence of all screening tests for inhibitors, most of which are based on one-stage coagulation techniques, such as the PT and aPTT ([103]). The presence of heparin may be confirmed in various ways, including use of thrombin time and reptilase time assays, correction by protamine sulfate, or direct assays for activity of heparin or low-molecular-weight heparin ([102]).

Tests for Physiologic Inhibitors of Coagulation

Several methods have been described for the assay of physiologic inhibitors of coagulation ([104]), such as antithrombin III (now referred to as *antithrombin*) ([105] , [106]), heparin cofactor II, protein C ([104] , [107]), and protein S ([108] , [109]). Both immunologic and functional assays are available for many of these components ([104]). Quantitative assays of such physiologic inhibitors may yield valuable information in patients with certain thromboembolic disorders (see Chapter 61).

Automated Coagulation Methods

Numerous instruments are available to detect automatically the endpoint of blood coagulation ([110]). These devices operate on a variety of principles: mechanical detection of the onset of fibrin formation, photometric recording of clot opacity, or the rate of fibrin polymerization. Such instruments are helpful in the performance of one-stage screening tests, such as the PT and aPTT ([111]), especially if a large number of tests must be done daily. The automated methods are not inherently more precise than those performed manually ([112]).

Totally automated methods for performing coagulation tests are widely used. The discrete clinical analyzer (ACA, DuPont, Wilmington, DE) has been adapted to measure fibrinogen ([113]), antithrombin ([114]), and plasminogen. This instrument is particularly convenient when a single assay is needed, in an emergency, or after regular laboratory hours. Automated instrument platforms have been developed to perform a large variety of coagulation methods with significant cost savings, permitting more laboratories to do comprehensive coagulation testing ([115]).

The *thromboelastograph*, an instrument that demonstrates changes occurring during blood coagulation and fibrinolysis, has been used by some investigators. Different coagulograms are described in association with various bleeding disorders and hypercoagulable states ([116] , [117]). However, this is not a commonly used method to diagnose coagulation abnormalities in most laboratories. Its primary use is as a point-of-care instrument in the surgical setting ([45]).

The activated clotting time (ACT) is a whole blood clotting assay now primarily used as a point-of-care test. The ACT measures the clotting time for a whole blood sample after addition of particulate (contact) activators such as kaolin or Celite; thus, this assay measures the intrinsic pathway of coagulation. The ACT is mostly used to monitor anticoagulation in the setting of cardio-pulmonary bypass, cardiac catheterization, or dialysis. The ACT is preferable to the aPTT in certain settings that require high-dose heparin, such as cardiopulmonary bypass ([118]).

Other point-of-care coagulation instruments are being used in the setting of outpatient or home-based oral anticoagulation monitoring. Numerous studies have found that these instruments are at least as effective in providing safe and efficacious anticoagulation as is provided by physicians with standard laboratory anticoagulation testing ([119]). This topic is discussed further in Chapter 61.

Chromogenic and Fluorometric Techniques

Artificial peptides release chromogenic substances or fluorophores when they are enzymatically cleaved ([120] , [121]). The hydrolysis of such peptides by activated coagulation factors provides a novel means for assessing various coagulation reactions ([122] , [123]). Such chromogenic and fluorometric techniques have been developed for the assay of prothrombin and factors VII, IX, and X ([124]); antithrombin ([125]); a $_2$-antiplasmin; heparin; urokinase ([126]); kallikrein ([127]); plasmin; and other components of the fibrinolytic enzyme system ([128]). Assays also have been developed for coagulants that do not have enzymatic activity, such as cellulose

sandwich fluoroimmunoassays for vWF antigen ([129]) and solid-phase front-surface fluorescence detection methods for factors VIIIc and IX ([130]). These methods appear to be intrinsically more precise and may be less time consuming than traditional coagulation methods, and instruments specifically designed for their performance are available. Chromogenic and fluorometric assays are expensive, however, and at present are used mainly in research and in large reference coagulation laboratories.

INITIAL LABORATORY EVALUATION

Primary Screening Tests

The initial laboratory study of the bleeding patient should be guided by the information obtained from the clinical evaluation. In many cases, however, the routine use of a small battery of screening tests has merit because it usually saves time, and the results direct the course of further study. It is generally agreed that the most essential information usually can be obtained from the three tests summarized in Table 51.3, which in view of their availability, simplicity, and low cost, are well suited to serve as primary screening tests. The platelet count provides the most reliable and reproducible test of primary hemostasis. The aPTT measures all of the coagulation factors involved in the intrinsic and common pathways (Fig. 51.5) and generally is accepted as the best single screening test for disorders of blood coagulation. When supplemented with the PT, which assesses the extrinsic as well as the common pathway, the abnormality usually can be localized to one of the three pathways and the factors involved therein (Fig. 51.5 and Table 51.3). The results of these three tests thus provide a presumptive diagnosis, which can then be clarified further by the confirmatory methods summarized in the next section. The bleeding time test has been omitted from this evaluation because of its nonspecificity in the general clinical setting ([14], [17]). The definitive laboratory diagnosis of individual bleeding disorders is discussed in Chapter 52, Chapter 53, Chapter 54, Chapter 55, Chapter 56, Chapter 57, Chapter 58, Chapter 59 and Chapter 60.

TABLE 51.3. Profiles of Hemostasis Screening Tests in Patients with Bleeding Disorders

Prothrom-bin Time	Activated Partial Thrombo- plastin Time	Platelet Count	Differential Diagnosis
?	—	—	Common Acquired factor VII deficiency (early liver disease; early vitamin K deficiency; early warfarin therapy) Rare Factor VII inhibitor; dysfibrinogenemia; some cases of DIC; inherited factor VII deficiency; certain factor X variants
—	?	—	Common Deficiency or inhibitor of factors VIII, IX, or XI; vWD; heparin Rare Lupus inhibitor with qualitative platelet defect; certain factor X variants
?	?	—	Common Vitamin K deficiency; liver disease; warfarin; heparin Rare Deficiency or inhibitor of factors X or V, prothrombin, or fibrinogen; lupus inhibitor with hypoprothrombinemia; DIC; dysfibrinogenemia; primary fibrinolysis
?	?	?	Common DIC; liver disease Rare Heparin therapy with associated thrombocytopenia
—	—	?	Common Increased platelet destruction; decreased platelet production; hypersplenism; hemodilution Rare Certain inherited platelet disorders (Wiskott-Aldrich syndrome, Bernard-Soulier syndrome)
—	—	?	Myeloproliferative disorders
—	—	—	Common Mild vWD; acquired qualitative platelet disorders (uremia) Rare Inherited qualitative platelet disorders; vascular disorders; fibrinolytic disorders; factor XIII deficiency; autoerythrocyte sensitization; dysfibrinogenemia; mild factor deficiency (VIII, IX, XI); disorders of platelet procoagulant activity

?, increased; ?, decreased; —, normal; DIC, disseminated intravascular coagulation; vWD, von Willebrand disease.

NOTE: The differential diagnosis of bleeding disorders suggested by results of the prothrombin time, partial thromboplastin time, and platelet count is listed for each profile. This table includes the differential diagnosis of hemostasis screening test results in patients with a history of bleeding. Consideration of patients with abnormal coagulation tests and negative bleeding histories is not included in this table.

Modified from Rodgers GM. Common clinical bleeding disorders. In: Boldt DH, ed. Update on hemostasis. New York: Churchill Livingstone, 1990:75–120.

It is important to realize that patients with mild bleeding disorders (factor VIII, IX, or XI deficiency) may have normal aPTT values because most aPTT reagents do not detect mild deficiency states (factor levels of 20 to 30%) ([53]). Consequently, if the clinical suspicion is high, specific factor assays for these disorders should be performed, even if the initial evaluation suggested in Table 51.3 is not productive.

CONFIRMATORY TESTS

Thrombocytopenia

Thrombocytopenia (see Chapter 52), like anemia, is a symptom, not a diagnosis. It is the most common of the acquired bleeding disorders. Additional laboratory tests usually are not indicated merely to confirm the presence of thrombocytopenia (Table 51.3) but are helpful in establishing the mechanism for thrombocytopenia. It is useful, however, to examine the thrombocytopenic patient's blood smear to exclude pseudothrombocytopenia that may be seen in a small number of patients ([19], [20]). The differential diagnosis of thrombocytopenia is discussed at length in Chapter 52, Chapter 53, Chapter 54 and Chapter 55. One approach to evaluating thrombocytopenia is shown in Figure 51.6.

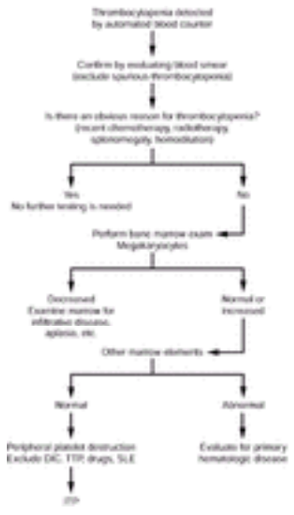

Figure 51.6. An approach for evaluation of thrombocytopenia. The necessity to do a bone marrow examination in the evaluation of idiopathic thrombocytopenic purpura (ITP) is controversial. DIC, disseminated intravascular coagulation; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura. (From Kjeldsberg C, ed. Practical diagnosis of hematologic disorders, 3rd ed. Chicago: ASCP Press, 2000:743, with permission.)

von Willebrand Disease

This disorder is the result of an abnormality in primary hemostasis combined with mild to moderate deficiency of factor VIIIc (see Chapter 59). In the classic case, the results of screening tests reveal a normal platelet count and a prolonged aPTT (Table 51.3). In many patients, however, the aPTT may be normal. Furthermore, the results of all of the laboratory tests tend to fluctuate from time to time ([131]). If the clinical suspicion is high, initial laboratory studies directed at excluding vWD should be performed, because vWD is more common than the inherited disorders of platelet function (Fig. 51.7). Useful tests include bioassay of factor VIII (VIIIc), immunoassay of vWF antigen, and measurement of ristocetin cofactor activity. In many cases, the diagnosis of vWD requires repeated testing.

Figure 51.7. Laboratory diagnosis of von Willebrand disease (vWD) and platelet dysfunction. The initial evaluation reveals mucocutaneous bleeding symptoms in a patient with a normal platelet count (*block in bold*). In vWD, the partial thromboplastin time also may be prolonged because of deficiency of factor VIIIc. Additional tests (*blocks*) and a suggested sequence for their performance are indicated as a flow diagram. Some patients with vWD may have normal assays for factor VIIIc, von Willebrand factor (vWF) Ag, and ristocetin cofactor activity. These patients may be diagnosed by abnormal ristocetin-induced platelet agglutination when aggregation studies are performed or by multimeric analysis of vWF. For patients with normal studies for vWD and platelet dysfunction who are strongly suspected of having an inherited disorder, von Willebrand studies should be repeated.

A more recently available test to evaluate patients for vWD is multimeric analysis of vWF. Patient plasma is separated by agarose electrophoresis, and vWF is identified by immunologic methods. The patient's multimeric pattern is compared to that of normal plasma. A more detailed description of this test is given in Chapter 59.

Qualitative Platelet Disorders

Symptoms of mucocutaneous bleeding in the presence of a normal number of platelets and normal results of coagulation tests (Table 51.3) are presumptive evidence of a disorder of platelet function (see Chapter 58). Inherited forms are uncommon, but bleeding caused by platelet dysfunction may be an important complication in patients with various acquired disorders, such as uremia. Commonly available confirmatory tests occasionally provide useful information regarding platelet dysfunction. Various morphologic abnormalities of the platelets may be seen on the blood smear. Strikingly large platelets are characteristic of certain inherited disorders, such as Bernard-Soulier syndrome. A markedly elevated platelet count is present in the myeloproliferative disorder essential thrombocytosis.

Definitive methods for the study of platelet dysfunction are time consuming and technically difficult. The absence of platelet aggregation by ADP, collagen, and epinephrine is characteristic of Glanzmann thrombasthenia. Deficient secondary wave aggregation is associated with various disorders of the release reaction, such as inherited deficiency of storage nucleotides, uremia, and aspirin ingestion. Abnormal responses to ristocetin indicate vWD or Bernard-Soulier syndrome. Disorders of platelet function are discussed in Chapter 58.

Disorders of the Intrinsic Pathway of Coagulation

Disorders of the intrinsic pathway of coagulation are characterized by a prolonged aPTT and a normal PT (Table 51.3). Inherited forms include deficiencies of factors VIII or IX (hemophilia A and B), prekallikrein, high-molecular-weight kininogen, factor XI, or factor XII (Fig. 51.8). Factor XII (Hageman factor) deficiency and deficiencies of prekallikrein or high-molecular-weight kininogen can be excluded readily because they are not associated with excessive clinical bleeding. Distinguishing between deficiencies of factors VIII, IX, and XI is done by performing specific assays for these factors. Screens (mixing studies) should also be performed to exclude antibodies to the intrinsic factor under study. If a factor VIII inhibitor is identified, the titer should be quantitated (see Chapter 60). An algorithm approach for evaluating bleeding patients with an isolated, prolonged PTT is shown in Figure 51.9.

Figure 51.8. Laboratory diagnosis of inherited coagulation disorders. Results of primary screening tests of coagulation [activated partial thromboplastin time (aPTT), prothrombin time (PT)] are summarized in the center block. Additional tests (*blocks*) and a suggested sequence for their performance are presented as a flow diagram. A more complete list of the differential diagnosis of bleeding disorders is presented in Table 51.3. A, abnormal; HMWK, high-molecular-weight kininogen; N, normal; PTT, partial thromboplastin time.

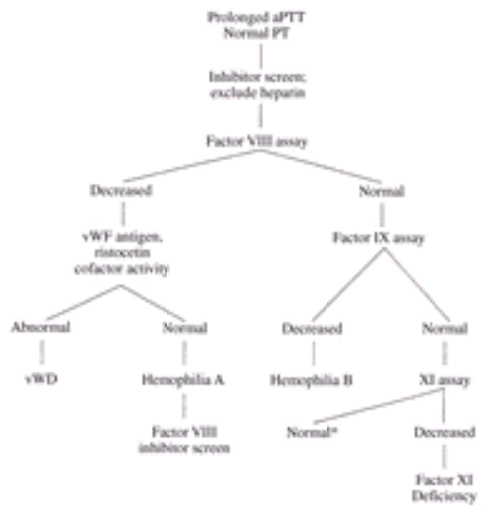

Figure 51.9. Evaluation of a patient with bleeding and an isolated, prolonged partial thromboplastin time (PTT). Asterisk indicates that patients with clinical bleeding but normal studies should be evaluated further for lupus anticoagulants associated with either platelet dysfunction or thrombocytopenia. aPTT, activated partial thromboplastin time; PT, prothrombin time; vWD, von Willebrand disease; vWF, von Willebrand factor. (From Kjeldsberg C, ed. Practical diagnosis of hematologic disorders, 3rd ed. Chicago: ASCP Press, 2000:780, with permission.)

Acquired coagulation disorders associated with a prolonged aPTT and a normal PT include the lupus inhibitor and antibodies to factor VIII. Prolongation of the aPTT is commonly the result of heparin administration or poorly collected blood samples.

Disorders of the Common Pathway of Coagulation

Prolongation of the aPTT and PT in a patient with an inherited bleeding disorder indicates a deficiency of one of the factors in the common pathway—factor X, factor V, prothrombin, or fibrinogen, or a dysfibrinogen (Table 51.3 and Fig. 51.8). Such isolated deficiencies are exceedingly rare. On the other hand, deficiency of one or more of these factors is associated with additional abnormalities in the intrinsic and extrinsic pathways in many of the common acquired coagulation disorders, such as vitamin K deficiency, liver disease, and DIC. A prolonged PT usually suggests an acquired disorder (excluding the rare cases of inherited factor VII deficiency) and usually is associated with a complex abnormality involving multiple pathways, such as DIC.

When confronted with this combination of findings, the first step should be to exclude or to identify an abnormality of fibrinogen. This may be accomplished by determination of the plasma fibrinogen level and tests for increased amounts of D-dimer or FDP. The most helpful ancillary procedures are the platelet count and examination of the blood smear for schistocytes. The laboratory findings characteristic of DIC are summarized in Chapter 60.

Inherited disorders associated with a low fibrinogen level include afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia (see Chapter 59). In certain dysfibrinogenemias, large amounts of unclotted fibrinogen remain in the serum and are detected by tests for FDP.

Inherited deficiencies of factor V, factor X, and prothrombin can be diagnosed by specific factor assays.

Disorders of the Extrinsic Pathway of Coagulation

A prolonged PT and a normal aPTT (Table 51.3) suggest an isolated deficiency of factor VII, which is rare and may be the result of an inherited or an acquired abnormality (Fig. 51.8 and Fig. 51.10). Less commonly, inhibitors of factor VII have been reported ([132], [133]). Additionally, certain cases of DIC or dysfibrinogenemia may present with isolated prolonged PT values ([134]). Because factor VII is essential only in the tissue factor–activated extrinsic pathway of coagulation, the Stypven time is normal in patients with this disorder.

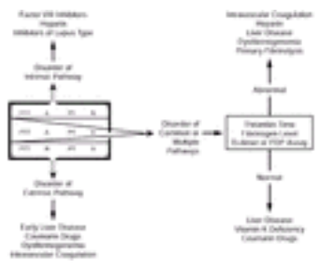

Figure 51.10. Laboratory diagnosis of acquired coagulation disorders. Results of primary screening tests of coagulation [partial thromboplastin time (PTT), prothrombin time (PT)] are summarized in the heavy black block. Additional tests (*blocks*) and a suggested sequence for their performance are presented as a flow diagram. Because of the complexity of acquired coagulation disorders and great variations in the results of laboratory tests that may be encountered in the various disorders and in individual patients, this diagram should be regarded as a general guide only. A more complete list of the differential diagnosis of bleeding disorders is presented in Table 51.3. A, abnormal; FDP, fibrin degradation products; N, normal.

Disorders in Which Results of Primary Screening Tests Are Normal

Screening tests usually yield normal results in patients with bleeding disorders related to vascular abnormalities (Table 51.3 and Table 51.4). The diagnosis is usually made from the associated clinical findings that are often characteristic, such as the skin lesions of hereditary hemorrhagic telangiectasia, allergic purpura, scurvy, and senile purpura. A positive reaction to a specific skin test may confirm the diagnosis of autoerythrocyte sensitization and related disorders. The results of screening tests also are normal in factor XIII (fibrin-stabilizing factor) deficiency, a disorder in which the diagnosis is made by the demonstration of characteristic clot solubility in urea or monochloroacetic acid.

TABLE 51.4. Bleeding Disorders in Which the Results of Primary Screening Tests May Be Normal

von Willebrand disease
Mild inherited coagulation disorders, particularly factor XI deficiency
Heterozygous carriers of inherited coagulation disorders
Factor XIII (fibrin-stabilizing factor) deficiency
Some forms of dysfibrinogenemia
Disordered platelet function, particularly deficient release reaction; Scott syndrome
Hereditary hemorrhagic telangiectasia
Allergic and other vascular purpuras
a $_2$-plasmin inhibitor deficiency
Elevated levels of plasminogen activator

Although abnormal in the typical case, the results of screening tests may be normal or equivocal in patients with mild coagulation disorders (including heterozygous

carriers), certain disorders of platelet function, mild forms of vWD, and dysfibrinogenemia or abnormal fibrinolysis ([102], [135]). More definitive tests are required to establish the diagnosis in these patients (Table 51.4). An increasing number of reports have indicated that many bleeding patients with normal screening studies have disorders of platelet procoagulant activity, such as Scott syndrome ([136]).

There are patients with a significant bleeding history in whom the results of detailed studies of hemostasis and blood coagulation are normal. Some have disorders of hemostasis that cannot be detected by methods currently available. The clinical management of these cases requires great care, and the fact that a clear-cut history of bleeding is always more significant than negative laboratory data cannot be overemphasized. Trauma may be denied in physically abused patients and may be self-inflicted in psychotic or neurotic patients.

PREOPERATIVE HEMOSTASIS EVALUATION

The value of obtaining routine screening tests before surgical procedures has been debated for years ([137]). The screening tests for hemostasis are not totally satisfactory in detecting all mild hemostatic defects. Nevertheless, routine preoperative laboratory screening is of great value in certain high-risk patients who have disorders that predispose them to unexpected postsurgical bleeding, even from limited biopsy procedures. Important in this category are patients with liver disease, biliary obstruction, renal disease (particularly if complicated by azotemia), myelofibrosis, polycythemia vera, and other myeloproliferative disorders, particularly those associated with thrombocytosis and those with paraproteinemias. Included in this list should be all patients scheduled to undergo procedures involving the use of extracorporeal circulatory devices.

One approach to the question of preoperative hemostasis screening tests is to balance the financial costs of laboratory testing with the extent of surgery to be performed and with the amount of bleeding that can be safely tolerated. This approach makes the patient's hemostasis history particularly important. Patients scheduled for minor surgical procedures (dental, skin biopsy) do not need routine hemostasis screening tests if they have a negative history. In contrast, patients undergoing neurosurgery or other procedures that may induce a hemostatic defect (use of a bypass pump) or patients with a positive bleeding history need a hemostasis evaluation by the laboratory. Table 51.5 summarizes the recommendations of Rapaport in evaluating preoperative patients ([137]).

TABLE 51.5. Guidelines for Preoperative Hemostasis Evaluation

Level	Bleeding History	Surgical Procedure	Recommended Hemostasis Evaluation
I	Negative	Minor	None
II	Negative	Major	Platelet count, aPTT
III	Equivocal	Major, involving hemostatic impairment	PT, aPTT, platelet count, factor XIII assay, euglobulin clot lysis time
IV	Positive	Major or minor	Level III tests; if negative, then factors VIII, IX, and XI assays, thrombin time, a $_2$-antiplasmin assay; consider von Willebrand disease and platelet aggregation testing; consider specific tests for abnormal fibrinolysis

aPTT, activated partial thromboplastin time; PT, prothrombin time.

NOTE: Information in this table is a revision based on the suggested preoperative guidelines for hemostasis testing by Rapaport ([137]). The bleeding time is omitted as a hemostasis test due to more recent appreciation of its weakness as a useful test.

From Rodgers GM. Preoperative hemostasis screening. In: Kjeldsberg C, ed. Practical diagnosis of hematologic disorders, 3rd ed. Chicago: ASCP Press, 2000:815, with permission.

EVALUATION OF THE NEONATE

Laboratory investigation of hemostasis and blood coagulation in the neonate and infant differs from that just outlined in several respects ([138], [139]). First, the quantity of blood that can be obtained is limited, and often, the venipuncture is difficult. Various microtechniques and modifications of standard coagulation techniques that involve the use of capillary blood have been developed to circumvent this problem ([140]). In most cases, however, they are not entirely satisfactory ([141]). Second, in terms of adult norms, the results of some tests are abnormal, even in healthy full-term infants (Table 51.6). Such physiologic abnormalities presumably are the result of deficiencies of the vitamin K–dependent factors and of additional abnormalities in the contact phase of coagulation and in the thrombin-fibrinogen reaction ([4], [142]). The results of screening tests in healthy newborns are similar to those of adults within 2 to 6 months of age.

TABLE 51.6. Age-Related Coagulation Reference Values in Newborns, Children, and Adults

	Age					
Coagulation Test	5 Days	90 Days	1–5 Yr	6–10 Yr	11–16 Yr	Adult
Fibrinogen (g/L)	1.62–4.62	1.50–3.79	1.70–4.05	1.57–4.00	1.54–4.48	1.50–3.50

Plasminogen activator inhibitor (U/ml)	—	—	1.0–10.0	2.0–12.0	2.0–10.0	2.0–15.0 [b]
a $_2$-antiplasmin (U/ml)	—	—	0.93–1.17	0.89–1.10	0.78–1.18	4.4–8.5 mg/dl [c]

[a] Results are of antigenic assays (all other results are of functional assays).

[b] The adult fibrinolysis tests (i.e., tissue plasminogen activator and plasminogen activator inhibitor) are based on reference range values drawn between 7 to 9 a.m.

[c] Adult a $_2$-antiplasmin values are listed in terms of mg/dl.

NOTE: Prothrombin time and partial thromboplastin time values are not shown because these values depend on reagent selection. Adult values represent those of the University of Utah Medical Center Hemostasis and Thrombosis Laboratory. Pediatric values are for healthy full-term infants taken from Andrew M, Vegh P, Johnston M, et al. Maturation of the hemostatic system during childhood. Blood 1992;80:1998; and Andrew M, Paes B, Johnston M. Development of the hemostatic system in the neonate and young infant. Am J Pediatr Hematol Oncol 1990;12:95.

From Kjeldsberg C, ed. Practical diagnosis of hematologic disorders, 3rd ed. Chicago: ASCP Press, 2000:910–911, with permission.

The PT may be prolonged but often is normal if vitamin K is administered to the infant or mother ([142]). Abnormalities of the thrombin time and the aPTT ([60]) are present in many normal neonates. These findings usually disappear within 2 to 6 months ([4], [139], [143]). These abnormalities and moderate deficiencies of the vitamin K–dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are more pronounced in the premature than in the full-term infant, and in extent, they are inversely proportional to gestational age and birthweight. Tests for FDP and the euglobulin lysis time may be unreliable if carried out on cord blood ([144]). Plasma levels of fibrinogen and factor VIII increase slightly with increasing gestational age in thriving premature infants (Table 51.6) ([145]). Levels of factors VIII and V as well as antithrombin may be low in extremely premature infants ([146]). Factor VIII levels and the ratio of vWF_{Ag} to VIIIc are higher in term infants than in adults or older children.

Levels of factor V are normal in both neonates and thriving premature infants ([142], [145], [147]). Levels of antithrombin and other physiologic inhibitors of coagulation and of factor XIII are below adult norms in term neonates ([148]). Significant abnormalities of platelet aggregation and of the results of other platelet function tests may be seen in normal neonates ([149]). The newborn also is abnormally susceptible to drugs that impair platelet function, including those transferred placentally from the mother. The platelet count in term infants, as well as in thriving premature infants, is within the range found in adults and older children. Table 51.6 summarizes coagulation reference ranges in newborns, children, and adults.

Thrombocytopenia: Pathophysiology and Classification

Purpura in association with pestilential fevers was described by Hippocrates and later writers, but it was not until the sixteenth century (Lusitanus) and the early part of the seventeenth century (La Riviere) that purpura in the absence of fever was recognized ([1]). In 1735, Werlhof distinguished *morbus maculosus hemorrhagicus* as a separate entity, and in 1808, Willan classified purpura under the headings *simplex, haemorrhagica, urticans*, and *contagiosa*, thus separating the types later described by Schönlein (1829) and Henoch (1868) that now bear their names. The marked diminution in “hematoblasts” (platelets) in purpura hemorrhagica was recognized by Krauss (1883) and Denys (1887). Hayem (1895) noted the nonretractility of the blood clot, and Duke (1912) demonstrated the prolonged bleeding time. Abnormal capillary fragility was observed by writers in different countries (*le signe du lacet*, Grocco-Frugoni sign, and the Rumpel-Leede phenomenon).

PATHOPHYSIOLOGY

Thrombocytopenia may be defined as a subnormal number of platelets in the circulating blood. It is the most common cause of abnormal bleeding. The pathophysiology of thrombocytopenia is similar to that of anemia, but the latter is better understood. Thus, despite the number and diversity of disorders that may be associated etiologically, thrombocytopenia results from only four processes: artifactual thrombocytopenia, deficient platelet production, accelerated platelet destruction, and abnormal distribution or pooling of the platelets within the body (Fig. 52.1). The changes in the basic parameters of thrombopoiesis that are characteristic of each of these processes are summarized in Table 52.1.

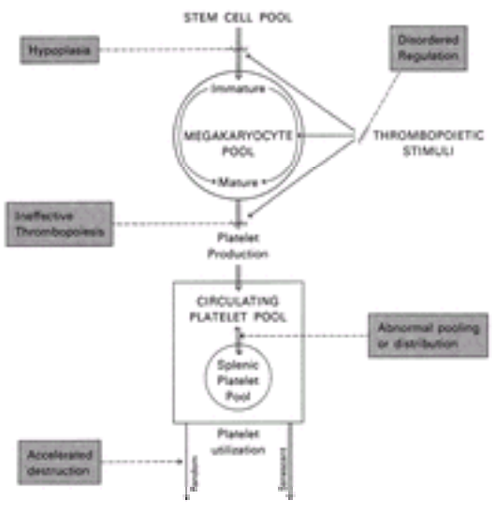

Figure 52.1. The pathophysiology of thrombocytopenia. A simplified diagram of the biodynamics of the megakaryocyte–platelet system (*solid lines*) and the mechanisms (*dashed lines*) by which pathologic processes (*shaded blocks*) produce thrombocyto-penia.

TABLE 52.1. Thrombokinetic Patterns in Various Forms of Thrombocytopenia

Measurement	Decreased Production		Accelerated Destruction [c]	Abnormal Pooling
	Hypoproliferation or Hypoplasia [a]	Ineffective Thrombopoiesis [b]		
Total megakaryocyte mass [d]	Decreased	Increased	M increased	V increased
Megakaryocyte number	Decreased	M increased	Increased	V increased
Megakaryocyte volume	Increased	Normal or V decreased	Increased	V increased
Platelet turnover rate or production rate [e]	Decreased	Decreased	Increased	V increased
Total platelet mass	Decreased	Decreased	Decreased	? Normal
Splenic platelet pool	Decreased	Decreased	Decreased [f]	Increased
Platelet survival	Normal	V shortened	Shortened	V shortened

M, markedly; V, variably.

[a] Includes myelophthisic processes.

[b] Mainly in megaloblastic hematopoiesis; component of accelerated destruction present in some cases.

[c] Minor component of ineffective thrombopoiesis present in some cases.

[d] Equated to total thrombopoiesis.

[e] Equated to effective thrombopoiesis.

[f] Not representative of sequestered antibody-sensitized platelets.

Based on references 10, 12, 17, and 18.

ARTIFACTUAL THROMBOCYTOPENIA

Artifactual thrombocytopenia, or falsely low platelet counts, occurs *ex vivo* when platelets are not counted accurately. This mechanism should be considered in patients who have thrombocytopenia but no petechiae or ecchymoses. Although inaccurate counting may occur in the presence of giant platelets ([2]) or with platelet satellitism ([3], [4]), the most common cause of artifactual thrombocytopenia is platelet clumping (pseudothrombocytopenia) ([5]). Platelet clumping in pseudothrombocytopenia appears to be caused by anticoagulant-dependent platelet agglutinins that are immunoglobulins (Igs) of IgG, IgA, or IgM subtypes. Although clumping is most commonly seen when blood is collected into ethylenediaminetetraacetic acid anticoagulant, other anticoagulants may cause clumping, even hirudin or Phe-Pro-Arg chloromethyl ketone ([6]). Platelet clumping is also time dependent and varies with the type of instrumentation used for automatic counting ([6]). There is evidence that the autoantibodies bind to glycoprotein IIb/IIIa ([7]), and in one study, there was over 80% concordance between the presence of anticardiolipin antibody and platelet agglutinins in individual patient plasmas ([8]). These autoantibodies have no known associations with disease or drugs and have been noted in

some patients for over 10 years ([9]).

ACCELERATED PLATELET DESTRUCTION

Accelerated platelet destruction is the most common cause of thrombocytopenia. It leads to stimulation of thrombopoiesis and, consequently, to an increase in the number, size, and rate of maturation of the precursor megakaryocytes (Fig. 52.1) ([10]). When the rate of platelet destruction exceeds this compensatory increase in platelet production, thrombocytopenia develops. “Compensated” platelet destruction without thrombocytopenia also may occur in patients with prosthetic heart valves and in patients with idiopathic thrombocytopenic purpura after splenectomy ([11] , [12] , [13] , [14] , [15] , [16] and [17]).

Platelet destruction may result from both intracorpuscular defects and extracorpuscular abnormalities. Intracorpuscular defects are rare but have been demonstrated in certain forms of hereditary thrombocytopenia, such as Wiskott-Aldrich syndrome (see Chapter 55) ([18]). In such disorders, the survival of affected platelets is shortened in the circulation of both the patient and normal recipients. Platelets injured by either intracorpuscular or extracorpuscular processes usually are removed from the circulation by the spleen, liver, and reticuloendothelial system. Platelet destruction most often is the result of extracorpuscular factors; various immunologic phenomena are the most common. Immunologic platelet destruction is discussed in Chapter 53.

Platelet consumption in intravascular thrombi or on damaged endothelial surfaces is another cause of thrombocytopenia. This occurs in disseminated intravascular coagulation (see Chapter 60) and in thrombotic thrombocytopenic purpura (see Chapter 54) and other microangiopathic processes. Thrombocytopenia caused by such nonimmunologic platelet destruction is discussed in Chapter 55.

DEFICIENT PLATELET PRODUCTION

Deficient platelet production may result from any of a number of processes. Those that depopulate the stem cell or mega-karyo-cyte compartments are the most common, such as marrow injury by myelosuppressive drugs or irradiation and aplastic anemia. Deficient platelet production also may be the consequence of disordered proliferation within a precursor compartment of normal or even increased size. For example, in disorders characterized by megaloblastic hematopoiesis, hypertrophy of the precursor compartment occurs in response to thrombopoietic stimuli, but thrombopoiesis is ineffective, and platelet production is insufficient. Rarely, abnormalities of the processes that normally regulate thrombocytopoiesis appear to underlie deficient platelet production, such as deficiency of thrombopoietin and cyclic thrombocytopenia.

ABNORMAL POOLING

Abnormal pooling or abnormal *in vivo* distribution of an essentially normal total platelet mass may produce thrombocytopenia. This type of thrombocytopenia is seen in the various disorders associated with splenomegaly (see Chapter 55), in which platelet production is normal or even increased, but most of the platelets are sequestered in the vastly enlarged extravascular splenic pool. Thrombocytopenia may also be caused by dilution of platelets when patients are massively transfused during blood loss. A discussion of various forms of thrombo-cytopenia attributable to deficient or ineffective thrombopoiesis or abnormal platelet pooling is included in Chapter 55.

CLASSIFICATION

A classification of thrombocytopenia based on pathophysiologic criteria is presented in Table 52.2. Such a classification must be regarded as tentative because current methods for studying thrombopoiesis are crude, and in many disorders, multiple pathogenetic factors may simultaneously or sequentially play a role in the production of thrombocytopenia. The discussion and various tables included in Chapter 53, Chapter 54, and Chapter 55 are based on the most suitable nosologic features of both the etiologic and the pathophysiologic classifications because neither alone is entirely satisfactory.

TABLE 52.2. Pathophysiologic Classification of Thrombocytopenia

- Artifactual thrombocytopenia
  - Platelet clumping caused by anticoagulant-dependent immunoglobulin (pseudothrombocytopenia)
  - Platelet satellitism
  - Giant platelets
- Decreased platelet production (see Chapter 55)
  - Hypoplasia of megakaryocytes
  - Ineffective thrombopoiesis
  - Disorders of thrombopoietic control
  - Hereditary thrombocytopenias
- Increased platelet destruction
  - Caused by immunologic processes (see Chapter 54)
    - Autoimmune
      - Idiopathic
      - Secondary: infections, pregnancy, collagen vascular disorders, lymphoproliferative disorders, drugs, miscellaneous
    - Alloimmune
      - Neonatal thrombocytopenia
      - Posttransfusion purpura
  - Caused by nonimmunologic processes
    - Thrombotic microangiopathies
      - Disseminated intravascular coagulation (see Chapter 60)
      - Thrombotic thrombocytopenic purpura (see Chapter 54)
      - Hemolytic-uremic syndrome (see Chapter 38)
    - Platelet damage by abnormal vascular surfaces (see Chapter 55)
    - Miscellaneous (see Chapter 55)
      - Infection
      - Massive blood transfusions
- Abnormal platelet distribution or pooling (see Chapter 55)
  - Disorders of the spleen (neoplastic, congestive, infiltrative, infectious, of unknown cause)
  - Hypothermia
  - Dilution of platelets with massive transfusions

Methods for the measurement of serum thrombopoietin concentrations or reticulated platelets have been recently established. These new techniques may both elucidate the pathophysiology of thrombocytopenia in various disease states and determine the mechanism of thrombocytopenia in individual patients. Serum thrombopoietin concentrations are elevated in patients with deficient platelet production and normal in patients with accelerated destruction, suggesting that thrombopoietin production correlates with megakaryocyte mass ([19] , [20]). Reticulated platelets can be identified with fluorescent dyes that bind to nucleic acids, especially RNA. Measurement of the percentage of reticulated platelets identifies platelets that have recently been released from the bone marrow. There is an increased percentage of reticulated platelets in patients with thrombocytopenia caused by increased destruction and a normal to reduced percentage of reticulated

platelets in patients with deficient production ([21], [22]). The sensitivity and specificity of this method of distinguishing between these categories are reported to be more than 95% ([23], [24]).

Thrombocytopenia Caused by Immunologic Platelet Destruction

Autoimmune thrombocytopenic purpura is believed to occur when platelets undergo premature destruction as a result of autoantibody or immune complex deposition on their membranes. The site of destruction is usually the reticuloendothelial system of the spleen and, less commonly, the liver. In many instances, the underlying disorder responsible for the formation of platelet antibodies or immune complexes is known. This is commonly called *secondary autoimmune thrombocytopenia*. In other instances, there are no known etiologic factors, and the disorder is called *idiopathic thrombocytopenic purpura* (ITP) (Table 53.1).

TABLE 53.1. Autoimmune Thrombocytopenic Purpura

Idiopathic (primary)
Secondary
Infections
Collagen vascular diseases
Lymphoproliferative disorders
Solid tumors
Drugs
Miscellaneous

In this chapter, both idiopathic and secondary types of immune thrombocytopenia are discussed. Human immunodeficiency virus–related autoimmune thrombocytopenia, which is also in major part due to the deposition of autoantibody or immune complexes, or both, on the platelet surface, is discussed in Chapter 69.

The diagnosis of autoimmune thrombocytopenic purpura is primarily a diagnosis by exclusion because currently available clinical assays for platelet-associated antibodies or serum antiplatelet antibodies/immune complexes are neither specific nor sensitive enough for routine clinical use. These disorders are characterized by peripheral thrombocytopenia (confirmed by examination of the peripheral smear), with a normal number of megakaryocytes present on bone marrow examination, and absence of significant splenomegaly. Those patients who have no identifiable underlying cause, which might include infections, collagen vascular diseases, lymphoproliferative disorders (chronic lymphocytic leukemia or lymphoma), or drugs, are diagnosed as idiopathic (i.e., ITP). In some instances, the ITP may be the presenting manifestation of an underlying disease, and additional manifestations appear weeks to months later. Idiopathic and secondary thrombocytopenic purpuras are discussed separately in this chapter.

IDIOPATHIC AUTOIMMUNE THROMBOCYTOPENIC PURPURA

The term *idiopathic thrombocytopenic purpura* usually refers to thrombocytopenia in which apparent exogenous etiologic factors are lacking and in which diseases known to be associated with secondary thrombocytopenia have been excluded. This syndrome has been reviewed in detail ([1], [2], [3], [4], [5], [6] and [7]).

Acute ITP and chronic ITP differ in incidence, prognosis, and therapy (Table 53.2). These differences may illustrate merely the wide spectrum of disorders that by definition are included in the syndrome, but many clinicians have long believed that acute ITP and chronic ITP are fundamentally different disorders.

TABLE 53.2. Features of Acute and Chronic Idiopathic Thrombocytopenic Purpura (ITP)

Feature	Acute ITP	Chronic ITP
Peak age of incidence	Children, 2–6 yr	Adults, 20–40 yr
Sex predilection	None	3:1 female to male
Antecedent infection	Common 1–3 wk before	Unusual
Onset of bleeding	Abrupt	Insidious
Hemorrhagic bullae in mouth	Present in severe cases	Usually absent
Platelet count	<20,000/µl	30,000–80,000/µl
Eosinophilia and lymphocytosis	Common	Rare
Duration	2–6 wk; rarely longer	Months or years
Spontaneous remissions	Occur in 80% of cases	Uncommon

Incidence

Acute ITP, defined as thrombocytopenia occurring for less than 6 months and usually resolving spontaneously, most often affects children and young adults. The incidence peaks in the winter and spring, following the incidence of viral infections ([8], [9]). Acute ITP is most common between 2 and 6 years of age. Approximately 7 to 28% of children with acute ITP develop the chronic variety ([9], [10] and [11]). Chronic ITP, lasting more than 6 months and requiring therapy to improve the thrombocytopenia, occurs most commonly in adults. In the oldest reported series in the literature, in which both acute and chronic ITP cases were reviewed, 67% of

271 patients and 45% of 737 patients were younger than 21 years of age and 15 years of age, respectively ([12], [13] and [14]). In chronic ITP in adults, the median age is usually 40 to 45 years ([15], [16]), although in one large series of patients, 74% of 934 cases were younger than age 40 (range, 16 to 87 years of age) ([17]). The ratio of females to males is nearly 1:1 in acute ITP ([9], [10] and [11], [18]) and 2 to 3:1 in chronic ITP ([16], [17]).

Pathophysiology

Evidence is now convincing that the syndrome of ITP is caused by platelet-specific autoantibodies that bind to autologous platelets, which are then rapidly cleared from the circulation by the mononuclear phagocyte system via macrophage Fc receptors ([19]) (Fig. 53.1). The ITP antibody does not fix complement *in vitro* when tested by the usual techniques, but activation of components of complement on the platelet surface may be demonstrated ([20], [21], [22], [23], [24], [25], [26] and [27]). Immune complexes have been detected in patients with chronic ITP, but their role in immune platelet destruction remains controversial ([28], [29], [30], [31] and [32]). The concomitant role of the antibody binding to the same antigens on megakaryocytes and the resultant effect of this binding on platelet production are still unknown.

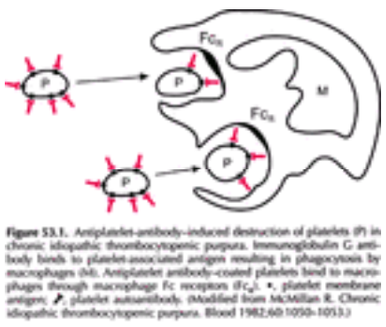

Figure 53.1. Antiplatelet-antibody–induced destruction of platelets (P) in chronic idiopathic thrombocytopenic purpura. Immunoglobulin G antibody binds to platelet-associated antigen resulting in phagocytosis by macrophages (M). Antiplatelet antibody–coated platelets bind to macrophages through macrophage Fc receptors (Fc $_R$). •, platelet membrane antigen; , platelet autoantibody. (Modified from McMillan R. Chronic idiopathic thrombocytopenic purpura. Blood 1982;60:1050–1053.)

PLATELET ANTIBODIES In 1951, Harrington and colleagues first reported that the infusion of plasma from patients with ITP predictably induced thrombocytopenia in normal recipients ([33]). Shulman and colleagues then demonstrated that the responsible factor was an immunoglobulin (Ig) of the IgG class that was species-specific and could be removed from serum by absorption with normal human platelets and subsequently eluted therefrom ([34]). In addition, the platelet-depressing factor produced effects *in vivc* that were quantitatively and qualitatively similar to those produced by known platelet antibodies. In 1982, van Leeuwen first identified platelet membrane glycoprotein IIb/IIIa (CD41) as a dominant antigen by demonstrating that the autoantibodies eluted from ITP patients' platelets bound to normal platelets but not platelets from patients with Glanzmann's thrombasthenia ([35]). Increased quantities of IgG have been demonstrated on the platelet surface, and the rate of platelet destruction in ITP is proportional to levels of such platelet-associated Ig ([36], [37]). Autoantibodies are readily found in plasma or platelet eluate in patients with active disease but are infrequently found in patients in remission ([38], [39]). Disappearance of the antibodies correlates with the appearance of normal platelet counts ([38]). The antiplatelet antibodies and platelet antigens involved in ITP have been extensively studied (Table 53.3) and several types of sensitive assays now permit the identification of the antigen for both plasma and platelet-associated autoantibody ([39], [40] and [41]). Platelet-associated autoantibodies have been detected in 75% of patients ([41], [42]). Serum antiplatelet IgG autoantibodies are detected in approximately 50 to 85% of patients. IgA serum antiplatelet antibodies appear to be as frequent as IgG, and in approximately 50% of cases, both Ig subtypes occur in the same patient. IgM antibodies are also detected in a small number of patients—but never as the sole autoantibody present ([43]). In one study, the presence of IgM antibodies had the strongest correlation with the platelet count ([44]). There is also evidence of light chain restriction of these autoantibodies that suggests clonal B-cell expansion in patients with chronic ITP ([45], [46], [47] and [48]).

TABLE 53.3. Characteristics of Platelet Autoantibodies in Idiopathic Thrombocytopenic Purpura

		Comments
Ig subtype	IgG, IgA, IgM	IgG and IgA have equal frequency
		IgM [a]
Antigen specificity	gpIIb/IIIa, Ib/IX	Most common antigens
	gpIa/IIa, IV	Never only antigen if positive
	Granule membrane protein-140	One patient reported
	Glycosphingolipid	Rare; ?pathogenetic importance
	Cardiolipin	Common; ?pathogenetic importance
Presence of antibody		
Plasma	85% of patients	
Platelet eluate	75% of patients	
Complement fixation by antibody	Rare	Unresolved importance
Circulating immune complexes	Rare	Unresolved importance

gp, glycoprotein; Ig, immunoglobulin.

[a] IgM is never present as the only antiplatelet Ig in an individual patient.

Antiplatelet autoantibodies bind to many of the major platelet membrane glycoproteins through the Fab portion of the molecule ([49], [50]) (Fig. 53.2). Platelet gpIIb/IIIa was the first platelet antigen detected, but microtiter assays using platelet monoclonal antibodies to gpIb and gpIIb/IIIa demonstrated that platelet autoantibodies bound to both major platelet membrane glycoproteins ([51], [52] and [53]). gpIIb/IIIa and gpIb/IX are found to be the major platelet antigens with almost equal frequency; however, some autoantibodies also react with gpIV and Ia/IIa, although the plasma from these patients usually also contains autoantibodies reacting with one of the other two major platelet membrane antigens ([54]). Only one patient has been reported who had serum autoantibodies that reacted with granule membrane protein-140 (P-selectin; CD42) in addition to gpIIb/IIIa ([55]). Serum antibodies to a $_V$ß $_3$ have been detected as well, but their clinical significance is unknown ([56]).

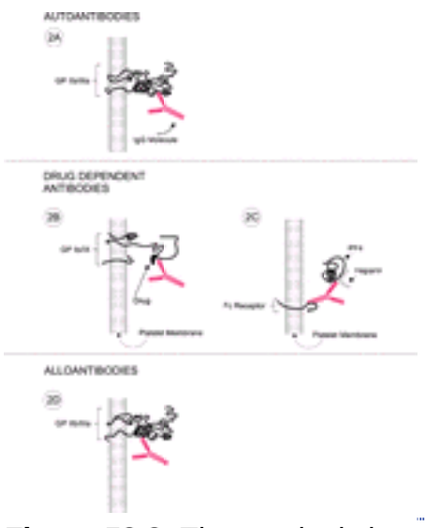

Figure 53.2. The serologic investigation of patients with antibody-mediated platelet destruction. **A:** Platelet autoantibodies bind to variable external and internal platelet epitopes. **B:** Quinine/quinidine-dependent antibodies. The antibody target is a complex of drug and glycoprotein (GP) (usually GPIb/IX or GPIIb/IIIa). **C:**

Heparin-dependent antibodies. The antigen-antibody complex [target: platelet factor 4 (PF4)/heparin] activates platelets by the binding of immunoglobulin G (IgG) to Fc?RII. **D:** Platelet alloantibodies bind to platelet tertiary conformational epitopes on the platelet membrane. (Modified from Kelton JG. The serologic investigation of patients with autoimmune thrombocytopenia. Thromb Haemost 1995;74:228–233.)

The incidence of serum autoantibodies to platelet gpIIb/IIIa is the same in the acute and chronic forms of childhood ITP (68% vs. 62%, respectively) ([57]). The presence of anti-gpIIb/IIIa, therefore, does not predict which children will develop the chronic form of the disease, and, in fact, these data provide the first evidence that the mechanism may be the same in both acute and chronic forms of ITP. The platelet membrane glycoproteins have a variety of antigenic epitopes that are recognized by the autoantibodies. There is considerable evidence that serum autoantibodies can react with IIb or IIIa or the intact IIb/IIIa complex ([53], [58], [59], [60], [61], [62], [63], [64], [65], [66], [67] and [68]). Platelet autoantibody binding to gpIb ([27]) and gp1ba ([54]) has been reported, but data indicate that the majority of Ib/IX autoantibodies are directed to the complex ([69]). Plasma autoantibodies and autoantibodies eluted from platelets in the same patient may have slight differences in antigen specificities within a membrane gp complex ([62]). The importance of the specific antigen epitopes on the course of the disease is controversial ([23], [62], [69]). Antibodies in ITP sera have also been demonstrated to bind to glycosphingolipids ([70], [71]) and cardiolipin ([72], [73], [74] and [75]). Although antiphospholipids were identified by lupus anticoagulant activity or anticardiolipin specificity in 46 and 38% of ITP patients at diagnosis, there was little clinical evidence that they played a role in the pathogenesis of the disease or affected outcome ([76], [77]). These autoantibodies bind to platelets and cause thrombocytopenia primarily by shortening platelet survival. However, rare autoantibodies have also been reported that bind to these glycoproteins and activate platelets ([78], [79], [80], [81] and [82]). Additionally, one patient with an anti-gpIIIa antibody is reported to have developed an antibody-related defect in aggregation and adhesion ([83]). The role of cell-mediated immunity in ITP remains uncertain, although data from patients with ITP suggest that T lymphocytes demonstrate phenotypic and functional abnormalities. Platelet reactive T-cell clones can be identified from the peripheral blood of adults and peripheral blood and spleens of children with chronic ITP, suggesting that autoreactive peripheral T lymphocytes may mediate or participate in the pathophysiology of this immune disorder ([66], [84], [85]). T lymphocytes from patients with ITP also demonstrate a defect in T-cell function that is not due to a serum suppressor factor, abnormal production of interleukin-2, or changes in the interleukin-2 receptor ([86]). These patients have increased numbers of $CD8^+$ cells, decreased numbers of $CD4^+$ cells ([87], [88], [89] and [90]), and impaired autologous mixed lymphocyte reaction-induced suppressor function ([91]).

PLATELET SURVIVAL Platelet survival, measured using ^{51}chromium- or ^{111}indium-labeled platelets, is shortened in ITP, and the measured survival time can range from 2 to 3 days to a matter of minutes ([92], [93], [94], [95], [96], [97], [98], [99], [100], [101], [102] and [103]). Using ^{111}indium-labeled autologous platelets, some investigators have found an inverse correlation between venous platelet count and platelet survival ([99], [101]), and others have not ([100]). These differences between studies may be because of the types of patients included, as patients with mild to moderate thrombocytopenia have a longer measured survival than patients with severe thrombocytopenia. Splenic sequestration accounts for the shortened survival in most patients ([104], [105]), but the liver, and even the reticuloendo-thelial cells of the bone marrow, can play a major role in the sequestration of antibody-coated platelets, especially in patients with very low platelet counts or continued thrombocytopenia after splenectomy ([96], [97], [101]). Patients with severe thrombocytopenia have been found to have elevated macrophage colony-stimulating factor ([106]) and increased *in vitro* monocyte-platelet rosette formation ([107]). There also appears to be an inverse correlation between platelet count/platelet survival and impaired reticuloendothelial system function as assessed by clearance of IgG-sensitized, chromium-labeled autologous erythrocytes ([108]). Investigators are now studying the role of Fc?RII and Fc?RIII polymorphisms in ITP but early data are conflicting ([109], [110]). The spleen has also been implicated as a site of antibody formation ([111], [112]). In a pathologic study of 83 spleens that had been removed after patients did not respond to steroid therapy, investigators found splenic weights of less than 300 g, prominent secondary lymphoid follicles (28%), foamy macrophages (67%), and megakaryocytic extramedullary hematopoiesis (60%) ([113]). These pathologic changes reflect the two major pathogenic roles of the spleen: antiplatelet antibody production and macrophage-mediated platelet destruction. Whether megakaryopoiesis is reduced in some or many of these patients is still controversial. Survival studies have demonstrated decreased, normal, and increased platelet turnover ([99], [102], [103]). Antiplatelet antibodies can also bind to precursor bone marrow megakaryocytes ([114], [115] and [116]), and it is thus postulated that the reduced megakaryopoiesis may be secondary to the effects of the antiplatelet antibodies on platelet production. Megakaryocyte size was small in patients with anti-gpIb/IX autoantibodies and increased in size and cytoplasmic area in patients with anti-gpIIb/IIIa autoantibodies, suggesting to investigators that the anti-gpIIb/IIIa autoantibody impairs platelet production ([117]). Megakaryocyte colony formation (colony-forming unit megakaryocyte) is increased ([118], [119]) in acute ITP. In chronic ITP, decreased colony-forming unit megakaryocyte has been reported ([120]).

Clinical Picture

ACUTE IDIOPATHIC THROMBOCYTOPENIC PURPURA In patients with acute ITP, the onset of the disorder usually is sudden (Table 53.2). A history of infection preceding the onset of bleeding has been documented repeatedly ([121], [122]). In one series, such infections were noted within 3 weeks of the onset of ITP in 84% of cases ([8], [9]). Common childhood exanthema (rubeola and rubella) and viral respiratory disease used to be the most common infections; now, varicella zoster virus and Epstein-Barr virus are the most frequently identifiable viruses, although nonspecific viral infections still predominate ([123]). Acute ITP may also occur after vaccination ([122], [124], [125]). Even though thrombocytopenia is likely to be severe, the bleeding manifestations of acute ITP in children usually are mild ([126]), and intracranial hemorrhage occurs in less than 1% of patients. The rare adult with the acute form of the disorder, however, may suffer hemorrhage and a more fulminant course. Acute ITP in children usually is self-limited; spontaneous remissions occur in as many as 90% of patients ([8], [9]). The duration of the disease ranges from a few days to a few months, with an average of 4 to 6 weeks ([127]). The favorable prognosis of ITP in children reflects the preponderance of the acute form of the disease in this age group. Children with thrombocytopenia of greater than 6 months' duration are classified as chronic ITP, although spontaneous remissions may still occur in an occasional child after 6 months ([128], [129]). Fever of mild degree has been reported, and the spleen tip may be palpable in up to 10% of patients, but this is believed to be the same incidence as is seen in normal children ([130]). The spleen is usually of normal weight in those patients who proceed to splenectomy ([121]).
CHRONIC IDIOPATHIC THROMBOCYTOPENIC PURPURA The onset of the chronic form of the disorder usually is insidious. A long history of hemorrhagic symptoms of mild to moderate severity is often described by the patient, but antecedent infections or fever and splenic enlargement are uncommon. Patients with chronic ITP usually have a fluctuating clinical course. Episodes of bleeding may last a few days or a few weeks and may be intermittent or even cyclic. Spontaneous remissions are uncommon and are likely to be incomplete. Relapses in some cases appear to be associated with vaccination ([131]). Occasionally, the clinical course is surprisingly benign.

Bleeding Manifestations

The hemorrhagic manifestations of ITP are of the purpuric type. Patients with only ecchymoses and petechiae have “dry” purpura; those with mucous membrane bleeding in addition to skin manifestations have “wet” purpura ([132]). Platelet counts are usually lower and the complication rates higher in those with wet purpura. In a series of 712 patients reported by the Israeli ITP study group, 82% of all patients had bleeding limited to the skin, although 43% of adult women reported menomet-rorrhagia ([122]).

In general, the severity and frequency of hemorrhagic manifestations correlate with the platelet count (Fig. 53.3) ([133]). Bleeding after trauma in the absence of spontaneous hemorrhage is usual in mildly affected patients with platelet counts higher than 50,000 per µl. Thrombocytopenia associated with counts between 10,000 and 50,000 per µl results in spontaneous hemorrhagic manifestations of varying severity, such as ecchymoses and petechiae. Patients with platelet counts below 10,000 per µl usually are at risk for serious morbidity and mortality from bleeding, although the mortality rate is actually quite low ([134]). Patients who have an increased risk of bleeding include those with a history of bleeding, those with additional bleeding diatheses, and patients of advanced age (>60 years of age) ([15], [134]). Older patients have also been reported to have an increased incidence of major, life-threatening bleeding ([135], [136]).

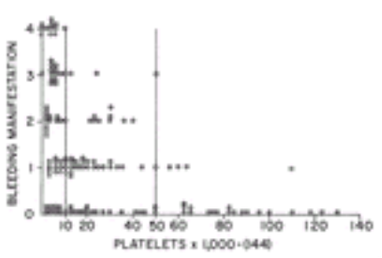

Figure 53.3. Bleeding manifestations in relation to platelet count in patients with idiopathic thrombocytopenic purpura. Bleeding manifestations (or duration) are graded from 0 to 4, as follows: 0, no bleeding; 1, minimal, resulting from trauma; 2, spontaneous, but self-limited; 3, spontaneous, requiring special attention (e.g.,

nasal packs); and 4, massive uncontrolled or poorly controlled. (From Lacey JV, Penner JA. Management of idiopathic thrombocytopenic purpura in the adult. Semin Thromb Hemost 1977;3:160–174.)

SKIN AND MUCOUS MEMBRANES Spontaneous bleeding into the skin in the form of petechiae is characteristic. These lesions are minute, red to purple hemorrhages that range in size from that of a pinpoint to that of a pinhead (Fig. 53.4). They are flat, do not blanch with pressure, and appear and regress, often in crops, over a period of days. They are most conspicuous in areas of vascular stasis, such as the areas below tourniquet sites, the dependent portions of the body (especially around the ankles), and areas subjected to constriction from belts or stockings, as well as on skin surfaces over bony prominences. The presence of petechiae on the face and neck is unusual, except as the result of coughing, and the patient may confuse these characteristic lesions with freckles or a rash.

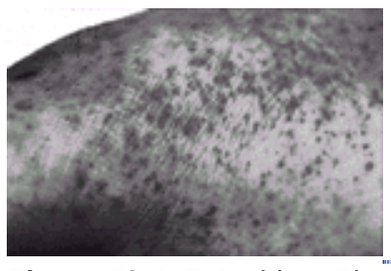

Figure 53.4. Petechiae. Pinpoint, nonblanching erythematous capillary bleeding sites are most common in dependent body areas or pressure points. See Color Plate.

Ecchymoses may develop on any skin surface. In ITP, they are seldom associated with subcutaneous hematomas and infrequently spread or dissect into deeper or adjacent structures. Large, purple, superficial ecchymoses may be seen, particularly on the back and thighs. Circular ecchymoses often surround even atraumatic venipuncture sites, but external bleeding from such sites is uncommon. Hemorrhagic vesicles or bullae may be seen inside the mouth and on other mucous surfaces. The bullae probably are the result of severe acute thrombocytopenia rather than a specific feature of any particular pathogenetic form. Gingival bleeding and epistaxis are common. The latter usually responds for a time to conservative measures, such as nasal packing or tamponade, often to recur intermittently. Epistaxis may originate from lesions resembling petechiae in the nasal mucosa. Such lesions also may be found in the mucous membranes of the throat and mouth, sometimes in the absence of cutaneous hemorrhage. In many patients, discrete bleeding points cannot be identified. The genitourinary tract is a frequent site of bleeding. Menorrhagia may be the only symptom of ITP and may appear for the first time at puberty. Hematuria also is a common symptom, the blood coming from the kidneys, the bladder, or the urethra, although bleeding into the kidney parenchyma is rare. Gastrointestinal bleeding is usually manifested by melena or, less often, by hematemesis.

CENTRAL NERVOUS SYSTEM Intracranial hemorrhage is the most serious complication of ITP. Fortunately, it is rare, affecting 1% or less of patients with severe thrombocytopenia ([9], [10]). The hemorrhages usually are subarachnoid, often are multiple, and vary in size from petechiae to large extravasations of blood. Numerous small hemorrhages often are seen in the retina; subconjunctival hemorrhage may also occur.

BLEEDING AFTER TRAUMA Excessive bleeding often follows tooth extractions, tonsillectomy, or other operations or injuries and may first suggest the diagnosis of ITP. In contrast to the hereditary coagulation disorders, such traumatic bleeding is seldom voluminous or rapid. Slow persistent oozing may occur after trivial cuts, razor nicks, and scratches. Delayed bleeding and spontaneous hemarthrosis, which are characteristic of the hereditary coagulation disorders, are extremely rare in association with ITP.

Laboratory Findings

BLOOD Abnormalities in platelet size and morphologic appearance are common. The platelets often are abnormally large (3 to 4 µm in diameter) and reveal more than normal variation in size and shape. Abnormally small platelets and platelet fragments (“microparticles”) also are evident and may represent the equivalent of microspherocytes and schistocytes ([137], [138], [139] and [140]). Although megakaryocyte fragments may be apparent in routine blood smears, quantitative studies reveal subnormal numbers of these fragments ([141]). Estimates of mean platelet volume (MPV) and the extent of platelet size heterogeneity (platelet distribution width) by means of automated particle counters may provide useful information in the evaluation of patients with ITP ([142]). The presence of numerous megathrombocytes results in high MPV values ([143]). Platelet distribution width also is increased, presumably reflecting an abnormal degree of platelet anisocytosis ([144]). The exact mechanism underlying such megathrombocytosis is still uncertain, but it may be the result of accelerated platelet production in response to platelet destruction. In patients with ITP, as in healthy subjects, MPV is inversely correlated in a nonlinear manner with the platelet count and remains within the normal range even in severe thrombocytopenia. These results contrast with significantly low values for MPV that have been reported in association with big spleen syndromes ([144]) and some myeloproliferative disorders, after chemotherapy with cytotoxic drugs, and in patients with septic thrombocytopenia ([145]). Anemia, if present, is proportional to the extent of blood loss and is usually normocytic. If bleeding has been severe and long standing, iron deficiency anemia may occur. Occasionally, recent severe hemorrhage may produce reticulocytosis and moderate macrocytosis. Antiplatelet antibodies in patients with ITP do not usually cross-react with erythrocytes, although erythrocyte fragmentation, presumably the result of weak complement activation, may occur ([139]). Patients may also have a positive Coombs test and autoimmune hemolytic anemia; the combination is known as *Evans syndrome* ([146], [147]). The total leukocyte count and the differential count usually are normal, except for those changes resulting from acute bleeding, such as slight to moderate neutrophilia with some increase in immature forms. Eosinophilia has been noted, particularly in children, but this finding is by no means consistent. Lymphocytosis with abnormal cells resembling those characteristic of infectious mononucleosis also has been reported ([148], [149]). Tests of hemostasis and blood coagulation reveal only changes attributable to thrombocytopenia, such as a prolonged bleeding time and absent or deficient clot retraction. The results of tests of blood coagulation, including prothrombin time, partial thromboplastin time, and fibrinogen, are normal in patients with uncomplicated thrombocytopenia. Slight increases in the levels of fibrinogen degradation products have been demonstrated in the plasma of some patients with ITP ([150]). Plasma levels of glycocalicin, a portion of platelet membrane gpIb, may be high in patients with ITP and other forms of platelet destruction, but concentrations of thrombopoietin are not significantly increased in contrast to patients with thrombocytopenia as a result of aplastic anemia.

BONE MARROW Alterations in the bone marrow are usually limited to the megakaryocytes, although normoblastic hyperplasia may develop as the result of blood loss. The leukocytes are essentially normal with the exception of occasional eosinophilia ([19], [151]). Megakaryocytes usually are increased in size ([152]) and are plentiful ([153], [154]), the numbers correlating roughly with the MPV. Morphologic abnormalities of these giant cells are present in most patients with ITP. “Smooth” forms with single nuclei, scanty cytoplasm, and relatively few granules are common. Presumably, they represent the results of markedly accelerated platelet production and the presence of many young forms ([155], [156]). Examination of the bone marrow is occasionally helpful, particularly in ruling out other conditions with which ITP may be confused. The changes just summarized are similar to those found in most forms of thrombocytopenia caused by accelerated platelet destruction and are not characteristic or diagnostic of ITP. Differences between megakaryocytes found in the acute and chronic forms of ITP are not clear-cut ([9]), and marrow examination is not particularly helpful in determining prognosis.

ANTIPLATELET ANTIBODIES A number of different types of antiplatelet antibody tests have been developed and reported through the years ([36], [157], [158], [159], [160], [161], [162], [163] and [164]). Most of these tests were quite cumbersome and therefore never became available for routine testing. In addition, the tests measured different types of Ig, including serum antiplatelet antibodies, platelet-associated surface Ig, or total platelet Ig. When the assays were tested in specialized laboratories, they were reported to be quite sensitive for detection of platelet Ig, and the antibody titers correlated with the clinical course in the patients with ITP. However, these assays for antiplatelet antibody are not specific for thrombocytopenia caused by idiopathic immune thrombocytopenia, and in fact, Ig concentrations are increased in patients with nonimmune thrombocytopenia ([165], [166], [167] and [168]) and even in some normal individuals. Normal platelets contain Ig in their a-granules, in addition to other serum proteins like albumin ([169]). The quantity of the Ig is directly proportional to the amount of Ig in the serum; therefore, patients with polyclonal or monoclonal gammopathies have increased platelet Ig ([170]). The platelet Ig is released, along with other a-granule proteins, such as platelet factor 4 and ß-thromboglobulin, during platelet activation and secretion. It is presumed that some of these released proteins bind to the platelet surface. These observations make it difficult to use either the platelet-associated IgG assays or the total platelet Ig assays for the diagnosis of ITP ([171]). The newest generation of antiplatelet antibody assays appears more promising ([40], [41]). In these tests, monoclonal antibodies for the specific platelet membrane glycoproteins that are implicated in ITP are used in antigen capture-type assays (also called *glycoprotein immobilization assays*; Fig. 53.5) ([42]). These tests are very specific for the presence of membrane-associated antibodies directed at specific platelet glycoproteins, but they are still not sensitive enough to detect the presence of antiplatelet antibody in more than 85% of patients ([41], [43], [172]). As long as these tests are not available for routine diagnostic use, the diagnosis of ITP in an individual patient will continue to be a diagnosis by exclusion.

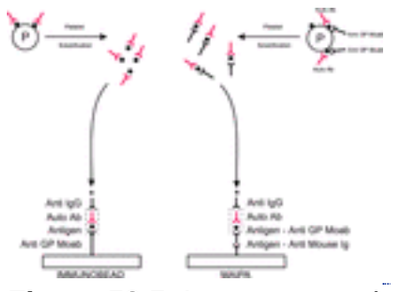

Figure 53.5. Immune complex capture assays. The immunobead assay and the monoclonal antibody–specific immobilization of platelet antigen assay (MAIPA) are diagrammed. *, antibody was labeled with either radioactivity or enzyme; antigen, protein containing the antigen; anti GP Moab, murine monoclonal antibody against the platelet glycoprotein containing the antigen; anti IgG, antibody against human immunoglobulin G; anti mouse Ig, antimouse immunoglobulin; auto Ab, autoantibody; P, platelet. (Modified from McMillan R. Clinical role of antiplatelet antibody assays. Semin Thromb Hemost 1995;21:37–45.)

Differential Diagnosis

The initial step in the evaluation of a thrombocytopenic patient is the inspection of the peripheral blood smear to confirm the decreased platelet count ([173]). Thrombocytopenia may be produced artifactually by clumping of the platelets in the blood sample caused by ethylenediaminetetraacetic acid–platelet agglutinins ([174] , [175]), or the platelets may be unavailable for counting because they are bound in rosette formation to the surface of white blood cells in the venous blood sample ("platelet satellitism") ([176] , [177]).

The diagnosis of ITP is usually a diagnosis by exclusion based on a demonstration of peripheral thrombocytopenia, with a history, physical examination, and complete blood count that do not suggest another cause for the thrombocytopenia. Slight splenomegaly may be found in patients with ITP ([121]), but moderate or massive splenomegaly suggests that the thrombocytopenia is a result of hypersplenism related to the presence of a separate underlying disease associated with splenic enlargement. Alcoholic liver disease with portal hypertension, splenomegaly, and thrombocytopenia is an example of hypersplenism.

The initial manifestations of acute leukemia, myelodysplastic syndrome ([178] , [179]), myelophthisic processes, and aplastic anemia may mimic ITP. These other types of underlying hematologic disorders are suggested by anemia out of proportion to blood loss and by changes in the leukocytes not attributable to either hemorrhage or complicating infection. ITP causes no characteristic bone marrow changes; therefore, bone marrow examination should not be routine. However, bone marrow aspiration may be helpful in the differential diagnosis of ITP versus myelodysplastic syndrome in patients older than 65 years of age or in patients who have atypical findings that may suggest some of these other etiologies.

The presence of schistocytes in the blood smear suggests that the thrombocytopenia may be associated with a microangiopathic process (see Chapter 54). In thrombotic thrombocytopenic purpura or hemolytic uremic syndrome, thrombocytopenia is associated with laboratory manifestations of hemolysis, including an elevated lactate dehydrogenase and indirect bilirubin. Patients may also have transient, multifocal neurologic signs or symptoms, or both, in thrombotic thrombocytopenic purpura or renal insufficiency in hemolytic uremic syndrome. Microspherocytes and coagulation abnormalities can also be found in thrombocytopenia resulting from disseminated intravascular coagulation.

After a diagnosis of immune thrombocytopenia, the next essential step is to distinguish between idiopathic immune thrombocytopenic purpura and secondary forms of immune thrombocytopenic purpura, such as human immunodeficiency virus, hepatitis C, or *Helicobacter pylori* infections; collagen vascular diseases like systemic lupus erythematosus (SLE); lymphoproliferative disorders like chronic lymphocytic leukemia; and drug ingestions. The importance of careful inquiry regarding drug ingestion or exposure to toxic substances cannot be overemphasized, because thrombocytopenia attributable to drugs or toxins often is indistinguishable from ITP. The development of thrombocytopenia in an adult, in particular, should arouse suspicion of a chemical etiologic agent, because many of the drugs associated with thrombocytopenia are used more often by adults than by children. If the patient is a hospitalized patient, it is also essential to eliminate the possibility that the thrombocytopenia is secondary to heparin administration. Immune thrombocytopenia may be produced by heparin administered in any dose and by any route of administration. It has even been reported in patients with indwelling heparin-bonded catheters ([180]). Finally, the antiphospholipid antibody syndrome is a recently recognized disorder that may produce isolated thrombocytopenia in the absence of a clearly definable associated disorder. In the usual case, this disorder may be associated with thromboembolic manifestations, anticardiolipin antibodies, coagulation inhibitors of the lupus type, and false-positive results of serologic tests for syphilis ([72]).

Treatment of Idiopathic Thrombocytopenic Purpura

Relatively few level 1 trials on the treatment of patients with ITP have been reported (i.e., randomized trials with low false-positive and false-negative errors). The American Society of Hematology has recently published a practice guideline on ITP, which was, therefore, primarily based on the opinions of a panel of experts ([181] , [182]). The reader is referred to this practice guideline for specific questions regarding the treatment of patients with ITP.

CHILDREN Childhood ITP is usually benign and self-limited. Treatment is therefore reserved for patients with severe thrombocytopenia (<20,000 per µl) and bleeding or patients who remain thrombocytopenic for more than 6 months—that is, those with chronic ITP (Table 53.4) ([183]). The greatest fear in the acute form is intracranial hemorrhage, which occurs in approximately 1% of patients with platelet counts less than 20,000 per µl. Thus, several multicenter randomized trials have been performed in these high-risk patients with acute ITP to define whether treatment is associated with a more prompt increase in platelet counts. These clinical trials demonstrated that treatment with both oral prednisone and intravenous Ig was associated with a more rapid rise in platelet count to greater than 20,000 per µl than either no therapy or treatment with anti-D. Only intravenous Ig shortened the time necessary to reach a platelet count of greater than 50,000 per µl ([125] , [184]). More recently, children with platelets fewer than 10,000 per µl or 10,000 to 29,000 per µl and mucosal bleeding were studied in a prospective randomized clinical trial, and intravenous Ig raised platelet counts faster than three corticosteroid regimens ([185]).

TABLE 53.4. Recommendations for Treatment of Idiopathic Thrombocytopenic Purpura Patients with Platelet Counts Less Than 20,000 µl

	Children	Adults
Asymptomatic	None	Prednisone (1–2 mg/kg/d)
Minor purpura	IVIg (1 g/kg × 1 d) High-dose oral glucocorticoid	Prednisone (1–2 mg/kg/d)
Mucosal membrane bleeding that may require clinical intervention	IVIg (1 g/kg × 1 d) Hospitalization IVIg (2 g/kg over 2–5 d) High-dose oral glucocorticoid	Prednisone (1–2 mg/kg/d) Hospitalization
Severe, life-threatening bleeding	Hospitalization IVIg (1 g/kg × 1 d) High-dose parenteral glucocorticoid IVIg (2 g/kg over 2–5 d) High-dose oral glucocorticoid	Hospitalization IVIg (1–2 g/kg over 1–5 d) Prednisone (1–2 mg/kg/d)

IVIg, intravenous immunoglobulin.

NOTE: In each category, the treatment options are listed in order of descending preference.

From George JN, Woolf SH, Raskob GE, et al. Idiopathic thrombocytopenic purpura: a practice guideline developed by explicit methods for the American Society of Hematology. Blood 1996;88:3–40, with permission.

ADULTS Patients with chronic ITP may have mild thrombocytopenia that can be followed without treatment. The incidence of bleeding is correlated with the platelet count; therefore, patients with platelet counts greater than 60,000 per µl rarely have spontaneous bleeding and may only require treatment if extensive operative

procedures are planned. Patients with platelet counts less than 20,000 per µl or significant mucosal membrane bleeding with platelet counts less than 50,000 per µl are usually treated (Table 53.4). No prospective, inception cohort studies on prognosis after treatment are reported. However, investigators recently reported that most adult patients have a good response to treatment (without necessarily returning to normal platelet counts) and have no excess mortality when compared to the general population ([186]). A small group of patients who had severe thrombocytopenia after 2 years of primary and secondary therapies had a mortality risk of 4.2 (95% confidence interval, 1.7 to 10.0) due to both bleeding and infectious complications related to therapy. ITP is uncommon in elderly patients; only 30% of patients in reported series are older than 45 years of age ([151] , [187]). However, these patients may be more refractory to therapy ([135]) and appear to have a higher incidence of hemorrhagic complications than younger patients ([15]). Guthrie and colleagues reported a 52% incidence of life-threatening or fatal bleeding in their series of 40 patients older than age 45 ([135]). This risk of fatal bleeding in patients with platelet counts that are chronically less than 30,000 per µl is estimated at 0.4% per year for patients younger than 40 years of age and 13.0% per year for patients older than 60 years of age ([188]). Patients with life-threatening bleeding may require parenteral glucocorticoids, intravenous Igs followed by platelet transfusions ([189]), plasmapheresis ([190]), or even emergency splenectomy as first-line treatment. Platelets should be administered as frequently as necessary to control the bleeding, even if there are only minimal changes in the platelet count. However, it has been demonstrated that some patients do have a demonstrable increase in platelet numbers, with 42% of platelet transfusions resulting in a platelet increase of at least 20,000 per µl ([191]).

Steroids Steroids are the conventional first-line therapy for adult ITP. Dameshek first reported his experience with prednisone therapy in 1958 ([192]) when 30 consecutive patients with acute (N = 11) or chronic (N = 19) ITP were treated with 20 to 150 mg/day of prednisone. Twenty-two of the patients demonstrated an increase in platelet count to normal after an average interval of 22 days and then were maintained on 2.5 to 15.0 mg/day of prednisone. In eight patients, prednisone was discontinued without relapse. Numerous retrospective studies of steroid treatment in both children and adults with ITP have been reported ([15] , [16] and [17] , [121] , [122] , [127] , [151] , [187] , [193] , [194] , [195] , [196] , [197] , [198] and [199]). The criteria for inclusion of patients in the individual studies and the criteria for response to treatment vary significantly among the reports; therefore, it is difficult to accurately combine the data. However, some useful observations can be made. Spontaneous remissions are very uncommon in adults, with an estimated occurrence of less than 5% ([16] , [17] , [193] , [194] and [195]). Most spontaneous remissions occur early; however, remissions have been described after 6 months in a small number of patients ([16]). Complete and partial (>50,000 per µl) responses in patients treated with prednisone (usually, 1 mg/kg/day as starting doses) average 65 to 85%, but sustained responses after discontinuation of the drug occur in only 25% or less of patients ([1] , [200]). Platelet counts increase within 1 week in responding patients and have usually reached peak values by 2 to 4 weeks. Patients who have not had any response by then are unlikely to respond to prednisone and therefore should be considered for splenectomy or other forms of treatment. No pretreatment patient characteristics have predicted a patient's response to steroids. Only two prospective randomized steroid treatment trials in patients with ITP have been reported ([201] , [202]). Bellucci and colleagues randomized patients between low (0.25 mg/kg/day) or high (1.0 mg/kg/day) prednisone for 3 weeks, with taper and discontinuation by the end of the fourth week ([202]). If bleeding continued, patients could be increased from low dose to high dose, or a second 4-week course could be given. *Complete response*, defined as a platelet count greater than 100,000 per µl for at least 6 months, was seen in 74% of children and 41% of adults. Complete or partial responses occurred in 83% of children and 59% of adults. No significant differences were seen between low- and high-dose regimens in either age group. Mazzucconi and colleagues randomized patients between 0.5 mg/kg/day and 1.5 mg/kg/day ([201]). The response rates in adults were not significantly different between patients treated with low- versus high-dose steroids—30% and 34% complete response, respectively. In children, however, the rates were 64% for low-dose versus 81% for high-dose prednisone. Therefore, there is evidence to support the use of lower doses of steroids in adults than have conventionally been used at the beginning of treatment. There was one prospective randomized, controlled trial comparing prednisone (1 mg/kg/day) to intravenous Ig (400 mg/kg/day for 4 days), or to both in a small number of patients ([203]). A platelet count greater than 50,000 per µl was achieved in 82%, 54%, and 92% of patients. The median times to peak platelet counts were 8.5, 7.0, and 7.0 days. These authors concluded that there was no advantage for intravenous Ig over conventional corticosteroid treatment. In another recent randomized control trial, platelet counts above 50,000 per µl were achieved faster in patients receiving intravenous Ig than intravenous methylprednisolone, but long-term outcomes were the same ([204]).

Mechanism of Action

EFFECT ON ENDOTHELIAL CELLS Experimental evidence suggests thinning of the endothelium with development of endothelial fenestrations in both animal models and humans with ITP, suggesting that platelets play a role in normal endothelial homeostasis ([205] , [206]). Clinically, steroids are known to ameliorate the purpuric bleeding in ITP patients before the platelet count actually increases. Experimentally, investigators have demonstrated that 3 days after steroid therapy in rabbits and 4 days after steroid therapy in patients, the endothelial thinning reverts toward normal, providing a scientific explanation for this clinical observation ([206] , [207]). This endothelial effect may in part be explained by the observation that when endothelial cells are cultured with steroids, cell morphology is altered, with greater confluence and increased protein synthesis and content ([208]).

EFFECT ON THROMBOCYTOPENIA The mechanism of action of steroids in treating the thrombocytopenia is probably complex. Steroids are currently believed to ameliorate the thrombo-cytopenia by one or more mechanisms. Steroids may (a) decrease consumption of antibody-coated platelets by the spleen ([209] , [210] and [211]) or bone marrow, (b) reduce antibody production by the spleen ([111] , [212]), (c) decrease antibody production by the bone marrow ([213]), or (d) increase marrow platelet production by undetermined mechanisms ([214]). There is little doubt that corticosteroids in high doses ameliorate splenic sequestration of antibody-coated platelets. Corticosteroids decrease antibody-coated red blood cell sequestration in guinea pig spleens by decreasing Fc? receptor proteins on macrophages ([215]), and corrected *in vivo* and *in vitro* data support a similar action of steroids in humans ([104] , [105] , [210] , [216] , [217]). Corticosteroids also decrease monocyte Fc receptors in autoimmune hemolytic anemia ([218]). This down-regulation of monocyte/macrophage Fc receptors may account for the early effects of steroid treatment on platelet counts. Chronic corticosteroid treatment is associated with a decrease in antibody production, but this usually occurs after several weeks of high-dose steroids. Steroid treatment also results in increased platelet production in some ITP patients ([214]), an effect that may be secondary to reduction of the antiplatelet Ig effect on thrombopoiesis, reduction in intramedullary destruction of antibody-coated platelets before their release into the circulation, or decreased antibody synthesis by bone marrow lymphocytes.

Splenectomy Patients with severe thrombocytopenia (<10,000 per µl) who do not respond to steroids (administered for up to 6 weeks) or who relapse during steroid tapering, and patients with platelet counts of less than 30,000 per µl for periods up to 3 months should be considered for splenectomy. This recommendation is based on only level 5 evidence (i.e., case reports) ([181]). Most patients demonstrate a response to steroids within 2 to 4 weeks, but a late response is possible. Therefore, the best time for splenectomy in a patient who does not respond to steroid therapy must be determined individually. Sustained complete responses to splenectomy (variously defined as platelet counts 100,000 or 150,000 per µl) have been reported in approximately 50 to 80% of patients, depending on the series of patients ([1] , [15] , [16] and [17] , [121] , [122] , [127] , [151] , [187] , [193] , [194] , [195] and [196] , [198] , [200] , [219] , [220] , [221] , [222] , [223] , [224] , [225] , [226] , [227] , [228] and [229]). After the operation, the platelet count may increase rapidly, often within 24 to 48 hours, and may reach levels as high as 1 million per µl or even higher in approximately 10 days ([121]). Operative mortality is less than 1%, and perioperative bleeding is rare ([16] , [17] , [122] , [193] , [194]). Platelet transfusions are usually only given if the patient has bleeding after the spleen has been removed. Postsplenectomy infections are also rare, especially if patients have received pneumococcal immunizations before splenectomy. Laparoscopic splenectomies in ITP patients are as successful as conventional splenectomies, although patients occasionally may require conversion to an open procedure ([230] , [231]). Therapeutic responses are reported also when splenic ultrasound ([232]), splenic radiation ([233] , [234]), or partial splenic embolization ([235]) was used instead of splenectomy. Patients who do not respond to splenectomy or who relapse after an initial response to splenectomy should be studied for the presence of accessory spleens ([226] , [236] , [237] , [238] , [239] and [240]). The incidence of accessory spleens found at the time of the original splenectomy ranges from 15 to 20% ([221] , [226]). The incidence of accessory spleens in patients who relapse after splenectomy may be as high as 50% ([151] , [227] , [228]), and surprisingly, the majority of these patients demonstrate postsplenectomy changes (i.e., Howell-Jolly bodies) on their peripheral blood smears. Relapse secondary to accessory spleen may occur weeks to years after the initial splenectomy. Scanning methods have varying sensitivities; conventional ^{99m}technetium scans, ^{99m}technetium scans using heat-denatured red blood cells, or CT scans can be used. Accessory spleens as small as 0.5 cm have been found when ^{111}indium scans were performed preoperatively and isotope detector probes were used intraoperatively to detect all accessory splenic tissue ([221]). A review of 56 published cases demonstrated a 73% excellent therapeutic response and a 27% moderate response to accessory splenectomy ([221]).

Mechanism of Action The effectiveness of splenectomy in the therapy for ITP is attributed to removal of the organ primarily responsible for the destruction of antibody-sensitized platelets. The increase in platelet count correlates with an increase in platelet survival, whereas platelet production remains unchanged ([214]). The removal of the spleen may also result in a reduction of antibody production, but this effect is probably of minimal significance in view of the immediate favorable responses to splenectomy. No factors have consistently predicted a response to splenectomy; age, concentration of platelet-associated IgG, the time between diagnosis and splenectomy, the patient's response to steroids, intravenous immune globulin or intravenous anti-D, and the peak postoperative platelet count have all been studied ([220] , [241] , [242] , [243] , [244] and [245]). The site of platelet sequestration, based on preoperative ^{51}chromium- and ^{111}indium-labeled platelet survival studies, may be predictive of response ([224] , [246]), but these techniques are seldom used.

Treatment of Refractory Idiopathic Thrombocytopenic Purpura No randomized controlled trials have been reported of treatment options for patients who do not respond to treatment with both steroids and splenectomy ([247]). Patients who are asymptomatic and have platelet counts between 30,000 and 50,000 per µl may be managed with careful observation ([1] , [181]). Symptomatic patients with platelet counts less than 30,000 per µl who had an initial response to steroids can be retreated with prednisone and then tapered to find the minimum dose that can maintain the patients hemorrhage-free even if the platelet count is not above 30,000 per µl. If they can be maintained on 10 mg every other day, additional treatment may not be indicated. Some patients observed for years with platelet counts of 10,000 per µl

have had no significant bleeding other than some ecchymoses or petechiae, even without steroid therapy ([219]). Additional therapies that have been beneficial in some patients with refractory ITP include intravenous Ig, pulse dexamethasone or methylprednisolone, anti-D, immunosuppression with azathioprine or cyclophosphamide, vinca alkaloids, danazol, and a-interferon. Because no level 1 evidence existed for these alternate therapies, there was little panel consensus regarding preferred therapy from the American Society of Hematology ITP Practice Guideline ([181]).

Immunosuppressive Drugs Immunosuppressive therapy for ITP has yet to be evaluated thoroughly; the overall effectiveness of these potent drugs has been variable, and the remissions achieved have been short lived. Poor results have been reported in children ([248]). Favorable results are nevertheless noteworthy, because they were obtained in patients who had not responded to splenectomy or to corticosteroids. Immunosuppressive therapy should probably be reserved for such refractory cases ([249]). Preliminary reports of successful treatment in refractory patients have been published, using high-dose methylprednisolone ([250] , [251]) and cyclophosphamide-based combination chemotherapy ([252]). Pulse high-dose dexamethasone was effective in a small series of patients ([253]), but this has not been confirmed by other investigators ([254] , [255] and [256]). Cyclophosphamide alone, either daily oral or pulse intravenous therapy, induced remissions in 16 to 55% of patients ([17] , [249] , [257] , [258] and [259]). However, this drug must be administered for several weeks before the platelet count rises and often must be continued for an indefinite period to maintain the remission, and side effects such as leukopenia, alopecia, and cystitis often are significant. Azathioprine, cyclosporine A, actinomycin, and other immunosuppressive agents, either alone or in combination with corticosteroids, are of variable success ([260] , [261] , [262] , [263] , [264] and [265]). Vincristine and vinblastine, administered intravenously at weekly intervals, may be as effective as cyclophosphamide but act more rapidly ([266] , [267] and [268]), often increasing the platelet count within 7 days ([266] , [269]). In addition to their suppressive effects on cellular and humoral immune responses ([270]), these agents increase platelet production in both animals and normal human subjects ([271] , [272]). In ITP, their mechanism of action has been postulated to be inhibition of microtubule-dependent events required for macrocyte-monocyte phagocytic function ([273] , [274]). Anti-CD20 monoclonal antibody, probably through its effect on B lymphocytes, can produce objective responses in up to 50% of patients ([275] , [276] and [277]). Most of the patients in these pilot studies had no response to prior treatments, including splenectomy. The side effects were mild and usually seen most commonly after the first of four weekly infusions. Many of these responses were maintained without additional therapy, and some patients who relapsed responded to an additional infusion.

High-Dose Immunoglobulin The intravenous administration of polyvalent Ig, first used in 1981 ([278]), may induce remissions in patients with life-threatening bleeding or in patients with refractory ITP. Ig therapy has proved most effective in infants and small children ([279] , [280]), an age group in which the response is difficult to evaluate because of the frequency of spontaneous remissions. In adults, this extremely expensive regimen has produced relatively less impressive long-term results ([281] , [282] , [283] and [284]), although an occasional patient enters complete remission after the initial treatment and a series of booster doses ([285] , [286] , [287] and [288]). In a review of 28 published reports of intravenous Ig in 282 adults, 64% of patients had a peak platelet count of greater than 100,000 per µl, and 83% had peak platelet counts greater than 50,000 per µl ([289]) after the initial infusion. Platelets may begin to rise after 2 days and usually reach peak levels by 1 week after treatment ([290]). Regimens of 400 mg/kg/day for 5 days versus 1000 mg/kg for 2 days ([291]) or 1000 mg/kg/day versus 500 mg/kg/day ([285]), each for 2 days, have been equally effective in randomized trials, and doses of 0.5 g/kg are as effective as 1.0 g/kg for maintenance therapy ([292]). These doses produce significant increases in serum and platelet levels of IgG ([279] , [285] , [287]). In a recent randomized controlled trial, 1000 mg/kg was superior to 500 mg/kg in raising platelet counts to greater than 80,000 per µl by day 4 ([293]). Most of these patients were being prepared for splenectomy or delivery. The mechanism of action of intravenous Ig is unclear ([294]). Some studies suggest blockade of the Fc receptors of the reticuloendothelial cells ([285] , [287] , [295] , [296] and [297]) and suppression of antibody production and binding ([298] , [299] , [300] and [301]), which may be a result of antiidiotype antibodies that bind antiplatelet antibodies and modulate the immune response ([302] , [303]). The ability of intravenous Ig to modulate antiinflammatory activity through the inhibitory Fc?RII receptor is also under active investigation ([304] , [305]). No evidence exists that reduction of antiplatelet antibodies accounts for the acute effects of therapy ([306]). Therapy with intravenous Ig remains expensive. The rapid nature of the response to treatment makes it an ideal agent for treatment of patients for life-threatening bleeding or before surgery; however, the role of intravenous Ig in long-term therapy remains uncertain. The major side effect of treatment is headache, although some patients develop fever, myalgias, and skin rashes ([303]). There are now also reports of acute renal failure occurring in up to 7% of patients, especially older patients and those with diabetes, or baseline increases in creatinine (or both) ([307] , [308]). The patients may be oliguric, and most demonstrate peak creatinine levels by day 5 after the Ig infusion. Hemodialysis may be required acutely; however, several patients required chronic dialysis.

Anti-D Intravenous Rho (D) immune globulin has been studied in children with acute ITP and refractory chronic ITP as an alternative to intravenous Ig ([184] , [309] , [310]). The mechanism of action is unknown; however, it is believed that the antibody coats the red blood cells of Rh-positive patients and either blocks the reticuloendothelial clearance of the patients' platelets or modulates the immune system, resulting in an increase in the platelet count ([310] , [311]). Children respond better than adults, and nonsplenectomized patients respond better than splenectomized patients ([312]). The platelet count does not begin to increase for 48 to 72 hours, so it is not effective for the treatment of life-threatening bleeding. The effect lasts for several weeks to a month, and patients respond well to retreatment. They may even respond to intramuscular injections given weekly as maintenance ([313]). Only occasionally, patients have a sustained remission ([314]). Most patients exhibit a modest decrease in hemoglobin, and most have signs of mild hemolysis ([312]), with decreased haptoglobin, increased lactate dehydrogenase, and increased indirect bilirubin. Red cell survival is only modestly reduced ([315]). No correlation has been found between the amount of hemolysis ([311]) and the platelet response, leading some investigators to question the proposed effect on reticuloendothelial blockade ([316]). Reinfusion of autologous red blood cells that have been opsonized with anti-D has produced both complete and partial remissions in a small number of patients, even after splenectomy ([317]).

Other Proposed Therapy A number of other therapies have been reported to be successful in single case reports or in small series of patients ([247]). Danazol, an attenuated androgen, has been effective in increasing platelet counts in patients with ITP in doses ranging from 50 mg/day ([318]) to 800 mg/day ([319] , [320] and [321]). The mechanism of action is postulated to be a danazol-induced reduction of Fc receptors on phagocytic cells ([322]). Recombinant a-interferon can increase platelet counts in up to 50% of patients when injected subcutaneously three times a week. Side effects are minimal, and some responses are durable after stopping treatment ([323] , [324] , [325] , [326] , [327] and [328]).

Supportive Measures Physical activity should be restricted to minimize the hazards of trauma, particularly head injury. Drugs that impair platelet functions should be avoided. Blood loss should be treated as otherwise indicated, and if platelets are needed, platelet concentrates should be administered ([329]). However, even large numbers of platelets produce only a slight and transitory increase in the platelet count—no doubt because of the rapidity with which they are destroyed *in vivo* ([330]). Platelet transfusions, nevertheless, may produce some increase in platelet numbers in many patients ([191]), often diminish bleeding for a time, and can be effective in the management of serious complications such as subarachnoid hemorrhage. They should be reserved for such life-threatening emergencies or for the immediate preoperative treatment of patients with serious hemorrhage before splenectomy. A single large dose of intravenous Ig followed by a platelet transfusion can be effective in arresting hemorrhage in some critically ill patients ([189]). In most patients with platelet counts greater than 50,000 per µl, preoperative platelet transfusions are not indicated. Platelet transfusions should be avoided in patients with chronic ITP because of the possible development of alloantibodies. Exchange plasmapheresis may be valuable in critically ill patients and may be particularly effective in children ([331] , [332] and [333]). Anovulatory hormones are useful when menorrhagia is a major complaint. Because of the risk of septicemia, polyvalent pneumococcal vaccine, *Haemophilus influenzae* B vaccine, and quadrivalent meningococcal polysaccharide vaccine should be administered at least 2 weeks before elective splenectomy in both adults and children ([181]).

IDIOPATHIC THROMBOCYTOPENIC PURPURA IN PREGNANCY Both immune and nonimmune thrombocytopenia may occur during pregnancy ([334] , [335]). Thrombocytopenia was present in 7% of women when they were admitted to the hospital for a full-term delivery in a prospective 7-year study of 15,741 mothers and 15,932 newborns ([336] , [337] and [338]). Most platelet counts were between 100,000 and 150,000 per µl; however, 1% of women had platelet counts less than 100,000 per µl. The thrombocytopenia was detected incidentally in the majority of women, and only 0.01% of their infants had fetal platelet counts less than 50,000 per µl. None of the infants had hemostatic impairment, and most mothers had normal or near-normal platelet counts by discharge. If the mothers had an obstetric or medical complication, the incidence of thrombocytopenia (<50,000 per µl) in the infants was 0.35%. It is unclear when the incidental thrombocytopenia (also called *gestational thrombocytopenia*) developed during the pregnancy, and the etiology of this mild abnormality is likewise unknown. Antiplatelet antibody testing was not sufficiently specific to differentiate patients with gestational thrombocytopenia from those with ITP ([339]). Maternal thrombocytopenia occurs in 7% of pregnancies, and 74% of these women appear to have incidental thrombocytopenia, and only 4% have immune thrombocytopenia ([340]). It is, therefore, recommended that healthy women, who, at delivery, have a platelet count of 70,000 to 80,000 to 150,000 per µl, require no specific treatment, and the mode of delivery should be determined only by obstetric indications. Platelet autoantibodies in pregnant patients with ITP cross the placenta and can produce thrombocytopenia and clinical bleeding in the infant. During pregnancy, both maternal and infant health must be considered. Management of women with ITP, diagnosed before or during the pregnancy, is therefore more difficult and still controversial ([340] , [341]). Women with severe thrombocytopenia should be treated with intravenous Ig or the lowest dose of corticosteroids needed to maintain a platelet count above 50,000 to 60,000 per µl, even though when mothers have been treated during pregnancy, changes in their platelet counts do not correlate with the fetal platelet counts when these have been sampled before and after treatment ([342]). When betamethasone or placebo was given for 4 weeks before delivery in a randomized trial, no differences were seen in either the maternal or infant platelet counts or the incidence of bleeding at delivery ([343]). Splenectomy during pregnancy may have higher complication rates, but it is not contraindicated. Intravenous Igs can be used before delivery to increase the platelet count rapidly. The safety of other forms of therapy used in nonpregnant ITP patients is uncertain. At the time of delivery, the physician must decide whether to deliver the infant by cesarean section or by vaginal delivery. When 474 infants were analyzed from series reported over a 20-year period, 10% of infants had platelet counts between 50,000 and 100,000 per µl, and 15% had platelet counts less than 50,000 per µl ([344]). Intracranial hemorrhages occurred in 3%, but no significant association existed between intracranial hemorrhage and mode of delivery. More recent data demonstrate that the incidence of morbidity and mortality in infants with

neonatal thrombocytopenia is lower than originally reported. In 1993, Burrows and Kelton published a systematic review of pregnancy in patients with ITP, selecting only those series with more than ten patients and those that included fetal platelet counts and infant outcome ([345]). Eleven series published between January 1980 and December 1990 fulfilled these criteria. They reported 288 live births and an incidence of fetal thrombocytopenia of 10% with platelet counts less than 50,000 per µl and 4% with platelet counts less than 20,000 per µl. There were no deaths and no cases of intracranial hemorrhage, and there was no difference in morbidity between cesarean sections and vaginal births. During the decade from 1990 to 2000, these cumulative totals from 13 prospective studies were 9% and 4% ([340]). Three percent of infants had minor bleeding complications, and 2% had major bleeding complications. Many studies have been done to determine what characteristics of the mother correlate with severe thrombocytopenia in the newborn ([340]) and to help with decisions regarding method of delivery. To date, only the birth of a previously affected infant correlates with the incidence of neonatal thrombocytopenia. Other variables that were analyzed, such as the mother's platelet count or prior splenectomy, were predictive in some studies but not in others. Fetal platelet counts might be able to predict newborn risks of bleeding, but scalp vein platelet counts can be artifactually low, and the incidence of complications to percutaneous umbilical blood sampling is higher than the incidence of postnatal major bleeding. In all of these reports, it was also noted that the infant platelet count could fall for several days after delivery. It is, therefore, currently recommended that the mode of delivery should be determined by obstetric indications.

SECONDARY AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Autoimmune thrombocytopenia is also associated with drugs and with several common diseases (i.e., SLE, infections, lymphoproliferative disorders, and Graves' disease). Secondary immune thrombocytopenias are discussed separately in this section because of their unique features and the issues of diagnosis and management. Immune thrombocytopenia associated with human immunodeficiency virus infection is discussed in Chapter 69.

Autoimmune Thrombocytopenic Purpura Secondary to Drugs

Numerous drugs have been associated with immune thrombocytopenia. In some cases, the evidence relating a given drug to the production of immune thrombocytopenia is circumstantial. However, a recent systematic review is available in which specific criteria were established to determine the likelihood of drug-induced immune thrombocytopenia due to specific drugs (Table 53.5) ([346], [347]). The most common drugs with level 1 evidence are quinidine, quinine, rifampin, trimethoprim-sulfamethoxazole, danazol, methyldopa (Aldomet), acetaminophen, and digoxin. The most common drugs with level 2 evidence are gold, procainamide, carbamazepine, hydrochlorothiazide, ranitidine, and chlorpropamide. Heparin, which causes immune thrombocytopenia in as many as 1% of patients, is discussed in Chapter 61.

TABLE 53.5. Drugs Associated with Immune Thrombocytopenia and Criteria for Their Classification

	Level 1 [a]	Level 2 [b]
Acetaminophen	Iopanoic acid	Acetazolamide
Alprenolol	Isoniazid	Ampicillin
Aminoglutethimide	Levamisole	Captopril
Aminosalicylic acid	Lithium	Carbamazepine
Amiodarone	Meclofenamate	Chlorpropamide
Amphotericin B	Mesalamine	Fluconazole
Amrinone	Methicillin	Glibenclamide
Atorvastatin	Methyldopa (Aldomet)	Gold
Cephalothin	Minoxidil	Hydrochlorothiazide
Chlorothiazide	Nalidixic acid	Ibuprofen
Chlorpromazine	Naphazoline	Oxyphenbutazone
Cimetidine	Nitroglycerine	Oxytetracycline
Danazol	Novobiocin	Phenytoin
Deferoxamine	Oxprenolol	Procainamide
Diatrizoate meglumine/diatrizoate sodium	Pentoxifylline	Ranitidine
	Piperacillin	Sulindac
Diazepam	Quinidine	Ticlopidine
Diazoxide	Quinine	
Diclofenac	Rifampin	
Diethylstilbestrol	Sulfasalazine	
Difluormethylornithine	Sulfasoxazole	
Digoxin	Tamoxifen	
Ethambutol	Thiothixene	
Haloperidol	Tolmetin	
Indinavir	Trimethoprim-sulfamethoxazole	
Interferon-a	Vancomycin	

Criteria [a, b]

1. The candidate drug preceded thrombocytopenia, and recovery from thrombocytopenia was complete and sustained after the drug was discontinued.
2. The candidate drug was the only drug used before the onset of thrombocytopenia, or other drugs were continued or reintroduced after discontinuation of the candidate drug with a sustained normal platelet count.
3. Other etiologies for thrombocytopenia were excluded.
4. Reexposure to the candidate drug resulted in recurrent thrombocytopenia.

[a] Level 1 evidence met criteria 1–4.

[b] Level 2 evidence met criteria 1–3.

From George JN, Raskob GE, Shah SR, et al. Drug-induced thrombocytopenia: a systematic review of published case reports. Ann Intern Med 1998;129:886–890, with permission; and Rizvi MA, Kojouri K, George JN. Drug-induced thrombocytopenia: an updated systematic review. Ann Intern Med 2001;134:346, with permission.

PATHOPHYSIOLOGY Drug-induced platelet antibodies are the result of an idiosyncratic reaction that develops in only a small percentage of persons exposed to a drug. This ranges from an estimated 38 cases per 1 million for trimethoprim-sulfamethoxazole, to 6 cases per 100 for rifampin ([348]), to as many as 1 in 100 patients for gold salts or heparin ([349], [350] and [351]). It is not clear whether there are predisposing risk factors for most of the drugs that cause immune thrombocytopenia. However, strong evidence suggests that the risk of developing antibodies to gold salts depends on host HLA type, and the majority of patients studied have had HLA-DR3 alloantigen. Drug-induced antibodies may be complement- or noncomplement-activating antibodies that react with platelets either in the absence (autoantibodies) or presence of drugs. The most completely studied antibodies are those that develop in response to quinidine/quinine and heparin. Most drug-induced antibodies bind specifically to platelet membrane glycoproteins in the IIb/IIIa or the Ib/IX complex through the Fab portion of the antibody molecule (Fig. 53.2B). Many recent studies demonstrate a strong preference for epitopes on Iba or IX ([348], [352], [353]). In contrast, antibodies to heparin bind to a heparin–platelet factor 4 complex, and the immune complex then binds to the platelet membrane via the Fc portion of the antibody molecule (Fig. 53.2C). More than ten patients have been studied who developed thrombocytopenia and hemolytic uremic syndrome in association with the administration of quinine, suggesting that this antibody may bind to both endothelial cells and platelets in this unique syndrome ([354], [355], [356] and [357]). Most of the drug-induced antibodies are developed in response to the parent drug, and drug-dependent antibodies can be demonstrated in a variety of *in vitro* tests. In some cases, however, these tests are negative when the parent compound is present but positive if known metabolites are used instead of the parent compound. Antibodies against drug metabolites have been reported with acetaminophen, paraaminosalicylic acid, naproxen, and trimethoprim-sulfamethoxazole ([40], [358], [359] and [360]).

CLINICAL FEATURES Drug-induced thrombocytopenia is associated with a heterogeneous clinical picture and varying degrees of bleeding. Thrombocytopenia and bleeding usually appear abruptly and may be severe. Mucosal membrane bleeding from all sites and oral hemorrhagic bullae may occur, and patients often develop fever, chills, nausea, vomiting, and fatigue as part of a prodrome to the bleeding. Severe thrombocytopenia usually develops within hours in sensitized patients ingesting quinidine or quinine; however, a minimum of 6 to 7 days are required to initiate a primary immune response in individuals taking the drug for the first time. Some patients do not develop thrombocytopenia for months or years—a characteristic that seems more dependent on the host than the type of drug. The amount of drug that is required to cause thrombocytopenia is quite variable; however, even the amount of quinine present in a gin and tonic (15 mg) is sufficient to produce severe thrombocytopenia and bleeding in a patient who has been previously sensitized to quinine ("cocktail purpura") ([361]). After the drug is stopped, platelet counts return to normal within days and usually are normal by 1 week. Thrombocytopenia induced by gold salts resolves more slowly, usually over weeks or months, because gold remains in the tissues.
DIAGNOSIS It is often difficult to make a definite diagnosis of drug-associated immune thrombocytopenia because either the patient has taken the medication intermittently or a hospitalized patient is receiving more than one drug that may cause thrombocytopenia. Although it may be possible to demonstrate drug-dependent antibodies against the parent drug or its metabolites, this type of testing is beyond the scope of hospital laboratories. The readministration of the suspected drug in an attempt to confirm an etiologic relationship is not recommended as a routine diagnostic measure. Most of the level 1 drugs listed in Table 53.5 were demonstrated to cause immune-mediated thrombocytopenia because of patient response to an inadvertent *in vivo* challenge.
TREATMENT Ordinarily, no therapy is needed, because withdrawal of the offending drug is followed by recovery. Intravenous Ig and plasmapheresis may be helpful if life-threatening bleeding occurs. Many patients are treated with corticosteroids, and a normal platelet count is usually restored within 1 week. The major exception is gold-induced thrombocytopenia, which may persist for weeks or even months. British antilewisite (dimercaprol) may accelerate the excretion of gold and speed recovery ([362]).

Autoimmune Thrombocytopenia in Systemic Lupus Erythematosus

Thrombocytopenia may complicate collagen-vascular diseases and other various disorders associated with disordered immunologic responses, for example, thymoma ([363]) and myasthenia gravis ([364] , [365] and [366]). In most instances, the ITP in SLE appears to result from immunologic platelet injury and is identical to idiopathic ITP in most respects.

From 5 to 15% of patients with ITP fulfill the criteria for diagnosis of SLE at the time of presentation ([151] , [187] , [367] , [368]). Other patients have a positive antinuclear antibody test when they are first diagnosed with ITP, and a small number of them may develop SLE within several years. Patients with high-titer antinuclear antibody (speckled pattern) and antibodies against native DNA and other nuclear antigens are the patients most likely to develop SLE ([367] , [369] , [370] , [371] and [372]). SLE is a chronic and fatal disease, so it is important to identify such patients so therapy can be directed at all aspects of the autoimmune disease.

ITP in SLE patients may be the result of either specific platelet autoantibodies or immune complex deposition on platelets. Only a few studies have been reported in which the newest platelet antigen capture autoantibody tests have been used, and in these patients, platelet autoantibodies to platelet membrane glycoproteins have been detected ([373] , [374] , [375] and [376]). Thrombocytopenia correlates with SLE disease activity ([377]) but not the presence of antiphospholipid antibodies ([378] , [379] and [380]). These antibodies, which may be present in SLE or in otherwise healthy patients, also bind to platelet membrane gpIIb/IIIa or Ib/IX ([375] , [376]). It is unclear, however, whether these autoantibodies are specific to these glycoproteins or cross-reactive.

Patients with ITP and SLE should be treated the same as patients with idiopathic immune thrombocytopenia even though there are conflicting reports on the success rate of splenectomy in this population ([381] , [382]).

Idiopathic Thrombocytopenic Purpura in Other Disorders

Immune thrombocytopenia has been reported in association with a number of other medical conditions, including infections, neoplasms, and thyroid disease, and it is unknown whether this increased platelet destruction is the result of binding of autoantibodies or immune complexes or to antibody-mediated complement activation.

Immune thrombocytopenia has been documented in patients with infectious mononucleosis, cytomegalovirus, varicella or zoster ([383] , [384] , [385] and [386]), hepatitis B and C ([387] , [388]), tuberculosis ([389]), and human immunodeficiency virus infections (discussed in Chapter 69). During the last several years, immune thrombocytopenia was also reported in patients with *Helicobacter pylori*, and platelet counts may or may not normalize with treatment directed only at *Helicobacter* ([390] , [391] , [392] , [393] , [394] and [395]).

ITP is a well-known complication of chronic lymphocytic leukemia ([396]), although it is not as frequent as autoimmune hemolytic anemia in these patients. It has also been reported in patients with other lymphoproliferative disorders including Hodgkin disease ([121] , [397] , [398] , [399] , [400] , [401] , [402] , [403] , [404] and [405]). Thrombocytopenia in patients with a variety of solid tumors has also been thought to most likely be immune mediated ([363] , [400] , [401]).

Thrombocytopenia may accompany Graves disease and Hashimoto thyroiditis ([406] , [407] , [408] and [409]), but it is not certain if it is immunologically mediated. Platelet-associated IgG has been increased when studied ([408] , [409]), but there may also be enhanced reticuloendothelial phagocytosis.

ALLOIMMUNE THROMBOCYTOPENIA

Platelets express membrane-associated epitopes due to polymorphisms in discrete regions of the platelet membrane surface glycoproteins ([410]). No natural antibodies to human platelet antigens are known. Acquired platelet alloantibodies are of clinical importance in three circumstances: (a) neonatal alloimmune thrombocytopenia, which is the result of the placental transfer of alloantibodies formed by the mother to incompatible fetal platelet antigens ([411]); (b) posttransfusion purpura (PTP), a rare disorder in which the transfusion of platelet-containing blood products provokes the formation of alloantibodies that act as autoantibodies ([412]); and (c) passive transfer of platelet alloantibodies after transfusion from a multiparous or multiply transfused donor ([413] , [414] , [415] and [416]).

Neonatal Alloimmune Thrombocytopenia

PATHOPHYSIOLOGY Immunologic thrombocytopenia in the newborn may result from the placental transfer of platelet antibodies formed as the result of active immunization of the mother by fetal platelet antigens. Pathophysiologically, such neonatal alloimmune thrombocytopenia is similar to erythroblastosis fetalis. Thus, as a consequence of the inheritance by the fetus of platelet antigens lacking in the mother, alloantibodies are formed in the maternal circulation and cross the placenta, producing thrombocytopenia in the fetus. Antibodies can be detected as early as the nineteenth week, and thrombocytopenia has been found *in utero* by 20 weeks' gestation ([417]). Immunization to human platelet alloantigen (HPA)-1a (PL ^{A}, Zw ^{A}) ([418] , [419] and [420]) and HPA-5b (Br ^{A}, Zav, Hc) ([421] , [422]) is most common; however, other antigens have been detected and found responsible for occasional cases of neonatal alloimmune thrombocytopenia (Fig. 53.2D) ([418] , [419] , [421] , [423] , [424] , [425] , [426] , [427] , [428] and [429]). All of the platelet polymorphisms found to date are caused by a single base pair mutation leading to a single amino acid substitution in the polypeptide chain of the specific gp. Rarely, HLA antibodies are responsible ([418] , [421]). Alloimmunization to platelet antigens commonly develops during the first pregnancy and then recurs in more than 80% of patients during subsequent pregnancies. However, not all mothers who are missing the antigens presented by the fetus develop antibodies, and not all fetuses and neonates develop thrombocytopenia in spite of antibody development ([420]). HPA-1 mismatch is present in 1 in 50 births, yet neonatal alloimmune thrombocytopenia only occurs in 1 in 1000 to 2000 births ([417] , [419] , [420] , [430]). Maternal HLA class II determinants appear important. A high incidence of maternal allotypes HLA-DR3 and HLA-DRw52a has been demonstrated in mothers isoimmunized to fetal alloantigen HPA-1 ([420] , [431]), and a high incidence of HLA-DR6 has been reported in mothers sensitized to PLA-5b ([421]).
CLINICAL FEATURES Infants with neonatal alloimmune thrombocytopenia are born with signs of purpura and severe thrombocytopenia. Thrombocytopenia usually is present at birth, but the platelet count may fall further during the perinatal period. Intracranial hemorrhage occurs in 20 to 30%, with one-half of the episodes occurring *in utero* ([432]). An overall mortality rate of 6 to 14% has been reported ([419] , [423]). Thrombocytopenia usually resolves after 10 to 14 days. Platelet antibody titers during the second half of the pregnancy appear to correlate with the risk of thrombocytopenia or bleeding, or both, in neonatal alloimmune thrombocytopenia ([433] , [434]).
LABORATORY DIAGNOSIS When infants are born with platelet counts less than 20,000 µl, neonatal alloimmune thrombocytopenia must be suspected, and platelet typing and platelet antibody assays should be performed on both parents. Neonatal alloimmune thrombocytopenia is diagnosed when platelet antigen incompatibility is found between the parents, maternal antipaternal platelet antibodies are present, and the antibody detected corresponds to the incompatibility of platelet antigens that have been noted.

TREATMENT Severely thrombocytopenic children should be treated aggressively with intravenous Ig and platelet transfusions of compatible, irradiated platelets. Maternal platelets can be obtained by pheresis, concentrated, irradiated, and transfused. Screening studies to detect neonatal thrombocytopenia during the first pregnancy have been limited to patients with known PL ^{A1} incompatibility and an HLA allotype associated with an increased incidence of antibody formation ([431]). However, after the birth of one child with neonatal alloimmune thrombocytopenia, subsequent pregnancies should be evaluated antenatally. It is recommended that fetal platelet typing ([418], [435], [436], [437] and [438]) and platelet counts should be obtained at, or approximately at, 20 weeks ([417], [439]). If platelet incompatibility is noted and the infant is thrombocytopenic, *in utero* platelet transfusions or maternal treatment with intravenous Ig should be instituted and maintained during the pregnancy ([417], [440], [441]). The use of cordocentesis may be associated with fetal exsanguination if the fetus is severely thrombocytopenic or a prior pregnancy was complicated by *in utero* intracranial hemorrhage. The use of steroids and exchange plasmapheresis is still controversial.

Posttransfusion Purpura

Alloantibodies that develop as a result of transfusion of incompatible platelets are responsible for the destruction of the transfused platelets. Rarely, however, severe thrombocytopenia in the recipient—that is, destruction of host platelets—is produced by the transfusion of incompatible platelets, and this potentially fatal reaction is known as *posttransfusion purpura* (PTP) ([442], [443] and [444]). PTP is characterized by the abrupt onset of thrombocytopenia and mucosal bleeding that occurs approximately 1 week after the transfusion of packed red blood cells. PTP has also occasionally been described after the transfusion of other blood components including fresh plasma ([445]).

The syndrome occurs most commonly in multiparous women; however, previously transfused patients may also develop PTP. The antibody most commonly develops against PL ^{A1} (HPA-1a) in PL ^{A2} (HPA-1b) homozygous recipients, but the Bak (HPA-3a/HPA-3b), Pen (HPA-4a/HPA-4b), Br (HPA-5a/HPA-5b), and Nak ^{a} polymorphisms have been implicated as well ([412], [443], [444], [446], [447], [448] and [449]) (Table 53.6). The diagnosis of PTP is a clinical one, and physicians must therefore consider this diagnosis in any patient developing thrombocytopenia within 3 to 14 days after transfusion of any blood product.

TABLE 53.6. Platelet Alloantigens Implicated in the Development of Posttransfusion Purpura

Serologic Designation	Alternative Designation	Phenotype Frequency	Antigen Location
PL ^{A1} (HPA-1a)	Zw ^{a}	0.96–0.99	gpIIIa
PL ^{A2} (HPA-1b)	Zw ^{b}	0.27	gpIIIa
Bak ^{a} (HPA-3a)	Lek ^{a}	0.78–0.89	gpIIb
Bak ^{b} (HPA-3b)	Lek ^{b}	0.50–0.70	gpIIb
Pen ^{a} (HPA-4a)	Yuk ^{b}	0.99	gpIIIa ^{a}
Pen ^{b} (HPA-4b)	Yuk ^{a}	0.01	gpIIIa ^{a}
Br ^{b} (HPA-5a)	Zav ^{b}	0.99	gpIa
Br ^{a} (HPA-5b)	Zav ^{a}	0.18–0.20	gpIa

HPA, human platelet alloantigen; gp, glycoprotein.

a Antigen appears to be distinct from PL ^{A1} (HPA-1a).

Modified from McCrae KR, Herman JH. Posttransfusion purpura: two unusual cases and a literature review. Am J Hematol 1996;52:205–211.

The pathophysiology of this rare but severe thrombocytopenia is still uncertain, but several hypotheses have been proposed: (a) autologous platelets are destroyed because of binding of immune complexes to their surface; (b) recipient platelets acquire the phenotype of the donor's platelets because they bind soluble antigens from the transfused blood product, and the platelets are then destroyed by the alloantibodies; and (c) exposure to foreign platelets in the transfused products induces the formation of autoantibodies to the recipient's platelets ([412], [450], [451]).

PTP is self-limited, resolving within 1 to 3 weeks in most patients. Treatment with steroids, plasmapheresis, or intravenous Ig may shorten the period of thrombocytopenia. Plasmapheresis is effective in 80% ([452], [453] and [454]), but intravenous Ig, in doses of 2 g/kg over 2 days, may be preferable because plasmapheresis requires central venous access with large bore catheters and places the patient in danger of significant bleeding ([455], [456] and [457]). Platelet transfusions should be reserved for life-threatening hemorrhage, because patients often develop a febrile reaction and infrequently respond by increasing their platelet count.

54 Thrombotic Thrombocytopenic Purpura and Other Forms of Nonimmunologic Platelet Destruction

Shirley Parker Levine

The various forms of thrombocytopenia discussed in this chapter result from platelet destruction by processes that are independent of immunologic phenomena (Table 54.1). They have little else in common. The major disease in this category is *thrombotic thrombocytopenic purpura* (TTP), which is one of the thrombotic microangiopathies (for recent review, see references [1], [2], [3] and [4]). Hemolytic-uremic syndrome (HUS), another thrombotic microangiopathic disorder, shares many features with TTP and may be closely related. However, it occurs more commonly in children and is discussed separately in Chapter 38. There are adults who have an HUS-like disease with more renal failure and less neurologic disease than with typical TTP. These patients are usually considered as having TTP-HUS and are included in the literature cited in this chapter.

TABLE 54.1. Causes of Nonimmunologic Platelet Destruction

Diffuse thrombotic microangiopathy
Thrombotic thrombocytopenic purpura: primary and secondary
Disseminated intravascular coagulation (see Chapter 60)
Localized thrombotic microangiopathy
Hemolytic-uremic syndrome (see Chapter 38)
Abnormal and artificial vascular surfaces
Stenosed or artificial heart valves
Catheters or artificial vascular grafts
Coronary artery bypass
Extracorporeal or implanted circulatory pumps
Miscellaneous
Burns, cryopathy, hypothermia
Platelet-agglutinating drugs
Hyperbaric exposure

THROMBOTIC THROMBOCYTOPENIC PURPURA

TTP is characterized by disseminated thrombotic occlusions of the microcirculation and a syndrome of hemolytic anemia, thrombocytopenia, neurologic symptoms, fever, and renal dysfunction. The disorder was first described by Moschcowitz in 1924 ([5]) and is one of the group of diseases called *thrombotic microangiopathies*, which includes TTP, HUS, and disseminated intravascular coagulation. TTP is more common in women than in men (ratio of 2:1) and has a peak incidence in people between the ages of 30 and 40 years. The disorder is uncommon but not rare, and its incidence may be increasing.

Pathophysiology

The thrombotic lesions of TTP typically involve terminal arterioles and capillaries ([5], [6]). The thrombi are composed of platelets, von Willebrand factor (vWF), and only small amounts of fibrin ([7]) and vary morphologically from loose platelet aggregates to densely coherent platelet plugs ([8]). The lesions are associated with hyaline deposits in the subendothelial layers of capillaries and between the endothelium and muscular layers of arterioles ([9]). The subendothelial lesions are regarded as the most characteristic histopathologic feature of the disorder ([10], [11]) and probably result from platelet thrombi that are eventually incorporated into the vascular wall and covered by newly formed endothelial cells ([7]). Fibrinoid necrosis, vascular inflammation, and perivascular inflammation are lacking.

The lesions of TTP are seen most commonly in the brain, kidney, pancreas, heart, spleen, and adrenal glands ([7]), but they may be found throughout the body. In the brain, vessels in the cortical gray matter and brain stem are most often affected. The clinical manifestations of TTP result from consumptive thrombocytopenia and partial and complete occlusions in many organs, which in turn lead to varying degrees of organ dysfunction. Red cells are damaged as the result of interactions with the microthrombi and fibrin networks in the small vessels (“microangiopathic” hemolysis and thrombotic microangiopathy). Such interactions produce schistocytes that have limited deformability and, as a result, are destroyed rapidly in the spleen and microcirculation (see Chapter 38).

Although little doubt exists that the thrombotic lesions give rise to the characteristic manifestations of TTP, the exact cause of the thrombotic lesions remains unclear. The primary process may involve endothelial damage caused by any number of immune, infectious, or chemical causes; the platelet thrombus may be initiated primarily by plasma-aggregating or -agglutinating agents; or the process may be a combination of both mechanisms, the predominance of which depends on the precipitating etiology. Attempts to transfer TTP passively have been unsuccessful ([12]).

There are a number of reports of TTP-HUS occurring in siblings, suggesting a genetic susceptibility to the development of thrombotic microangiopathies ([13], [14], [15], [16], [17] and [18]). Preliminary data suggest that the absence of the supertypic HLA II antigen DR53 may govern this susceptibility ([19]).

VASCULAR ABNORMALITIES There is growing evidence that TTP plasma can injure endothelial cells and increase apoptosis ([20], [21], [22], [23], [24], [25], [26] and [27]). This occurs primarily in microvascular endothelial cells, mimicking the distribution of hyaline thrombi in TTP. The endothelial damage may be due to antibodies ([28], [29] and [30]), immune complexes ([31], [32]), infections ([33]), toxins ([34]), or other as yet unidentified factors. An antibody to CD36 (platelet membrane glycoprotein IV, which is also found on endothelial cells) is present in 65 to 80% of TTP serum tested, depending on the assay used ([29]). Damage to the endothelial cells then may promote platelet thrombi formation by release of ultra-large endothelial cell vWF (ULvWF), changes in the normal endothelial cell modulation of procoagulant and anticoagulant forces, or both ([32], [35], [36], [37], [38], [39], [40] and [41]).
von Willebrand Factor *vWF* is a multimeric protein that is synthesized and stored in endothelial cells. There is considerable evidence that perturbed endothelial cells release vWF and that release of ULvWF multimers plays an important role in the pathogenesis of platelet thrombi in TTP ([42]) (Fig. 54.1). In normal individuals, ULvWF molecules are released from endothelial cells, unfolded by exposure to high shear stresses present in the microvascular circulation, and proteolyzed by a metalloprotease between the amino acids tyrosine 842 and methionine 843. The vWF metalloprotease gene on chromosome 9 was recently cloned, and the protease was determined to be a member of the ADAMTS family of metalloproteases (ADAMTS13) ([43], [44], [45], [46] and [47]). In TTP, there is either a familial deficiency of the

metalloprotease or an acquired deficiency due to either an antibody inhibitor or release of ULvWF from injured endothelial cells ([48], [49], [50] and [51]). These ULvWF multimers bind avidly to platelets, promoting platelet agglutination as is seen in the arterioles and capillaries of patients with TTP. Patients with TTP have increased platelet-associated vWF and circulating platelet aggregates when studied by flow cytometry, lending support to this hypothesis ([52]).

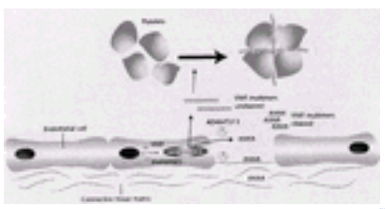

Figure 54.1. von Willebrand factor (VWF) is synthesized in endothelial cells as a monomer that is subsequently made into multimers that are secreted. Large multimers best support platelet adhesion to collagen, but the largest multimers have high affinity for platelets and may cause platelets to agglutinate. It is hypothesized that ADAMTS13, a metalloprotease, cleaves secreted VWF to limit the size of the multimers and prevent platelet agglutination in the circulation. See Color Plate.

Moake was the first investigator to implicate abnormal vWF homeostasis in TTP. He reported that 50% of patients who had a single episode of TTP demonstrated the presence of unusually large multimers of vWF (ULvWF) in their earliest plasma samples ([53], [54]). These ULvWF multimers resembled those synthesized by endothelial cells when analyzed by sodium dodecyl sulfate–agarose gel electrophoresis and may represent vWF released from injured endothelial cells or stimulation of vWF release from endothelial cell Weibel-Palade bodies. In patients with intermittent or chronic relapsing TTP, plasma vWF multimer patterns showed the presence of ULvWF multimers between episodes and when patients were in remission, and the disappearance of both the ULvWF and largest plasma multimers of vWF during relapse ([54], [55] and [56]). The disappearance of these largest multimers during relapse may reflect binding to platelets, leading to agglutination. Infusion of fresh frozen plasma or supernatant from cryoprecipitated plasma was followed by a decrease or disappearance of the ULvWF within 30 to 90 minutes, suggesting the presence of a plasma protease for ULvWF ([57]). Several different types of metalloprotease assay are now available. Almost all healthy control subjects have normal protease concentrations, although levels are lower in neonates, elderly patients, and women in their third trimester of pregnancy ([58]). In the initial reports of protease activity in TTP patients, severe deficiencies were found in almost all patients with classic TTP ([50], [51]). An immunoglobulin (Ig) inhibitor could be demonstrated in the majority of these patients and in 76% of patients studied in the Canadian Apheresis Trial ([58]). In more recent large survey studies, many, but not all, TTP patients have decreased protease activity (<10%), and many of these latter patients do have measurable inhibitors ([59], [60] and [61]). In contrast, most patients with HUS have normal protease levels. Protease deficiencies are also reported in other patient groups: cirrhosis, renal insufficiency, inflammatory diseases, and disseminated intravascular coagulation (DIC). Recent studies on the ADAMTS13 protease gene should make it possible to develop immunoassays that may improve the ability to diagnose TTP and differentiate TTP and HUS. There is a congenital, severe deficiency of metalloprotease that is transmitted in an autosomal-recessive manner (Upshaw-Shulman syndrome) and becomes manifest during infancy or childhood ([48], [62], [63] and [64]). In these patients, the plasma ULvWF accumulates slowly, resulting in cyclical thrombocytopenia and microangiopathic hemolysis. These intervals occur most commonly at 3- to 4-week intervals, although less frequent episodes are reported in some patients. Many children with this congenital deficiency of metalloprotease can be maintained in long-term remission by prophylactic administration of plasma infusions approximately every 21 days ([65], [66]). Several groups of patients with secondary TTP have also been studied since the metalloprotease assays were developed. Patients with ticlopidine-associated TTP were found to have increased platelet-associated vWF, decreased concentrations of the largest plasma vWF multimers, severe deficiency of the metal-loprotease, and IgG inhibitors ([67]). Several patients with clopidogrel-associated TTP and one patient with human immunodeficiency virus–TTP demonstrated severe deficiency of metalloprotease and IgG inhibitors to the protease ([68], [69]). In contrast, patients with bone marrow transplant–associated TTP have normal concentrations of metalloprotease, which may explain why they respond poorly to plasma therapy ([70]).

PLATELET-AGGREGATING AGENTS Investigators have demonstrated that plasma from many affected patients contains substances that induce platelet agglutination or aggregation ([71], [72]). At least three types of factors have been described, each from a small subset of patients. The relationships among these aggregating agents and vWF and the incidence of each factor in TTP are unknown, so their importance still is controversial. Platelet-aggregating factor p37 (PAF p37) is a 37-kd polypeptide, compact, globular glycoprotein that has been identified and purified from plasma of a subset of patients with active TTP ([71], [73], [74]). It agglutinates autologous and homologous platelets and does not require fibrinogen, vWF, calcium, energy metabolism, adenosine diphosphate release, or cyclooxygenase activity. Calpain, a second PAF, has been identified in 86% of a small series of patients with acute, untreated TTP when a platelet aggregation assay was enriched with vWF to increase the sensitivity ([75]). This aggregating factor is the cysteine protease calpain, which is normally found in the cytosol of platelets and many other cell types ([76]). A third aggregating factor has been described from plasma and serum samples of patients with active TTP but not after remission ([77], [78]). This factor is also a cysteine protease, but the sensitivity of the enzyme to standard inhibitors demonstrates that it is a lysosomal cathepsin rather than a cytoplasmic calpain.

Clinical Manifestations

TTP is characterized by the pentad of microangiopathic hemolytic anemia, thrombocytopenia, neurologic symptoms, renal dysfunction, and fever (Table 54.2). In the series of 258 patients reported by Ridolfi and Bell, 74% of patients had the triad consisting of anemia, thrombocytopenia, and neurologic disorders, and only 40% of the patients had the full pentad of features ([79]), incidences that have been confirmed in more recent series of patients ([80]). Many patients presented with nonspecific symptoms, such as malaise and weakness, in addition to one or more symptoms of the pentad. Neurologic symptoms or hemorrhagic symptoms were the most common chief complaints. Neurologic symptoms may develop and progress rapidly, although they are classically multifocal and transient but recurrent in nature. Diffuse lesions are less often transient ([81]). Manifestations can include headache, cranial nerve palsies, dysphasia or aphasia, paresis, confusion, stupor, coma, and seizures. Purpura and retinal hemorrhages are the most common type of hemorrhage, but gastrointestinal and genitourinary hemorrhages are also seen. Fever is present at admission in approximately 50% of patients but develops during the course of the illness in many others, although the fever may now be more commonly a side effect of plasma exchange. Renal manifestations include proteinuria, hematuria, and mild renal insufficiency.

TABLE 54.2. Incidence of Pentad Features in Patients with Thrombotic Thrombocytopenic Purpura

	Amorosi and Ultmann (6)		Ridolfi and Bell (79)	
Symptom	**Symptom (N)/Study (N)**	**%**	**Symptom (N)/Study (N)**	**%**
Microangiopathic hemolytic anemia	246/256	96	254/258	98
Thrombocytopenic purpura or other bleeding	241/251	96	214/258	83
Neurologic symptoms	250/271	92	218/258	84
Renal disease	191/217	88	196/258	76
Fever	237/243	98	252/258	98

Other manifestations may occur during the course of TTP. These include acute respiratory distress syndrome ([82]), cardiac conduction abnormalities and infarcts ([83], [84]), abdominal pain caused by pancreatitis ([6], [85], [86]) or bowel wall infarcts ([87], [88]), and erythromelalgia ([89]).

TTP usually occurs in previously healthy people, but in a significant number of cases, the syndrome is associated with other disorders (Table 54.3). A thrombotic microangiopathy that may resemble TTP or HUS has been described in association with infections, drugs, cancer, bone marrow transplantation, collagen-vascular diseases, and pregnancy. The thrombotic microangiopathy in these patients may not be identical in pathophysiology to primary TTP in that many of these disorders are associated with vasculitis and DIC or more closely resemble HUS. The prognosis in these patients may vary significantly depending on the associated condition.

TABLE 54.3. Diseases Associated with Thrombotic Thrombocytopenic Purpura

Infections
  Human immunodeficiency virus (33, 80, 90, 91, 92, 93, 94, 95, 96, 97 and 98)
  Escherichia coli, *Shigella* (99, 100, 54 and 102)
Pancreatitis (103, 104)
Drug treatment
  Cyclosporin A, tacrolimus (FK506) (105, 106, 107 and 108)
  Antineoplastic agents (106, 109, 110 and 111)
  Ticlopidine, clopidogrel (67, 68, 112)
  Quinine (113)
Collagen-vascular diseases (114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130 and 131)
Pregnancy and the puerperium (132, 133)
Cancer (134, 135 and 136)
Bone marrow transplantation (137)

Laboratory Findings

Erythrocyte abnormalities in TTP are those of microangiopathic red cell destruction. The reticulocyte count is increased to a degree appropriate for the severity of the anemia. The blood smear reveals polychromasia, stippling, nucleated red cells, and schistocytes (Fig. 54.2). Serum lactic dehydrogenase (LDH) and unconjugated bilirubin concentrations are increased, with LDH concentrations ranging from 400 to more than 1000. The LDH increase may be due to release from a variety of injured tissues in addition to the breakdown of red blood cells (138). Hemolysis is of the intravascular type, meaning that haptoglobin levels are reduced and hemoglobinuria and hemosiderinuria usually are present. The majority of patients have hemoglobin concentrations less than 10 g/100 ml. Moderate neutrophilia with some increase in immature forms is common. Platelet counts can range from less than 10,000/µl to 100,000/µl, but most patients have platelet counts below 50,000/µl (139). LDH levels and the platelet count are sensitive indices of the response of the disorder to therapy (140, 141).

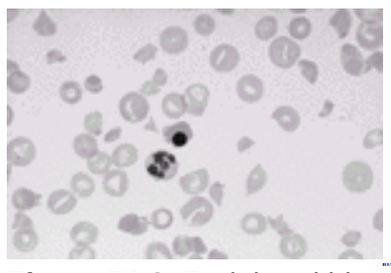

Figure 54.2. Peripheral blood smear from a patient with acute thrombotic thrombocytopenic purpura. Polychromasia, a nucleated red blood cell, and numerous schistocytes are present (×1000; Wright-Giemsa stain). See Color Plate.

Normoblastic hyperplasia and increased numbers of megakaryocytes usually are apparent in the bone marrow. Surveys of large numbers of patients with TTP reveal that significant intravascular coagulation is rarely associated with TTP (139, 142, 143). The results of screening tests of coagulation usually are normal, although slight elevations in the levels of fibrin degradation products are common (41, 144). Measurements of plasma vWF antigen and factor VIIIc by the usual methods yield normal or increased levels; special techniques, such as agarose gel electrophoresis, are required to demonstrate the presence of abnormal vWF multimers. Proteinuria and microscopic hematuria, mild azotemia, and abnormalities of liver function tests are common. Analysis of the cerebrospinal fluid usually reveals elevated protein levels and some xanthochromia; less commonly, it is frankly bloody. Computed tomograms and magnetic resonance imaging of the brain may reveal reversible bilateral cerebral edema, ischemic strokes, and frank hematomas (145, 146 and 147).

The antemortem histopathologic demonstration of lesions of TTP often is difficult. Skin, gingivae, and bone marrow may be biopsied and examined for hyaline thrombi within arterioles (Fig. 54.3) (6, 10, 11, 79, 148, 149, 150, 151 and 152). Biopsies are diagnostic in only approximately 50% of cases, and similar abnormalities often are noted in association with DIC, various forms of vasculitis, HUS, and a variety of unrelated disorders.

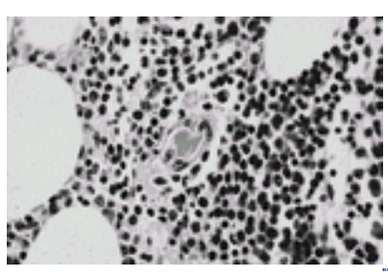

Figure 54.3. Bone marrow biopsy in a patient with acute thrombotic thrombocytopenic purpura. There is a hyaline thrombus within one of the arterioles in the bone marrow (×1000; hematoxylin and eosin stain). See Color Plate.

Differential Diagnosis

HUS and related microangiopathic processes (see Chapter 38) are closely related to TTP. HUS may be regarded as a localized form of the disorder in which microangiopathic blood destruction and vascular damage occur principally in the kidney. The incidence of HUS is high in children, and the disorder often follows a prodromal infection. Abdominal pain and gastrointestinal symptoms often usher in HUS; anuria, severe renal failure, and hypertension are common early in the course of the disorder. However, abdominal pain secondary to pancreatitis or bowel wall infarcts can also be seen in patients with TTP. Neurologic symptoms are less common in patients with HUS, and complement levels often are low. Spontaneous remission occurs in many cases and relapses are rare.

In pregnant women, eclampsia or hemolysis, elevated liver enzymes, and low platelet count (“HELLP”) syndrome may present with many similar manifestations, which may be confused with TTP. In contrast to TTP, eclampsia has a favorable prognosis and may be associated with low-grade intravascular coagulation. Other disorders that may mimic TTP include microangiopathic hemolysis associated with disseminated cancer or intravascular coagulation, active systemic lupus erythematosus with immune thrombocytopenic purpura and vasculitis, severe idiopathic thrombocytopenic purpura with autoimmune hemolytic anemia (especially if intracranial hemorrhage has occurred), and paroxysmal nocturnal hemoglobinuria.

Treatment

Before the introduction of exchange plasmapheresis and plasma infusions in the 1970s for the treatment of TTP, the disease was fatal in more than 80% of patients within 3 months; fewer than 10% survived 1 year (6). Over 80% of patients who are treated aggressively with exchange plasmapheresis now survive the initial episode of TTP (1, 32, 80, 127, 143, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168 and 169). Investigators have not consistently found any presenting factors that can predict which patients will have a favorable outcome; in fact, patients with significant renal failure have the same response rate to aggressive plasma exchange (32, 169, 170 and 171). The exact mechanism of these remarkable therapeutic effects remains unknown. Possible explanations include the removal of abnormal vWF multimers, PAFs, or circulating immune complexes and the replacement of a processing factor that can modify ULvWF multimers (i.e., cleaving metalloprotease) or prostacyclin production. The therapeutic effects of plasmapheresis in the critically ill patient with TTP often are dramatic. Severe neurologic manifestations may disappear, and laboratory abnormalities may diminish in a few hours. Some patients may respond completely to infusions of large

amounts of fresh plasma daily ([143], [172], [173], [174] and [175]), but in the controlled prospective therapeutic trial of plasma exchange or plasma infusion, plasma exchange was demonstrated to be significantly better ([143]). Use of cryoprecipitate-poor plasma for replacement as initial therapy during plasma exchange was not superior to fresh frozen plasma in a recent small randomized controlled trial ([176]).

Seriously ill patients should receive plasma infusions for several hours until plasmapheresis can be arranged. Thereafter, plasma exchange of at least a single plasma volume daily should be performed until several days after the platelet count is normal and there is minimal hemolysis. The procedure must sometimes be continued for 10 days or longer to obtain a complete remission in seriously ill patients. Therapy is then frequently tapered and discontinued if normal values are maintained. Up to one-third of patients may have early relapses (i.e., less than 1 month after complete remission) or late relapses up to 10 years after their first episode ([177]).

Evaluating other therapeutic measures in TTP is difficult because most patients are given multiple therapeutic agents simultaneously (Table 54.4). Patients are often treated with corticosteroids or antiplatelet drugs during plasmapheresis, but the benefit of these therapies is still uncertain ([159], [178], [179], [180] and [181]). Patients who are refractory to plasmapheresis may respond to cryosupernatant plasma therapy ([57], [182], [183] and [184]), vincristine ([185], [186], [187], [188], [189], [190], [191] and [192]), intravenous Ig ([193], [194], [195], [196], [197], [198], [199], [200], [201] and [202]), prostacyclin ([203], [204], [205] and [206]), or splenectomy ([207], [208], [209], [210], [211], [212], [213], [214], [215], [216], [217] and [218]), but these therapies have not been systematically studied in this setting. Therefore, individual hematologists have their own preferred salvage therapies. Some patients with chronic, relapsing TTP have responded to splenectomy.

TABLE 54.4. Treatment of Thrombotic Thrombocytopenic Purpura

Plasmapheresis with exchange of at least one volume of plasma daily.
Inclusion of antiplatelet agents and corticosteroids is of unproven benefit.
Salvage therapy.
Infusions of fresh frozen plasma
Plasmapheresis and exchange with cryosupernatant plasma
Vincristine
Intravenous immunoglobulin
Splenectomy
Prostacyclin

Platelet transfusions should be avoided because patients have had marked deterioration in either renal or neurologic status during platelet transfusions ([164], [219], [220] and [221]). There is even concern that rapid recovery of the platelet pool during treatment may explain subsequent deterioration in some patients' clinical course ([221]).

PLATELET DAMAGE BY ABNORMAL VASCULAR SURFACES

To an even greater extent than erythrocytes, platelets are subject to damage by interactions with “unphysiologic” surfaces within the vascular system. Pathologic alterations of vessels that may produce such platelet damage include stenotic and roughened heart valves ([222]), extensive atherosclerosis, metastatic cancer ([223]), and kidney diseases that are associated with severe vascular changes in renal vessels ([224]). An increasing number of surgical techniques involve the implantation of devices containing foreign material within the vascular system. Such circulatory prostheses include cardiac valves, vascular grafts of many types, indwelling catheters [including Swan-Ganz catheters ([225])], intraaortic balloon pumps ([226]), extracorporeal life support ([227]), and artificial hearts. An attempt has been made to render such materials nonthrombogenic, but most of these devices produce varying degrees of platelet destruction as well as hemolysis ([228]). Finally, even short-term contact between platelets and foreign surfaces, as in cardiopulmonary bypass, is associated with platelet damage ([229]).

Bleeding during cardiopulmonary bypass surgery appears to be multifactorial. In addition to dilution of clotting factors, inadequate neutralization of heparin, and mild thrombocytopenia, there is a defect in platelet function that results in a prolongation of the bleeding time. Hemodilution leads to a rapid reduction in platelet counts by as much as 50% shortly after cardiopulmonary bypass surgery begins. The bleeding time defect is maximal during cardiopulmonary bypass surgery and usually disappears within 24 hours of surgery. Similar changes in platelet counts, bleeding time, and postoperative bleeding occur regardless of whether bubble or membrane oxygenators are used ([229]). The nature of the platelet defect is controversial, and there is currently disagreement as to whether it is even intrinsic ([230], [231], [232] and [233]) or extrinsic ([233]) to the platelet. Investigators report partial platelet degranulation, circulating activated platelets by flow cytometry, and defects in platelet membrane glycoprotein Ib/IX and IIb/IIIa ([234], [235]). Platelet survival is shortened, and accumulation of radio-labeled platelets can be demonstrated both on the membrane in the cardiopulmonary pump and in the patient liver ([236]). Bleeding can be reduced by infusions of normal platelets, 1-deamino-8-D-arginine vasopressin, epsilon amino caproic acid, or aprotinin ([237], [238], [239] and [240]). Additional agents that provide temporary, reversible inhibition of platelet activation are being tested in simulated extracorporeal circulation ([241]).

MISCELLANEOUS FORMS OF NONIMMUNOLOGIC PLATELET DESTRUCTION

Extensive burns are associated with mild to moderate thrombocytopenia that results from nonimmunologic platelet destruction ([242]). The mechanism by which this occurs is unclear. Thrombocytopenia may become severe and bleeding may develop when complicating sepsis or DIC develops. Fortunately, the latter syndrome is uncommon, even in cases involving severe burns in the absence of infection. Thrombocytopenia has been well described after hepatic cryotherapy ([243]) and in moderate hypothermia treatment for hemispheric stroke ([244]). Certain drugs may produce thrombocytopenia by nonimmunologic phenomena. Ristocetin, an antituberculosis agent no longer used clinically, promotes the attachment of vWF to a platelet receptor and initiates direct platelet-to-platelet interaction by means of an agglutination phenomenon. Studies of risto-cetin-induced platelet aggregation have provided much information concerning von Willebrand disease (see Chapter 59). vWF concentrates of bovine or porcine origin predictably produce platelet aggregation and mild thrombocytopenia in the recipient, apparently as the result of attachment of the heterologous vWF to a platelet receptor. Similar agglutination phenomena also are produced by polycations, such as polybrene, protamine, and pentosan ([245]). Protamine may produce reversible sequestration of platelets in the liver ([246]) but seldom is the cause of significant thrombocytopenia. Aggregation of platelets independent of immune mechanisms plays a role in type 1 heparin-induced thrombocytopenia. Thrombocytopenia is a consistent feature of postdecompression sickness in divers and has been attributed to intravascular platelet aggregation ([247]).

Miscellaneous Causes of Thrombocytopenia

This chapter provides a summary of various miscellaneous forms of congenital and acquired thrombocytopenia (Table 55.1), including thrombocytopenia attributable to deficient platelet production, associated with abnormal platelet pooling in the spleen, and resulting from dilution with massive transfusions.

TABLE 55.1. Miscellaneous Forms of Thrombocytopenia

Congenital thrombocytopenia
Congenital thrombocytopenia with megakaryocytic hypoplasia
Autosomal-recessive disorder (congenital amegakaryocytic thrombocytopenia) due to c- *mpl* receptor mutations
Autosomal-recessive disorders associated with absent radius: thrombocytopenia with absent radius syndrome
Autosomal-dominant disorders associated with radial-ulnar synostosis and *HOX*A11 gene mutations
Autosomal-dominant giant platelet disorders (*MYH9* gene defects)
May-Hegglin anomaly
Sebastian syndrome and variants
Fechtner syndrome
Epstein syndrome
X-linked microthrombocytopenia (WAS gene mutations)
Wiskott-Aldrich syndrome (WAS)
X-linked thrombocytopenia (XLT)
X-linked macrothrombocytopenia with dyserythropoiesis (*GATA1* mutations)
Acquired thrombocytopenias
Decreased platelet production
Thrombocytopenia caused by abnormal platelet pooling
Disorders of the spleen
Hypothermia
Thrombocytopenia associated with infections
Viruses
Bacteria and protozoans
Thrombocytopenia after massive blood transfusion

CONGENITAL THROMBOCYTOPENIA

Enormous recent progress has been made in our understanding of the congenital thrombocytopenias. Hereditary forms of thrombocytopenia with diverse genetic, clinical, and laboratory features have now been documented in numerous kindreds. In this section, the genetic abnormalities identified as of early 2002 are reviewed.

Hereditary thrombocytopenias have been well documented and may be inherited as an autosomal-dominant trait, an autosomal-recessive trait, or an X-linked recessive trait. Bleeding can be mild, and in some instances, the affected family members are virtually asymptomatic, being identified only through incidental platelet counts or family studies after the identification of the propositus. It is important to recognize these mild forms of familial thrombocytopenia because although they resemble autoimmune thrombocytopenic purpura, patients do not respond to steroid treatment or intravenous immunoglobulin, and these forms of therapy may be harmful.

Congenital Thrombocytopenia with Megakaryocytic Hypoplasia

Congenital thrombocytopenia associated with megakaryocytic hypoplasia occurs in several different types of disorders. In some cases, thrombocytopenia with megakaryocytic hypoplasia on bone marrow examination appears during childhood and appears to be an early manifestation of bone marrow aplasia ([1], [2], [3] and [4]). In other cases, megakaryocytes are the only progenitor cell affected, and the thrombocytopenia occurs early in the neonatal period and is associated with skeletal and soft tissue abnormalities. The best studied group of patients are those with thrombo-cytopenia with absent radius.

Purpura and ecchymoses usually are apparent in affected infants at birth, and serious bleeding manifestations, particularly intracranial bleeding, are often noted. Examination of the bone marrow reveals marked diminution in the number of megakaryocytes; in many patients, they may be totally absent. A leukemoid reaction of the granulocytic type or eosinophilia with myeloid hyperplasia of the marrow has been documented in as many as 50% of patients ([5]). Shortened platelet survival and platelet dysfunction with decreased platelet-dense bodies have been demonstrated in some cases ([6], [7]). These findings, as well as the platelet count, may fluctuate from time to time.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA Congenital amegakaryocytic thrombocytopenia is a rare autosomal-recessive disorder characterized by thrombocytopenia at birth and progressive bone marrow aplasia with pancytopenia ([8], [9], [10], [11] and [12]). These patients all have markedly elevated serum levels of thrombopoietin and mutations in the c- *mpl* gene. Multiple mutations have recently been reported, including deletions, nonsense mutations, and missense mutations. Many of the patients studied are compound heterozygotes with one mutation inherited from each parent. Stem cell transplant is the only curative treatment for these patients, and matched sibling transplants have been successful. Investigators postulate that thrombopoietin and c- *mpl* must play an important role in the growth and maintenance of multipotent stem cells because these patients all develop progressive bone marrow aplasia.

THROMBOCYTOPENIA WITH ABSENT RADIUS Thrombocytopenia with absent radius syndrome is a group of disorders with neonatal thrombocytopenia, marked hypoplasia of megakaryocytes, skeletal abnormalities, and other soft tissue congenital defects ([5], [13], [14], [15], [16] and [17]). Associated skeletal abnormalities are present in virtually every patient, most commonly bilateral agenesis of the radius ([13]). In some infants, the ulna and humerus are also absent, but fingers and thumbs are always present. Less commonly, patients manifest cardiac defects (atrial septal defects and tetralogy of Fallot), microcephaly, micrognathia, and various other minor

anomalies ([18] , [19]). These patients have elevated serum thrombopoietin and normal c- *mpl* and *HOX* genes. However, they have a profound defect in megakaryocyte differentiation and platelet production and no response of megakaryocytes to thrombopoietin ([20] , [21] and [22]). There may be a slight increase in platelet count in response to recombinant human erythropoietin ([23]). Diagnosis is rarely difficult and may be made prenatally by radiography, ultrasonography, and fetal platelet counts ([24] , [25] , [26] , [27] and [28]). Congenital rubella and some variants of Fanconi syndrome should be excluded. Platelet counts gradually increase during the first 2 years of life. With few exceptions, corticosteroid administration, intravenous immunoglobulin, and splenectomy have proved therapeutically useless.

THROMBOCYTOPENIA WITH RADIO-ULNAR SYNOSTOSIS Thrombocytopenia with radio-ulnar synostosis is a newly described congenital thrombocytopenic disorder that is characterized by amegakaryocytic hypoplasia and extremely limited pronation and supination of the forearm ([29] , [30]). Two unrelated, nonconsanguinous families were studied and found to have mutations in the *HOXA11* gene.

Autosomal-Dominant Macrothrombocytopenia

A number of families have been described who have autosomal-dominant inheritance of an isolated mild thrombocytopenia characterized by normal platelet survival and a normal number of bone marrow megakaryocytes; a constellation of findings that suggests ineffective thrombopoiesis ([31] , [32] and [33]). Thrombocytopenia (platelet counts between 20,000 and 100,000/µl) or a history of increased bruisability is apparent early in life, and examination of the peripheral blood smear demonstrates platelet macrocytosis (mean platelet volume above 10 µm ^{3}). Splenic size is always normal. Platelet aggregation abnormalities have been described in some families, but platelet membrane glycoproteins have been normal when studied ([32]).

MUTATIONS IN *MYH9* GENE FOR NONMUSCLE MYOSIN HEAVY CHAIN A group of autosomal-dominant macrothrombocytopenias due to mutations in the *MYH9* gene with variable penetrance and expression was recently defined ([34] , [35] , [36] , [37] , [38] , [39] , [40] , [41] , [42] and [43]). These include May-Hegglin anomaly, Sebastian syndrome and its variants, Epstein syndrome, and Fechtner syndrome. Although all of these disorders have congenital macrothrombocytopenia, there are differences in the presence of Döhle-like inclusions in granulocytes, hereditary deafness, and hereditary nephritis (Table 55.2). The genetic defects in these disorders all affect the *MYH9* gene located at chromosome 22q12.3-13.1, and more than ten mutations have already been defined. The function of the *MYH9* gene and how these mutations cause the thrombocytopenia are currently unknown.

TABLE 55.2. Syndromes Caused by *MYH9* Gene Defects

Syndrome	Macrothrombocytopenia	Döhle-Like Bodies	Nephritis	Deafness	Cataracts
May-Hegglin	Yes	Yes	No	No	No
Sebastian	Yes	Yes	No	No	No
Fechtner	Yes	Yes	Yes	Yes	Yes
Epstein	Yes	No	Yes	Yes	No

May-Hegglin anomaly and Sebastian syndrome both have macrocytopenia and granulocyte inclusions, but ultrastructural analysis of the Döhle-like inclusions demonstrates diagnostic differences between these two syndromes and that both types of inclusions can also be distinguished from the Döhle bodies seen in acute infection. Fechtner syndrome and Epstein syndrome both are Alport-like disorders but can be distinguished based on the presence or absence of granulocyte inclusions ([44] , [45] , [46] , [47] , [48] and [49]). These two disorders are due to allelic mutations at amino acid 702, which cause conformational changes to the myosin head. The R702H mutation in Epstein syndrome does not result in protein aggregation, and these patients lack granulocyte inclusions. There is a recent report of a family with congenital dysmegakaryopoietic thrombocytopenia (Paris-Trousseau) in which there are giant platelet a-granules and a chromosome 11 deletion at 11q23 ([50]). This deletion was previously described in children with mental retardation and other structural anomalies; only 47% have been thrombocytopenic. Platelet-type von Willebrand disease is another autosomal-dominant type of hereditary thrombocytopenia characterized by abnormal binding of large von Willebrand factor multimers to platelets. This intrinsic platelet defect results in mild thrombocytopenia, increased ristocetin-induced platelet aggregation, and a selective loss of high-molecular-weight von Willebrand factor multimers from the plasma. This disorder most resembles type IIb von Willebrand disease (see Chapter 59).

X-Linked Congenital Macrothrombocytopenia

Wiskott-Aldrich syndrome and X-linked thrombocytopenia are allelic mutations of the WASp gene at Xp11.22-p11.23 ([51] , [52] , [53] , [54] , [55] , [56] and [57]). All of the patients present with thrombocytopenia and small platelets with mean platelet volume approximately half normal. At one end of the clinical spectrum, patients exhibit platelet abnormalities only and, at the other end, manifest thrombocytopenia, eczema, and immune abnormalities with progressive T-cell lymphopenia and increased susceptibility to infection. Multiple mutations in the WASp gene have been identified in these patients, and the milder phenotypes are more commonly associated with mutations in exon 2 ([52]). However, even within families, the same genotype can be associated with varying phenotypes. Measurement of the WASp protein is now possible, making diagnosis less difficult ([53]).

The WASp protein is expressed in the cytoplasm of hematopoietic cells and plays a role in the regulation and organization of actin. However, cytoskeletal abnormalities are not apparent in these platelets, and it is now believed that the WASp protein delays apoptosis ([54]). Severe protein deficiencies are found in Wiskott-Aldrich patients, and abnormal regulation of the apop-totic response may explain the progressive lymphopenia and severe immune abnormalities in these children.

Megakaryocyte mass is normal or increased. Differentiation and platelet production are normal, and platelets produced *in vitro* are normal in size. These observations suggest that increased destruction in the spleen is responsible for both the thrombocytopenia and decreased platelet size. Splenectomy definitely improves platelet counts in these patients, which frequently returns to normal ([52]).

X-Linked Macrothrombocytopenia with Dyserythropoiesis

GATA1 transcriptional activator, which is necessary for megakaryocyte differentiation, is mutated in families with macrothrombocytopenia and dyserythropoiesis with or without anemia ([58] , [59] , [60] and [61]). Each of the missense mutations occurs in the *N*-terminal zinc finger, and different amino acid substitutions at the same site result in different severities of disease. Mutations that interfere most with the association of *GATA1* with FOG1 (friend of *GATA1*) result in the most severe macrothrombocytopenia and anemia. The human gene encoding *GATA1* is located at Xp11.23, but platelet size, the severity of bleeding, and the lack of immune abnormalities distinguish *GATA1* disorders from Wiskott-Aldrich syndrome.

ACQUIRED THROMBOCYTOPENIA

Deficient Platelet Production

Deficient platelet production may result from three mechanisms: hypoplasia or suppression of the precursor megakaryocytes; ineffective thrombopoiesis despite a normal precursor mass; or, rarely, deficiency or aberration of thrombopoietic control mechanisms.

ACQUIRED PURE AMEGAKARYOCYTIC THROMBOCYTOPENIC PURPURA Acquired pure amegakaryocytic thrombocytopenic purpura is a rare cause of thrombocytopenia associated with decreased or absent megakaryocytes in an otherwise normal bone marrow. A wide variety of exogenous factors and endogenous processes may lead to hypoplasia of the megakaryocytes and deficient platelet production, including viral infections, toxin exposure, drug ingestion, cytokine deficiencies, antibody-mediated suppression of megakaryocytopoiesis, and cellular suppression of megakaryocytopoiesis ([62] , [63] , [64] and [65]). It may also be an early manifestation of an intrinsic stem cell abnormality, as some patients have subsequently developed aplastic anemia or leukemia. In uncomplicated marrow hypoplasia, platelet survival usually is normal. The differential diagnosis of patients with severe thrombocytopenia and isolated amegakaryocytosis includes a misdiagnosis of immune thrombocytopenic purpura; ethanol use or drug ingestion; immune suppression associated with diseases such as systemic lupus erythematosus; and prodromal manifestations of acquired aplastic anemia, myelodysplastic disorders, or acute leukemia ([65] , [66]). Thrombocytopenia and amegakaryocytosis caused by postchemotherapy or postradiation therapy myelosuppression should be apparent. Patients with acquired amegakaryocytic thrombocytopenia do not have a palpable spleen. The platelets are usually small or normal in size. An increased mean cell volume is a common red cell finding, and associated immune abnormalities, such as

a positive Coombs test, may suggest a previously undiagnosed underlying autoimmune disorder, although positive antinuclear antibody tests are not uncommon ([65], [67], [68]). Chromosome studies are usually normal, but a duplication of the long arm of chromosome 3 and a Philadelphia chromosome, without any features of chronic myelocytic leukemia, have been reported ([68], [69] and [70]). In most patients, an etiology cannot be determined, and empirical therapy is necessary. Platelet transfusions should be used to treat bleeding and may be required prophylactically in some patients. Although there are occasional spontaneous remissions, most sustained remissions have occurred in patients receiving immunosuppressive therapy ([71]). Patients may respond to treatment with corticosteroids, cyclophosphamide, vinca alkaloids, cyclosporin A, and antithymocyte globulin ([71], [72], [73], [74] and [75]). Two patients treated with antithymocyte globulin and cyclosporin A demonstrated rapid improvement and a sustained remission after discontinuing therapy ([76]).

CHEMICAL AND PHYSICAL AGENTS THAT PRODUCE GENERALIZED BONE MARROW SUPPRESSION Chemical and physical agents, such as ionizing radiation, alkylating agents, antimetabolites, and cytotoxic drugs, may produce thrombocytopenia as the result of a predictable suppression of the marrow. The mechanisms by which these agents act are well defined, and thrombocytopenia is a common complication when they are used in immunosuppression and cancer chemotherapy. In addition, many drugs, such as chloramphenicol, produce marrow hypoplasia as a result of idiosyncratic reactions. The pathophysiology in these cases is poorly understood. Drugs producing thrombocytopenia by both mechanisms damage other bone marrow precursors as well as megakaryocytes, and the usual picture is one of diffuse bone marrow hypoplasia and pancytopenia. Rarely, only thrombocytopenia may be present. Platelets often are the last cell type to return to normal after recovery from bone marrow hypoplasia; in some patients, thrombocytopenia may persist indefinitely.

DRUGS THAT SELECTIVELY SUPPRESS THE MEGAKARYOCYTE

Chlorothiazides Chlorothiazides and various congeners may produce thrombocytopenia by one of at least two mechanisms: by the formation of platelet antibodies or by a poorly understood suppression of thrombopoiesis ([77]). The latter action is by far the most common. Evidence of marrow suppression is largely indirect ([78]). Serologic tests for platelet antibodies usually yield negative results. Diminution in the number of megakaryocytes has been observed in infants born of mothers who were taking these drugs, but few instances of megakaryocytic hypoplasia have been documented in adults. Mild asymptomatic thrombocytopenia may occur in as many as 25% of patients taking these agents, an observation that implies that thrombocytopenia may be a pharmacologic rather than an idiosyncratic effect. Recovery from thrombocytopenia associated with the use of thiazide drugs is slow, and thrombocytopenia usually can be reproduced only by readministration of the drug for a protracted period.

Estrogens Estrogenic hormones appear to affect platelet kinetics in animals both by facilitating reticuloendothelial phagocytosis and by impairing thrombopoiesis. Neither effect has been convincingly demonstrated in humans, but several instances of “amegakaryocytic” thrombocytopenia have been reported after the administration of diethylstilbestrol. In one patient, thrombocytopenia recurred when the hormone was readministered ([79]).

Ethanol Ethanol can suppress platelet production, a phenomenon that may be a common cause of mild thrombocytopenia in the alcoholic patient ([80]). In most reported cases, nutritional factors, folate deficiency, and splenomegaly were excluded, but patients did have evidence of impaired hepatic function ([81], [82], [83] and [84]). Platelet counts below 100,000/μl occur in as many as 26% of acutely ill alcoholics ([80], [84]), and platelet counts as low as 10,000/μl have been described ([82]). The experimental administration of ethanol produces thrombocytopenia with decreased platelet survival and platelet turnover ([85], [86]). Large doses are required, and the duration of ethanol administration before the onset of thrombocytopenia ranges from hours to weeks, observations suggestive of a component of individual idiosyncrasy. Bleeding is rare, and when ethanol is withdrawn, the platelet count begins to increase in 2 to 3 days and returns to normal or supranormal levels in 2 to 3 weeks ([82], [84]). Several patients developed venous thromboembolic disease when platelet counts reached values above 500,000/μl ([87]). Pathophysiologic studies in alcohol-induced thrombocytopenia reveal accelerated platelet destruction and a subnormal compensatory increase in thrombopoiesis ([85], [88], [89]). Platelet function abnormalities have also been described ([80], [90], [91]). The bone marrow usually reveals normal numbers of megakaryocytes, although in one patient, megakaryocytes could be recognized only by immunologic techniques ([92]). Pronormoblasts and promyelocytes may demonstrate vacuolization ([81]). Studies using mice and guinea pig megakaryocytes demonstrate that the effect of ethanol is primarily on the maturing megakaryocyte, a finding consistent with ineffective thrombopoiesis ([93]). Several cases of bone marrow hypoplasia secondary to consumption of excessive alcohol have also been described ([94], [95]). Colony-forming unit granulocyte-macrophage–derived colony formation in one of these patients was inhibited by much lower concentrations of ethanol than that of normal volunteers ([94]).

INEFFECTIVE THROMBOPOIESIS Ineffective thrombopoiesis may play a role in several different types of thrombocytopenia. Thrombocytopenia is a consistent feature of megaloblastic hematopoiesis that results from deficiency of vitamin B_{12} or folic acid. Although seldom severe and rarely of clinical significance, this form of thrombocytopenia results from a distinctive abnormality of platelet production called *ineffective thrombopoiesis*. This abnormality was first demonstrated in thrombokinetic studies and is characterized by diminished platelet production despite the presence of an increased megakaryocyte mass. Thus, it is analogous to ineffective erythropoiesis, which is also characteristic of the megaloblastic anemias. Platelet production, whether calculated per megakaryocyte or per nuclear unit, is diminished. Although the number of megakaryocytes increases in response to thrombopoietic stimuli, the normal concomitant increase in their volume does not occur. This phenomenon presumably results from impaired DNA synthesis and the consequent limitation in nuclear endoreduplication. In stained smears, the megakaryocytes often appear hyperlobulated, and circulating platelets are abnormally large ([96]). Moderate shortening of platelet survival and, rarely, hypoplasia of the megakaryocytes may be important contributory factors in the production of thrombocytopenia in some cases.

Thrombocytopenia Caused by Abnormal Platelet Pooling

DISORDERS OF THE SPLEEN The splenic pool normally contains approximately one-third of the total platelet mass, and this pool may increase in size as a result of disorders that are associated with splenomegaly, such as cirrhosis with portal hypertension, sarcoidosis and other granulomatous infections, Gaucher and other lipid storage diseases, leukemias and lymphomas, and Felty's syndrome ([97], [98] and [99]). This shift of platelets into the spleen may result in thrombocytopenia in the circulating blood despite a normal or even increased total platelet mass. The clinical picture in hypersplenic thrombocytopenia is usually dominated by the underlying disease, and numerous other hematologic abnormalities, such as neutropenia, anemia, and coagulation defects, may also be present. The pathophysiology of thrombocytopenia in disorders associated with splenomegaly is not completely understood. Rat spleens demonstrate large numbers of platelets adherent to reticuloendothelial cells ([100]). It is also hypothesized that the increase in splenic pool may occur because of very slow passage of platelets through the tortuous splenic vasculature. The platelets in the splenic pool are in equilibrium with the circulating pool and can be mobilized with an infusion of epinephrine or during plateletpheresis ([101], [102] and [103]). This is in contrast to the irreversible thrombocytopenia caused by splenic removal of damaged or antibody-coated platelets in disorders such as autoimmune thrombocytopenic purpura. There is some evidence for accelerated platelet destruction in many instances of thrombocytopenia associated with disorders of the spleen ([104], [105]). Survival of isotopically labeled platelets is shortened in some patients with cirrhosis and portal hypertension, even though the major mechanism of thrombocytopenia in these patients appears to be splenic pooling. The usual laboratory findings are pancytopenia with mild thrombocytopenia and a normal or moderately increased number of megakaryocytes in the bone marrow. Platelet counts in cirrhotic patients have been as low as 20,000/μl, although thrombocytopenia of this severity is uncommon. Patients with hypersplenism have smaller platelets than those with autoimmune thrombocytopenia, so platelet sizing may provide a means of differentiating between thrombocytopenia primarily related to immunologic platelet destruction and that related to big-spleen syndromes. In general, the severity of the thrombocytopenia correlates poorly with the size of the spleen, but it is nonetheless difficult to entertain a diagnosis of thrombocytopenia caused by abnormal splenic platelet pooling in the absence of significant splenic enlargement ([106]). Therapy is seldom indicated for thrombocytopenia alone, but splenectomy, embolic occlusion of the splenic vasculature, and splenic damage secondary to infusion of radiolabeled particles can improve the thrombocytopenia and sometimes alleviate the pancytopenia completely ([104], [107], [108], [109], [110], [111] and [112]). Patients with thrombocytopenia secondary to cirrhosis with portal hypertension may benefit from portocaval shunts or transjugular intrahepatic portosystemic shunts ([113], [114]).

HYPOTHERMIA Platelets become more sticky, swell, and undergo various morphologic changes when stored *in vitro* at temperatures below 37°C. This process usually is reversible, but clumping, release of adenosine diphosphate, and irreversible aggregation follow protracted chilling ([115]). Similar changes *in vivo* may lead to sequestration of platelets in the spleen and liver and may underlie the thrombocytopenia that is associated with hypothermic anesthesia ([116], [117]). In humans, mild reversible thrombocytopenia is a predictable consequence of surgical hypothermia below 25°C and is usually of no clinical consequence ([117]). In some patients, thrombocytopenia persists after rewarming and may produce hemorrhage. In children subjected to deep hypothermia, brain damage was attributed to *in vivo* platelet clumping ([118]). Thrombocytopenia has also been noted after hypothermia caused by environmental exposure, and in three patients with episodic hypothermia, thrombocytopenia was associated with erythroid hypoplasia and sideroblastic anemia ([119], [120]). Finally, thrombocytopenia occurs in almost all patients undergoing one- or two-cycle cryotherapy for hepatic metastases from colorectal adenocarcinoma ([121], [122]). There is a significant correlation between serum alanine aminotransferase concentrations and the percentage reduction in platelet count. The maximal reduction occurs the first or second day after surgery in most patients. It is interesting that two patients who had previously been splenectomized did not develop thrombocytopenia, suggesting that splenic sequestration of damaged platelets may occur.

Thrombocytopenia Associated with Infections

Purpura was recognized as a manifestation of pestilential fevers 2000 years ago. Several factors are now known to cause bleeding in association with infections, of which thrombocytopenia is the most common.

VIRUSES Viruses may produce thrombocytopenia by several different mechanisms: impaired platelet production as a result of invasion of megakaryocytes by the

virus, impaired platelet production caused by toxic effects of viral proteins on progenitor cells, viral-induced hemophagocytosis, destruction of circulating platelets by the virus, and increased platelet destruction caused by binding of viral-induced autoantibodies or viral antigen–antibody complexes. The administration of live measles vaccine produced significant yet subclinical thrombocytopenia in most normal children ([123]). Degenerating, vacuolated megakaryocytes were evident 3 days after administration of the vaccine, at which time plasma levels of acid phosphatase were subnormal. The nadir of the platelet count occurred 7 days after vaccination. There are now several reports of thrombocytopenia occurring after immunization with measles–mumps–rubella vaccine, monovalent measles vaccine, and measles–mumps vaccine ([124] , [125]). Thrombocytopenia has been severe (below 20,000/µl), and some patients have had significant hemorrhagic complications. The majority of the patients have been younger than 2 years of age, but the age range was 1 to 40 years ([125]). There is no proof of a causal relationship between the thrombocytopenia and the vaccination, and there are no data regarding the pathophysiology. Thrombocytopenia after vaccination for hepatitis A and B and varicella has also been noted ([126] , [127] , [128] and [129]). Children with neonatal infections with mumps and rubella are often thrombocytopenic ([130] , [131] and [132]), and hepatomegaly and splenomegaly may also be present. The pathophysiology of the thrombocytopenia remains speculative. Cytomegalovirus infection is usually asymptomatic in immunocompetent adults. However, there are reports of severe thrombocytopenia and even thrombocytopenia with hemolysis ([133] , [134]). It is unclear whether the thrombocytopenia is caused by a direct cytopathologic effect of the virus on megakaryocytes, viral-induced hemophagocytosis, or immunologic destruction. Parvovirus B19 is the etiologic agent responsible for erythema infectiosum. It is also cytotoxic to erythroid progenitors and can cause aplastic crises in patients with hemolytic anemia and chronic bone marrow failure in immunocompromised hosts. Thrombocytopenia may occur in some of these patients, and recent studies demonstrate cytotoxic effects of viral nonstructural-1 proteins on megakaryocytes ([135] , [136] and [137]).

BACTERIA AND PROTOZOANS Thrombocytopenia commonly is associated with septicemia resulting from both gram-negative and gram-positive bacteria. This complication is particularly common in infants and children, and the presence of unexplained thrombocytopenia, particularly in this age group, should always alert the physician to the possibility of septicemia. The etiology of thrombocytopenia may be multifactorial. Thrombocytopenia may be caused by disseminated intravascular coagulation (DIC), and the diagnosis of DIC may be apparent when coagulation studies are performed. Thrombocytopenia has also been described in patients with gram-negative or gram-positive septicemia, and 46% of these patients had elevated platelet-associated immunoglobulin G without evidence of DIC. These studies were interpreted as demonstrating the presence of platelet destruction caused by splenic destruction of immune complex–coated platelets. These data must be reinterpreted with third-generation immune complex capture assays that can better define platelet autoantibodies and immune complexes. Platelet adherence to damaged vascular surfaces may also account for thrombocytopenia in certain bacterial infections, such as meningococcemia. Endotoxins, exotoxins, or platelet-activating factor may damage platelets, resulting in increased clearance. Patients with sepsis syndrome may develop hemophagocytic histiocytosis with phagocytosis of platelets, white cells, and platelets in bone marrow histiocytes ([138]). Thrombocytopenia may also be caused by direct platelet toxicity caused by the microorganism. Thrombocytopenia occurs in over 80% of patients with malaria, and human platelets have been demonstrated to contain plasmodia ([139]). Early experimental evidence demonstrated that patients with malaria had elevated platelet-associated immunoglobulin G, suggesting immune-mediated destruction. However, in 1993, it was demonstrated that there were significant ultrastructural changes in platelets of patients with malaria, and the extent of abnormal findings correlated with the level of parasitemia ([140]). Theoretically, any bacterial or protozoal infection can be associated with thrombocytopenia that is caused by one of the mechanisms hypothesized in this chapter. There are recent reports of thrombocytopenia in Lyme disease and *Mycoplasma pneumoniae*, a manifestation of these infections that appears to be uncommon ([141] , [142]). Patients with thrombocytopenia associated with infection should be tested for the presence of DIC. At this time, no other clinically available tests can be used to define the precise etiology in patients without evidence of DIC. The most important therapy for infection-related thrombocytopenia is that directed at the underlying infection. Platelet transfusions, even when they do not result in an increased platelet count, can be used to control bleeding until the antimicrobial therapy takes effect.

Thrombocytopenia after Massive Blood Transfusions

Massive blood transfusion is defined as complete replacement of a patient's blood volume within 24 hours, usually ten units of packed red blood cells in an average-sized adult. Current practices in the United States favor the use of crystalloid over colloids with packed cell transfusions for replacement of blood volume. Because packed red blood cells do not contain a significant number of functional platelets and do not replace labile clotting factors, there has been concern about the incidence of developing hemostatic abnormalities and clinical bleeding in patients given only packed red blood cells.

Some studies demonstrate a correlation between the number of units of packed red blood cells transfused and both reduction in platelet counts (“dilutional thrombocytopenia”) and increases in prothrombin and partial thromboplastin times. However, significant changes (platelets, 50,000 to 100,000/µl) are not apparent until patients have received more than 15 units of blood ([143] , [144]). *Severe thrombocytopenia*, defined as a platelet count below 50,000/µl, is most common in patients receiving more than 20 units of blood ([143] , [144]). Microvascular bleeding occurs in 20 to 60% of patients who are massively transfused, but neither the platelet count nor changes in coagulation studies can be used to predict which patients will bleed ([145]). Although bleeding appears to be more dependent on thrombocytopenia than on coagulation abnormalities, prophylactic administration of platelets was not any more effective than equivalent volumes of prophylactic fresh frozen plasma infusions in preventing this bleeding ([146]). Therefore, it is currently recommended that platelet and plasma replacement during massive transfusions be guided by serial monitoring of platelet counts, prothrombin time, and partial thromboplastin time, and that platelet counts be kept above 75,000/µl and prothrombin time and partial thromboplastin time below 1.5 times normal ([144]). The coagulopathy associated with massive blood transfusion is discussed further in Chapter 60.

Bleeding Disorders Caused by Vascular Abnormalities

Purpura is the term used to describe the skin lesions that develop when red blood cells extravasate from capillaries. *Purpura* refers to pinpoint lesions called *petechiae* or more widespread lesions known as *ecchymoses*. Purpura can be differentiated from other erythematous lesions by the use of diascopy, which is the application of a glass slide to the border of the lesions. True purpura does not blanch with pressure ([1]).

This chapter discusses causes of bleeding that are not the result of thrombocytopenia, coagulation factor deficiency, or qualitative platelet defects.

MECHANICAL PURPURA

External pressure such as blunt trauma results in ecchymoses when the force is sufficient to disrupt vascular integrity and allow extravasation of red blood cells. The size of the resulting lesion is dependent on the durability of the tissue traumatized, the vascularity of the region, the density of the surrounding tissue, and the time elapsed ([2] , [3]). The extent of bruising can increase over time, and tracking through tissue planes can occur, resulting in bruises in areas remote from the area of trauma ([4]). The color of the lesion is in part dependent on the location of the red cells—lesions near the surface have a more reddish color, and deeper lesions appear bluish. This finding is due to optical scattering in the dermis, and the fact that blue wavelengths scatter and reflect more than red ([5]). Bruises change color with time, but recent evidence suggests more variability in this than previously recognized ([4]).

Mechanical purpura can be seen on occasion with minor trauma such as blood pressure cuff monitoring in anticoagulated patients ([3]) or even vigorous scratching. Young adults playing active sports such as basketball can develop calcaneal petechiae resulting from relatively minor, but repetitive, heel trauma ([6]). Periorbital, face, or neck purpura can occur after a sudden increase in intravascular pressure with a Valsalva maneuver ([7]) and has been described after bungee-jumping ([8]). This may also be the mechanism of purpura in other forms of exercise-induced, nontraumatic purpura recently described ([9] , [10] and [11]).

Suction purpura occurs when negative pressure is applied to the skin in sufficient force to result in extravasation of erythrocytes. Young healthy people develop petechiae with 350 to 400 mm Hg negative pressure, but the required amount of pressure to induce purpura decreases with age to as low as 100 mm Hg ([12]). The application of rubber suction devices to the forehead can result in circumscribed purpura. This seems to occur mostly when new parents apply children's suction toys to their foreheads and has been termed *Cyclops purpura* ([13]). A similar, relatively common cause of suction purpura is seen in adolescents who place a drinking glass over their chin and suck out the air to form a vacuum, ultimately causing chin or perioral purpura ([14]). Adolescents are also prone to develop small purpuric lesions in the neck region from “hickeys” or “love bites,” another form of suction purpura.

Larger ecchymotic areas also may demonstrate certain patterns that can be a clue to underlying pathology. The well-known Cullen sign refers to bluish discoloration around the umbilicus, and Grey Turner sign is flank ecchymosis. Both may indicate hemorrhagic pancreatitis or a rectus sheath hematoma ([15]). Scrotal ecchymosis may be a clue to intraperitoneal hemorrhage, and perianal ecchymosis has been described as a manifestation of aneurysmal rupture into the sigmoid mesocolon ([16] , [17]). “Raccoon eyes” and mastoid ecchymosis (Battle sign) may indicate a basilar skull fracture after head trauma ([18]).

STRUCTURAL MALFORMATIONS OF VESSELS

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) was first described in 1864 by Sutton ([19]) and later recognized and reported by Rendu ([20]), Osler ([21]), and Weber ([22]

), and it is thus also known as *Osler-Weber-Rendu syndrome*. It is an autosomal-dominant disorder characterized by multiple telangiectatic lesions involving the skin and mucous membranes associated with epistaxis and other bleeding complications. HHT has an estimated prevalence of 1 in 50,000 but may be as high as 1 in 16,500 ([23]), with complete penetrance by 40 years of age ([24]). Some geographic locations have even a higher prevalence ([25]).

Recent genetic studies have begun to identify the genetic defects responsible for the vascular malformations. In 1994, linkage analysis established the loci for HHT in some families to markers on chromosome 9q33-34 ([26] , [27]). The gene was later identified as the endoglin gene ([28]). *Endoglin* is an integral membrane glycoprotein expressed on endothelial cells in arterioles, venules, and capillaries. This glycoprotein serves as a binding protein for transforming growth factor-ß. Some families show linkage to another locus on chromosome 12q ([29]). This gene has now been identified as ALK1, another receptor for transforming growth factor-ß ([30]). Transforming growth factor-ß regulates many transcriptional targets and plays a crucial role in vascular development and homeostasis. The molecular defects in HHT have been recently reviewed ([31] , [32]).

The mechanisms by which these genetic defects result in telangiectatic lesions have not been identified. Ultrastructural analysis of cutaneous HHT lesions suggests that postcapillary venule dilation is the earliest identifiable morphologic abnormality ([25] , [33]). As the venules enlarge, they become convoluted and interconnect with arterioles through capillary segments. The capillary segments eventually disappear, and direct arteriolar-venular communications are established (Fig. 56.1). An infiltrate of mononuclear cells appears in the perivascular region of the HHT lesions.

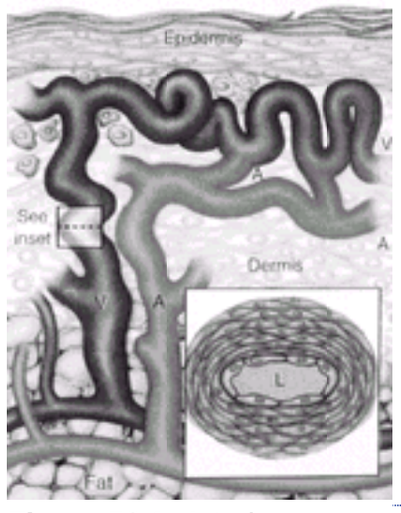

Figure 56.1. Arteriovenous malformations in hereditary hemorrhagic telangiectasia. In a fully developed cutaneous telangiectasia, the venule (*V*) and its branches have become dilated and convoluted throughout the dermis. The connecting arterioles (*A*) have also become dilated and communicate directly with the venules without intervening capillaries. A perivascular infiltrate is present. The thickened wall of a dilated postcapillary venule is also shown. L, lumen of the vessel. See Color Plate. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. N Engl J Med 1995;333:918–924, with permission.)

The bleeding manifestations are thought to occur because of an inherent mechanical fragility of these vessels. However, some investigators have reported various abnormalities of the hemostatic system as possible contributing factors in some patients. The significance of these reports is not clear, but common abnormalities in the hemostatic system do not seem to represent a major factor in the underlying bleeding tendency.

CLINICAL MANIFESTATIONS The cutaneous lesions usually appear in affected persons by 40 years of age, and they increase in number with age. The lesions measure 1 to 3 mm in diameter and are sharply demarcated in appearance (Fig. 56.2). They blanch with pressure, but the blanching may be incomplete as a result of "strangulation" of coiled loops of vessels ([34] , [35]). The telangiectatic lesions are most commonly found on the face, lips, nares, tongue, nailbeds, and hands. Some patients have only a few lesions necessitating a thorough search in anyone suspected of having HHT. Bleeding from these cutaneous telangiectasias is uncommon and rarely of clinical importance.

Figure 56.2. Telangiectasias of the tongue and lower lip in a patient with hereditary hemorrhagic telangiectasia. See Color Plate. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. N Engl J Med 1995;333:918–924, with permission.)

Epistaxis is the presenting complaint in up to 90% of patients with HHT. This symptom results from bleeding telangiectatic lesions over the inferior turbinates and nasal septum. Symptoms usually occur before 35 years of age and are highly variable. Approximately one-third of patients have mild symptoms requiring no treatment, and another third has moderate symptoms requiring only outpatient treatment. The remaining third has severe symptoms often requiring inpatient treatment, transfusions or chronic iron replacement therapy, and surgery ([35]). The nosebleeds may become more difficult to control as the patient ages. Pulmonary arteriovenous malformations (PAVMs) occur in 5 to 30% of patients with HHT, and 85 to 90% of people with PAVM are found to have HHT ([25] , [34] , [35] , [36] and [37]). Recent genetic linkage studies have found that patients with 9q-linked mutations have significantly higher rates of PAVMs than HHT patients with other mutations ([38] , [39] and [40]). The PAVMs are primarily located in the lower lung lobes and are multiple. These PAVMs may result in a significant right-to-left shunt, and patients may develop significant dyspnea, cyanosis, clubbing, fatigue, decreased exercise tolerance, migraine headaches, and polycythemia. Paradoxic emboli can occur and result in brain abscesses, transient ischemic attacks, and strokes. The prevalence of cortical infarcts has been reported to be as high as 14% in patients with a single PAVM and increases to 27% in patients with multiple PAVMs ([41]). These lesions may also bleed and result in hemoptysis or hemothorax. The detection of PAVMs may be difficult in patients with few or no symptoms. Physical examination may uncover an end-inspiratory bruit ([34]). A chest x-ray may detect a coin lesion but often misses smaller lesions. Gravitational shifts in blood flow to the lung bases result in increased right-to-left shunting in the sitting or standing position. Physiologic tests such as measuring O_2 saturation in the supine and standing position (on room air and 100% O_2) can detect the positional change in shunting and can be used to screen patients for PAVMs. However, the best screening test for PAVM appears to be contrast echocardiography ([42] , [43]). Patients with a positive screening test should undergo an unenhanced spiral computed tomography to confirm and further characterize the PAVM ([44] , [45]). Pulmonary angiography is a less-sensitive study but is necessary in treatment planning. Approximately 20% of patients with HHT develop significant upper and lower gastrointestinal (GI) tract hemorrhage. Bleeding is rare before the fifth decade of life. Approximately 40% of the bleeding episodes occur from upper GI tract lesions, whereas only 10% occur in the colon, and a full one-half are indeterminate after evaluation ([35]). Unlike epistaxis, spontaneous regression of GI bleeding is rare, and steady progression or chronic intermittent bleeding is the norm. Symptomatic hepatic involvement by HHT is rare. Patients may have hepatomegaly, a hepatic bruit or thrill, or elevated liver function studies ([36] , [46]). Significant left-to-right arteriovenous shunting results in high-output heart failure ([46] , [47]), and the shunt can be detected by cardiac catheterization with oximetry. Anicteric cholestasis and atypical cirrhosis caused by HHT have been reported ([46] , [47]). Hepatic arteriovenous malformations (AVMs) can be detected by dynamic computed tomography ([46]), color Doppler ultrasound ([48]), or celiac angiography. The neurologic manifestations of HHT result from PAVM in up to two-thirds of cases ([25]). The remainder of the neurologic symptoms are the result of cerebrovascular telangiectasias, AVMs, aneurysms, and cavernous hemangiomas ([36]). Ten to twenty percent of patients with HHT have cerebral AVM, but only 10% of people who have cerebral AVM are found to have HHT ([49]). The cerebral AVMs are often multiple ([49] , [50]). The annual risk of bleeding from cerebral AVM is low, reported as 0.41 to 0.72%/year (compared to 2 to 4% risk for sporadic, non-HHT AVM) ([49] , [51]). Magnetic resonance imaging is probably the best test for detecting these lesions, but the role of screening asymptomatic patients is controversial ([51] , [52]).

TREATMENT Recurrent epistaxis can be a perplexing problem, and few trials exist that compare various treatment modalities. Prophylactic measures include humidification and saline nose drops. Nasal trauma from vigorous nose blowing, straining, and finger manipulation should be avoided. Antihistamines should also be avoided to prevent drying of the nasal mucosa. Mild bleeding can be treated with absorptive packing and direct pressure. Cautery is commonly used to stop persistent bleeding, but repeated cauterizations can result in necrosis and septal perforation and should be avoided ([53]). The neodymium:yttrium-aluminum-garnet (Nd:YAG)

laser system has been shown to be effective treatment for epistaxis. One center emphasizes the technique of using 1064-nm wavelengths for greater depth of penetration, moisturizing the mucosa first to prevent coagulation necrosis of the superficial mucosa, and using low-power wattage with short application times ([54]). Argon plasma coagulation also appears promising, and application of topical estrogens may improve the benefit ([55]). Arterial embolization or ligation is effective in some patients. Septal dermoplasty is a technique of removing diseased nasal mucosa and the subepithelial telangiectasias and replacing abnormal tissue with an enduring barrier. In refractory cases, rhinotomy with forehead flap reconstruction may be required ([53], [54], [56]). The use of estrogen and e-aminocaproic acid is discussed in the following section. PAVMs are treated with transcatheter embolotherapy ([57], [58]) to diminish the risk of paradoxic emboli and other complications. PAVMs with feeder artery diameters greater than 3 mm should be treated. This procedure is effective at decreasing the right-to-left shunt and improving oxygen saturation, and it has a low complication rate. In cases in which embolotherapy is technically difficult, surgical resection should be used. After embolotherapy or surgery, small AVMs may enlarge and become clinically significant. For this reason, patients should undergo screening helical computed tomography scans every 5 years ([25]). Because brain abscesses and septic emboli occur in 1 to 20% of patients with HHT and PAVM, these patients should receive prophylactic antibiotic therapy before dental or surgical procedures ([59]). Bleeding GI vascular malformations can be treated with endoscopic thermal devices including bipolar electrocautery and laser techniques. The mucosa coagulates and sloughs, leaving a small ulcer in the place of the vascular lesion ([60]). The ulcer reepithelializes over the next few days. These treatments are rarely effective for the long-term, however, because new lesions continue to develop and small intestinal lesions are not accessible. Estrogen and progesterone have been effective in decreasing the bleeding episodes. Cerebral AVMs have been treated with surgery, stereotactic radiosurgery, and embolotherapy. A follow-up angiogram should be repeated at 1 year, followed by periodic magnetic resonance imaging. Hepatic malformations have been treated with transcatheter embolization using a polyvinyl alcohol sponge, but the complication rate is significant ([61]). The mortality rate of this procedure in HHT has been calculated to be as high as 25 to 40% ([60], [62]). Other treatments that have been successfully used include hepatic artery ligation for localized vascular malformations ([63]) and liver transplant in patients with extensive lesions ([64]).

MEDICAL THERAPY Observations in the 1950s that epistaxis decreased during pregnancy and increased after menopause led to the use of estrogens as therapy for HHT. Estrogens in large doses result in metaplasia of the nasal mucosa, resulting in thick layers of squamous epithelium, and electron microscopy studies indicated that estrogen reestablished endothelial cell continuity ([65], [66]). A small randomized trial of 3 months' duration showed no benefit in reducing the number of bleeding episodes with estradiol valerate ([67]). However, another author reported 100% success in an uncontrolled series of 67 consecutively treated patients who continued with high-dose estrogen therapy ([65]). Several case reports and one small randomized controlled trial evaluated the use of low-dose estrogen-progesterone combination therapy in patients with severe GI bleeding. The bleeding episodes and transfusion requirements significantly diminished in treated patients ([68]). Aminocaproic acid has been useful in some patients with HHT and recurrent bleeding ([69]), but other patients have not responded ([70]). Recent reports suggest that oral or intranasal tranexamic acid may be helpful as well ([71]). Virtually all patients with HHT have iron-deficiency anemia. The treatment of iron-deficiency anemia in this setting usually requires more than oral iron replacement. Patients with significant blood loss and anemia who do not respond or do not tolerate maximal doses of oral iron should be given intravenous iron therapy. Three products are available for parenteral iron therapy: iron dextran, iron gluconate, and iron sucrose. Patients who have toxicity with iron dextran should receive one of the other products. With the currently available options for iron replacement in anemic HHT patients, red cell transfusion should rarely be necessary. Genetic counseling should be part of the treatment, and referral to a designated HHT center should be considered in most cases. Six U.S. and Canadian HHT centers currently exist and are listed on the HHT Foundation International, Inc. Web site (www.hht.org).

Vascular Malformations

Vascular malformations result from localized errors of angiogenic development. The underlying molecular genetics of angiogenesis are complex and are the subject of recent reviews ([72], [73]) (see Chapter 22). Mutations in the angiogenic pathways can result in a variety of malformations including capillary or venous angiomas, cerebral cavernous malformations, and AVMs, either as isolated or multifocal lesions. Bleeding problems occur from rupture or leakage from these vascular anomalies, and the clinical sequelae depend on their location.

Skin lesions are the most common vascular malformation and include a variety of birthmarks. Central nervous system vascular lesions include AVMs, berry aneurysms, and cavernomas. Bleeding from these lesions in the lung may account for 30% of spontaneous intraparenchymal lobar bleeds ([74]). These lesions are usually detected by magnetic resonance imaging/magnetic resonance angiography, but some lesions are only detected by angiography ([75]). Hemoptysis can result from pulmonary vascular anomalies including AVM and a rare disease known as *pulmonary capillary hemangiomatosis*. Hematuria may rarely be due to genitourinary AVMs or hemangiomas.

GI bleeding may be due to vascular malformations such as the blue rubber nevus syndrome, gastric antral vascular ectasia, telangiectasias, and AVM. GI angiodysplastic lesions deserve special attention given their frequency. They appear to be due to degenerative dysplasia and are the most frequent cause of obscure GI bleeding. The cause is thought to be due to intermittent obstruction of the submucosal veins where they penetrate the muscular layers of the colon, ultimately leading to dilated, tortuous submucosal veins and venules ([76]). Small intestinal angiodysplastic lesions can be particularly hard to detect, but it is hoped that the new technique of wireless capsule endoscopy will facilitate this diagnosis ([77]). Endoscopic-based therapy or surgery may be required for treatment. This disorder is frequently associated with aortic stenosis, and there are reports of cessation of bleeding after aortic valve repair. Continuous estrogen-progestin treatment is not useful in the prevention of rebleeding from GI angiodysplasia ([78]).

Kasabach-Merritt Syndrome

Patients with this syndrome have structural vascular abnormalities resulting in large cavernous hemangiomas. A bleeding diathesis may occur as a result of localized disseminated intra-vascular coagulation, and patients may present with ecchy-moses. This syndrome is discussed in detail in Chapter 60.

Other Vasculopathies

AMYLOIDOSIS Patients with multiple myeloma or systemic amyloidosis may have light chain deposits in the cutaneous blood vessels. These vessels are particularly fragile, and purpura can occur as a result of minor trauma (“pinch purpura”). The eyelids and periorbital regions are particularly prone to developing purpura (Fig. 56.3), and a classic sign is postproctoscopic periorbital purpura occurring after proctoscopies (for diagnostic rectal biopsies done in the past) or after Valsalva maneuvers. Purpura also commonly develops in other flexural skin areas such as the nasolabial folds, neck, axillae, and umbilicus ([79]). Biopsies of the cutaneous vascular lesions demonstrate amyloid deposits in the dermis and subcutaneous tissues, and inflammatory cells are scarce. The diagnosis and treatment of these disorders are discussed in detail in Chapter 99.

Figure 56.3. Periorbital purpura in a 58-year-old woman with immunoglobulin A ? plasma cell dyscrasia associated with secondary amyloidosis. See Color Plate. This photograph was kindly provided by Drs. Theresa Scholz and Pamela Nemzer (Department of Dermatology, University of Utah Health Sciences Center).

MOYAMOYA DISEASE *Moyamoya disease* is a chronic cerebral vasculopathy initially described in Japan. The disease is characterized by occlusion of the terminal portion of the internal carotid arteries along with an abnormal vascular network in the regional area of occlusion. Cerebral infarcts are common in children, but adults have a higher propensity for intracranial hemorrhage. The risk of bleeding appears to be highest in adult Asians ([80]). The etiology is unknown, and diagnosis rests on characteristic angiographic findings.

CALCIPHYLAXIS *Calciphylaxis* is a small vessel vasculopathy noted in patients with renal failure. Histologically, the vessels demonstrate calcification of the tunica media with intimal proliferation. This vasculopathy results in tissue ischemia and necrosis; patients present with painful skin lesions that progress to ulcers. Risk factors for calciphylaxis include female sex, obesity, and diabetes. The mortality rate is high. Treatment includes tissue débridement, skin grafting, hyperbaric oxygen, and control of calcium and phosphorus levels ([81]).

BLEEDING DUE TO DISORDERS OF PERIVASCULAR TISSUE

Ehlers-Danlos Disease

The *Ehlers-Danlos syndromes* (EDSs) are a group of rare connective tissue disorders caused by abnormalities of collagen synthesis or processing. The prevalence is estimated to be between 1 in 10,000 to 20,000 births. A simplified classification system has identified six major types of EDSs and their genetic defects ([82], [83]). The clinical features include hyperextensible, fragile skin associated with joint hypermobility. The majority of patients with EDSs also report a history of excessive bruising and bleeding ([84], [85]). Other bleeding manifestations may include subcutaneous nodular hematomas, mucosal oozing after dental procedures, hemoptysis, and GI bleeding. In most patients, screening tests show no hemostatic abnormalities, and the bleeding is thought to result from abnormalities in the perivascular collagens leading to fragility of the subcutaneous vessels. However, several authors have noted abnormal bleeding times and platelet aggregation studies, as well as factor deficiencies in individual patients ([84], [86]).

Certain types of EDSs have an increased risk of major bleeding episodes. In particular, vascular EDS (type IV) has unique clinical features of interest to hematologists. This disorder is due to quantitative or qualitative defects in type 3 collagen, which is particularly abundant in the arterial wall ([82], [87]). Patients with this disorder are prone to develop arterial aneurysms and dissections as well as significant bleeding complications from spontaneous rupture of vessels ([87], [88] and [89]). Carotid-cavernous fistula is another well-documented complication, and clinical diagnosis is based on the findings of pulsatile exophthalmia, tinnitus, thrill, and headache. In addition to vascular abnormalities, patients with vascular EDS have characteristic facial features and thin, translucent skin with a conspicuous venous network. Papyrus scarring (Fig. 56.4) may be present, but patients usually have minimal joint hypermobility (often limited to the hands) or skin hyperextensibility. The diagnosis can be confirmed by biochemical or molecular assays of type 3 collagen.

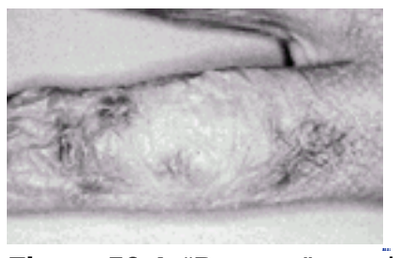

Figure 56.4. "Papyrus" scarring and thin skin with petechiae in a patient with Ehlers-Danlos syndrome. (From Anstey A, Mayne K, Winter M, et al. Platelet and coagulation studies in Ehlers-Danlos syndrome. Br J Dermatol 1991;125:155–163, with permission.)

Patients with EDS, particularly vascular EDS, should generally avoid contact sports and isometric exercise and are advised to avoid medications with antiplatelet properties ([87]). Arterial rupture should be considered in the differential diagnosis when these patients present with new-onset symptoms such as abdominal pain. Diagnostic procedures that involve arterial puncture are relatively contraindicated because of a high incidence of complications ([87], [88]). Surgery should be avoided when possible, as there is an increased risk of fatal intraoperative vascular complications. If surgery is mandatory, extreme care should be used in the manipulation of vascular tissues. Postpartum hemorrhage is a major risk for pregnant patients with EDS, and the management of pregnancy has been recently reviewed in case reports ([90], [91] and [92]). Genetic counseling and referral to the Ehlers-Danlos National Foundation (www.ednf.org) should be considered. An educational CD-Rom for the patient and caregivers has been developed and can be useful in the general management of patients with this disorder.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is an autosomal-dominant disease characterized by brittle bones with pathologic fractures as a result of a deficiency in bone matrix. Approximately 95% of cases are caused by mutations in the genes COLA1 and COLA2, which code for the pro-a1(1) and pro-a2(2) peptides of type 1 collagen ([93]). There are two a_1-chains and one a_2-chain in each type 1 collagen, and more than 100 different mutations in the genes coding for these subunits have been characterized ([94]). Four clinical types of OI are currently recognized ([95]). Approximately 25% of patients have been noted to bruise easily; this tendency appears to vary with the clinical type ([96]). Skin contains predominantly type 1 collagen, and bruising is thought to be the result of defective supporting structures. The ecchymoses are generally mild and insignificant compared to the broader clinical picture. Excessive bleeding from wound sites after surgery has also been described ([97], [98]). Recombinant factor VIIa and desmopressin have been reported to be useful in postoperative bleeding in case reports ([99], [100]). The Osteogenesis Imperfecta Foundation can be accessed at the following Web address: www.oif.org.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is an inherited connective tissue disorder that results in calcification of elastic fibers ([101]). The basic genetic defect is now known to be a variety of mutations in the gene encoding the transmembrane transporter protein ABC-C6 ([102], [103]). This protein is in the multiple drug resistance family of proteins and may function as an efflux pump, but it is not yet known what the substance transported is or how the mutation causes the disease. It is possible that this defect could result in accumulation of compounds that could lead to the calcification of the elastin fibers ([103]).

Patients with pseudoxanthoma elasticum have skin that becomes grooved and thickened over time and has been described as resembling Moroccan leather ([104]). Other cutaneous features include the development of yellow cutaneous plaques usually in the neck or axillary region or in other flexural sites. Ocular disease results from ruptures in elastin-containing membranes and presents as angioid streaks (Fig. 56.5A and Fig. 56.5B). Cardiovascular disease results from calcification of the arterial internal elastic lamina. Criteria for the diagnosis of pseudoxanthoma elasticum have been published ([101], [105]), and five clinical types are identified.

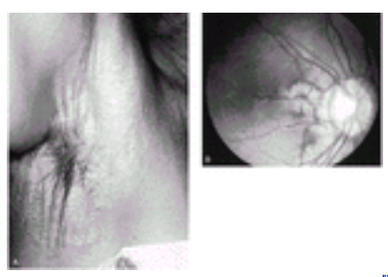

Figure 56.5. Cutaneous plaques with redundant skin folds **(A)** and angioid streaks **(B)** in a patient with pseudoxanthoma elasticum. (From Lebwohl M, Neldner K, Pope FM, et al. Classification of pseudoxanthoma elasticum: report of a consensus conference. J Am Acad Dermatol 1994;30:103–107, with permission.)

Bleeding can result when the calcified vessels rupture. The manifestations include bruising, epistaxis, and bleeding from the uterus, bladder, and joints ([101]). GI bleeding occurs in 13% of patients, usually between 20 and 30 years of age, and is usually of gastric origin ([106]). Treatment should include the avoidance of gastric irritants and careful control of hypertension and hypercholesterolemia. Regular ophthalmology evaluations are also recommended ([107]). The National Association for Pseudoxanthoma Elasticum can be contacted at 1240 Ogden Street, Denver, Colorado, USA, 80128 [(303) 832-5055].

Marfan Syndrome

Marfan syndrome is a genetic disorder with characteristic ocular, skeletal, and cardiovascular abnormalities. The basic defect has recently been identified as mutations in the fibrillin gene on chromosome 15 ([108]). Easy bruisability has been reported ([109]) but does not seem to be a major feature of the Marfan syndrome ([110]). However, the risk of postpartum hemorrhage is reported to be increased ([111]). The National Marfan Foundation web address is www.marfan.org.

Scurvy

Humans require vitamin C in the diet to promote the peptidyl hydroxylation of procollagen. In the absence of vitamin C, collagen strands are weakened as a result of abnormal triple helical structures. The abnormal collagen results in defective perivascular supportive tissues, which predispose to capillary fragility and delayed wound healing ([112], [113], [114] and [115]).

The clinical manifestations of scurvy depend on the severity of vitamin C deficiency. Patients classically develop perifollicular petechiae (Fig. 56.6) ([112]). The petechiae can coalesce and form purpura, particularly in a “saddle” distribution, and patients may develop gingival or intramuscular hemorrhage ([113]). Up to 75% of patients have a multifactorial normochromic, normocytic anemia ([114]). Other manifestations include peripheral edema and fatigue.

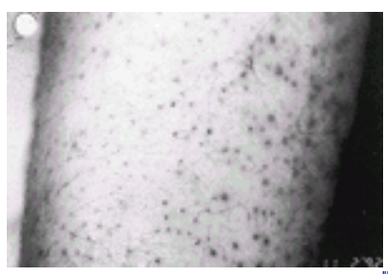

Figure 56.6. Perifollicular hemorrhages and corkscrew hairs in a patient with scurvy. (From Ghorbani AJ, Eichler C. Scurvy. J Am Acad Dermatol 1994;30:881–883, with permission.)

Patients at risk for scurvy include elderly edentulous patients who cook for themselves, alcoholics, mentally ill patients, and people on unusual diets. The treatment is replacement of ascorbic acid in doses of 200 mg/day ([112]).

Steroid-Induced Purpura

Patients on chronic steroids develop thinning of the connective tissues, and minor trauma can result in extensive purpura, especially in older patients. Avoidance of trauma is the best prophylaxis for bleeding in these patients.

Senile Purpura

Senile purpura is a common phenomenon first described in 1817 by Bateman. The lesions are typically located on the extensor surfaces of the forearms and dorsum of the hands and occur without recognized preceding trauma (Fig. 56.7) ([116]). The prevalence in hospitalized patients older than 65 years of age is approximately 5% but increases exponentially with age to include up to 30% of men 90 years of age or older ([117]). The skin in elderly people is thin as a result of loss of subcutaneous fat and changes in both the amount and quality of collagen ([118]). Skin lesions are thought to develop by incidental lateral displacement of slack skin with resulting capillary shearing. The lesions tend to last longer than other purpuric lesions and do not generally undergo the changes in hue that other ecchymotic lesions do ([116]). Hemostasis tests are normal, and no treatment other than reassurance is indicated.

Figure 56.7. Senile purpura (also known as *Bateman purpura*) in a 70-year-old man. See Color Plate. This photograph was kindly provided by Dr. Kappa Meadows (Department of Dermatology, University of Utah Health Sciences Center).

VASCULITIS

The nomenclature of the vasculitides is quite confusing, but a recent international consensus conference has proposed a system based on vessel size. This classification system recommends abandoning the term *hypersensitivity vasculitis* in favor of *microscopic polyangiitis* for small vessel vasculitides with few or no immune complexes and *cutaneous leukocytoclastic vasculitis* for small vessel vasculitis with isolated skin involvement ([119]).

Cutaneous Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis is characterized by immune complex deposition in postcapillary venules resulting in an inflammatory infiltrate, red cell extravasation, fibrinoid necrosis of the vessel wall, and fragmentation of nuclei (leukocytoclasis). The lesions typically develop 7 to 10 days after exposure to the offending antigen.

Palpable purpura is the classic clinical finding associated with cutaneous small vessel vasculitis. The lesions are the result of extravasation of erythrocytes into the inflamed dermis; therefore, the lesions do not blanch with pressure. The lesions range in size from pinpoint to several centimeters in diameter and are most prominent on the lower legs. The diagnosis should be confirmed by skin biopsy. Evaluation for the etiologic agent can be challenging and requires a detailed history to identify causative agents (Table 56.1) ([120], [121], [122] and [123]). Helpful laboratory studies include complete blood cell count, blood cultures, serum protein electrophoresis, cryoglobulins, rheumatoid factor, antinuclear antibody, antineutrophil cytoplasmic antibodies (ANCAs), and complement. Systemic involvement should be determined by the history and physical as well as a urinalysis, chest x-ray, and electrocardiogram.

TABLE 56.1. Etiologies of Leukocytoclastic Vasculitis

Underlying disorders
Malignancy (leukemia, lymphoma, myeloma, cryoglobulinemia)
Autoimmune disease (systemic lupus, ulcerative colitis, periarteritis nodosa, Sjögren syndrome, viral hepatitis, primary biliary cirrhosis, and so forth)
Infections (viral, bacterial, mycobacterial, fungal)
Drugs/chemicals
Penicillin, aspirin, phenothiazines, tetracycline, retinoids, colony-stimulating factors, contrast dye, insecticides, herbicides
Idiopathic

Antineutrophil Cytoplasmic Antibody–Positive Vasculitis

A major advance in understanding and classifying vasculitides has been the recognition of ANCAs in specific vasculitic syndromes. Patients with ANCA-associated small vessel vasculitis include three major categories, which are histologically identical. Speed in the diagnosis of ANCA-associated small vessel vasculitis is critical, as early treatment with immunosuppressive drugs can prevent life-threatening organ damage ([120]).

Wegener granulomatosis is distinguished by necrotizing granulomatous inflammation and pulmonary, upper respiratory, and renal involvement. Vascular inflammation in these areas can cause epistaxis, hemoptysis, and hematuria. Churg-Strauss disease is defined by the presence of necrotizing granulomas with asthma and eosinophilia. Vasculitis affects the nerves, GI tract, and skin primarily. Microscopic polyangiitis is recognized by the characteristic histology with the absence of asthma and granulomas. The vasculitis typically occurs in males older than 50 years of age. Prodromal symptoms include fever, myalgias, and arthralgias. Microhematuria, proteinuria, and oliguric renal failure may develop, and 30 to 40% of patients develop cutaneous lesions (splinter hemorrhages, palpable purpura). Pulmonary involvement occurs in one-third of patients.

Cryoglobulinemia

Essential cryoglobulinemic vasculitis is a vasculitis with cryoglob-ulin immune deposits. Cryoglobulins are immunoglobulins (Igs) that form a precipitate in cooled serum. They were first described by Wintrobe and Buell in 1933 ([124]). The cryoglobulins can precipitate in dermal vessels and result in leukocytoclastic vasculitis ([125]) and palpable purpura. When the cryocrit is significantly elevated (e.g., in lymphoproliferative diseases), hyaline thrombi can form and result in vasculopathy without associated vasculitis ([125]). Clinically, patients develop crops of purpuric macules, papules, and patches most prominently over the lower extremities that are occasionally associated with burning or pruritus. Cutaneous infarcts and petechiae are also occasionally present. Only rarely are these symptoms precipitated by exposure to cold; more commonly, prolonged standing or exercise is the inciting event. Systemic manifestations of cryoglobulinemia include arthralgias, asthenia, neuropathy, and renal disease ([125]).

Cryoglobulinemia can be divided into three types depending on the clonality of the precipitated Ig ([126]). Type I cryoglobulinemia is present when the cryoglobulin is monoclonal, and it is often associated with lymphoproliferative disease. Type II cryoglobulins are both polyclonal and monoclonal, and type III is polyclonal only. Types II and III are usually associated with autoimmune or inflammatory disease.

Essential cryoglobulinemia is diagnosed when no underlying disease is identified. With the development of sensitive assays for the hepatitis C virus (HCV), it has become evident that 43 to 85% of cases previously diagnosed as essential mixed cryoglobulinemia are associated with chronic infection with HCV ([127] , [128]). These patients have more cutaneous involvement and higher cryocrits than patients with essential cryoglobulinemia who are HCV-negative. The HCV antigens are present in the serum as well as in the cryoprecipitate. Interferon is effective treatment for skin manifestations of HCV-related cryoglobulinemia ([129]), but the cryoglobulins invariably recur when HCV becomes detectable again after interferon therapy is discontinued. Combination therapy with interferon and ribavirin showed much better short- and long-term results, but treatment needs to be continued for 18 to 24 months ([128] , [129] and [130]). Other treatments that may be effective in acute settings include steroids, immunosuppression, and plasmapheresis. Chronic symptoms may be refractory to therapy. Cryoglobulinemia is further discussed in Chapter 101.

Hypergammaglobulinemic Purpura

Hypergammaglobulinemic purpura (HP) is a syndrome first described by Waldenström in 1943; this disorder is characterized by polyclonal hypergammaglobulinemia associated with recurrent attacks of palpable or nonpalpable purpura ([131]). The syndrome has a marked predilection for women. The onset is often in the third and fourth decades of life, but young children and octogenarians have also been reported to develop this syndrome ([132] , [133]). The attacks of purpura are often sudden in onset and sometimes occur after prolonged standing, exercise, dancing, wearing tight-fitting clothes (e.g., jeans), and alcohol ingestion ([133] , [134]). Some patients have premonitory symptoms such as stinging, itching, or mild pain before the development of purpura ([134]). The purpura typically involves the lower extremities and is palpable in approximately 75% of cases ([135]). Associated systemic symptoms include arthralgias (particularly adjacent to the purpura), low-grade fever, and lower extremity edema. The purpura usually resolves over 2 to 10 days. Recurrences are common but highly variable. Some patients have up to four attacks/week; others have only rare recurrences ([135]).

HP can be divided into primary and secondary forms. Primary HP occurs with no underlying disease process; secondary HP is identified when the typical symptoms of HP develop in patients with underlying diseases such as Sjögren syndrome, systemic lupus erythematosus, or other autoimmune, inflammatory, or neoplastic diseases ([134] , [135] and [136]). The purpuric lesions can occur years before ([134]) or after ([135]) the diagnosis of autoimmune disease.

The laboratory features of HP include hypergammaglobulinemia, elevated erythrocyte sedimentation rate, mild anemia, and mild leukopenia. Both primary and secondary HP have a high prevalence of positive rheumatoid factor (88 to 100%) ([134] , [135]). Anti-Ro antibodies are similarly elevated in both primary HP and HP associated with Sjögren syndrome ([133] , [137]) and in up to 100% of HP associated with systemic lupus ([135]). Histopathologically, the lesions show inflammation of the superficial dermal vessels with an early neutrophil infiltrate followed by a mononuclear cell infiltrate and varying degrees of leukocytoclasis. Skin biopsies are often positive under direct immunofluorescence for IgM and IgG. Circulating immune complexes have also been identified ([132] , [133] , [135]).

Treatment in the past has been described as unsatisfactory ([134]). However, a recent prospective, nonrandomized trial of 17 patients suggests that milder cases respond to indomethacin or hydroxychloroquine (200 mg twice daily) and more severe cases respond to prednisone at doses more than 20 mg/day ([135]). Plasmapheresis results in only temporary relief of symptoms ([132] , [138]).

A relative deficiency of IgG_2 has been reported in some patients despite the hypergammaglobulinemia. IgG subclass determination should be considered in HP patients with recurrent infections ([139]).

Urticarial Vasculitis

Patients who present with purpura after resolution of urticaria may have urticarial vasculitis. Typically, the urticarial lesions burn, sting, or itch and last longer than 24 hours. Residual hyperpigmentation may be present after resolution of the skin lesions. The pathogenesis appears to be due to immune complexes that activate complement and lead to mast cell degranulation. Patients with normal complement levels usually have minimal, if any, systemic involvement, whereas patients with depressed complement levels may have more severe disease ([140]).

Acute Infantile Hemorrhagic Edema

Acute infantile hemorrhagic edema is a leukocytoclastic vasculitis confined to the skin in infants 4 to 24 months of age. Patients present with the dramatic onset of ecchymotic purpura involving the limbs and face with inflammatory edema. Spontaneous and complete resolution occurs in 1 to 3 weeks. Pathology shows leukocytoclastic vasculitis. Perivascular IgA deposits are often identified, and some authors consider this disorder to be a variant of Henoch-Schönlein purpura (HSP) ([141] , [142] and [143]).

Henoch-Schönlein Purpura

HSP is an acute vasculitic syndrome with features of colicky abdominal pain, nephritis, arthritis, and palpable purpura. The manifestations of the syndrome were initially described by Schönlein in 1837 and further developed by Henoch in 1874 ([142] , [143]). The disease occurs primarily in children, with a peak incidence occurring between 4 and 11 years of age. There appears to be a seasonal variation, with most reported cases occurring from fall to spring and a paucity of cases in the summer ([142] , [144]). Many of the cases occur after upper respiratory infections. Streptococcal infections are thought to be a common preceding event, but studies have not conclusively demonstrated this. Epidemiologic studies generally suggest that HSP occurs as sporadic cases, but clustering does occasionally occur. In 1987, a series of 20 cases occurred in Connecticut in a 5-month span and were found to be clustered in one ethnic group ([145]). This space-time clustering suggests a possible role for an infectious agent in precipitating the disease.

Biopsies of the superficial dermis and bowel in HSP show an acute vasculitis of precapillary arterioles and postcapillary venules. Immunofluorescent staining

commonly shows IgA deposits in the walls of the arterioles of both the involved and noninvolved skin ([146]). Only the IgA1 subclass appears to be involved, and preliminary evidence suggests that aberrant glycosylation of IgA1 may be important in the pathogenesis. In patients with renal involvement, a proliferative and necrotizing vasculitis is described, and IgA deposits are found in the glomerular mesangium ([147]). Circulating immune complexes containing IgA are detected in approximately 70% of patients shortly after the onset of purpura, followed by the appearance of complement and IgA, IgM, and IgG immune complexes later in the disease course ([148]). IgG autoantibodies to a mesangial cell antigen have also been described and appear to correlate with the severity of hematuria ([149]).

The onset of symptoms is usually acute, with fever and palpable purpura involving the extremities and buttocks ([142] , [143]). The purpuric lesions appear in symmetric crops with a predilection for extensor surfaces of the extremities (Fig. 56.8). They are most abundant around the knees, ankles, and elbows ([143]). A transient oligoarticular arthritis involving the large joints occurs in approximately 40% of cases, and the pain is often out of proportion to the physical findings. Renal involvement is manifest as proteinuria or hematuria. The renal abnormalities are almost always transient in younger children, but up to 20 to 25% of older children and adults have progressive renal disease ([142] , [150]). Poor prognostic factors for renal disease include nephrotic syndrome and greater than 50% glomerular crescent formation on renal biopsy ([151]).

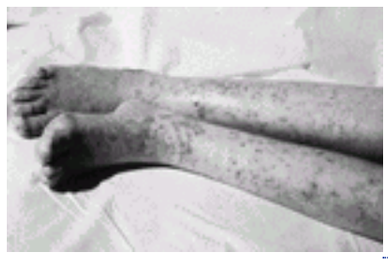

Figure 56.8. Lower extremity palpable purpura in a patient with Henoch-Schönlein purpura. See Color Plate. (From Van Hale HM, Gibson LE, Schroeter AL. Henoch-Schönlein vasculitis: direct immunofluorescence study of uninvolved skin. J Am Acad Dermatol 1986;15:665–670, with permission.)

Diffuse, crampy abdominal pain occurs in more than one-third of the cases and may occur before the characteristic purpura. The abdominal pain can be severe enough to mimic a surgical abdomen. Rare complications that require surgery do occur, however, and include intussusception, perforation, and bowel necrosis ([152]). Melena and testicular pain may also occur.

Criteria for the classification of HSP have been published ([142]). The presence of two of the following four criteria can usually accurately differentiate HSP from other forms of vasculitis: palpable purpura, age of onset 20 years or younger, acute abdominal pain, and biopsy showing granulocytes in the walls of arterioles or venules. The prognosis depends in part on the age at presentation. Children usually recover completely from HSP, but relapses may occur over a 3- to 6-week period before complete resolution of symptoms ([142]). Adults have more severe disease at presentation, with a worse renal prognosis. Mortality in one larger study with long follow-up was high (26%), but the leading cause of death was cancer ([150]).

Supportive care alone is used to treat mild cases. Steroids may be useful in GI vasculitis and in severe cases, but their effectiveness is controversial ([153]). In adults with HSP, steroids can relieve some of the signs and symptoms of the acute stage and may prevent progression of the renal disease in some cases ([154]).

Serum Sickness

Serum sickness is a specific clinical syndrome with systemic features and immune complex–induced vasculitis. The clinical syndrome typically occurs 7 to 12 days after administration of heterologous serum. The features include fever, urticaria, palpable purpura or other rash, and lymphadenopathy ([155]). The purpura is caused by immune complex deposition, and skin biopsies show a necrotizing angiitis. Drugs such as cefaclor, penicillin, hydralazine, sulfonamides, and thiazide diuretics have been associated with serum sicknesslike reactions ([156]).

PURPURA ASSOCIATED WITH INFECTION

Infectious agents can cause petechiae, purpura, and diffuse bleeding manifestations through a variety of mechanisms including disseminated intravascular coagulation, vasculitis, septic emboli, vascular toxins, and direct vascular or endothelial invasion ([157]). Certain clinical syndromes in the latter two categories are considered here.

Acute Febrile Illness with Petechiae

Acute febrile illnesses in children are often associated with petechiae and immediately raise the concern for possible meningococcemia. Although a florid meningococcal infection may be instantly recognizable, children who present with small skin hemorrhages and fever, but who are not acutely ill, can be a diagnostic challenge. Petechiae that are present only above the nipple line in the distribution of the superior vena cava are often due to the coughing or vomiting that accompanies the acute infection. Bacterial agents such as streptococcal infections, pneumococcus, and *Haemophilus influenzae* may cause fever and petechiae. Viral illnesses due to enterovirus and adenovirus are well-known causes of fever and petechiae as well. To help clinicians distinguish between the agents responsible (and to avoid missing an early meningococcal infection), algorithms have recently been developed ([158] , [159] and [160]). Certain febrile illnesses such as rickettsial infections and parvovirus B19 infections have well-described syndromes that are discussed below.

Papular-Purpuric Gloves and Socks Syndrome

Patients with sharply demarcated purpura involving the hands and feet may have a newly described syndrome known as *papular-purpuric "gloves and socks" syndrome* as shown in Figure 56.9. This syndrome was initially described in 1990 ([161]) and has been confirmed in several other reports ([162] , [163] and [164]). Patients are usually adolescents or young adults that present in the spring or summer with pruritic edema and erythema of the hands and feet. Petechiae and confluent purpura follow, with a relatively sharp demarcation at the wrists and ankles. Oral mucosal involvement is common, and patients may have other systemic signs or symptoms including lymphadenopathy, fever, elevated liver function studies, and cytopenias. The syndrome is usually associated with parvovirus B19, but cytomegalovirus, hepatitis B, measles, rubella, and human herpesvirus 6 have also been implicated. Immunohistochemical and virology studies show invasion of the endothelial cells and epidermal cells by the parvovirus ([165]).

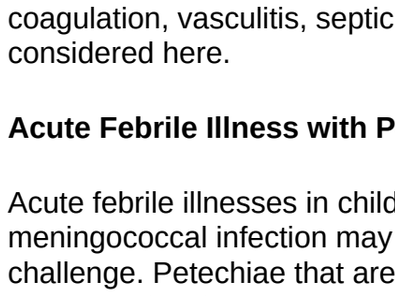

Figure 56.9. Skin lesions of hands and feet associated with papular-purpuric gloves **(A)** and socks syndrome **(B)**. See Color Plate. (From Harms M, Feldmann R, Saurat J-H. Papular-purpuric "gloves and socks" syndrome. J Am Acad Dermatol 1990;23:850–854, with permission.)

Rickettsial Diseases

Rickettsiae are small gram-negative obligate intracellular bacteria that reside free in the cytosol of infected endothelial cells. Infection results in damage to the

endothelial cell with a characteristic multifocal lymphohistiocytic immune response causing increased vascular permeability, decreased perfusion, and activation of coagulation.

Rocky Mountain spotted fever is transmitted by the bite of ixodid ticks and, therefore, has a peak incidence in the United States in May, June, and July. The incubation period is 2 to 14 days (mean, 7 days), and symptoms usually include the sudden onset of fever, chills, headache, and myalgia. A pink macular rash develops on the wrists, hands, and ankles and spreads to cover most of the body. After 2 to 7 days, the lesions become petechial, and hemorrhagic areas may coalesce to form large areas of ecchymosis. The major complications are a result of vascular injury, and multiple organs may become involved. Diagnosis is based on serologic studies showing a rise in antibody titers or biopsy of the skin lesions with immunofluorescent identification of the organisms. Treatment is with a tetracycline or chloramphenicol.

Other rickettsial diseases such as Mediterranean spotted fever, Asian tick typhus, and Queensland tick typhus are generally milder and have an eschar (tache noire) at the site of the primary tick bite. The treatment is the same as for Rocky Mountain spotted fever ([166]).

Brazilian Purpuric Fever

Brazilian purpuric fever is a disease of pediatric patients and usually begins with purulent conjunctivitis followed 7 to 16 days later by acute onset of fever, bacteremia, petechiae, purpura, and vascular collapse. The etiologic agent is *H. influenzae* biogroup aegyptius. The purpuric tendency appears to be due to direct invasion of endothelial cells with subsequent vascular damage ([167]).

Rat Bite Fever

Rat bite fever is an acute illness caused by rodent bite or exposure, due to organisms that are part of the normal oral flora. Most cases are due to *Streptobacillus moniliformis*, but others are due to *Spirilla minus*. The onset of symptoms is usually within 1 week of the bite but can occur several weeks after the wound has healed. Initial symptoms include headache, fever, chills, malaise, and cough and are followed by morbilliform or petechial rash often involving the palms and soles. Migratory polyarthritis develops in 50% of patients with the *Streptobacillus* type. Treatment is with procaine penicillin, tetracycline, or streptomycin ([168]).

Strongyloides

Disseminated strongyloidiasis occurs in immunocompromised hosts, especially in patients in the southeast United States taking corticosteroids. The infective larvae may molt at a rapid rate, and hyperinfection can occur. Periumbilical and diffuse purpura have been described, and biopsy of the skin lesions frequently reveals the larvae ([169]). Other bleeding manifestations include alveolar hemorrhage.

Hemorrhagic Fever Viruses

The *hemorrhagic fever viruses* are a diverse group of small RNA viruses with a lipid envelope. The clinical presentations vary, but symptoms usually begin with fever, headache, and myalgias progressing to generalized malaise. These symptoms last 3 to 4 days and are followed by petechiae, mucosal bleeding, and GI tract hemorrhage. The pathophysiology for most of the hemorrhagic fever viruses is not well defined. However, infection of the endothelium may be common to all ([170]). Some of the viruses have almost no cytopathologic effect, whereas others are highly destructive to the endothelial cells. Varying degrees of thrombocytopenia and disseminated intravascular coagulation are present and contribute to the bleeding diathesis (Table 56.2).

TABLE 56.2. Hemorrhagic Fever Viruses

Viral HF	Cytopathic Effect	Endothelial Cell Infection	Cytokine Activation	Disseminated Intravascular Coagulation
South American HF	±	++	++++	No
Lassa fever	±	++	+++	No
Rift Valley fever	++++	?	?	Yes
Crimean Congo HF	+	+	?	Yes
Hantavirus pulmonary syndrome	0	++++	++++	No
Filovirus HF	+++	+++	+++	Yes
Yellow fever	++	?	?	No

HF, hemorrhagic fever; 0, no effect; ±, negligible effect; + through ++++, minimal to major effect.

The major etiologic agents and the distinctive clinical features are outlined in Table 56.3 ([171]). A high index of suspicion is required to diagnose hemorrhagic fever virus. Risk factors for naturally occurring cases include foreign travel, handling of animal carcasses, contact with sick animals or people, and arthropod bites within 21 days of the onset of symptoms. Lack of identifiable risk factors should raise the suspicion of a bioterrorist attack.

TABLE 56.3. Clinical Syndromes of Some Viral Hemorrhagic Fevers

Virus	Clinical Syndrome	Person-to-Person Transmission	Mortality (%)
Ebola	Fever, prostration, rash, DIC	Yes	50–90
Marburg	Fever, myalgias, rash, DIC	Yes	23–70
Lassa fever	Fever, nausea, abdominal pain, pharyngitis, oral ulcers, cervical adenopathy, head and neck swelling	Yes	15–20
Rift Valley fever	Fever, headache, photophobia, jaundice	No	<1
Yellow fever	Fever, myalgia, facial flushing; late symptoms: fever, jaundice, renal failure, bleeding	No	20

DIC, disseminated intravascular coagulation.

Adapted from Borio L, Inglesby T, Peters CJ, et al. Hemorrhagic fever viruses as biological weapons. Medical and public health management. JAMA 2002;287:2391–2405.

Rapid diagnosis is currently available only by sending clinical specimens to the Centers for Disease Control and Prevention or the U.S. Army Medical Research Institute of Infectious Disease in Fred-erick, Maryland. Suspected cases should be reported immediately to the health department. Protective measures from nosocomial spread should be followed. A consensus conference recommends the use of IV ribavirin in unknown cases, but this has not been approved by the U.S. Food and Drug Administration, and the clinician should check for the latest recommendations from the Centers for Disease Control and Prevention.

PURPURA ASSOCIATED WITH VASCULAR OBSTRUCTION

Although oversimplified, it is often convenient to think of some disorders as causing purpura by intravascular obstruction with subsequent hemorrhage due to hemorrhagic necrosis, vasculitic injury, or consumptive coagulopathy. Table 56.4 lists disorders that can be grouped together as causing decreased blood flow with some tendency to bleed. Note that cold agglutinins are not included given the fact that necrosis and bleeding are not expected complications. Most of these conditions

are discussed in Chapter 34.

TABLE 56.4. Classification of Bleeding Disorders Associated with Vascular Obstruction

Vascular Obstruction Component	Disease Examples
Thrombus	Warfarin-induced skin necrosis, disseminated intravascular coagulation
Emboli	
Thromboemboli	Atrial fibrillation
Septic emboli	Endocarditis
Marantic emboli	Sterile endocarditis
Cholesterol emboli	Invasive vascular procedures, warfarin blue toe syndrome
Immunoglobulins	Waldenström macroglobulinemia, myeloma
Plasma proteins	Cryoglobulinemia
Fibrin	Cryofibrinogenemia
Red cells	Polycythemia
Platelets	Thrombocytosis, heparin-induced skin necrosis
Fat	Fat emboli syndrome

Cryofibrinogenemia

Cryofibrinogens are cold-precipitable plasma proteins that dissolve when plasma is rewarmed. These proteins are distinct from cryoglobulins, which precipitate on cooling of serum. Approximately 3% of hospitalized patients have detectable cryofibrinogens when appropriate assays are used ([172]). Cryofibrinogens can be associated with underlying malignancies or inflammatory processes or be present as an isolated finding (essential cryofibrinogenemia). A familial form has been described as well ([173]). When analyzed, the cryoprecipitate contains fibrinogen, fibrin, fibronectin, and other plasma proteins ([174]).

Although patients with cryofibrinogenemia are often asymptomatic, they may present with symptoms of cold intolerance, cutaneous purpura, gangrene, or Raynaud phenomenon ([175]). Most patients have an elevated total fibrinogen level ([172]). The pathogenesis of the cutaneous lesions is believed to be the result of fibrin thrombi obstructing the small dermal vessels ([175]). Biopsies of these lesions show eosinophilic thrombi with a sparse lymphocytic infiltrate ([176]). Leukocytoclasis has been described in a few patients ([177]).

To measure cryofibrinogens, blood should be anticoagulated with ethylenediaminetetraacetic acid, citrate, or oxalate. Heparin can result in false-positive results ([178]). The sample should be maintained at 37°C until centrifuged, and the separated plasma should be chilled to 4°C for 72 hours. The cryocrit is expressed as a percentage of the plasma sample volume ([178]).

Cryofibrinogenemia may be asymptomatic and require no treatment. Mild cases can be treated with avoidance of cold. Patients with more severe symptoms have been treated with heparin, warfarin, fibrinolytic agents, and plasmapheresis with variable results. Immunosuppressive agents have been reported to be effective as well ([176]). A small clinical trial suggested that stanozolol, an androgenic steroid with fibrinolytic activity, produced excellent results ([175], [179]).

Cholesterol Embolization Syndrome

Cholesterol embolization syndrome is an increasingly recognized disorder caused by dislodging cholesterol crystals from atherosclerotic plaques. This occurs after vascular procedures or can be due to warfarin (blue toe syndrome) and results in renal insufficiency, peripheral emboli, and, possibly, GI or central nervous system involvement. Livedo reticularis is the most common skin finding and can best be appreciated with the patient in an upright position. Cyanosis, purpura, ulcers, and gangrene can all occur ([180]). The diagnosis can be made by biopsying the cutaneous lesions, including livedo reticularis ([181]). There is no specific treatment.

PURPURA ASSOCIATED WITH SKIN DISEASES

Pigmented Purpuric Dermatitis

Pigmented purpuric eruptions encompass a group of related skin diseases that have in common the clinical appearance of red-brown skin pigmentation (caused by hemosiderin deposits) associated with purpura or petechiae. These lesions tend to develop on the lower extremities of middle-aged people and are usually chronic. Histologically, there is a mononuclear upper dermal infiltrate without evidence of leukocytoclasis. Extravasated red blood cells are present around the capillaries, and hemosiderin deposits are found in older lesions. Six skin diseases are commonly classified as pigmented purpura. In Schamberg progressive pigmentary dermatosis, the lesions appear as orange-brown patches of skin with “cayenne pepper spots” at the borders or within the lesion (Fig. 56.10). Majocchi purpura annularis is distinguished by an annular 0.5- to 2.0-cm patch of reddish-brown macules. Eczematoid-like purpura has a seasonal pattern and appears as pinpoint lesions that spread rapidly over 2 to 4 weeks and develop a slight scale. The lesion in pigmented purpura lichenoid dermatitis (Gougerot-Blum purpura) is a reddish-brown macule with telangiectasias. These lesions tend to coalesce and form plaques. Itching purpura presents with an acute onset of pigmented macules associated with severe pruritus. Lastly, lichen aureus is described as “grouped copper-orange to purple lichenoid papules forming an irregular, usually singular, plaque” ([182]). The etiology of pigmented purpura is unknown, but some degree of venous stasis is apparent in many patients and may be a factor in its development. The importance of these lesions is to differentiate them from other causes of chronic purpura with hemosiderin deposits such as purpura associated with abnormal proteins. The lesions may clear in up to two-thirds of patients with long-term follow-up ([183]). Pigmented purpuric eruptions have been described in children ([184]) (Fig. 56.11). Treatment in the past has been with fluorinated steroids, but recently, psoralen plus ultraviolet light of A wave length has been found to be effective in some cases ([185]).

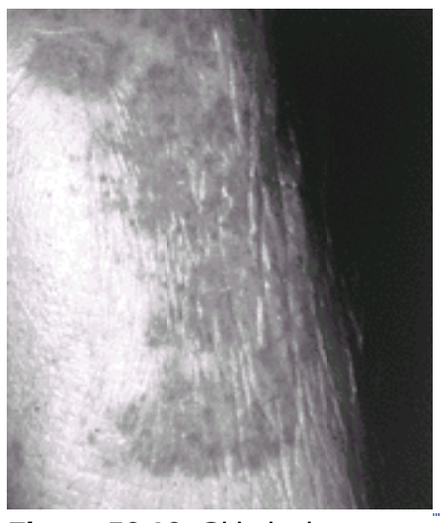

Figure 56.10. Skin lesions associated with Schamberg progressive pigmentary dermatosis. Note the irregular patches of punctate hemorrhagic lesions with yellow-brown discoloration of hemosiderin deposits. See Color Plate. (From Sherertz EF. Pigmented purpuric eruptions. Semin Thromb Hemost 1984;10:190–195, with permission.)

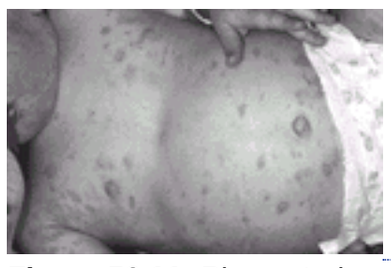

Figure 56.11. Pigmented purpura in a child. See Color Plate. This photograph was kindly provided by Drs. Payem Tristani-Firouzi and Sheryll Vanderhooft (Department of Dermatology, University of Utah Health Sciences Center).

Purpuric Contact Dermatitis

Purpura can be a presenting sign of allergic contact dermatitis. Reported antigens include textile dyes and resins, benzoyl peroxide, epoxy resin, and agave sap (186).

Drug Reactions

Drug reactions can cause a nonthrombocytopenic purpura by a number of different mechanisms, including leukocytoclastic vasculitis, serum sickness, and, occasionally, a pigmented purpura. These topics are discussed in the section Vasculitis. A fixed drug reaction can occur, with an isolated purpuric-appearing lesion occurring in a location without preceding trauma (Fig. 56.12).

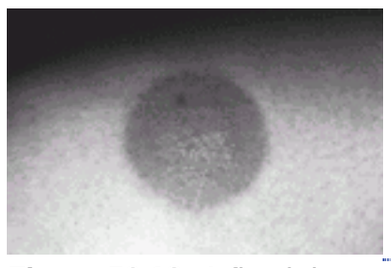

Figure 56.12. A fixed drug eruption lesion. This 30-year-old woman developed this thigh lesion after taking ibuprofen. See Color Plate. This photograph was kindly provided by Dr. Pamela Nemzer (Department of Dermatology, University of Utah Health Sciences Center).

PSYCHOGENIC PURPURA

Autoerythrocyte Sensitization

Autoerythrocyte sensitization is a rare disorder characterized by recurrent spontaneous ecchymotic lesions in patients with otherwise normal hemostasis. The syndrome was first described in 1955 by Gardner and Diamond after their discovery that intra-dermal injections of autologous red blood cells reproduced the skin lesion (187). Since the original description, more than 200 cases have been described, with the largest series collected by Ratnoff (188).

The cutaneous lesions are usually preceded by localized symptoms, including pain and a burning or stinging sensation in the involved area. The area then becomes erythematous, raised, and warm, and within hours, ecchymoses occur in the inflamed area. The ecchymoses can range in size from 1 to 2 cm to extensive involvement of the trunk or an extremity. The erythema and swelling usually subside within 48 hours of the development of ecchymoses. The lesions can recur weeks to years later. The ecchymotic lesions are usually only one symptom among many. Patients commonly have systemic symptoms including headaches, paresthesias, syncopal episodes, abdominal pain, nausea, vomiting, chest pain, dyspnea, dysuria, and arthralgia.

Autoerythrocyte sensitization typically affects adolescent to middle-aged females who have significant underlying emotional problems. Patients are commonly found to suffer from depression, anxiety, and inability to handle hostile feelings, as well as hysterical and masochistic character traits. They have often sustained significant physical and emotional trauma in the past, and up to two-thirds of the patients describe significant emotional stress present at the time the initial purpuric lesions develop.

The skin lesions can classically be reproduced in most patients with the intradermal injection of 0.1 ml autologous whole blood, packed red blood cells, or red cell stroma (Fig. 56.13). However, this test has limited sensitivity, and some authorities recommend using clinical criteria to diagnose this disorder (189).

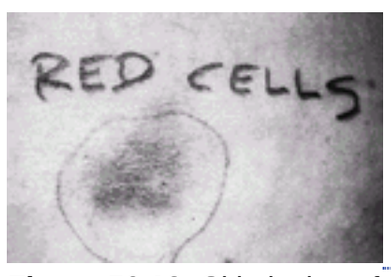

Figure 56.13. Skin lesion of psychogenic purpura (autoerythrocyte sensitization) induced by administration of intradermal autologous blood. A saline control elicited no response. See Color Plate. [From Berman DA, Roenigk HH, Green D. Autoerythrocyte sensitization syndrome (psychogenic purpura). J Am Acad Dermatol 1992;27:829–832, with permission.]

No specific therapy is of proven value in psychogenic purpura. Psychotherapy appears to be beneficial in some younger patients but is less effective in the older population.

Autosensitivity to DNA

A similar syndrome of recurrent ecchymoses after a prodrome of localized itching was described in 1961 by Levin and Pinkus (190). This patient developed the typical skin lesions described above after the intradermal injection of frozen and thawed buffy coat leukocytes or purified calf thymus DNA. There are few data concerning the emotional background of these patients. Since the initial description, a few other cases have been reported, but some of these also had a positive reaction to intradermal injection of blood or washed red cells (191, 192, 193, 194 and 195). Chloroquine can induce remissions, and cyproheptadine was useful in one patient (191, 192, 193, 194 and 195).

Factitious Purpura

Self-inflicted ecchymoses can be difficult to diagnose. This disorder should be considered when there is a clear secondary gain present, when the lesions only occur in accessible areas, or when ecchymotic lesions assume unusual shapes. Circular, well-circumscribed lesions around the upper limbs and breasts may be a result of sucking of the skin.

Religious Stigmata

Purpuric religious stigmata are bruises that allegedly occur spontaneously and resemble the wounds of the crucified body of Christ. The phenomenon usually occurs in women, and many have belonged to a religious order. The etiology is thought to be either a conversion reaction or self-induced ([188]).

Thrombocytosis

Thrombocytosis is the presence of an abnormally high number of platelets in the circulating blood. It may result from the various physiologic stimuli and pathologic processes summarized in Table 57.1. It is a common feature of the myeloproliferative syndromes, in which there is clonal hematopoiesis: essential thrombocythemia, polycythemia vera (see Chapter 85), chronic myelocytic leukemia (see Chapter 84), and myelofibrosis (see Chapter 86). Thrombocytosis may be a significant pathophysiologic feature in the production of hemorrhage or thrombosis in these disorders. An elevated platelet count also is commonly associated with various infections and inflammatory and neoplastic disorders. In these conditions, the increase in platelet numbers seldom produces symptoms but often is of considerable diagnostic significance.

TABLE 57.1. Causes of Thrombocytosis

Physiologic
Exercise, parturition, epinephrine
Primary
Myeloproliferative syndromes
Essential thrombocythemia
Polycythemia vera
Chronic myelocytic leukemia
Myelofibrosis
Secondary
Infectious diseases
Inflammatory diseases
Neoplasms
Rapid blood regeneration after hemorrhage and in various hemolytic anemias
Rebound after recovery from thrombocytopenia
Asplenia (anatomic or functional)
Miscellaneous: iron deficiency, postsurgical procedure

ETIOLOGY

Transitory thrombocytosis may result from the mobilization of extravascular platelet pools, as after epinephrine administration ([1]), childbirth, or vigorous exercise ([2],[3]). Chronic thrombocytosis can result from mobilization of the intrasplenic pool after splenectomy or in the presence of functional asplenia, as is seen in patients with sickle cell disease. There also are reports of benign familial thrombocytosis affecting multiple family members in several generations ([4],[5]). All other forms of thrombocytosis apparently are the result of accelerated platelet production, which may be autonomous, as in the clonal myeloproliferative disorders (MPDs), or the result of increased concentrations of one or more hematopoietic growth factors or inflammatory cytokines.

In primary thrombocytosis, platelet production is unresponsive to normal regulatory processes. Autonomous production of platelets has been likened to neoplastic proliferation of other hematopoietic cells. The factors leading to accelerated platelet production in reactive thrombocytosis are now being elucidated, and several pathophysiologic mechanisms may be responsible depending on the underlying disease. One mechanism, for which there are accumulating data, is the presence of increased concentrations of interleukin-6 (IL-6), one of the hematopoietic growth factors.

Most cases of thrombocytosis are reactive, and, when it is found to be a manifestation of a myeloproliferative disorder, only a small percentage of patients have essential thrombocytosis (ET). When 100 consecutive patients with platelet counts greater than 500,000/µl were reported in 1973 ([6]), 36% were found to have a malignancy (which was usually disseminated) and only 6% a myeloproliferative disorder (five patients had polycythemia vera, one patient had chronic myelocytic leukemia). Only 8% had an acute infection. In a more recent 1-year prospective study of sequential Saudi Arabian patients with platelet counts greater than 500,000/µl ([7]), 21% of 777 thrombocytosis cases were found to be caused by infection, 18% by tissue damage, 13% by chronic inflammation, and 19% by rebound after bleeding, iron deficiency, or cancer chemotherapy. Thrombocytosis occurring in patients with malignancy, splenectomy or myeloproliferative disorders accounted for less than 5% in each instance. In a study of sequential patients presenting with platelet counts above 1 million/µl, reactive thrombocytosis accounted for 82% of patients, myeloproliferative disorders accounted for 14%, and 4% were of uncertain etiology ([8]). Infection was the most common cause of reactive thrombocytosis (31%), with postsplenectomy (19%), malignancy (14%), and trauma (14%) being the next most common etiologies. Among the patients with myeloproliferative disorders, nearly half had chronic myelocytic leukemia (42%), 29% essential thrombocythemia, 13% polycythemia vera, 5% myelofibrosis, and 11% unclassified. In a brief report of 158 sequential patients described as “platelet millionaires,” myeloproliferative disorders accounted for 18% ([9]).

HEREDITARY THROMBOCYTHEMIA

There are at least 12 families reported with familial thrombocytosis affecting several generations. At presentation, they are difficult, if not impossible, to distinguish from other patients with thrombocytosis, and many of them have thrombohemorrhagic complications. All except one of these families demonstrate autosomal-dominant inheritance; in a Bedouin Arab family, there is presumed X-linked transmission ([10]).

Genetic studies performed in several families suggest that these cases are due to mutations involving the thrombopoietin gene on chromosome 3, which results in increased translation and production of thrombopoietin through loss of translational repression ([11],[12],[13] and [14]). These patients have both elevated platelet counts and elevated thrombopoietin levels. Other families have near normal thrombopoietin levels and normal thrombopoietin and *c-mpl* genes ([15],[16]).

ESSENTIAL THROMBOCYTHEMIA

Thrombocythemia (primary, essential), first described by Epstein and Goedel in 1934, is characterized by abnormal proliferation of the megakaryocytes and belongs to the spectrum of myeloproliferative disorders discussed in Chapter 84, Chapter 85, and Chapter 86 ([17]). The disease has been demonstrated to be a clonal disorder of a multipotent stem cell, a mechanism common to chronic myelocytic leukemia, polycythemia vera, and myelofibrosis ([18]). Its major clinical manifestations are bleeding and thromboembolic diathesis ([19], [20], [21], [22], [23] and [24]). The disorder is uncommon and is seen most commonly in people in middle and adult life, although series of younger patients ([25], [26]) and children have been reported ([27], [28], [29] and [30]). There are several reports of familial thrombocytosis. In some families, this occurs without other types of myeloproliferative disorders ([5], [31], [32], [33], [34], [35], [36] and [37]). In others, multiple generations are affected by various myeloproliferative disorders ([29], [38]).

Pathophysiology

Essential thrombocythemia has been demonstrated by X-chromosome–linked polymorphisms to be a clonal disorder of a multipotent stem cell that gives rise to erythrocytic, granulocytic, or megakaryocytic series in the majority of patients studied. X-linked polymorphic markers and methods used include the protein glucose-6-phosphate dehydrogenase ([39]); DNA methylation of specific genes, such as the human androgen receptor (HUMARA) ([40], [41], [42] and [43]); and expression of RNA transcripts for polymorphic genes ([44]). In a 1994 study in which monoclonality was assessed by restriction fragment length polymorphisms of the X-chromosome phosphoglycerate kinase and hypoxanthine phosphoribosyltransferase, all 13 patients with thrombocythemia had monoclonal patterns of X-inactivation in the granulocyte fraction, with nonclonal patterns of X-inactivation in the T-lymphocyte fraction in 8 of the 13 patients and with monoclonal patterns in the remaining five ([45]). This suggests that, in some patients, the clonal proliferation involves a multipotent stem cell that gives rise to both lymphoid and myeloid lineages. These analyses of clonality are complicated by the observation that there is increased skewing of alleles in older normal women, and T cells are needed as a control. In addition, many studies are equivocal or demonstrate polyclonal hematopoiesis in patients who fulfill the diagnostic criteria for essential thrombocythemia as established by the Polycythemia Vera Study Group ([41]).

In early thrombokinetic studies, platelet production was demonstrated to be 2 to 15 times normal, and the decrease in megakaryocyte size normally resulting from an increase in circulating mass was not seen ([46]). There is spontaneous growth of megakaryocyte colonies from peripheral blood or bone marrow from patients with ET ([47], [48], [49], [50], [51] and [52]), even in serum-free culture systems ([53], [54], [55] and [56]). The colonies are increased in size, and endomitotic megakaryocyte development is abnormal with subnormal endoreduplication reported ([57]). The pathophysiology of autonomous growth of megakaryocytes in essential thrombocythemia is still uncertain. The increased colony formation is not caused by increased megakaryocyte colony-stimulating activity in the plasma of patients with ET, and growth is not modified by addition of antibodies to IL-3, IL-6, or granulocyte-macrophage colony-stimulating factor (GM-CSF). Thrombopoietin levels in plasma and serum are normal or increased ([58], [59], [60], [61], [62] and [63]), and there is decreased expression of *c-mpl*, the thrombopoietin receptor on platelets and megakaryocytes ([64], [65] and [66]). No mutations in the *c-mpl* receptor DNA and no change in the activation state of the receptor have been found ([56], [64], [65], [66] and [67]).

Cytogenetic analysis demonstrates abnormalities in less than 25% of patients, and multiple abnormalities (i.e., no dominant patterns) have been found. Trisomy 8 was most common in one group of 12 patients ([68]). In a series of 33 patients in which criteria for diagnosis were rigidly performed, modal chromosome number was 46 in all except two elderly men who were missing Y chromosomes, and banding analysis of 50 metaphases in each patient failed to reveal any deletions or translocations ([69]). There is a preliminary report of p53 gene mutations in 3 of 51 patients with essential thrombocythemia in chronic or leukemic phase ([70]). None of this series of patients had ras oncogene mutations, unlike other BCR/ABL-negative chronic myeloproliferative disorders.

The mechanisms by which thrombocythemia produces either hemorrhage or thrombosis are not well defined. There are a number of reports of qualitative abnormalities of the platelets, but some of these findings are not found in enough patients to represent a major or universal mechanism, and many of them are also seen in platelets of patients with reactive thrombocytosis. There was a comprehensive review of reported abnormalities in 1984 ([71]). Abnormalities reported in the last decade include decreased aggregation with collagen, adenosine diphosphate, and epinephrine ([72]), hyperaggregation ([72]) or spontaneous aggregation, defects in the intracellular concentrations of adenine nucleotides ([73]) and serotonin, decreased intracellular platelet-derived growth factor ([74]) and ß-thromboglobulin ([75]), increased thromboxane generation ([76], [77] and [78]), decreased prothrombinase expression ([79]), changes in the membrane glycoproteins ([80]), decreased platelet membrane sialylation ([81]), increased membrane thrombospondin and P-selectin ([82], [83]), and an abnormal proteolyzed form of thrombospondin ([84]) or an abnormal “flip-flop” mechanism of the membrane resulting in an increase in thrombin generation ([85]).

In addition to the platelet abnormalities described above, there are reports of decreased von Willebrand factor (vWF) activity and decreased high-molecular-weight vWF multimers in some patients with myeloproliferative disorders and, especially, essential thrombocythemia ([86], [87], [88], [89], [90], [91] and [92]). Factor VIII:C and vWF antigen concentrations are normal. The most significant changes have been seen in the patients with the highest platelet counts and correlate directly with both a prolonged bleeding time and hemorrhagic symptoms. Reduction of the platelet count is associated with normalization of the vWF parameters. Similar changes have also been reported in patients with reactive thrombocytosis postsplenectomy, suggesting that these changes are secondary to the increased number of platelets, not abnormalities in clonal populations of platelets ([90]). Normal amounts of vWF are released in ET patients in response to 1-deamino-8-D-arginine vasopressin, but the half-life of vWF activity is significantly reduced ([93]). These changes are also normalized after cytoreduction.

There are preliminary reports of reduced concentrations of antithrombin, protein C, and protein S in patients with ET, especially when comparing patients with a history of thrombosis with those who had not had thrombotic complications. These were not familial deficiencies in patients in whom family studies were conducted, suggesting that the deficiencies were acquired, possibly secondary to low-grade activation of coagulation ([94], [95]).

Clinical Picture

The earliest series of patients with essential thrombocythemia were published in the 1960s ([96], [97]). However, the diagnostic criteria were quite different from those being used in current studies; for example, in the Gunz report, patients had to have an extremely high platelet count and a history of hemorrhage to be included. Accurate information about the clinical picture is therefore best obtained from series of patients in which criteria for inclusion were better defined, although in these studies the platelet count required for inclusion varies from over 450,000/µl to over 700,000/µl ([29], [98], [99] and [100]). The average age of patients at diagnosis ranges from 50 to 60 years. In almost every series reported, female subjects outnumber male subjects. The majority of patients are symptomatic at the time of diagnosis. The most common presenting symptoms are caused by disturbances of the microcirculation, especially fingers and toes (erythromelalgia) ([101], [102]) and the central nervous system, in which headache, dizziness, and visual and acoustic symptoms are common ([103], [104]). A variable number of patients present with thrombotic (18 to 84%) or hemorrhagic problems (13 to 37%) ([29], [98], [99]). A smaller number of patients present with a combination of both.

Occlusion of the microcirculation, *erythromelalgia*, is characterized by warm, red, congested extremities and painful burning sensations, especially of the forefoot sole and one or more toes. It affects the lower extremities more than the upper extremities and may be asymmetric. The pain is initiated and aggravated by standing, exercise, or warmth and is relieved by elevation or cooling of the affected extremity ([105]). Erythromelalgia may lead to painful acrocyanosis and peripheral gangrene ([106], [107], [108] and [109]). Biopsies from these patients demonstrate arteriolar inflammation with vessel narrowing caused by proliferation of smooth muscle cells (Fig. 57.1) ([108], [110], [111]). Arterioles are often occluded by thrombi composed of platelet aggregates and platelet prostaglandins, and other secretion products are believed to be of primary importance in the development of these lesions ([104]). Patients have dramatic improvement in symptoms and platelet survival lasting several days and reversal of vascular changes after treatment with aspirin ([108], [112], [113] and [114]). Erythromelalgia has also been seen when thrombocytosis occurs in the other myeloproliferative disorders ([115]).

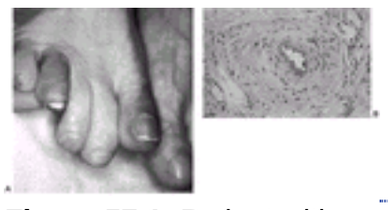

Figure 57.1. Patient with erythromelalgia secondary to essential thrombocythemia. **A:** There are painful, erythematous toes on both feet. **B:** Biopsy of affected region demonstrates smooth muscle cell hyperplasia of the arteriole (×430; hematoxylin and eosin stain). See Color Plate. (From Naldi L, Brevi A, d'Oro LC, et al. Painful distal erythema and thrombocytosis. Arch Dermatol 1993;129:105–106, 109, with permission.)

The clinical course is complicated in the majority of patients by hemorrhage and thrombosis ([68], [116], [117]). Thrombosis has been reported to be more common than hemorrhage, and arterial thrombi are more common than venous. The occurrence of thrombosis appears to be independent of either the platelet count or tests of hemostasis ([118], [119]). It is unclear whether arterial thrombi are more common in patients with cardiovascular risk factors, although the risk appears to be increased by smoking ([120], [121]). Some investigators believe that the frequency of hemorrhage increases with increasing platelet count, and many investigators have demonstrated that the incidence is greatest when the platelet count is greater than 1 million. However, others found no correlation between hemorrhage or thrombosis and platelet count ([122]).

A recent cohort of patients who were younger than 60 years old, had a platelet count of less than 1.5 million/μl, and no prior history of hemorrhage or thrombosis had a very low incidence of thrombohemorrhagic complications ([123]). Therefore, some authors recommend only aspirin therapy, not chemotherapy, for younger patients ([25], [122], [124]) regardless of the platelet count. However, Mitus et al. reported a 39% incidence of hemorrhage or thrombosis in 44 patients younger than age 45 ([125]). Twenty-three of the complications were serious, and two patients died of thrombosis: An 18-year-old died a sudden cardiac death and was found to have a myocardial infarction at autopsy, and a 17-year-old died of cerebral sinus vein occlusion. In another recently reported series of young patients (younger than age 40), four of eight patients presented with life-threatening complications, including portal vein thrombosis and variceal hemorrhage, mesenteric vein thrombosis and small bowel infarction, femoral artery thrombosis requiring amputation, and, lastly, retinal artery occlusion and two episodes of deep vein thrombosis/pulmonary embolism ([120]). Finally, in a third series of patients between the ages of 22 and 35, 11 of 13 patients presented with thrombohemorrhagic symptoms, and two of these had acute myocardial infarctions and one a cerebrovascular accident ([126]). There is also evidence, in patients with essential thrombocythemia or other MPDs, that antiplatelet therapy increases the incidence of gastrointestinal bleeding ([122], [127]) and that such patients have a more pronounced prolongation of bleeding time than control group patients, 2 hours after a single intravenous infusion of aspirin ([128]).

Arterial thrombi occur in the cardiac, cerebral, or peripheral arteries ([129], [130]). Venous thrombosis has been reported in the deep venous system of the legs, the splanchnic-mesenteric system, and the cerebral venous sinuses. Gastrointestinal hemorrhage is most common, but skin and mucosal bleeding in other sites also occurs. Moderate splenomegaly has been reported in 20 to 50% of patients ([29], [96], [98], [99] and [100], [131], [132]); however, progressive enlargement is unusual. Hepatomegaly may be present, but lymphadenopathy is rare.

Investigators who calculated actuarial survival for 247 Spanish patients demonstrated that essential thrombocythemia is associated with a life expectancy close to normal ([133]). However, the relative risk of death was increased fourfold in a 1999 analysis of 187 consecutive Italian patients ([134]). A small number of patients undergo transformation to acute nonlymphocytic leukemia (French/American/British classification, M0–M7) or acute lymphocytic leukemia ([135], [136], [137], [138], [139] and [140]), but the majority of these patients have been treated with alkylating agents ([29], [31], [98], [99], [141], [142], [143], [144] and [145]).

Laboratory Findings

In most patients with thrombocythemia, the platelet count exceeds 1 million/μl, and counts as high as 14 million/μl have been recorded ([96]). Abnormalities of size, shape, and structure often are striking, and megakaryocyte fragments may be apparent in the blood (Fig. 57.2) ([29], [98]). Mild anemia may occur, but most patients have normal hemoglobin concentrations ([29], [98], [99]). Leukocytosis, usually less than 20,000/μl, is found in 35 to 72% of patients. White blood cell counts have been reported as high as 30,000/μl, although this is rare. The differential demonstrates neutrophilia, and a mild shift to the left may be seen. Slight eosinophilia and basophilia often are present ([29]). Leukocyte alkaline phosphatase may be increased in up to 40% of patients ([98]).

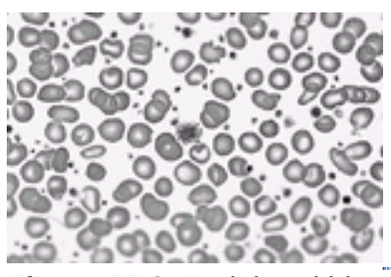

Figure 57.2. Peripheral blood smear from a patient with newly diagnosed essential thrombocytosis and a platelet count of 2 million/μl. A significant increase in platelets and one giant platelet can be seen in this field (×1000; Wright-Giemsa stain). See Color Plate.

The bleeding time is prolonged in very few patients, which is surprising considering the number of patients who have hemorrhagic symptoms at presentation or during their course. Other screening tests of hemostasis (prothrombin time, partial thromboplastin time) are usually normal. Serum uric acid and lactate dehydrogenase are elevated in up to 25% of patients. The presence of thrombocytosis produces pseudohyperkalemia as well as spurious increases in serum levels of acid phosphatase and inorganic phosphorus ([146], [147] and [148]).

The bone marrow reveals marked hyperplasia of the megakaryocytes, which often appear in clumps (Fig. 57.3). Bone marrow reticulin is increased in the majority of patients, but collagen is rarely seen. Hyperplasia of the granulocyte or erythrocyte precursors is a common finding. Cytogenetic studies are usually normal.

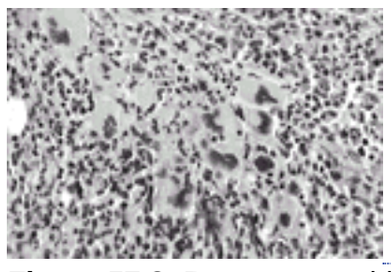

Figure 57.3. Bone marrow biopsy from the patient with newly diagnosed essential thrombocythemia and a platelet count of 2 million/μl presented in Figure 57.2. Megakaryocytes are increased in number and present in clusters (×1000; Wright-Giemsa stain). See Color Plate.

Differential Diagnosis

There have been many attempts to develop criteria for a positive diagnosis of essential thrombocythemia, but most often, it is still diagnosed by exclusion of other entities that may present with thrombocytosis ([149]). The most commonly used criteria are those established and then modified by the Polycythemia Vera Study Group ([127], [150]) (Table 57.2). These criteria were established to distinguish essential thrombocythemia from the other MPDs and from all of the many causes of reactive thrombocytosis. Some patients may be diagnosed with essential thrombocythemia at platelet counts less than 600,000/μl ([151], [152]). In addition, some essential

thrombocythemia patients may have the *BCR/ABL* gene rearrangement but no difference in prognosis or clinical course ([153], [154] and [155]).

TABLE 57.2. Polycythemia Vera Study Group Diagnostic Criteria for Essential Thrombocythemia

I. Platelet count >600,000/μl
II. Hemoglobin =13 g/dl or normal red blood cell mass (males <36 ml/kg, females <32 ml/kg)
III. Stainable iron in marrow or failure of iron trial (<1 g/dl rise in hemoglobin after 1 mo of iron therapy)
IV. No Philadelphia chromosome (t9;22)
V. Collagen fibrosis of marrow
  A. Absent or
  B. <1/3 biopsy area without both splenomegaly and leukoerythroblastic reaction
VI. No known cause for reactive thrombocytosis

From Murphy S, Iland H, Rosenthal D, Laszlo J. Essential thrombocythemia: an interim report from the Polycythemia Vera Study Group. Semin Hematol 1986;23:177–182.

In a number of recent publications, investigators compare diagnostic tests in patients with thrombocytosis (Table 57.3). Patients with thrombocytosis must first be diagnosed as having primary or reactive thrombocytosis, and then decisions about the type of MPD must be made. Spontaneous megakaryocyte and erythroid colony formation occurs in most of the bone marrows from patients with MPDs and, rarely, with the bone marrows of patients with reactive thrombocytosis, but this is neither discriminatory nor diagnostic ([50], [55], [156], [157], [158] and [159]). DNA analysis by X-linked DNA polymorphism in conjunction with methylation patterns can distinguish patients with clonal proliferation from those with reactive proliferation, but not all patients who are believed to have essential thrombocythemia demonstrate clonal hematopoiesis ([160]).

TABLE 57.3. Clinical and Laboratory Features That Distinguish Essential Thrombocythemia from Reactive Thrombocytosis

Feature	Essential Thrombocytosis	Reactive Thrombocytosis
Thrombosis or hemorrhage	+	–
Splenomegaly	+	–
Increased acute phase reactants	–	+
Interleukin-6		
C-reactive protein		
Plasma fibrinogen		
BM reticulum fibrosis	+	–
BM megakaryocyte clusters	+	–
Clonal hematopoiesis	+	–
Spontaneous colony formation	+	–
Abnormal cytogenetics	+	–

BM, bone marrow.

Modified from Tefferi A, Hoagland HC. Issues in the diagnosis and management of essential thrombocythemia. Mayo Clin Proc 1994;69:651–655.

Majer et al. compared platelet size, aggregation and adhesion, dense granule and a-granule components, plasma fibrinogen, and vWF and found considerable overlap between patients with MPDs and reactive thrombocytosis. The plasma fibrinogen was the best discriminator, with values greater than 500 mg/dl indicating reactive thrombocytosis ([161]). However, plasma fibrinogen failed to accurately predict thrombocytosis in four patients with iron deficiency in a retrospective survey of 31 patients with MPD and 26 patients with reactive thrombocytosis ([162]). Serum IL-6 concentrations were elevated in 86% of 143 patients with reactive thrombocytosis, but concentrations were elevated in none of the 13 patients with thrombocytosis and MPD ([163]). Tefferi et al. measured plasma IL-6 and C-reactive protein (CRP) levels in reactive versus clonal thrombocytosis and found that these tests were elevated in 60% of patients with reactive thrombocytosis ([164]). There was a correlation between IL-6 and CRP levels (R = 0.6), so the CRP can be used as a surrogate measurement. Therefore, a normal IL-6 or CRP value is not discriminatory, but an elevated value suggests reactive thrombocytosis. Serum thrombopoietin levels are nondiscriminatory ([165], [166]).

Bone marrows from 47 patients with MPD and 16 patients with reactive thrombocytosis and platelet counts over 1 million/μl were analyzed by three independent pathologists who were blinded to diagnosis. They assessed bone marrow cellularity, iron and reticulin content, the number of megakaryocytes per square millimeter, and the presence of megakaryocyte clusters and concluded that the spectrum of bone marrow findings was indistinguishable among the MPDs and there was considerable overlap with reactive thrombocytosis ([167]). Megakaryocyte ploidy, by analysis of Feulgen-stained bone marrow aspirate smears and by two-color flow cytometry, was also assessed in patients with ET and reactive thrombocytosis and was not found to be discriminatory ([168], [169] and [170]). The presence of emperipolesis in paraffin sections of the bone marrow was also not discriminating ([171]).

A simple scoring system has been devised for distinguishing patients with MPD from patients with reactive thrombocytosis ([172]). Items to be scored include splenomegaly, endogenous erythroid production in culture, platelet nucleotide ratio, platelet distribution width, and the presence or absence of clinical ischemia. Although this scoring system did predict primary thrombocythemia, it has not been confirmed and is not easily translated into clinical practice.

Treatment

Treatment of patients with ET remains controversial, although many physicians have long favored treatment of all symptomatic patients or patients who have platelet counts above 1 million/μl or 1.5 million/μl. Earliest treatment modalities included radioactive phosphorus (^{32}P) ([173], [174]) or alkylating agents (i.e., melphalan and busulfan) ([173]), but both of these therapies appear to increase the transition rate to acute leukemia, myelodysplastic syndrome, and secondary malignancies. Current investigation continues to be directed toward finding the least leukemogenic therapy, especially for young patients who require long-term therapy.

ANTIPLATELET AGENTS Aspirin is effective at reducing symptoms and signs of microvascular occlusion in essential thrombocythemia and should be considered the treatment of choice for these lesions. A single dose of aspirin relieves symptoms of erythromelalgia for 2 to 3 days in the majority of patients ([108], [115]). Daily aspirin therapy also abolishes cerebral microvascular symptoms, although aspirin may prolong the bleeding time more in ET patients than in healthy controls ([104], [175]).
HYDROXYUREA There is now extensive experience using hydroxyurea, a ribonucleotide reductase inhibitor, for treatment of ET and the other MPDs ([176]). When this drug was introduced, it was not believed to be leukemogenic. Recent studies demonstrate that the incidence of acute leukemia is less than 5%, and cytogenetic changes in chromosome 17 can be detected ([177], [178]). The incidence increases in patients treated with hydroxyurea in combination with other alkylating agents ([135], [177], [178] and [179]). Hydroxyurea (at doses of 15 to 30 mg/kg/day) has a rapid onset of action, with control of thrombocytosis achieved in most patients between 2 and 6 weeks ([127]). Patients who are symptomatic and require emergent care should simultaneously begin daily plateletpheresis. In combination with hydroxyurea at a dose of 1.5 to 3.0 g/day, plateletpheresis can lower platelet counts to 500,000/μl or less in several daily treatments ([180]). Dose-related, rapidly reversible leukopenia is the major side effect of hydroxyurea, so close monitoring of the blood count is recommended. Patients also develop chronic macrocytosis, with mean corpuscular volume typically in the range of 100 to 120 μm ^{3}, and hydroxyurea-induced dermatologic manifestations ([181], [182]). Bone marrow myelofibrosis has been reduced during

treatment with hydroxyurea in patients with essential thrombocythemia and other MPDs ([183]). Hydroxyurea was the drug used in the only published prospective trial in which patients with ET were either treated or observed to determine the benefit of therapy ([184]). Patients who were older than 60 years of age, or had a previous thrombosis, or both, and had a platelet count between 600,000 and 1,500,000/µl were randomized between observation and treatment, and the rates of thrombosis and hemorrhage were compared. There was a significant difference in thrombotic episodes between the groups; the treated group had one cerebral and one cardiac occlusive episode, and the untreated patients had 14 episodes: 1 cerebral occlusive episode, 5 transient ischemic attacks, 5 episodes of digital microvascular ischemia, 2 episodes of superficial phlebitis, and 1 episode of iliofemoral venous thrombosis. The authors recently extended their period of observation of these patients to a median of 6 years. It is important that none of the 20 patients who remained untreated developed a secondary malignancy compared to 3.9% in the hydrea-alone group and 33.0% of the hydrea-plus-busulfan group ([178]). Although this is a landmark prospective randomized study of treatment versus no treatment, these results must be examined carefully before all patients with thrombocythemia are committed to potentially harmful long-term treatment programs. At this time, it is appropriate to treat patients with platelet counts greater than 1.5 million/µl, symptomatic patients, and asymptomatic older patients who may also have vascular disease, which makes them more likely to have cardiovascular or cerebrovascular complications of thrombocytosis. Asymptomatic younger patients with platelet counts less than 1.5 million/µl can probably be followed closely without treatment to reduce the risk of leukemia, which still may be a concern of long-term hydroxyurea treatment.

ANAGRELIDE Results of a multicenter trial demonstrate that daily oral anagrelide, a quinazolin derivative, promptly lowers platelet counts in over 80% of patients with essential thrombocythemia ([185], [186], [187], [188] and [189]). The drug probably lowers platelet counts in humans by inhibiting the maturation of megakaryocytes and decreasing megakaryocyte proliferation, not by changing platelet survival ([190], [191]). Anagrelide has little effect on the white blood cell count but does lower the red blood cell count slightly in approximately one-third of patients. Long-term treatment may be associated with significant anemia (>3 g/dl) in up to 25% of patients ([189]). The most common and prominent nonhematologic side effects in the study were cardiovascular, with 25% of patients developing fluid retention or edema. Several patients developed congestive heart failure, and there were two episodes of sudden death. Patients may also develop headaches, nausea, or diarrhea, which decrease with continued treatment.

a-INTERFERON A number of reports document the effectiveness of a-interferon administered subcutaneously in reducing platelet counts and reducing the number of symptoms in patients with thrombocythemia and thrombocytosis caused by other MPDs ([192], [193], [194], [195], [196], [197], [198], [199], [200], [201], [202], [203], [204], [205], [206] and [207]). Dosages used have ranged from 21 to 35 million units per week for the induction phase of treatment, which usually lasts 4 to 6 weeks. Complete and partial response rates are usually above 80% in most patient series reported. Maintenance doses are then based on the minimal dose required to sustain a complete (below 450,000/µl) or partial (below 600,000/µl) remission and usually are 3 million units three times per week to 3 million units daily. Side effects include initial flulike symptoms and then leukopenia, weight loss, alopecia, and development of thyroiditis ([199]) or thyroid antibodies ([196]) with long-term treatment. Platelet counts usually rise quickly after therapy is stopped ([195], [196], [208]), but there are several reports of patients who have maintained sustained responses lasting months after a long-term maintenance dose was stopped ([199], [204], [205]). a-Interferon appears to reduce platelet counts primarily by its antiproliferative effect, as demonstrated in both *in vivo* and *in vitro* studies ([209], [210] and [211]). A slight reduction was noted in platelet mean lifespan, but no effect was noted on splenic platelet pools ([212]) or reticuloendothelial activity in the spleen. Serial bone marrow examinations have demonstrated decreased megakaryocyte density and size ([196], [213]) but little reduction in reticulin in most patients ([198]). Serial platelet function studies have demonstrated only partial correction despite reduction in platelet numbers ([201]).

TREATMENT DURING PREGNANCY Patients with ET who become pregnant have a normal delivery of a full-term, healthy infant in 50 to 57% of pregnancies ([214], [215] and [216]). The remainder of the pregnancies were complicated by increased first trimester spontaneous abortions, intrauterine death, or growth retardation ([29], [215], [216], [217], [218], [219], [220], [221] and [222]). Placentas from some of these pregnancies demonstrate infarction and villous fibrosis, suggesting that platelet aggregation results in placental thrombosis and fetal intrauterine growth retardation ([213], [218], [223], [224]). Platelet counts decrease during pregnancy in patients who were either untreated or treated with only aspirin ([216], [217], [219], [223], [224] and [225]). In each of the reported cases, the platelet count then rose to prepregnancy levels in the postpartum period. The nadir in platelet count occurred during the second trimester and was maintained until term ([216], [225]). During normal pregnancy, a reduction in platelet count of 15 to 20% is not uncommon because of the modest increase in blood volume ([226], [227]). However, the reduction of platelet counts in patients with ET is greater than expected and has been theorized to be caused by either increased concentrations of estrogen or adrenocortical hormones ([217]) or the elaboration of a placental or fetal factor that down-regulates platelet production ([223]). Patients with essential thrombocythemia who become pregnant have been either observed ([214], [223], [228]) or treated with aspirin ([213], [214], [215], [216], [217], [218] and [219], [222], [224], [225], [229]), plateletpheresis ([220], [221]), hydroxyurea ([230]), or a-interferon ([231], [232], [233], [234], [235] and [236]). There is no evidence that any of these therapies made a significant difference in outcome, and the need for treatment and the best treatment remain controversial. However, if a patient needs to be treated, a-interferon appears to be well tolerated, and even if the therapy is started before conception, the pregnancies have resulted in normal, full-term infants.

REACTIVE THROMBOCYTOSIS

As noted in Table 57.1, there are a number of causes for secondary or reactive thrombocytosis ([237], [238], [239], [240], [241], [242], [243], [244], [245] and [246]), and the Polycythemia Vera Study Group criteria for the diagnosis of essential thrombocythemia require that each of them be ruled out before a diagnosis of essential thrombocythemia is made.

Pathophysiology

Reactive thrombocytosis may result from persistent overproduction of one or more thrombopoietic factors that act on megakaryocytes or their precursors. IL-6, leukemia inhibitory factor, stem cell factor ([247]), and granulocyte colony-stimulating factor or GM-CSF ([248]) may all contribute to the platelet overproduction. The evidence for a primary role for IL-6 is currently the strongest, and there is evidence in mice that other cytokines, such as IL-1 and tumor necrosis factor, increase megakaryocytopoiesis through production of IL-6 ([249]). IL-6 is a growth factor produced mainly by monocytes, although lymphocytes, endothelial cells, and fibroblasts are also capable of production ([250]). Serum levels of IL-6 are increased in inflammatory disorders, malignancies, and after surgery and trauma, and it is believed to play a role in inflammation and the immune response. Increased serum IL-6 was found in only a few patients with thrombocytosis and iron deficiency ([163]), suggesting that thrombocytosis in these patients may have an entirely different pathophysiologic mechanism.

Recombinant IL-6 increases megakaryocyte counts ([251]) and megakaryocyte size ([252]) in culture, and infusions of IL-6 lead to increased platelet production and numbers in mice ([253]), primates ([254], [255]), and humans ([256], [257]). Treatment with anti–IL-6 in patients with IL-6 infusion-induced thrombocytosis progressively diminishes platelet counts with a return to baseline several days after the infusion is stopped ([256]).

Cultured mesothelial tumor cells from a patient with marked thrombocytosis produced large amounts of IL-6 and small amounts of GM-CSF and macrophage colony-stimulating factor ([258]), and serum IL-6 concentrations were reported to be increased in patients with metastatic cancer-related thrombocytosis ([259]). Serum and ascitic fluid concentrations of IL-6 were increased in patients with epithelial ovarian cancer ([260]). Serum IL-6 levels correlated with disease activity and thrombocytosis in patients with rheumatoid arthritis ([261], [262]). Finally, serum concentrations were increased in more than 80% of patients with reactive thrombocytosis ([24], [163]).

Temporally, serum IL-6 increases before thrombopoietin levels, and then platelet counts rise in postoperative patients, patients with acute infection, and patients with thrombocytosis and Kawasaki disease ([263], [264] and [265]). Administration of IL-6 to cancer patients results in a corresponding increase in thrombopoietin plasma levels ([266]). The relationship between IL-6 and thrombopoietin still needs to be clarified.

Clinical Picture

Patients with reactive thrombocytosis may have platelet counts as high as those of patients with MPDs, but hemorrhage and thrombosis are unusual. Schilling's series of “platelet millionaires” demonstrated that only 28 of 158 patients had a MPD ([9]). The remainder of patients had reactive thrombocytosis. There is even a single report of a patient with lung cancer who had a sustained platelet count of 6 million/µl, which decreased to normal after a single course of chemotherapy and irradiation of the lung neoplasm ([267]). Bleeding, thrombosis, and vasoocclusive phenomena occur in less than 5% of patients, although there are case reports of acute myocardial infarctions and cerebrovascular occlusions in patients after splenectomy or coronary artery bypass surgery and in those with iron deficiency–related thrombocytosis ([244], [245], [268]).

Thrombocytosis is a predictable finding after splenectomy, with platelet counts peaking 1 to 3 weeks after surgery at levels that may exceed 1 million/µl. The platelet count usually returns to normal, but weeks, months, or even years may be required. If a splenectomy is performed in patients with thrombocytosis associated with

hemolytic anemia, the postsplenectomy thrombocytosis persists for as long as the anemia persists. These findings suggest some relationship between erythropoietic and thrombopoietic control mechanisms. This relationship may explain in part the thrombocytosis of iron deficiency associated with chronic blood loss as well.

Laboratory Findings

There are no specific laboratory findings in patients with reactive thrombocytosis, and the diagnosis ultimately depends on diagnosis of the underlying problem. Serum IL-6 concentrations (measured by activity assays or enzyme-linked immu-nosorbent assay) are increased in the majority of patients believed to have reactive thrombocytosis and in none of the patients with clonal megakaryopoiesis, but these tests are not clinically available.

Hollen found increased serum IL-6 concentrations in 80 to 100% of his patients with inflammation, malignancy, or recent surgery ([163]). Only 50% of the anemic patients had increased concentrations of IL-6, and only one of five patients with iron deficiency were in this group.

Tefferi et al. compared serum IL-6 and CRP in patients with primary and secondary thrombocytosis, hoping to find a surrogate marker for IL-6 production ([164]). They found that 19% of patients with reactive thrombocytosis had an increased serum IL-6 but a normal CRP, and 19% had normal serum concentrations of both. Thus, an elevated CRP might be useful for diagnosis of reactive thrombocytosis, but a normal serum concentration is not discriminatory.

Treatment

Reactive thrombocytosis resolves when the underlying disorder is treated successfully, and it is rare for any additional therapy to be required. However, symptomatic patients may benefit from simultaneous plateletpheresis and hydroxyurea therapy until symptoms resolve and the platelet count is controlled.

Qualitative Disorders of Platelet Function

Disorders of platelet function are difficult to classify because of the rarity of many of the disorders and the numerous incompletely studied cases. However, the study of patients with congenital disorders of platelet function has made it possible to understand the critical structure-function relationships that determine the normal function of platelets. Information concerning disordered platelet function has accumulated at an unprecedented rate in the past decade and has been reviewed comprehensively ([1], [2], [3], [4], [5], [6], [7], [8], [9], [10] and [11]).

In the classification presented in Table 58.1 and Figure 58.1, hereditary disorders are divided into groups based primarily on the major platelet abnormality responsible for the coagulopathy. Platelet dysfunction also may complicate a wide variety of acquired disorders, but seldom is it the sole abnormality. The acquired disorders of platelet function discussed in this chapter emphasize disorders in which abnormal platelet function appears to be a major cause of bleeding.

TABLE 58.1. Disorders of Platelet Function

Hereditary disorders of platelet function
Adhesion defect
Bernard-Soulier syndrome
Aggregation defect
Glanzmann thrombasthenia
Secretion disorders
Granule deficiencies
a-Granule abnormalities
Gray platelet syndrome
d-Granule (dense body) abnormalities
Storage pool disease: isolated dense body deficiency
Hermansky-Pudlak syndrome
Chédiak-Higashi syndrome
Wiskott-Aldrich syndrome
Thrombocytopenia and absent radii
a/d-Granule deficiency
Defects of signal transduction and secretion
Impaired liberation of arachidonic acid
Cyclooxygenase deficiency
Thromboxane synthetase deficiency
Thromboxane A_2 receptor abnormalities
Defects in calcium mobilization
Defects of platelet coagulant activity
Miscellaneous
Hereditary macrothrombopathy/sensorineural hearing loss
Acquired disorders of platelet function
Drug-induced platelet dysfunction
Analgesics
Antibiotics
Cardiovascular drugs
Psychotropic drugs
Uremia
Disorders of the hematopoietic system
Paraproteinemias
Myelodysplastic syndrome/acute nonlymphocytic leukemia
Myeloproliferative disorders

HEREDITARY DISORDERS OF PLATELET FUNCTION

Defect in Platelet Adhesion: Bernard-Soulier Syndrome

Bernard-Soulier syndrome is a rare disorder that was first described in 1948 as “dystrophie thrombocytaire hemorrhagipare congenitale” ([12]). It is characterized by an increased bleeding time, mild thrombocytopenia, giant platelets, defective adhesion, and bleeding out of proportion to the reduction in platelet numbers ([1], [3], [13]). The morphologic abnormalities of the platelets are the most consistent and striking feature of the disorder (Fig. 58.2), with platelets as large as 10 µm or more in diameter ([14]). In one study, platelet size was normal when intact platelets were studied in plasma, in contrast to marked platelet “giantism” evident in stained smears, suggesting that giant platelets are formed as the result of an aberrant shape change after platelet activation ([15]).

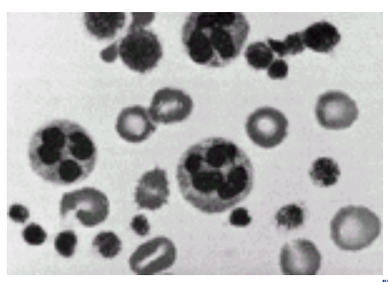

Figure 58.2. Bernard-Soulier platelets. Giant platelets in the Bernard-Soulier syndrome (×1200, Wright stain). (From Bithell TC, Parekh SJ, Strong RR. Platelet function studies in the Bernard-Soulier syndrome. Ann N Y Acad Sci 1972; 201:145–160, with permission.)

There are no specific abnormalities in the ultrastructure of affected platelets, but a dilated canalicular system, prominent dense tubular system, and vacuolization have been described ([16], [17]). Freeze-fracture studies have demonstrated abnormal distribution and size of membrane-associated particles that were similar to those changes seen in thrombasthenia, the other major defect of platelet membrane glycoproteins ([18]). The megakaryocytes are normal or increased in number, but they reveal no characteristic morphologic abnormalities when viewed with light microscopy. Electron microscopic studies have revealed abnormalities of the dense tubular system ([19]) and vacuolization of the demarcation membrane system ([20]).

GLYCOPROTEIN ABNORMALITIES Biochemical studies of platelets from patients with the Bernard-Soulier syndrome reveal a quantitative or qualitative abnormality of the membrane GPIb/IX/V complex in platelets ([21], [22], [23], [24], [25], [26], [27], [28] and [29]) and megakaryocytes ([20], [30]). GPIb is a surface membrane heterodimer consisting of an alpha (Iba) and a beta chain (Ibß) that are covalently linked by a disulfide bond. Glycoprotein Ib forms a noncovalent complex with GPIX and GPV. These glycoproteins are all members of the leucine-rich glycoprotein family and are required in the interaction between von Willebrand factor (vWF) and the platelet membrane that is essential for normal platelet adhesion during the early phases of primary hemostasis ([31]). This view has been supported by the demonstration that affected platelets do not adhere to denuded vascular segments when perfused at a high shear rate ([19], [32], [33] and [34]) and do not bind normally to noncollagenous subendothelial microfibrils ([35]). Deletion of glycoprotein Ib/IX/V also explains the failure of affected platelets to aggregate in the presence of ristocetin (even after addition of normal plasma or vWF) or bovine vWF. A variety of mutations in the glycoprotein Iba, Ibß, and IX genes have been now described in classic Bernard-Soulier patients ([36]). A genetic mutation and deficiencies of GPIba, GPIbß, or GPIX, but not GPV, result in decreased expression of the Ib/IX/V complex on the surface of the platelets ([37], [38] and [39]). Variant forms of Bernard-Soulier syndrome have also been described in which patients have decreased, but measurable amounts of presumably nonfunctional glycoproteins on the platelet surface ([40], [41], [42], [43], [44], [45] and [46]).

CLINICAL FEATURES Onset of moderate to severe bleeding of the purpuric type, including bruising, epistaxis, gingival bleeding, and menorrhagia, usually begins at an early age. Petechiae are rare, and patients do not usually demonstrate spontaneous bleeding, but posttraumatic and postoperative bleeding may be severe; hemorrhagic deaths have occurred. The disorder is usually inherited as an autosomal-recessive disorder, and consanguinity is common in reported kindreds. An occasional patient with dominant inheritance has been reported ([47]). Heterozygotes typically are asymptomatic but have “giant” platelets and reduced levels of GP Ib/IX/V ([14]). An acquired pseudo–Bernard-Soulier syndrome has been reported in association with autoantibody formation ([48], [49]). A platelet autoantibody isolated from a patient with the Bernard-Soulier syndrome who had received multiple transfusions was shown to impair aggregation of normal platelets induced by ristocetin and bovine vWF ([50]). An additional Bernard-Soulier patient developed a transient autoantibody to Ib/IX ([51]).

LABORATORY FINDINGS Laboratory findings usually are characteristic (Table 58.2). The magnitude of thrombocytopenia is variable, appearing to fluctuate from time to time in some patients. The bleeding time is prolonged, but clot retraction and platelet aggregation by adenosine diphosphate (ADP), epinephrine, and collagen are normal. Platelet aggregation by ristocetin is deficient ([52], [53]) and is not corrected by the addition of normal vWF. Platelet survival studies have demonstrated shortened survival in some patients ([30]). Determination of GPIb/IX/V levels in platelets by using platelet membrane analysis and/or immunologic techniques is a precise method for diagnosis of this disorder ([27], [30], [36], [54], [55]).

TABLE 58.2. Laboratory Findings in Disorders of Platelet Function

Test	Bernard-Soulier Syndrome	Thrombasthenia	Storage Pool Disease	Abnormal Release Mechanism
Platelet count	Mild to moderate thrombocytopenia	U normal	U normal	U normal
Platelet morphology	Characteristic “giant” platelets	Normal [a]	Normal; microcytic or macrocytic in some cases	U normal
Bleeding time	U prolonged	Markedly prolonged	V abnormality	U prolonged
Clot retraction	Normal	Deficient	Normal	Normal
Specific tests for platelet factor-3 activity	U normal	Abnormal [b, c]	V abnormality [b]	V abnormality [b]
Platelet retention in glass-bead columns (glass “adhesion”)	Reduced	Reduced [c]	Reduced [d]	Reduced
Platelet aggregation by 5 µM ADP	Normal [e]	Deficient	Normal	Normal
Platelet aggregation by “threshold” concentrations of ADP (0.2–1.5 µm)	Normal [e]	Deficient	Deficient second phase with subsequent disaggregation	Deficient second phase with subsequent disaggregation
Platelet aggregation by dilute collagen suspensions and 5 µM epinephrine	Normal [e]	Deficient	Deficient [f]	Deficient [f]
Platelet aggregation by ristocetin (1.2–1.5 mg/ml)	Deficient [e, g]	Normal	Normal	Normal
Storage nucleotide pool	Normal [h]	Normal	Diminished	Normal
Ancillary laboratory features	Initial shape change lacking or aberrant; membrane GPlb/IX/V deficient	Platelet fibrinogen commonly decreased; platelet alloantigen PLA-1 absent; membrane GPIIb and IIIa deficient	Platelet dense bodies reduced in number; ratio platelet ATP:ADP increased; aggregation abnormalities may be “corrected” by addition of aspirin-treated platelets	*In vitro* effects of aspirin are additive; ratio platelet ATP:ADP normal

ADP, adenosine diphosphate; ATP, adenosine triphosphate; GP, glycoprotein; U, usually; V, variable.

[a] Platelets appear discrete and rounded in stained smears.

[b] Results depend on exact technique used.

[c] Not corrected by added ADP.

[d] Corrected by added ADP.

[e] Aggregation may be abnormally rapid.

[f] Second wave of epinephrine-induced aggregation absent or reduced.

[g] Not corrected by added factor VIII.

[h] Corrected for increased platelet volume.

TREATMENT No effective treatment for the Bernard-Soulier syndrome has been described. The effects of platelet transfusions have not been studied systematically, but in one case, massive platelet transfusions shortened the bleeding time and appeared to be therapeutically effective. However, alloimmunization may occur when platelet transfusions are used in patients with any of these platelet disorders, and HLA-matched platelets may be required. Administration of deamino-D-arginine-vasopressin (DDAVP) may transiently improve the bleeding time ([56], [57] and [58]) and hemostasis following procedures ([59]). Recombinant factor VIIa was used successfully to treat recurrent epistaxis in a child with Bernard-Soulier syndrome ([60]). Results from use of antifibrinolytic agents are more variable, and the administration of adrenal corticosteroids and splenectomy are usually ineffective.

Defect in Platelet Aggregation: Glanzmann Thrombasthenia

Glanzmann thrombasthenia is an autosomal-recessive disorder of platelet aggregation characterized by a life-long bleeding tendency due to quantitative or qualitative abnormalities of the platelet membrane complex glycoprotein IIb-IIIa (GPIIb-IIIa) ([61], [62], [63], [64], [65], [66], [67] and [68]). In denuded vascular segments, thrombasthenic platelets adhere to the subendothelium and undergo shape change and degranulate normally, but platelet-to-platelet interaction is totally lacking due to the lack of GPIIb-IIIa, the site of platelet fibrinogen binding ([69], [70]). Binding sites for thrombin are preserved in thrombasthenic platelets ([71]). Furthermore, studies of platelet enzymes and of the biochemical pathways within affected platelets that lead to the synthesis of prostaglandins and thromboxanes and provide energy for various cellular functions appear normal ([72]).

GLYCOPROTEIN ABNORMALITIES Deficiency or aberration of either membrane glycoprotein IIb or IIIa is the basic biochemical defect in thrombasthenia. GPIIb-IIIa is a calcium-dependent heterodimer complex that is a member of the integrin family of cellular receptors ($a_{IIb}ß_3$) and can bind fibrinogen, fibronectin, vitronectin, and vWF. The genes for GPIIb and GPIIIa are distinct but are physically located within 250–260 kb of each other on the long arm of chromosome 17 (17;q21-22). The genetic abnormalities that have been identified involve one or the other glycoprotein; however, heterodimer assembly in the Golgi region, is required to form the normal membrane complex. If genetic defects prevent normal synthesis of one of the glycoproteins, the heterodimer is not normally formed in the Golgi region and neither molecule of the heterodimer is expressed on the cell surface ([73], [74] and [75]). The unaffected glycoprotein is then retained in the endoplasmic reticulum and degraded. This results in the lack of a fibrinogen receptor and defective fibrinogen binding after platelet activation. Platelet aggregation, which requires this protein, is therefore deficient or completely absent ([65], [76], [77]), and the binding of fibronectin to thrombin-stimulated thrombasthenic platelets is also reduced ([78]). The glycoprotein abnormalities associated with thrombasthenia are uniform throughout the platelet population ([79]) and are present in the precursor megakaryocyte ([80]) and endothelial cells ([81]). Thrombasthenic patients are classified as type 1, type 2, or variant depending on the severity of their GPIIb-IIIa deficiency, fibrinogen binding, and clot retraction ([82], [83]) (Table 58.3).

TABLE 58.3. Classification of Glanzmann Thrombasthenia

Glycoprotein IIb-IIIa	Fibrinogen Binding	Clot Retraction
Type 1 <5%	Absent or severely deficient	Absent
Type 2 10–20%	Present	Normal or moderately deficient
Variant >50%	Variable	Variable

More than 50 genetic abnormalities have been described in patients with Glanzmann thrombasthenia, including missense mutations, nonsense mutations, splice site mutations, deletions, and point mutations ([84], [85]). Both GPIIb and IIIa mutations are found in each of the types of thrombasthenia, and the genetic defects are constant within a specific cluster of patients. The Iraqi Jews and the Arab patients in Israel have distinct and separate genetic defects even though they are phenotypically identical. Marked diminution of platelet alloantigens associated with GPIIb and GPIIIa occurs in patients with thrombasthenia. These include PLA-1 (Zwa) and its allele PLA-2, Bak (Lek), and Pen (Yuk) ([86], [87], [88] and [89]). Autoantibodies that presumably are specific for the deleted glycoproteins were demonstrated in the blood of transfused patients with thrombasthenia ([90], [91]), and these antibodies could reproduce the thrombasthenic defect in normal platelets. Acquired thrombasthenia has resulted from *de novo* development of similar antibodies ([92]).

CLINICAL FEATURES Thrombasthenia is inherited as an autosomal-recessive trait, and consanguinity is often present in affected kindreds, resulting in geographic clusters of patients in various parts of the world. Most patients are diagnosed before 5 years of age. Common clinical manifestations include bleeding of the purpuric type, epistaxis, menorrhagia, and gingival bleeding ([83], [93], [94]). Bleeding at menarche is severe enough to require transfusions in most patients. Petechiae are uncommon, but generalized ecchymoses may be striking. Spontaneous bleeding is uncommon but may be disabling. Dissecting hematomas and hemarthrosis are rare ([83], [95]), but posttraumatic and postoperative hemorrhage may be serious. Pregnancy and delivery represent a severe hemorrhagic risk, and bleeding may not always be preventable with platelet transfusions. Thrombasthenia can be classified as a severe bleeding disorder. However, the severity of bleeding manifestations is quite variable, and there is no correlation with the amount of GPIIb-IIIa on the platelet membrane. Prognosis is excellent with supportive care, and patients rarely die of hemorrhage. The severity of bleeding appears to decrease with increasing age. Heterozygotes are asymptomatic, and laboratory studies usually reveal no abnormalities ([96]). Carriers of thrombasthenia have approximately one-half the normal amount of membrane GPIIb and IIIa; techniques involving the use of hybridoma-produced antibodies or monoclonal antibodies may provide an accurate means of detecting such heterozygotes ([96], [97] and [98]).

LABORATORY FINDINGS The laboratory findings associated with this disorder are summarized in Figure 58.3 and Table 58.2. A prolonged bleeding time, deficient clot retraction, and deficient platelet aggregation with ADP, collagen, epinephrine, and thrombin are characteristic and constant features. Ristocetin-induced aggregation and coagulation tests are normal. Thrombasthenic platelets are present in normal numbers and are morphologically normal when viewed by light microscopy. In stained blood smears, however, the platelets remain discrete, round, and separate as a result of deficient aggregation. This phenomenon may explain reports of morphologic abnormalities. Electron microscopic analysis reveals only variable and probably nonspecific ultrastructural abnormalities in thrombasthenic platelets ([99]). Studies using the freeze-etching technique, however, reveal consistent membrane abnormalities ([18]). Methods using monoclonal antibodies are highly sensitive and specific as a means of demonstrating the thrombasthenic defect in the platelet membrane ([27]).

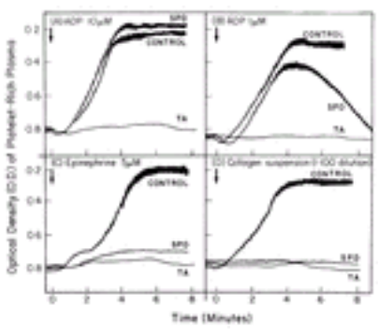

Figure 58.3. Aggregometry tracings in patients with storage pool disease and thrombasthenia **(A)**. Aggregating agents were added at zero time. Storage pool disease (SPD): note the disaggregation observed with low adenosine diphosphate (ADP) concentrations **(B)**, the absence of a secondary wave of epinephrine-induced aggregation **(C)**, and the absence of collagen-induced aggregation **(D)**. The patient was a 31-year-old man with partial albinism. Ancillary findings included characteristic pigmented reticulum cells in the bone marrow and abnormally small platelets. Thrombasthenia (TA): note the absence of aggregation. The patient was a 25-year-old woman.

TREATMENT No specific treatment for thrombasthenia is known. It is important to anticipate the risks of bleeding before performing procedures and to administer

prophylactic platelet transfusions even if the patient does not have a history of prior bleeding, because bleeding in thrombasthenia is so unpredictable. Transfusions should be continued until wound healing is complete. However, a significant number of transfused patients will develop HLA and/or specific antibodies to IIb/IIIa, which will limit future treatment with platelets. Bleeding can also be treated with local measures (compression), local agents (topical thrombin, fibrin glue), and antifibrinolytic agents (e-aminocaproic acid, tranexamic acid). Some patients demonstrate shortening of their bleeding time after treatment with DDAVP ([57]). Patients who have severe menorrhagia should be treated with hormone therapy. Birth control pills usually will control blood loss, and iron should be replaced as necessary to prevent iron deficiency anemia. There is accumulating evidence that recombinant VIIa infusions are both effective and usually quite safe in patients with inherited platelet qualitative disorders, including thrombasthenia ([100], [101] and [102]). Several patients with severe bleeding have been successfully treated with allogeneic bone marrow transplantation, and there is a recent report of successful megakaryocyte synthesis of the integrin ß $_3$ subunit after gene therapy ([103] and [104]).

Defects in Secretion

Abnormal platelet secretion may be caused by either defects or deficiencies in platelet granules (a, d, or both) or defects in receptor-mediated signal transduction. Patients have been identified with each of these types of defects, and their platelets have been well studied to define the defect as accurately as possible. However, little is known about the pathogenetic mechanisms for these abnormalities of platelet morphogenesis or abnormal secretion.

a-GRANULE DEFICIENCY: GRAY PLATELET SYNDROME Gray platelet syndrome is a rare platelet disorder characterized by a selective deficiency in the number and contents of platelet a-granules ([105], [106]). Megakaryocytes demonstrate early formation of a-granules, but granules then decrease during maturation, resulting in mature megakaryocytes with only occasional small, abnormal granules ([106], [107] and [108]). GPIV ([109]), GPIIb-IIIa ([110]), and P-selectin ([111], [112]) are present in the membranes of these abnormal granules and demonstrate redistribution during activation. Endothelial cells in the dermal capillary network in gray platelet patients demonstrate normal Weibel-Palade bodies, vWF, and membrane P-selectin; therefore, the defect appears limited to megakaryocytes and platelets ([113]). A similar defect in neutrophils was recently reported in a single family ([114]). Deficiencies of a-granule proteins include platelet factor 4, ß-thromboglobulin, fibrinogen, fibronectin, vWF, platelet-derived growth factor, and thrombospondin ([115], [116], [117], [118], [119] and [120]). These proteins appear to be synthesized but not stored normally in the a-granules. Immunoglobulins and albumin are variably present ([121], [122]). Lysosomes, mitochondria, and dense bodies are present in normal numbers in gray platelets, and dense bodies contain normal amounts of adenine nucleotides and serotonin ([107], [119]). The lack of a-granules gives rise to characteristic morphologic abnormalities of affected platelets. In Wright-stained blood smears, they are gray or blue, vacuolated, and washed-out or ghostlike in appearance (Fig. 58.4). In electron photomicrographs, an almost total lack of a-granules is evident in platelets and in megakaryocytes (Fig. 58.5) ([107], [116]). The a-granules that are present are both small and abnormal in appearance. Some patients may demonstrate increased emperipolesis ([123]). Gray platelets have a normal aggregation and release response to arachidonic acid and ionophore and generate thromboxane normally. Aggregation to ADP, epinephrine, collagen, and thrombin is more variable. Release from dense bodies usually is subnormal, particularly when induced by thrombin ([119], [122]). Abnormal calcium influx and mobilization from intracellular stores have also been reported ([124], [125]).

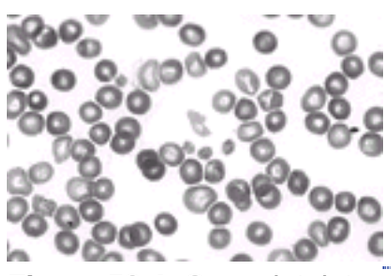

Figure 58.4. Gray platelet syndrome platelets. Giant platelets in the gray platelet syndrome. (×1200, Wright stain). See Color Plate.

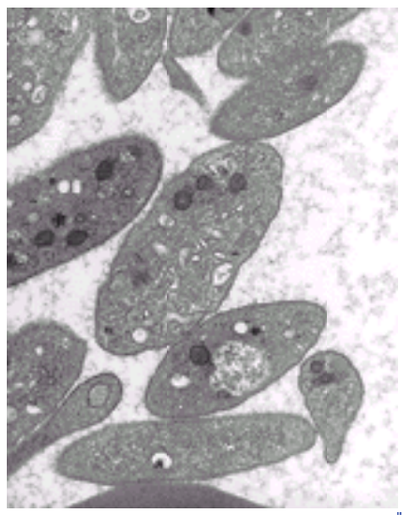

Figure 58.5. Gray platelet syndrome platelets. The large platelets are devoid of a-granules but contain normal numbers of mitochondria and dense bodies. (Figure courtesy of Dr. Paula E. Stenberg.)

Clinical Features The disorder is inherited as an autosomal trait and is associated with mild to moderate thrombocytopenia (20,000 to 150,000/µl) and moderately enlarged platelets ([126]). Bleeding time usually is prolonged, and platelet aggregation induced by collagen or thrombin usually is deficient ([116], [119]). Platelet survival may be shortened, but splenomegaly is rare ([127]). The bleeding diathesis usually is mild, and treatment is seldom required. The bone marrow in many patients is inaspirable and demonstrates a normal number of megakaryocytes and increased reticulin, occasionally around clusters of megakaryocytes ([116], [126], [127], [128], [129] and [130]). Patients do not, however, demonstrate clinical signs of myelofibrosis.

Treatment Corticosteroids are ineffective, and DDAVP shortens the bleeding time in some ([120]), but not all, patients ([131]). Platelet transfusions have not been evaluated systematically.

d-GRANULE DEFICIENCY: DENSE BODY DEFICIENCY Some patients have a single deficiency of dense bodies; others have dense body deficiency in association with other defects such as oculocutaneous albinism (i.e., Hermansky Pudlak syndrome) or immune deficiencies (Wiskott-Aldrich syndrome).

Storage Pool Disease The abnormality of the release reaction associated with this disorder appears to be the result of a deficiency of dense bodies (d-granules), which store adenine nucleotides and serotonin in affected platelets and megakaryocytes ([132], [133] and [134]). The platelets are morphologically normal on Wright-stained smears, but they are deficient in dense bodies by electron microscopy. Electron microscopic analysis has revealed both subnormal numbers of dense bodies in the platelets of patients with this disorder ([17], [133]) and empty dense bodies ([135], [136]). The morphologic changes that accompany activation of platelets, including the “centralization” of organelles and degranulation, are essentially normal in storage pool disease (SPD) ([133]). a-Granules are normal, and lysosomal granule enzymes are secreted normally ([137]). The total amount of platelet ADP and adenosine triphosphate (ATP) in the platelet is reduced, and the ratio of ATP to ADP is increased due to the change in distribution between the metabolic and granule pools of nucleotides ([132], [138], [139]). The conversion of labeled ATP into inosine monophosphate and hypoxanthine proceeds normally, an observation that suggests the pathways that supply metabolic ATP to the release mechanism are intact ([132], [140], [141]). The platelets are deficient in serotonin, calcium, and pyrophosphate, which are also contained in the dense bodies ([141], [142] and [143]). Abnormalities of platelet adhesion have been reported in some patients ([132], [144], [145]), especially at hematocrit concentrations between 30 and 40% ([146]). These abnormalities can, however, be corrected by the addition of red blood cells, suggesting that ADP may be necessary for normal platelet spreading on the subendo-thelium ([146]). The release mechanism also is abnormal in some patients with SPD ([137]). Collagen-induced production of prosta-glandins E $_2$ and F $_2$a and the potentiating effects of prostaglandin E $_2$ on the release reaction are deficient ([147]), even though the platelets can convert arachidonic acid to the prostaglandin metabolites (malondialdehyde, PGG $_2$, PGH $_2$, thromboxane A $_2$) ([148], [149]).

Clinical Features Patients with SPD have a bleeding diathesis that can be mild to moderate. The most common symptoms are epistaxis, purpura, menorrhagia, and posttraumatic and postsurgical bleeding. The ADP content of the dense bodies has been correlated with the bleeding time ([150]). Inheritance is believed to be autosomal dominant ([139]).

Laboratory Findings Bleeding time is increased, with normal platelet counts and morphology. Aggregation studies are abnormal, demonstrating an impaired response to collagen and a deficient secondary wave with ADP, epinephrine, and low concentrations of thrombin (Fig. 58.3, Table 58.2) ([134], [139]). Ristocetin

aggregation is normal ([134], [139]). Subsets of patients have been identified who have a prolonged bleeding time, decreased dense bodies, and ADP release but normal platelet aggregation ([151], [152]). The diagnosis of dense-body SPD requires a combination of studies, including bleeding time, platelet aggregation with lumiaggregometry to assess storage pool adenine nucleotides, thrombin-induced radioactive serotonin uptake and release, and transmission electron microscopy. Methods have recently been developed to diagnose SPD using mepacrine and flow cytometry ([153], [154]).

Treatment Approximately 75% of patients with SPD demonstrate shortening of their prolonged bleeding times 1 hour after infusion of DDAVP ([57], [155], [156] and [157]). This improvement in hemostasis is associated with less bleeding after procedures ([158]), and in combination with an antifibrinolytic agent, such as tranexamic acid ([159]) or ethamsylate ([160]), the treatment may be even more effective. There is no correlation between pretreatment concentrations of plasma vWF antigen or activity and response to DDAVP. In addition, there is no correlation between efficacy and posttreatment changes in platelet aggregation ([57]). Preliminary data suggest that intranasal concentrated DDAVP may be similarly effective ([161]). Side effects of DDAVP are minimal, but very young children should have electrolytes and fluid intake followed for 24 hours. However, this response to DDAVP has not been confirmed in a double-blind, placebo-controlled trial in four patients ([162]). Hemostasis is also improved after infusion of cryoprecipitate ([163]). Platelet transfusions should be reserved for life-threatening bleeding because of the development of alloantibodies.

Other Storage Pool Abnormalities SPD, when associated with oculocutaneous albinism and ceroid pigment accumulation in reticuloendothelial cells, has been termed the *Hermansky-Pudlak syndrome* ([164], [165] and [166]). This disorder is inherited as an autosomal-recessive trait. There is worldwide distribution, although the highest prevalence is in Puerto Rico. Three separate Hermansky-Pudlak–causing genes are known ([167], [168]). Patients have a life-long history of easy bruisability, minor bleeding episodes, and prolonged bleeding times. More severe bleeding has been demonstrated to be associated with simultaneous familial deficiencies of vWF ([169], [170]). Pulmonary fibrosis and inflammatory bowel disease, associated with infiltration of ceroid-pigmented reticuloendothelial cells in the lung and colon, have been reported in several cases of this syndrome ([171]). SPD also may be associated with the Chédiak-Higashi syndrome ([172], [173], [174] and [175]), Wiskott-Aldrich syndrome ([176], [177], [178], [179], [180] and [181]), and TAR syndrome (thrombocytopenia with absent radii) ([182], [183]).

a-d–GRANULE DEFICIENCY Patients have been described who demonstrate both a deficiency in dense bodies and a variable deficiency of a-granules ([141], [148]). These platelets form significantly smaller thrombi in flowing blood than even platelets with dense body deficiency ([145]). Platelet aggregation studies demonstrate defects in secondary aggregation and defects in primary aggregation that are even greater than in SPD ([149]). One patient with severe a-granule deficiency also demonstrated decreased P-selectin after activation ([111]). Bleeding in this disorder is clinically similar to bleeding in SPD and gray platelet syndrome.

Abnormal Receptor-Mediated Signal Transduction and Secretion

Abnormalities of platelet secretion may be caused by abnormalities of membrane receptors for one specific agonist ([184], [185], [186] and [187]) or post receptor-mediated secretory events. A variety of platelet function defects exist that are characterized by an aspirinlike defect in aggregation and secretion. Platelet counts are normal, bleeding times are usually prolonged, and platelet aggregation studies demonstrate abnormalities with weak agonists (i.e., lack of secondary aggregation responses with ADP and epinephrine, and variably deficient aggregation and secretion with collagen) ([2]). The platelets usually aggregate and secrete normally with thrombin and ristocetin. These defects have been reported in case reports only or a limited series of patients. Patients demonstrate mild to moderate bruising, mucosal membrane bleeding, and bleeding after procedures.

IMPAIRED LIBERATION OF ARACHIDONIC ACID Four patients have been described in whom platelet aggregation and secretion responses are normal to exogenous arachidonic acid, with normal generation of thromboxane B_2, but who demonstrate impaired hydrolysis of membrane arachidonic acid and decreased aggregation, secretion, and thromboxane B_2 with ADP, epinephrine, and collagen. Calcium-dependent myosin light chain phosphorylation was normal, demonstrating that the defect is not related to calcium-dependent phospholipase activity ([188]).

CYCLOOXYGENASE DEFICIENCY Several patients have demonstrated abnormal aggregation and secretion responses to exogenous arachidonic acid but normal aggregation and secretion with exogenous PGG_2 and PGH_2 ([189], [190], [191], [192], [193] and [194]). This suggests that the defect in the prostaglandin metabolic pathway is related to the cyclooxygenase enzyme. The defect was also present in the endothelial cell in one patient, resulting in deficient prostacyclin synthesis as well ([192]). Cyclooxygenase has been present in normal amounts but nonfunctional when measured ([194]).

THROMBOXANE SYNTHETASE DEFICIENCY At least three patients have demonstrated a defect in thromboxane synthetase activity with absent aggregation with arachidonic acid and prostaglandin endoperoxides and decreased production of thromboxane B_2 ([195], [196]). These patients and the patients with deficient cyclooxygenase activity produce increased products from the lipoxygenase pathway (hydroxy-eicosatetraenoic acid) instead of thromboxane B_2 and HHT.

IMPAIRED RESPONSE TO THROMBOXANE A_2 Thromboxane A_2 generated from hydrolysis of platelet membrane arachidonic acid is a powerful platelet-activating agent, and its activity, in combination with ADP released from dense bodies, is critical for platelet activation with weak agonists such as ADP, epinephrine, and low concentrations of collagen. Several patients have demonstrated normal thromboxane B_2 production with arachidonic acid but abnormal aggregation and secretion with ADP and epinephrine ([197], [198], [199] and [200]). There is also a defective platelet response to U46619, a thromboxane A_2 agonist, suggesting that the thromboxane receptor is abnormal in this group of patients. An Arg60 to Leu mutation in the thromboxane A_2 receptor has been documented in two unrelated families, with normal ligand-binding affinities, but decreased guanosine triphosphatase activity and second messenger formation as a result of this mutation ([201], [202]). Phospholipase A_2–mediated reactions remain normal in these patients, suggesting a dissociation between phospholipase C–mediated and phospholipase A_2–mediated reactions.

IMPAIRED CALCIUM MOBILIZATION Several patients have been reported to have abnormal platelet function, which is characterized by an abnormal response to A23187 (calcium ionophore) and appears to be limited to abnormalities in calcium mobilization ([203], [204], [205], [206], [207], [208] and [209]). Platelets from these patients may have a variety of defects, each of which could result in the inability to release calcium from intracellular storage organelles and/or influx of extracellular calcium across the plasma membrane. These include abnormalities in thrombin-induced calcium mobilization in patients with macrothrombocytopenia and abnormal membrane complexes ([209]), an abnormality in phospholipase C–mediated hydrolysis of phosphotidylinositol biphosphate and formation of inositol triphosphate and diacylglycerol ([207], [208]), or a defect in calcium-mediated phosphorylation of one of the proteins necessary for normal secretion ([204]).

Defects of Platelet Coagulant Activity

Isolated abnormalities of platelet coagulant activity have been described in several patients ([210], [211], [212] and [213]), but the best studied and understood defect is that found in Scott syndrome ([214]). Mrs. Scott had a normal bleeding time and no increased bruising or bleeding from superficial cuts. She bled extensively after procedures and developed a spontaneous pelvic hematoma. The defect in these patients is manifested by reduced platelet coagulant activity; platelet adhesion, aggregation, secretion, and morphology are all normal. The binding of factors Va-Xa and factors VIIIa-IXa complexes is impaired, resulting in decreased thrombin generation and impaired platelet-dependent fibrin formation on subendothelium. These defects are linked to a defect in calcium-mediated vesiculation of the plasma membrane and decreased membrane exposure of phosphatidylserine, which may be due to a defect in the enzyme scramblase ([214], [215], [216], [217], [218] and [219]).

ACQUIRED DISORDERS OF PLATELET FUNCTION

Drug-Induced Platelet Dysfunction

A great many chemically and biologically active substances can be shown to inhibit platelet function. These range from various ionophores, structural analogues of ADP, and supraphysiologic concentrations of various drugs, to common dietary items such as garlic ([220], [221], [222] and [223]), red pepper ([224]), various Chinese herbs ([225]), black tree fungus ([226]), and fish oil ([227]). The present discussion is limited to drugs in common use that impair platelet function in therapeutic concentrations (Table 58.4). An extensive list of drugs that impair platelet function has recently been published ([228]), and the drugs that are used to treat thromboembolic disorders are discussed further in Chapter 61.

TABLE 58.4. Drugs Affecting Platelet Function

Analgesics
Aspirin
Nonsteroidal antiinflammatory drugs
Acetaminophen
Antibiotics

ß-Lactams: penicillins, cephalosporins
Cardiovascular drugs
Nitrates
Nitroprusside
Psychotropic drugs

In otherwise healthy persons, the impairment of platelet function produced by drugs usually is of no clinical significance. On the contrary, in patients with coagulation disorders, in uremic or thrombocytopenic patients, and in patients receiving heparin or coumarin anticoagulants, impairment of platelet function by drugs may remove one of the remaining hemostatic defenses and result in serious bleeding ([229]). Analgesics that are presumably safe for use by these patients include codeine and other opiates and synthetic narcotics such as meperidine, acetaminophen, and propoxyphene. However, even acetaminophen has some effect on *in vitro* and *ex vivo* platelet function ([230]).

ANALGESICS

Aspirin Acetylsalicylic acid is a potent inhibitor of the platelet release reaction as the consequence of acetylation by the drug of the active center of platelet cyclooxygenase (COX-1>COX-2), the enzyme responsible for the conversion of arachidonic acid into cyclic endoperoxides within the platelet ([231]). This effect occurs within 15 to 30 minutes after ingestion with doses as low as 40 to 80 mg, is irreversible, and persists as long as the affected platelet cohort survives ([232] , [233] and [234]). Consequently, a single small dose of aspirin impairs the release reaction for up to 96 hours ([234]). However, some patients may be nonresponders who do not demonstrate an effect on platelet function when ingesting 325 mg of aspirin ([235]). Inhibition of cyclooxygenase blocks the synthesis of prosta-glandins E_2 and F_2a and thromboxane A_2 by the platelet, as well as production of prostacyclin (PGI_2) by the endothelium ([236]). Prostacyclin production is less completely and less persistently inhibited than is the synthesis of thromboxane A_2 and prostaglandin E_2, with the result that the effects of aspirin are, overall, antithrombotic in the doses usually administered ([232]). When aspirin-treated platelets are perfused through denuded arterial segments, they adhere normally to the subendothelium but do not interact with one another ([144]). Electron photomicrographs reveal that centralization of organelles, which normally occurs in collagen-activated platelets, does not occur in aspirin-treated platelets ([133]). Aggregometry tracings obtained with aspirin-treated platelets reveal deficient collagen-induced aggregation and the absence of the secondary wave of aggregation induced by epinephrine and low concentrations of ADP ([237]). Aspirin-treated platelets fail to release normal amounts of ADP, ATP, and serotonin, but higher doses may be necessary to block a-granule secretion ([238]). Aspirin prolongs the bleeding time significantly but seldom produces values that are above the normal range. This effect is more pronounced in men than women ([239] , [340]). In a small percentage of normal subjects, and in some patients with minor platelet dysfunction, the bleeding time is markedly prolonged after aspirin ingestion ([241]). Aspirin has a dose-related gastrointestinal toxic effect ([242]). Studies using ^{51}Cr-labeled erythrocytes demonstrate that aspirin ingestion predictably causes the loss of small amounts of blood into the gastrointestinal tract, and this effect is enhanced by the ingestion of ethanol ([232] , [243] , [244]). Current evidence suggests that aspirin only affects surgical bleeding in patients undergoing surgery in areas where increased fibrinolytic activity may compound the effect of nonsteroidal antiinflammatory drugs (NSAIDs) (oral cavity or genitourinary tract) or in patients with other coexisting coagulation disorders ([245]).

Nonsteroidal Antiinflammatory Drugs Both the analgesic effects and the antiinflammatory actions of a wide variety of nonsteroidal drugs are the consequence of inhibition of prostaglandin synthesis, and they affect platelet function by blocking prostaglandin synthesis in a reversible reaction ([246]). Although it is apparent that most NSAID use is associated with increases in bleeding times, there is still controversy about whether there is increased bleeding following procedures ([247]). The effect of NSAIDs on platelet function usually resolves within 48 hours, but, the long-acting drug piroxicam blocks prostaglandin synthesis for longer than 72 hours ([248]). The COX-2 inhibitors were recently developed to provide antiinflammatory effects of cyclooxygenase blockade without affecting platelet function.

ANTIBIOTICS ß-Lactam antibiotics produce dose-dependent platelet dysfunction *in vitro* and *ex vivo*, increase the bleeding time, and predispose patients to increased bleeding, especially if they have renal insufficiency or are undergoing surgical procedures ([249] , [250] , [251] , [252] and [253]). The effect on platelet function can be measured in aggregation studies in which platelets incubated with these antibiotics or exposed *in vivo* demonstrate a dose-dependent reduction in aggregation to ADP, epinephrine, and collagen ([254] , [255] , [256] , [257] and [258]). These drugs appear to bind to and modify the platelet membrane, resulting in decreased agonist binding and decreased calcium flux ([259] , [260] and [261]). The effect can be demonstrated after several days of treatment with these antibiotics and does not resolve until 7 to 10 days after discontinuation. This suggests that megakaryocyte membranes may be similarly affected. Penicillins and cephalosporins that have an a-carboxy group adjacent to the ß-lactam ring are most likely to produce platelet dysfunction and clinical bleeding. Moxalactam and cefotetan can produce clinical bleeding as a result of both platelet dysfunction and the N-methythiotetrazole side chain effect on vitamin K–dependent clotting factor synthesis ([262] , [263] and [264]).

CARDIOVASCULAR DRUGS A number of cardiovascular drugs affect platelet function *in vitro* and after ingestion or infusion. There is no evidence that these effects result in increased bleeding; in fact, the antiplatelet effect may be beneficial in patients with coronary syndromes or undergoing cardiopulmonary bypass. Whole blood flow cytometry assessment of platelet activation antigens now permits more accurate assessment of these drugs. In one of the first of these types of evaluations, in normal volunteers, nitrate infusions inhibited aggregation (fibrinogen binding) and degranulation (P-selectin expression), the calcium channel antagonist amlodipine enhanced platelet degranulation, and the ß-blocker atenolol enhanced aggregation ([265]).

PSYCHOTROPIC DRUGS Psychotropic drugs, such as phenothiazines and tricyclic antidepressants, have been demonstrated to have an inhibitory effect on platelet aggregation when drugs are incubated with platelets *in vitro* ([266] , [267]). These effects are believed to be due to a direct effect of the drugs on the phospholipid bilayer and by inhibition of arachidonic liberation from platelet membranes ([268] , [269]). However, the clinical relevance of this effect on platelet function is uncertain, as therapeutic doses of these drugs, when administered to human subjects, demonstrate little effect on platelet aggregation and no prolongation of the bleeding time ([270] , [271]).

Uremia

Uremia was one of the first “acquired thrombopathies” to be described. Although the hemostatic defect in uremia is complex and may include thrombocytopenia and minor coagulation abnormalities, platelet dysfunction is probably the most consistent and clinically important feature as evidenced by the prolonged bleeding time. Although multiple abnormalities in platelet function have been described, including abnormalities of adhesion, aggregation, and secretion, there is still no unifying pathophysiologic mechanism to explain all of the recognized platelet defects. In addition, the degree of anemia is also an important determinant of bleeding and correlates directly with the prolongation of the bleeding time in uremia ([272] , [273] and [274]).

These defects in platelet function have been ascribed to the accumulation of guanidinosuccinic acid, phenol and phenolic acids, uremic middle molecules, and, most recently, nitric oxide ([275] , [276] , [277] , [278] , [279] , [280] , [281] and [282]).

ENDOTHELIAL CELL FUNCTION Uremic patients have increased concentrations of L-arginine (precursor of nitric oxide) and cyclic guanosine monophosphate (the second messenger for nitric oxide), uremic platelets generate more nitric oxide, and uremic plasma promoted nitric oxide synthesis by cultured vascular endothelium, supporting a possible role for nitric oxide in uremic bleeding ([283] , [284]). In support of this mechanism is the data that when normal volunteers inhale nitric oxide there is prolongation of their bleeding time, and infusion of nitric oxide inhibitors shortens the bleeding time ([280]).

PLATELET ADHESION Some investigators have demonstrated that platelet adhesion is abnormal as demonstrated by the observation that uremic platelets do not adhere and spread on subendothelial surfaces in experiments performed with flowing blood ([285] , [286]). Others have found adhesion of uremic platelets to be equal to control platelets but demonstrated that more vWF was required to maintain this level of adhesion ([287]). The amount of vWF, vWF multimer patterns, and vWF antigen/activity ratios have been described as both normal and abnormal in reported studies ([287] , [288] , [289] and [290]). Platelet GPIb/IX receptor number and function is described as both normal and reduced ([291] , [292]).

PLATELET AGGREGATION Shear-induced platelet aggregation with high shear stresses is reduced with platelets from uremic patients, but it is unclear whether these changes are due to reductions in the availability of GPIIb/IIIa ([293]) or GPIb ([294]). Activation-dependent receptor function of GPIIb/IIIa for binding the adhesive proteins fibrinogen and vWF was reported to be defective in uremia, even though the number of receptors was normal ([291]). This reduction in GPIIb/IIIa-fibrinogen binding has been observed by other investigators ([295] , [296]), and the number of GPIIb receptors and extent of fibrinogen binding does not return to normal, even after 4 months of hemodialysis ([297]). Platelet aggregation to exogenous agents is also reduced in many uremic patients ([298]). Threshold aggregating concentrations for collagen, ADP, and epinephrine have been found to be higher, and thromboxane B_2 generation and granule content of ADP lower for uremic than control platelets ([299] , [300]); however, aggregation responses to ADP, collagen, and ristocetin were normal or increased with uremic platelets in another study ([301]). In some patients, aggregation with platelet-activating factor was the only aggregating defect noted ([302]).

PLATELET SECRETION Increased platelet concentrations of adenylate cyclase and cyclic adenosine monophosphate and a decreased rise in platelet cytosolic calcium concentration have been noted in some patients with uremia, demonstrating that there are intrinsic platelet defects ([303], [304]). There is also an impairment of cytoskeletal organization in resting and thrombin-treated uremic platelets, suggesting a defect in the association of the contractile proteins with the cytosolic matrix of platelets upon activation ([305]).

CLINICAL MANIFESTATIONS Bleeding may be severe in the uremic patient. Widespread ecchymoses and intractable slow gastrointestinal bleeding are common, and large hematomas into serous cavities and into muscles may occur. The incidence of serious hemorrhage associated with uremia has diminished significantly in recent years as the result of more intensive dialysis and the avoidance of drugs, such as aspirin, that compound the defects in platelet function.

THERAPY Hemodialysis and peritoneal dialysis remain the mainstays in the treatment of uremic bleeding ([281], [306]); however, there appears to be a transient worsening of platelet function immediately after dialysis, which may be multifactorial ([307]). There is a decrease in shear-induced platelet aggregation due to loss of platelet membrane glycoproteins Ib and IIb/IIIa but no change in calcium flux or thromboxane B_2 generation. There is also an increase in P-selectin exposure early during hemodialysis demonstrating platelet activation ([308]). Finally, there is a decrease in platelet aggregation and platelet RNA content after hemodialysis, suggesting that the youngest and most active platelets may be more prone to activation and loss during dialysis ([309]). When platelet function was prospectively evaluated after renal transplantation, platelet aggregation, F-actin, and platelet cytoskeletal abnormalities were completely normal by 8 weeks after renal transplant (310). Either red blood cell transfusions or improvement of anemia by erythropoietin therapy (rHUEPO) is associated with decreased bleeding, shortening of the bleeding time, and increased platelet adhesiveness in hemodialyzed uremic patients ([311]). The effects of rHUEPO result from both an increase in red blood cell mass and a slight effect on platelet function that is independent of the increased hematocrit ([312]). However, there also was an increase in fistula thrombosis in a placebo-controlled trial of patients treated with rHUEPO, suggesting that some patients may become hypercoagulable ([313]). Preliminary studies demonstrated that the administration of cryoprecipitate (10 units at 24-hour intervals) or DDAVP (0.3 µg/kg) shortens the bleeding time and is temporarily effective in the control of bleeding in some uremic patients ([314], [315]). The mechanism by which cryoprecipitate and DDAVP improve hemostasis is unknown, although improvement in adhesion and changes in vWF activity have been postulated ([316], [317]). A prolonged reduction in the severity of uremic bleeding was reported after the administration of conjugated estrogens ([318]). However, a single perioperative dose does not improve hemostasis (as measured by bleeding time, platelet aggregation, changes in factor VIII or vWF) or intraoperative blood loss ([319]).

Paraproteinemias

The bleeding diathesis that may complicate the various paraproteinemias that may occur in association with multiple myeloma, Waldenstrom macroglobulinemia, monoclonal gammopathies of undetermined significance, or even polyclonal hypergammaglobulinemia is very complex. A variety of mechanisms have been postulated, including (a) thrombocytopenia or impaired platelet function, (b) inhibitors to plasma coagulation factors, (c) circulating monoclonal proteins that bind to coagulation factors and promote enhanced clearance of the complex, and (d) hyperviscosity syndrome ([320], [321]).

Bleeding occurs more commonly in patients with IgA myeloma and macroglobulinemia than with other types of myeloma and often is limited to purpura and mucosal membrane bleeding ([322]). Abnormalities in platelet function that correlate best with clinically significant bleeding are the bleeding time and platelet adhesion. There is poor correlation between a prolonged bleeding time and results of other tests of platelet function ([321]), although abnormalities in every type of platelet function test have been documented when large numbers of patients have been studied ([321], [322], [323], [324] and [325]).

Abnormal platelet function is believed to be the result of nonspecific binding of immunoglobulins to the platelet surface, and in fact a correlation between serum IgG, platelet membrane IgG, and platelet function with both monoclonal and polyclonal hypergammaglobulinemia has been demonstrated ([326]). Only a few patients have been reported in whom the monoclonal antibody appears to modify platelet function by a specific antigen-antibody reaction. Antibodies have been reported that bind to platelet membrane GPIIIa, collagen, and components of the factor VIII–vWF complex ([327], [328], [329], [330], [331], [332] and [333]). Although antibodies against factor VIII-vWF are not strictly related to the platelet, adhesion of platelets to vascular subendothelium is compromised.

Clonal Hematopoietic Disorders

MYELODYSPLASTIC SYNDROME/ACUTE NONLYMPHOCYTIC LEUKEMIA In addition to well-known abnormalities of hemostasis, such as thrombocytopenia or acute and chronic disseminated intravascular coagulation, a relatively specific abnormality of platelet function may contribute to the hemorrhagic diathesis associated with myelodysplastic syndrome (MDS) and acute nonlymphocytic leukemia. Electron photomicrographs of the bone marrow in patients with these disorders reveal micromegakaryocytes with hypolobulation and hypogranularity ([334], [335], [336], [337] and [338]). These morphologically abnormal megakaryocytes suggest that thrombopoiesis is similarly affected. When studied ultrastructurally, affected platelets manifest a number of abnormalities, including a marked variation in size, a dilated canalicular system, and a diminished number of poorly structured marginal microtubules ([339], [340]). The most striking abnormality, however, is granular dysplasia ([341], [342], [343] and [344]). Granules may be markedly reduced, or giant platelet granules may be formed by the fusion of several single granules, changes that may be evident even on ordinary blood smears (Fig. 58.6). Platelets with such giant granules and unilobar, atypical micromegakaryocytes have been regarded as markers of a stem cell disorder that often terminates in acute leukemia.

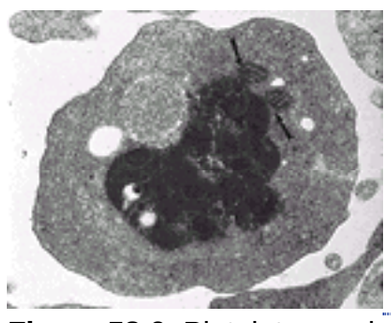

Figure 58.6. Platelet granular dysplasia in myelomonoblastic leukemia. Gigantic “fusion” granule with perhaps as many as 14 subcomponents. Note mitochondria (*arrows*) approximating or being included in the abnormal granule (×39,700). (From Maldonado Jr. Platelet granulopathy: a new morphologic feature in preleukemia and myelomonocytic leukemia: light microscopy and ultrastructural morphology and cytochemistry. Mayo Clin Proc 1976;51:452–462, with permission.)

Platelet function is difficult to study because of the frequent presence of thrombocytopenia. Bleeding times are usually prolonged more than would be expected based on platelet count, and multiple platelet aggregation defects can be detected ([340], [345], [346]). An acquired Bernard-Soulier–like platelet defect was described in a patient with juvenile MDS, demonstrating that even acquired defects in the platelet membrane can occur ([347]).

MYELOPROLIFERATIVE DISORDERS Abnormalities of aggregation and the release reaction, deficient lipid peroxidation and responses to thromboxane A_2, subnormal serotonin uptake and storage, abnormal expression of Fc receptors, and a combined defect in membrane expression and activation of GPIIb-IIIa complexes have been demonstrated in the platelets of patients with myelofibrosis, polycythemia vera, chronic myelocytic leukemia, and thrombocythemia ([347], [348], [349], [350], [351], [352], [353], [354], [355], [356] and [357]). Acquired SPD has also been well documented ([358]). Although bleeding is recognized as a complication of these disorders, the clinical importance of platelet dysfunction remains unclear. Common manifestations include ecchymoses, epistaxis, gastrointestinal bleeding, and a propensity to serious hemorrhage after trauma or minor surgical procedures. The pattern of laboratory abnormalities often is inconsistent, and the correlation between the extent of these abnormalities and the severity of bleeding is poor ([348], [349], [358]). Studies of megakaryocyte replication using ultrastructural and cell culture techniques suggest that, as in MDS and acute leukemia, platelet dysfunction in chronic myeloproliferative disorders is determined at the level of the progenitor cell ([334], [359]). Patients with chronic myeloproliferative disorders may also have abnormal platelet function that resembles von Willebrand disease, due to the reduction of high-molecular-weight forms of plasma and platelet vWF ([360], [361], [362] and [363]). These abnormalities in vWF may be associated with increased bleeding times, especially in essential thrombocytosis ([360]). It is currently hypothesized that the loss of high-molecular-weight vWF is related to proteolysis, which may result from white blood cell or platelet protease activity. This hypothesis is strengthened by the observation that vWF multimers normalize after reduction in white blood cell and platelet counts ([362]).

Inherited Coagulation Disorders

Inherited disorders of coagulation usually are the result of a deficiency or abnormality of a single plasma protein. As a consequence, these disorders provide a unique opportunity to study the phenomena of blood coagulation. If von Willebrand disease (vWD) is included, the inherited coagulation abnormalities (Table 59.1) are common; for example, vWD may affect up to 1% of the population. The other inherited coagulation disorders affect at most 1 in 10,000 to 15,000 persons.

TABLE 59.1. Inherited Disorders of Coagulation

X-linked recessive traits
Hemophilia A
Hemophilia B (i.e., CRM $^{+}$ and CRM $^{-}$ variants; hemophilia B $_{m}$, B Leyden, etc.)
Autosomal-recessive traits
Factor XI deficiency
Prothrombin deficiency
Factor V deficiency
Factor VII deficiency
Factor X deficiency (i.e., Prower variant, Stuart variant, Friuli variant, others)
Afibrinogenemia
Hypofibrinogenemia
Factor XII deficiency
Factor XIII deficiency
Autosomal-dominant traits
von Willebrand disease
Dysfibrinogenemias
Combined abnormalities
Associated with factor VIII deficiency (i.e., factor V deficiency, hemophilia B, factor XI deficiency, factor VII deficiency, von Willebrand disease, dysfibrinogenemias, platelet dysfunction)
Involving vitamin K–dependent factors (i.e., factors II, VII, IX, and X; factors IX and XII; others)
Miscellaneous
Prekallikrein deficiency
High-molecular-weight kininogen deficiency
Deficiency of physiologic inhibitors [i.e., a $_{2}$-antiplasmin, abnormal a $_{1}$-antitrypsin (antithrombin Pittsburgh)]

CRM, cross-reacting material.

With the exception of vWD, the inherited coagulation disorders associated with bleeding produce similar signs and symptoms, regardless of the particular factor that is lacking. Consequently, the clinical picture of hemophilia A is emphasized in the following discussion as the prototypical bleeding disorder. Clinical features of the other forms that differ significantly from this prototype are cited in the sections dealing with these other conditions. Treatment of the inherited coagulation disorders is discussed later in the chapter.

NOMENCLATURE

Many names have been proposed for the inherited coagulation disorders, most of which incorporate the word *hemophilia*, such as *pseudohemophilia* or *parahemophilia*. The international roman numeral designations for these disorders are summarized in Table 21.1. The term *hemophilia A* is synonymous with *factor VIII deficiency*, and *hemophilia B* is also known as *factor IX deficiency* or *Christmas disease*.

Like abnormal hemoglobins, qualitatively abnormal fibrinogens are designated by the name of the city in which they were first discovered, as in *fibrinogen Paris*. Specific terms are also used for variants of other disorders, if such terms have become widely used, such as *factor X Friuli*.

The activity of the various coagulation factors is expressed in terms of units, defined as the activity present in 1 ml of fresh plasma from normal donors. The concentration of all coagulation factors in normal-pooled plasma is thus 1 U/ml or 100 U/dl, or 100% activity; levels in blood bank plasma are approximately 80 U/dl because of the dilution with anticoagulant.

PRINCIPLES OF PATHOPHYSIOLOGY

With the exception of fibrinogen and prothrombin, the coagulation factors are trace proteins. Traditional laboratory measurements of their activity are bioassays, which are inherently incapable of distinguishing between a quantitative abnormality (the absence of a specific factor) and a qualitative abnormality (a nonfunctional or hypofunctional factor that is present in normal amounts). For many years, the general assumption was that the inherited coagulation disorders were the result of a quantitative deficiency of trace plasma proteins. However, results of studies using various immunologic techniques demonstrate that the absence of coagulant activity in the plasma of patients with these disorders may result from either deficient biosynthesis of a requisite protein or defective biosynthesis, leading to the production of normal amounts of functionally inactive or functionally abnormal analogs ([1]).

The results of immunologic tests for the presence of coagulation factors usually can be expressed as positive or negative for cross-reacting material (CRM). A positive test for CRM implies that a substance that is antigenically similar to the normal coagulation factor is present in the plasma. A coagulation disorder characterized by the presence of such a substance often is described as a *CRM-positive or qualitative disorder or variant*. Designations based on immunologic cross-reactivity are meaningful only with respect to a specific antibody and a specific neutralization technique.

Some qualitatively abnormal coagulation factors produce abnormalities in coagulation that differ from those associated with a true quantitative deficiency of the factor. For want of a more specific term, such factors are called *abnormal* or *aberrant factors* to distinguish them from completely nonfunctional analogs. The most clearly defined disorders of this type are the dysfibrinogenemias, in which the abnormal fibrinogen is not totally nonfunctional but may inhibit the function of normal fibrinogen. Other disorders characterized by aberrant coagulation factors include the B $_{m}$ variant of hemophilia B and some of the variants of prothrombin deficiency. Aberrant procoagulant proteins also may be synthesized in acquired deficiencies of the vitamin K–dependent factors (Chapter 60).

A negative test for CRM indicates the absence of antigenically competent protein and suggests that the disorder is caused by deficient biosynthesis of the requisite factor. Such quantitative or CRM-negative disorders include afibrinogenemia and factor V deficiency. However, available techniques do not exclude aberrations of sufficient magnitude to alter the antigenic determinants of the molecule, the subunit of the active coagulation factor, or the production of an analog that is catabolized at an abnormally rapid rate ([1], [2]). Multiple variants of many of the inherited coagulation disorders have been defined, such as factor X deficiency, which may be CRM

positive or CRM negative or associated with an aberrant form of factor X.

Two major genetic aberrations of the factor VIII–von Willebrand factor (vWF) complex are now well documented: hemophilia A and vWD, the two most common inherited bleeding disorders. These disorders are the result of qualitative or quantitative abnormalities of different subunits or regions of the factor VIII complex (factor VIII–vWF) and give rise to distinct clinical disorders. In this chapter, the international nomenclature for subunits of the factor VIII molecule is used (Table 59.2). The unqualified term *factor VIII* still is commonly used with reference to preparations containing varying amounts of factor VIII and vWF. These abbreviations are used in a functional sense; the exact biochemical or structural features of this complex molecule that determine its functions and attributes are discussed in Chapter 21. *Factor VIII coagulant activity* (factor VIIIc) refers to the functional property of the factor VIII molecule that corrects the coagulation defect of patients with hemophilia A. The antigenic expression of factor VIIIc activity is called *factor VIIIAg*. The large plasma protein required for normal platelet adhesion that is deficient or aberrant in patients with vWD is called *vWF*. The antigenic expression of this protein is designated *vWF antigen* (vWFAg). The functional property of vWF that promotes platelet agglutination by the drug ristocetin is called *ristocetin-cofactor activity*.

TABLE 59.2. Nomenclature for Factor VIII and von Willebrand Factor

Definition	International Nomenclature	Outmoded Synonyms
Protein lacking or aberrant in hemophilia A	Factor VIII	Factor VIIIc; antihemophilic factor
Functional property of factor VIII that is deficient in hemophilia A and measured using coagulation assays	Factor VIIIc	Factor VIII coagulant activity
Antigenic property of factor VIII that is measured by immunoassays in which homologous antibodies are used	Factor $VIII_{Ag}$	Factor $VIIIc_{Ag}$
Protein required for normal platelet adhesion that is aberrant or deficient in von Willebrand disease	von Willebrand factor (vWF)	Factor VIII–related antigen (VIIIR:Ag); Factor $VIII_{vWF}$
Antigenic property of vWF that is measured by immunoassays in which heterologous antibodies are used	von Willebrand factor antigen (vWFAg)	Factor VIIIR:Ag
Property of vWF required for platelet agglutination by ristocetin	Ristocetin cofactor activity (vWF:RCo)	Factor VIIIR:RCo

NOTE: This table is based on recommendations of the International Committee on Thrombosis and Haemostasis.

HEMOPHILIA A

A severe and often fatal hemorrhagic diathesis that affected the male children of certain families was well recognized in antiquity. This is evident from the writings of Rabbi Simon ben Gamaliel (second century A.D.) in the Talmud, and those of Maimonides, the Hebrew physician and philosopher, and Albucasis, the Arab (twelfth century) ([3]). Complete monographs have reviewed the early literature ([4]).

Pathophysiology

The hemostatic abnormality in hemophilia A (factor VIII deficiency, classic hemophilia) is a deficiency or abnormality of a plasma protein. This substance (the antihemophilic factor, antihemophilic globulin, factor VIII) was elusive and difficult to purify. Preparations of factor VIII are capable of correcting all coagulation abnormalities in the blood of hemophiliacs; they are equally effective *in vitro* and *in vivo*, and their administration can prevent and arrest hemorrhage in patients with hemophilia A.

Factor VIII normally circulates in the plasma bound to a much larger molecule, vWF, as part of the factor VIII complex. The functional attribute of this complex that is essential in coagulation is designated *VIIIc*. Factor VIIIc and its functional and immunologic properties are aberrant or deficient in patients with hemophilia A. vWF (formerly called *VIIIAg*) acts as a carrier for factor VIII and is abnormal in vWD. The production of vWF is coded by an autosomal gene, and this protein apparently is qualitatively normal and is present in normal or increased amounts in patients with hemophilia A (Fig. 59.1) ([5], [6] and [7]). Few *in situ* studies of hemostatic plugs in patients with hemophilia A have been performed. Available evidence suggests that reinforcement of platelet plugs with fibrin is defective ([8]).

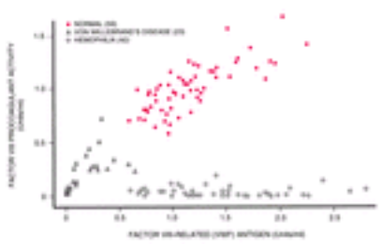

Figure 59.1. The relationship of factor VIII procoagulant activity and factor VIII–related antigen [von Willebrand factor (VWF)] in the plasma of normal subjects and patients with hemophilia or von Willebrand disease. (From Hoyer LW. The factor VIII complex: structure and function. Blood 1981;58:1–13, with permission.)

Incidence

Hemophilia A has been recognized in all areas of the world where adequate information is available. Hemophilia A is the second most common of the inherited coagulation disorders. Estimates of its incidence range from 1 in 20,000 to as high as 1 in 10,000 persons ([9]). The disorder seems to be rare among Chinese, and the early literature indicated that hemophilia A was uncommon in Africans ([10]). However, a population-based study of the southeastern United States by the Centers for Disease Control and Prevention found that 11 cases per 100,000 persons had hemophilia A and that the prevalence was similar among different racial groups ([11]). This same survey estimated that in 1994, there were 13,320 cases of hemophilia A and 3640 cases of hemophilia B in the United States ([11]).

Genetics

Hemophilia A is the classic example of an X-linked recessive trait ([10]). The genetics of this disorder has been studied intensively ([12], [13]). In such a disorder, the defective gene is located on the X chromosome ([14]); the factor VIII gene maps to Xq28. In males who lack a normal allele, the defect is manifested by clinical hemophilia (Fig. 59.2; generation I, number 1). The affected male does not transmit the disorder to his sons (generation II, numbers 4 and 5) because his Y chromosome is normal. However, all of his daughters are carriers of the trait because they inherit his X chromosome (generation II, numbers 2 and 3). Most of these women are unaffected clinically because of the presence of a normal allele from the mother. The female carrier transmits the disorder to half of her sons (generation III, numbers 6 and 7) and the carrier state to half of her daughters (generation III, numbers 8 and 9).

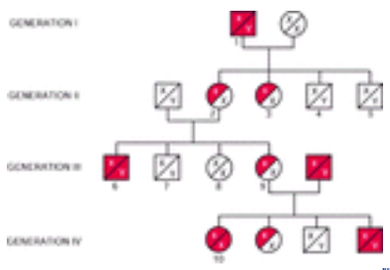

Figure 59.2. The inheritance of hemophilia A and hemophilia B. The pedigree is hypothetical. Squares indicate male; circles indicate female; fully shaded squares or circles indicate affected members; half-shaded circles indicate carriers. X, normal X chromosome; x, abnormal X chromosome.

The severity of bleeding—that is, the expressivity of the genetic defect—varies from kindred to kindred in hemophilia A. Within a given kindred, however, the clinical severity of the disorder is constant; that is, relatives of severe hemophiliacs are likely to be affected severely ([15]). Hemophilia A has been observed several times in twins ([16]). The coinheritance of the factor V Leiden mutation (discussed in Chapter 61) with hemophilia A in certain patients may explain the variability in clinical phenotype observed between patients sharing the same molecular defect in factor VIII ([17]). The coinheritance of the factor V Leiden mutation or other prothrombotic risk factors in children with severe hemophilia A delays the first symptomatic bleeding event ([18]).

It might be expected that, with random mating in a large population, a rare defect, such as hemophilia A, would die out after several generations, particularly because in the past the disorder was often fatal in childhood. That this has not occurred suggests that the mutation rate for the responsible gene may be unusually high ([19]). The large size of the factor VIII gene (186 kb) and the presence of hot spots (e.g., CpG dinucleotide mutations) predispose the factor VIII gene to mutation ([20]). In fact, no evidence or history of abnormal bleeding is found in other members of the families of at least one-third of all hemophiliacs ([21]). This percentage is consistent with the Haldane hypothesis, which predicted that maintenance of a consistent frequency of a genetic disorder in the population would require that approximately one-third of cases result from spontaneous mutation. In other instances, neonatal deaths or the passage of the trait through a succession of female carriers may explain the negative family history. For practical purposes, therefore, a negative family history is of little value in excluding the possibility of hemophilia A.

Examination of hemophilic genes by detailed molecular methods has failed to demonstrate a uniform abnormality ([2] , [22]). In an early study of 200 hemophilia genes, seven different mutations were demonstrated by Western blotting techniques. Four of these mutations were transpositions of single bases, of which three transformed a codon for arginine into a stop codon, which arrested factor VIII synthesis and resulted in truncated factor VIII and severe hemophilia. The fourth mutation resulted in substitution of a single amino acid and mild hemophilia. The other three mutations involved deletion of several thousand nucleotides and produced severe hemophilia ([2]). A 1995 hemophilia A database has been published ([23]), and a web site exists for continual update of the hemophilia A mutation database ([24]). The genetic defects of hemophilia A encompass deletions, insertions, and mutations throughout the factor VIII gene ([25]). Point mutations involving CpG dinucleotides are especially common. Approximately 5% of patients with hemophilia A have large (>50 nucleotides) deletions in the factor VIII gene ([26]).

Approximately 40% of severe hemophilia A results from a major inversion of a section of the tip of the long arm of the X chromosome, one breakpoint of which is situated within intron 22 of the factor VIII gene ([27]). This common inversion is associated with severe hemophilia A. It is presumed that in the absence of homologous X chromosome pairing during male meiosis, an intrachromosomal recombination event occurs on the single X chromosome, resulting in this inversion. Another common inversion accounts for 5% of severe factor VIII deficiency ([28]). Thus, two inversions of the factor VIII gene are seen in nearly one-half of all severely affected patients with hemophilia A. In contrast, point mutations are most likely found in patients with mild to moderate hemophilia A ([25]). The genetic basis for CRM(+) patients with hemophilia A has also been described ([29]). The first case of hemophilia A caused by unequal homologous Alu/Alu recombination has been reported ([30]). Because there are approximately 50 Alu repeats in the factor VIII gene, it is possible that many cases of hemophilia may result from this mechanism ([30]). Approximately 80 to 95% of hemophilia A patients have mutations detected ([31]). Approximately 2% of hemophilia A patients have no detectable mutations in the coding region of the factor VIII gene ([32]). These results indicate that a substantial number of families with severe hemophilia A can undergo accurate gene tracking and carrier analysis. An algorithmic approach to rapid laboratory genetic testing has been described ([33]).

Variants

Hemophilia A with autosomal-dominant transmission has been reported ([34]). In two other families, marked deficiencies of factor VIII and hemorrhagic manifestations in the female carriers appeared to be the consequence of an unusual allele or an abnormality of genes that independently affect the biosynthesis of factor VIII ([35]). It is important to distinguish these variant hemophilia A patients with negative X-linked transmission from patients with variant vWD (type 2N, vWD Normandy), an autosomal vWD subtype caused by defective factor VIII binding to vWF and with a clinical picture similar to hemophilia A ([36]).

Carrier Detection

Carrier detection is based on three approaches: first, patient and family history; second, coagulation-based assays; and third, DNA testing. Some family history predictors of the female carrier state exist: If a female being evaluated for the carrier state had a hemophilic father, then she is a carrier; if she has two sons with hemophilia, then she is a carrier; if she has one son with hemophilia and a family history of hemophilia, then she is a carrier; if she has one son with hemophilia and a negative family history, the odds are approximately 67% that she is a carrier.

COAGULATION-BASED ASSAYS These assays may be useful in confirming or excluding the carrier state, although they have limitations. The regularity with which the abnormal factor VIII gene is suppressed by the normal allele in female carriers of hemophilia varies because of the phenomenon of random X-chromosome inactivation (the Lyon hypothesis). Thus, although the mean concentration of factor VIIIc in the plasma of heterozygous female carriers is approximately 50% of that in normal women ([15] , [37]), observed values scatter widely around this mean and often overlap with those found in the normal population ([15]). This is a result, in part, of the large error of assay methods and the wide range of factor VIIIc levels in normal subjects ([15]). Although the demonstration of subnormal levels of factor VIIIc by means of the usual assay methods strongly suggests the presence of the carrier state, the converse statement cannot be made with equal certainty—that is, the presence of normal levels of factor VIIIc does not reliably exclude the carrier state ([38]). Furthermore, pregnancy and hormonal medications may increase the levels of factor VIIIc in female carriers ([39]). Some investigators report lower levels of vWFAg in maternal carriers than in paternal carriers ([40]) or concordant reductions in the two subunits ([41]). Normal women and carriers with blood types A, B, or AB have higher levels of VIIIc and vWFAg than those with blood type O ([36]). A link between genes coding for ABO blood group antigens and vWF production has been proposed ([42]). The use of immunoassays for vWF has improved carrier detection in hemophilia A ([43]). These methods allow measurement of levels of vWF, which are normal ([44]) or increased in carriers of the disorder, despite mild but variable deficiencies of factor VIIIc. Results obtained when a bioassay and an immunoassay are performed on the same sample and the ratio of VIIIc to vWF is computed differentiate between the carrier population and the normal population with minimal overlap ([45]). This ratio normally ranges from 0.74 to 2.20 and was found to be from 0.18 to 0.90 in obligatory carriers. The overall detection rate ranged from 72 to 94% in such obligatory carriers ([43] , [44] , [46]) and from 48 to 51% in women without hemophilic sons or fathers ([43]). In the latter group (possible carriers), 50% would be predicted to be carriers. Abnormally low ratios of VIIIc:vWF (false-positives) have been encountered in an occasional normal subject ([44] , [46]), in whom they may be attributable to nonspecific variables such as stress ([47]). Pregnancy and the use of oral contraceptives, blood type ([42]), or contamination of plasma samples with thrombin ([47]) or other proteolytic enzymes may produce falsely high ratios (false-negatives) in documented obligatory carriers. Testing of several samples from the same woman improves the accuracy of carrier detection and may be essential in some cases ([44]). Linear discriminant analysis ([44] , [48]) has been recommended for the expression and analysis of such laboratory data. The carrier detection rates using standardized assays with discriminant analysis exceed 90% ([49] , [50]).

DNA-BASED ASSAYS Previously, techniques using polymorphic probes required identification of the specific gene defect in the affected male hemophiliac; potentially affected family members could then be screened for the known genetic defect. However, these linkage analysis methods were unsuccessful in a significant number of patients. The identification of the intron 22 ([27]) and other ([28]) inversions has increased the detection rate to more than 90%, especially in kindreds of severe hemophilia A patients. Based on the frequency of the intron 22 inversion, severe hemophilia A patients should be initially screened for this defect. Inversion-negative patients and those with mild or moderate hemophilia A should have systematic sequencing of the factor VIII promoter, exons, and splice junctions performed. Such an approach has been reported to identify mutations in 97% of hemophilia A patients ([33]). These methods have also been adapted to prenatal diagnosis ([51]). The preferred method is to obtain chorionic villi samples during the eleventh to twelfth gestational week and perform direct genotype testing ([52]). Alternatively, genetic linkage analysis of polymorphisms can be performed. The subject of genetic counseling in hemophilia has been reviewed ([51] , [53]).

Hemophilia in the Female

Hemophilia has been well documented in human females ([54], [55] and [56]). The most common form is that seen in a minority of heterozygous carriers, discussed previously, in whom X-chromosome inactivation may occur at an unusually early stage of embryogenesis, resulting in unusually low levels of factor VIII.

A second cause of female hemophilia is a mating between an affected male and a carrier female (Fig. 59.2; generation IV, number 10) ([56], [57]). One-half the female offspring of such a match would inherit two abnormal X chromosomes, one from the father and one from the mother. Such homozygous female hemophilia was once thought to be lethal and to inhibit the development of the embryo. That this is not true was first suggested by the successful experimental production of hemophilia in female dogs. Homozygous hemophilia is now well authenticated in several women ([56], [57] and [58]) and resembles the disorder seen in affected males in all respects.

In a unique kindred, three generations of women were affected with severe hemophilia A transmitted as an autosomal-dominant trait ([34]). These latter patients may be difficult to distinguish from patients with type 2N vWD, which is transmitted in an autosomal-recessive manner ([36]). A chromosomal abnormality resulting in a hemizygous genotype in the female rarely may be responsible such as 45XX/45X mosaicism ([55]), 46 XY karyotype ([59]), inactive X isochromosome ([60]), or deleted X chromosome (Turner syndrome) ([61]). Unusual degrees of X-chromosome inactivation (hyperlyonization) may produce severe factor VIII deficiency in some carriers of hemophilia A.

Clinical Manifestations

The most dramatic manifestation of hemophilia A is exsanguinating hemorrhage from a trivial traumatic injury. However, the most characteristic bleeding manifestations, such as hemarthrosis, often develop without significant trauma. Their frequency and severity generally are related to the blood level of factor VIII ([9], [62]) (Table 59.3). Three categories of severity have been defined by a consensus committee (Table 59.3) ([63]). Severe deficiency (factor VIII level <1 U/dl) is manifested clinically by repeated and severe hemarthroses that almost invariably result in crippling arthropathy in the absence of replacement therapy; such severe cases often are called *classic hemophilia*. Moderate deficiency (factor VIII level of 1 to 5 U/dl) is associated with less frequent and less severe hemarthroses and seldom results in serious orthopedic disability. In mild deficiency (factor VIII level of 6 to 40 U/dl), hemarthroses and other spontaneous bleeding manifestations may be absent altogether, although serious bleeding may follow surgical procedures or traumatic injury ([64]). As indicated in Table 59.3, most patients with hemophilia A have severe disease. However, one epidemiologic survey reported variable differences of severity between individual states within the United States; for example, 13% of hemophilia cases were of moderate severity in Massachusetts, whereas 35% of cases in Georgia were classified as moderate severity ([11]).

TABLE 59.3. Prevalence and Severity of Hemophilia A and Hemophilia B in the United States

Factor VIII or IX Level (U/dl)	Clinical Picture [a]	Incidence (%) [b]	
		Hemophilia A	Hemophilia B
<1	Severe, spontaneous bleeding	70	50
1–5	Moderate bleeding with minimal trauma or surgery	15	30
6–40	Mild bleeding with major trauma or surgery	15	20

[a] The criteria for classifying hemophilia severity are taken from White GC, Rosendaal F, Aledort LM, et al. Definitions in hemophilia. Thromb Haemost 2001;85:560.

[b] Incidence figures are for the United States in 1989 and were provided by the National Hemophilia Foundation (Courtesy of Kathleen F. Cortes, PhD).

From Rodgers GM. Common clinical bleeding disorders. In: Boldt DH, ed. Update on hemostasis: contemporary management in internal medicine. New York: Churchill-Livingstone, 1990:75–120, with permission.

HEMARTHROSIS *Hemarthrosis* is the most common, the most painful, and the most physically, economically, and psychologically debilitating manifestation of the inherited coagulation disorders (Fig. 59.3).

Figure 59.3. Hemophilic arthropathy. This figure illustrates the sequelae of recurrent joint bleeding. See Color Plate.

Pathophysiology Bleeding presumably originates from the synovial vessels and develops spontaneously or as the result of imperceptible or trivial trauma. Hemorrhage occurs into the joint cavity or into the diaphysis or epiphysis of the bone. In the acute stage, the synovial space is distended with blood. Muscular spasm further increases the intrasynovial pressure. Hemorrhage into the periarticular structures is a common complicating feature that occurs most often around small joints. The joint may regain normal function after the first episodes of hemarthrosis. More often, however, the absorption of intraarticular blood is incomplete, the retained blood produces chronic inflammation of the synovial membrane, and the joint remains swollen, tender, and painful for months or years, often in the absence of bleeding. The accumulation of iron within synovial cells triggers cytokine-mediated inflammation. Release of inflammatory cell proteolytic enzymes initiates destruction of cartilage and bone ([65]). Acute hemarthroses almost invariably recur from time to time. With each recurrence, the synovium becomes progressively more thickened and vascular; folds and villi, which predispose to synovial injury during even minimal activity, may form. Proliferating synovium often fills and distends the joint, which remains swollen and enlarged in the absence of bleeding or pain (chronic proliferative synovitis) ([66]). Together with the weakening of the periarticular supporting structures, this process predisposes the joint to recurrent episodes of bleeding. Repeated bouts of hemarthrosis, with the associated subchondral and synovial ischemia, result in progressive loss of hyaline cartilage, particularly at the margins of the joint. Large punched-out areas of destruction are sometimes produced by subchondral hemorrhages and, in the cancellous structure of the bone, cavitation may be caused by intraosseous hemorrhage. Through disuse, diffuse demineralization of the involved bones also may occur. Subperiosteal hemorrhages are not common. The terminal stage of hemarthrosis is called *chronic hemophilic arthropathy* ([67]). It is manifested by fibrous or bony ankylosis of larger joints; complete destruction may take place in the smaller articulations because of the weaker joint structure and the thinner cortices of the smaller bones. Other permanent sequelae of hemarthrosis include atrophy and proliferation of bone, roughening of the articular surfaces with lipping and osteophyte formation, bone necrosis and cyst formation, stunted growth as the result of interference with the nutrition of the bone, and accelerated development and overgrowth of the epiphyses caused by excessive blood flow (Fig. 59.3 and Fig. 59.4). Chronic hemophilic arthropathy is less common now because of widespread use of prophylactic replacement therapy and improved availability of factor replacement therapy.

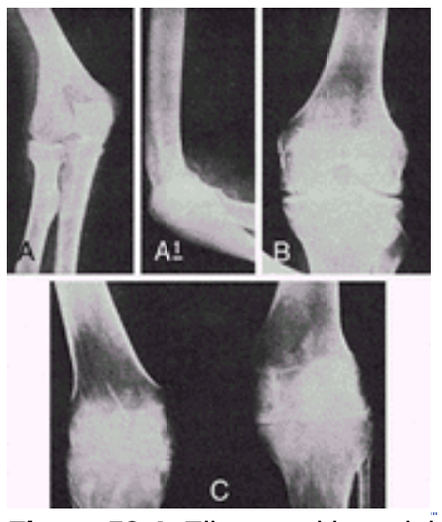

Figure 59.4. Elbow and knee joints in a patient with hemophilia A. Thickening of synovium with deposition of calcium is shown in **(A)** and **(A1)**; increased intercondylar notch is shown in **(B)**; increased density and decreased interarticular space are shown in **(A)**, **(B)**, and **(C)**; and lipping along the borders of the joint surfaces is shown in **(C)**.

A radiologic classification of hemophilic arthropathy has been proposed ([68]); this scoring system includes identifying radiologic changes of osteoporosis, epiphyseal enlargement, subchondral irregularity, joint space narrowing, subchondral cyst formation, joint erosion, and deformity ([68]). Magnetic resonance imaging is superior to standard radiography for assessment of early arthropathy ([69]). A scoring system for magnetic resonance joint evaluation has also been reported ([69]) (Table 59.4).

TABLE 59.4. Scoring System for Hemophilic Arthropathy Using Magnetic Resonance Imaging

Score	Abnormalities on Imaging
O	None
I	Minimal hemosiderin
II	Large amount of hemosiderin and cartilaginous erosion
III	Cartilage destruction, bone erosion, subchondral cysts
IV	Osteoarthritis with or without ankylosis

Clinical Picture Some hemophiliacs report a characteristic warm, tingling sensation before the onset of hemarthrosis; this is called the *aura*. The earliest definite symptom is pain, which in the acute form may be excruciating. Physical examination reveals muscle spasm and limited motion of the affected joint. The joint may be warm and grossly distended and discolored, but external evidence of bleeding may be minimal or absent in chronically damaged large joints because of thickening of the articular capsule. Generally, only one joint is involved at a time, although bleeding may develop simultaneously in two or more joints. The knee is most commonly affected and is the joint most often permanently crippled. Other joints that may be involved are the ankles, elbows, hips, wrists, shoulders, and small joints of the hands and feet, the vertebral articulations, and the temporomandibular joints.

SUBCUTANEOUS AND INTRAMUSCULAR HEMATOMAS Large ecchymoses and subcutaneous and intramuscular hematomas are common in hemophilia A and characteristically spread within fascial spaces and dissect deeper structures (see Fig. 51.2). Subcutaneous bleeding may extend over as much as one-half the body and does so in a characteristic manner. At the site of origin, the tissue is hard, indurated, raised, and purplish black. From this center, the hemorrhage extends in all directions, with each successive concentric extension less deeply colored. The point of origin of the hemorrhage may be absorbed entirely while the margin is still progressing. Intramuscular and subcutaneous hematomas may produce leukocytosis, fever, and severe pain in the absence of significant discoloration of the overlying skin. Hematomas may produce serious consequences from the compression of vital structures. Bleeding into the tongue, throat, or neck may develop spontaneously and is especially dangerous because it may compromise the airway with surprising rapidity ([70]). Gangrene may result from pressure on arteries, and ischemic contractures are common sequelae of hemorrhage into the calves or forearms, as in Volkmann contracture. Peripheral nerve lesions of varying severity are common complications of hemorrhage into joints or muscles, as in femoral nerve compression caused by hematomas of the iliacus. Hemophilic cysts are discussed in the section Special Aspects of Treatment.

PSOAS AND RETROPERITONEAL HEMATOMAS Spontaneous hemorrhage into internal fascial spaces and muscles of the abdomen is common in hemophilia A ([71]). Bleeding into or around the iliopsoas muscle produces pain of progressively increasing severity and tenderness; when it occurs on the right side, it may closely simulate acute appendicitis. Femoral nerve involvement may be partial or complete, with the development of pain on the anterior surface of the thigh. The psoas sign is positive, and the hip is held in partial flexion. Paresthesias, partial or complete anesthesia, and, ultimately, weakness or paralysis of the thigh extensors with eventual muscular atrophy may ensue. Retroperitoneal hemorrhage and intraperitoneal hemorrhage also are common. Computed tomography may be helpful in the diagnosis of these hematomas ([71]).

GASTROINTESTINAL AND GENITOURINARY BLEEDING Hemorrhage from the mouth, gums, lips, frenulum, and tongue is common and often serious. The eruption and shedding of deciduous teeth usually occur without abnormal bleeding, but they may be accompanied by hemorrhage that lasts for days or weeks. Epistaxis occurs in many patients and may be of exsanguinating proportions. Hematemesis, melena, or both are not uncommon. The source of the blood is usually the upper gastrointestinal tract. In most patients in whom bleeding is persistent or recurrent, it originates from a structural lesion, most commonly a peptic ulcer or gastritis. Hemorrhage may be accompanied by abdominal pain, distention, increased peristalsis, fever, and leukocytosis. Intramural bleeding into the intestinal wall may result in intussusception or obstruction. Hematuria, although more common than gastrointestinal bleeding, is less often the result of a demonstrable pathologic condition in the genitourinary tract. The bleeding may arise in the bladder or in one or both kidneys and may persist for days or weeks ([72]). When clots form, ureteral colic may develop.

TRAUMATIC BLEEDING Patients with coagulation disorders seldom bleed abnormally from small cuts such as razor nicks. After larger injuries, however, hemorrhage out of proportion to the extent of the injury is characteristic. This may persist as a slow continuous oozing for days, weeks, or months, or it may be massive and life-threatening. Delayed bleeding is common. Thus, although hemostasis after an injury or a minor surgical procedure may appear to be adequate, hemorrhage, often of sudden onset and serious proportions, may develop several hours or even days later. This phenomenon apparently occurs because the processes of primary hemostasis are only temporarily effective. Delayed bleeding may occur in patients with mild hemophilia and is a significant hazard after minor surgical procedures, particularly those performed on an outpatient basis, such as tooth extractions and tonsillectomy. Venipuncture, if skillfully performed, is without danger to the hemophiliac because of the elasticity of the venous walls. If venipuncture is traumatic, digital pressure on the puncture site or a pressure dressing may prevent further complications. Subcutaneous, intracutaneous, and small intramuscular injections seldom produce hematomas if firm finger pressure is maintained for at least 5 minutes. Large intramuscular injections should be avoided.

OTHER CLINICAL ASPECTS Infants usually are asymptomatic because they are insulated from trauma ([73]); hematomas are seen first when children become active, and hemarthroses seldom develop until they begin to walk. Occasionally, evidence of the disorder is not seen until patients reach teenage or young adult life. Spontaneous hemorrhage may be cyclic in nature. Petechiae, which are characteristic of disorders of platelets and blood vessels, are rare in patients with hemophilia but have been noted in severely affected patients during an exacerbation of bleeding. Hemorrhage from the umbilical cord or stump is unusual, but prolonged bleeding after circumcision is common and brought hemophilia to the attention of the ancient Hebrews. Pulmonary and pleural bleeding are uncommon, although mediastinal and pleural shadows have been noted radiographically and presumably originate from fresh or old hematomas. Intraocular hemorrhage is uncommon, but bleeding into the orbit and conjunctiva occurs often. Spontaneous rupture of the spleen has been reported. Wound healing is often slow in hemophiliacs, probably because of continued or intermittent hemorrhage or complicating infection. There is no evidence that factor VIII has any specific role in wound healing, as has been postulated for fibrinogen and factor XIII. Intracranial bleeding is discussed in the section Special Aspects of Treatment. The Web site for the National Hemophilia Foundation is http://www.hemophilia.org.

Course and Prognosis

In recent years, the prognosis in severe hemophilia has improved greatly. With proper treatment using sterile replacement products, a nearly normal lifespan can be expected, and the crippling sequelae of the disease can be minimized. The disorder does not appear to protect older hemophiliac patients from thromboembolic disorders ([74]) or atherosclerosis ([75] , [76]). Details of hemophilia complications are discussed in the section Special Aspects of Treatment.

Laboratory Diagnosis

Basic hematologic examinations reveal nothing characteristic in hemophilia A. The presence or absence of anemia or of signs of blood regeneration depends on the severity and frequency of bleeding. Neutrophilia may accompany severe hemorrhage. As in other instances of posthemorrhagic anemia, the bone marrow reflects the response to blood loss.

SCREENING TESTS OF HEMOSTASIS AND COAGULATION The partial thromboplastin time (PTT) usually is prolonged in patients with hemophilia A (Table 59.5). Abnormal results are usually obtained if the factor VIII level is less than 25% of normal; however, some PTT reagents are insensitive to mild factor VIII deficiency ([77]). The abnormality of the PTT can be normalized by mixing the patient's plasma with normal plasma if no factor VIII antibodies are present.

TABLE 59.5. Laboratory Findings in Common Inherited Coagulation Disorders

Disorder	Partial Thromboplastin Time	Prothrombin Time	Thrombin Time	Ancillary Tests
Hemophilia A	A	N	N	vWF antigen and activities are normal or increased, ratio VIIIc:vWF is low.
Hemophilia B [a]	A	N [a]	N	—
von Willebrand disease [a, b]	vA	N	N	vWF antigen and VIIIc are usually low, ratio VIIIc:vWF is variable; ristocetin-induced platelet aggregation and ristocetin cofactor activity are usually diminished.
Afibrinogenemia	A	A	A	Platelet function may be abnormal.
Dysfibrinogenemia [a]	vA	vA	A [c, d]	Hypofibrinogenemia, [e] reptilase time is prolonged, [a] fibrin(ogen) degradation products levels are increased. [a]
Hypoprothrombinemia [a]	A	A	N	Two-stage assay is abnormal. [f]
Factor V deficiency	A	A	N	—
Factor VII deficiency [a]	N	A	N	Stypven (Russell viper venom) time is normal.
Factor X deficiency [a]	A	A	N	Stypven time is abnormal.
Factor XI deficiency	A	N	N	—
Factor XII deficiency	A	N	N	—
Factor XIII deficiency	N	N	N	Clot solubility tests are abnormal.

A, abnormal; N, normal; v, variable; vWF, von Willebrand factor.

[a] Findings are significantly different in some variants.

[b] Coagulation abnormalities are caused by deficiency of factor VIIIc.

[c] Patient's plasma may inhibit normal coagulation.

[d] Abnormality may be corrected by increasing calcium concentration and may be magnified by diluting the thrombin solution.

[e] Abnormality varies depending on technique.

[f] Results of one-stage techniques may be uninterpretable.

The platelet count usually is normal or elevated. Throm-bocytosis may reflect a response to acute or chronic hemorrhage, but in many hemophiliacs, it has been found in the absence of significant bleeding.

FACTOR VIIIC ASSAYS Assay of factor VIII is a simple technique. Two-stage methods ([78]), one-stage methods ([79]), and micromethods ([80]) are suitable for diagnosis. The one-stage techniques are used most widely because they are simple to perform. They require either a supply of plasma from a known severe hemophiliac, which is available commercially, or artificial substrate plasma ([81]). Two-stage assays detect approximately 20% more factor VIII than do one-stage methods ([82]), and they are less subject to variables ([83]) such as fluctuations attributable to contaminating traces of thrombin or other proteolytic enzymes. The World Health Organization makes international standards, but many laboratories purchase commercial secondary standards that are calibrated to the international standard. Under most circumstances, a pool of citrated plasma carefully collected from normal subjects and frozen in individual laboratories also serves as an acceptable standard. The factor VIII assay has a large potential for error, even in expert hands. Therefore, when borderline values are obtained, the assay should always be repeated. Extensive studies of the many variables of the factor VIII assay have been reported ([84], [85]). Assays for both factor VIII and vWF may be carried out with reasonable accuracy on material obtained by fetoscopy—that is, mixtures of blood and amniotic fluid ([86]) or unmixed fetal blood ([87]). The availability of a new recombinant form of factor VIII (B domain–deleted factor VIII, Refacto) has raised concerns about accurate laboratory monitoring of patients receiving this product ([88]). Chromogenic substrate assays or typical one-stage PTT assays using physiologic phospholipids are needed to accurately quantitate factor VIII levels in patients receiving B domain–deleted factor VIII ([89]). Alternatively, a standard one-stage PTT assay using B domain–deleted factor VIII as the assay standard would be appropriate. The use of concentrate standards (rather than plasma standards) diluted in factor VIII–deficient plasma has been proposed as a solution to resolve discordant results using different assay methods ([90]).

FACTOR VIIIAG (CAG) ASSAYS Highly specific but complicated assays using immunoradiometric methods (immunoradiometric assay) and enzyme-linked immunoabsorbent assay (ELISA) techniques ([91]) are available to measure factor VIIIAg (VIIIAg). The latter methods use liquid- and solid-phase principles and both natural factor VIII antibodies and monoclonal antibodies. ELISA techniques were more precise than immunoradiometric assay methods in one comparative study ([92]). The results of both of these techniques demonstrate the absence of factor VIIIAg in most severely affected hemophiliacs and correlate well with factor VIIIc measurements in most cases. Results are more variable when mild hemophiliacs are tested. In most series, approximately 10% of patients have detectable levels of factor VIIIAg and a low VIIIc to VIIIAg ratio (the CRM-positive variant). Immunoassays for vWF are discussed in the section Laboratory Diagnosis.

Differential Diagnosis

The diagnosis of hemophilia A is seldom difficult, especially in the severely affected patient in whom repeated and often serious hemorrhagic manifestations, including such characteristic signs as hemarthrosis, are clearly apparent early in life. Hemarthrosis with significant orthopedic disability is rare in patients with coagulation disorders other than hemophilia A and hemophilia B.

In patients with the mild forms of the disorder, however, failure to recognize the existence of the disease or to make the correct diagnosis is more likely. Such patients may have little spontaneous bleeding, and the family history tends to be vague or negative. Because the diagnosis of hemophilia often is equated erroneously with a prolonged PTT value, a normal value may be misleading. It must be emphasized that mildly affected hemophiliacs are prone to hazardous hemorrhage after trauma or during surgical procedures ([93]). A normal PTT value cannot be relied on to exclude the possibility of hemophilia. In the mildly affected patient, specific factor assays must be performed to confirm or exclude the diagnosis of hemophilia.

The results of screening tests (Table 59.5) usually are sufficient to exclude the possibility of acquired hemorrhagic disorders associated with serious bleeding. Such disorders are seldom associated with a prolonged PTT and a normal prothrombin time (PT), a combination that strongly suggests an inherited disorder or an inhibitor. Among the inherited disorders characterized by this combination of findings [hemophilia A, hemophilia B, and deficiencies of factors XI, XII, prekallikrein, and high-molecular-weight kininogen (HMWK)], deficiency of the latter three factors can be readily excluded because their deficiency is not associated with excessive clinical bleeding. Factor XI deficiency in males may mimic mild hemophilia, and hemophilia B is clinically identical to hemophilia A. Both factor XI deficiency and hemophilia B must be distinguished from hemophilia A in the laboratory. The best way to accomplish this in evaluating patients with an isolated prolonged PTT is by performing specific assays of these three factors in the order of their statistical frequency—that is, VIII, IX, and XI. A PTT-mixing study should also be performed to exclude an inhibitor. A definitive diagnosis is of great importance because specific products are used to treat each of these disorders.

Severe vWD in males may be indistinguishable from mild hemophilia A. Confirmatory tests for vWD are needed to make this distinction. Patients with the uncommon type 2N vWD may also be clinically indistinguishable from patients with hemophilia A ([36]). An X-linked family history of bleeding supports a diagnosis of hemophilia A in these patients, and an autosomal-recessive family history of bleeding supports a diagnosis of type 2N vWD.

Bleeding manifestations in hemophilia may simulate a variety of conditions. However, serious confusion results only when the correct diagnosis has not been considered and appropriate laboratory studies have not been ordered. Thus, a deep hematoma may be mistaken for a suppurative condition, and surgical drainage may be attempted. Bleeding into a small joint may produce a clinical and radiologic picture suggestive of sarcoma; when larger joints are involved, findings simulate tuberculosis, arthritis, or Perthe disease. Bleeding elsewhere may suggest local causes such as kidney tumor, pulmonary disease, or peptic ulcer.

Intraabdominal bleeding raises particularly serious diagnostic and therapeutic problems in the patient with hemophilia, even when the hemophilia has been accurately diagnosed. Thus, hemorrhage into the psoas, when on the right side, may simulate acute appendicitis so closely that, in the opinion of many experienced clinicians, there is no reliable clinical means to differentiate between the two. A retroperitoneal hematoma may be mistaken for an appendiceal abscess. Intraperitoneal hemorrhage and bleeding into and around other viscera may simulate perforating peptic ulcer, bowel obstruction, or virtually any acute intraabdominal condition. Computed tomography scanning and sonography may be particularly helpful in differentiating between intraabdominal conditions that require surgical intervention and retroperitoneal and psoas hemorrhages ([94]).

VON WILLEBRAND DISEASE

The historical confusion that has surrounded the pathogenesis of vWD is apparent from the many names that have been applied to this disorder. These designations include *angiohemophilia, vascular hemophilia, pseudohemophilia, constitutional throm-bopathy*, and *idiopathic prolonged bleeding time*. von Willebrand first recognized the disorder in a 1926 study of the inhabitants of the Åaland islands ([95]). von Willebrand thought that the hemostatic defect resulted from combined defects in platelet function and vascular endothelium. The discovery that plasma from normal volunteers or patients with hemophilia A corrected the hemostatic defect of vWD suggested that a plasma protein distinct from factor VIII caused vWD. In its most common form (type 1), the disorder is characterized by mild mucocutaneous hemorrhage, a prolonged bleeding time, deficiency of vWF, and less pronounced reduction in levels of factor VIIIc. The disorder is not homogeneous, however, in part due to the multiple physiologic functions played by vWF. The recognition of a number of variants ([96] , [97]), together with the demonstration of multiple genetic patterns, suggests that vWD is very heterogeneous. However, all forms of vWD can be traced to insufficient amounts of vWF or defective function of this protein. Recently, both brief and more extensive reviews of this topic have been written ([98] , [99]).

Incidence

Epidemiologic studies indicate that vWD is the most common bleeding disorder, affecting approximately 1% of the population. The high incidence of the disease is not limited to certain ethnic groups ([100] , [101]); however, only a fraction of people come to medical attention because of bleeding symptoms. This may be due to either the relatively mild nature of disease in many affected individuals or a lack of recognition of excessive bleeding in response to either physiologic challenge (e.g., heavy menstrual bleeding) or trauma.

Nomenclature

The identification of numerous variants of vWD has led to attempts to simplify classification of this disorder ([102]). Table 59.6 summarizes the revised classification. Quantitative defects are divided into partial deficiency (type 1) and severe deficiency with complete absence of vWF (type 3). The qualitative defects (type 2) are divided into four categories according to the nature of the defect of vWF function. *Type 2A* refers to variants with impaired interaction between vWF and platelets due to a deficiency of intermediate- and high-molecular-weight multimers of vWF. *Type 2B* refers to variants in which vWF exhibits increased affinity for its receptor, platelet glycoprotein (gp) Ib. Paradoxically, bleeding in these patients develops due to clearance of larger vWF multimers and platelets from the circulation. *Type 2M* refers to variants with defective interaction between vWF and the platelet gpIb receptor that is not due to deficiency of high-molecular-weight multimers of vWF from plasma but to defects within the gpIb binding domain of vWF. Finally, variants of vWD in which decreased affinity of vWF for factor VIII results in depressed plasma factor VIII levels are classified as *type 2N* ([102]).

TABLE 59.6. Revised Classification of von Willebrand Disease

Revised Type	Features	Previous Type [a]
1	Partial deficiency of vWF	I-1, I-2, IA
2A	vWF variants with loss of high-molecular-weight multimers and decreased platelet-dependent function	IIA, IIC, IID, IIE, IIF, IIG, IIH
2B	vWF variants with loss of high-molecular-weight multimers caused by increased affinity for platelet glycoprotein Ib	IIB, I New York, Malmo
2M	vWF variants with decreased platelet-dependent function not associated with the loss of high-molecular-weight multimers	B, Vicenza, IC, ID
2N	vWF variants with decreased affinity for factor VIII	Defective VIII binding Normandy
3	Severe deficiency of vWF	III

vWF, von Willebrand factor.

Genetics

A gene on chromosome 12 codes the synthesis of the vWF macromolecule. The genetic message is composed of 52 exons covering a span of 158 kb ([103] , [104]). The vWF gene encodes for a protein with multiple copies of homologous motifs, including three A, three B, two C, and four D motifs. These motifs, in turn, encode for protein domains that subserve the various functions of vWF. The A1 domain contains binding sites for platelet gpIb and ristocetin ([105]), the A2 domain contains a protease-sensitive domain that may play a regulatory role in vWF function ([106] , [107]), the A3 domain contains an important collagen-binding domain ([107] , [108]), the C1 domain has an RGD sequence capable of interacting with platelet gpIIb/IIIa ([109]), and the D' and D3 domains contain a factor VIII binding sequence ([107]).

vWD appears to be inherited by multiple genetic mechanisms (Table 59.7). The most common form of the disorder (type 1 vWD) is inherited as an incompletely dominant autosomal trait with variable penetrance. The expressivity of the genetic abnormality is highly variable, even among members within a single kindred. For example, an affected parent would be predicted to transmit vWD to 50% of his or her children; however, because of variable penetrance and expression of vWD, only approximately 33% of children may be affected. Figure 59.5 illustrates one of the original pedigrees described by von Willebrand.

TABLE 59.7. Features of Common Variants of von Willebrand Disease

Features	Type 1	Type 2A	Type 2B	Type 3	Platelet-Type
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive	Autosomal dominant
Bleeding time	Normal or prolonged	Prolonged	Prolonged	Prolonged	Prolonged
Factor VIIIc in plasma	Normal or reduced	Normal or reduced	Normal or reduced	Reduced	Normal or reduced

vWF antigen	Normal or reduced	Normal or reduced	Normal or reduced; increased affinity for platelets	Reduced	Normal or reduced; increased affinity for platelets
vWF multi-meric analysis	Normal	Absence of large and intermediate-sized multimers	Absence of large multimers	Variable abnormalities; preponderance of small multi-mers or absent multimers	Reduction in large multimers caused by “consumption” by platelets
Ristocetin cofactor activity	Normal or reduced	Reduced	Normal or reduced	Reduced	Reduced or normal
Ristocetin-induced platelet aggregation	Normal or diminished	Diminished	Increased aggregation at low ristocetin concentrations	Markedly diminished	Hyperaggregation with patient's platelets, normal plasma, and low concentration of ristocetin
vWF in platelets	Normal or reduced	Normal or absence of large and intermediate-sized multimers	Normal	Absent	Normal
Ancillary findings	DDAVP usually produces significant increase in plasma VIIIc and duration vWF	DDAVP produces rise in factor VIIIc, but functional vWF increase is variable and may be of short	Variable response to DDAVP, with intravascular platelet aggregation and thrombocytopenia in some cases; ristocetin cofactor levels and ristocetin-induced platelet aggregation enhanced in presence of patient's plasma; cryoprecipitate does not aggregate platelets *in vitro* unless ristocetin is added	Response to DDAVP lacking; endothelial vWF absent; carriers difficult to detect	Transfusion of vWF or DDAVP may produce intravascular platelet aggregation and thrombocytopenia; cryoprecipitate produces *in vitro* platelet aggregation

DDAVP, 1-deamino-8-D-arginine vasopressin; vWF, von Willebrand factor.

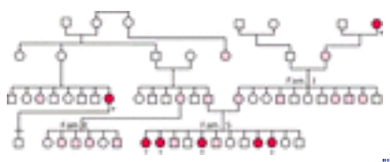

Figure 59.5. Pedigree of patients described by von Willebrand. Three families are emphasized: S, E, and J. Clinical details of bleeding events in these families have been reported. Open circles indicate female nonbleeders, open squares indicate male nonbleeders. Shaded circles and squares indicate female and male bleeders, respectively. Solid symbols indicate family members who experienced severe bleeding, and crosses indicate family members who experienced hemorrhagic deaths. (Modified from von Willebrand EA. Ü;ber hereditäre pseudohämophilie. Acta Med Scand 1931;76:521–550, with permission of the publisher.)

Twin studies demonstrated that approximately 60% of the variation in vWF level and approximately 50% of the variation in factor VIII level is attributable to genetic factors ([110]). The genetic mutations that underlie type 1 vWD remain largely undefined. Genetic loci outside of the vWF gene contribute to variation of vWF level. Individuals with blood group O have vWF levels that are on average 30% lower than that of people with blood groups A, B, or AB ([111]), and it is likely that carbohydrate groups attached to vWF play a subtle role in clearance of vWF from plasma ([112]). In addition, variation in expression of levels of other hemostatically active proteins, such as variation in the level of platelet adhesion receptors, may modulate the severity of symptoms conferred by vWF deficiency ([113]). vWF levels are under hormonal and other controls, which further complicates disease expression. Variation in levels of as much as 20% has been reported with menstrual cycle, with levels lowest in the early follicular phase (before day 7 of the cycle), and levels increase with age, rising approximately 15% for each decade increase in age ([114]).

Type 2 vWD is characterized by production of a qualitatively defective protein, and the genetics of these variant forms is more straightforward than that of type 1 vWD. In families affected by types 2B and 2M, as well as in the majority of families with type 2A vWD, inheritance is autosomal dominant. Rare cases of type 2A disease are transmitted in an autosomal-recessive fashion, as are most cases of type 2N disease. vWF gene sequencing studies combined with vWF mutation expression analysis have revealed that single missense point mutations underlie the majority of type 2 disorders ([115] , [116]). Type 3 vWD is also inherited as a recessive trait and occurs when both copies of the vWF gene are defective. In type 3 disease, gene abnormalities include large or partial gene deletions, disruption of orderly messenger RNA transcription (frameshift mutation, splice site, or nonsense mutation), and missense mutation. For patients with recessively inherited vWD phenotypes (type 2N, type 3, or some rare type 2A), genetic analysis may reveal either homozygous or compound heterozygous gene abnormalities. Members of the International Society of Thrombosis and Haemostasis maintain a database of vWD mutations (http://www.shef.ac.uk/vwf/index.html).

Pathophysiology

The basic defect in vWD is a deficiency or abnormality of vWF function. vWF is synthesized in endothelial cells and megakaryocytes ([117]). The primary transcription product is 2813 amino acids in length. It undergoes extensive further processing, including dimerization and polymerization, to form very-large-molecular-weight multimers ([118]). Multimerization and intracellular trafficking of vWF are directed by the vWF propeptide (vWFpp, formerly called *von Willebrand antigen II*), which is cleaved off the “mature subunit” after multimer assembly ([119]). Large vWF multimers are stored in endothelial cells in Weibel-Palade bodies ([120]) and in platelet a-granules ([121]). The majority of circulating vWF is present in plasma, with approximately 15% of circulating vWF present intracellularly within platelets. Ultra-large multimers released into the plasma are further degraded to smaller multimers, presumably through the activity of “vWF cleaving protease” ([106]). The cDNA sequence of this protein has recently been determined and shown to be a metalloproteinase of the ADAMTS family ([122] , [123]). The physiologic importance of enzymatic degradation of vWF after release is demonstrated clinically by the association of an inherited form of thrombotic microangiopathy (Schulman-Upshaw syndrome) with congenital absence of the protease due to defects of the ADAMTS-13 gene ([122]) and the observation of plasma deficiency of the protease with presence of autoantibody in some patients with sporadic thrombotic thrombocytopenic purpura ([124] , [125]). Endothelial stores of vWF can be released therapeutically through administration of desmopressin ([126]).

vWF is required for normal platelet adhesion (Chapter 20) and also acts as a carrier of factor VIII in the plasma. When vWF is deficient or aberrant, both factor VIII deficiency and abnormalities in the early steps of primary hemostasis result. vWD is thus manifested as a hybrid hemostatic defect. Both abnormalities—factor VIII deficiency and abnormal primary hemostasis—give rise to characteristic and distinct laboratory abnormalities, and both defects contribute to the bleeding tendency.

ABNORMALITIES OF PRIMARY HEMOSTASIS Until the 1950s, the abnormality in primary hemostasis in vWD was thought to be the result of either a primary vascular defect or an intrinsic abnormality of the platelets. Neither of these hypotheses found significant support, and convincing evidence now exists that the platelets, although intrinsically normal, do not adhere to subendothelium normally because of deficient or defective vWF ([127]). This abnormality is well demonstrated by methods that measure platelet adhesion to subendothelial surfaces under flow conditions (the Baumgartner technique). Results of experimental studies suggest that platelet adhesion to collagen in a flowing stream of blood may be particularly deficient at high rates of shear when only a short time is available for formation of a platelet–collagen bond ([128]). Deficient platelet plug formation has been observed directly in experimental wounds ([129]).

ABNORMALITIES OF SECONDARY HEMOSTASIS A second function of vWF is as a molecular chaperone for factor VIII, increasing the plasma half-life of factor VIII approximately fivefold ([130]). This effect may occur through the protection of factor VIII from activated protein C–mediated degradation ([131]). Furthermore, the binding of vWF to subendothelium at sites of vascular injury serves to co-localize factor VIII, where it can participate in its role in the regulation of hemostasis on the activated platelet membrane ([105]).

ABNORMALITIES OF VON WILLEBRAND FACTOR Quantitative or qualitative abnormalities of vWF underlie the abnormality in primary hemostasis described earlier. Materials rich in this factor correct deficient platelet adhesion as measured by the Baumgartner method ([132]). When administered intravenously to patients with vWD, vWF-containing concentrate shortens the bleeding time for a brief period. Immunoassays reveal subnormal levels of vWF activity in most patients with

vWD. In most patients with the type 1 disorder, vWF is qualitatively normal, and vWF activity is decreased in proportion to vWF antigen assay. In keeping with the chaperone role of vWF, both vWF antigen and factor VIII activity are diminished in most patients with type 1 vWD; however, factor VIII levels are generally reduced to a lesser extent. In severe vWD (type 3), vWF and its propeptide (vWFpp) are completely absent ([133]). Factor VIII levels are in the mild to moderate hemophilia range in type 3 vWD. This situation contrasts with hemophilia A ([134]), in which a selective deficiency or aberration of factor VIIIc is associated with normal or supernormal levels of vWF. Some observations point to heterogeneity of type 1 vWD. Platelet levels of vWF are normal to low in the type 1 disorder, and the bleeding time may correlate more closely with the platelet content of vWF than with plasma ristocetin cofactor activity ([135]). Functional assay of vWF interaction with platelets is generally assessed with the antibiotic ristocetin, which induces platelet agglutination. The process that occurs in the presence of this drug is not dependent on platelet metabolic activity and may not fully mirror the physiologic activation of vWF that occurs at sites of vascular injury ([136]). The empiric observation that ristocetin does not agglutinate the platelets of many patients with vWD to a normal extent provides a unique tool for the study of the disorder ([137]). The ristocetin cofactor activity represents one functional property of vWF, and abnormalities of ristocetin cofactor activity often are dissociated from other vWF properties in patients with qualitative abnormalities of vWF (type 2 vWD).

ABNORMALITIES OF FACTOR VIII Factor VIII is noncovalently bound to vWF in normal plasma and is diminished in amount in most patients with vWD. The factor VIII deficiency is attributable to failure of vWF to bind, protect, or stabilize factor VIII ([138]). The exact explanation for this phenomenon remains to be clarified. Plasma levels of vWF usually are proportional to levels of VIIIc or VIIIAg (cAg) in normal individuals, but in cases of quantitative vWF deficiency, the ratio of VIIIc to vWF may be moderately increased. Thus, factor VIIIc levels may be normal or near normal in type 1 vWD. This finding may also be observed after transfusion therapy in vWD (Fig. 59.6).

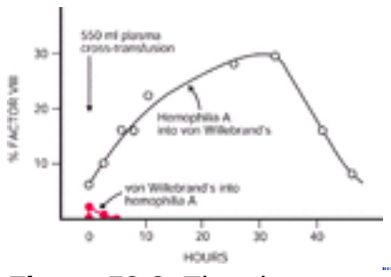

Figure 59.6. The phenomenon of new factor VIII synthesis in patients with von Willebrand disease (vWD) who receive plasma transfusion. Open circles indicate changes in the plasma factor VIII levels of a patient with vWD after infusion of plasma from a patient with severe hemophilia A. A significant and sustained increase in the factor VIII levels of the recipient was observed even though no active factor VIII was present in the infused plasma. Solid circles indicate effects of infusing plasma from a patient with vWD into a patient with severe hemophilia A. The factor VIII level in the infused plasma was 15% of normal. Note the slight and transitory effects. [From Shulman NR, Cowan DH, Libre EP, et al. The physiologic basis for therapy of classic hemophilia (factor VIII deficiency) and related disorders. Ann Intern Med 1967;67:856–882, with permission.]

Response to Transfusion

When blood products containing the vWF–factor VIII complex are infused into patients with hemophilia A, peak levels of factor VIIIc are present immediately after the infusion; this activity then declines rapidly, with an overall half-life of 8 to 10 hours (Fig. 59.6). Twenty-four hours later, factor VIIIc activity is minimal. This response is highly predictable and is discussed in a later section concerning replacement therapy for hemophilia A. In most patients with vWD, the infusion of normal vWF–factor VIII complex produces an initial peak level of factor VIIIc that is predicted from the preinfusion level and the amount of factor infused. This is followed by a sustained but variable rise in factor VIIIc activity that reaches a plateau approximately 24 hours later and may persist for 48 to 72 hours. This phenomenon is highly variable and irregular; in some patients, a rapid initial fall of factor VIIIc is followed by a secondary rise in activity. This disproportionate response to transfused factor VIII has been called the *secondary transfusion response*, *de novo* or *new factor VIII synthesis*, or *in vivo complementation* and apparently is a unique feature of vWD.

Various hypotheses have been advanced to explain the disproportionate response to transfusion described above. The leading hypothesis is that the infused vWF results in stimulation of increased factor VIII release into the plasma with the attachment of the newly released factor VIII onto infused vWF ([138]).

Transfusions of blood products containing vWF shorten the bleeding time to a variable degree in patients with vWD. This corrective effect seldom persists for more than a few hours, even after massive transfusions that raise vWF to high levels. The correction of the bleeding time apparently requires the large molecular forms of vWF that are present in cryoprecipitate and select intermediate-purity factor VIII concentrates ([139]) but completely absent from monoclonally purified or recombinant concentrates of factor VIII ([140]). Failure of the skin template bleeding time of patients with vWD to show sustained correction with appropriate replacement therapy has been noted and does not necessarily predict defective surgical hemostasis ([141]). This apparent paradox may be due to sensitivity of the bleeding time test to platelet a-granule vWF, which is not replenished during vWF replacement therapies ([142]).

Clinical Manifestations

The bleeding manifestations in vWD are heterogeneous but consistent with the dual roles of vWF in supporting both primary and secondary hemostasis ([105]). Thus, in the mild forms of vWD, the clinical picture is dominated by cutaneous and mucosal bleeding, which appears to be mainly the result of disordered primary hemostasis. In the most severe forms of the disorder, in which factor VIII levels are low, hemarthroses and dissecting intramuscular hematomas may develop. As in mild classic hemophilia, serious hemorrhage resulting from traumatic injuries or after surgical procedures is a significant hazard in severe vWD. Petechiae are rare, but hematoma formation and the extent of bruising are excessive compared with the inciting trauma.

The bleeding manifestations in the usual patient with type 1 vWD are mild, however, and many patients are virtually asymptomatic. The disorder may be symptomatic at any age but is not always recognized. Mucosal bleeding is particularly common. Childhood epistaxis, a life-long history of easy bruising, bleeding with dental extraction, heavy menstrual bleeding or anemia attributed to excessive menstrual blood losses, or postpartum hemorrhage are all included in the spectrum of vWD symptomatology. Systemic bleeding disorders are often not considered in women with menorrhagia ([143]), but clinical studies reveal that the prevalence of vWD is significant in individuals who present with this complaint ([144]). Angiodysplasia of various vascular beds, particularly those in the gut, has been demonstrated in some patients with vWD and may be an important contributory factor in chronic gastrointestinal bleeding ([145]). The disorder may decrease in severity with advancing age. In type 1 vWD, symptoms usually become milder during pregnancy or with estrogen therapy when the vWF and factor VIIIc level rises significantly ([39]). Bleeding manifestations tend to be more prominent in patients with more severe quantitative deficiency and in patients with qualitative (type 2) defects.

While eliciting the history of bleeding, one should bear in mind that women are often inaccurate assessors of whether their menstrual flow is normal or excessive. Supplemental questioning regarding the frequency of changes of menstrual protection and questions regarding a history of iron deficiency anemia may be informative. Retrospective studies of women with vWD show that abnormal bleeding can often be traced to menarche ([146]). Family history also may provide important clues to a diagnosis. The physician should specifically seek history of the response to hemostatic challenge such as dental extraction, tonsillectomy, surgical procedure, menstruation, and peripartum hemorrhage. Excessive bleeding in response to challenge with aspirin may also point toward a bleeding disorder, but this history is not specific for vWD.

Laboratory Diagnosis

Criteria for the laboratory diagnosis of vWD are imperfect. The large number of assays available reflects the breadth of function of vWF, and no test by itself is sensitive or specific enough to diagnose all patients ([147]). Furthermore, the results of various tests correlate imprecisely with the extent of hemorrhagic manifestations ([105]). Both vWF and factor VIII are “acute phase reactants,” increasing with stress, trauma, estrogen therapy, or pregnancy, such that levels may fluctuate from time to time ([97]). In one study, less than one-half of the patients had decreased levels of factor VIIIc, and in 20% of cases, both the bleeding time and the factor VIIIc levels were normal ([148]). Even with the more elaborate confirmatory tests now available, the diagnosis of this disorder may be difficult and may require repeated observations over a period of time. However, pregnancy and acute phase reaction are unlikely to obscure diagnosis in patients with more severe quantitative deficiency or qualitative defects.

Diagnosis of vWD is complicated, due to both the breadth of vWF functions and the spectrum of disorders constituting vWD. Consequently, a battery of studies should be considered to conclusively evaluate a patient for vWD ([105]). Screening tests, such as bleeding time and PTT, are supplemented with specific tests such as

vWF antigen, vWF activity, and factor VIII level. Correlating the value of these various quantitative assays with each other or obtaining qualitative tests, such as vWF multimer analysis or low-dose ristocetin-induced platelet aggregation, may provide important clues toward a diagnosis of type 2 vWD (Table 59.7).

BLEEDING TIME The template bleeding time, the Ivy bleeding time, or technical modifications thereof may be useful in detecting the abnormality characteristic of vWD. However, the bleeding time may be normal in many patients with vWD ([149]). Consequently, the bleeding time adds to the diagnosis of vWD if it is prolonged but otherwise may have little clinical use in the diagnosis and management of patients with vWD. The bleeding time may not correct after replacement therapy with vWF, and monitoring is generally not recommended ([141]), as surgical bleeding is generally prevented through replacement of plasma vWF.

PLATELET FUNCTION ANALYZER Standardization issues, inconvenience, and residual scarring of patients are some of the issues that have fostered development of *in vitro* techniques to replace the bleeding time. The PFA-100 is a new platelet function analyzer that evaluates platelet adhesion and aggregation to collagen in a whole blood assay under high shear conditions ([150]). Citrate-anticoagulated whole blood is aspirated through an aperture in a collagen-coated membrane, and the device measures the time from first flow until flow ceases as the "closure time." PFA-100 closure times are sensitive to multiple factors, including vWF function, platelet count, platelet function, and hematocrit. Studies in vWD patients have revealed that the assay is sensitive to most forms of vWD. However, the closure time may remain normal in acquired vWD despite a very reduced plasma vWF level, as the platelet vWF level may be normal, and in patients with type 2N vWD in which the major defect is low factor VIII levels. Correction of plasma vWF level in the absence of concomitant correction of the platelet vWF may be insufficient to correct the closure time, so that this test may not be very helpful for peri-operative monitoring of patients on replacement therapy ([151], [152] and [153]).

PARTIAL THROMBOPLASTIN TIME AND FACTOR VIIIC ASSAY Among the simple screening tests (Table 59.5), the PTT may be abnormal, reflecting reduced levels of factor VIIIc. Plasma levels of factor VIIIc vary greatly in this disorder and range from as low as 3 U/dl in patients with type 3 vWD to normal in patients with mild type 1 vWD. Because factor VIIIc deficiency is often mild in patients with vWD, a diagnosis of vWD may be missed by the routine screening PTT, especially in patients with mild disease. Consequently, a specific assay is required to reliably detect factor VIIIc deficiency in this syndrome.

VON WILLEBRAND FACTOR IMMUNOASSAY The immunoassay of vWF is a quantitative measure of vWF protein and is one of the most sensitive methods available for the diagnosis of vWD ([154]). A variety of methods have been used, all of which depend on antibodies specific to vWF. The electroimmunodiffusion method of Laurell was initially widely used because it was simple to perform, but ELISA or automated assays using related methodology have now largely replaced this technique. Average levels of vWF antigen (vWF:Ag) obtained by different laboratories vary, but a level of approximately 45 to 50 U/dl is the lower limit of normal reported by many laboratories. The ratio of factor VIIIc to vWF also varies by laboratory but normally ranges from approximately 0.7 to 2.2 (Fig. 59.1). Plasma levels of vWF:Ag are regulated to some extent by carbohydrate residues attached to the protein; lower vWF antigenic levels have been noted in patients with blood type O compared to patients with other blood types ([42]). Whether these patients actually have vWD type 1 is subject to debate, and some laboratories use blood group–specific reference ranges for diagnosis of vWD ([105]). Patients with type 2 vWD may have normal vWF:Ag levels, emphasizing the need to use more than just a vWF antigen assay to evaluate a patient for vWD.

VON WILLEBRAND FACTOR FUNCTIONAL ASSAYS vWF has multiple functions, and assays have been devised to specifically evaluate many of these. The function most often clinically assessed is its ability to interact with platelets. An assay that evaluates the ability of vWF to interact with collagen has also been proposed as a functional assay, but the relevance of collagen binding activity analysis is questioned for routine screening. Collagen-binding activity assay has not gained widespread acceptance in the United States. Finally, vWF binding of factor VIII can be assessed in special circumstances when questioning whether mild factor VIII deficiency is due to failure of vWF chaperone function. vWF functional assay generally correlates well with vWF:Ag in patients with quantitative disorders of vWF. Observing a discrepancy between vWF function and vWF:Ag provides a useful clue for qualitative defects provided that the testing laboratory uses the same control plasma for performing both assays ([155]).

RISTOCETIN COFACTOR ACTIVITY AND RISTOCETIN-INDUCED PLATELET AGGREGATION The assay for ristocetin cofactor activity (vWF:RCo) is a quantitative technique for estimating the ability of vWF in the plasma to bind target platelets that are specially preserved or fixed for use in the assay ([156]). Ristocetin induces an "activation" of vWF such that it then binds platelets via the platelet gpIb receptor, mimicking the *in vivo* sequence that drives an interaction between subendothelial tissue–bound vWF with platelets. Quantitation of vWF:RCo is held to be the single most sensitive and specific assay for vWD by multiple authorities ([105], [157], [158] and [159]). vWF:RCo activity is adversely affected by loss of the larger-molecular-weight vWF multimers. The discrepancy between vWF:RCo and vWF:Ag that is observed in qualitative defects characterized by loss of both the intermediate- and higher-molecular-weight multimers (e.g., type 2A vWD) is thought to be on this basis. Ristocetin cofactor activity is also generally used to follow a vWD patient's response to therapeutic interventions. However, the typical ristocetin cofactor activity is a time-consuming procedure, and assay standardization remains somewhat problematic. Simpler ELISA-based methods using monoclonal antibody to the gpIb binding domain of vWF have been explored for estimating vWF activity ([160]). However, commercialized functional epitope assays have not performed sufficiently well to allow them to replace vWF:RCo assay ([161], [162]). Ristocetin-induced platelet aggregation is a test distinct from ristocetin cofactor activity. Ristocetin-induced platelet aggregation is a qualitative test that involves evaluating the rate or extent of agglutination of patient-derived platelet-rich plasma in response to the addition of the antibiotic ristocetin. The concentration of vWF and platelets present in the test plasma, as well as the amount of ristocetin added, affect ristocetin-induced platelet aggregation. The assay is relatively insensitive to mild deficiency of vWF ([148]) but is abnormal both in more severe deficiency and in patients with Bernard-Soulier syndrome (in which platelets are missing the gpIb receptor). Titrating down the amount of ristocetin added in the assay may be of specific interest in defining variants of vWD in which there are "gain of function" mutations (type 2B and platelet-type pseudo-vWD) that are characterized by increased sensitivity of patient vWF or platelets to the effect of ristocetin ([163]). However, insensitivity of patient samples to low-dose ristocetin aggregation is seen in occasional patients with type 2B vWD when there is marked reduction in the amount of high- and intermediate-molecular-weight multimers, and genetic analysis may be required to distinguish some cases of type 2B disease from type 2A vWD. In addition, low-dose ristocetin aggregation cannot differentiate type 2B vWD from the rarer platelet-type (pseudo) vWD, and mixing studies using patient plasma and donor platelets have been devised to help make that distinction at the phenotypic level ([164]).

VON WILLEBRAND COLLAGEN-BINDING ACTIVITY vWF contains collagen-binding sites in both the A1 and A3 domains of the vWF protein, and collagen-binding activity (vWF:CB) may be an important function to allow vWF to tether to platelets at sites of vascular injury. The assay is done in an ELISA format, in which type I or type III collagen is plated into microtiter wells, and the amount of vWF captured is assayed ([165], [166]). vWF:CB correlates well with vWF:Ag in normal individuals and those with quantitative deficiency of vWF, and discrepant results are indicative of vWD subtypes that are characterized by deficiency of larger vWF multimers. A single case of vWD characterized by mutation of the vWF A3 domain with isolated loss of collagen-binding function despite the presence of a normal multimer distribution has recently been described ([108]).

ASSAY OF VON WILLEBRAND FACTOR'S ABILITY TO BIND FACTOR VIII Factor VIII binding by vWF (vWF:FVIIIB) can be measured in a few reference coagulation laboratories and is indicated for the evaluation of patients suspected of having factor VIII deficiency on the basis of defective vWF chaperone function (type 2N vWD) ([167]). In this ELISA format assay, ELISA plate wells are coated with antibody to vWF to capture vWF from patient plasma. After washing patient-derived factor VIII from the well, the ability of patient-derived vWF to capture recombinant factor VIII (r-FVIII) is assessed using a chromogenic assay for factor VIII, and the quantity of patient-derived vWF:Ag in the well is quantified by standard ELISA technique. The calculated ratio of r-FVIII to vWF:Ag is expected to be in the normal range when testing plasma from a patient with hemophilia A, whereas it is abnormally low in the rare cases of type 2N vWD ([168]).

MULTIMERIC ANALYSIS OF VON WILLEBRAND FACTOR Normal vWF in plasma consists of a complex series of multi-mers, ranging in size from approximately 800 kd to 20,000 kd. vWD initially diagnosed by abnormal assays for factor VIIIc, vWF antigen, or ristocetin cofactor activity should be further characterized by multimeric analysis. In this test, the structural integrity of the patient's vWF is assessed by size-based separation of vWF multimers via agarose gel electrophoresis, and vWF multimers are imaged by immunologic methods such as autoradiography or immunoperoxidase technique ([169]). This method confirms the presence of the entire spectrum of vWF multimers in normal individuals and those with type 1 vWD and allows identification of the loss of intermediate- or high-molecular-weight multimers of vWF as is characteristic of the type 2A and type 2B qualitative defects ([169]). However, distinction between type 2A and type 2B vWD is not always possible using multimer analysis alone, necessitating further testing. Results of multimeric analysis may be helpful in predicting response to 1-deamino-8-D-arginine vasopressin (DDAVP; desmopressin) therapy. Multimeric analysis is a very labor-intensive test and is usually performed only in coagulation reference laboratories. The multimeric composition of plasma from normal subjects and patients with vWD is shown in Figure 59.7.

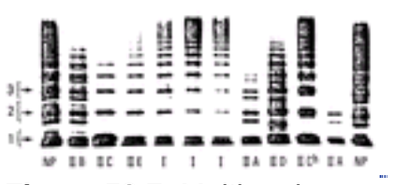

Figure 59.7. Multimeric composition of von Willebrand factor from normal plasma and that from types I, IIA, IIB, IIC, IID, and IIE von Willebrand disease (vWD), as well as from a type IIC heterozygote (IIC ^{h}). Using the revised classification scheme, these types would correspond to 1, 2A, 2B, 2A, 2A, and 2A, respectively. The three brackets include the smallest normal oligomers, with arrows pointing to the central predominant band in each. In type 1 vWD, the relative concentration of large multi-mers varies. (From Zimmerman TS, Ruggeri ZM. von Willebrand disease. Hum Pathol 1987;18:140–152, with permission.)

GENETIC STUDIES OF SPECIFIC CDNA REGIONS Direct mutational analysis by vWF gene sequencing, allele-specific polymerase chain reaction, or restriction enzyme analysis is useful in confirming a diagnosis of type 2 variant vWD ([170]). The functional domain structure of the vWF gene results in clustering of the various type 2 vWD defects in limited areas of the vWF sequence ([171]). vWF exon 28 encodes for the A1 loop of vWF responsible for the interaction of vWF with platelet gpIb, and vWD variants characterized by defects of this interaction (types 2B and 2M) are encoded for by genetic mutations clustered in this exon ([172]). Mutations of

exon 28 also underlie the majority of type 2A defects, as it also encodes for the A2 domain. The A2 domain may direct intracellular vWF transport but also contains a protease-sensitive area. On rare occasions, type 2A vWD results from a defect of the multimerization process. The carboxy-terminal of the vWF peptide (encoded by exons 51 to 52) is involved in dimer formation, and the amino-terminal (encoded by exons 1 to 17) of the vWF peptide is involved in subsequent multimer assembly. Mutations responsible for defective interaction of vWF with factor VIII (type 2N vWD) are predominantly clustered in exons 18 to 20, which encode for the factor VIII binding domain of vWF; however, rare cases have been attributed to mutation in exon 24. An on-line database of defects found in vWD patients can be accessed at http://www.shef.ac.uk/vwf/index.html/ ([173]).

Quantitative Defects of von Willebrand Factor

Decreased production of a functionally normal protein underlies type 1 vWD. Complete absence of vWF is responsible for the most extreme form of vWD, and this is classified as type 3 vWD ([102]).

TYPE 1 VON WILLEBRAND DISEASE Patients with bleeding attributed to decreased production of qualitatively normal vWF are classified as having type 1 vWD. Most patients with vWD (70 to 80%) fall into this category ([105]). The majority of type 1 vWD patients have a mildly symptomatic disorder, but bleeding may increase with physical trauma or surgery or during menstruation. vWF levels are usually in the 30 to 50 U/dl range, with concordant reduction of vWF:Ag and vWF:RCo (and vWF:CB if that is measured). Factor VIII levels are generally equal to, or higher than, vWF levels, and all vWF multimers should be present if that analysis is performed as part of the patient evaluation. Although type 1 vWD has been subcategorized by platelet vWF content and this may help predict DDAVP responsiveness ([174]), most laboratories do not perform such specialized testing. The majority of type 1 vWD patients show a favorable response to DDAVP, which is the preferred form of therapy to raise vWF levels in type 1 vWD ([99]).

TYPE 3 VON WILLEBRAND DISEASE Type 3 vWD is the most severe form of vWD, due to complete failure of vWF synthesis. This bleeding disorder is generally diagnosed during infancy. Hematoma formation is common, epistaxis may be life-threatening, and hemarthrosis may occur owing to the low factor VIII levels that are seen in this condition. Plasma from patients with type 3 vWD contains essentially no detectable vWF, and vWF is not present in either platelets or endothelial cells. The factor VIII level is generally in the 1 to 10 U/dl range, similar to that seen in moderate to mild hemophilia A. Multimeric analysis of the little vWF present yields variable results—in some cases revealing only small multimers ([169]). Type 3 vWD is rare, with an estimated frequency of 1 in 1 million persons ([175]). Genetic analysis reveals either homozygous or compound (double) heterozygous defects of the vWF gene with gene deletions, frameshift mutations, missense mutations, or nonsense mutations ([176]). Careful laboratory evaluation of the parents of patients with type 3 disease may reveal mild quantitative deficiency of vWF, but parents are frequently asymptomatic, consistent with the impression that type 3 disease is inherited as a recessive trait. Consanguinity is common in kindreds with this variant. In some patients with type 3 vWD, large gene deletions have been identified on one or both vWF alleles ([102], [115], [177]). Such patients are at increased risk of developing inhibitory alloantibodies to vWF after transfusion therapy ([177]). Because these patients lack vWF in their endothelial cells and platelets, there is no rise in vWF level in response to DDAVP. For replacement therapy, these patients require vWF-containing concentrates, usually in the form of specific intermediate-purity factor VIII concentrates that have been documented to contain intact vWF ([139]). Because these patients possess a normal factor VIII gene but are missing the vWF chaperone, posttransfusion factor VIII recovery and survival may be longer in a patient with type 3 vWD than in a patient with hemophilia A, owing to endogenous factor VIII production. In one case, infusion of a vWF concentrate devoid of factor VIII was shown to result in normalization of the factor VIII level at 8 hours and persistence of factor VIII for 48 hours after the infusion ([178]). Thus, although for life-threatening bleeds, immediate replacement of both vWF and factor VIII is required, replacement with vWF alone may be sufficient if therapy is begun 12 to 24 hours before elective surgery.

Qualitative Defects of von Willebrand Factor

Several subsets of patients with vWD differ substantially from those with the common quantitative deficiency states (Table 59.6) ([105]). Classified as type 2 variants, these qualitative defects of vWF are less common but may represent up to 10 to 15% of cases of vWD. Type 2 forms of vWD are suspected when the severity of the patient's symptoms seems in excess of the observed vWF and factor VIII levels, when there are discordant reductions between vWF antigen and vWF functional activity or factor VIII assay, or when there is concomitant vWF deficiency and thrombocytopenia. Examining the structure of patient vWF may provide further definition of the nature of qualitative defect. This was initially performed by methods such as crossed immunoelectrophoresis, but current methods now include vWF multimer analysis (Fig. 59.7), supplemental studies of vWF function, and genetic analysis of the vWF gene ([105], [115], [169], [176], [179]). Type 2 defects were initially classified using a roman numeral system, but further understanding of the genetics of vWD led to the consolidation and reclassification into types 2A, 2B, 2M, and 2N ([102], [115]) based on the nature of the vWF functional defect. In addition to the well-defined variants described in this chapter, other forms of vWD continue to be described. Figure 59.8 illustrates the genetic basis for many patients with variant vWD.

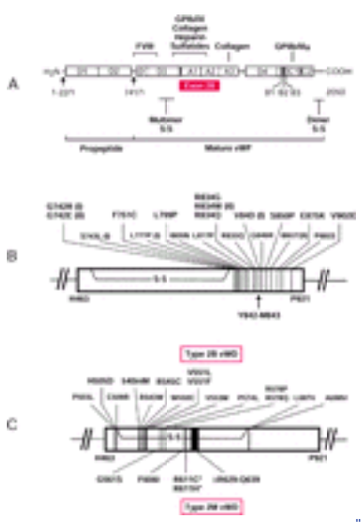

Figure 59.8. A: Structure and functional domains of von Willebrand factor (vWF). The open rectangles indicate domains of pre–pro-vWF. The first 22 amino acids of pre–pro-vWF are the signal sequence. The left arrow identifies the site of cleavage of the signal peptide, resulting in pre-vWF monomers. Pro-vWF monomers form dimers, and the vWF propeptide (vWAgII) is cleaved from mature vWF (right arrow indicates cleavage site). Dimer S-S and multimer S-S indicate locations of disulfide bonds that covalently link monomeric vWF into dimers and dimeric vWF into multimers, respectively. The red rectangle identifies exon 28, which encodes the A1 and A2 domains of mature vWF. Functional domains are identified above the open rectangles. The factor VIII binding site is located in the D' and D3 domains in the amino terminal, 272 amino acids of mature vWF. The A domains of vWF contain the binding site for the platelet glycoprotein (gp) Ib/IX complex, as well as binding sites for heparin, collagen, and sulfatides. The gpIIb/IIIa complex binding site of activated platelets is located at the carboxy-terminal portion of the C1 domain and contains the Arg–Gly–Asp sequence. The numbers below the open rectangles indicate amino acid numbers: signal peptide, 22 amino acids; propeptide (vWAgII), 741 amino acids; mature vWF, 2050 amino acids. **B:** Mutations associated with type 2A von Willebrand disease (vWD). The open rectangle represents vWF exon 28 encoding domains A1 and A2. The arrow indicates the site of proteolysis seen in type 2A vWD. Mutations are identified using the single letter code for amino acids. I and II identify group I and group II missense mutations that result in impaired synthesis of vWF or increased sensitivity to proteolysis in plasma, respectively. The disulfide bridge shown represents the boundary of the Cys 509–Cys 695 loop in the A1 domain. Type 2A vWD mutations associated with defective vWF multimerization are not shown in this figure; these latter mutations occur in the propeptide (vWAgII) D1 and D2 domains. **C:** Mutations associated with types 2B and 2M vWD. The large open rectangle represents exon 28, which encodes domains A1 and A2 of vWF. The mutations responsible for type 2B vWD are shown above the rectangle. Most type 2B mutations lie between residues 540 and 578 of mature vWF. The mutations responsible for type 2M vWD are shown below the rectangle. Asterisks identify mutations that reduce the platelet-dependent function of vWF and vWF multimeric size. ? indicates deletion of an amino acid sequence. [Modified from the Symposium Proceedings of the National Hemophilia Foundation's 1995 Annual Meeting. Diagnosis and management of severe von Willebrand disease (types 2 and 3). Kroner PA, Montgomery RR. The molecular basis of von Willebrand disease. 1996:15–25. Published with permission of Advanstar Communications.]

TYPE 2A vWD based on defective interaction of vWF and platelets due to deficiency of intermediate- and high-molecular-weight forms of vWF is classified as type 2A vWD ([102]). This form of the disorder is generally inherited as an autosomal-dominant trait ([180]) and accounts for the majority of patients with type 2 defects. Levels of factor VIIIc and vWF:Ag in the plasma may be normal or reduced. The vWF activity as assayed by either vWF:RCo or vWF:CB is significantly lower than vWF:Ag because of the absence of the larger multimers (which are more potent in their ability to interact with platelet gpIb and collagen). Analysis of vWF multimers reveals a relative reduction in intermediate- and high-molecular-weight species ([169]). In structural terms, the presence of abnormal amounts of 176,000-d and 140,000-d subunits has been identified ([181]), and additional studies suggested that *in vivo* proteolytic degradation of vWF occurs and may explain the multimeric abnormalities ([182]). Further protein studies and then genetic analysis of the basis of type 2A vWD revealed multiple mechanisms for the generation of this disorder ([181], [183], [184]). In

some patients, there is failure to synthesize full-length multimers (group 1). However, other patients are able to synthesize large multimers that are, in turn, rapidly degraded in plasma through proteolysis (group 2). Other investigators identified the site of cleavage as occurring between tyrosine 842 and methionine 843 of the mature vWF protein sequence. More recently, a plasma metalloproteinase capable of performing this cleavage has been identified ([185]). Inheritance of type 2A vWD is generally autosomal dominant, with the majority of cases caused by mutations clustered in the region of exon 28, which encodes the vWF A2 homologous repeat (Fig. 59.8) ([102], [115]). Rare recessive forms of type 2A vWD (formerly called *types IIC* and *IID*) due to defective multimerization attributed to defects in the vWF propeptide or carboxy-terminal region have also been described. Because of the abnormality of the vWF produced in these patients, neither stress nor pregnancy significantly increases the functional amount of protein. Similarly, the administration of DDAVP does not consistently normalize either the bleeding time or platelet adhesion in patients with the type 2A variant, but a very short-lived correction may be observed in some patients.

TYPE 2B This bleeding disorder is characterized by deficient vWF function attributable to mild reduction of vWF:Ag, a somewhat more marked deficiency of vWF:RCo activity, and multimeric analysis reveals a deficiency of the highest-molecular-weight vWF multimers. Measurements of factor VIIIc are variable. Many patients with the type 2B variant have mild persistent thrombocytopenia ([186]). Type 2B vWD is actually a paradoxic bleeding disorder, as increased interaction of patient vWF with platelets is demonstrated *in vitro* in the presence of low doses of ristocetin. Increased *in vivo* interaction of the larger multimers of type 2B vWF with platelets is thought to result in the formation of vWF/platelet complexes, which are subsequently cleared from circulation, leaving the patient with a hemostatic defect caused by the absence of larger multimers from plasma and mild thrombocytopenia. The platelet count may fall further during physiologic stresses or pregnancy, in association with surgical procedures, or after the administration of DDAVP ([187]). Further laboratory evaluation is required to support a diagnosis of type 2B vWD. This includes (a) multimeric analysis revealing the absence of higher-molecular-weight forms of plasma vWF and (b) platelet aggregation studies involving the use of titered doses of ristocetin to reveal enhanced interaction of patient vWF and platelets with unusually small amounts of the drug. Finally, to differentiate the more common type of 2B vWD from the rare platelet type, pseudo-vWD, one should prove that the defect resides in vWF. This is done either through performing mixing studies of patient plasma with donor platelets ([164]) or by sequence analysis of the patient's vWF gene. Type 2B vWD is inherited as an autosomal-dominant trait. A small cluster of mutations within the portion of vWF exon 28, which encodes for the vWF A1 domain that interacts with platelet gpIb, accounts for the majority of cases of type 2B vWD (Fig. 59.8) ([102], [115]).

TYPE 2M The *type 2M vWD variant* is defined by the diminished interaction of patient vWF with platelets, which is not due to deficiency of vWF multimers ([115]). Thus, these patients have a laboratory profile that in many ways is similar to that of patients with type 2A vWD, revealing variable deficiency of vWF:Ag but disproportionately decreased interaction of vWF with platelets in the presence of ristocetin as measured by vWF:RCo assay. Factor VIII level is proportionate to the vWF:Ag, and the platelet counts are normal. What differentiates type 2M vWD from the type 2A patients is that the vWF multimeric analysis is normal (and if measured, the vWF:CB is, therefore, similar to the vWF:Ag). Type 2M vWD is inherited as an autosomal-dominant trait, and, when investigated, mutations have been found in the region of exon 28 that encodes the A1 domain of vWF. Unlike the type 2B mutations, 2M mutations cause impairment of the binding of vWF to the gpIb receptor and have been shown to be localized to an alternative area in the A1 domain (Fig. 59.8) ([172]).

TYPE 2N Mutations affecting the association of vWF with factor VIII can result in “autosomal hemophilia” in which factor VIII levels are significantly reduced relative to vWF ([36]). Affected patients have factor VIII levels in the 5 to 30 U/dl range, attributed to mutations at the factor VIII binding site near the amino terminus of the vWF subunit ([188]). Indeed, genetic studies have indicated that the majority of mutations underlying type 2N vWD involve vWF exons 18, 19, and 20, which encode for the bulk of the factor VIII binding domain of vWF. The other functions of the vWF in patients with type 2N vWD are qualitatively normal; thus, vWF laboratory parameters (vWF:Ag, ristocetin cofactor activity, and so forth) are usually normal (unless there is co-inheritance of type 1 vWD). This variant was originally named *vWD Normandy* and has been renamed *type 2N vWD* in the revised classification ([102]). The factor VIII binding defect in these patients is inherited in an autosomal-recessive manner; thus, affected patients must inherit 2N alleles from each of their two parents or inherit type 1 vWD from one parent and a 2N allele from the other. Patients with factor VIII deficiency and a bleeding disorder that is not clearly transmitted as an X-linked disorder or who respond incompletely to hemophilia A therapy should be evaluated for type 2N vWD ([189]). Currently, only a few reference laboratories perform assays that assess the interaction of factor VIII with vWF ([167], [168]) or genetic studies of the vWF gene. A survey of almost 400 unrelated patients with either hemophilia A or type 1 vWD indicated a prevalence of type 2N vWD in these patient populations of 3.0% and 1.5%, respectively ([190]).

Platelet-Type (Pseudo) von Willebrand Disease

Platelet-type (pseudo) vWD resembles type 2B vWD in most respects except the basis for platelet-type vWD is a structural defect in platelet gpIb ([191]) rather than a defect of vWF [thus, platelet-type (pseudo) vWD is a form of platelet dysfunction]. However, similar to type 2B vWD, a genetic defect results in increased affinity of gpIb for normal vWF. Phenotypically, platelet-type (pseudo) vWD is manifested by mild thrombocytopenia, a prolonged bleeding time, and variable deficiency of plasma vWF and factor VIIIc. The reductions in plasma vWF and factor VIIIc may be a result of the attachment of these proteins to platelets that are subsequently removed from the circulation. This “consumption” of vWF and platelets results mainly in a loss of high-molecular-weight multimers ([191]). *In vitro* platelet aggregation studies reveal platelet agglutination at unusually low concentrations of ristocetin. Spontaneous intravascular platelet clumping may also occur. Platelet-type pseudo-vWD is inherited as an autosomal-dominant trait in most families ([191], [192]).

The differentiation between the rare platelet-type pseudo-vWD from type 2B disease requires special studies. In type 2B vWD, the ristocetin-induced platelet hyperaggregability is the result of an abnormality of plasma vWF; ristocetin-induced platelet aggregation is abnormal only when plasma from the patient is used. In platelet-type vWD, ristocetin-induced aggregation is abnormal only when platelets from the patient are used. Thus, mixing studies using patient and normal plasma and platelets to study aggregation in the presence of low-dose ristocetin may be informative. Evaluation of whether *in vitro* platelet aggregation is induced by the addition of cryoprecipitate to patient platelet-rich plasma may also be useful in distinguishing between platelet-type pseudo-vWD and type 2B vWD ([193]). A monoclonal antibody assay using patient plasma and formalin-fixed donor platelets has been developed to distinguish between type 2B vWD and platelet-type vWD ([164]). Finally, genetic analysis of the vWF and gpIb gene can clarify the diagnosis.

HEMOPHILIA B

That hemophilia represents at least two different disorders was recognized in 1947 ([194]). Hemophilia B (Christmas disease, factor IX deficiency, and plasma thromboplastin component or plasma thromboplastin component deficiency) was first distinguished from hemophilia A by Aggeler et al. in 1952 ([195], [196] and [197]). Hemophilia A is four to eight times more common than hemophilia B ([21]).

Variants

When plasma from patients with hemophilia B is tested against autologous antibodies, three distinct groups can be defined: a CRM-positive variant, the most common form; a CRM-negative variant; and a third form of the disorder in which antibody neutralization is variable in extent and is approximately proportional to coagulant factor IX activity (the CRM-R variant) ([198]).

In a disorder called *hemophilia B Leyden* ([199]), the clinical manifestations tend to diminish with advancing age in association with a rise in the factor IX level from as low as 1 U/dl in childhood to levels of 20 U/dl or more in adult life. The Leyden variant is characterized as CRM negative at birth but becomes CRM positive or CRM-R with advancing age ([200]). The basis for this variant is that mutations responsible for hemophilia B Leyden occur in the factor IX gene promoter region; this region contains an androgen response element that, with age, stimulates factor IX gene transcription and protein synthesis ([200], [201]).

In another variant of hemophilia B, the PT is prolonged when performed with ox brain thromboplastin ([202]). This disorder has been called *hemophilia* B_m and is characterized by the presence in the plasma of CRM that neutralizes both autologous and heterologous antibodies to factor IX ([202]). The degree of abnormality of the ox brain PT is proportional to the plasma level of CRM in both affected males and carrier females. This variant results from mutations in the carboxy terminus of the factor IX molecule, resulting in a factor IX molecule that interacts abnormally with ox brain thromboplastin.

A number of factor IX mutations have been recognized. Factor IX purified from the plasma of affected members of one kindred did not fragment normally when activated *in vitro* (hemophilia B Chapel Hill) ([203]). The molecular defect was found to be a substitution of histidine for arginine at position 145, a defect that inhibits cleavage by factor XIa ([204]). Studies of factor IX obtained from another family ([205]) revealed biochemical abnormalities identical to those characteristic of the descarboxy analog of this factor that is found in vitamin K deficiency or produced by coumarin drugs. Such molecules lack Ca^{2+}-binding sites and do not undergo conformational changes induced by Ca^{2+}. Another report concerns a unique variant with deficient Ca^{2+} binding and an abnormally high-molecular-weight (factor IX Zutphen) ([206]).

Genetics

Hemophilia B is inherited as an X-linked recessive trait, but the locus on the X chromosome of the gene controlling factor IX production is remote from that involved with factor VIII biosynthesis ([13]). Factor IX levels below 10% have been documented in a few women, including some with chromosomal abnormalities ([207] , [208] and [209]). Ten useful polymorphisms have been described that are associated with the factor IX gene ([51]). A 1998 hemophilia B database includes more than 1700 patient mutations with clinical data ([210]); an updated Internet listing of mutations is available at http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html. Unlike hemophilia A, the spontaneous mutation rate is low ([19]), and most patients with hemophilia B have positive family histories.

Detection of Carriers

Detection of heterozygous carriers of hemophilia B involves the same principles and limitations described for hemophilia A. Carrier detection based on coagulation assay alone usually is more clear-cut than is the case with hemophilia A ([211]). Thus, in one series of 45 obligatory carriers, the mean factor IX level in the plasma was 33 U/dl; 40 from the group had levels below 50 U/dl, and 10 had levels below 25 U/dl. As a consequence of these low levels of factor IX, abnormal hemorrhage is not uncommon in carriers of hemophilia B.

Results of immunoassays of factor IX and the ratio of factor IX–related antigen to coagulant factor IX levels in the carrier population overlap with the normal population to a considerable degree, particularly in the CRM-positive variants ([212]). Such studies provide a lower overall detection rate among obligatory carriers of hemophilia B than is the case with hemophilia A ([212] , [213]). Levels of factor IX–related antigen obtained by immunoassay are significantly increased by the use of oral contraceptives. The use of DNA probes ([57] , [214]) and monoclonal immunoassays ([215]) provides a highly accurate method of determining carrier status. Prenatal diagnosis of hemophilia B has been successful in the CRM-negative variants ([216]).

Clinical Features

Severely affected patients (those with factor IX levels <1 U/dl) are less common than in hemophilia A (Table 59.3), but the clinical manifestations of the two disorders are identical. Specific factor assays are necessary to distinguish between hemophilia A and hemophilia B. Mild factor IX deficiency should always be considered in the differential diagnosis of patients with coagulation-type bleeding and normal routine coagulation test results (PT, PTT) ([217]). Many PTT reagents do not detect mild factor IX deficiency (factor IX levels of 20 to 30%) ([77]).

Laboratory Diagnosis

The laboratory diagnosis of hemophilia B involves the same approach and methods as those described for the recognition of hemophilia A (Table 59.5). The screening tests reveal similar abnormalities in the two disorders, except the PT is abnormal in the B_m variant when either ox brain or Thrombotest is used as the thromboplastin.

Hemophilia A may be easily distinguished from hemophilia B by a specific factor assay. One-stage and two-stage assays for factor IX use the same principles as those discussed for factor VIIIc. Sensitive immunoassay methods for factor IX have been developed ([218]).

CLINICAL DISORDERS OF THE FIBRINOGEN MOLECULE

The clinical disorders of fibrinogen can be divided into overlapping classes of abnormalities based on whether the defect is predominantly a quantitative or qualitative abnormality of the fibrinogen molecule. Quantitative abnormalities are disorders associated with the complete absence of fibrinogen (afibrinogenemia) or with low levels of fibrinogen (hypofibrinogen-emia). Qualitative abnormalities are disorders resulting from synthesis of an abnormal fibrinogen molecule (dysfibrinogen-emia) with altered properties. Dysfibrinogenemia may be asymptomatic and identified only through laboratory studies or may be associated with either hemorrhagic or thrombotic consequences.

Fibrinogen is a 340-kd plasma protein that circulates at a concentration of 1.5 to 3.5 mg/ml. It is a symmetric disulfide-linked dimer with a central E domain linked via “coiled-coil” peptide chains to outer D domains ([219]). Each half-molecule consists of a set of three different peptide chains termed *Aa*, *Bß*, and ?, which are linked at their amino terminals by disulfide bonds to form the E domain. The D domains are formed by disulfide linkages near the carboxy terminals of the peptides. Fibrinogen is synthesized in hepatocytes ([220] , [221]) by coordinated expression of three separate genes on chromosome 4 ([222] , [223]). The circulation half-life of plasma fibrinogen is approximately 4 days. Fibrinogen participates in multiple physiologic processes, including fibrin clot formation mediated by the enzymatic activities of thrombin and factor XIIIa, and cohesion of activated platelets through interaction with the gpIIb/IIIa receptor. Fibrinogen also acts as a plasma carrier for factor XIII. Several excellent reviews provide detailed discussion of fibrinogen physiology ([219] , [224]).

The congenital disorders of fibrinogen associated with afibrinogenemia and hypofibrinogenemia are reviewed in the next section, followed by a discussion of the dysfibrinogenemias. Afibrinogenemia is a very uncommon condition. The first case was described in 1920 ([225]), and approximately 300 cases have been reported since then ([224]). Congenital hypofibrinogenemia was first reported in 1935 ([226]), and at least 40 cases have been reported in the literature. However, it is likely that many of the cases of hypofibrinogenemia were actually cases of dysfibrinogenemia with a reduced level of circulating clottable fibrinogen.

Pathogenesis of Quantitative Fibrinogen Disorders

In congenital afibrinogenemia and hypofibrinogenemia, defects in synthesis, secretion, or intracellular processing of the final gene product result in deficiency of plasma fibrinogen ([227] , [228] and [229]). When newly synthesized fibrinogen is not secreted, the protein may accumulate in the rough endoplasmic reticulum of hepatocytes or other cells, resulting in amyloidlike accumulations ([219] , [230] , [231]). In both afibrinogenemia and hypofibrinogenemia, the fibrinolytic system and other coagulation pathways are completely normal. Similarly, there is no evidence of blood coagulation activation, which could cause consumption, or degradation of the fibrinogen molecule. The fibrinogen gene locus is located on chromosome 4; it contains three distinct genes that encode for the Aa, Bß, and ? peptide chains that compose the fibrinogen molecule ([232]). The inheritance pattern of afibrinogenemia is autosomal recessive in nature ([233]), and many reported cases are the result of consanguineous relationships between asymptomatic parents with symptomatic homozygote offspring. The molecular basis for this genetic defect is currently an area of ongoing study. Deletion of an 11-kb region of the fibrinogen a gene appears to be a recurrent finding in unrelated families from both Europe and the United States, but nonsense, splice-site, and frameshift mutations involving all three of the components of the fibrinogen gene locus have been described ([234]). A database, which includes genetic defects that have been identified in patients with afibrinogenemia, is accessible at http://www.geht.org/pages/database_ang.html. As of late 2002, 282 molecular abnormalities were present in the database.

Afibrinogenemia

It is somewhat of an anomaly that patients who are afibrinogenemic have little hemorrhage, despite the fact that their blood cannot clot normally. This may be, in part, due to the presence of functional vWF, which allows platelet adhesion and aggregation, with the formation of loose thrombi even in the absence of fibrinogen ([235]). A similar phenotype was recently described for afibrinogenemic mice created by gene-targeted knock-out ([236]). In patients with afibrinogenemia, life-threatening hemorrhages do occur, but in many situations, the bleeding is not as severe as is seen in hemophilia. The diagnosis is often made early in infancy when prolonged umbilical stump bleeding occurs ([233]). A major cause of death is intracranial hemorrhage during infancy or childhood ([233] , [237]). The clinical manifestations include mucosal membrane bleeding such as epistaxis, menorrhagia, or gastrointestinal hemorrhage. An increased incidence of first-trimester abortion, placental abruption, and postpartum hemorrhage has also been observed in these patients ([233] , [238]). Fetuses of female afibrinogenemic patients rarely reach full term unless replacement therapy is given. Although 20% of afibrinogenemic patients are affected with hemarthrosis, the severity is generally less than that seen in patients with hemophilia. There is a paradoxic increase in thromboembolic disease in patients with afibrinogenemia who are given fibrinogen replacement therapy ([239]), and transgenic afibrinogenemic mice demonstrate abundant thrombus formation in a vascular injury model ([235]). The basis for this is not well understood but may be in part related to the fact that fibrinogen has nonsubstrate binding sites for thrombin that could potentially modulate thrombin availability to activate platelets ([240]). Patients with congenital hypofibrinogenemia do not typically have any spontaneous bleeding unless the fibrinogen level is less than 50 mg/dl. These patients may actually have

hypodysfibrinogenemia, which is discussed in the section Dysfibrinogenemia.

LABORATORY DIAGNOSIS Coagulation tests from afibrinogenemic and hypofibrinogen-emic patients typically have a marked prolongation of all tests in which the endpoint is the appearance of fibrin clot, as severe fibrinogen deficiency renders plasma nonclottable. These tests include the PT, PTT, thrombin clotting time, and reptilase time. These test abnormalities are usually corrected when patient plasma is mixed with normal plasma. A diagnosis of afibrinogenemia depends on the specific finding of undetectable fibrinogen antigen in the plasma of these patients ([241]). Platelet fibrinogen is also absent. Mild thrombocytopenia has been reported in some afibrinogenemic patients, but typically the platelet count is usually not lower than 100,000/µl ([242]). The bleeding time is prolonged in approximately one-third of patients with afibrinogenemia, presumably caused by the failure of platelets to aggregate in the absence of plasma or platelet fibrinogen. These abnormalities are correctable by infusion of plasma ([243]). Furthermore, afibrinogenemic patients who undergo hypersensitivity reaction skin testing do not typically show an induration response to allergens ([244]). They show only erythema because the later phases of the hypersensitivity reaction depend on the deposition of subcutaneous fibrin.
DIFFERENTIAL DIAGNOSIS AND THERAPY OF AFIBRINOGENEMIA Congenital quantitative defects in fibrinogen must be carefully distinguished from acquired quantitative defects in the fibrinogen molecule, which are often seen in the setting of liver disease or disseminated intravascular coagulation. Acquired hypofibrinogenemia has been reported after therapy with L-asparaginase, which impairs hepatic synthesis of fibrinogen ([245]). Furthermore, patients with aplastic anemia treated with antithymocyte globulin and corticosteroids are prone to develop hypofibrinogenemia ([246]). In the absence of purified fibrinogen concentrates, cryoprecipitate administration is used for replacement therapy for patients with severe afibrinogenemia. Prophylactic therapy is recommended only for pregnant patients or patients with a history of central nervous system (CNS) hemorrhage ([247]). Replacement therapy is indicated for any episode of acute active bleeding, preoperatively, and in pregnant patients. Fibrinogen levels between 50 and 100 mg/dl are usually adequate for normal hemostasis ([248]). Levels greater than 100 mg/dl are recommended for maintenance during pregnancy based on empiric clinical observations ([224]). Each bag of cryoprecipitate contains approximately 250 mg of fibrinogen; five to ten bags of cryoprecipitate are usually sufficient in the average adult patient. Each bag of cryoprecipitate typically raises plasma fibrinogen levels by approximately 10 mg/dl. Because the fractional catabolic rate of fibrinogen is 25%/day, acute-care patients should receive one-third of their loading dose daily for as long as fibrinogen support is desired ([219]). Measurement of plasma fibrinogen levels after infusion is recommended to confirm that a patient has obtained the desired therapeutic effect. The complications of replacement therapy in afibrinogenemia include allergic reactions, development of antifibrinogen antibodies, and anaphylaxis ([249]). Thromboembolic complications after cryoprecipitate infusions include deep venous thrombosis and pulmonary emboli; the risk of these complications may be increased when an inhibitor of fibrinolysis or oral contraceptive therapy is also administered ([239], [250]). Low-molecular-weight heparin in combination with fibrinogen replacement has been used to avoid these thromboembolic complications ([251]).

Dysfibrinogenemia

The first reported case of dysfibrinogenemia mediated by a qualitatively abnormal fibrinogen molecule occurred in 1965; since that time, more than 300 families have been reported with this disorder. The molecular genetic basis of fibrinogen dysfunction has been fairly well established in many families that have been studied. However, uncertainty persists concerning the linkage of genetic defects of fibrinogen and the disease phenotype expressed by patients, as environmental factors and other concomitant genetic abnormalities may be influencing disease manifestations. For more in-depth discussions of the fibrinogen biology, molecular genetics, and mechanisms of disease, the reader is referred to several recent reviews that contain compendia of the described defects underlying dysfibrinogen-emia and discussion of the biochemical and clinical consequences of these defects ([219], [224]). A database containing an updated list of the genetic defects is accessible at http://www.geht.org/pages/database_ang.html.

MOLECULAR BASIS OF DYSFIBRINOGENEMIA The reported abnormalities in the fibrinogen molecule include defects in each of the major steps of fibrin formation and stabilization. The conversion of fibrinogen to an insoluble fibrin clot requires that the molecule first be cleaved by thrombin between arginine 16 and glycine 17 of the Aa-chain to release fibrinopeptide A and between arginine 14 and valine 15 of the Bß-chain to release fibrinopeptide B. This produces a fibrin monomer capable of undergoing the second step, fibrin polymerization. Once these molecules polymerize, they are stabilized by the action of factor XIIIa. Fibrinogen also supports the hemostatic process through interaction with platelets during platelet cohesion (aggregation). Finally, during the process of wound healing and tissue remodeling, the fibrin clot undergoes fibrinolysis by concerted activities of plasminogen and plasminogen activators. Fibrinogen dysfunction may affect any of these various steps of fibrin clot formation, platelet interaction, or lysis. It is, therefore, expected that the dysfibrinogenemias can be associated with abnormal clinical bleeding, thrombotic tendency, disorders of wound healing, or no clinically apparent disease. Domain location of a mutation does not necessarily predict the associated disease phenotype. Defects of fibrinopeptide release have been associated with both hemorrhagic and thrombotic complications. Similarly, disruption of D-D interactions has been associated with both bleeding and thrombosis. Patients who have heterozygous dysfibrinogenemia typically have approximately 50% of normal fibrinogen levels, which should be adequate for hemostasis. Clottable fibrinogen protein measurements may not be a reliable indicator of plasma fibrinogen concentration because functionally abnormal molecules are not always incorporated into the clot. An abnormal fibrinogen may actually inhibit the conversion of normal fibrinogen to fibrin, so the tendency for many of these patients to bleed is higher than one would suspect. Hypodysfibrinogenemia occurs when an abnormality of the fibrinogen molecule results in decreased secretion or increased clearance of the protein. Approximately 23 families have been reported with hypodysfibrinogenemia. Autosomal amyloidosis has been attributed to genetic disorders of fibrinogen, as well as to genetic disorders of several other proteins (including transthyretin, gelsolin, apolipoprotein A, and lysozyme) ([252], [253]). Hereditary renal amyloid disease has been associated with genetic defects of the Aa-chain ([219]), and renal amyloid has recurred in renal transplants ([253], [254]). Hepatic amyloid disease has also been attributed to abnormalities of fibrinogen ([255]). Dysfibrinogenemia is typically inherited as an autosomal-dominant trait with high levels of penetrance. Most of these patients are heterozygotes, but a few homozygotes and some rare compound heterozygotes have been reported in the literature. Approximately 40% of dysfibrinogenemic patients are asymptomatic, and 45 to 50% have a bleeding disorder ([256]). The remaining 10 to 15% have either a thrombotic disorder (venous or arterial) or both bleeding and thrombotic tendencies. The bleeding associated with dysfibrinogenemia is generally mild and includes soft tissue hemorrhage, easy bruising, and menorrhagia. Although intraoperative and postoperative bleeding have been reported, most bleeding is not life-threatening. There are only a few families in which a thrombotic tendency can unambiguously be associated with dysfibrinogenemia, and criteria for making this association have been proposed. These criteria include a demonstrated molecular defect, thrombosis at an early age or in multiple family members, presence of no other predisposing factor for thrombosis, strong association between the fibrinogen defect and thrombus complications within a family, and association of the same molecular defect with thrombosis in another unrelated kindred ([257], [258]). Studies indicate a distinct thrombotic tendency in individuals with dysfibrinogenemia related to defects in the a-C domain of the Aa-chain of fibrinogen, especially if new cysteine residues are encoded that can become disulfide linked to albumin. In contrast, dysfibrinogenemic patients with defective cross-linking experience primarily defective wound healing.
LABORATORY DIAGNOSIS OF DYSFIBRINOGENEMIA The thrombin clotting time remains a sensitive screening test for dysfibrinogenemias, and the PT appears to be more sensitive than the PTT to the effects of dysfibrinogenemia. In some cases, clot formation may be absent. The reptilase time is often more prolonged than the thrombin clotting time, especially in patients who have defective fibrinopeptide A release. Some dysfibrinogenemias exhibit a very short thrombin clotting time, and these patients may have thrombotic complications. The fibrinogen concentration can be either low or normal in these patients. Most patients with dysfibrinogenemia have a significant discrepancy between the level of clottable fibrinogen and that detected by immunologic methods. Criteria for diagnosing dysfibrinogens using ratios of immunologic and functional fibrinogen assays have been reported ([259]). The euglobulin clot lysis time is a crude measure of fibrinolytic potential and may be helpful in detecting abnormal fibrinogens that show increased susceptibility to fibrinolysis. For example, with fibri-nogen St. Louis ([260]), the euglobulin clot lysis time is shortened, and fibrinogen degradation products are elevated in the plasma. The diagnosis of inherited dysfibrinogenemia must be distinguished from hypofibrinogenemia, which is either acquired or congenital in nature. Acquired dysfibrinogenemia occurs typically in the setting of severe liver disease, and the suspicion can be readily investigated by evaluation of liver function tests. Acquired dysfibrinogenemias are also associated with malignancies that produce an abnormal fibrinogen molecule [e.g., some hepatomas (Chapter 60) and renal cell carcinoma ([261])], as well as autoimmune disorders. Acquired inhibitors to fibrin formation that interfere with fibrinogen to fibrin conversion may also be confused with dysfibrinogenemia. These acquired inhibitors include heparinlike molecules, elevated levels of fibrin split products, and antibodies at concentrations as may occur in macroglobulinemia, multiple myeloma, or other disorders that interfere with fibrin polymerization ([262], [263]). Acquired antibodies against the fibrinogen molecule are quite rare but have been reported in association with a variety of diseases ([264], [265] and [266]).
THERAPY The majority of patients with dysfibrinogenemia do not require any specific therapy. Any bleeding complications that develop can be managed with transfusion of either plasma or cryoprecipitate. Antifibrinolytic drugs have been used in some patients but should be especially avoided in patients who have thrombotic tendencies. Patients with repeated venous thrombotic episodes may actually require long-term antithrombotic therapy. A patient with life-threatening thrombophilic manifestations was successfully managed with plasma exchange before surgery ([267]), but one wonders whether simple anticoagulation therapy would have been sufficient to provide a satisfactory outcome. In women with dysfibrinogenemia, recurrent miscarriages may be prevented using prophylactic cryoprecipitate, and successful pregnancy outcomes in such cases have been reported ([268], [269]).

FACTOR XIII DEFICIENCY

The initial hemostatic plug is not sufficient to prevent blood loss unless it is stabilized by the action of plasma factor XIII (fibrin-stabilizing factor). A complex set of reactions among thrombin, fibrin, and plasma factor XIII is necessary for clot stabilization (Chapter 21). When fibrin begins to polymerize after thrombin cleaves the

fibrinopeptides, a complex forms between thrombin and fibrin, which promotes the conversion of factor XIII to factor XIIIa. Fibrin is the main catalytic substrate for factor XIIIa ([270]). Factor XIIIa transforms the unstable, noncovalently associated fibrin clot to a stable covalently cross-linked set of fibrin fibers that are mechanically stronger, more rigid, and more elastic. A cross-linked fibrin clot is more resistant to mechanical as well as enzymatic degradation by plasmin than non–cross-linked fibrin. Factor XIIIa is a transglutaminase that catalyzes the formation of intermolecular ?-glutamyl-e-lysyl covalent (isopeptide) bonds between the ?-chains and a-chains of fibrin strands within the clot. Cross-linkage of ?-chain Gln 398 and Lys 406 residues appears to occur earlier, with a-chain linkages between Gln 328 and 366 with Lys 508, 556, and 562 occurring more slowly ([271]). In addition, several other plasma and extracellular matrix proteins are linked to the fibrin clot through the action of factor XIII. Incorporation of a $_2$-antiplasmin into fibrin clots further increases the resistance of the clot to plasmin degradation ([272]). Linkage of fibrin to fibronectin may improve adhesion to vessel walls ([273]) and may play a role in cell migration during wound healing ([274]). In fact, fibronectin is the second most abundant material in fibrin clot, accounting for 4% of the total protein ([275]).

The importance of factor XIII function in normal health is emphasized by the clinical scenarios characteristic of inherited and acquired deficiency of factor XIII. In the following sections, the pathogenesis, molecular genetics, and clinical laboratory, diagnostic, and therapeutic elements of the diagnosis and treatment of factor XIII deficiency are discussed.

Pathogenesis

In 1944, Robbins postulated that a deficiency of fibrin-stabilizing factor, which later became known as *factor XIII*, would produce a serious bleeding disorder ([276]). However, it was not until the first case of factor XIII deficiency was described in 1960 that the severe nature of this bleeding disorder was recognized ([277]). During the last four decades, more than 200 cases of congenital factor XIII deficiency have been reported in the literature ([274]). It is estimated that approximately 1 in every 1 to 5 million persons has factor XIII deficiency ([278]). The disorder is inherited as an autosomal-recessive trait ([279]).

The factor XIII molecule is present in plasma and blood platelets and monocytes. Approximately 50% of the total blood factor XIII activity resides in the platelet. Tissue-based factor XIII resides in monocyte/macrophages. Structurally, platelet and monocyte factor XIII consists of only A-dimers, present within the cytoplasm of both platelets and megakaryocytes. The plasma factor XIII molecular complex is a heterotetramer, containing two of each of the A and B subunits. The A subunit mediates factor XIII function, containing an activation peptide, calcium-binding site, and enzymatic domain with an active site sulfhydryl residue that is characteristic of this class of enzymes ([280]). The three-dimensional structure for the A subunit has been determined by x-ray crystallography ([281]). The majority of the A subunit in circulation is derived from cells of marrow origin ([282]). The B subunit of plasma factor XIII is synthesized in the liver and probably associates with the A subunit in the plasma phase after release from the hepatocyte. The B subunit appears to promote stabilization of the A subunit in plasma and may play an important role in regulating both the localization of the A subunit to the fibrin clot and thrombin-dependent activation of the protein ([283]). Three distinct forms of factor XIII deficiency have been described, based on whether the A and B subunits are absent or present ([274] , [284] , [285]). In type I deficiency, the concentration of both the A and B subunits is reduced. In type II deficiency, the A subunit is absent, and the B subunit is present. In type III deficiency, there is a selective deficiency of the B subunit.

Molecular Genetics

The genetics of factor XIII deficiency is beginning to be carefully defined using recent advances in molecular biology. Since the protein was initially described in human serum in 1944, both the A and B subunits have been purified, and cDNA sequence and gene structure have been established ([286] , [287] , [288] and [289]). The A subunit is encoded on chromosome 6 ([290]), containing 15 exons, and spans a region of 160 kb. A common genetic polymorphism of the A subunit has been described that results in Val 34 replacement by Leu only three amino acid residues from the site of cleavage of the activation peptide. This polymorphism may influence factor XIII activation and has been investigated in reference to risk for myocardial infarction ([291]). The B subunit is encoded by chromosome 1 ([292]). Because the mode of inheritance of factor XIII deficiency is autosomal recessive in nature, only homozygotes or compound heterozygotes are clinically symptomatic. The homozygotes reported in the literature are often children of consanguineous marriages ([293]).

In the cases reported to date, factor XIII deficiency is more frequently attributed to mutation of the gene encoding for the A subunit, confirming the functional importance of this subunit. To date, at least 30 mutations have been described ([274]). The majority of defects observed are “point mutations” resulting in stop codons, missense errors, or frameshifts and small deletions. Inherited deficiency of the factor XIII–A-chain is not restricted to any specific ethnic group ([294]).

Factor XIII–B-chain deficiency is a very rare autosomal-recessive disorder, with only three reported cases in the literature ([295]). One unique patient displayed a complete absence of the B-chain and a shortened half-life of the A-chain. Interestingly, this B-chain–deficient patient had many of the same symptoms as an A-chain–deficient patient. The ability of the B-chain to promote A-chain binding to the fibrinogen molecule may account for this clinical finding ([296]).

Clinical Aspects

Clinically affected factor XIII–deficient patients typically have plasma levels that are less than 1% of normal ([297]), with bleeding attributed to accelerated fibrin clot degradation. Abnormal bleeding manifests shortly after birth, when bleeding from the healthy umbilical cord remnant occurs ([298]). This has been a prominent feature in many of the reported cases ([293]) but is an uncommon presentation for other congenital bleeding disorders. Rebleeding at circumcision is also common. Other bleeding manifestations in these patients include soft-tissue hemorrhage, hemarthrosis, hematomas, and the development of large pseudocysts ([298]). Surgery in these patients is often complicated by abnormal wound healing and excessive postoperative bleeding, which can occur either immediately or later ([277] , [299]). Delayed bleeding may occur several days after surgery or tissue injury, and patients may experience cycles of repetitive bleeding that span weeks to months. The most life-threatening complication of factor XIII deficiency is spontaneous intracranial hemorrhage. Intracranial hemorrhage is more prevalent in factor XIII deficiency than in other inherited bleeding disorders ([293]). Approximately 25% of factor XIII–deficient patients experience intracranial hemorrhage ([297]), and this forms the basis for the recommendation for prophylactic therapy of factor XIII–deficient patients. The affected males in some families also have oligospermia, resulting in infertility. Furthermore, infertility in affected females results from spontaneous abortions. Females with this deficiency cannot carry a pregnancy to term unless plasma factor XIII levels are maintained at levels that prevent bleeding ([300]).

Differential Diagnosis

Congenital or acquired factor XIII deficiency must be considered when a patient has a major bleeding disorder and all of the initial screening laboratory tests are normal, including PT, PTT, platelet count, and bleeding time. Bleeding can occur spontaneously or after major surgery. It remains imperative in the adult to exclude both inherited and acquired factor XIII deficiency because patients can develop antibodies to factor XIII that interfere with fibrin stabilization. Specific antibodies to factor XIII were reported in patients taking isoniazid ([301]), phenytoin ([302]), procainamide ([303]), and penicillin ([304]). Factor XIII antibodies also occur in association with autoimmune disease, in patients with monoclonal gammopathy, or as an idiopathic occurrence. Acquired factor XIII deficiency has been reported in Henoch-Schönlein purpura ([305]), liver disease, Crohn disease ([306]), and ulcerative colitis ([307]).

Laboratory Diagnosis

The solubility of a fibrin clot in 5 mol/L urea or 1% monochloroacetic acid is the most useful screening test for factor XIII deficiency. The PT and PTT assays are normal (Table 59.5). In these conditions, clots formed in the absence of factor XIII activity dissolve within minutes ([308]). In contrast, normal clots covalently modified by factor XIIIa remain insoluble for at least 24 hours. Most clinical laboratories currently use the 5 M urea solubility test (also called the *clot stability test*). Deficiency of a $_2$-antiplasmin may also cause a bleeding disorder with normal coagulation screening studies and increased urea clot solubility; a specific assay for a $_2$-antiplasmin should be considered to exclude this possibility ([309]). Quantitative measurements of factor XIIIa activity can also be done, and specialized laboratories can measure either ammonia production (an end product of the factor XIIIa reaction) ([310]) or the incorporation of fluorescent or radioactive amines (e.g., dansylcadaverine) into proteins such as casein ([311]). However, the most sensitive and specific measurement of factor XIIIa activity remains the functional assay measuring the stability of a covalently cross-linked fibrin clot ([312]). Finally, immunologic-based assays that detect factor XIII antigen are available such as ELISAs specific for either the A or B subunits of factor XIII ([313]). These immunologic assays correlate with factor XIII activity assays.

PROTHROMBIN DEFICIENCY

Hereditary hypoprothrombinemia is exceedingly rare, with fewer than 100 cases reported ([314], [315], [316], [317] and [318]). There are no human cases of total prothrombin deficiency, and mice with prothrombin gene deletions experience embryonic lethality due to bleeding ([319]). It is also proposed that embryonic lethality of prothrombin deficiency also results from absence of developmental activity of thrombin on yolk sac vasculature. The human disorder is inherited as an autosomal-recessive trait and manifests clinically as a mild hemorrhagic diathesis. Spontaneous hemorrhage is uncommon, and posttraumatic bleeding is the most common complaint. Bleeding from the umbilical stump is common in affected infants. Hemarthrosis has been reported ([318]). The extent of prothrombin deficiency does not necessarily correlate with clinical bleeding.

As with deficiencies of the other vitamin K–dependent coagulation factors, both CRM-positive (dysprothrombinemia) and CRM-negative variants of hypoprothrombinemia have been described; both are autosomal-recessive traits. The CRM-negative form is characterized by a true deficiency of prothrombin and appears to be the more common variety ([315]). In true hypoprothrombinemia, immunoassays correlate closely with functional assays. A significant hemostatic defect is not induced unless prothrombin levels are less than 1 to 2% of normal; normal hemostasis requires prothrombin levels above 25% ([315]). Homozygotes usually have prothrombin activity levels less than 10% of normal, whereas heterozygotes have 40 to 60% of normal activity ([314]).

In the CRM-positive variants, the presence of antigenically competent prothrombin in amounts that far exceed functional prothrombin has been demonstrated by quantitative immunologic assays. These disorders have been called *constitutional dysprothrombinemias* ([315], [317]), and the abnormal prothrombins have been designated by various proper names such as *prothrombin Cardeza* ([317]). Calcium binding by prothrombin San Juan I is deficient; most other abnormal prothrombins appear to be normal in this respect ([315]). The genetic basis for dysprothrombinemias is missense mutations that result in either a protein with abnormally slow prothrombin activation or a protein that is activated to a defective thrombin molecule (dysprothrombin) ([320]). For example, prothrombins Barcelona ([321]) and Madrid ([322]) demonstrate loss of the factor Xa cleavage site, whereas prothrombins Quick I and II are dysprothrombins that exhibit diminished activity toward fibrinogen ([323], [324]). Figure 59.9 illustrates the relationship between the location of certain prothrombin mutations and the resulting functional abnormality.

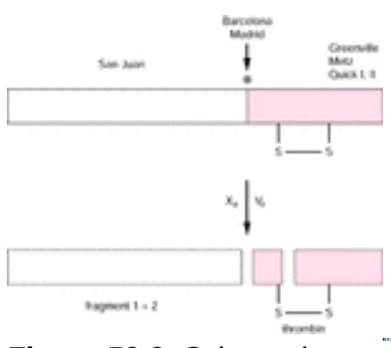

Figure 59.9. Schematic representation of prothrombin activation by factors Xa and Va and sites of certain prothrombin mutations leading to inherited prothrombin deficiency. The fragment 1+2 domain contains ?-carboxyglutamic acid (Gla) residues responsible for prothrombin binding to calcium and phospholipid surfaces. Prothrombin San Juan possesses abnormal calcium-binding properties. Prothrombins Barcelona and Madrid have a mutation at the factor Xa cleavage site (*asterisk*) (Arg ^{271} ?Cys). Mutations in the thrombin domain, such as occurs in prothrombins Metz, Greenville, and Quick I and II, result in abnormal thrombin activity toward substrates such as fibrinogen.

New prothrombin mutations continue to be identified ([325], [326]). Analysis of structures of these mutant prothrombin molecules has led to proposals for functional consequences of mutant prothrombins ([326]). As of 2002, 32 genetic defects in the prothrombin molecule had been identified ([327]).

The laboratory findings in this disorder are summarized in Table 59.5. Specific factor assays for prothrombin are used in diagnosis. Acquired deficiency of prothrombin caused by vitamin K deficiency or to an antiprothrombin antibody associated with antiphospholipid antibodies should be considered before making the diagnosis of inherited prothrombin deficiency. Treatment of prothrombin deficiency with plasma or prothrombin complex concentrates (PCCs) is discussed in Table 59.10.

TABLE 59.10. Replacement Therapy in Other Inherited Coagulation Disorders

Disorder	Therapeutic Material	Loading Dose	Maintenance Dose
von Willebrand disease	Humate-P [a]	40–60 U/kg	40–50 U/kg every 12 h for up to 7 d
	Cryoprecipitate [b]	Not required	1 bag/10 kg daily
Fibrinogen deficiency	Cryoprecipitate	1–2 bags/10 kg	1 bag/10 kg every other d
	Purified fibrinogen [c]	50–100 mg/kg	20 mg/kg every other d
Prothrombin deficiency	Fresh frozen plasma [d]	15 ml/kg	5–10 ml/kg daily
Dysprothrombinemia	Purified prothrombin complex [e]	20 U/kg	10 U/kg daily
Factor V deficiency	Fresh frozen plasma	20 ml/kg	10 ml/kg every 12–24 h
Factor VII deficiency	Fresh frozen plasma [d]	20 ml/kg	5 ml/kg every 6–24 h
	Purified prothrombin complex [e]	30 U/kg	10–20 U/kg every 6–24 h
Factor X deficiency	Fresh frozen plasma [d]	15–20 ml/kg	5–10 ml/kg daily
	Purified prothrombin complex [e]	15 U/kg	10 U/kg daily
Factor XI deficiency	Fresh frozen plasma [d]	15–20 ml/kg	5 ml/kg every 12–24 h
Factor XIII deficiency	Fresh frozen plasma [f]	5 ml/kg every 1–2 wk	Not usually required

NOTE: The replacement therapy regimens suggested in this table are for major bleeding or surgical prophylaxis. Patients with minor bleeding may require lower dosages of these replacement materials. Confirmation of hemostatic levels of the appropriate coagulation factor being replaced should be done, with dosage adjustments performed as needed.

[a] Labeled in ristocetin cofactor units. Alphanate can also be used to treat von Willebrand disease.

[b] Recommended only if purified factor replacement therapy is not available.

[c] Not routinely available in the United States.

[d] Plasma after removal of cryoprecipitate is satisfactory.

[e] Prothrombin complex concentrates are thrombogenic and should be used only for major bleeding or major surgery. Antifibrinolytic drugs (e-aminocaproic acid, tranexamic acid) should not be used in conjunction with prothrombin complex concentrates.

[f] A factor XIII concentrate is currently under investigation in the United States.

FACTOR V DEFICIENCY

Inherited deficiency of factor V (parahemophilia, labile factor, or proaccelerin deficiency) is an uncommon disease that was first described by Owren ([328]). It has been reported from various parts of the world and is transmitted as an autosomal-recessive trait that manifests clinically only in patients who inherit the defective gene from both parents. Other modes of inheritance have been implicated in certain kindreds ([329]). In heterozygotes, the levels of factor V in the plasma are approximately one-half of normal, and the carriers are easy to identify by routine laboratory studies. The incidence of factor V deficiency is estimated at 1 in 1 million. As of 1999, approximately 150 cases of inherited factor V deficiency had been reported ([318]).

Pathophysiology

The basic pathophysiologic mechanism in most patients with factor V deficiency is failure of biosynthesis of the requisite protein. The absence of CRM in the plasma of most patients with this disorder has been demonstrated by antibody neutralization studies ([330]). Variants with an abnormal, nonfunctional factor V protein have been defined ([331]). The platelets of patients with factor V deficiency contain variable amounts of factor V–related antigen ([332]). Factor V Quebec is a disorder associated with moderately reduced plasma factor V levels and significantly depressed platelet factor V levels ([333]). This variant results from deficiency of a unique platelet protein, multimerin, which apparently serves as an important carrier protein for platelet factor V ([334]).

Clinical Features

The clinical manifestations of the disorder usually are mild but vary greatly, even within the same family. Mildly affected patients experience spontaneous epistaxis, tendency to bruise easily, menorrhagia, and excessive bleeding after dental extractions or surgical procedures. In severely affected patients, hematomas, spontaneous gingival bleeding, and bleeding into the gastrointestinal tract or CNS may occur. The disorder seldom produces bleeding in affected neonates and has been associated with a high incidence of other congenital abnormalities ([329]).

A genetic model of factor V deficiency has been developed in mice. In addition to significant hemorrhage, homozygous factor V–deficient mice have increased fetal loss *in utero*, suggesting not only that factor V is critical for hemostasis, but also that this protein is important in development ([335]). In contrast, a patient with severe factor V deficiency (no detectable plasma and platelet factor V) has been reported with only mild bleeding symptoms ([336]). One possible explanation for these discordant observations is that minimal factor V gene expression, below limits of routine detection, may “rescue” affected patients ([337]). Even though very low levels of factor V are associated with delayed thrombin generation, the amount of thrombin generation can be significant ([338]). Bleeding symptoms may correlate better with the platelet factor V content than the plasma factor V level ([333]).

The variable clinical manifestations of inherited factor V deficiency likely result from a variable spectrum of mutations in the factor V gene seen in these patients. As of 2001, 17 mutations had been reported associated with factor V deficiency ([339]); most are found in unique families, and most result in type I deficiency ([339]).

Laboratory Diagnosis

The usual laboratory features of factor V deficiency are summarized in Table 59.5. Specific assays for factor V are based on the PT and are easy to perform. Good results may be obtained by using aged oxalated or ethylenediaminetetraacetic acid plasma as a factor V–deficient substrate ([340]) or artificially depleted substrate plasmas.

Inherited factor V deficiency must be distinguished from combined deficiency of factors V and VIII ([341]). Consequently, specific assays for factors V and VIII should be performed to exclude the rare combined deficiency, which would require different replacement therapy. Acquired factor V deficiency due to liver disease, disseminated intravascular coagulation, or antibodies to factor V should also be excluded before making a diagnosis of inherited factor V deficiency. Treatment of factor V deficiency with plasma is discussed in Table 59.10.

FACTOR VII DEFICIENCY

Factor VII deficiency was first described in 1951 by Alexander et al. under the name *serum prothrombin conversion accelerator deficiency* ([342]). Approximately 200 cases of true factor VII deficiency have been reported, and the population prevalence is estimated to be 1 in 500,000 ([318]). Also known as *stable factor* or *proconvertin deficiency*, the condition is inherited as an autosomal-recessive trait that produces severe deficiency in the homozygote and mild deficiency, usually without clinical manifestations, in the heterozygote.

Pathophysiology

Factor VII is secreted as a single-chain proenzyme glycoprotein of approximately 50 kd by hepatocytes. Factor VII has the shortest plasma half-life of all coagulation factors (approximately 5 hours), and its plasma concentration is very low, approximately 500 ng/ml ([343] , [344]). The 406–amino acid zymogen undergoes extensive processing before secretion, with steps that include vitamin K–dependent ?-carboxylation of glutamic acid residues, ß-hydroxylation of aspartic acid 63, O- and N-linked gly-cosylation steps, and cleavage of the signal and propolypeptides. Structurally, the protein contains the *N*-terminal gla domain, two epidermal growth factor–like domains, an activation peptide sequence, and the serine protease domain. Factor VII is activated via limited proteolysis by cleavage of the arginine 152–isoleucine 153 bond to form the active (two-chain) factor VIIa. This limited proteolysis activation step can be performed by factor Xa, factor IXa, or thrombin, or via autoactivation activity of factor VIIa ([309]). Factor VIIa is detectable in trace amounts in normal plasma ([345]), and sensitive assays indicate that approximately 1% of circulating factor VII is in the activated form ([345]). The circulating half-life of activated factor VIIa is quite long, at approximately 2.5 hours ([346]). Tissue factor increases the rate of activation of factor VII significantly ([345] , [347]), and the current theory is that coagulation is initiated in the presence of tissue factor that is exposed at sites of vascular injury or on blood monocytes ([348]).

The factor VII gene includes nine exons and spans 128 kb on chromosome 13 ([349]). It is located just upstream of the factor X gene. In a mouse knock-out model in which factor VII is completely lacking, fatal hemorrhage occurs perinatally ([350]). In humans, factor VII deficiency occurs as a recessive trait due to homozygous or compound heterozygous mutation. Thirty-five mutations had been reported by 1997 ([351]), and more than 115 mutations were listed in 2002 in a registry maintained by the Medical Research Council (http://europium.csc.mrc.ac.uk). Most reported genetic defects are single base substitutions, including missense, splice site, and nonsense mutations. Most mutations affect only a few patients, but one mutation (Ala ^{242}Val) was detected in 23 “apparently” unrelated Jews in Israel. More extended haplotype testing suggests a “founder effect” ([352]). Although Dubin-Johnson syndrome is associated with factor VII deficiency ([344]), the genetic defect underlying that syndrome is located on chromosome 10, and the association of Dubin-Johnson syndrome and factor VII deficiency may simply reflect a high consanguinity rate in one population ([309]).

Clinical Features

Only severe factor VII deficiency is associated with hemorrhagic symptoms, and heterozygous carriers are asymptomatic. Factor VII levels do not completely correlate with the severity of symptoms, but patients with levels greater than 10 to 15 U/dl rarely manifest bleeding ([353] , [354]). Patients with levels between 5 and 10 U/dl tend to have milder symptoms such as epistaxis and gingival, genitourinary, and gastrointestinal bleeding. Patients with levels below 1 U/dl may have symptoms similar to patients with hemophilia A or hemophilia B, with spontaneous joint and deep-muscle bleeding. Bleeding into the CNS is particularly common and was observed in 16% of 138 patients in one series ([355]). CNS bleeds often present during the neonatal period ([355]), and the risk of recurrence is high enough that prophylaxis with factor replacement therapy should be considered in patients who present with this complication ([356]). The severity of bleeding after trauma or surgical procedures varies to a surprising degree in this disorder, with oral and urogenital cavity procedures being particularly troublesome, possibly reflecting the high local fibrinolytic activity in these regions of the body. Some report that patients with factor VII deficiency may also be more prone to various thromboembolic manifestations ([357]). The explanation for this phenomenon is unknown, but some authors report diet-responsive factor VII deficiency in the metabolic disorder homocystinuria ([358]) and hypothesize that many patients with inherited factor VII deficiency who experience thrombotic events may have homocystinuria (homocysteinemia) and that the metabolic disorder may explain both factor VII deficiency and thrombosis in these patients ([358]).

Laboratory Diagnosis

In factor VII deficiency, normal results are obtained with coagulation tests that bypass the extrinsic pathway of coagulation and factor VII (Table 59.5) —that is, the PTT and Stypven time. Thus, a diagnosis of factor VII deficiency is suspected in a patient with a life-long history of bleeding when there is an isolated prolonged PT and normal PTT. The PT corrects on 1:1 mixing of patient plasma with normal plasma, but a diagnosis of factor VII deficiency requires a specific factor VII assay for confirmation. Levels of factor VII in heterozygous carriers overlap the normal range. Before making a diagnosis of factor VII deficiency, one should exclude causes for acquired abnormalities such as vitamin K deficiency, liver disease, or warfarin therapy. Also, rare conditions, such as combined deficiency of all vitamin K–dependent factors, and combined factor VII and factor X deficiency should be considered.

Phenotypically, patients have been characterized by possessing plasma levels of factor VII antigen (or CRM). CRM $^{-}$ patients have low factor VII antigen due to lack of synthesis or increased factor clearance, whereas CRM $^{+}$ patients produce factor VII that is antigenically detected but structurally abnormal with deficient function. CRM-R individuals presumably represent a combination of these two entities. Further complexity of the factor VII–deficient phenotype is introduced because of insensitivity of some factor VII activity assays to low levels of factor VII or from variability in assays that is introduced by the use of varying animal sources of tissue thromboplastin.

Treatment of factor VII deficiency with plasma or PCCs is discussed in the section Prothrombin Complex Concentrates, Factor IX, and Factor VII (VIIa). Although the necessity for correcting factor VII deficiency has been questioned ([359]), patients who have factor VII deficiency and a history of excessive clinical bleeding should be given replacement therapy before surgery. It has been reported that patients with factor VII deficiency who have factor VII levels above 10% when assayed using human thromboplastin reagents have minimal bleeding symptoms.

FACTOR X DEFICIENCY

Factor X deficiency was discovered independently by Telfer et al. ([360]) and Hougie et al. ([361]) and is known also by the surnames of the patients who were first found to manifest the defect [Stuart ([361]) and Prower ([360])]. Fewer than 100 cases have been reported ([318]). Factor X deficiency is inherited as an autosomal incompletely recessive trait, and the genetic features and clinical manifestations resemble those of factor VII deficiency. Patients with factor X levels of 10% or more have a mild bleeding disorder. However, patients with factor X levels less than 10% have severe bleeding, and in a comparative analysis of uncommon bleeding disorders, severe factor X–deficient patients appear to have the most serious bleeding disorder ([318]). This clinical observation is supported by studies in factor X knock-out mice in which factor X $^{-/-}$ mice exhibited partial embryonic lethality and fatal neonatal bleeding ([362]).

In several studies using the techniques of immunodiffusion and antibody neutralization, investigators established the existence of CRM-positive and CRM-negative variants of factor X deficiency ([363] , [364]). Significant differences in the laboratory abnormalities encountered in various kindreds further suggest at least two different CRM-positive variants ([363]), namely, that present in the Prower kindred ([360]), in which the Stypven time is abnormal, and factor X Friuli ([365]), in which the Stypven time is normal. In the CRM-negative variant (the disorder in the Stuart kindred), the Stypven time is abnormal ([361]).

A variety of mutations have been found in inherited factor X–deficient patients ([320] , [366] , [367]), including deletions, nonsense mutations, and missense mutations. Deletion mutations usually result in loss of the factor X catalytic domain, whereas missense mutations may impair phospholipid binding, activation of factor X, or synthesis or secretion of the protein. As of 2002, 47 mutations had been reported in association with inherited factor X deficiency ([367]).

Factor X deficiency typically results in prolongation of the PT and PTT assays. A specific factor assay for factor X is used to diagnose factor X deficiency. Prolongation of the Stypven time is characteristic in the Stuart and Prower variants (Table 59.5). Factor X variants associated with isolated prolongation of the PT ([368]) or the PTT ([369]) have been reported. Consequently, patients who present with features of an inherited bleeding disorder, and in whom the typical disorders are excluded based on PT and PTT profiles (Table 59.5), should be evaluated with a specific factor X assay to exclude variant factor X deficiency.

Acquired factor X deficiency [vitamin K deficiency, liver disease, warfarin therapy, amyloidosis ([370])] should be excluded before a diagnosis of inherited deficiency is made. Treatment of factor X deficiency with plasma or PCCs is discussed later in the section Prothrombin Complex Concentrates, Factor IX, and Factor VII (VIIa) and in Table 59.10.

FACTOR XI DEFICIENCY

Factor XI deficiency (plasma thromboplastin antecedent or plasma thromboplastin antecedent deficiency) was first recognized by Rosenthal et al. in 1953 ([371]) and was called *hemophilia C*. Factor XI deficiency is transmitted as an incompletely recessive autosomal trait manifested either as a major defect in homozygous patients with factor XI levels below 20 U/dl or as a minor defect in heterozygous patients with levels ranging from 30 to 65 U/dl ([372]). The incidence of this disorder varies widely, with estimates of frequency in the general population being 1 in 1 million persons. A particularly high frequency of the disorder exists in people of Jewish extraction ([372] , [373]), with an estimated gene frequency of 5 to 11% in Ashkenazi Jews ([374]). Up to 0.3% of this population is homozygous for factor XI deficiency ([374]).

Factor XI deficiency has been reported to result from three major types of mutations: Type I mutations result in disruption of splicing; type II mutations result in a stop codon and nonfunctional molecule; and type III mutations result in amino acid substitutions and a dysfunctional molecule ([375]). Patients with type II mutations have the greatest bleeding tendency ([376]). Type II and III mutations are most common in Ashkenazi Jews. The type II mutation is also common in Iraqi Jews ([377]), who may represent the ancient gene pool of Jews ([378]). In general, all factor XI mutations result in decreased factor XI protein proportionate to factor XI clotting activity. Approximately 20 factor XI mutations have been reported ([379]).

Clinical Features

The clinical manifestations of factor XI deficiency are extremely variable and generally are milder than those of hemophilia A or B ([379] , [380]). As a rule, spontaneous bleeding is rare, and hemorrhage usually occurs only after trauma or a surgical procedure. The extent of factor XI deficiency does not correlate with bleeding ([379] , [380]). Hemarthrosis is uncommon, but delayed bleeding is a particularly treacherous feature in some patients ([371] , [381] , [382]), especially for surgical procedures involving tissues rich in fibrinolytic activity. Mild factor XI deficiency may be associated with Noonan syndrome ([383]) and Gaucher disease ([384]). Hemorrhagic manifestations may be absent in certain patients ([385] , [386]), especially in those with type I mutations. Approximately one-half of heterozygous factor XI–deficient patients have a bleeding tendency ([387]). Factor XI deficiency should be considered in female patients with menorrhagia ([388]). In one study of women with menorrhagia, the prevalence of factor XI deficiency was 4% ([389]).

Laboratory Diagnosis

In the homozygous form of factor XI deficiency ([390]), the PTT is prolonged. In most patients, factor XI levels in the plasma are in the range of 3 to 15 U/dl. In people with the mild form of the disorder, the PTT often is normal because most PTT reagents are insensitive to mild factor XI deficiency ([77]). Abnormalities in the plasma of such mildly affected patients may be removed by freezing. Specific factor assays are used to diagnose factor XI deficiency. The bleeding time and thrombin time are normal. Factor XI deficiency has also been reported in combination with inherited factor IX deficiency (type VI familial multiple factor deficiency) ([391]).

Treatment of factor XI deficiency with plasma is discussed later in this chapter in Table 59.10 and the section Plasma.

FACTOR XII DEFICIENCY

Factor XII deficiency was discovered by Ratnoff and Colopy during routine preoperative coagulation studies on John Hageman, an adult who had no evidence or

history of abnormal bleeding ([392], [393] and [394]). The disorder, subsequently named *Hageman factor deficiency*, is inherited as an autosomal-recessive trait. Factor XII deficiency has been identified in 1.5 to 3.0% of a healthy blood donor population ([395]).

Pathophysiology

The plasma of most patients with factor XII deficiency does not contain material that reacts with antibodies to this factor, as judged by antibody neutralization, hemagglutination inhibition, and immunodiffusion ([396], [397]). Radioimmunoassays with heterologous antibodies have demonstrated antigenic material identical to normal factor XII in only 2 of 42 ([398]) and 2 of 31 ([397]) separate kindreds. One large study of 31 factor XII–deficient kindreds identified most mutations in the serine protease domain ([397]).

Clinical Features

Factor XII deficiency usually is not associated with hemorrhagic manifestations ([392], [399]). It is noteworthy that myocardial infarction and thrombophlebitis have been observed in patients with severe factor XII deficiency ([400]) and that Hageman died of thromboembolic complications ([401]). It was originally thought that factor XII deficiency might actually predispose to thrombosis, possibly as the result of deficient activation of fibrinolysis ([402]). However, more recent surveys indicate that factor XII deficiency is not associated with an excessive risk of thrombosis ([74], [403], [404]).

Results of *in vitro* experiments suggest that factor XII has a central role in the initiation of the intrinsic pathway of coagulation and apparently mediates a variety of other processes such as fibrinolysis, complement activation, inflammation, and chemotaxis ([399], [405]). The physiologic importance of these factor XII–mediated phenomena nevertheless remains obscure because patients with even severe deficiency of this proenzyme reveal no evidence of deficiency or aberrance of host defenses.

The discrepancy between *in vitro* evidence of grossly abnormal blood coagulation and the absence of hemorrhagic manifestations in factor XII deficiency poses a fundamental question regarding the role of the intrinsic coagulation pathway in hemostasis and the significance of laboratory measurements of coagulation. Alternative mechanisms for initiation of coagulation are discussed in Chapter 21. For practical purposes, factor XII deficiency remains a laboratory curiosity and is of little clinical significance.

Laboratory Diagnosis

Factor XII–deficient patients typically present with a negative history of clinical bleeding and an isolated, prolonged PTT that corrects with mixing with normal plasma. The coagulant effects of contact activation are diminished or absent in plasma from subjects with factor XII deficiency ([406]). Normal levels of factor XII range from 50 to 150 U/dl. As with factor XI, accurate assays of factor XII depend on a source of deficient substrate plasma. Laboratory demonstration of the heterozygous state is difficult. The mean level of factor XII in the plasma of carriers is approximately 50% of normal, but observed values are distributed in a bimodal manner, an observation interpreted to suggest the presence of multiple abnormal alleles ([407]).

PREKALLIKREIN DEFICIENCY

An additional abnormality of the intrinsic pathway of coagulation was defined and named *Fletcher factor deficiency* by Hathaway in 1965 ([408]). In 1972, Wuepper et al. established that Fletcher factor was identical to plasma prekallikrein, a protein that had been studied for many years in terms of its role in inflammation ([409]). The convergence of these two avenues of research demonstrated that prekallikrein, in addition to its role in inflammation and chemotaxis, is essential for the optimal activation and fragmentation of factor XII in the early steps of coagulation ([405]).

Pathophysiology

Prekallikrein deficiency apparently is inherited as an autosomal-recessive trait ([408]), although genetic information is scanty. Heterozygotes with approximately 50% of normal plasma levels of prekallikrein can be identified. The disorder is associated with the absence of antigenically competent prekallikrein in most cases ([410], [411]). A CRM-positive variant has been demonstrated in several cases.

Clinical Features

Prekallikrein deficiency, like factor XII deficiency, is not associated with abnormal bleeding. Studies of affected patients revealed variable deficiencies in stress-induced fibrinolysis, chemotaxis, immediate and delayed inflammatory responses, and responses to preformed permeability enhancing activity (PF-Dil) ([412]). These abnormalities are not associated with any apparent deleterious effects. Most patients with prekallikrein deficiency are of African ancestry ([413]). Prekallikrein deficiency is not associated with an excessive risk of thrombosis ([74]).

Laboratory Diagnosis

Prekallikrein deficiency is associated with a moderate prolongation of the PTT. The PT and thrombin time are normal. The euglobulin lysis time is prolonged. The time required for release of vascular plasminogen activators *in vivo* after venous occlusion is prolonged ([414]). The disorder is characterized by abnormally slow contact activation. Thus, the PTT may be normalized by prolonged incubation (10 to 15 minutes) of plasma with particulate activators ([408], [415]). This phenomenon appears to result from autoactivation of factor XII ([416]). Specific assays for prekallikrein are based on traditional coagulation techniques and chromogenic substrate assays ([417]).

HIGH-MOLECULAR-WEIGHT KININOGEN DEFICIENCY

A unique inherited coagulation abnormality associated with deficiencies of kinin formation and fibrinolysis was described in three unrelated kindreds in 1975. The disorder received the names of the affected families [*Fitzgerald trait* ([418]), *Williams trait* ([419]), *Flaujeac trait*, and *Fujiwara trait* ([420])] and has subsequently been found to be the result of deficiency of HMWK. Patients with this disorder are asymptomatic. The data suggest that HMWK functions in its nonactivated form as a cofactor, binding prekallikrein and factor XI to anionic surfaces, accelerating their activation by surface-bound factor XIIa (Chapter 21).

Pathophysiology

Deficiency of HMWK appears to be inherited as an autosomal-recessive trait ([421]). Mildly affected heterozygotes have been identified in some families. Detailed biochemical studies of five kindreds revealed considerable heterogeneity ([419], [421]). Thus, HMWK levels in the plasma ranged from nil ([419]) to 50 U/dl ([418]). With the exception of the Fitzgerald kindred, associated deficiencies in low-molecular-weight kininogen have been demonstrated in all families. Variable deficiency of prekallikrein also was present in the Williams, Fitzgerald, and Fujiwara kindreds; prekallikrein levels were normal in the Flaujeac kindred. Immunologic studies revealed the absence of kininogen antigen in the homozygotes and 50% of normal levels in the heterozygotes ([422]). The associated prekallikrein deficiency also apparently is of the CRM-negative type ([422]). The absence of the stabilizing effects of HMWK may lead to accelerated degradation and deficiency of prekallikrein in this disorder ([422]). HMWK deficiency is not associated with excessive clinical bleeding or thrombosis. There is limited information on the genetic basis for HMWK deficiency ([423], [424]).

Laboratory Diagnosis

Deficiency of HMWK is manifested by an isolated, prolonged PTT. The PTT assay results are abnormal whether particulate or soluble contact activators are used, and values are not normalized by prolonged incubation of the plasma with particulate activators. The euglobulin lysis time is prolonged.

MISCELLANEOUS INHERITED COAGULATION DISORDERS

Combined Defects

Of unusual interest are reports concerning the presence of combined deficiencies of two or more coagulation factors. Deficiency of factors V and VIII and combined deficiency of various vitamin K–dependent factors appear to be the most common combined deficiency disorders. Several other combined coagulation defects have been described (Table 59.1).

Deficiency of Factors V and VIII

This combined defect, reported in fewer than 100 kindreds, is inherited as an autosomal-recessive trait ([425], [426]) by means of two different genetic mechanisms: a doubly heterozygous pattern (type I) and a dual abnormality of a common gene (type II) ([427], [428]). Combined deficiency of factors V and VIII manifests clinically with mild mucosal and cutaneous bleeding. Severe posttraumatic and postsurgical bleeding is common (e.g., after tooth extractions) ([426]). Hemarthrosis is rare. Laboratory findings in homozygous patients include a prolonged PTT and PT and levels of factor VIIIc and Vc that average 15 U/dl ([425]). Levels of factor VIIIAg (VIIIcAg) and VAg are low and are proportional to those obtained by coagulation measurements ([429]).

Linkage analysis of combined factor V and VIII deficiency to chromosome 18q excluded all known hemostasis proteins, suggesting that the basis for the disease is a defect affecting a process common to the biosynthesis of factors V and VIII. Indeed, subsequent studies by two groups identified the genetic basis for most patients with the disorder as mutations in the endoplasmic reticulum–Golgi intermediate compartment (ERGIC) protein 53. ERGIC-53 functions as a molecular chaperone for the transport of several secreted proteins, including factors V and VIII ([430], [431]). Other patients with this combined defect have mutations in another protein termed *CFD2* ([432]).

Combined Deficiency of Factors II, VII, IX, and X

This coagulation disorder has been identified in only a small number of patients ([433]). In addition to affecting levels of the vitamin K–dependent factors, skeletal abnormalities may also be seen, due to effects on bone Gla proteins ([434]). Levels of the vitamin K–dependent proteins range from less than 12 to 50% of normal; thus, clinical bleeding manifestations may vary widely. Mutations in the ?-glutamyl carboxylase gene have been identified in a few patients with this disorder ([435], [436]), and another group has identified a second gene locus causing this defect ([437]). Some patients have clinical improvement and correction of the coagulopathy with vitamin K therapy ([433], [436]).

ABNORMALITIES OF PROTEASE INHIBITORS

Rare abnormalities of three plasma antiproteases, which are associated with bleeding, are described in this section. Other, more numerous abnormalities of the components of the antiprotease system and the fibrinolytic enzyme system that may be associated with thrombosis are discussed in Chapter 61.

a $_2$-Antiplasmin Deficiency

Severe bleeding, including hemarthrosis, was associated with deficiency of a $_2$-antiplasmin in several kindreds ([438], [439] and [440]). This disorder appears to be inherited as an autosomal-recessive trait, in which heterozygotes have detectable deficiencies of this antiprotease but only mild bleeding. CRM-positive and CRM-negative forms have been identified ([441]). A review published in 2001 identified 13 cases; five cases had genetic abnormalities defined ([442]). Three of these five cases had mutations in exon 10, which is the location of the active site, and the plasminogen binding site ([442]).

Bleeding presumably is the result of premature lysis of hemostatically important fibrin plugs caused by unregulated plasmin activity. The laboratory findings are variable. Hypofibrinogenemia and increased clot solubility in urea have been reported, but in many patients, only a shortened euglobulin clot lysis time can be demonstrated. Fibrinogen degradation product levels and platelet counts were normal in most cases ([441]). When assayed qualitatively by fluorometric or photochromogenic techniques, a $_2$-antiplasmin levels usually are below 10 U/dl. Treatment of bleeding episodes with tranexamic acid and other antifibrinolytic agents may be helpful in some cases.

Plasminogen Activator Inhibitor-1 Deficiency

Deficiency of this inhibitor to tissue plasminogen activator is associated with a moderate bleeding disorder ([443]). Only approximately 10 to 20 families have been reported ([444]). One study investigated a large kindred with multiple family members homozygous for this disorder ([445]). Homozygous patients, but not heterozygous patients, exhibited clinical bleeding ([445]). The null gene mutation responsible for plasminogen activator inhibitor (PAI)-1 deficiency was identified in this kindred ([445]). The basis of the bleeding is similar to that described for a $_2$-antiplasmin deficiency: excessive plasmin activity, caused in this case by excessive activation of plasminogen. Laboratory screening studies are typically normal, but the euglobulin clot lysis time is shortened. It is recommended that measurement of PAI-1 antigen and activity in both serum and plasma be done to screen for PAI-1 deficiency ([445]).

a $_1$-Antitrypsin Pittsburgh

A life-long hemorrhagic diathesis in a 14-year-old boy was associated with a unique qualitatively abnormal form of a $_1$-antitrypsin (antithrombin III Pittsburgh) ([446], [447]). This disorder is the result of the substitution of a single amino acid (arginine for methionine at position 358 in the a $_1$-antitrypsin molecule) ([447]). This site corresponds to the P1 residue or “bait” amino acid of the molecule, and the substitution produced a mutation of a $_1$-antitrypsin, a weak antiprotease with little affinity for thrombin, into a potent antithrombin that impaired blood coagulation to a significant degree. The mutant molecule also is a potent inhibitor of factor XIa, factor XIIf, and kallikrein, a property lacking in the normal molecule ([448]). The plasma concentration of the abnormal molecule increased after trauma, possibly as the result of an acute phase reaction. The patient ultimately died of bleeding. Other amino acid substitutions at position 358 have been produced artificially by genetic engineering ([449], [450]).

TREATMENT

Various styptics, drugs, diets, and hormones periodically have been advocated for the treatment of the inherited coagulation disorders. These include oral contraceptives ([451]) and corticosteroids ([452]). In general, none of these remedies is of proven value, although estrogens may be useful in treating female patients with vWD ([453]). Topical hemostatics may be temporarily effective in small injuries, and certain other measures may prove to have adjunctive value under specific circumstances such as DDAVP and inhibitors of fibrinolysis ([454]). The principal treatment for the inherited coagulation disorders, however, is replacement therapy—that is, the intravenous administration of the required factor in the form of blood products derived from normal people or animals ([455]) or recombinant coagulation proteins ([456]).

Replacement Therapy

The objective of replacement therapy is to obtain a concentration of the required factor at the bleeding site such that coagulation may become hemostatically effective. Its achievement involves a consideration of several biodynamic properties of the various coagulation factors (Table 59.8), a general knowledge of the available therapeutic materials, and clinical assessment of the severity of the hemorrhagic manifestations. Replacement products can be given on the basis of body weight (Table 59.9 and Table 59.10) or plasma volume. This latter method may be more precise in patients who do not have a normal plasma volume because of bleeding. In this method, blood volume is considered to be 7% of body weight; plasma volume is then calculated using the patient's hematocrit. Next, the therapeutic objective is assessed (e.g., the desired incremental increase in factor VIII level). For example, if a patient with severe hemophilia A (<1% factor VIII) has a plasma

volume of 3000 ml and requires major surgery, the target factor VIII level should be 100% of normal. Infusion of 3000 U factor VIII would result in a calculated peak factor VIII level of 1 U/ml (100% of normal). Peak factor levels should be monitored to document attainment of the expected response; dosage adjustment can then be made, if needed.

TABLE 59.8. Biodynamic Properties of Coagulation Factors of Concern in Replacement Therapy

Disorder	Hemostatic Level (U/dl) [a]	Initial *In Vivo* Recovery (% of Infused Material)	*In Vivo* Survival of Infused Coagulation Factors	
			First Phase Diffusion Half-Life (h)	Second Phase Biologic Half-Life (h)
Hemophilia A (factor VIII deficiency)	25–30	80	4–6	12
Hemophilia B (factor IX deficiency)	15–30	25–50	2–3	24
Fibrinogen deficiency	100 mg/dl	50	12	77–106
Prothrombin deficiency	?20–40	50–100	8	72–96
Factor V deficiency	15–25	?50–100	[b]	?12–36
Factor VII deficiency	10–20	?100	0.5	5
Factor X deficiency	10–20	50–100	2–9	24–48
Factor XI deficiency	10–20	~100	[b]	?48–84
Factor XIII deficiency	3–5	50–100	[b]	~9 d

?, insufficient data or significant disagreement among published figures.

[a] Values represent the minimum desired level. Patients undergoing major surgery or experiencing major bleeding should receive dosages to achieve higher factor levels; for example, patients with hemophilia A should have replacement such that factor VIII levels approach 100% of normal. For patients with factor XIII deficiency and major trauma, plasma factor XIII levels of at least 25% should be achieved.

[b] In most patients, the survival curve is monophasic and lacks an initial component.

TABLE 59.9. Replacement Therapy in Hemophilia A and Hemophilia B

Disorder	Therapeutic Material	Minor Bleeding (i.e., Uncomplicated Hemarthroses; Hematomas in Noncritical Areas; Hematuria; Dressing Changes; [a] Arthrocentesis; [a] Removal of Sutures and Drains [a])		Major Bleeding (Hematomas in Critical Locations; Traumatic Injuries; Multiple Tooth Extractions; Major Surgical Procedures)	
		Loading Dose	Maintenance Dose	Loading Dose	Maintenance Dose
Hemophilia A (factor VIII deficiency)	Cryoprecipitate [b]	Not required	1.25–1.75 bags/10 kg every 12 h for 1–3 d	3.5 bags/10 kg	1.75 bags/10 kg every 8 h for 1–2 d; every 12 h thereafter
	Purified factor VIII [c]	Not required	10–15 U/kg every 12 h for 2–4 d	30–40 U/kg	30–40 U/kg every 12 h
Hemophilia B (factor IX deficiency)	Prothrombin complex [b, c]	20–30 U/kg	15 U/kg every 24 h for 2–4 d	40–60 U/kg	20–25 U/kg every 24 h
	Purified factor IX [c, d]	20–30 U/kg	15 U/kg every 24 h for 2–4 d	60–70 U/kg	20–40 U/kg every 24 h

NOTE: Because weight-based calculations may not correctly predict plasma volumes in bleeding patients, confirmation of the hemostatic level of the coagulation factor being replaced should always be performed for patients with major bleeding indications, with appropriate dosage adjustments performed based on these results.

[a] Single dose of 15 U/kg or equivalent amounts of concentrated material usually are sufficient.

[b] Recommended only if purified factor replacement therapy is not available. Antifibrinolytic therapy should not be used with prothrombin complex concentrates.

[c] Initial *in vivo* recovery of active factor varies somewhat depending on preparation.

[d] Recombinant factor IX may require higher doses.

Hemostatic Levels

The *hemostatic level* may be defined as the lowest plasma concentration of a given coagulation factor that is required for normal hemostasis (Table 59.8). This value was determined by purely empiric means—that is, by measurement of the blood levels of the deficient factor at which bleeding appeared to stop in patients with one of the inherited coagulation disorders during the course of replacement therapy. Such estimates obviously may be inaccurate. In patients with hemophilia A, the hemostatic level of factor VIIIc is approximately 25 to 30 U/dl; in those with hemophilia B, values range from 15 to 30 U/dl. Plasma levels of factor XIII as low as 2 to 3 U/dl are adequate for normal hemostasis. However, for patients with major trauma or those undergoing surgery, higher plasma levels of these coagulation proteins should be achieved (i.e., 100% for factors VIII or IX; 25 to 50% for factor XIII).

In Vivo Recovery and Survival of Infused Coagulation Factors

When a coagulation factor is infused intravenously into a recipient deficient in that factor, the levels present in the circulation after intravascular mixing usually are significantly lower than those that would be expected merely from dilution in the recipient's plasma. That this initial *in vivo* recovery of infused coagulation factors (Table 59.8) is less than 100% presumably is the result of loss of these proteins out of the intravascular space. The adsorption of coagulation factors by platelets and various cell and vascular surfaces may also be involved. The initial recovery of infused coagulation factors is difficult to quantify and ranges from nearly 100% of factor XI to as low as 30% of factor IX.

After *in vivo* mixing is complete, the activity of most coagulation factors in the plasma declines in a biphasic manner—that is, an initial rapid loss of activity is followed by a more gradual decline (Fig. 59.8) ([457]). The first or rapid phase presumably is the result of diffusion into extravascular pools. This diffusion half-life (Table 59.8) ranges from minutes for factor VII to several hours for factor VIII. In general, it is the rapidity of this first phase, together with the initial *in vivo* recovery of the particular factor, that determines the necessity for and the size of the preliminary or loading dose of therapeutic material.

The second or slow phase of the survival curve presumably is the result of degradation and reflects the true biologic half-life of the infused factor (Table 59.8; Fig. 59.10). This parameter, together with the hemostatic level for the factor of concern, is the main determinant of the frequency of administration and the size of the maintenance dose of therapeutic material. For example, approximately 80% of factor VIII infused is initially recovered in the circulation; its initial (diffusion) and subsequent (biologic) half-lives are approximately 6 and 12 hours, respectively ([458]). Thus, in the treatment of patients with hemophilia A, doses are administered

every 8 to 12 hours. In patients with hemophilia B, the initial recovery of factor IX is 50% or less; its initial and subsequent half-lives are approximately 3 and 24 hours, respectively ([459]). Hence, a large loading dose is essential, but only small and infrequent daily maintenance doses are required.

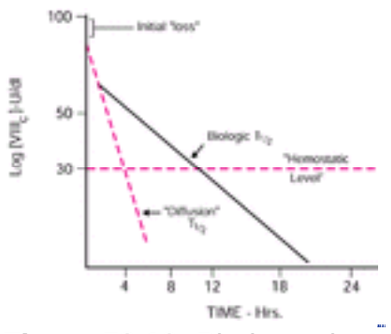

Figure 59.10. Biodynamics of factor VIII. A hypothetical survival curve obtained in a patient with severe hemophilia A after transfusion of sufficient factor VIII to increase the plasma factor VIIIc level to 100 U/dl is shown. $T_{1/2}$, half-life.

After a large loading dose or after several courses of therapeutic material have been administered, the survival curves of infused coagulation factors become nearly monophasic, presumably because extravascular spaces and the other mechanisms that remove infused coagulation factors from the circulation are saturated.

Materials

Before 1960, plasma was the only agent generally available for the treatment of the inherited coagulation disorders. Several concentrated blood products are now available for this purpose, as well as recombinant coagulation proteins. The potency or extent of purification of various preparations of coagulation factors usually is expressed in terms of the ratio of coagulant activity:unit weight of protein in the concentrate to that in plasma. Table 59.9, Table 59.10, Table 59.11 and Table 59.12 summarize therapeutic choices available to treat certain inherited bleeding disorders.

TABLE 59.11. Comparison of Factor VIII Products

Product	Comments	Cost/IU
Human plasma-derived factor VIII products		
Koate-DVI (Bayer)	—	$0.92
Humate-P (Aventis)	More vWF than monoclonal antibody-purified products	$1.00
Alphanate (Alpha Therapeutics)	Useful in von Willebrand disease	$0.90
Human plasma-derived factor VIII products with immunoaffinity purification		
Monarc-M (American Red Cross)	—	$0.93
Hemofil M (Baxter)	Reduced amounts of vWF	$0.98
Monoclate-P (Aventis)	Reduced amounts of vWF; highly purified source of factor VIII	$0.95
Recombinant factor VIII products		
Recombinate (Baxter)	High-purity source of factor VIII [a]	$1.30
Helixate FS (Aventis)	High-purity source of factor VIII	$1.38
Refacto (Wyeth)	High-purity source of factor VIII	$1.36
Kogenate FS (Bayer)	High-purity source of factor VIII	$1.41
Porcine factor VIII product		
Hyate:C (Ipsen)	For patients with human factor VIII inhibitors	$2.15

vWF, von Willebrand factor.

NOTE: Commercial products used to treat hemophilia A are summarized, including their hospital acquisition cost per international unit (IU) for the University of Utah Health Sciences Center Pharmacy in 2002. Humate-P and Alphanate are also useful in the treatment of von Willebrand disease.

[a] This product contains pasteurized human albumin added as a stabilizer.

TABLE 59.12. Comparison of Factor IX Products and Recombinant Factor VIIa

Product	Comments	Cost
Factor IX complex products		
Konyne-80 Factor IX Complex (Bayer Biol)	Not indicated for factor VII deficiency. Indicated for factor IX deficiency and factor VIII inhibitor therapy. Thrombotic potential exists.	$0.50/IU
Proplex T Factor IX Complex (Baxter)	Indicated for factor VII and factor IX deficiency and factor VIII inhibitor therapy. Thrombotic potential exists.	$0.35/IU
Profilnine SD (Alpha Therapeutics)	Not indicated for factor VII deficiency. Indicated for factor IX and factor VIII inhibitor therapy. Thrombotic potential exists.	$0.75/IU
Bebulin VH (Baxter)	Thrombotic potential exists.	$0.58/IU
Activated factor IX complex products		
Autoplex T (Nabi)	Thrombotic potential exists.	$1.50/IU
Feiba VH (Baxter)	Thrombotic potential exists.	$1.53/IU
Purified factor IX products		
Alpha Nine SD (Alpha Therapeutics)	Indicated for factor IX deficiency. Low risk of thrombotic potential.	$1.10/IU
Mononine (Aventis)	Indicated for factor IX deficiency. Low risk of thrombotic potential.	$1.18/IU
Recombinant factor IX		
BeneFIX (Genetics Institute/Wyeth)	No exogenous proteins are added.	$0.78/IU
Recombinant factor VIIa		
NovoSeven (Novo Nordisk)	Indicated for inhibitor patients but also used in other hemostatic disorders.	$1680/1.2 mg

NOTE: Commercial products used to treat hemophilia B are summarized, including their hospital acquisition cost per international unit (IU) or per mg to the University of Utah Health Sciences Center Pharmacy in 2002.

PLASMA Although most current replacement therapies of coagulation factor deficiencies involve sterile purified concentrates or recombinant proteins, plasma therapy is still important in treating some deficient states such as factor XI deficiency. Fresh frozen plasma is usually preferred for therapeutic purposes. Both the rate of administration and the total dose of plasma administered are limited by the possibility of acute or chronic circulatory overload. The volume expansion resulting from even moderate doses of plasma also limits the blood levels that can be attained. As a consequence, therapy with plasma alone can be expected to increase the levels of a deficient factor no more than 20 U/dl above baseline values. When plasma is the only therapeutic agent available, plasmapheresis may be of adjunctive value (

[460]). A sterile solvent detergent–treated plasma preparation is available ([461]), but activity of certain coagulation proteases and inhibitors in this product is not equivalent to that of fresh frozen plasma ([462], [463]).

PURIFIED OR CONCENTRATED COAGULATION FACTORS

Cryoprecipitate A major advance in the therapy of hemophilia A was the demonstration by Pool et al. that cold insoluble material obtained from plasma contains high concentrations of factor VIII and fibrinogen ([464]). This cryoprecipitate, which for many years was discarded during clarification of plasma, is prepared by slowly thawing rapidly frozen plasma at 2° to 4°C, then harvesting the precipitate by centrifugation. Cryoprecipitate prepared from 200 ml of fresh plasma (one unit) contains 50 to 120 units of factor VIII, approximately 250 mg of fibrinogen, and therapeutically useful amounts of factor XIII and vWF that are rich in the high-molecular-weight multimers. Cryoprecipitation provides 7- to 20-fold purification of factor VIII with respect to plasma and can be carried out by means of a closed double-bag system, even in small blood banks without special equipment. With the widespread availability of sterile factor VIII concentrates to treat hemophilia A and vWD, cryoprecipitate is now used primarily to treat hypofibrinogenemia.

PURIFIED FACTOR VIII Among the many methods developed to purify factor VIII, several are suitable for the large-scale production of concentrates of the human protein for therapeutic use. They are sufficiently potent to attain *in vivo* factor VIIIc levels as high as 100 U/dl in hemophilic patients without significant expansion of the plasma volume. Most plasma-derived factor VIII concentrates contain vWF but lack the high-molecular-weight vWF multi-mers found in cryoprecipitate or plasma. Therapeutic doses are usually self-administered by patients. Before the mid-1980s, a considerable risk of viral transmission attended the use of most concentrated preparations because they were prepared from large plasma pools and specific virucidal treatment was not used. The risk of virus transmission has been greatly diminished by serologic testing of the plasma for viruses and by sterilization of the concentrate by solvent detergent treatment or heat sterilization ([465]). A high-potency preparation of factor VIII can be obtained by affinity chromatography using monoclonal antibodies ([466]). Recombinant factor VIII is also available for clinical use ([467]). Although these methods have reduced the risk of transmitting lipid-enveloped viruses [e.g., human immunodeficiency virus (HIV) and hepatitis B and C], transmission with non–lipid-enveloped viruses, such as hepatitis A and parvovirus B19, has been reported with sterilized plasma-derived products ([468]). Whether high-purity factor concentrates should be used exclusively is a controversial issue ([469]). Although *in vitro* studies suggest that the non–high-purity factor VIII products have immunosuppressive properties, the clinical importance of these studies is uncertain ([470]). The significant cost difference between products also enters into this controversy ([469]). A report that parvovirus B19 DNA ([471]) and the TT virus ([472]) are present in certain recombinant factor VIII products (a likely result of the addition of human albumin as a stabilizer) has also contributed to this discussion. Increasing use of recombinant factor products in prophylactic programs and manufacturing shortages of these products have led to limited availability and debate over whether recombinant products should continue to be the product of choice as recommended by hemophilia authorities ([473]). Although plasma-derived products are appropriate when recombinant products are not available, the safety data to date favor recommendation to exclusively use recombinant products ([473]). Table 59.11 and Table 59.12 summarize information on currently available products used to treat hemophilia A and hemophilia B. A second-generation product, B domain–deleted recombinant factor VIII (Refacto), is available; this product does not contain human albumin ([474]). Additionally, a full-length factor VIII product formulated with sucrose does not contain human albumin ([475]). One concern with the B domain–deleted product is that laboratory monitoring of patients receiving this product requires use of specific assays ([88], [89]).

PORCINE FACTOR VIII Factor VIII purified from porcine plasma is available for treatment of hemophiliacs with high-titer factor VIII inhibitors ([476]). This product is antigenic, a drawback that usually limits its use to a single therapeutic course. Mild thrombocytopenia and other adverse reactions may develop in the recipient. Heterologous factor VIII apparently is less reactive with acquired antibodies to factor VIII than is the homologous protein, a property that is advantageous in the treatment of bleeding caused by such antibodies (Chapter 60) ([476]).

PROTHROMBIN COMPLEX CONCENTRATES, FACTOR IX, AND FACTOR VII (VIIA) The vitamin K–dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are avidly absorbed by aluminum hydroxide or barium sulfate and can be readily concentrated by elution therefrom. This simple procedure is the starting point for several methods of preparing therapeutically useful concentrates of these proteins ([477]) (Table 59.12). Concentrates of vitamin K–dependent coagulation factors contain small but significant amounts of activated coagulation factors that may be thrombogenic when administered in large doses. The thrombogenicity of such concentrates varies from preparation to preparation and from lot to lot and has been variously attributed to thrombin, factor VIIa ([478]), factor Xa ([479]), factor IXa ([480]), and coagulant phospholipids ([481]). Attention has been directed to the serious and even fatal thromboembolic complications of these products, including disseminated intravascular coagulation ([479], [482]). Such complications are particularly common in infants and in patients with liver disease ([483]), as discussed in Chapter 60. The availability of monoclonally purified and recombinant factor IX products has led to decreased use of PCCs in the treatment of hemophilia B ([484], [485] and [486]). PCCs are now used primarily to treat patients with inhibitors to factor VIII, a condition in which the presence of thrombogenic materials is clinically useful ([487]). PCCs are also useful in treating deficiencies of prothrombin and factors VII and X. When treating hemophilia B with replacement factor IX products, it should be noted that factor IX distributes to both intravascular and extravascular compartments. Consequently, loading doses required to achieve 100% of the normal plasma factor IX level are usually 1.5 to 2.0 times greater than that calculated from the patient's plasma volume. Thus, when purified factor IX products are used, twice the calculated amount of factor IX should be given for the initial dose. On the other hand, PCCs are thrombogenic, and when these products are used to treat patients with hemophilia B, the dosage should be reduced below that given when the purified products are used. A factor VII concentrate was under investigation in the United States for treatment of patients with inherited factor VII deficiency ([356]). This material has been used prophylactically for patients with severe factor VII deficiency and for operative coverage in less severely affected patients ([356]). Recombinant factor VIIa is being used primarily for treatment of bleeding episodes in patients with hemophilia with inhibitors ([488]) but also in patients with bleeding due to refractory thrombocytopenia, platelet dysfunction, factor VII deficiency (discussed in section Factor VII Deficiency), or severe liver disease (discussed in Chapter 60).

THERAPEUTIC ADJUNCTS A congener of vasopressin, DDAVP, was originally developed for the treatment of diabetes insipidus. Its extrarenal actions stimulate vascular endothelial cells to release several proteins, including vWF in amounts sufficient to raise the plasma levels of this protein and associated factor VIII two to five times (Fig. 59.11) ([489], [490]). This effect is therapeutically useful in most patients with type 1 vWD ([489], [491]) and some with mild hemophilia A ([492]), and it is particularly useful because the biohazards of blood products are avoided ([493]). Excellent responses were obtained in the prevention of bleeding after minor surgical procedures, such as tooth extractions, and in some major surgical procedures ([494], [495]). It has been noted that young boys with mild to moderate hemophilia A have a lower response rate to DDAVP; the response rate of these patients improves later in life, and nonresponder children are candidates for retesting when they are older ([496]).

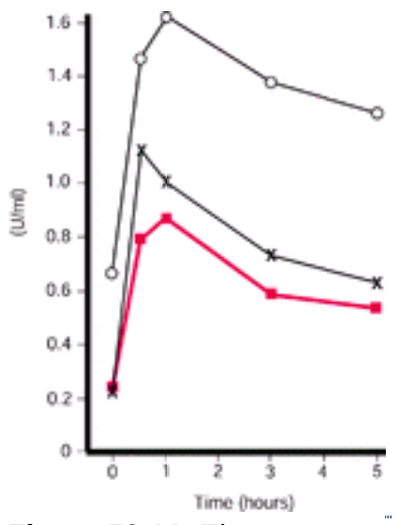

Figure 59.11. The response to desmopressin infusion (0.3 µg/kg body weight) in a hemophilic patient. Open circles indicate von Willebrand factor antigen, solid boxes indicate factor VIIIc activity, and crosses indicate factor VIIIc antigen. (From de la Fuente B, Kasper CK, Rickles FR, et al. Response of patients with mild and moderate hemophilia A and von Willebrand disease to treatment with desmopressin. Ann Intern Med 1985;103:6–14, with permission.)

The vWF released in response to DDAVP is rich in high-molecular-weight multimers ([497]) that increase adhesion and spreading of platelets at injury sites. This effect may explain the therapeutic efficacy of the drug in several disorders of platelet function, including uremia ([498]). DDAVP-responsive endothelium requires the presence of V_2 receptors ([499]). DDAVP has also been reported to be clinically useful in patients with hemophilia B ([500]). Although factor IX levels are minimally increased by DDAVP, the improved PTT values in hemophilia B patients given DDAVP associated with increases in factor VIII and vWF activity probably account for drug efficacy ([500]). Another group found DDAVP useful in hemophilia B patients when combined with antifibrinolytic therapy ([501]). DDAVP also induces the release of endothelial cell–derived plasminogen activators and has produced exaggerated fibrinolytic phenomena in several cases. For this reason, it is sometimes given with e-aminocaproic acid (EACA) or other fibrinolytic enzyme inhibitors. DDAVP is a pressor agent and an antidiuretic. Neither effect has proved to be a major problem in its therapeutic use, but clinicians should use caution when treating patients with hypertension or congestive heart failure. Repeated doses of DDAVP may produce progressively diminishing amounts of vWF (tachyphylaxis), presumably because of exhaustion of stored vWF. DDAVP is available for parenteral use or by the nasal spray Stimate ([502]). DDAVP can be given parenterally (0.3 µg/kg, up to a maximal dose of 20 to 24 µg) ([503]). Physicians should be aware that two DDAVP nasal sprays are available and that only the higher DDAVP concentration nasal spray (Stimate, 1.5 mg/ml) is effective in treating vWD. DDAVP should be used cautiously in

older patients with vascular disease because of the potential risk of drug-induced thrombosis ([503], [504]). Increasing use of DDAVP has revealed certain limitations of this hemostatic drug. One report in adult patients indicated that approximately 20% of patients experienced toxicity with DDAVP, including nausea and headache, and symptomatic hyponatremia was seen in approximately 5% of patients ([505]). These side effects may be minimized with water restriction. Limitations of DDAVP in the pediatric population have been summarized ([506]). Inhibitors of fibrinolysis, such as EACA or tranexamic acid, may diminish bleeding in patients with inherited coagulation disorders, particularly those that arise in the mouth, tongue, tonsils, and pharynx and those associated with operative dental procedures ([507], [508]). These drugs act to protect labile hemostatic plugs from fibrinolytic degradation. The use of EACA alone has been effective in the treatment of patients with mild hemophilia A (plasma levels of factor VIII >5 U/dl) ([509]) and those with other mild inherited coagulation disorders such as vWD or factor XI deficiency. Some clinicians have used EACA as an adjunct to single-dose ([510]) or various other factor replacement regimens. EACA should be administered in oral doses (pills or syrup) of 6 g every 6 hours to adults and 100 mg/kg every 6 hours to children, for 3 to 4 days after tooth extraction. The drug can be given intravenously (1 g/hour) for patients who cannot swallow. Hematuria or abnormal renal function is a contraindication to the use of this drug because of the hazard of intrarenal or ureteral obstruction by blood clots ([511]). EACA also should not be given to patients with disseminated intravascular coagulation or active hepatitis or patients receiving PCCs, although an EACA mouthwash can be used with these latter drugs ([508], [512]). These drugs may be teratogenic and should be used with caution in pregnant women.

MAJOR AND MINOR BLEEDING

General treatment guidelines for patients, including newborns with hemophilia and other bleeding disorders, have been published ([512], [513] and [514]).

For purposes of replacement therapy, the various bleeding manifestations commonly encountered in the inherited coagulation disorders may be divided into major and minor categories. Although this distinction is somewhat artificial, it has proved helpful clinically.

Manifestations falling into the minor category include bleeding associated with uncomplicated hemarthrosis, symptomatic hematomas in noncritical areas, and minor traumatic injuries, as well as such therapeutic procedures as minor dental procedures, arthrocentesis, and dressing changes. Small cuts and scratches, removal of stitches or drains, superficial ecchymoses, and small hematomas may require no replacement therapy.

Major bleeding is by definition life-threatening and includes hematomas in critical locations and bleeding resulting from traumatic injuries, particularly those in which external blood loss is significant. Major bleeding occurs in surgical procedures, including tonsillectomy and the extraction of molar teeth. In the treatment of major bleeding, the *in vivo* levels of the deficient factor should be maintained above the hemostatic level. In bleeding of a particularly critical nature, such as intracranial hemorrhage, or for the prevention of excessive bleeding during neurosurgery, factor levels should be maintained at 100% of normal.

Hemophilia A Minor Bleeding

DDAVP is effective in the treatment of minor bleeding manifestations in hemophiliacs with baseline factor VIIIc levels greater than 5 U/dl, if patients have been previously demonstrated to respond ([494], [495]). Side effects are more prominent if the total dose exceeds 24 µg. Both parenteral and intranasal administration produce significant increases in factor VIIIc and vWF ([515]). Repeated doses of DDAVP at approximately daily intervals may produce useful increments of factor VIII in many patients. At least 24 hours should elapse before repeat administration of the drug. Patients should be tested before surgery for their response to DDAVP by documenting factor VIII levels 30 to 60 minutes after treatment. This ensures that the drug will be effective in appropriate responders. Only small amounts of factor VIII are produced by DDAVP in severely affected hemophiliacs, and the use of this drug in patients with factor VIII levels below 5 U/dl is not recommended, even for minor bleeding manifestations. EACA (6 g orally every 6 hours) or tranexamic acid (25 mg/kg orally every 6 to 8 hours) has been administered together with DDAVP in an attempt to minimize fibrinolysis ([508]). For maximal effectiveness, antifibrinolytic drugs should be given before oral surgical procedures.

Although effective in minor bleeding, plasma or cryoprecipitate is not currently used in the treatment of patients with hemophilia A. Factor VIII concentrates are widely available and are the most useful therapeutic materials. The regimens summarized in Table 59.9 illustrate one approach to treating hemophilia A. For some minor bleeding manifestations, treatment for a minimum of 3 days is required, but in most cases, a single dose of 10 to 15 U/kg of factor VIII usually suffices ([516]). In the treatment of minor bleeding, loading doses are not required, and laboratory monitoring of *in vivo* factor VIII levels is unnecessary. The minor bleeding treatment regimens summarized in Table 59.9 typically result in peak factor VIII levels of approximately 30%.

Hemophilia A Major Bleeding

In the therapy for major bleeding in patients with hemophilia A, an initial loading dose of factor VIII should always be administered, and sufficient factor VIII must be given often enough to ensure that the blood level does not fall below 30 to 50 U/dl for any length of time. Maintenance doses usually are given every 8 to 12 hours. Regimens of continuous infusion of factor VIII are being used with increasing frequency ([517]). The administration of 2 U/kg/hour of factor VIII produces a mean factor VIIIc level in the plasma of approximately 50 U/dl and appears to be more cost effective than twice-daily intravenous bolus treatments ([518]). Continuous infusion also has the advantage of maintaining a consistent, therapeutic factor level ([519]). Cost-savings may approach 30 to 40% ([520]). Note that the treatment of postsurgical or major traumatic hemorrhage in patients with mild hemophilia A requires nearly as much therapeutic material as is needed for the severely affected patient. Most authors recommend treatment for 10 to 14 days after major surgical procedures, whereas others administer the full doses indicated in Table 59.9 for 10 days and continue half doses for 4 days.

Determination in the laboratory of the *in vivo* levels of factor VIIIc is highly desirable in the treatment of patients with major hemorrhage. Incidents of unexpected subtherapeutic responses to infused factor VIII have been reported ([521]). The peak level of factor VIII 10 to 30 minutes after infusion of therapeutic material should be at least 75 U/dl if the level is not to fall below 25 U/dl on a 12-hour schedule. The use of the PTT to guide factor VIII replacement therapy is not recommended because the results of these tests may be normal at hazardously low levels of factor VIII ([77]).

von Willebrand Disease

In a disease as heterogeneous as vWD, decisions about treatment begin with accurate diagnosis and complete evaluation. Fortunately, in the usual patient with vWD, bleeding manifestations are mild, and replacement therapy is seldom required. Unlike the situation in hemophilia in which there is a close correlation between factor levels and clinical outcome, treatment decisions are more complicated in vWD because it is unclear which measurement (of either vWF, factor VIII, or platelet function) best correlates with the severity of bleeding or clinical outcome ([99]). Many experts recommend following the vWF:RCo and factor VIII level ([522]). Bleeding times may not normalize, but a normal bleeding time is not required for a satisfactory response, and monitoring of the bleeding time is not recommended ([523]). Therapeutic goals include resolution of active bleeding and prevention of excessive bleeding in response to invasive procedures or trauma. The spectrum of therapeutic interventions includes desmopressin (DDAVP) for nonexogenous replacement therapy, blood product or concentrate infusion for transfusion replacement therapy, and adjunctive therapy with medications that modulate bleeding symptoms by affecting either menstrual pattern or fibrinolysis. Dosing recommendations in vWD are empiric. In the case of a patient with major surgery or trauma, one recommendation is that clinicians attempt to bring the vWF (and factor VIII) level to near 100 U/dl and maintain it above 40 to 50 U/dl for the first 3 to 5 days, after which one recommended goal is to maintain the factor VIII level above 40 U/dl for a total of 7 to 10 days or until healing is completed ([99], [105]). In surgical settings, monitoring of factor levels seems prudent, but monitoring of bleeding time is discouraged, as surgeries have been done successfully in patients with type 3 vWD in the face of only partial bleeding time correction ([524]).

DDAVP is effective in the treatment of patients with mild forms of type 1 vWD. The dosage, route of administration, and contraindications described in the section Therapeutic Adjuncts also apply to the use of the drug in vWD. vWF and factor VIII levels generally increase by two- to fourfold over baseline. Concerns regarding tachyphylaxis, hyponatremia, and rare thrombotic complications are similar to those of treating patients with hemophilia A. Note that patients with non–type 1 vWD respond poorly or unpredictably to DDAVP. Type 3 patients have essentially no endogenous vWF synthesis and are DDAVP nonresponsive. In one large series of patients with type 2B vWD, the platelet count fell from an average of 86,000/µl to 60,000/µl after administration of this drug ([186]). Because thrombocytopenia may worsen after administration of DDAVP to patients with type 2B and the platelet-type form of the disorder, patients with these variants should not be treated routinely with DDAVP ([99]). However, some authors report good-responder–type 2B vWD patients who received DDAVP ([525]). Response in type 2A vWD is variable and may be of shorter duration than in type 1 patients due to increased vWF proteolysis. Similarly, factor VIII levels may rise in response to DDAVP in patients with type 2N vWD, but due to the deficient factor VIII stabilizing activity of vWF in this variant, levels of factor VIII then fall at an accelerated rate ([526]). Because of interindividual variability, a documented therapeutic response to DDAVP should be obtained before surgical prophylaxis with the drug to ensure adequate hemostasis

postoperatively. It is recommended that this DDAVP trial be performed at the time of diagnosis of vWD.

Transfusion therapy with plasma-derived products is the therapy of choice in DDAVP-unresponsive patients who require factor support. To treat both the factor VIII deficiency and the defect in primary hemostasis seen in patients with severe vWD, it is generally necessary to give a product with factor VIIIc activity that also contains high-molecular-weight multimers of vWF. The concentration of vWF and factor VIII in fresh frozen plasma is insufficient for appropriate therapy. Cryoprecipitate contains approximately 80 to 100 U/bag, five to ten times the concentration of these factors compared to plasma. Cryoprecipitate has a small residual risk of viral transmission and is not currently suited to viral-inactivation therapy; pathogen-inactivated intermediate-purity factor VIII concentrates with demonstrated preservation of vWF multimers have been the preferred replacement product in the United States and Europe. At the time of this writing, only one commercial product was licensed in the United States for this indication (Humate-P, known as *Haemate-P* in Europe). However, several other commercial products have been used off-label for this indication ([139]). With its licensure in 1999, vials of Humate-P are now labeled by both its vWF:RCo and factor VIII activities. A Canadian multicenter study confirmed “excellent” or “good” outcome in 97% of patients treated, with a median recovery of 1.23 U/kg per IU/kg infused ([527]). Similarly, Alphanate was shown to ultimately control all bleeding episodes in one large multicenter trial ([528]). Alphanate is currently only labeled in factor VIII units, but vWF:RCo has been reported to be approximately 50% lower than the labeled Factor VIII content ([139] , [528]). A chromatographically purified vWF concentrate with minimal factor VIII content is under investigation ([529]). Very-high-purity plasma-derived factor VIII concentrates and recombinant factor VIII concentrates are essentially devoid of vWF and should not be used in vWD.

Some authors suggest using platelet transfusion in patients with severe vWD who exhibit bleeding despite plasma factor VIII concentrate therapy ([530]). Thrombocytopenia may be exacerbated by the administration of normal exogenous vWF in the platelet-type pseudo-vWD ([531]) but not in type 2B vWD. Patients with platelet-type vWD should receive platelet transfusions for significant bleeding or surgery.

With the recent labeling of vWF products such as Humate-P as to both factor VIII activity and vWF:RCo activities, reports of venous thrombosis have appeared in association with therapy ([532]). This complication may be due to the excessive rise in factor VIII achieved when ristocetin cofactor activity is normalized with these products. Optimal future therapy should provide correction of the vWF defect without increasing factor VIII levels excessively. A recombinant vWF product is under investigation ([533]).

Adjunctive therapy for vWD patients with menorrhagia usually takes the form of oral contraception or other hormonal intervention ([9]). Antifibrinolytic therapy and DDAVP have also found a role in control of menorrhagia ([126]). Failure of medical therapy may require surgical approaches such as endometrial resection ([534]) or even hysterectomy.

Pregnancy is a special situation for patients with vWD. vWF levels generally improve in patients with type 1 vWD as pregnancy proceeds, but improvement is less likely in type 2A vWD, and thrombocytopenia may actually worsen in patients with type 2B and platelet-type (pseudo) vWD variants. Older literature on this subject suggests a high rate of bleeding at delivery for these patients. More recent information indicates that the patient's factor VIII coagulant activity at delivery predicts the risk of bleeding, with a factor VIII level below 50% of normal at term being associated with excessive bleeding ([535]). If sufficient factor VIII levels are achieved, aggressive surgical hemostasis and efficient uterine contraction should prevent peripartum bleeding. If sufficient factor VIII levels are not achieved before delivery and the patient is known to respond to DDAVP, this drug can be given to the mother immediately postpartum. If the patient does not respond to DDAVP, then vWF/factor VIII concentrate should be administered peripartum. Finally, vWF levels fall quickly after parturition, and DDAVP or replacement therapy may be useful to prevent late bleeding in patients with vWD.

Hemophilia B

Most of the comments concerning the replacement therapy of patients with hemophilia A apply to the treatment of those with hemophilia B (Table 59.9). Because of the low initial *in vivo* recovery and the rapid initial disappearance of factor IX from the circulation, loading doses are recommended, even for the treatment of minor bleeding. In patients with hemophilia B, purified factor IX concentrates are recommended for the treatment of major or minor hemorrhage because of the thrombotic potential of PCCs ([479] , [482]). At least two purified factor IX products are available that are not thrombogenic (Table 59.12) ([485] , [536]). Recombinant factor IX is now available for clinical use ([537] , [538]); one disadvantage of recombinant factor IX compared to plasma-derived factor IX is a lower *in vivo* recovery of recombinant factor IX (approximately 30% lower than predicted), perhaps related to different posttranslational modifications of the recombinant protein ([538]). It appears that higher doses of recombinant factor IX need to be routinely given to achieve therapeutic levels, and monitoring factor IX levels with this product should be routinely done ([539]), especially in young children ([540]).

An unusual complication of hemophilia B therapy is anaphylaxis. These patients typically have severe factor IX deficiency with inhibitors and complete gene deletions ([541]). These patients can be treated with immune tolerance induction with steroid and antihistamine pretreatment; nonresponders should be treated either with PCCs or recombinant factor VIIa (Chapter 60) ([542]).

Gene Therapy for Hemophilia

Gene therapy for the inherited bleeding disorders is under active investigation ([543] , [544]). Viral and nonviral constructs containing genes for factor VIII or factor IX have been used, as well as modified retrovirus, adenovirus, or adeno-associated virus vectors (Figure 59.12). Sustained partial correction of factor IX deficiency was observed in mice ([545]) and in a dog model of hemophilia B using gene therapy ([546]). Even if gene therapy could only increase endogenous factor VIII or factor IX levels from less than 1% to 1 to 2 U/dl, this incremental change would dramatically alter the clinical course and treatment of patients with severe hemophilia.

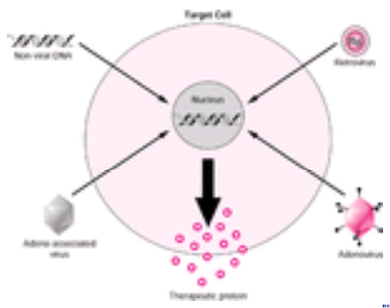

Figure 59.12. Experimental approaches for gene therapy of hemophilia using viral and nonviral constructs.

A small number of trials have been reported or are in progress in hemophilia A and B patients. Experimental approaches for hemophilia B include *ex vivo* transduction of fibroblasts using a retrovirus ([543]) and gene transfer using an adeno-associated virus into muscle ([547]). Experimental approaches for hemophilia A include *ex vivo* transfection with a nonviral vector into fibroblasts subsequently implanted into omentum ([548]) and retrovirus infusion ([543]). In general, low levels of factor expression have been seen in these trials without significant toxicity. A major research focus will be to enhance factor expression to improve the clinical benefit without increasing toxicity.

Factor VII Deficiency

There is no agreement on the likelihood of excessive bleeding in a patient with factor VII deficiency undergoing surgery, so multiple issues should be considered in the perioperative care of factor VII–deficient patients ([309] , [549]). Consider the patient's prior experiences and symptomatology: Patients with a history of hemarthrosis or CNS hemorrhage are at a higher risk for bleeding complications. Consider the area of the body involved: The oral and urogenital tracts are areas of high local fibrinolytic activity. Consider the patient's baseline factor VII level. The minimum factor VII level required for surgical hemostasis is not known; patients with levels below 3 U/dl are at high risk for bleeding, whereas patients with levels of 15 to 25 U/dl are less likely to develop bleeding complications if associated with surgery. Finally, one should consider the logistics of therapy, as factor VII has a short half-life of approximately 5 to 6 hours ([344]). Volume overload is likely if plasma is used

as a source for factor replacement, and the safety profile of the various factor VII–containing products varies.

Traditionally, plasma, PCCs, or plasma-derived factor VII concentrate have been used for factor VII replacement therapy ([550], [551]). More recently, recombinant factor VIIa has joined the list of potential sources for factor replacement therapy ([552]). For patients treated with plasma, a loading dose of 15 to 20 ml/kg, followed by 4 to 6 ml/kg every 6 hours for 7 to 10 days, has been recommended. Care should be exercised to avoid volume overload; plasma exchange therapy has been used in some patients ([553]). PCCs have been used, but they carry some thrombotic risk, which may be associated with the generation of unnecessarily high levels of other activated vitamin K–dependent coagulation proteins. This is especially a problem with extended PCC use. A survey of several PCC products revealed that one PCC (Proplex T) was particularly rich in factor VII content ([554]). Proplex T (Baxter Healthcare) is viral-attenuated through dry-heat processing and labeled to indicate the factor VII content. Recovery studies indicate that an administered dose of 1 IU/kg raises the patient's plasma factor level by approximately 2 U/dl. If available, the use of further purified factor VII concentrate might decrease the thrombotic risk associated with the use of less-specific PCC. A heat-treated intermediate-purity factor VII concentrate (manufactured by Immuno A.G.) has been used for treatment of acute bleeds, as perioperative prophylaxis, and for prevention of recurrent CNS hemorrhage. Factor VII levels rose approximately 2.33 U/dl for each IU/kg infused, and the factor VII half-life was approximately 6 hours. Despite the short half-life of factor VII, infusions as infrequent as once/week were successful in preventing recurrent intracranial bleeding ([356]). For replacement therapy in a surgical setting, factor level monitoring is recommended to ensure that perioperative factor levels are above 25 U/dl.

Although initially developed and licensed for the treatment of hemophilia patients with inhibitors, recombinant human activated factor VII (rFVIIa) is clearly effective in the treatment of patients with factor VII deficiency ([549], [555], [556]). In a pilot study of patients with hemarthrosis or in need of surgery, all 17 patients were judged to have achieved an excellent response with dosing at approximately 25 µg/kg (calculated to normalize the PT 15 minutes after infusion) ([556]). Further reports of more than 40 patients with hereditary factor VII deficiency indicate successful treatment for bleeding episodes or surgery. In general, doses of between 15 to 30 µg/kg of rFVIIa were administered at intervals of 4 to 6 hours in these reports ([549], [552], [557], [558]). The half-life of recombinant factor VIIa is between 2.5 and 3.0 hours, and the roles for continuous factor infusion and laboratory monitoring remain to be defined.

Factor XIII Deficiency

Therapy for the congenital deficiency of factor XIII is based on the principle that only a small quantity of factor XIII must be present in human plasma to promote normal hemostasis. The long half-life of factor XIII [estimated between 9 and 19 days in the literature ([559])] makes prophylactic therapy both practical and highly advisable given the high frequency of intracranial hemorrhage ([293], [300]). Factor concentrates have been successfully used to prevent factor XIII–associated bleeding, and these remain the treatment of choice. Pasteurized factor XIII concentrate that contained only the A subunit prepared from human placenta ([560]) has been replaced by a plasma-derived preparation that contains both the A and B subunit ([559], [561]). Two preparations in use are Fibrogammin-P (manufactured by Aventis Behring), which is licensed in many countries (but not the United States or Canada), and a factor XIII preparation from Bio Products Laboratory that is only available in United Kingdom. Kinetic studies with Fibrogammin-P indicate a mean recovery of 65% and a plasma half-life of approximately 9 days ([561]). In the United States, Fibrogammin-P is obtained by compassionate release under a U.S. Food and Drug Administration investigational new drug license (the investigational new drug license was held by Dr. Diane Nugent at the time of this writing). Recommended dosing for factor XIII concentrate is 10 to 20 U/kg of body weight every 4 to 6 weeks for prophylaxis against unprovoked bleeding. Prophylactic therapy of affected patients undergoing surgery may actually require more intensive replacement therapy. If concentrates are unavailable, patients are typically given either fresh frozen plasma or cryoprecipitate ([298], [299], [562]). The typical plasma dose is 2 to 3 ml/kg of body weight, every 4 to 6 weeks. Cryoprecipitate at a dose of 1 bag/10 to 20 kg of body weight every 3 to 4 weeks is an alternative therapy that has the advantage of requiring transfusion of a smaller volume. It is recommended that factor XIII levels be kept between 25 and 50% of normal to achieve normal hemostasis after major trauma in these patients; doses of concentrate recommended are 35 U/kg preoperatively, followed by 10 U/kg/day for 5 more days. Affected patients with a history of spontaneous abortions can complete a normal pregnancy when they are managed with prophylactic fresh frozen plasma or factor XIII concentrates every 21 days ([563], [564]).

In the acquired deficiency states, more than 50% of the patients need aggressive therapy. The most useful therapy for patients who have acquired inhibitors to factor XIII remains exchange plasmapheresis with or without immunosuppression with cytotoxic drugs. In addition, infusions of platelets can be given with occasional success because platelets contain large amounts of factor XIII. Alternatively, replacement therapy with a factor XIII concentrate can be considered.

Miscellaneous Disorders

Therapeutic regimens recommended for the treatment of patients with any of the less common inherited coagulation disorders are summarized in Table 59.10. Patients with factor XI deficiency usually respond well to fresh or fresh frozen plasma. A solvent detergent plasma preparation has been developed ([565]) and may be the desired therapy not only for factor XI deficiency, but also for other factor deficiencies in which sterile concentrates are not available. However, some of these products have been shown to be thrombogenic in early clinical studies ([566]), and their clinical use may be limited by this toxicity.

The management of major bleeding caused by deficiencies of factor X and prothrombin has been facilitated by the availability of PCCs. However, the thrombogenicity of these products may be a serious problem ([479], [482]). Cryoprecipitate is also used in replacement therapy for afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia. When a sterile, nonthrombogenic fibrinogen concentrate becomes routinely available, it should replace cryoprecipitate for treating these latter disorders.

SPECIAL ASPECTS OF TREATMENT

Hemarthrosis

All patients with hemarthrosis should receive adequate replacement therapy because only in this manner can the permanent disability resulting from repeated bleeding into the joints be minimized. Pain usually is relieved promptly and is a reliable index of the therapeutic response. Supportive therapy includes immobilization and the administration of analgesics.

Arthrocentesis usually is unnecessary, but it may be of significant benefit when the joint is severely distended or when resolution of the hemarthrosis is delayed despite adequate replacement therapy ([567]). Large volumes of blood seldom can be aspirated, but even a small volume may relieve symptoms. If performed, arthrocentesis should be done immediately after the administration of a covering dose of factor VIII.

Early but careful physiotherapy aimed at restoring the full range of motion of the affected joint should be instituted as soon as the acute stage of hemarthrosis has resolved. More energetic physiotherapeutic techniques should be carried out only in conjunction with an adequate course of replacement therapy. Various orthopedic devices (orthotics), such as braces and removable bivalve plaster casts, which provide additional support for chronically injured joints, have proved useful in reducing the frequency of recurrent hemarthrosis, particularly in the knee and ankle joints ([568]). For pain management of hemophilic arthropathy, nonsteroidal antiinflammatory agents may be helpful ([569]). In particular, salsalate (Disalcid) or choline magnesium trisalicylate (Trilisate) or the newer cyclooxygenase-2 inhibitors may be useful in patients with bleeding disorders because these drugs have antiinflammatory activity but do not impair platelet function. Daily or alternate-day prophylactic therapy with factor concentrates may prevent or significantly delay progression of hemophilic arthropathy (see the section Home Treatment Programs).

Many reconstructive surgical procedures are available to improve the function of chronically damaged joints ([570], [571] and [572]). Favorable results have been reported with total knee arthroplasty in several series ([571]). Long-term follow-up (>5 years) indicates adequately functioning prostheses and persistent pain relief in most patients. Synovectomy is effective in reducing the frequency of hemarthrosis that cannot be controlled by replacement therapy ([573]). Radioisotopic synovectomy is also effective therapy for hemophilic arthropathy ([574]). A review of the literature on radioisotopic synovectomy indicates that approximately 80% of patients benefit from the procedure ([575]).

Hemophilic Cysts

This serious complication most commonly develops in patients with severe hemophilia A or B. Also known as *hemophilic pseudotumors*, such cysts are gradually expanding blood-filled loculations that apparently originate from hemorrhages into confined subperiosteal, tendinous, or fascial spaces (Fig. 59.13). The osmotic

pressure created by breakdown products of blood in such confined spaces may produce further influx of fluid; this, together with recurrent bleeding, explains the progressive increase in the size of the cyst and its ability to erode contiguous structures. Such cysts most commonly develop in the thigh and may destroy bone as well as the soft tissues as they increase in size. These lesions are more readily prevented than treated. Although long-term replacement therapy combined with x-ray treatment has been successful in a few cases ([576]), hemophilic pseudocysts may require radical surgical procedures such as extensive resections or amputations. Even with optimal supportive therapy, these procedures often are unsuccessful and are often complicated by infection. A recent review has summarized surgical and nonsurgical approaches for pseudotumors ([577]). The modern use of home prophylaxis has made pseudo-tumors an unusual complication of hemophilia at this time.

Figure 59.13. Pseudotumor and destruction of the ilium in a patient with hemophilia B. (From Silber R, Christensen WR. Pseudotumor of hemophilia in a patient with PTC deficiency. Blood 1959;14:584–590, with permission.)

Intracranial Bleeding

Despite the widespread use of prophylaxis programs, hemorrhage, including intracranial hemorrhage, remains a leading cause of death among hemophiliacs ([578]). A hemophilia A mortality survey for the years 1995 to 1998 found that hemorrhage was the listed cause of death for 22% of hemophilia A patients who died during that time period ([11]). Approximately 50% of cases are associated with head injury ([579]); the etiology is not apparent in 38% of cases (spontaneous cases) ([580]). Bleeding may be subdural, epidural, or intracerebral. Subarachnoid bleeding occurs least commonly, but it carries the best prognosis. Hemorrhage also may develop in the spinal cord or spinal meninges. In cases associated with head trauma, the presence of a lucid interval and the absence of localizing neurologic signs at the time of presentation are commonly seen ([580]).

Significant head injury must be treated early and intensively in patients with inherited coagulation disorders. Those with hemophilia A and B should immediately receive sufficient concentrate to raise the plasma level of deficient factor to 100 U/dl. Samples for essential coagulation studies should be drawn before administration of replacement therapy, but treatment should not be delayed while waiting for results of these studies. Radiologic procedures, such as computed tomography scanning, can be done while the therapeutic material is administered. If performed expertly, lumbar puncture usually can be carried out without serious risk, but many clinicians prefer to wait until replacement therapy has been given. In one series, replacement therapy given within 6 hours of head injury prevented any intracranial bleeding ([581]). Computed tomography scanning has proved particularly valuable in locating and monitoring the progression or resolution of bleeding ([582]).

In cases involving major cranial trauma, if neurologic signs or symptoms develop, or if intracranial bleeding is confirmed radiologically or otherwise, the administration of factor VIII or factor IX concentrates should continue on a schedule in doses sufficient to keep the nadir levels of the deficient factor above 30 U/dl. Treatment should be maintained for 10 to 14 days ([580]). Before the widespread use of factor VIII concentrates, the mortality rate after intracranial bleeding averaged 70% ([579]). In a more recent series, the overall mortality rate was 34%, even with optimal replacement therapy ([581] , [583]). Because of these risks, patients with hemophilia should always have ready access to factor concentrates, even those with mild disease.

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome (AIDS) was first recognized in 1978 and was found to be transmitted in blood products thereafter ([584]). A particularly high degree of viral contamination was found in concentrated preparations of factor VIII and IX. Such therapeutic materials are prepared by pooling the plasma of multiple donors so that the recipient receives hundreds to thousands of donor exposures with each therapeutic dose. Predictably, this practice produced rapid and widespread dissemination of HIV in the hemophilic population. Serologic evidence of AIDS is most common in severe hemophiliacs, as distinguished from mildly affected patients. In the 1980s, more than 90% of patients requiring extensive replacement therapy developed positive results of screening tests for HIV antibody and, ultimately, full-blown AIDS. The advent of sterile concentrates, together with rigid donor testing instituted in 1985, as well as the availability of recombinant products, has greatly diminished the risk of viral transmission. Many seropositive patients remain who do not yet have the diagnosis of AIDS but who constitute a pool of patients at high risk.

Cases of AIDS in association with hemophilia B are less common, probably because of the rarity of the disorder ([585]). Sterilization measures for hemophilia products have been summarized ([465]). A retrospective analysis of hemophilia mortality between 1900 and 1990 indicates that although survival in this population improved after widespread use of factor concentrates between 1971 and 1980 (median life expectancy of 68 years), median life expectancy in the next decade (1981 to 1990) declined to 49 years ([586]). This increase in relative mortality in hemophilia patients was attributed primarily to AIDS ([587]). It is likely that in the absence of viral infection, the life expectancy of patients with hemophilia would be similar to that of the general male population. The most recent mortality analysis for hemophilia A patients in the United States found a 41% decrease in HIV-related deaths; this improvement was attributed to increased use of antiviral therapy ([588]). Protease inhibitor therapy of HIV infection can be associated with an increased incidence of bleeding ([589] , [590]).

Thrombocytopenia

Mild to moderate thrombocytopenia is not uncommon in hemophiliacs who receive large amounts of factor VIII concentrates ([591]). Most of these patients have positive tests for HIV, and their clinical findings are consistent with AIDS-related complex. The clinical features resemble the idiopathic thrombocytopenic purpura syndrome. Differences were noted between the serologic patterns in hemophiliacs, patients with idiopathic thrombocytopenic purpura, and drug addicts and homosexual men ([590] , [592]). Because of the desire to avoid steroid therapy or splenectomy in this immunocompromised population, immune thrombocytopenia persisting after optimal antiviral therapy has been treated with intravenous immunoglobulin G or anti-Rh(D) ([593]).

Hepatitis

In the United States mortality survey of hemophilia A patients between 1995 and 1998, liver disease was listed as a cause of death in 15% of patients ([588]). As many as 75% of hemophiliacs have abnormalities of liver function that may persist for years, even though clinical evidence of hepatic dysfunction is minimal ([594]). Liver biopsies have confirmed the presence of chronic active hepatitis in most patients ([595]), and postnecrotic cirrhosis may occur in some cases. The disorder is usually the result of persistent infection with the hepatitis C virus ([596]). There is evidence that other viruses may be responsible in some patients ([597]). A prospective study of United States hemophiliacs found that 88% were infected with hepatitis C and that 66% of the hepatitis C–infected hemophiliacs also had HIV infection ([598]). Coinfection was associated with a five- to sixfold increase in end-stage liver disease ([598]). Modern sterilization methods appear to render factor concentrates virus-free, especially the lipid-enveloped viruses. Patients who are seronegative for the hepatitis A and B viruses should receive immunizations for these viruses. However, standard solvent detergent–inactivated products may still transmit non–lipid-enveloped viruses such as parvovirus ([471]), hepatitis A ([599]), and other viruses ([600]). An unresolved issue is the transmission potential of the agent causing Creutzfeldt-Jakob disease. The concern about transmission of human viruses by products derived from human plasma has led many clinicians and patients to use recombinant factor products exclusively.

Antibodies to Coagulation Factors

Many hemophiliacs develop antibodies (inhibitors) to factor VIII. This complication is less common in patients with hemophilia B and other inherited coagulation

disorders. Such antibodies may seriously complicate the treatment of these patients (Chapter 60).

Home Treatment Programs

In general, replacement therapy of hemarthrosis is more effective, and subsequent joint damage is minimized if treatment is begun immediately after the onset of symptoms. The availability of factor VIII concentrates that are stable in home refrigerators led to the development of various early home care programs ([601]). Parents and patients are trained to administer the material at the first sign of bleeding. Such programs have resulted in decreased bleeding episodes and improved preservation of joint function ([602] , [603]). Typical prophylactic regimens are 25 to 40 U/kg factor VIII three times/week for hemophilia A, and 25 to 40 U/kg factor IX twice/week for hemophilia B ([603]). Such therapy usually maintains the trough factor level at or above 1% of normal. A 30-year follow-up report confirms the efficacy of prophylaxis ([604]). An economic analysis of prophylaxis found that although higher costs were associated with prophylaxis programs, the approach was justified on medical grounds ([605]). It is recommended that patients begin prophylaxis soon after the first joint bleed ([606]).

Dental Care

Special attention should be given to preventive dental care in patients with coagulation disorders, so as to minimize the complications, expense, and hazards of operative dental procedures. The extraction of even a single tooth may require replacement therapy. Multiple extractions may save time and expense but create a major bleeding hazard. Acrylic splints, orthodontic rubber bands, and other specialized dental techniques reduce the chance of serious postoperative bleeding. The suturing of bleeding tooth sockets after extractions, particularly of the third molar, should be avoided because it may lead to extension of bleeding into the neck. Mandibular block anesthesia produces similar complications in some patients but appears to be safe if performed expertly ([509] , [510]). Most authorities recommend that dental procedures in patients with inherited coagulation disorders be carried out under cover of replacement therapy and EACA. Probably the safest practice is to regard tooth extractions, particularly of molar or multiple contiguous teeth, as a major bleeding hazard, although only 2 to 3 days of maintenance therapy usually are needed ([509] , [510]).

Acquired Coagulation Disorders

Abnormalities in blood coagulation may complicate a large number of disorders (Table 60.1). The acquired coagulation disorders are more complex than the inherited forms. In contrast to inherited disorders in which deficiency or abnormality of a single factor is characteristic, the acquired forms usually are associated with multiple coagulation abnormalities, and the disorder often is complicated by thrombocytopenia, deficient platelet function, abnormal inhibitors of coagulation, and vascular abnormalities. Because of the compound nature of the hemostatic defect, the severity of bleeding often correlates poorly with the results of laboratory tests in patients with acquired coagulation disorders, and replacement therapy may be ineffective. With some notable exceptions, however, bleeding usually is less severe than in the inherited forms, and the clinical picture often is complicated by signs and symptoms of the underlying disease.

TABLE 60.1. Acquired Coagulation Disorders

Deficiencies of vitamin K–dependent coagulation factors
Hemorrhagic disease of the newborn (vitamin K deficiency bleeding)
Biliary obstruction (gallstone, strictures, fistulas)
Malabsorption of vitamin K (sprue, idiopathic steatorrhea, celiac disease, ulcerative colitis, regional enteritis, gastrocolic fistulas, *Ascaris* infestation)
Nutritional deficiency
Drugs
1. Pharmacologic antagonists of vitamin K (coumarins, indandiones, others)
2. Those that alter gut flora (broad-spectrum antibiotics, sulfonamides)
3. Miscellaneous (cholestyramine)
Liver disease (see Table 60.3)
Accelerated destruction of coagulation factors
Disseminated intravascular coagulation (see Table 60.4)
Fibrinolysis (liver disease, thrombolytic agents, tumors, after surgery)
Inhibitors of coagulation
Specific inhibitors (antibodies) (see Table 60.7)
Antiphospholipid–protein antibodies
Miscellaneous (antithrombins, paraproteinemias)
Miscellaneous
After massive transfusion
After extracorporeal circulation
Drugs (antibiotics, antineoplastic agents, others)
Miscellaneous (polycythemia vera, congenital heart disease, amyloidosis, nephrotic syndrome, Sheehan syndrome, Gaucher disease, leukemia, others)

DEFICIENCIES OF VITAMIN K–DEPENDENT FACTORS

Prothrombin; factors VII, IX, and X; and proteins C and S are synthesized by the liver by a process that depends on vitamin K (see Chapter 21 and Fig. 60.1) ([1]). When stores of this vitamin are deficient or abnormal, hypofunctional analogs of these factors are synthesized, which inhibit normal coagulation. These descarboxy analogs of the vitamin K–dependent factors do not bind to cellular phospholipid surfaces and, therefore, do not participate in cell-associated coagulation reactions. This may occur in disorders in which intake or absorption of vitamin K is deficient and in disorders that impair the biosynthetic capacity of the liver (Fig. 60.1). A similar coagulation abnormality may be produced by anticoagulant drugs such as coumarin and indanediones, which antagonize the action of vitamin K (see Chapter 61).

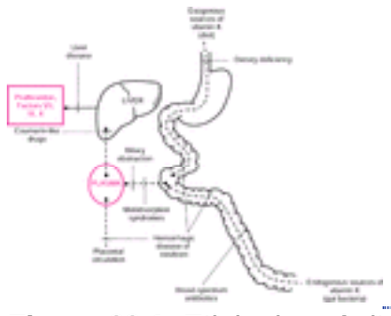

Figure 60.1. Etiologies of vitamin K deficiency. Sources of vitamin K include the diet and gut bacterial synthesis. Processes leading to vitamin K deficiency are indicated with a solid line ending in a squiggle.

Vitamin K Deficiency Bleeding (Hemorrhagic Disease of the Newborn)

Hemorrhagic disease of the newborn is the result of vitamin K deficiency in the neonate; this phrase was first used more than 100 years ago ([2]). The preferred term is *vitamin K deficiency bleeding* (VKDB) *in infancy* as proposed by a consensus committee ([3]). Formerly a major cause of bleeding, this disorder is now uncommon because of the routine administration of vitamin K at birth ([4]); however, it is still encountered in economically deprived populations.

PATHOPHYSIOLOGY The normal newborn has a moderate but significant deficiency of the vitamin K–dependent coagulation factors. The plasma levels of these factors normally fall even further during the first 2 to 5 days of life, rise again when the infant is 7 to 14 days old, and attain normal adult levels at approximately 3 months of age ([5]) (see also Table 51.6). This sequence of events normally does not produce bleeding. However, in VKDB, the initial fall is accentuated, and the secondary restoration is delayed and incomplete. As a consequence, coagulation abnormalities become severe, and bleeding results. The deficiency of the vitamin K–dependent coagulation factors that is present at birth, as well as the slow rate at which adult levels are attained, presumably is the result of intrinsic “liver immaturity”; neither of these physiologic phenomena is affected by vitamin K administration ([5]). On the other hand, the diminution in levels of these factors that occurs at age 2 to 5 days is prevented by vitamin K administration because it is the result of a transitory physiologic deficiency of this vitamin. Factors that further diminish the amount of vitamin K available at this juncture and those that further impair the synthetic capacity of the liver predispose neonates to hemorrhagic disease of the newborn. These factors are (a) prematurity, (b) inadequate dietary intake, (c) delayed gut colonization by bacteria, (d) various obstetric and perinatal complications, and, possibly, (e) maternal deficiency of vitamin K. Prematurity often has been associated with VKDB ([6], [7]). Levels of the vitamin K–dependent factors at birth are approximately proportional to gestational age and birth weight ([8]). In premature infants, the physiologic immaturity of the liver is marked, and the response to vitamin K that is present is subnormal. Most factors associated with deficient intake of vitamin K also delay the colonization of the gut by bacteria. These factors include delayed feeding, breast-feeding, vomiting, severe diarrhea, and antibiotics, including those present in maternal milk. Human milk and colostrum are poor sources of vitamin K ([5]), and reliance on breast milk as the sole source of nutrients in the neonatal period is an important factor in many cases of VKDB ([4]). Coumarin and indanedione drugs cross the placenta and may produce hemorrhagic disease in the newborn ([9]). Infants born of mothers who were taking diphenylhydantoin or other anticonvulsants, including barbiturates, or salicylates have developed a syndrome similar to VKDB ([10]). Treatment of the mother with vitamin K during the last trimester may prevent this complication.

CLINICAL FEATURES AND LABORATORY DIAGNOSIS VKDB etiology is considered idiopathic (no cause other than breast-feeding) or secondary (malabsorption of vitamin K, liver disease, drugs) ([3]). VKDB can also be classified in terms of age of onset: early (onset <24 hours of age); classic (onset usually between 3 to 5 days); and late (onset on or after 8 days). Early VKDB is uncommon and usually results from placental transfer of maternal drugs that antagonize vitamin K in the newborn. Late VKDB occurs almost exclusively in breast-fed infants who may also have hepatobiliary disease ([3]). Bleeding in classic VKDB is severe ([2]). The most common manifestations are melena, large cephalohematomas, and bleeding from the umbilical stump and after circumcision. Generalized ecchymoses, often without petechiae, intracranial bleeding, and large intramuscular hemorrhages also may develop ([2], [5]). Laboratory diagnosis is relatively simple (Table 60.2), but physiologic differences in the results of various coagulation tests in normal neonates must be kept in mind (see Table 51.6) ([11], [12]). In infants with VKDB, the prothrombin time (PT) always is prolonged. The partial thromboplastin time (PTT) is also prolonged. The results of these tests may also be abnormal in unaffected neonates. Specific factor assays reveal deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S. The presence of normal antigenic levels of the vitamin K–dependent factors may be demonstrated by immunoassays ([13]). Factors V and VIII, as well as fibrinogen, are present in normal amounts. The consensus committee recommends diagnosing VKDB with a prolonged PT value, a normal fibrinogen level, and a normal platelet count ([3]).

TABLE 60.2. Laboratory Findings in Acquired Coagulation Disorders

	Hemorrhagic Disease of the Newborn	Severe Liver Disease	Disseminated Intravascular Coagulation	Primary Fibrinolysis	Antibodies to Factor VIII	Inhibitors of Lupus Type
Screening tests						
Platelet count [a]	N	vD	D	uN	N	V [a]

Miscellaneous tests						
Antithrombin	N	vD	vD	uN	N	N
Protein C	D	D	V	uN	N	uN
Protein S	D	D	V	uN	N	V

D, decreased; FDP, fibrin(ogen) degradation products; I, increased; N, normal; u, usually; v, variably; V, variable.

[a] May reveal effects of acute bleeding or abnormality characteristic of underlying disease.

[b] Results may differ from adult norms in normal neonates.

[c] One-stage assays may yield aberrant results.

[d] Hypofibrinogenemia may alter results.

[e] The presence of immunoglobulin M rheumatoid factors in certain patients may lead to a false-positive result in latex-agglutination assays.

The clinician should not assume that bleeding in the neonate is invariably the result of vitamin K deficiency ([3]). In the differential diagnosis of VKDB, virtually all causes of bleeding, particularly thrombocytopenia (see Chapter 52) and disseminated intravascular coagulation (DIC), must be considered ([14], [15]). The inherited coagulation disorders (see Chapter 59) also may produce serious hemorrhage in the neonatal period, but significant prolongation of the PT is not found in the most common forms, for example, hemophilia A and hemophilia B. Umbilical bleeding and hemorrhage after circumcision are relatively less common in the inherited coagulation disorders than in VKDB.

TREATMENT Vitamin K_1 (0.5 to 1.0 mg given intramuscularly) is dramatically effective in the treatment of VKDB ([16]). Shortening of the PT may be expected within 6 hours, and normal neonatal levels of the vitamin K–dependent factors usually are attained within 24 hours of administration. Parenteral administration of vitamin K is clearly more clinically beneficial than oral administration ([16], [17]). In severe cases, two or three doses of vitamin K_1 at 4- to 8-hour intervals may be required. Larger (2 mg) or repeated (every 4 to 8 hours) doses of vitamin K_1 may be required to counteract the effects of coumarin drugs in infants ([5]). The response in premature infants to vitamin K_1 usually is incomplete. The administration of large doses of vitamin K may produce hemolysis, hyperbilirubinemia, and even kernicterus in the neonate. These complications appear to be associated more commonly with the synthetic derivatives than with vitamin K_1, but even the latter may be dangerous in large doses ([5]). In severe cases of VKDB, the transfusion of plasma may be helpful ([5]). Concentrates of vitamin K–dependent coagulation factors are effective but have led to thrombosis and intravascular coagulation in some infants, particularly in premature infants. This result has been attributed to immaturity of the hepatic clearance functions and physiologic deficiency of antithrombin. Fortunately, such replacement therapy is seldom required. Because VKDB is primarily a disease of breast-fed infants ([18]), VKDB can be prevented by the administration of vitamin K to the mother before delivery. Most authorities, however, recommend administering vitamin K_1 (1 mg parenterally; 2 mg orally) to the infant. This procedure is now routine in most nurseries. Many pediatricians also recommend the prophylactic administration of vitamin K_1 to infants 1 to 5 months of age, especially those who are breast-fed or who have a disorder that may impair vitamin K absorption ([19]). The usual dosage in such older infants is 50 to 100 µg daily or 1 mg monthly. Most pediatricians would attribute the decrease in incidence of VKDB in recent years to the prophylactic administration of vitamin K. Nevertheless, the value of this procedure has been questioned because of the rarity of biochemically evident vitamin K deficiency in apparently normal-term infants at birth ([20]). Additionally, some investigators question whether unknown hazards may exist for the widespread prophylactic use of vitamin K in newborn infants ([21], [22]). Nonetheless, there is widespread consensus on continuing vitamin K prophylaxis to newborns ([3], [16]). Administering vitamin K antenatally to premature neonates does not appear to be beneficial ([23]).

Other Causes of Vitamin K Deficiency

Obstruction of the biliary tract, either intrahepatic or extrahepatic, produces vitamin K deficiency because of the absence of bile salts in the gut. Complete obstruction may lead to severe coagulation abnormalities and bleeding within 2 to 4 weeks. This was a major obstacle to surgical procedures on the biliary tract before the discovery of vitamin K.

Most malabsorption syndromes and various other chronic gastrointestinal disorders also may give rise to vitamin K deficiency. Such disorders include celiac disease, sprue, gastrocolic fistulas, ulcerative colitis, regional enteritis, extensive gut resections, protracted diarrhea of any cause, *Ascaris* infestations, and cystic fibrosis. The last named disorder often is complicated by liver disease ([13]). Severe abnormalities of coagulation and bleeding are less common in association with these disorders than with biliary obstruction, presumably because absorption of vitamin K is seldom completely deficient.

Because vitamin K normally is available from two independent sources (Fig. 60.1), neither nutritional deficiency nor gut sterilization alone produces deficiency of a degree that results in significant coagulation abnormalities. In normal adults, the daily oral intake of vitamin K must be reduced to 20 µg or less for several weeks to produce significant hypoprothrombinemia ([1]). However, vitamin K deficiency is more common than is usually realized in hospitalized patients with poor or negligible oral food intake, especially if they are also taking antibiotics ([24], [25]). Significant coagulation abnormalities may arise with surprising rapidity in such patients, and when unsuspected, they may be confused with DIC or may first be revealed by serious, unexpected postoperative hemorrhage ([24]). Antimicrobial agents presumably impair vitamin K production by inhibiting the synthesis of menadiones by gut bacteria ([26]), but they may also directly affect carboxylation reactions ([27], [28]). Vitamin K deficiency also may result from use of drugs other than antimicrobial agents, such as cholestyramine ([29]), which acts by binding bile salts, or mineral oil and other cathartics when used for protracted periods. Vitamin E may antagonize the metabolic action of vitamin K and potentiate the action of coumarins ([5]). When taken in large doses, this vitamin may prolong the PT ([30]). Antibiotic therapy, poor diet, or any of the aforementioned disorders may predispose patients to coumarin toxicity (see Chapter 61) ([31], [32]). Large doses of aspirin, as given to treat rheumatic disorders or in amounts associated with overdosage of the drug, may also induce vitamin K deficiency ([33]).

TREATMENT In adults, the parenteral administration of 10 to 20 mg of vitamin K_1 abolishes coagulation abnormalities within 12 to 24 hours if they are the consequence of a deficiency of this vitamin. Failure of vitamin K to normalize the PT is evidence for the presence of a complicating process, such as liver disease or DIC. Larger doses (50 mg) may be required to reverse the effects of coumarin toxicity. The synthetic vitamin K_3 (menadiones) may be absorbed in the absence of bile salts and in various malabsorption syndromes. However, these congeners of vitamin K have a more transient effect than the natural forms of this vitamin and offer minimal therapeutic advantage in the usual case. Replacement therapy with fresh frozen plasma is effective in the treatment of emergent vitamin K deficiency. Vitamin K may produce hemolytic anemia in patients with inherited deficiencies of various red cell enzymes (see Chapter 33). Because the intravenous route of administration is associated with a risk of anaphylaxis ([34]), subcutaneous injection is recommended in adults. Malnourished patients receiving broad-spectrum antibiotic therapy should receive vitamin K prophylactically, 5 mg twice weekly, orally or subcutaneously ([35]). Commercially available rodenticides that exhibit long-acting vitamin K antagonism have been associated with significant bleeding disorders when these compounds have been ingested by humans ([36]). These drugs are chemically distinct from warfarin, are 100 times more potent than warfarin, and can induce vitamin K deficiency lasting for months. In 1995 alone, more than 13,000 people were exposed to these agents and treated ([37]). Initial treatment of these patients may require up to 100 mg of vitamin K daily to normalize vitamin K metabolism ([37]).

LIVER DISEASE

Virtually every hemostatic function may be impaired in patients with severe hepatic disease (Table 60.3) ([38], [39] and [40]) as the result of failure of both the biosynthetic and clearance functions of the liver. The pathophysiology of some of these abnormalities is tied to thrombocytopenia (see Chapter 52), platelet dysfunction (see Chapter 58), intravascular coagulation and fibrinolysis, and the effects of products of fibrinogen catabolism on hemostasis (see the following discussion).

TABLE 60.3. Abnormalities of Hemostasis and Coagulation in Liver Disease

Deficient biosynthesis
Of fibrinogen; prothrombin; coagulation factors V (46), VII, IX, X, XI (47), XII, XIII (48); prekallikrein; high-molecular-weight kininogen
Of antiplasmins (74), antithrombin (73), proteins C and S
Aberrant biosynthesis
Of abnormal fibrinogen (50, 53), factor V, factor VIII (59, 63)
Of abnormal inhibitory analogs of prothrombin, factors VII, IX, and X (56)
Deficient clearance
Of hemostatic “products,” [e.g., fibrin monomers, fibrin(ogen) degradation products, platelet factor-3]
Of activated coagulation factors [IXa, Xa (195), XIa]

- Of plasminogen activators (64)

Accelerated destruction of coagulation factors
- Disseminated intravascular coagulation (82, 83, 84 and 85)
- Localized intravascular coagulation (hepatic cell necrosis) (82)
- Abnormal fibrinolysis (65)

Thrombocytopenia
- Hypersplenism (portal hypertension)
- Folic acid deficiency
- Chronic ethanol intoxication
- Disseminated intravascular coagulation

Platelet dysfunction
- Acute and chronic ethanol intoxication
- Effects of products of fibrinogen degradation (66, 67)
- Uremia

Miscellaneous
- Inhibition of coagulation byproducts of fibrinogen degradation (69, 70)
- Loss or consumption of coagulation factors in ascitic fluid (87)

Pathophysiology

THROMBOCYTOPENIA Patients with significant liver disease have portal hypertension, splenomegaly, and splenic sequestration of platelets, contributing to thrombocytopenia (see Chapter 52). The liver is also the major site of production of thrombopoietin, the principal humoral factor involved in megakaryocyte maturation and platelet formation (see Chapter 19). Recent studies have evaluated whether deficient levels of thrombopoietin occur in liver disease. Results indicate that thrombocytopenia in liver disease is not explained by deficient hepatic production of thrombopoietin (41, 42). However, there is a correlation between the extent of liver disease and platelet expression of the thrombopoietin receptor, c-Mpl (42), and this reduced expression may contribute to thrombocytopenia seen in liver disease.

DEFICIENT OR ABERRANT SYNTHESIS OF COAGULATION FACTORS In patients with liver disease, all coagulation factors except factor VIII may be deficient as a consequence of synthetic failure of the hepatic cells. Failure of biosynthesis of coagulation factors often correlates with the severity of hypoalbuminemia, but exceptions to this rule are common. Deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S result mainly from synthetic incompetence. For example, factor VII expression in liver biopsies from patients with liver disease decreases as the severity of hepatic dysfunction increases (43). Impaired carboxylation of precursors may contribute to the defect (13). Superimposed vitamin K deficiency may result from a poor diet or malabsorption caused by insufficient production of bile salts or by exocrine pancreatic insufficiency (44). The failure of these coagulation abnormalities to respond to vitamin K administration provides good evidence of hepatic cell dysfunction, although large doses of vitamin K may prolong the PT in patients with liver disease. The explanation of this paradoxic effect is obscure (45). Factors V (46), XI (47), and XIII (48) are synthesized by the liver but are not vitamin K–dependent; all of these factors may be deficient in patients with severe liver disease. Plasma levels of factor XII, prekallikrein (Fletcher factor), and high-molecular-weight kininogen (Fitzgerald factor) also may be low in association with liver disease. Deficiencies of these latter three factors do not contribute to a bleeding diathesis. Hypofibrinogenemia rarely may result from deficient hepatic biosynthesis (46, 49) or may be the consequence of fibrinogenolysis or DIC, as discussed subsequently. In many patients with liver disease, prolongation of the thrombin time can be significant in the absence of hypofibrinogenemia or increased levels of fibrin(ogen) degradation products (FDPs) (50). This apparently is the result of a qualitatively abnormal fibrinogen that is synthesized by the diseased hepatic cell. Such acquired dysfibrinogenemia has been reported in most forms of liver disease, ranging from mild acute hepatitis to acute hepatic necrosis and cirrhosis (51, 52). Fibrin monomer polymerization is delayed (53), and the abnormal fibrinogen molecule acts as an antithrombin (50). Additionally, this hepatic disease dysfibrinogen may have an abnormally high content of sialic acids (54) and may produce a structurally defective fibrin clot (55). Acquired dysfibrinogenemia, abnormal inhibitors of fibrinolysis, and the presence within the plasma of descarboxy analogs of prothrombin (56) have been reported in patients with hepatomas (57). Hepatoma-associated dysfibrinogens have also been noted to have an increased carbohydrate content (58). Plasma levels of factor VIIIc usually are elevated in both parenchymal and cholestatic liver disease (59, 60); in some cases, levels may rise as high as 2000 to 3000 U/dl (61). Increases in both factor VIIIc and von Willebrand factor (vWF) have been demonstrated (62). Factor VIII in liver disease may be qualitatively abnormal (63).

FIBRINOGENOLYSIS AND FIBRINOLYSIS Endogenous plasminogen activators normally are removed from the circulation by the liver. In patients with severe liver disease, however, they may circulate for an abnormally long time and lead to the chronic or intermittent activation of the fibrinolytic enzyme system (64). This process usually is of no clinical importance, but in some patients, surgical procedures, trauma, certain drugs, or electroshock therapy may induce acute fibrinogenolysis (65) or serious oozing postoperatively as the result of the lysis of hemostatically important fibrin plugs. This process may be a contributory factor in the pathogenesis of hypofibrinogenemia in patients with liver disease. It also leads to the production of large amounts of FDP, which persist in the circulation for abnormally long periods because of deficient hepatic clearance, and may impair blood coagulation and platelet function (66, 67). Such proteolytic activity also may produce a shift in the mean molecular weight of circulating fibrinogen from the normal species to a less-reactive species of lower molecular weight (68), thereby contributing to the “antithrombins of liver disease” (69, 70). The incidence of hyperfibrinolysis was surveyed in patients with cirrhotic and noncirrhotic liver disorders (71). Hyperfibrinolysis, as measured by a shortened euglobulin clot lysis time, was present in approximately 30% of cirrhotic patients but not present in noncirrhotic patients (71). The role of thrombin-activatable fibrinolysis inhibitor deficiency in liver disease in contributing to hyperfibrinolysis has been studied; thrombin-activatable fibrinolysis inhibitor levels are reduced in liver disease, with lower levels seen in more severe liver disease (72). However, there was no association of low thrombin-activatable fibrinolysis inhibitor levels with hyperfibrinolysis, even in cirrhotic patients. These studies suggest that hyperfibrinolysis is not common in liver disease, even in cirrhosis (71, 72). Plasma levels of antithrombin (73), antiplasmin (62, 74), and plasminogen (62, 75) are subnormal in patients with liver disease. The cirrhotic liver produces qualitatively abnormal forms of antithrombin (62) and plasminogen activator, as well as unstable antiplasmins (64). All of these abnormalities are of uncertain clinical importance.

INTRAVASCULAR COAGULATION Severe liver disease theoretically predisposes individuals to the development of DIC because DIC is associated with deficient hepatic clearance of activated coagulation factors and other coagulant substances. The *in vivo* turnover rates of prothrombin (76), fibrinogen (77), plasminogen (76), and antithrombin (73) often are accelerated in patients with cirrhosis and in those with extrahepatic obstruction of the portal vein. Plasma levels of fibrinopeptide A are elevated in most patients with cirrhosis (78). All of these abnormalities may be normalized in some cases by the administration of heparin (79). The accelerated turnover of fibrinogen also may be normalized by the infusion of antithrombin concentrates (80). It has been hypothesized that accelerated catabolism of coagulation factors in these disorders is the result of DIC. The nature of the initiating process is unclear, but one suggestion is that DIC is activated by hypoperfusion of the congested portal bed (49). Indirect evidence suggests that in severe liver disease, activators of coagulation, possibly endotoxin, may originate in the gut. Evidence of DIC also is a common finding in patients with bleeding varices (81) and those with acute hepatic necrosis, a disorder in which fibrin deposits may be demonstrated histologically in liver sinusoids adjacent to necrotic hepatic cells (82). Low-grade DIC or localized intravascular coagulation indeed may occur in association with severe liver disease, but overt DIC is responsible only rarely for bleeding in the absence of other etiologic factors that trigger this process, for instance, sepsis, shock, and cancer (83, 84). This conclusion is supported by findings in patients with stable cirrhosis that demonstrated no increased levels of markers of activation of coagulation, such as prothrombin fragment 1+2, thrombin-antithrombin complex, and so forth (85). Evidence for accelerated fibrinogen turnover in ascitic fluid suggests that the loss or consumption of coagulation factors in peritoneal fluid may be a contributory factor in the coagulopathy of chronic liver failure. Shunting of ascitic fluid into the venous circulation by means of LeVeen shunts consistently produces coagulation abnormalities consistent with DIC in cirrhotic patients (86). Although this phenomenon usually is attributed to intravascular coagulation, evidence shows that it may result in part from the presence of plasminogen activators and active plasmin (87) or collagen (88) in peritoneal fluid. A transitory coagulation disorder that resembles intravascular coagulation with active fibrinolysis has been documented during liver transplantation procedures. Coagulation abnormalities disappear promptly if the graft is successful (89). The complex coagulopathy seen with liver transplantation has been reviewed (90).

Clinical Manifestations

In view of the numerous hemostatic abnormalities associated with severe liver disease, it is surprising that many patients do not bleed abnormally. Gastrointestinal hemorrhage is the most common bleeding manifestation, but it almost always originates from a local lesion, such as esophageal varices, peptic ulcer, or gastritis. The degree to which coagulation abnormalities contribute to such bleeding is uncertain. In one large series, gastrointestinal bleeding was not significantly more severe or protracted in patients with coagulation abnormalities than in those without them ([91]). In another study, serious hemorrhage occurred only in patients with prolonged PTs and significant factor IX deficiency ([92]). Moderate generalized bleeding manifestations, such as recurrent ecchymoses and epistaxis, are not uncommon, and severe generalized bleeding may complicate surgical procedures, including biopsies, tooth extractions, and other minor procedures.

Laboratory Diagnosis

The laboratory findings in liver disease vary with the cause and severity of the underlying disorder and range from a slight prolongation of the PT in anicteric hepatitis to the findings summarized in Table 60.2, which are seen in severe decompensated cirrhosis. In cirrhosis, coagulation abnormalities correlate with the presence of portal hypertension and may be minimal in inactive cirrhosis; thrombocytopenia alone is common in association with portal hypertension. Acute fibrinogenolysis is significantly more common in patients with cirrhosis ([71]) than in those with acute hepatocellular disease, such as hepatitis, although elevations of FDP are consistently found in people with chronic aggressive hepatitis ([51]). Coagulation abnormalities are seldom marked in biliary cirrhosis, and some patients with this disorder have abnormally high levels of prothrombin and factors VII and X. Hemostatic abnormalities of any sort are rare in metastatic liver disease. In acute liver failure, the PT value has prognostic value and is indicative of the need for liver transplantation ([93]). The spectrum of coagulation abnormalities in liver disease has been reviewed ([38]).

Although screening tests of coagulation are almost invariably performed before liver biopsy, they apparently are of little value in predicting hemorrhage after this and other minor surgical procedures ([94], [95]). Similarly, the bleeding time test is of little clinical use in predicting bleeding ([96]). Many physicians use the international normalized ratio (INR) as a substitute coagulation test for the PT ([97]). When measured with a sensitive thromboplastin, the INR can quantitate vitamin K deficiency due to liver disease, but it should not be interpreted as in patients receiving warfarin ([97]).

Treatment

Not all patients with the coagulopathy of liver disease require hemostatic correction before procedures such as liver biopsy. A retrospective study looked at the PT ratio (patient PT/mean of reference range PT) and degree of thrombocytopenia to determine the necessity of plasma and platelet transfusion ([98]). In patients with platelet counts of 50,000/µl or greater, there was no increased bleeding with liver biopsy compared with patients with normal platelet counts. With regard to elevated PT values, if the PT ratio was less than 1.5, no increased bleeding was observed ([98]). Therefore, patients with moderate thrombocytopenia and mild liver disease coagulopathy do not need routine hemostatic correction with blood products. One exception to this recommendation is patients with a diagnosis of malignancy, who may have a higher bleeding risk, possibly due to chronic DIC and elevated FDP levels ([98]).

Elevated FDP levels may be a significant hemostasis risk factor in liver disease. High levels of FDP may impair platelet function and fibrin monomer polymerization. The thrombin time can screen for the latter defect. A prolonged thrombin time in a patient with a normal functional fibrinogen level and high FDP levels, who is not receiving heparin, may constitute a significant bleeding risk, especially in the setting of moderate thrombocytopenia.

Vitamin K_1, in doses of 10 to 20 mg, produces some improvement in the coagulation abnormalities in approximately 30% of patients with liver disease ([92]), but the PT often becomes prolonged again after an initially favorable response. Patients with severe liver disease have minimal or no response to vitamin K therapy.

Replacement therapy with fresh frozen plasma is indicated only in the presence of serious bleeding or before surgical procedures, and its effect is often disappointing in patients with liver disease ([92]). Reasons for this may include the short *in vivo* half-life of factor VII, hypervolemia, the loss of transfused factors into ascitic fluid, and the fact that the *in vivo* recovery of transfused factor IX is significantly lower than that of other factors, even in the absence of liver disease. Concentrates of vitamin K–dependent coagulation factors [prothrombin complex concentrate (PCC)] have been used in the replacement therapy of bleeding in patients with liver disease with variable success but, in several cases, have led to thromboembolic complications and DIC ([99]). Thrombosis presumably develops because such concentrates contain trace amounts of activated coagulation factors, particularly factors IXa and Xa ([99], [100]), that normally are not cleared from the circulation by the diseased liver and because of antithrombin deficiency, which is commonly present. Because of this hazard, the use of these concentrates can be recommended in patients with liver disease only in the case of life-threatening hemorrhage. Fresh frozen plasma is preferable, but the effects of even maximum doses (20 to 30 ml/kg of body weight) often are transitory. The administration of antithrombin concentrates has been therapeutically successful in a few cases of acute hepatic necrosis, including cases associated with pregnancy and severe acquired deficiency of antithrombin ([101]). Cryoprecipitate is useful to maintain fibrinogen levels over 100 mg/dl.

Infusion of 1-desamino-8-D-arginine vasopressin (DDAVP) has diminished coagulation abnormalities in some cirrhotic patients. The mechanism of this effect is obscure ([102]). However, a controlled trial found that DDAVP is not helpful in management of variceal bleeding in cirrhotic patients ([103]).

Recombinant factor VIIa (rVIIa) is a promising therapy for liver disease patients with significant coagulopathy. It has been studied in diverse groups of liver disease patients, including those undergoing liver biopsy ([104]), experiencing variceal bleeding ([105]), and undergoing liver transplantation ([106]). A typical dose of 80 µg/kg of rVIIa normalized prolonged PT values for more than 12 hours ([107]). Additional trials are needed to determine if the laboratory correction with rVIIa is translated into clinical benefit. Disadvantages of rVIIa include its high cost and risk of DIC and thromboembolic complications.

The administration of antifibrinolytic agents may be indicated in patients with fibrinogenolysis, but the assessment of the clinical effectiveness of these enzyme inhibitors has proved difficult in chronic liver disease. In one series, e-aminocaproic acid (EACA) produced favorable results in the treatment and prevention of acute postsurgical bleeding after placement of portacaval shunts ([108]). Another study found that liver disease patients with hyperfibrinolysis (assessed by the euglobulin clot lysis time) had clinical benefit with EACA when used to treat mucocutaneous bleeding ([71]). Thromboembolic complications have been reported after the administration of antifibrinolytic drugs in some patients ([109]).

Even though heparin administration may normalize fibrinogen catabolism, little evidence is cited that it decreases the duration or severity of bleeding in patients with low-grade DIC and severe liver disease ([62]). Heparin may be useful in conjunction with PCC therapy. In this setting, the addition of small amounts of normal plasma and heparin to vials of these thrombogenic concentrates inactivates activated proteases and minimizes the thrombotic risks of these concentrates ([110]).

For patients requiring liver biopsy who are deemed “high-risk” from the hemostasis perspective, the transjugular approach should be considered.

DISSEMINATED INTRAVASCULAR COAGULATION

The syndrome of DIC (defibrination syndrome, consumption coagulopathy) has been one of the most intensively studied subjects in hematology. The development of new and highly sensitive diagnostic techniques has resulted in the recognition of DIC in a seemingly endless variety of clinical situations. This large body of information has been summarized in many detailed reviews and monographs ([111], [112], [113], [114] and [115]).

Etiology and Incidence

DIC has been well documented in association with the disorders summarized in Table 60.4. Several retrospective studies suggest that DIC remains a relatively uncommon entity, but in one large general hospital, its overall incidence was 1 in 1000 admissions ([116]). The incidence of the syndrome in association with many disorders is likely proportional to the energy with which the diagnosis is pursued ([116]). In one study, the most prevalent etiologic factor was infection ([116]), whereas in another institution, more than 50% of cases were obstetric patients ([117]). A recent Japanese study found that in a hospital population, 45% of DIC cases were associated with malignancy ([118]). In many of the disorders listed in Table 60.4, DIC develops only in an occasional case. Thus, it is rare in heatstroke ([119]), autoimmune disorders ([120]), and hemolytic anemias ([121]). DIC is present in most cases of venomous snakebite, which is probably one of the most common causes of

the disorder worldwide.

TABLE 60.4. Etiologies of Disseminated Intravascular Coagulation

Obstetric complications
Abruptio placentae (227, 228), septic abortion and chorioamnionitis, amniotic fluid embolism, intrauterine fetal death, miscellaneous [degenerating hydatidiform moles and leiomyomas, postpartum hemolytic-uremic syndrome, abdominal pregnancy, tetracycline-induced hepatorenal failure, fetomaternal blood passage, saline- (236) and urea-induced (237) abortions]
Infections
Viral (herpes, rubella, smallpox, acute hepatitis, Reye syndrome, cytomegalic inclusion disease, various epidemic hemorrhagic fevers, others)
Rickettsial (Rocky Mountain spotted fever, others)
Bacterial (meningococcemia, septicemia, particularly that due to gram-negative organisms, many others)
Mycotic (histoplasmosis, aspergillosis)
Protozoal [malaria (161), kala-azar, trypanosomiasis]
Neoplasms
Carcinomas (122) (prostate, pancreas, breast, lung, ovary, many others)
Miscellaneous (metastatic carcinoid, rhabdomyosarcoma, neuroblastoma, others)
Disorders of the hematopoietic system
Acute leukemia [promyelocytic (258), other types]
Intravascular hemolysis [transfusion of incompatible blood (271), drug-induced (672), paroxysmal nocturnal hemoglobinuria (673), sickle cell anemia (674), fresh-water submersion (675)]
Histiocytic medullary reticulosis
Vascular disorders
Malformation [giant hemangiomas (Kasabach-Merritt syndrome [265]), aneurysms, coarctations of the aorta and other large vessels, Takayasu aortitis, large prosthetic arterial grafts (676), cyanotic congenital cardiac lesions]
Collagen-vascular disorders (677)
Hypoxia and hypoperfusion [congestive failure with pulmonary emboli (678), myocardial infarction, cardiac arrest (679), various forms of shock, hypothermia]
Massive tissue injury
Large traumatic injuries and burns (270), extensive surgical intervention (680), extracorporeal circulation, fat embolism (681)
Miscellaneous
Acute iron toxicity, head trauma (682), snakebite (273), anaphylaxis, concentrates of vitamin K–dependent coagulation factors (99), heatstroke (119), allograft rejection, graft-versus-host disease, severe respiratory distress syndrome (165), diabetic acidosis (683), status epilepticus (684), acute pancreatitis (685), homozygous deficiency of protein C (686)

Pathophysiology

MECHANISMS BY WHICH DISSEMINATED INTRAVASCULAR COAGULATION IS INITIATED The pathophysiology of DIC is complex. The mechanisms that activate or “trigger” DIC act on processes that are involved in normal hemostasis—namely, the processes of platelet adhesion and aggregation and contact-activated (intrinsic) and tissue factor–activated (extrinsic) pathways of coagulation (Fig. 60.2). These mechanisms have in common the capacity, in terms of either the magnitude or the duration of the activating stimulus, to exceed normal compensatory processes. Thrombin is persistently generated, and fibrin is formed in the circulating blood. Fibrinogen, various other coagulation factors, and platelets are consumed. The fibrinolytic mechanism is activated, and large amounts of FDP are produced, which further impair hemostatic function. Bleeding, shock, and vascular occlusion commonly supervene and produce profound alterations in the function of various organ systems. Normal compensatory processes may become impaired, creating a self-perpetuating “vicious cycle.” The ultimate outcome is determined by a dynamic interplay between the various pathologic processes and compensatory mechanisms; in other words, fibrin deposition versus fibrinolysis; depletion versus repletion of coagulation factors and platelets; and production versus clearance of fibrin, FDPs, and other products of coagulation (Fig. 60.3). In most forms of DIC, the initiating factors are multiple and interrelated. For example, in meningococcemia, endothelial cell injury may lead to expression of tissue factor and to collagen exposure; the latter then initiates platelet adhesion, aggregation, and thrombosis.

Figure 60.2. Initiating mechanisms of disseminated intravascular coagulation (DIC). The solid arrows indicate normal hemostatic pathways, and dotted arrows indicate pathways by which certain disorders associated with DIC initiate or promote the coagulopathy of DIC. Initiation of coagulation by expression of tissue factor activity is probably the most important mechanism triggering DIC.

Figure 60.3. Pathophysiology of disseminated intravascular coagulation (DIC). The critical event in DIC is the generation of thrombin in an unregulated fashion. The clinical consequences of thrombin production depend on the rate of thrombin formation as well as underlying host factors (marrow reserve of platelet production, liver function). Patients with adequate compensatory responses (ability to enhance platelet or coagulation factor production, fibrinolysis, intact clearance mechanisms) may have minimal symptoms, whereas other patients with defective compensatory responses may bleed, thrombose, or both. Major compensatory factors that influence clinical events are indicated in colored blocks. The zig-zag line indicates interruption of an adverse clinical event by a compensatory factor. FDP, fibrin(ogen) degradation products; PF, platelet factor.

Tissue Factor The exposure of procoagulant tissue extracts to blood is a major contributory factor in most forms of DIC and is of major pathogenetic importance in cases associated with abruptio placentae, intrauterine fetal death, acute promyelocytic leukemia, amniotic fluid embolism, massive trauma, and various neoplasms (

[122]). The active component of such extracts is tissue factor (thromboplastin); that is, tissue factor interacts with factor VIIa to activate the extrinsic pathway of coagulation. In abruptio placentae ([123]), decidual fragments, serum-containing activated coagulation factors, and other substances from the placental site enter the intervillous "maternal lake" and, hence, the venous circulation. This process is initiated by rupture of the basal decidual plate. In amniotic fluid embolism, relatively weak thromboplastins that increase in potency with gestational age ([124]) and large amounts of particulate matter enter the circulation suddenly. Amniotic fluid contains high concentrations of plasminogen proactivators, but it lacks plasminogen activators. In intrauterine fetal death, thromboplastic substances from the dead fetus are slowly but continuously absorbed, producing a picture of chronic but progressive DIC. In neoplasms, tumor microemboli and tumor "vesicles" ([125]) are thought to enter the circulation and act as thromboplastins ([122], [126]). Tumor cell surface expression of tissue factor has been demonstrated ([127]). Some neoplasms secrete a factor X activator ([128]) or fatty acids that alone, or when combined with albumin ([129]), act as thromboplastins. DIC in association with acute leukemia presumably results from the formation or release of tissue factor by leukemic cells ([130]). Additional leukocyte enzymes such as elastase may contribute to DIC by proteolysis of coagulation zymogens and fibrinogen ([131]). Malignant promyelocytes, as seen in promyelocytic leukemia, express high levels of annexin II, a phospholipid-binding protein and receptor for plasminogen and tissue-plasminogen activator ([132]). This overexpression of annexin II results in enhanced plasmin production and increased fibrinolytic activity ([132]). The granules of various "blast" forms contain tissue factor, with the promyelocyte containing particularly high concentrations ([130]). In addition to myeloid leukemia being associated with DIC, T-cell lymphoid leukemias also have been linked with DIC. The induction of tissue factor by leukocytes as a result of the action of endotoxin is discussed later in this chapter. In DIC associated with massive trauma ([133]), major surgical procedures, or large burns, damaged tissue expressing tissue factor activity presumably is a major initiating factor. In such cases, additional abnormalities and complications are important contributory factors ([134]): for example, "hypercoagulability," azotemia, shock, intravascular hemolysis, massive transfusions of stored blood, septicemia, and hypoxia. Cerebral trauma of sufficient magnitude to produce significant brain destruction induces a brief episode of DIC, which, although transitory, may be significant in that it may perpetuate cerebral bleeding ([135]).

Monocyte-Associated Procoagulants It has been known for many years that monocytes and tissue macrophages may, when suitably activated, express substances capable of initiating blood coagulation ([136]). This phenomenon is thought to be of importance in inflammation and in tissue localization of infectious agents and tumors. More recently, it has become apparent that "recognition-coupled" responses of the monocyte-macrophage system ([137]) may be important in triggering DIC in association with meningococcemia ([138]) and other forms of septicemia, certain forms of leukemia, major transfusion reactions, and anaphylaxis. The best defined model of this process is the induction of tissue factor by monocytes exposed to endotoxin ([139]) or immune complexes ([140]). This phenomenon is potentiated by corticosteroids and arachidonate and may explain the protective effects of leukopenia in animal models of endotoxin-induced DIC. Other substances that may induce monocyte procoagulant activity include anaphylatoxins ([141]), mitogens ([142]), aggregated Igs, and cytokines ([142]). Most of these substances induce the formation of monocyte coagulants only in the presence of T lymphocytes ([143]) and the complement system ([141], [144]). A prothrombinase-like activity ([145]) and a specific activator of factor X ([146]) also are formed by appropriately conditioned monocytes.

Vascular Endothelium In addition to monocytes or macrophages, vascular endothelium can be induced to express tissue factor activity in the setting of experimental DIC ([147]). Endothelium can also be down-regulated in terms of anticoagulant properties (e.g., thrombomodulin activity, fibrinolysis) by stimuli relevant in the pathogenesis of DIC (see Chapter 22). This altered endothelium is referred to as *activated*; properties of activated endothelium include conversion of the normally anticoagulant phenotype to a procoagulant phenotype, expression of adhesion molecules, production of inflammatory mediators, and production of vasoactive agents ([148]). Many of these pathologic events are amplified by endothelial cell protease-activated receptors (see Chapter 22). Vascular endothelium may also promote coagulation by formation of thrombogenic microparticles, which express anionic phospholipid ([149]). Microparticles in DIC may also originate from platelets or granulocytes ([150]). Thrombin generation caused by activation of factor XII in DIC appears to be less important than that initiated by tissue factor ([151]). Contact activation, instead, appears critical in mediating DIC-associated hypotension ([152]).

Infections DIC often accompanies septicemia as a result of bacteria that possess potent endotoxins. This correlation has led to the intensive study of the effects of endotoxin on the hemostatic mechanism. Purified endotoxin produces several effects that may lead to DIC—namely, activation of factor XII ([153]), platelet aggregation, inhibition of fibrinolysis, leukocyte aggregation, direct endothelial injury ([154]), cellular induction of tissue factor activity ([155]), and impairment of compensatory clearance functions. Many of these phenomena may be mediated by the interaction between endotoxin and monocytes, as discussed earlier. The coagulation abnormalities and the histopathologic appearance of lesions produced by endotoxin in the generalized Sanarelli-Shwartzman phenomenon in animals resemble those found in human DIC. Studies of the Shwartzman reaction in animals revealed the following to be of particular importance to DIC in humans: (a) Shwartzmanlike phenomena may be produced by agents other than endotoxin, such as factor Xa ([156]), substances that produce contact activation and platelet aggregation, and purified platelet factor-3 ([157]); (b) infusion of FDP, tissue factor (thromboplastin), red cell hemolysates, corticoste-roids, and inhibitors of fibrinolysis produces changes that simulate the effects of reticuloendothelial blockade; (c) heparin ([158]), coumarin anticoagulants, granulocytopenia, thrombocytopenia ([159]), activators of endogenous fibrinolysis, and inhibitors of factor XII activation inhibit the Shwartzman phenomenon; (d) continuous, slow infusion of endotoxin produces DIC in the absence of either a "priming" dose or reticuloendothelial blockade; and (e) the Shwartzman phenomenon can be produced in pregnant animals with only one dose of endotoxin. The pertinence of these data to human disease nevertheless remains uncertain. The Shwartzman phenomenon and the effects of endotoxin in general are highly species-specific, and DIC may complicate acute infections involving bacteria that lack potent endotoxins—for example, pneumococci, which produce DIC most often in asplenic individuals ([160]). In pneumococcal sepsis, intact pneumococci, their polysaccharide capsular antigens, or antigen-antibody complexes formed there may trigger coagulation by interacting with the complement system. In meningococcemia and other forms of endotoxemia ([154]), direct vascular injury results in the induction of tissue factor activity and even release of fragments of endothelial cells, platelets, and granulocytes ([150]) into the general circulation. A similar phenomenon may be involved in rickettsial and viral infections. These latter infectious agents have been shown to induce tissue factor activity in cultured endothelium (see Chapter 22). Patients with malaria ([161]) may experience massive intravascular hemolysis. In most severe infections, the complicating influence of septic shock may be considerable.

Shock, Hypoperfusion, and Hypoxemia It has been suggested that DIC is involved in all forms of shock and that it is the central feature in irreversible or refractory forms. In septic shock, the interrelationships between septicemia, shock, and endotoxemia are exceedingly complex. In septicemia, both thrombocytopenia and septic shock may occur without DIC. Shock may favor the development of DIC by potentiating various activating stimuli that ordinarily would not exceed the capacity of compensatory processes and may perpetuate DIC after a transient activating stimulus has been dissipated. Hypoperfusion, even of normal vessels, acidosis, and hypoxemia produce hypercoagulability and favor intravascular platelet aggregation. Furthermore, splanchnic hypoperfusion impairs reticuloendothelial and hepatic clearance functions and is present in virtually all forms of shock. Shock also may impair hepatic synthesis of coagulation factors and thus contribute to the coagulation defect in DIC. Activated neutrophils may generate oxygen radicals and proteases to alter vascular permeability. Vascular injury may also occur with ischemia/reperfusion that elicits inflammatory responses. DIC in association with giant hemangiomas (Kasabach-Merritt syndrome) ([162]) or with aneurysms of the aorta or other large vessels ([163]) has been attributed to hypoperfusion and stasis in local vascular beds. In Kasabach-Merritt syndrome, large gaps in the endothelium that expose subendothelial collagen and other fibers, together with the induction of thromboplastic substances by poorly supported, recurrently injured vessels within the tumor, also may be important factors leading to the initiation of DIC. In adult respiratory distress syndrome and in pulmonary embolism, hypoxic injury to pulmonary capillary endothelial cells may trigger DIC, and obstruction of or damage to the pulmonary microvasculature by thrombin ([164]), platelet aggregates, or FDP may aggravate the pulmonary edema ([165]).

Miscellaneous Activating Stimuli Snake venoms contain enzymes that may trigger coagulation in unique ways. Such venoms may produce defibrination without affecting other coagulation factors, such as ancrod, an enzyme purified from the venom of the Malayan pit viper (*Agkistrodon rhodostoma*). Other venoms contain thrombinlike enzymes or substances that specifically activate factor X or prothrombin ([166]). Crude venoms also contain substances that act as thromboplastins and produce intravascular red cell hemolysis and massive vascular damage ([167]). An inventory of the biochemical properties of snake venoms and their constituent enzymes has been summarized elsewhere ([168], [169], [170] and [171]).

Consumption of Coagulation Factors DIC constitutes a model of accelerated turnover of various coagulation factors, the levels of which at any time are determined by the size of the plasma pool and the differences between the rates at which they are being destroyed and replenished. Results of quantitative studies have demonstrated accelerated turnover rates for platelets, fibrinogen ([172]), and prothrombin. Numerous factors complicate a simple kinetic approach. For example, the depletion of plasma fibrinogen induces a compensatory release of large amounts of fibrinogen into the circulation, possibly from the hepatic-lymphatic system, and also increases the rate of fibrinogen synthesis. Other complexities include impaired hepatic synthesis of coagulation factors and the phenomenon of postdepletion "rebound" and "overshoot" ([173]). Generalizations based on the consumption of coagulation factors during *in vitro* coagulation are not always consistent with laboratory findings in patients with DIC. Plasma levels of factors that are normally consumed, such as fibrinogen, prothrombin, and factors V and XIII, often are reduced in severe DIC, but factors that normally are not consumed also may be deficient, such as factors VII, IX, and X. Prothrombin, which is consumed completely *in vitro*, often is at a normal level in patients with DIC. Significant hypoprothrombinemia must reflect either massive and protracted activation of coagulation or complicating factors, because in animals, severe depletion of platelets, fibrinogen, and factors V and VIII results from activation of only 10% of plasma prothrombin ([174]). Factor VIIIc levels are reduced to a greater extent than are vWF antigen levels ([175]). Proteins other than coagulation factors may be depleted as a result of DIC; those of potential importance include antithrombin ([176]), a $_2$-antiplasmin ([177]), and plasminogen ([178]). Plas-minogen has great avidity for fibrin and may coprecipitate in fibrin thrombi. In experimental animals, depletion of tissue plasminogen activator, as well as plasminogen, can be produced by the protracted infusion of tissue factor. The numerous and diverse defense processes that are mediated by factor XIIa are activated in DIC, including the complement system and the kallikrein system. It has been suggested that the hypotensive effects of bradykinin may explain the conspicuous presence of hypotension in patients with DIC triggered by activation of factor XII (

[179]), for example, that associated with endotoxemia.

Consumption of Platelets In DIC, the platelet count often is depressed out of proportion to the severity of coagulation abnormalities. This presumably reflects the limited production capacity of the megakaryocytes. Furthermore, thrombocytopenia may result from processes other than the consumption of platelets in thrombotic lesions. These processes include adhesion to denuded or damaged endothelial cell surfaces and intravascular aggregation with subsequent sequestration, which may be caused by endotoxin, antigen-antibody complexes, thrombin, particulate matter, and, possibly, fibrin-FDP complexes. All of these agents initiate the platelet release reaction, which may produce a population of partially activated platelets that are depleted of storage nucleotides (acquired storage pool disease). The resulting expressed platelet factor-3 activity alone may further accelerate the process of DIC ([157]). Partially activated platelets may contribute to impairment of clearance functions. Epinephrine and serotonin are released from the platelets and may reach extremely high concentrations in hypoperfused vascular beds. This process may produce sustained constriction of the afferent renal arteriole and may predispose to cortical necrosis. Serotonin also may produce pulmonary and cerebral hypoperfusion.

Intravascular Fibrin Formation The formation of fibrin, in the form of small strands and "microclots" ([180]), is the immediate result of DIC; the ultimate consequence of this process is determined by a balance between the rate of fibrin formation and the rate of its clearance from the circulation or lysis by the fibrinolytic enzyme system. Erythrocytes are injured mechanically during passage through fibrin networks in the microcirculation. Such microangiopathic hemolysis leads to the production of schistocytes and microspherocytes. Erythrocyte damage in metastatic carcinoma appears to be caused mainly by fibrin strands that form around tumor cell emboli as a result of low-grade DIC ([181]).

Fibrinolysis Fibrinolysis is present in virtually every patient with DIC, but it generally plays a homeostatic rather than a pathologic role. In the setting of DIC, this "secondary fibrinolysis" is an appropriate response to persistent thrombin generation. Fibrinolysis may be activated by several mechanisms. The major endogenous source of plasminogen activators is in the vascular endothelium of the microcirculation, and in DIC, such activators, especially tissue-plasminogen activator, are apparently released as a result of thrombin formation and fibrin deposition on endothelial surfaces, endothelial injury, or hypoxia. Many of the thromboplastic substances that initiate DIC, such as tumor tissues and extracts of leukemic cells, also contain plasminogen activators. The release of plasminogen activators from platelets and leukocytes also may be significant. Finally, factor XIIa activates plasminogen by interacting with normal proactivators and the kinin system ([182]). Fibrinolysis must be distinguished clearly from the process of fibrinogenolysis, in which fibrinogen and other coagulation factors are proteolytically destroyed in the circulation. Fibrinogenolysis may be an inappropriate response in DIC associated with amniotic fluid embolism ([183]), heatstroke ([119]), and, rarely, carcinoma. It is uncommon in other forms of DIC; when present, it is usually transitory and overshadowed by marked fibrinolysis. Disorders in which fibrinogenolysis arises in the absence of DIC (primary fibrinolysis) are discussed elsewhere in this chapter.

Fibrin(ogen) Degradation Products The stepwise process by which fibrin is degraded proteolytically and the biologic effects of the various products of the process (FDPs) are discussed in Chapter 21 ([184]). These protein fragments act as antithrombins ([69], [70]), inhibit fibrin polymerization, produce a structurally defective fibrin polymer ([185], [186]), and may impair platelet ([66], [67]) and reticuloendothelial clearance functions. The presence of large amounts of FDP in the circulation is a major factor in the production of hemorrhage in many patients with DIC. The infusion of large amounts of FDP (fragment D) into rabbits produces changes that resemble the posttraumatic respiratory distress syndrome in humans ([187]). This observation suggests that large amounts of FDP may directly damage the pulmonary vasculature, leading to respiratory distress syndrome, which has been reported in association with DIC and the use of thrombolytic agents ([188]). The smallest FDPs are peptides of 3000 to 4000 molecular weight that inhibit smooth muscle contractility, an effect that may explain the frequency of uterine inertia in abruptio placentae ([189]). In DIC, a large amount of fibrin remains in a soluble state as a consequence of the formation of complexes between fibrin monomers, various FDPs, and fibrinogen. This solubility has been regarded as a final defense against vascular occlusion. *In vitro*, the complexes dissociate in the presence of alcohol or protamine sulfate to form gels or precipitates of various types (paracoagulation).

Impairment of Clearance Mechanisms The numerous processes that normally remove procoagulant material from the circulation are of the utmost importance in DIC because of the presence of massive amounts of both activators and products of coagulation. Most of the products of intravascular coagulation [prothrombinase, platelet factor-3 activity, various types of FDPs and complexes thereof ([190], [191]), and, possibly, free fibrin ([192])] as well as various initiators of the process (tissue fragments, endotoxin, antigen-antibody complexes, tissue factor, and red cell stroma) are removed from the circulation by the reticuloendothelial system ([193]) (Fig. 60.3). The Kupffer cells of the liver ([194]) and splenic macrophages are of particular importance. In certain forms of DIC, large amounts of relatively inert particulate matter (e.g., amniotic fluid embolism) place an additional burden on the reticuloendothelial system. The hepatic cells are of primary importance in the clearance of activated coagulation factors [IXa, Xa ([195]), and XIa]. Investigators have suggested that various substances saturate and produce an "autoblockade" of reticuloendothelial and hepatic clearance functions in DIC in a manner comparable to that produced experimentally in the Shwartzman reaction ([193], [196]). This blockade may be an important pathophysiologic factor, particularly in perpetuating DIC after a transient activating stimulus. Shock and endotoxemia, both of which produce significant hepatic hypoperfusion, may contribute indirectly to autoblockade of clearance functions.

Chronic or "Compensated" Disseminated Intravascular Coagulation Certain forms of DIC result from a weak or intermittent activating stimulus. In such patients, destruction and production of coagulation factors and platelets are balanced (Fig. 60.3). The pathophysiology of such chronic, subacute, or "compensated" DIC is fundamentally the same as that in the acute case. Nevertheless, the distinction is valuable because the clinical picture and laboratory findings in the chronic form are quite variable and may be diagnostically confusing. Chronic DIC has been described in most patients with intrauterine fetal death or giant hemangiomas (Kasabach-Merritt syndrome) and in many cases of adenocarcinoma ([122]). Other etiologic factors that may produce chronic DIC include various forms of vasculitis, acute leukemia, aneurysms, hemangiomatous transformation of the spleen, and renal allograft rejection. Chronic DIC has many clinical and laboratory features that resemble an intermediate stage between the "hypercoagulable state" (see Chapter 61) and acute DIC, an observation of more than theoretical interest. In cancer patients, a virtually continuous spectrum of clinical and laboratory features has been described; these range from recurrent venous thrombosis or arterial embolism ([122]) with high levels of platelets and coagulation factors to acute DIC with severe hemorrhage ([122]). The clinical and experimental evidence is incontrovertible that pregnancy, the best studied form of hypercoagulability, is associated with an increased propensity for the development of DIC ([197]). Indeed, even normal pregnancy has been suggested as a form of low-grade "physiologic" DIC ([197]), which, at term, becomes overt for a short time. Thus, transitory but significant elevations of FDP and corresponding diminution in fibrinogen levels are observed regularly during the first 4 hours after delivery ([197]). This may be triggered, in part, by the release of tissue factor into the circulation. Thus, the hypercoagulable state likely represents merely low-grade intravascular coagulation.

Clinical Features

The major clinical features of DIC are bleeding, often of serious magnitude and abrupt onset; a variable element of shock that is often out of proportion to apparent blood loss; and symptoms of hypoperfusion of various vascular beds. Acute renal failure is common, and thromboembolic manifestations often are noted ([198]). Any of these features or signs and symptoms of the underlying disorder may predominate in a given case.

Evidence of major organ dysfunction is a common finding in patients with DIC, most often including signs, symptoms, and laboratory evidence of abnormal pulmonary, renal, hepatic, and central nervous system function. Although virtually all of these manifestations have been attributed to the underlying DIC, the clinical manifestations that have been described were the result of the underlying disorder. For example, one study observed that patients with DIC due to aortic aneurysm had laboratory features of DIC but minimal clinical manifestations. Patients with DIC due to obstetric disorders all had bleeding, but only 20% had organ dysfunction. In contrast, of patients with DIC due to sepsis, only 15% had bleeding, but 76% had organ failure ([118]). These results suggest that marked heterogeneity exists in clinical manifestations of DIC, and that the etiology of DIC is a major predictor of clinical events ([118]).

In this section, the clinical manifestations and diagnosis of DIC are discussed in general terms. Various specific clinical features and details regarding treatment of the most common forms follow in a separate section.

ACUTE DISSEMINATED INTRAVASCULAR COAGULATION Bleeding manifestations of virtually every kind have been described, and they may evolve rapidly in the patient with acute DIC. Generalized ecchymoses, petechiae, and bleeding from previously intact venipuncture sites or around indwelling intravenous needles or catheters are noted in many patients. Large, spreading, hemorrhagic skin lesions often are superimposed on familiar exanthems in patients with rickettsial and viral infections. "Geographic" acral cyanosis is a prominent feature in some patients. This grayish discoloration of the tips of the fingers, toes, and ears often develops in a symmetric distribution. Large, sharply demarcated ecchymotic areas may result from thrombotic occlusion of dermal vessels and may progress to skin infarction. Such infarcts are particularly common in patients with purpura fulminans (Fig. 60.4) and are seen also in coumarin-induced skin necrosis and inherited homozygous deficiency of protein C (see Chapter 61). In patients with meningococcemia, cutaneous hemorrhage may be striking. Bleeding from apparently normal gingivae, epistaxis, gastrointestinal bleeding, pulmonary hemorrhage, and hematuria are common. In patients who develop DIC after surgical procedures, alarming hemorrhage may develop around drains and tracheostomies, and accumulations of blood may be concealed in serous cavities.

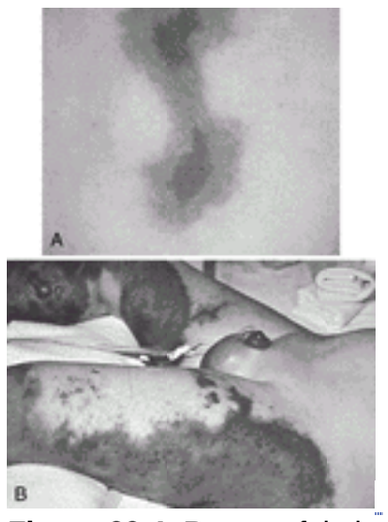

Figure 60.4. Purpura fulminans in infection-associated disseminated intravascular coagulation. Early lesions **(A)** are circumscribed; progressive lesions **(B)** may become necrotic. See Color Plate. (From Dudgeon DL, Kellogg DR, Gilchrist GS, et al. Purpura fulminans. Arch Surg 1971;103:351–358; copyright 1971, American Medical Association, with permission.)

CHRONIC DISSEMINATED INTRAVASCULAR COAGULATION Superficial but extensive ecchymoses of the extremities, often without petechiae, may develop intermittently or may persist. Recurrent episodes of epistaxis or more serious internal mucosal bleeding may punctuate the course. Thrombophlebitis may develop in unusual sites, such as the axillary vein, and may occur repeatedly after cessation of anticoagulant therapy. Clearly, Trousseau sign (recurrent migratory thrombophlebitis in association with cancer) in most instances is a manifestation of chronic DIC. More serious hemorrhagic manifestations may develop as the underlying disease progresses or may arise with dramatic suddenness after surgical procedures such as a prostatectomy. Acute DIC may be heralded by further thrombophlebitis or pulmonary emboli. In some patients, evidence of vascular obstruction (e.g., impairment of renal function, confusion, transitory neurologic syndromes, or repeated episodes of cerebral thrombosis) may develop with minimal bleeding.

Laboratory Diagnosis

The laboratory findings in DIC are summarized in Table 60.2. Contrary to what is commonly assumed, they may be quite variable. The plasma fibrinogen level, PTT, PT, platelet count, and estimates of FDP or D-dimer are the cornerstones on which the diagnosis of DIC is based. These simple tests should always be performed first. Additional information may confirm, but seldom refutes, the diagnosis of DIC if typical abnormalities are demonstrated by these tests. Laboratory data may change with remarkable rapidity in DIC, based on disease progression or therapy.

Laboratory data must be interpreted with caution. Levels of platelets and various coagulation factors, fibrinogen, and factor VIII, in particular, may be elevated in many of the conditions associated with DIC, including pregnancy. Thus, a fibrinogen level of 200 mg/dl, although within the normal range determined in healthy subjects, may represent a significant decrease in a patient whose baseline level was 800 mg/dl.

The best test for diagnosing DIC is the D-dimer assay. The semiquantitative method is sensitive ([199]), and D-dimer values greater than 2000 ng/ml have been reported to be consistent with DIC ([200]). More sensitive, quantitative D-dimer assays are available, but DIC diagnostic ranges are not yet defined for this latter method.

A new test, measurement of the biphasic waveform in the PTT assay, has been reported to precede development of DIC and to predict DIC better than the D-dimer assay ([201]). The biphasic waveform results from the formation of a precipitate on plasma recalcification; the precipitate contains very-low-density lipoprotein complexed with C-reactive protein. If confirmed, this assay may be a useful addition to laboratory tests for DIC.

BASIC BLOOD EXAMINATIONS In patients with DIC, routine hematologic tests may reveal evidence of acute bleeding, accelerated red cell destruction, or signs of the underlying disease. Examination of the blood smear reveals schistocytes in approximately 50% of cases ([117] , [202]), but the degree of schistocytosis bears no necessary correlation with other facets of the disorder. More subtle evidence of intravascular hemolysis often is found, such as increased serum levels of lactic acid dehydrogenase and diminished haptoglobin levels. Rarely, massive intravascular hemolysis with hemoglobinemia and hemoglobinuria is noted ([180]).
Thrombocytopenia is an early and consistent sign of acute DIC, and the consideration of this diagnosis in the presence of a persistently normal platelet count is difficult. Platelet counts in the range of 50,000 to 100,000/μl are the usual finding, but thrombocytopenia may be severe.
COAGULATION DEFECT The PTT, PT, and thrombin time are prolonged in most patients with acute DIC. Early in the course of the disorder and in chronic DIC, the PTT may be normal or even shorter than normal, which may be the result of the procoagulant effects of activated coagulation factors or elevated factor VIII levels. Occasionally, one can follow the process of DIC from its inception, and specific assays for various coagulation factors obtained at the time of diagnosis reveal a variable and rapidly changing picture. The plasma levels of fibrinogen and of factors V and XIII usually are significantly depressed; fibrinogen and factor V are the most consistently affected ([203]). The level of factor X may be lower than that of other "stable" factors (factors VII, IX, and XI), which usually are present in normal amounts ([203]). In many patients, particularly those with abruptio placentae, normal prothrombin levels are maintained ([123] , [203]), but marked hypoprothrombinemia often is present in those with septic DIC ([204]). The levels of factors VIII, IX, and XI as determined by one-stage assays may fluctuate widely as the result of the presence of activated factors ([205]), such as thrombin, and factor Xa ([198]). This problem is minimized in two-stage assays ([203]). Levels of factor VIIIc often are normal or increased, particularly when assayed by two-stage techniques ([206]). In many patients, the levels of coagulation factors tend to "overshoot" after repletion. As a consequence of the inhibitory effects of FDPs, the thrombin time may be prolonged out of proportion to the reduction in the fibrinogen level.
TESTS FOR FIBRINOLYSIS: FIBRIN MONOMERS, FIBRIN(OGEN) DEGRADATION PRODUCTS, AND D-DIMER In most patients with DIC, FDP levels as determined by quantitative methods, such as red cell hemagglutination inhibition or latex agglutination, are 25-μg fibrinogen "equivalents"/ml or higher ([203]). All methods are most sensitive to large or "early" FDPs. These fragments, particularly fragment X, retain thrombin-binding sites or may form a complex with fibrinogen and consequently be removed during the preparation of serum for FDP tests. This phenomenon or the presence of only small FDPs may explain the normal levels of FDPs in some patients with otherwise typical DIC. Fibrinopeptide A and certain fibrinogen fragments that are formed by the lysis of cross-linked fibrin, such as the DD-dimer and the DD-dimer–E complex, can be demonstrated by using special techniques. These latter FDPs provide direct evidence of the action of thrombin on fibrinogen and provide a means of differentiating fibrin degradation products from fibrinogen degradation products ([207] , [208]). The simplicity, specificity, and sensitivity of the D-dimer test have led many laboratories to replace less sensitive or less convenient tests for DIC with the D-dimer test. Because false-positive results may be seen with FDP latex agglutination tests in patients with dysfibrinogenemia, the D-dimer test may be more specific in diagnosing DIC, especially in distinguishing the coagulopathy of liver disease from DIC ([84] , [199] , [209]). False-positive D-dimer latex agglutination tests may occur in patients with elevated levels of Ig (immunoglobulin) M (rheumatoid factor). "Paracoagulation" techniques are simple to perform, but they are less specific than tests for FDPs. The results of the ethanol gelation test, in particular, often are negative in DIC. To the contrary, results of protamine gelation tests usually are positive ([210]), but abnormal results are obtained in numerous other disorders, including many that commonly are associated with DIC.
OTHER LABORATORY FINDINGS Plasma levels of fibrinopeptide A ([211]) and the rate of incorporation of ^{14}C-labeled glycine ethyl ester into soluble "circulating fibrin" ([212]) are exceptionally sensitive indicators of DIC and may be abnormal even in patients with normal levels of FDP. Levels of antithrombin ([213]), a $_2$-antiplasmin, and proteins C and S may be diminished in some cases. Other parameters of activation of coagulation and fibrinolysis have been studied in DIC, especially in sepsis. Thrombin–antithrombin III (TAT) complexes and plasmin–a $_2$-antiplasmin (PAP) complexes are often elevated in sepsis-associated DIC. Assays such as TAT and PAP complexes may have prognostic significance in DIC, as may other coagulation parameters, including plasminogen activator inhibitor type-1, vWF antigen, and a $_2$-antiplasmin ([214]). In a primate model of gram-negative sepsis, a number of molecular markers of coagulation were investigated for their use in monitoring DIC ([215]). Markers such as soluble thrombomodulin and soluble fibrin monomer are useful in assessing the status of microvascular injury. The role of these assays in diagnosing or managing DIC patients at this time is uncertain. The International Society on Thrombosis and Haemostasis (ISTH) has proposed clinical and laboratory criteria using routine and esoteric assays to better define the spectrum of DIC cases ([216]).

Differential Diagnosis

The causes of severe hemorrhage of abrupt onset in a patient who was previously free of bleeding are relatively few, and only a small number of acquired disorders give rise to significant coagulation abnormalities in which the cause is not obvious. Thus, the syndrome of DIC is seldom difficult to recognize. Problems arise when

the diagnosis simply is not considered or in chronic forms, when the underlying coagulation disorder may be masked by features of the basic disease or by thromboembolic complications ([217]).

Two disorders, however, produce laboratory abnormalities that resemble DIC: severe liver disease, which is common, and primary fibrinogenolysis or “pathologic” fibrinolysis, which is rare (Table 60.2).

In patients with primary fibrinogenolysis, the following conditions may be evident: hypofibrinogenemia; increased levels of FDP; abnormalities of the PTT, PT, and thrombin time; and deficiencies of factors V and VIIIc. The euglobulin lysis time is significantly and persistently shortened, often in association with plasminemia. However, the platelet count usually is normal, the D-dimer level should be normal or only minimally elevated, and protamine sulfate tests should be negative. Hypoprothrombinemia and deficiencies of stable coagulation factors VII, IX, X, and XI are rare. Thus, routine coagulation tests should be able to distinguish DIC from primary fibrinogenolysis.

In patients with liver disease, coagulation abnormalities and thrombocytopenia may originate from many pathologic processes (Table 60.3). Chronic or intermittent fibrinogenolysis with high levels of FDP is common, particularly in patients with cirrhosis. In such patients, the exclusion of the diagnosis of DIC may be difficult. Factor VIIIc levels usually are elevated when liver disease is severe, and the levels of factors VII and IX typically are low. A helpful test in discriminating between the coagulopathy of liver disease and DIC is the D-dimer test, the results of which should be abnormal in DIC but normal in liver disease [unless additional disorders coexist ([84] , [209])].

DIC, particularly that associated with carcinoma, may be confused with various microangiopathic hemolytic anemias, such as thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome; in these disorders, the clinical picture may resemble that of DIC in many respects. High levels of FDP may be encountered in patients with microangiopathic hemolytic anemias, but significant coagulation abnormalities are not commonly present. Many other disorders may produce slight to moderate elevations of FDP—for example, pulmonary embolism and chronic renal disease with uremia.

Moderate thrombocytopenia is a common consequence of the use of extracorporeal circulatory devices, and coagulation abnormalities often are noted immediately after their use because of the presence of residual heparin. Heparin levels also may rise several hours later (the rebound phenomenon) ([218]). In such patients, the presence of thrombocytopenia together with the effects of heparin may be confused with DIC; similar difficulties may arise after hemodialysis. Even the small amounts of heparin required to irrigate indwelling catheters, or to contaminate Hickman catheters, are a common cause of “pseudo-DIC.”

Treatment

DIC always is the end result of a serious underlying disorder. Although the patient may benefit greatly from measures directed at the DIC or from the replacement of depleted coagulation factors and platelets, cure of the syndrome depends on prompt and energetic treatment of the primary disorder. This—not the therapeutic measures described in this section—remains the cornerstone of therapy.

ANTICOAGULANTS Heparin is a specific activator of the physiologic antithrombin system and thereby inhibits a number of proteolytic enzymes, including factors IXa and Xa and thrombin (see Chapter 61). Antithrombin can neutralize free thrombin rapidly and can retard or prevent its further formation. The therapeutic efficacy of heparin is unquestionable in some animal models of DIC, but assessment of its effectiveness in humans has proved more difficult. In view of the complexity of DIC, inhibition of coagulation alters only one facet, albeit a fundamental one, of the pathophysiologic cycle. In patients with chronic DIC, the results of heparin therapy usually are favorable and may be dramatic. In most patients, heparin would not be expected to alter ultimate mortality because of the nature of the underlying diseases; however, this drug typically does reduce the severity of bleeding and thromboembolic manifestations and produces parallel improvement in the abnormalities of laboratory test values. Elevated levels of D-dimer and FDPs drop rapidly, and accelerated fibrinolysis, if present, disappears after the administration of heparin, often before the coagulation defect has been alleviated. The response of the platelet count to heparin therapy for DIC is slow and often erratic. In patients with acute DIC, particularly that associated with sepsis, the results of heparin therapy have been less encouraging ([219] , [220]). Heparin has been given concomitantly with numerous other therapeutic measures in most patients, and in those with acute forms of DIC in which the activating stimulus is transitory (e.g., abruptio placentae), spontaneous cure is the rule. The apparent paradox of administering anticoagulants to a patient with a serious bleeding disorder has been emphasized repeatedly. Most clinicians are reluctant to use heparin in patients with acute DIC. Laboratory control of heparin therapy for DIC is difficult. Because baseline PTT values are usually prolonged in acute DIC, heparin levels may be required to monitor therapy (see Chapter 61).

REPLACEMENT THERAPY WITH PLATELETS AND COAGULATION FACTORS Many patients with DIC ultimately receive large amounts of blood products, even though evidence is only anecdotal that they are necessary or therapeutically effective ([221]). The major aim of replacement therapy with blood products in DIC is to replenish fibrinogen. This goal is best accomplished by the administration of cryoprecipitate, each unit of which contains approximately 250 mg of fibrinogen ([222]). The amount of cryoprecipitate given should be sufficient to elevate the plasma fibrinogen level to at least 100 to 150 mg/dl. As a general guide, 3 g of fibrinogen can be expected to raise the plasma level of an adult patient approximately 100 mg/dl. Fibrinogen administration probably should be restricted to the occasional patient with hypofibrinogenemia and significant bleeding, in whom DIC is self-limited or has been controlled by heparin therapy (e.g., in intrauterine fetal death before surgical intervention). Sterile fibrinogen concentrates are not yet available for routine therapeutic use in the United States. In theory, the infusion of fibrinogen in the presence of active DIC “adds fuel to the fire.” Thromboembolic complications have developed in some patients after the administration of lyophilized concentrates of this protein ([223]). In a larger number of patients, fibrinogen produced no apparent adverse effects. Patients with DIC, bleeding, and platelet counts less than 50,000/µl should be considered for platelet transfusion. Due to the acquired storage pool defect seen with DIC, as well as FDP inhibition of platelet function, DIC patients may require a higher platelet count for adequate hemostasis than patients with thrombocytopenia in the absence of platelet dysfunction. Infusions of semipurified antithrombin have produced encouraging results in some patients ([224]). The availability of purified, sterile antithrombin concentrates has led to its investigation in treating DIC. As seen in most studies ([225]), although antithrombin concentrates can normalize plasma levels of this protein in patients with DIC and improve hemostasis parameters, consistent clinical benefit in terms of survival is not evident. A large clinical trial recently demonstrated that high-dose antithrombin therapy in patients with sepsis had no effect on mortality ([226]). Novel therapies for DIC are discussed in the section Novel Therapies for Disseminated Intravascular Coagulation .

OTHER THERAPEUTIC MEASURES Treatment of shock should be immediate and vigorous in all patients with DIC. Packed erythrocytes should be given promptly if indicated. The indiscriminate use of EACA and other antifibrinolytic drugs should be discouraged. EACA has been administered together with or after heparin in a few patients in whom DIC was associated with significant fibrinogenolysis. No serious adverse effects were observed, but the therapeutic value of EACA was difficult to assess. Because of the potential risks, fibrinolytic enzyme inhibitors should be administered only to carefully selected patients—that is, those in whom DIC has resulted from a transitory stimulus or has been arrested by heparin administration and in whom fibrinogenolysis or inappropriate fibrinolysis, hypofibrinogenemia, and adequate renal function have been clearly documented. The therapeutic use of EACA in fibrinogenolysis and appropriate dosage schedules are discussed elsewhere in this chapter.

Specific Features of Various Forms of Disseminated Intravascular Coagulation

OBSTETRIC DISORDERS

Abruptio Placentae DIC complicates abruptio placentae in approximately 25% of cases ([227] , [228]) in which fetal compromise occurs. Shock develops rapidly, but vaginal bleeding may be minimal or absent for a time and bears little relationship to the extent of abruption. Brisk external hemorrhage may originate from episiotomies and lacerations, and large amounts of blood may be concealed behind the placenta and within the wall of the uterus. Severe placental abruption associated with fetal death is often linked with DIC ([229]). Hemorrhage is the major factor leading to shock and renal complications in abruptio placentae, and the most essential therapeutic measures are the vigorous treatment of blood loss and the prompt evacuation of the uterus. Extensive replacement therapy seldom is required. Often, fibrinogen replacement is given if immediate surgical treatment is necessary. Fibrinogen replacement may be most useful in patients with fetal death requiring cesarean delivery. If the coagulation defect and thrombocytopenia are severe or persist for an unusually long time, the administration of platelets, fibrinogen in the form of cryoprecipitate, and fresh frozen plasma ([230]) may reduce hemorrhage. Most obstetricians do not administer heparin because it may increase bleeding and because rapid spontaneous remission of DIC is usual when the uterus is evacuated.

Intrauterine Fetal Death In the event of intrauterine fetal death, definite laboratory abnormalities are not seen until the dead fetus has been retained for 3 to 5 weeks; plasma levels of FDPs then begin to rise, and the platelet count and fibrinogen level gradually decline. Bleeding may be inconspicuous, but a progressive loss of renal function is not uncommon. In most women in whom delivery of the dead fetus is induced promptly according to usual obstetric practice, bleeding is not serious, even in the presence of low-grade DIC. Operative intervention is dangerous when hypofibrinogenemia is severe, and such patients should receive heparin until safe fibrinogen levels are restored ([231]). If immediate surgery is imperative, heparin administration should be followed by platelet replacement and enough fibrinogen, in the form of cryoprecipitate, to produce plasma fibrinogen levels of 150 mg/dl or greater ([232]). This situation is one of the few indications for the use of fibrinogen in the presence of DIC. Intrauterine fetal death rarely may be associated with the acute form of DIC.

Amniotic Fluid Embolism In women who survive amniotic fluid embolism (mortality rate of up to 80%), DIC with severe hemorrhage may develop within 1 to 2 hours (

[233]). More recent surveys indicate a mortality rate of 20 to 30% ([234]); 66% of patients with amniotic fluid embolism cases had DIC ([234]). Often, the syndrome is complicated by significant fibrinolysis and even fibrinogenolysis ([183]). Hypoxia and other sequelae of pulmonary vascular obstruction dominate the clinical picture and usually determine the outcome. The release of serotonin and other vasoactive substances from platelets may contribute to the profound pulmonary vasoconstriction. Heparin often is given, and the administration of EACA has been recommended when evidence of a disproportionate or inappropriate fibrinolytic response appears. Nevertheless, the efficacy of these drugs and risks associated with their use remain uncertain ([235]), as does the value of intensive replacement therapy aimed at correcting the coagulation defect and thrombocytopenia.

Miscellaneous Obstetric Disorders Intravascular coagulation has been well documented after abortions induced by intraamniotic injection of hypertonic saline solutions ([236]) and hypertonic urea ([237]), but it apparently does not complicate abortions performed by suction curettage or those induced by prostaglandin F_{2a} ([232]).

DISSEMINATED INTRAVASCULAR COAGULATION IN NEONATES AND INFANTS Several disorders unique to the neonate and infant may be associated with DIC (Table 60.2) ([238]). The transplacental passage of thromboplastins or other procoagulant substances has been the apparent cause of DIC in neonates born of mothers affected with DIC owing to abruptio placentae, eclampsia, or septicemia. Asphyxia may be a common precipitating factor for DIC in these disorders ([239]). The development of DIC in a twin fetus has been attributed to “fetofetal” passage of thromboplastins ([240]). Bacterial infection and generalized viral infections (e.g., herpes simplex, cytomegalic inclusion disease, and rubella), acidosis, and hypoxia are more common causes of DIC in infants than in adults ([241]). DIC secondary to giant hemangiomas and purpura fulminans has been reported in neonates. Management of septic DIC in the neonate should emphasize treatment of underlying infection. A controlled study that compared treatment with heparin, extensive replacement therapy with blood products, and supportive care only revealed no significant differences in outcome for the three groups ([242]). A more recent study confirms that clinical trials in neonatal sepsis have not identified a beneficial therapy ([243]). DIC associated with sepsis produces bleeding with approximately the same frequency and in the same clinical patterns as in other forms of DIC ([244]). The diagnosis seldom is difficult, but DIC must be distinguished from septic shock, endotoxin shock, or simple thrombocytopenia, all of which may develop independently of DIC in severe infections ([245]). Therapy should be directed at the underlying infection and complicating shock, if present. In many patients, no additional measures are required. No evidence has been cited that heparin has diminished mortality ([204]). In one series, the alleviation of septic shock appeared to be more important in the ultimate prognosis than did correction of the coagulation abnormalities ([204]). Recombinant activated protein C has been demonstrated to reduce mortality in adult patients with sepsis ([246]). Whether this therapy is effective in neonatal or pediatric sepsis is unknown.

PURPURA FULMINANS The hemorrhagic manifestations of purpura fulminans develop several days after an acute infection; these are most commonly scarlet fever or various viral respiratory diseases ([244]). Purpura fulminans is most common in children but is also well documented in adults. The most common manifestations are symmetric ecchymoses of the lower extremities and buttocks, sharply circumscribed infarcts of the skin and genitalia, and gangrene of the extremities that often involves the digits symmetrically ([247]). These ecchymotic lesions often become necrotic, ultimately forming blood-filled bullae (Fig. 60.4). Petechiae are rare. Fever and prostration are seen, but visceral lesions, including renal involvement, are relatively uncommon. The mortality rate associated with purpura fulminans ranges from 18% ([244]) to 40 to 70% ([248]). Heparin in therapeutic doses has often proved therapeutically effective, and it has been suggested that poor results obtained previously with this anticoagulant reflect late treatment of moribund patients. In patients with purpura fulminans, relapses are particularly common after cessation of heparin therapy ([244]), and the administration of this anticoagulant, possibly in reduced doses, should always be continued for 2 to 3 weeks. Evidence that purpura fulminans may be a manifestation of homozygous protein C deficiency ([249]) is discussed in Chapter 61. The efficacy of protein C and activated protein C therapies in patients with sepsis and purpura fulminans is discussed below (see section Novel Therapies for Disseminated Intravascular Coagulation).

NEOPLASTIC DISORDERS

Carcinoma In patients with DIC associated with carcinoma, the clinical picture is quite variable and often consists of a combination of bleeding and thromboembolic phenomena, including arterial embolism ([122], [126], [127]). The association of chronic DIC, thromboembolism, and cancer is often called *Trousseau syndrome* ([122]). Laboratory findings are variable. Evidence of chronic DIC, hypercoagulability, or acute DIC may be found ([122], [126], [127]). In a study of more than 1000 patients with solid tumors, 7% were diagnosed with DIC using standard coagulation tests (platelet count, fibrinogen, D-dimer, FDPs) ([250]). Risk factors associated with the occurrence of DIC included older age, male gender, advanced disease, breast cancer, and necrosis of the tumor specimen ([250]). One reason for the variability in cancer patients having venous thromboembolism relates to the histology of the malignancy. Analysis of a very large database of Medicare patients with cancer identified tissue-specific differences in thrombotic risks among cancers ([251]). Those cancers with a high risk of thrombosis included uterine, brain, leukemia, ovary, and pancreas (= twofold risk), whereas prostate, liver, head or neck, bladder, and breast cancer had less than a onefold risk (compared to noncancer patients) ([251]). DIC in association with carcinoma disappears with effective treatment of the underlying tumor. Heparin or low-molecular-weight heparin in therapeutic doses has proved effective in controlling the hemorrhagic and thromboembolic symptoms ([122], [126], [252], [253]). There is a suggestion in the literature that the use of low-molecular-weight heparin therapy is associated with improved mortality in cancer patients ([254]). Prospective trials to formally address this hypothesis are under way. A significant minority of patients with cancer and thrombosis do not have success with oral anticoagulation ([122]) and benefit from long-term heparin or low-molecular-weight heparin. In the case of DIC associated with prostate cancer, adjunctive therapy with ketoconazole ([255]) or antiandrogens ([256]) may be useful.

Acute Promyelocytic Leukemia DIC has been reported in association with all forms of acute leukemia ([257]), but it is most common in the “hypergranular” promyelocytic variety ([258]), in which it may complicate from 60 to 100% of cases. The cause of the coagulopathy is multifactorial—tissue factor is present in the granules of the abnormal promyelocytes ([130]) as well as increased fibrinolysis and leukocyte proteases, including elastase ([259]). Enhanced fibrinolysis also results from increased promyelocyte expression of annexin II, a receptor for plasminogen and tissue-plasminogen activator ([132]). Additionally, the malignant promyelocytes contain plasminogen activators ([260]). The clinical picture usually is one of chronic progressive DIC with a significant fibrinolytic component that may antedate the other manifestations of the disease. Acute fulminant DIC may develop spontaneously or may be triggered by the administration of chemotherapeutic agents, which cause the release of thromboplastic contents of the promyelocytes. In some patients with acute leukemia, accelerated fibrinolysis is a conspicuous finding ([259]). In one series of patients, depletion of a $_2$-antiplasmin developed during induction of chemotherapy, a finding that was more predictive of bleeding complications than traditional indices of DIC, such as levels of fibrinogen, antithrombin, and plasminogen ([261]). This study suggests that “unregulated” fibrinolysis, by destroying functional hemostatic plugs and depleting fibrinogen, may be more important than DIC in some cases. In the past, heparin has produced clear-cut remissions in patients with chronic forms of DIC associated with acute leukemia. One approach ([259]) recommends fibrinogen replacement therapy for fibrinogen levels less than 100 mg/dl and platelet transfusion for platelet counts less than 20,000/μl. Fresh frozen plasma is given to patients with prolonged PT and PTT values who are bleeding. If the fibrinogen level is difficult to maintain over 100 mg/dl, or if FDP levels are rising, heparin is infused at 500 U/hour ([259]). When a $_2$-antiplasmin levels are below 30% of normal, EACA or another antifibrinolytic agent should be added to this regimen ([261]), and a $_2$-antiplasmin levels should be monitored during induction of chemotherapy. A newer approach that has virtually replaced the need for heparin and antifibrinolytic agents in the treatment of acute promyelocytic leukemia is the administration of all- *trans*-retinoic acid. This differentiation therapy appears to be successful ([262]). However, these patients still may require replacement therapy for hypofibrinogenemia and thrombocytopenia ([262]). Current protocols for acute promyelocytic leukemia combine all- *trans*-retinoic acid and combination chemotherapy to ameliorate the coagulopathy ([263]). Relapsed or refractory acute promyelocytic leukemic patients may benefit from arsenic trioxide therapy, another differentiation agent ([264]).

KASABACH-MERRITT SYNDROME (GIANT HEMANGIOMAS) The severity and incidence of DIC tends to parallel the size of the vascular tumors in the Kasabach-Merritt syndrome (Fig. 60.5) ([265]). Platelet consumption, activation of coagulation, and microangiopathic red cell destruction take place mainly within the hemangioma (“sequestered” or localized intravascular coagulation), but laboratory evidence of DIC in the general circulation usually is clear-cut ([162], [265]). Recurrent bleeding from the surface of the tumor is the major hemorrhagic manifestation; in the presence of DIC, this bleeding may be intractable. Periodic swelling of the lesions often is observed. This phenomenon may be a consequence of intermittent obstruction of blood outflow from the hemangioma and may provoke serious hemorrhage. Irradiation and corticosteroids have produced favorable results in a few cases, but surgical removal of the tumors has ultimately been required in most patients ([265]). Interferon-a has been successful in large numbers of patients; this cytokine probably acts as an antiproliferative/antiangiogenic agent ([265]). Antifibrinolytic therapy has been reported to be useful in controlling the coagulopathy ([266], [267]). Other useful therapies include cryoprecipitate and platelets for replacement therapy to correct a severe coagulopathy. The use of heparin therapy is uncertain ([265]).

Figure 60.5. Kasabach-Merritt syndrome in a 17-year-old girl. This giant hemangioma enlarged progressively during childhood. Chronic disseminated intravascular coagulation was present, which responded to heparin therapy. (Courtesy of William Futrell.)

For patients with aneurysms associated with DIC, low-molecular-weight heparin has been reported to be useful in resolving the coagulopathy ([268]).

SHOCK AND MASSIVE TRAUMA Heparin therapy may be hazardous for patients with massive injuries. Even in the face of DIC, intensive supportive care and replacement therapy with plasma and platelets are the mainstays of treatment ([269]). In the occasional patient who develops overt DIC in association with severe burns, heparin has proved effective in the management of DIC ([270]).

HEMOLYTIC TRANSFUSION REACTIONS DIC is present in many patients with hemolytic transfusion reactions. Severe, acute hemolytic transfusion events are triggered by antigen-antibody reactions that initiate complement activation and activation of coagulation ([271]). These reactions are usually a result of ABO incompatibility. These patients may experience not only DIC, but also shock and renal failure. Primary therapy is directed to control of hypotension and restoration of renal blood flow. Fluid, diuretics, and dopamine may be useful therapies. Heparin therapy for DIC in hemolytic transfusion reactions is controversial ([272]).

SNAKEBITE DIC associated with snakebite differs from the usual form of the syndrome in several respects. Hemorrhage may be relatively inconspicuous ([273]), even in the presence of incoagulable blood ([274]). When present, it is mainly the result of a vascular toxin. Platelets often are spared, although the venom of the timber rattlesnake (*Crotalus horridus horridus*) contains a unique serine protease that acts as a potent platelet activator ([275]). In some cases, a disorder manifested mainly by brisk fibrinolysis in the absence of evidence of DIC has been described ([276]). The specific coagulopathy seen in individual patients in large part depends on venom constituents present in the particular snake species. Detailed lists of venom constituents affecting hemostasis have been published ([166] , [168] , [170] , [171] , [274]). The treatment of snakebite involves the administration of specific antivenom and intensive supportive care. Heparin therapy has proved marginally effective at best ([273] , [277]). In general, it is not indicated when specific antivenom is available. Cryoprecipitate should be given to maintain the fibrinogen level over 100 mg/dl.

Pathology

The fatality rate associated with DIC is up to 60% ([175]). In many cases, death is attributed to bleeding or thrombosis. Mortality increases with age, the number of clinical manifestations, and the severity of laboratory abnormalities.

The deposition of fibrin in small vessels represents the ultimate result of DIC. In many patients, fibrin can be formed and lysed without significant vascular occlusion. Indeed, after autopsy, fibrin thrombi in some subjects were absent or were demonstrated only with special stains or by electron microscopy. This may result from postmortem lysis or from deposition of thin films of fibrin on the vast endothelial surface and on the erythrocytes. The localization of fibrin thrombi varies somewhat with the cause of DIC. The usual distribution of lesions in the gut, pancreas, adrenal glands, brain, liver, skin, and kidneys is well documented. Bone marrow necrosis is a rare finding. The kidney is the single most common site of fibrin thrombi. Renal lesions range from patchy tubular necrosis to massive bilateral cortical necrosis and have been attributed to a sieving effect of the renal microvasculature. Nonthrombotic endocarditis and pulmonary hyaline membranes have been found in many patients ([122] , [278]), especially those with cancer.

Novel Therapies for Disseminated Intravascular Coagulation

The recognition of pathogenic mechanisms critical in initiation or progression of DIC has led to investigation of new therapeutic agents in animal models of DIC and clinical trials in humans. For example, protease inhibitors such as aprotinin ([279]) or gabexate ([280]) have been studied. Because aprotinin use can be associated with thrombosis ([281]), concomitant therapeutic heparin may need to be used. However, survival advantages have not been shown with these agents. Similarly, high-dose antithrombin replacement therapy has no effect on mortality in patients with severe sepsis ([226]).

The key role of tissue factor in triggering DIC ([282]) has led to studies in which neutralizing antibodies to this procoagulant were found to prevent lethal septic shock in animal models ([283] , [284] and [285]). Inhibition of tissue factor activity by drugs such as dithiocarbamates has been investigated *in vivo* ([286]), and tissue factor pathway inhibitor is being studied in animal models and human DIC ([287]). A phase II study of recombinant tissue factor pathway inhibitor in septic patients demonstrated a trend toward mortality reduction and reduction in markers of activation of coagulation in treated patients ([288]). However, a phase III trial did not meet the primary endpoint in mortality reduction ([289]).

The role of protein C in ameliorating the mortality of sepsis has also been demonstrated; neutralization of protein C activity exacerbated the lethal response ([290]), and infusion of protein C ([291]) or activated protein C ([290]) prevented the lethal response in humans with meningococcemia or in a primate model, respectively. The promising results with these novel agents have been confirmed in human studies demonstrating that recombinant activated protein C significantly reduced mortality in patients with sepsis ([246]). It has been speculated that activated protein C may be more effective than protein C in treating sepsis patients because the vascular endothelium in these patients may be dysfunctional and unable to efficiently activate the zymogen for patients given protein C ([292]). However, there are no clinical data supporting this hypothesis.

In summary, although numerous agents have been tested in animal models of DIC, only activated protein C has been rigorously shown to alter clinical outcomes ([246]). There are suggestive, but unproven, data with protein C and tissue factor pathway inhibitor (Table 60.5).

TABLE 60.5. Novel Therapies for Disseminated Intravascular Coagulation

Classification of Therapy	Mechanism	References
TF inhibitors		
Monoclonal antibodies	Inhibits TF activity	283, 284 and 285
TFPI	Inhibits TF activity; binds to endotoxin	287, 288
Protein C pathway components		
Protein C	Promotes generation of APC	290, 291
APC	Promotes anticoagulation; inhibits inflammation	246, 292

TF, tissue factor.

NOTE: Human trials in sepsis/disseminated intravascular coagulation have been reported for tissue factor pathway inhibitor (TFPI), protein C, and activated protein C (APC). As of 2002, only APC has been demonstrated to improve survival (246).

PRIMARY FIBRINOLYSIS (FIBRINOGENOLYSIS)

Fibrinolysis is an appropriate response to thrombosis and necessary in the reestablishment of blood flow. This localized response, termed *physiologic fibrinolysis*, is discussed in Chapter 21. The term *pathologic fibrinolysis* has been used indiscriminately to refer to any situation in which *in vitro* evidence of fibrinolysis was associated with bleeding. In retrospect, it seems probable that fibrinolysis in many cases was secondary to DIC and that in others it represented an essentially physiologic response to anoxia, shock, or stress. In fibrinogenolysis, on the other hand, the proteolytic destruction of fibrinogen and other proteins occurs in the general circulation, and severe bleeding may develop. The pathophysiology of fibrinogenolysis may represent a disproportionate or "inappropriate" response to underlying DIC or may result from a defective fibrinolytic mechanism that may be inherited or acquired.

Etiology

Fibrinogenolysis may complicate various disorders, among which severe liver disease ([64]) is the most common. Fibrinogenolysis is a predominant laboratory feature in several patients with disseminated neoplasms ([293], [294] and [295]), especially urogenital neoplasms ([296]). The mechanism for enhanced fibrinolysis in these patients is probably increased secretion of plasminogen activators such as urokinase ([294]). Fibrinogenolysis and marked fibrinolysis rarely complicate the immediate puerperium ([232]), and they have been reported in association with acute promyelocytic leukemia ([259], [261]). Enhanced fibrinolysis has also been associated with cardiac bypass surgery ([297]) and aortic clamping during vascular surgery ([298]); the protease inhibitor aprotinin is effective in reducing blood loss in these patients ([299], [300]). Inherited deficiency of plasminogen activator inhibitor type-1 ([301]) or a $_2$-plasmin inhibitor ([302]) also results in hyperfibrinolysis and a bleeding tendency.

Pathophysiology

Fibrinogenolysis is a consequence of the generation of plasmin within the general circulation (plasminemia). Potent plasma inhibitors (antiplasmins) normally neutralize free plasmin rapidly (see Chapter 21); the result is that the proteolytic effects of this enzyme normally are restricted to fibrin. Fibrinogenolysis occurs only when the capacity of the antiplasmins is exceeded.

The proteolytic action of plasmin is nonspecific. In addition to fibrin and fibrinogen, this enzyme may degrade factor VIIIc, factor XIII, other coagulation factors, and a wide variety of other plasma proteins, such as complement and various hormones. Free plasmin also may activate bradykinin, a phenomenon that may underlie the marked hypotension present in some patients with fibrinogenolysis. Thus, *pathologic proteolysis* is an appropriate synonym for *fibrinogenolysis*.

Fibrinogenolysis is activated by mechanisms that are remarkably similar to those that initiate DIC. Therefore, tumor tissue contains plasminogen activators in addition to tissue factor ([294]). The secretion of these activators into the circulation may rapidly activate most of the circulating plasminogen.

Hypoxia and hypoperfusion may lead to plasminogen activation and, occasionally, to fibrinogenolysis. However, in many of these patients, bleeding is minimal; when present, it cannot be clearly related to the presence of fibrinogenolysis. In these patients, fibrinogenolysis probably is a nonspecific, essentially physiologic response. Fibrinogenolysis may also result from therapy with thrombolytic agents, as discussed in Chapter 61.

Clinical Features and Laboratory Diagnosis

The clinical picture in most reported cases of fibrinogenolysis is similar to that of DIC. The usual laboratory findings are summarized in Table 60.2 and are discussed in an earlier section of this chapter. Hypofibrinogenemia may be seen. The PTT, PT, and thrombin time may be prolonged because of the anticoagulant effects of FDPs. Moderate concentrations of EACA (4×10^{-4} mol/L) inhibit plasminogen activators but not free plasmin. Thus, the euglobulin lysis time, which invariably is shortened in patients with fibrinogenolysis, is unaffected by the addition of EACA if free plasmin is present. Fibrinolysis in heated fibrin plates also measures free plasmin because plasminogen activators are thermolabile. Among the coagulation factors, factors V and VIIIc are the most sensitive to the proteolytic action of plasmin; factor XIII also is deficient in some patients. The plasma levels of other factors (e.g., factors VII and IX), including some that are degraded by plasmin *in vitro*, usually are normal in patients with fibrinogenolysis. Depletion of plasminogen and a $_2$-antiplasmin and the presence of a $_2$-antiplasmin–plasmin complexes in the plasma also may be demonstrated in many patients with fibrinogenolysis and in those with DIC and active fibrinolysis ([303]).

The standard FDP test does not discriminate between fibri-nogen degradation products and fibrin degradation products. Measurements of fibrinopeptide A and the D-dimer, which is a specific indication of degraded cross-linked fibrin, yield normal results in fibrinogenolysis. Thus, patients with hypofibrinogenemia, prolonged PT and PTT values, elevated FDP levels, and a normal D-dimer may have primary fibrinogenolysis. In the absence of intravascular coagulation, paracoagulable complexes containing fibrin monomers do not form in plasma; thus, plasma protamine gelation tests are negative in fibrinogenolysis. Assays for plasminogen and for the various inhibitors of the fibrinolytic enzyme system may reveal a pattern of depletion. In addition to normal results for D-dimer, patients with fibrinogenolysis have normal platelet counts or mild thrombocytopenia with bleeding out of proportion to the reduction in platelet count ([294]).

Treatment

Antifibrinolytic agents would seem therapeutically desirable in the treatment of fibrinogenolysis; however, these drugs are hazardous in the presence of DIC ([109]). EACA and related agents are specific and potent inhibitors of fibrinolysis and fibrinogenolysis ([304]). In low concentrations (10^{-4} mol/L), EACA inhibits plasminogen activation competitively; in high concentrations (0.06 M), it inhibits plasmin directly in a noncompetitive manner. The clinical effectiveness of this drug is dramatic in carefully selected patients ([305]). EACA should be administered intravenously (0.1 g/kg every 6 hours, up to 24 g/day) if bleeding is severe. The drug is absorbed rapidly after oral administration, and intravenous doses of 1 g/hour, after a 5-g loading dose, are also effective. The total dosage should not exceed 24 g in a 24-hour period. Tranexamic acid is a newer antifibrinolytic agent that, like EACA, possesses the ability to bind to the lysine binding sites of plasminogen, thereby preventing plasmin that is generated from binding to fibrin. The oral dosage of tranexamic acid is 25 mg/kg, three or four times daily. The intravenous dosage is 10 mg/kg given three or four times daily.

Because antifibrinolytic agents are potentially dangerous drugs in the presence of DIC ([109]), the diagnosis of DIC should be excluded in these patients using a specific test, such as D-dimer, before administering these agents. Patients with DIC and a substantial secondary fibrinolytic component should be considered for heparin therapy before administration of antifibri-nolytics ([296]).

Patients with hormone-refractory prostate cancer and fibri-nogenolysis have been reported to benefit from docetaxel, with resolution of bleeding symptoms and laboratory evidence of hyperfibrinolysis ([306]).

Pathologic Inhibitors of Coagulation

Circulating anticoagulants are pathologic endogenous inhibitors that can act at any stage in the process of coagulation. Most are antibodies that act as specific inhibitors, inactivating a single coagulation protein. The clinical and laboratory manifestations resemble the corresponding inherited coagulation disorders in many respects. Antibody disorders with wider effects on the coagulation system are sometimes seen, especially in the antiphospholipid–protein antibody (APA) disorders that have been traditionally called the *lupus inhibitor syndrome*. Other inhibitors of coagulation often have heparinlike activities and are much less common.

Antibodies to Factor VIII

Factor VIII is the most common target of monospecific acquired anticoagulant antibodies ([307]). Conditions that are associated with monospecific factor VIII antibodies are outlined in Table 60.6.

TABLE 60.6. Conditions Associated with Monospecific Factor VIII Antibodies

Alloantibodies in hemophilia A
Autoantibodies in nonhemophilic patients
  Autoimmune disease
    Systemic lupus erythematosus
    Rheumatoid arthritis
    Dermatologic conditions
      Psoriasis
      Pemphigus vulgaris
    Pregnancy (peripartum)
    Malignancy
      Lymphoproliferative disorders
      Plasma cell dyscrasias
      Nonhematologic
  Medications: penicillin, sulfa antibiotics, chloramphenicol, phenytoin
  Idiopathic

ALLOANTIBODIES IN HEMOPHILIA A

Frequency of Inhibitors In older retrospective studies, alloantibodies to factor VIIIc were noted in 5 to 20% of patients with hemophilia A, averaging approximately 5 to 10% in all patients with hemophilia and approximately 10 to 15% in those more severely affected ([308], [309] and [310]). Prospective studies suggest a higher incidence of inhibitors than that historically appreciated ([311], [312] and [313]) (up to 45%), even in patients treated with traditional factor VIII concentrates. However, many patients have only transient inhibitors, and perhaps only 5 to 10% of hemophiliacs have persistent inhibitors ([314]). As a consequence, initial concerns ([315], [316]) based on historical prevalence controls suggesting that newer factor VIII concentrates, such as those purified by monoclonal antibody affinity chromatography or produced by recombinant technology, might be inducing an increased percentage of inhibitors that appear to be allayed. In fact, continued longitudinal surveillance of patients receiving such products indicates a similar or perhaps lower incidence of clinically significant persistent inhibitor induction ([317], [318]). Those at high risk of development of inhibitors include patients with CRM-negative severe hemophilia A whose factor VIII mutation prevents factor VIII synthesis or patients with CRM-positive mild or moderate hemophilia A whose factor VIII mutation in the A2 domain or near the junction of the C1-C2 domains results in an abnormal factor VIII molecule ([314]). This latter mutation results in a factor VIII molecule identified by the patient's immune system as abnormal. Other factors affecting the risk of inhibitor development include the patient's HLA class II haplotype and the type of factor VIII therapy used ([314]). Additional reports have confirmed these conclusions in patients with mild to moderate hemophilia ([319], [320]). A recent provocative study reported that patient age at initiation of therapy was an independent risk factor for inhibitor development ([321]). Patients beginning therapy before 6 months of age had three times the rate of inhibitors than patients beginning therapy after 1 year of age ([321]). If these data are confirmed, exposure of hemophilia A patients to factor VIII should be delayed, and patients should be treated with other products during the first year of life.

Induced Antibody Titer It is recognized, particularly in patients with mild hemophilia, that 50 to 75% of inhibitors are subclinical, occur relatively early (median of 10 days) after product exposure, are of low titer, are transient, and often resolve even with continuing product exposure ([313], [317]). Hemophiliacs with inhibitors can be categorized as either strong or weak responders to administered factor VIII. Once an antibody has developed in a hemophiliac, further administered factor VIII may act as an inducing antigen. Additionally, it has been appreciated that certain factor VIII products, depending on the manufacturing process, may be immunogenic in hemophilia A patients ([314]).

AUTOANTIBODIES TO FACTOR VIII IN THE NONHEMOPHILIC PATIENT It is estimated that acquired factor VIII autoantibodies are seen in 0.2 to 1.0 person/million population annually ([322]). Monospecific antibodies to factor VIII can arise spontaneously in association with various autoimmune and chronic inflammatory diseases, such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and ulcerative colitis ([323], [324] and [325]). Antibodies to factor VIII can develop in the puerperium ([326]), usually appearing at term or within several months after parturition in association with a first pregnancy. The antibody may disappear spontaneously in postpartum patients after 12 to 18 months. Reappearance during subsequent pregnancy seems to be very unusual, and in those patients who have persistent antibodies, remission can occur during a subsequent pregnancy ([327]). Acquired hemophilia may also be seen in association with hematologic malignancies and solid tumors ([328], [329] and [330]); certain medications such as penicillin ([331]), sulfa antibiotics, chlorpromazine ([332]), and phenytoin ([333]); and dermatologic conditions such as psoriasis and pemphigus vulgaris ([324]). Most often, acquired factor VIII antibodies are idiopathic, particularly in older persons without apparent underlying disease ([334]). In children, penicillin therapy appears to be a significant risk factor for development of antibodies to factor VIII ([331]).

Pathophysiology of Development of Antibodies to Factor VIII The immunologic mechanism that underlies inhibitor induction in a select minority of patients with hemophilia A and the corresponding presumed lack of immunologic tolerance is unclear. Although inhibitor induction is more common in more severely affected patients, inhibitors are also seen in mild hemophilic patients ([319], [335], [336]). In patients with severe hemophilia, major deletions, the intron 22 inversion, nonsense mutations, and early initiation of replacement therapy are risk factors for antibody development ([314], [318], [321], [331]). Underlying genetic susceptibility factors have been suggested by studies of brother pairs with a significant predisposition to the development of inhibitors ([337]). Specific associations between factor VIII genotype and HLA class II phenotype have been made ([338]), but the associations are weak. Genetic influences on inhibitor development are postulated to be additive and polygenic ([338]). Mutations resulting in a major loss of factor VIII gene coding information and a lack of circulating factor VIII antigen are associated with a high incidence of inhibitor formation ([339]). For example, a high frequency (70%) of inhibitor development is seen in patients with either large, multidomain deletions or nonsense mutations in the factor VIII A3 domain ([340]). Fewer patients with other gene defects (missense point mutation) form inhibitors. However, the presence of inhibitors is not consistent, even in a given family with similar factor VIII mutations, suggesting that other factors contribute to induction of factor VIII antibodies ([314]). Another hypothesis as to how inhibitors to factor VIII might occur is that these antibodies arise from the expansion of preexisting natural factor VIII clones that possess neutralizing properties ([341]); such antibodies have been identified from the IgG fraction of plasma from normal people ([341]). Clonal expansion of anti–factor VIII antibodies may be modulated by the presence of antiidiotypic antibodies ([342]). The immunizing events leading to the spontaneous development of antibodies in nonhemophilic individuals remain obscure. Incompatibility between maternal and fetal allotypes of factor VIII could explain the development of antibodies in the puerperium, but little evidence supports this hypothesis. No evidence exists that exogenous factor VIII acts as an antigen in nonhemophilic patients. Clonal expansion of preexisting factor VIII antibodies has been postulated to also explain autoantibodies in nonhemophilic patients ([341]).

Characteristics of Factor VIII Inhibitory Antibodies The majority of antibodies to factor VIII are IgG immunoglobulins ([343]) that appear to be specific for the coagulant subunit of the factor VIII complex (VIIIc) ([344], [345]). Common epitopes for allo- and autoantibodies include those in the A2 domain, the C2 domain, or both ([346]). Typically, hemophilic alloantibodies recognize both domains ([347]), whereas autoantibodies recognize the C2 domain more frequently than the A2 domain ([346]). Circulating factor VIII immune complexes have been identified in plasma from patients with acquired hemophilia A with autoantibodies ([348]). IgA or IgM inhibitors are rare, as are antibodies that inhibit both VIIIc and vWF ([349]).The factor VIII inhibitory antibody subunits in hemophilia A show limited heterogeneity ([350]) but are not truly monoclonal. In nonhemophiliacs, antibodies to factor VIII more often reveal normal heterogeneity of their subunits. Antibodies to factor VIII are disproportionately often of the IgG_4 subclass and do not fix complement. Precipitation and immunodiffusion techniques usually yield negative results because the factor VIII–antibody complex is soluble under most conditions ([351]). Antibodies inactivate factor VIII in a time- and temperature-dependent process ([352]), the kinetics and stoichiometry of which are variable. Two types of antibody inhibition are described ([353]): Type I inhibitors completely inhibit factor VIII activity following second-order kinetics (linear time course of inactivation); these antibodies are seen in hemophilia patients ([354]). Type II inhibitors have complex kinetics and do not completely inhibit factor VIII activity; these are autoantibodies seen in nonhemophilic patients ([355]). The type II inhibition phenomenon may produce aberrations in the assay system and may explain certain puzzling laboratory features in atypical cases, such as detectable factor VIII clotting activity in a patient with a high-titer inhibitor ([356]). A report on alloantibody inhibition of factor VIII activity indicated that certain alloantibodies possess catalytic activity that can proteolyze factor VIII ([357]).

Laboratory Evaluation Simple mixing techniques based on the PTT usually suggest the presence of an inhibitor. Factor VIII levels usually are undetectable in severely affected patients but may be detectable in patients with autoantibodies. Specific tests for antibodies involve the demonstration of progressive and time-dependent inactivation of factor VIII *in vitro* by the plasma or serum of the patient. Methods for detecting low-titer inhibitors and for quantifying the levels of antibody have been devised ([358]), and standardized inhibitor units [the Bethesda unit in the United States ([359]) and the Oxford unit in Britain ([360])] have been defined. In the Bethesda assay, *in vitro* tests are performed at 37°C using 2-hour incubation mixtures of various dilutions of patient plasma with normal plasma. The inhibitor titer is the reciprocal of the dilution of inhibitor plasma that neutralizes 50% of normal factor VIII activity. Because the Bethesda assay may underestimate the inhibitor titer in acquired hemophilia, it is recommended that the titer should be calculated from the lowest dilution that results in 50% residual factor VIII activity after the incubation period ([361]). The New Oxford method measures residual activity at 37°C after a 4-hour incubation. A Bethesda unit is generally equivalent to 1.21 Oxford units. The standard Bethesda assay does not control pH, permitting variable low-level inactivation of factor VIII by nonimmunologic mechanisms. The Nijmegen

modification controls pH, thus improving classification of positive and negative samples ([359]). The Nijmegen modification of the Bethesda assay has been endorsed by the ISTH ([362]). Additional improvements in this assay have been described ([363]). Although an inhibitor unit does not imply that any specific number of factor VIII units infused into the patient will neutralize any specific number of inhibitor units, the titer provides a general estimate of the initial likelihood of response to infusion of factor VIII products.

Clinical Manifestations Acquired factor VIII inhibitors may explain some reports of hemophilia in women and may also underlie apparent occult hemophilia presenting later in life. The bleeding manifestations resulting from antibodies to factor VIII are often similar to those seen in hemophilia A ([324], [334], [364]). Prolonged or unexpectedly severe hemorrhage may occur after comparatively trivial trauma, postoperatively, or postpartum. Soft tissue or muscle hematomas, hematuria, and spontaneous and intractable epistaxis seem relatively common. For unknown reasons, hemarthrosis is relatively less common than in congenital hemophilia A, but it may be severe ([364]). Figure 60.6 illustrates soft tissue hematomas occurring in a nonhemophilic patient with an acquired inhibitor to factor VIII. When antibodies arise in patients with mild hemophilia A, bleeding typical of severe deficiency may develop; more significant, the bleeding may be refractory to replacement therapy. This condition may have serious consequences, and fatal events are seen in 10 to 20% of clinically symptomatic patients ([324], [365]). Antibodies to factor VIII arising during pregnancy may cross the placenta.

Figure 60.6. Soft-tissue hemorrhage in a 76-year-old man with a high-titer factor VIII inhibitor. This patient has a history of ischemic cardiomyopathy and diabetes and developed spontaneous extremity bruising as shown. The antihuman factor VIII antibody titer was 10 Bethesda units. See Color Plate. (Courtesy of Alan Grosset.)

Treatment The treatment of bleeding in patients with antibodies to factor VIII presents several challenges ([366], [367]). No adequate randomized trials have been conducted to evaluate different forms of therapy or to investigate the timing and sequence of their application; therefore, practical treatment decisions are somewhat arbitrarily based on estimates of benefits and risks deduced from retrospective literature review and consideration of each patient's circumstances and comorbidities. A consensus group from the United Kingdom has published guidelines on treatment of inhibitors in patients with hemophilia ([368]). An algorithm that has some general applicability is shown in Figure 60.7. As a first step, basic clinical information should be obtained, including whether the inhibitor arose in the setting of hemophilia or is acquired; the severity of bleeding; anticipated surgical procedures; inhibitor titer and persistence; prior inhibitor response and relation in time to previous factor infusions; possible triggering events such as recent medication exposure or pregnancy; and the presence of other diseases. For example, the mere presence of an inhibitor may in itself not warrant immediate therapy because we now know that many inhibitors are present in low titer and are often transient. Spontaneous remissions may occur in a significant number of patients, particularly if the inhibitor develops after penicillin therapy ([335]) or during the puerperium ([326]). At the other end of a spectrum, an unfortunate clinical scenario might involve significant spontaneous clinical hemorrhage, a persistent high-titer inhibitor, and incidental comorbidities such as cardiac, hepatic, or renal insufficiency.

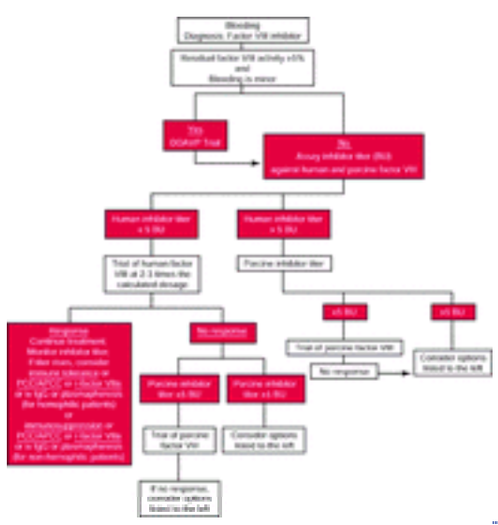

Figure 60.7. A strategy for management of factor VIII inhibitors in hemophilic and nonhemophilic patients. Key decisions are based on antihuman and antiporcine factor VIII inhibitor titers. Multiple options for patients not responding to human or porcine factor VIII are available. BU, Bethesda units; DDAVP, 1-desamino-8-D-arginine vasopressin; PCC/APCC, prothrombin complex concentrate/activated prothrombin complex concentrate. Rituximab is an emerging treatment option for nonhemophilic patients. (Information in this figure is from the literature, including Morrison AE, Ludlam CA. Acquired haemophilia and its management. Br J Haematol 1995;89:231–236.)

In patients with low-titer inhibitors who do not have any clinical bleeding and for whom no surgical procedures are foreseen, the most reasonable approach may be to monitor the abnormal laboratory finding. Steroids and cytotoxic therapy (usually cyclophosphamide) are usually ineffective when inhibitors arise in patients with congenital hemophilia A, but they are effective in the setting of nonhemophilic patients ([322], [324], [369]). Cyclosporin has also been used to treat acquired antibodies to factor VIII ([370]). Procedures or medications (antiplatelet drugs) that would increase hemostatic risks should be avoided, and ancillary local therapeutic measures to control minor bleeding are recommended and may in themselves be sufficient. For patients with minor bleeding who have residual factor VIII activity greater than 5% of normal, DDAVP therapy may be helpful (0.3 μg/kg, up to 24 μg maximal dose) ([322], [371]). Antifibrinolytic therapy, such as the administration of EACA or tranexamic acid, may be helpful, especially in dental procedures; however, this therapy should be used cautiously in muscle bleeds because it appears to be less effective, and it should not be used in conjunction with the PCCs or activated prothrombin complex concentrates (APCCs). The inhibitor titer and its prior response to factor VIII infusion may be of particular use in guiding therapeutic decisions (Fig. 60.7). As a rule, replacement therapy with factor VIII in the usual doses is ineffective. If clinical bleeding mandates active therapy, patients with a low Bethesda titer (<5 U/ml), particularly if they are known to be low-responders, usually respond to high-purity or recombinant human factor VIII ([368]) given as a large initial 150 U/kg bolus followed by a continuous infusion of 1000 U/hour. The therapeutic response to human factor VIII should be clinically assessed; factor VIII levels and repeat assays of inhibitor titer response may be helpful. Therapy with human factor VIII is seldom successful in patients with high-titer antibodies (>5 Bethesda U/ml), high-affinity antibodies, and infinite coagulation times ([322]). As an alternative, particularly in patients with high-titer inhibitors or a history of an anamnestic response, or routinely in medical centers that prefer to reduce the uncertain risk of inducing an increased inhibitor titer, the use of inhibitor-bypassing products may be useful. These include the PCCs, APCCs, and rVIIa. There is no consensus as to the best therapeutic approach ([372]). For example, 75 U/kg PCCs that provide a complex of the vitamin K–dependent factors, such as Konyne, but not high-purity or recombinant factor IX products, may bypass the inhibitor, probably by providing activated factors (discussed in Chapter 59). The use of these concentrates is successful in approximately 50% of bleeding events ([373]), but prolonged and repeated infusions of PCC can be associated with a risk of thrombotic complications ([374]), DIC, and possible viral transmission. PCC products that are intentionally activated (APCCs, e.g., FEIBA and Autoplex; sometimes called *antiinhibitor coagulant complexes*) may be effective if PCC is ineffective, but theoretically, they carry an increased risk of inducing thrombosis ([375]). Recommended doses of APCC (Autoplex-T) are 80 to 100 U/kg at 4- to 8-hour intervals ([376]). PCC and APCC products have trace amounts of factor VIII antigen and rarely cause an increased inhibitor response, although this has been reported ([377]). rVIIa is a new treatment option for inhibitor patients ([378], [379]). This drug was originally thought to exert activity by binding to tissue factor at sites of vascular injury to initiate coagulation. More recent data indicate that at the pharmacologic concentrations of factor VIIa achieved during rVIIa therapy, there may be platelet-dependent, tissue factor–independent mechanisms to mediate hemostasis ([380]). The standard dose of rVIIa is 90 μg/kg every 2 hours for serious bleeding ([381]) or 90 μg/kg every 3 hours for mild to moderate bleeding in home treatment ([382]). Continuous infusion of rVIIa is also effective, targeting factor VII levels to 30 to 40 U/ml ([383]). rVIIa is also a useful therapy in children with inhibitors and serious bleeding ([384]). rVIIa, like PCC and APCC therapy, is associated with potential thrombotic complications, although the thrombosis rate appears to be low ([381], [382]). However, additional long-term monitoring of rVIIa adverse events is important ([385]). There are no studies directly comparing the efficacy of rVIIa versus PCC or APCC in inhibitor patients with serious bleeding. These products have similar efficacies ([386], [387]), and consensus recommendations generally include multiple treatment options ([368], [388]). For refractory patients, sequential therapy with PCC and rVIIa has been reported ([389]). Another useful product in inhibitor patients is porcine factor VIII (Hyate:C). Obtaining an antiporcine antibody titer is useful, but as a rule of thumb, the initial antiporcine titer is often 25% of the antihuman titer. However, the antiporcine titer may rapidly rise after administration of porcine factor VIII, and its use is associated with occasional thrombocytopenia. A 1994 survey reported that 80% of porcine factor VIII infusions in hemophilic patients with inhibitors resulted in a good or excellent clinical effect, with less than 10% of infusions resulting in a nonresponse ([390]). Some investigators consider porcine factor VIII to be the therapy of choice for patients with factor VIII antibodies in which the antibody has minimal cross-reactivity

to porcine factor VIII ([391]), and consensus groups consider porcine factor VIII an appropriate treatment option ([368] , [388]). A literature review ([392]) of the efficacy of intravenous Ig in the treatment of acquired factor VIII antibodies found a cumulative response rate of only 12%, suggesting that other modalities should be attempted first for these patients. In some patients with low- to intermediate-titer inhibitors (<5 Bethesda units), initial plasmapheresis with adsorption to a protein A column ([393]) or, sometimes, with adjunctive administration of intravenous Ig (1 g/kg for 2 days) ([342]) is used, but this approach is usually unsatisfactory because it is time consuming and ineffective in rapidly reducing levels of IgG. Standard immunosuppression should be reserved for patients with autoantibodies because this therapy is rarely beneficial in the alloimmune setting. Corticosteroids (e.g., prednisone in doses of 1.0 to 1.5 mg/kg/day) produced some improvement in approximately 50% of patients when administered on a long-term basis ([324]), with the best results obtained with nonhemophilic patients. Similar therapeutic responses have been reported when immunosuppressive drugs, such as cyclophosphamide (2 to 3 mg/kg/day), were administered alone or with prednisone ([369]). Remission of bleeding and reduction of antibody titer have been well documented, but total suppression of the antibody is rare. A randomized trial of steroid and cytotoxic therapy has reported that one-third of patients responded to steroids alone and that 50% of steroid nonresponders could be successfully treated with a cytotoxic drug (cyclophosphamide) with or without steroids ([394]). More recent reports confirm the efficacy of this regimen ([395]). Rituximab, a monoclonal antibody to the CD20 antigen on B cells, has been reported to be effective in initial case series of patients with acquired factor VIII antibodies ([395a]). In many patients with hemophilia A who have developed antibodies to factor VIII, infused factor VIII provokes a rapid increase in the antibody titer. However, in many of these patients, the administration of large doses of factor VIII for periods of months to years may produce immune tolerance to factor VIII. An international registry of patients treated with this approach reported that approximately 70% of patients achieved long-lasting tolerance ([396]). A 1997 update of this registry indicated that 52% of patients were successfully treated with immune tolerance ([397]). Several immune tolerance regimens have been summarized ([398] , [399]). The registry data suggest that success of inducing tolerance is greatest in patients given more than 100 U/kg/day factor VIII who had an initial inhibitor titer of less than 10 Bethesda U ([396] , [397]). Data from the North American Immune Tolerance Registry have been reported; the overall success rate was 70% ([400]). Achievement of tolerance to factor VIII in hemophilia A patients with inhibitors is associated with the development of antiinhibitors (idiotypes) ([401]). The cost-effectiveness of immune tolerance therapy has been demonstrated ([402]), but questions related to ideal patient selection and the optimal regimen remain ([403]).

Monospecific Antibodies to Other Coagulation Factors

Table 60.7 summarizes certain conditions associated with antibodies to other coagulation factors.

TABLE 60.7. Acquired Disorders Associated with Deficiency of a Single Coagulation Factor

Deficient Factor	Specific Inhibitors [a]	Other Disorders
Fibrinogen	Hereditary afibrinogenemia (437); lupus erythematosus; liver disease	—
Prothrombin	Previously normal persons (438)	Lupus inhibitors (440)
Factor V	Previously normal persons (413); often associated with streptomycin (414, 415); rarely in inherited factor V deficiency; postoperative patients who received bovine thrombin (416, 417, 418, 419, 420 and 421)	Chronic myelocytic leukemia (688)
Factor VII	Bronchogenic carcinoma (447), acquired immunodeficiency syndrome (448)	Aplastic anemia (659), liposarcoma (660)
Factor VIII (VIIIc)	Hemophilia A (310); puerperium (326); inflammatory disorders; drug reactions; in absence of underlying disease (324)	—
von Willebrand factor	Previously normal persons; lymphoproliferative disorders (427, 428, 429 and 430); rarely in von Willebrand disease; thrombocytosis	Wilms tumor (687)
Factor IX	Hemophilia B (404, 405); rarely in previously normal persons (406)	Nephrotic syndrome (653); Sheehan syndrome (657); Gaucher disease (658)
Factor X	—	Amyloidosis (643, 644, 645, 646, 647, 648, 649 and 650); upper respiratory infection (446)
Factor XI	Lupus erythematosus (443); rarely in inherited factor XI deficiency (444); previously normal persons (442, 445)	—
Factor XII	Lupus erythematosus, rarely	Nephrotic syndrome; chronic myelocytic leukemia
Factor XIII	Previously normal persons, often associated with isoniazid (433); rarely in inherited factor XIII deficiency (431)	Acute and chronic leukemia (661), Crohn disease (662)

[a] Evidence suggests these inhibitors are antibodies. In patients with inherited deficiencies of the various factors, their development usually is related to transfusion of blood or blood products.

FACTOR IX Inhibitors of factor IX have been demonstrated in approximately 5% of patients with hemophilia B ([404] , [405]) and rarely in previously normal persons (acquired hemophilia) ([406]). Hemophilia B patients who acquire antibodies to factor IX often have gross gene deletions ([407]). In contrast to antibodies to factor VIII, factor IX antibodies act instantaneously. One series of eight hemophilia B inhibitor patients found that antibodies typically were IgG_1 and IgG_4, and that the antibodies targeted the Gla domain and protease domain epitopes of factor IX ([408]). Extracorporeal immunoabsorption of the blood of one patient with a factor IX inhibitor with protein A-Sepharose resulted in marked diminution in antibody concentration ([409]). More recently, rVIIa ([410]) or immune tolerance therapy ([400]) has been used, although immune tolerance for hemophilia B inhibitor patients may be less effective than for hemophilia A inhibitor patients ([411]). PCCs are also a treatment option ([412]). Patients with antibodies to factor IX may experience anaphylaxis when treated with factor IX–containing products ([411]); rVIIa may be the appropriate therapy for this patient group. A British consensus group has published guidelines on treating factor IX inhibitor patients ([368]).

FACTOR V Inhibitors of factor V ([413]) have developed spontaneously in previously normal older persons after administration of streptomycin ([414] , [415]), gentamycin, or penicillin and after surgical procedures. More rarely, factor V inhibitors have been associated with tuberculosis, femoral fracture, and bullous pemphigoid and, occasionally, in inherited factor V deficiency after transfusion. These antibodies are usually of IgG isotype. Alloantibodies to factor V may occur in factor V–deficient patients who receive blood products ([416]). Over the past 20 years, an iatrogenic coagulopathy has been identified: the occurrence of antibodies to thrombin and factor V in patients treated with bovine thrombin during surgery ([416] , [417]). The antithrombin antibody neutralizes bovine thrombin and therefore can prolong the thrombin time when bovine thrombin is used for this test ([418] , [419] and [420]). However, no clinically significant hemostatic defect appears to result from this single laboratory abnormality. Some patients acquire additional antibodies to human factor V, which may result in significant factor V deficiency and bleeding ([418] , [419]). In a large surgical series of patients exposed to bovine thrombin, more than 95% of patients developed antibodies to bovine thrombin or factor V, and 50% of these patients had antibodies cross-reacting to human coagulation proteins ([421]). These latter patients have a bleeding risk ([421]). In contrast to most other specific inhibitors, antibodies to factor V seldom produce serious hemorrhage ([416] , [422]). Patients with alloantibodies to factor V typically have significant bleeding ([421]). In several patients with severe hemorrhage, platelet transfusions were therapeutically more effective than plasma ([423] , [424]). Plasmapheresis ([425]) and immunosuppression have been reported to be effective in resolving antibodies to factor V. In some cases, these antibodies resolve spontaneously ([421]). A small number of patients have been described with thrombosis symptoms associated with factor V antibodies. These patients may ([416]) or may not ([426]) have coexisting antiphospholipid antibodies.

VON WILLEBRAND FACTOR Acquired von Willebrand disease (vWD) has been reported in association with a variety of disorders, primarily including patients with lymphoproliferative disorders, myeloproliferative disorders, solid tumors, and autoimmune disease. An international registry identified lymphoproliferative and myeloproliferative disease as accounting for more than 60% of acquired vWD ([427]). A literature review concluded that most cases of acquired vWD result from an antibody that recognizes high-molecular-weight multimers of vWF and mediates subsequent antigen-antibody clearance ([428]). Another mechanism for the development of this disorder includes adsorption of vWF by tumor cells ([429]). Ristocetin cofactor activity is usually decreased, whereas factor VIII activity may be normal ([427]). In most patients, the hemostatic abnormalities disappear when the underlying disorder is treated. For patients with acquired vWD resulting from a lymphoproliferative disorder or monoclonal gammopathy, intravenous Ig may be effective ([430]). The consensus group recommends a trial of DDAVP as initial therapy

([427]); DDAVP failures are then treated with vWF concentrates (e.g., Humate-P) ([427]). Intravenous Ig is reserved for those patients having no success with DDAVP and vWF concentrates ([427]).

FACTOR XIII Inhibitors of factor XIII have been described after transfusions in patients with inherited deficiency of this proenzyme and in previously normal persons ([431], [432]). Many of the latter group had received isoniazid ([433]), and it was suggested that this drug may alter factor XIII in such a manner that it becomes antigenic ([434]). These inhibitors may recognize the zymogen, impair the activation of factor XIII by thrombin, or may be directed against the cross-linking sites of fibrin ([432]). In one case, cyclophosphamide was therapeutically effective ([435]). A factor XIII concentrate, Fibro-gammin, if available, may also be useful ([436]).

FIBRINOGEN AND PROTHROMBIN A precipitating antibody to fibrinogen has been demonstrated after transfusions in patients with hereditary afibrinogenemia ([437]). Dysfibrinogenemia may occur in patients with liver disease or hepatoma (discussed in the section Deficient or Aberrant Synthesis of Coagulation Factors). Antibodies to prothrombin have also been reported ([438]). An unusual case of an autoantibody to prothrombin was described; the antibody induced protease activity from the zymogen, leading to neutralization by antithrombin ([439]). Hypoprothrombinemia usually occurs in the setting of the lupus anticoagulant when patients have antibodies to prothrombin that clear prothrombin activity from blood ([440], [441]).

FACTOR XI Specific inhibitors of factor XI have been described ([442]), most often in association with autoimmune disease ([443], [444] and [445]).

FACTOR X Antibodies to factor X are highly associated with upper respiratory tract infections ([446]), either viral or mycoplasma; however, in these cases, inhibitors to factor X have been directly proved infrequently ([446]). Bleeding has been controlled using PCCs ([446]).

FACTOR VII Antibodies to factor VII are rare, having been reported in lung cancer ([447]) and human immunodeficiency virus infection ([448]) and with no apparent disorder ([449]). Immunosuppression has been used successfully in anecdotal case reports of autoantibodies to factor VII ([450]).

TISSUE FACTOR Antibodies to tissue factor are very uncommon, with one group reporting two patients who developed anti–tissue factor antibodies after liver surgery ([451]). Similar to patients who acquire antithrombin and anti–factor V antibodies after use of fibrin glue ([416], [417] and [418]), the patients who developed anti–tissue factor antibodies were both treated with a topical hemostatic agent prepared from bovine tissue that contained tissue factor. The antibodies to bovine tissue factor did not cause clinical bleeding but did prolong PT values ([451]).

Antiphospholipid–Protein Antibodies: Lupus Anticoagulants and Anticardiolipin Antibodies

HISTORICAL CONSIDERATIONS AND NOMENCLATURE The two most important clinical types of antiphospholipid–protein antibodies are traditionally called *lupus anticoagulant* (LA) and *anticardiolipin* (aCL) *antibodies*. These antibodies are associated in some patients, but not in others, with clinical illness ([452], [453], [454] and [455]) of varying severity. Individual patients may manifest arterial or venous thromboembolic disease, thrombocytopenia, recurrent pregnancy loss, and neurologic and skin abnormalities. The clinical importance, particularly of the LA or higher-titer aCL antibodies, has been increasingly recognized; these antibodies or their functional consequences are found in approximately 10% of patients with venous thromboembolic events ([456], [457]). Bleeding is quite uncommon, and when present, it is usually the result of severe thrombocytopenia, platelet dysfunction, hypoprothrombinemia, or the effects of an underlying disease. On the other hand, thrombosis and its many manifestations are common. Synonyms for LA and aCL antibodies include *antiphospholipid* (aPL) *antibodies*, *APAs*, and *autoantibodies to phospholipid-binding plasma proteins* ([458]). The associated clinical manifestations including thrombosis are variously called the *LA syndrome*, *antiphospholipid syndrome* (APS), or *antiphospholipid-protein syndrome*. Although each of these terms reflects improved pathophysiologic understanding of this family of antibodies, these insights are relatively recent, and the synonyms are linguistically cumbersome. APS without a known well-defined autoimmune disease is termed *primary APS* (PAPS). A few patients with APA develop an acute, severe, multiple-organ APS illness. These patients are designated as having *catastrophic APS* (CAPS). The existence of these antibodies was first detected indirectly almost 50 years ago when it became apparent that approximately 15% of patients with active SLE have a false-positive Venereal Disease Research Laboratory (VDRL) test ([459]). The VDRL test assesses antibody reactivity to “reagin” (antigen), an acidic-phospholipid complex that is chemically extracted from bovine heart tissue. Reagin consists of a mixture of lecithin, cholesterol, and cardiolipin. A nonspecific antibody reaction to reagin is also seen less often in other autoimmune disorders and in some apparently healthy patients. Other laboratory assays discussed in this section identified a family of antibodies that were initially thought to have direct specificity to various phospholipids, although it is now known that the antibodies recognize phospholipid-protein complexes. The proteins often serve a critical cofactor role ([460]), and the antibodies collectively are thus most accurately called *antiphospholipid–protein antibodies* ([461]). Coagulation assays are sensitive to some of these antibodies. Plasma samples from some patients with SLE, often those with the abnormal VDRL tests, show an *in vitro* inhibitor effect in several coagulation assays. This association gave rise to the term *lupus anticoagulant* ([462]). Most often, a prolonged PTT result that is not corrected on mixing with normal plasma is observed; other phospholipid-dependent assays, including the modified Stypven time [dilute Russell viper venom time (DRVVT)], are also affected ([422]). Despite persistent clinical use, it is now known that most patients with an LA phenomenon do not have SLE ([422]). Moreover, clinical thrombosis is much more often seen than is bleeding with these APS antibodies. Patients with SLE occasionally have inhibitors to other hemostatic factors ([463]), but these inhibitors are not considered LAs. In addition to the biologically false-positive VDRL results and the paradoxic *in vitro* lupus-anticoagulant effect, laboratory studies found a third phenomenon, initially detected by radioimmunoassay: antibodies to cardiolipin ([464]). In aCL-antibody assay systems, serum Igs bind to various anionic phospholipid-protein complexes, most commonly to cardiolipin in a coated microwell enzyme-linked immunosorbent assay (ELISA). The sensitivity and specificity of this assay are substantially higher than those of the VDRL. Most often these protein-dependent interactions have been investigated with anionic phospholipids, but antibodies with reactivity to the neutral phospholipids such as phosphatidylethanolamine have been described ([465]). More recently, a phospholipid-binding protein, ß$_2$-glycoprotein I (ß$_2$gpI), has been identified ([466]), and antibodies to this antigen can also be demonstrated in patients with APS ([467]).

EPITOPE SPECIFICITY In these disorders, the antibodies were initially thought to react with anionic phospholipids directly, but the presence of specific plasma proteins associated with phospholipids is now known to be of great importance ([468]). In the case of LAs, the seemingly paradoxic discordance between laboratory screening test results and clinical symptoms is most commonly the consequence of antibodies that bind to a complex of phospholipid-bound prothrombin ([440], [469], [470]). This antibody binding impairs the function of the standard prothrombin-binding synthetic anionic phospholipids ([471]) that are used routinely in the laboratory to replace platelets in phospholipid-dependent coagulation assays, such as the PTT. Less commonly, a lupus-anticoagulant effect is seen with the aCL antibodies that are discussed in the following paragraph. Other more natural phospholipids, or platelets themselves, are less affected by this phenomenon and are used in some assays as correction factors. In the case of aCL antibodies, especially in autoimmune and drug-induced aCL, ß$_2$gpI ([472]) serves as a mandatory protein cofactor ([466]). ß$_2$gpI is a 57-kd plasma apolipoprotein with an uncertain physiologic role, but it is often considered a noncomplement member of the complement-control family of proteins, with structural similarity to complement factor H but with distinct functions ([473]). ß$_2$gpI has a number of anticoagulant activities ([474], [475] and [476]), but inherited deficiency of ß$_2$gpI has no thrombophilic association ([477]). The plasma concentration of ß$_2$gpI in patients with clinical thrombophilia and aPLs is normal ([478]) or high ([479]). The antibodies in these settings are often of IgG isotype, are relatively persistent and high in titer, are associated with an LA phenomenon in approximately 60% of patients, and are clearly associated with the clinical syndromes discussed subsequently ([460]). IgM and IgA antibodies occur less often. The general thinking now is that aCL antibodies are not directed primarily against cardiolipin itself, but against epitopes formed after ß$_2$gpI binds to anionic phospholipid membranes or anionic synthetic surfaces. Recent data suggest that the epitopes for some APAs are adducts of oxidized phospholipid and ß$_2$gpI ([480]). Although cardiolipin has no known procoagulant function, the aCL antibodies also bind to other procoagulant anionic phospholipids, including phosphatidylserine. The subgroup of aCL antibodies that enhances binding of ß$_2$gpI to anionic phospholipids in such a way that coagulation assay abnormalities result has been termed *aCL type A*. Currently, there is no known difference in the clinical behavior of antiprothrombin-dependent LA antibodies and anti-ß$_2$gpI–dependent aCL antibodies with LA activity; consequently, clinical laboratories do not routinely distinguish between them. ß$_2$gpI may also mediate aCL binding to endothelial cell membranes ([481]). Other proteins have been occasionally implicated as possible obligatory cofactors, including annexin V ([482]), factor Xa, protein C, protein S ([483]), phospholipase A$_2$, and placental anticoagulant protein ([484]). Anti-ß$_2$gpI antibodies have been reported to induce acquired resistance to activated protein C ([485]). It was previously thought that APA recognized neoepitopes of the above phospholipid-binding proteins expressed on cell-surface binding. More recent information suggests that the true antibody target is an appropriate density (“clustering”) of proteins bound to phospholipid surfaces, which is necessary for antibody recognition ([486]). For example, based on *in vitro* data, it has been proposed that ß$_2$gpI acts as an antigen *in vivo* only when the antigen (ß$_2$gpI) clusters on membrane surfaces such as endothelium. When clustering occurs, this increased antigenic density allows antibody recognition to occur, leading to antibody binding and endothelial cell activation and potentially triggering cellular events resulting in thrombosis ([487]). Figure 60.8 illustrates how this phenomenon might occur.

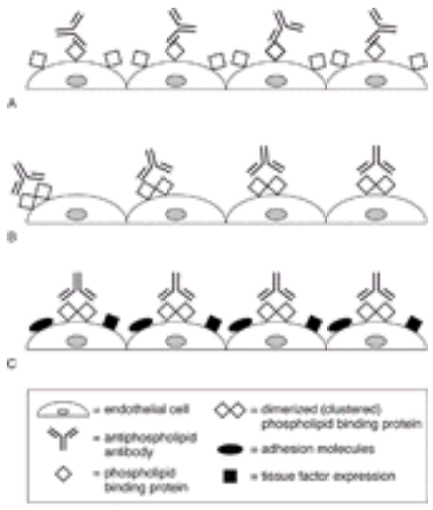

Figure 60.8. A proposed mechanism by which antiphospholipid antibodies induce endothelial cell activation and thrombosis. **A:** Endothelial cells express a phospholipid-binding protein (e.g., ß $_2$gpI). In the absence of high antigenic density ("clustering"), antibody binding is inefficient. **B:** Endo-thelial cells with dimerized ("clustered") antigen, which allows for efficient antibody binding, resulting in endothelial cell activation and promotion of thrombosis **(C)**.

In some other settings, particularly those related to infection, the aCL antibodies are often of IgM isotype, are often of low titer and relatively transitory, and have no identified cofactor protein ([460]). Although ß $_2$gpI is an absolute protein cofactor requirement for aCL activity in autoimmune settings, it may, in contrast, be inhibitory in the infection-related circumstance ([460]). The clinical association with thrombophilia is less strong ([488]), particularly thrombosis occurring after drug administration ([489]), although exceptions to this generalization have been noted ([490]). The detection of subgroups of aPLs has been reviewed ([455]).

MECHANISM OF THROMBOSIS Three hypotheses have been presented to explain how aPL induces thrombosis ([455]). These include (a) endothelial cell activation, (b) oxidant-mediated vascular injury, and (c) interference with the function of phospholipid-binding proteins in regulating coagulation. In the first hypothesis, aPL antibodies directly bind to endothelium to up-regulate expression of adhesion molecules and cytokine secretion ([455]). In the second hypothesis, autoantibodies to oxidized low-density lipoprotein occur with aCL antibodies, and aCL antibodies recognize oxidized phospholipids and phospholipid-binding proteins ([491]). In the third hypothesis, aPL antibodies may interfere with the anticoagulant functions of protein C or annexin V or enhance procoagulant activity ([455]). Immunologic studies lend strong support for a direct pathophysiologic role of these antibodies in the clinically observed thrombotic syndromes ([492]). In animal models using standardized vessel injury to induce thrombosis, either passively conferred APA ([493]) or active induction of antibody with either APA or ß $_2$gpI ([494] , [495]) resulted in thrombosis; this suggested that APAs are not merely epiphenomena of thrombi arising for other reasons but, in some cases, play a direct role in initiation, propagation, or maintenance of thrombosis. Immunization of mice or rabbits with ß $_2$gpI produces two populations of antibodies: one with specificity for ß $_2$gpI alone without binding to phospholipids and the other with specificities for both cardiolipin and ß $_2$gpI ([496]). This dual specificity of antibodies is also seen with those aPLs that are present in patients with autoimmune diseases. It is possible that in some circumstances, APAs are epiphenomena that develop on antigen exposure or that the antibodies do not initiate thrombosis but might somehow augment or maintain a thrombotic process that is under way. For example, conformational changes of platelet phospholipids may influence ß $_2$gpI binding and activity. Anionic phospholipids are asymmetrically located in the inner leaflet of the resting platelet membrane. Loss of this asymmetry occurs on platelet activation, and the newly exposed anionic phospholipids may then bind ß $_2$gpI and, through the ß $_2$gpI, indirectly but prerequisitely bind the IgG aPLs ([497]). Similar pathologic procoagulant surfaces may arise in apoptotic lymphocytes and senescent red blood cells ([498]). It appears that when ß $_2$gpI is bound to anionic phospholipids or other suitable surfaces, a cryptic epitope is then expressed, and antibodies then bind to the ß $_2$gpI-phospholipid complex ([499]). Epitope mapping studies using synthetic peptides to probe for the target sequence have been done ([500]); these studies may clarify the pathologic events mediated by these antibodies. The concept of hexagonal phase configuration has been popularized. This configuration is thought to arise *in vivo* in response to membrane damage ([501] , [502]). Normally, polar heads of the phospholipids exist on the external surface, whereas in the hexagonal phase, lipid cylinders exist with internal aqueous channels formed by polar head groups ([503]). LA and aCL may represent antibodies generated in response to these neoantigens. APAs have been generated in mice immunized with hexagonal phase phospholipid ([504]); these antibodies reacted with cardiolipin and possessed functional LA activity. The precise cause of thrombosis in APS is unknown. Presumably, APAs act by interfering with coagulation ([505] , [506]), possibly involving dysfunction or apoptosis ([507]) of endothelial cells, platelets, and coagulation proteins, and affect pregnancy outcome by interfering with embryo implantation and fetal development ([455]). Several reasons for pursuing further investigation in this area are given: the possible laboratory identification of specific pathophysiologic events that can serve as useful markers to help predict if and when individual patients with APAs will develop APS; a possible direct therapeutic importance by interrupting the relevant thrombotic mechanism; and a means to monitor therapy. None of these objectives is currently met because a poor correlation exists between thrombosis *in vivo* and the diverse laboratory inhibitory effects. Specific mechanisms of thrombosis that have been implicated include inhibition of activated protein C ([508]), acquired free protein S deficiency, platelet activation, and abnormalities in the antigenic levels or activity of endothelium-derived hemostatic factors, including inhibition of prostacyclin secretion, fibrinolysis, or disruption of annexin V ([509]). The thrombogen-icity of APAs may also result from their interference with endothelial cell phospholipids required for antithrombin and proteins C and S anticoagulant activity and prostacyclin synthesis and increased endothelial cell expression of the following procoagulants: tissue factor, vWF, platelet-activating factor, and plasminogen activator inhibitor type-1 ([455] , [510]).

EPIDEMIOLOGY AND CLINICAL ASSOCIATIONS Young, apparently healthy control subjects are reported to have a prevalence of 1 to 5% of aPL antibodies ([511]). In patients with systemic lupus, aPL occurs in 12 to 34%. After prolonged follow-up, APS may develop in more than 50% of patients with systemic lupus ([455]). LA and aCL antibodies have been reported in a variety of clinical disorders, including SLE and other autoimmune and connective tissue diseases and in disorders that are unrelated to SLE (Table 60.8). As with all associative relations, the degree to which a pathophysiologic condition contributes to clinically significant symptoms by APA in these disease settings is uncertain. The presence of phospholipid-binding antibodies could in some cases be an epiphenomenon, a sign of other underlying vascular alterations that are potentially thrombogenic per se. In other cases, APAs may be of profound direct etiologic relevance. In general terms, although there are individual patient exceptions, clinical symptoms are seen less often with aCL than with LA, particularly when APAs are associated with infection or medication, are of low titer, and are of IgM isotype.

TABLE 60.8. Clinical Diagnoses Associated with Antiphospholipid–Protein Antibodies

Primary antiphospholipid-protein syndrome
Autoimmune disorder with no apparent cause
Secondary autoimmune disorders
Systemic lupus erythematosus; other autoimmune and connective tissue diseases; drug-induced: procainamide, hydralazine, quinidine, phenothiazines, penicillin
Malignancies
Leukemia, lymphoproliferative and plasmacytic disorders, solid tumors, essential thrombocytosis
Infections
Viral, bacterial, protozoal, fungal
Neurologic disorders
Liver disease
Valvular heart disease
Peripheral arterial disease
Chronic renal failure
Sickle cell disease
Ethylenediaminetetraacetic acid–dependent pseudothrombocytopenia
No apparent disease

Interpretation of estimates of APA frequency must consider the sensitivity of the diverse assay systems that have been used by investigators. Different LA assay systems have been tested with plasma samples from a rigorously defined group of patients with the antiphospholipid-protein syndrome, confirming the importance of variables such as the concentration and composition of phospholipids used in the assay ([512]), phospholipid reagent conformation ([503]), and so forth. Laboratory aspects of antiphospholipid-antibody testing are discussed in the text that follows. In a large series of internal medicine patients, 7% were APA positive, and 2%

fulfilled the criteria of antiphospholipid-antibody syndrome ([513]). The most commonly associated diseases were cancer and chronic or acute alcoholic intoxication. In another study, elevations of APA were found in approximately 20% of an unselected autopsy population, 10% of age- and sex-matched controls, and 2% of healthy normal subjects ([514]). Inhibitors of the lupus type originally were recognized in association with SLE ([422]). The prevalence of the LA in patients with SLE strongly depends on the type of LA assay system used; three standard PTT reagents detected LA in only 10% of SLE patients ([515]). A modified PTT with a reduced concentration of phospholipid detected LA activity in approximately 50% of SLE patients ([515], [516]). The kaolin clotting time, a test similar to the PTT, detected LA in 70% of patients with SLE ([517]). LA activity was associated with higher mortality in SLE patients ([518]). APAs have been seen in other connective tissue disorders, including rheumatoid arthritis and Behçet syndrome. APAs are present in many patients with malignancy ([519]). APAs have been associated with monoclonal gammopathy of undetermined significance and Waldenström macroglobulin-emia. APAs have been identified in liver disease, the prevalence increasing significantly as the liver disease progresses; APA positivity was as high as 80% in patients with alcoholic hepatitis or cirrhosis ([520]). The antibodies have been found in many infections, including hepatitis C ([521]), infection with human immunodeficiency virus ([522], [523]), human T-cell lymphotrophic virus-1–associated tropical spastic paraparesis, Q fever, and malaria ([524]). Children with viral infections often acquire a transient LA effect ([515]). Perhaps as a result of the structural changes in the red cell membrane with increased hexagonal-phase content, APAs are common in sickle cell disease ([525]). Patients with transient ischemic attacks and cardiac valve lesions had a high incidence of APAs ([514]). APAs have been seen in a variety of unrelated neurologic disorders ([526]). Patients with essential thrombocytosis have an increased prevalence of APA and increased risk of thrombosis ([527]). Several medications are associated with APA, most often, phenothiazines such as chlorpromazine ([489]), procainamide ([528]), quinine and quinidine ([529]), hydralazine, and penicillin ([530]). APAs were common in patients with ethylenediaminetetraacetic acid–dependent pseudothrombocytopenia ([531]). aCL antibodies can occur in both active and quiescent Crohn disease, usually without concomitant LA expression ([532]), but their role in the thrombotic complications that can occur in the active phase of this disease is uncertain. APA positivity is a common finding in patients with idiopathic thrombocytopenic purpura ([533]), with either LA or elevated aCL antibodies in almost one-half of patients. Moreover, APA levels were not influenced by immunosuppressive therapy with steroids and are not related to the activity of idiopathic thrombocytopenic purpura. aCL antibodies and, less often, LA are seen in apparently healthy people ([534]), especially in the elderly ([535]). In studies of normal blood donors, 5 to 10% have aCL antibodies, often present transiently and in relatively low titer without a concomitant LA effect; these donors do not have an increased risk of developing thrombosis ([536]). An inherited predisposition to the development of lupus inhibitors was suggested by their presence in two pairs of siblings ([537]) and in familial studies ([538], [539]). Further investigations have suggested associations with certain HLA types ([540], [541]).

CLINICAL MANIFESTATIONS Although LAs are immunologically distinct from aCL antibodies, clinical manifestations associated with each antibody appear to be similar. Clinical experience suggests that venous thrombosis is more likely associated with the LA, and arterial thrombosis is more likely associated with high-titer aCL antibodies. The antiphospholipid-antibody syndrome is characterized by the clinical events of fetal loss or thromboembolic disease (arterial or venous), or both (Table 60.9) ([542]). These clinical features are most highly associated with aPL antibodies in prospective studies ([542]). Older definitions included immune thrombocytopenia as a clinical event ([543]), but the newer classification omits thrombocytopenia ([542]). A wide variety of clinical features may be seen with APA ([544], [545], [546] and [547]). However, many patients with APA are asymptomatic. A proportion of asymptomatic patients develop SLE ([548]) or other disorders ([549]). The diverse clinical manifestations of APA are listed in Table 60.10.

TABLE 60.9. Criteria for Diagnosis of the Antiphospholipid-Antibody Syndrome (APS)

Clinical Event	Laboratory Abnormality
Venous thrombosis	Positive lupus anticoagulant test (according to guideline in Table 60.12)
or	*or*
Arterial thrombosis	Positive anticardiolipin antibody test (moderate-titer or high-titer IgG or IgM antibodies)
or	
Small-vessel thrombosis	Laboratory abnormality should persist for two or more occasions at least 6 wk apart
or	
Complications of pregnancy	
One or more unexplained deaths of normal fetuses at or after 10 wk of gestation	
One or more premature births of normal neonates at or before 34 wk of gestation	
Three or more unexplained consecutive spontaneous abortions before 10 wk of gestation	

Ig, immunoglobulin.

NOTE: A diagnosis of definite APS requires the presence of at least one clinical event and at least one laboratory abnormality.

Criteria from Levine JS, Branch DW, Rauch J. The antiphospholipid syndrome. N Engl J Med 2002;346:752–763; and Wilson WA, Gharavi AE, Koike T, et al. International consensus statement on preliminary classification criteria for definite antiphospholipid syndrome: report of an international workshop. Arthritis Rheum 1999;42:1309–1311.

TABLE 60.10. Clinical Manifestations of Antiphospholipid Antibodies

Asymptomatic
Arterial and venous thromboembolism
Avascular osteonecrosis
Hematologic
Cytopenias: thrombocytopenia, autoimmune hemolytic anemia, leukopenia
Coagulopathy: platelet dysfunction, prothrombin deficiency
Neurologic
Acute ischemia (cerebrovascular accident, transient ischemic attack, encephalopathy); severe migraine; multiple infarct dementia; seizures; peripheral neuropathy; myasthenia gravis
Dermatologic
Livedo reticularis; acrocyanosis (distal cutaneous ischemia, ulceration, gangrene); widespread cutaneous necrosis; pyoderma gangrenosum–like skin lesions; anetoderma in human immunodeficiency virus-1 disease
Cardiopulmonary
Marantic endocarditis; myocardial ischemia and infarction; intracardiac thrombotic mass; peripheral arterial disease; thromboembolic and nonthrombotic pulmonary hypertension
Obstetric
Recurrent spontaneous abortion; intrauterine growth restriction; preeclampsia; chorea gravidarum; low Apgar scores; prematurity
Catastrophic antiphospholipid syndrome

Arterial and Venous Thromboembolic Disease The most common clinical presentation of patients with LA or aCL antibodies, or both, is arterial or venous thromboembolism ([550], [551] and [552]), affecting up to 70% of patients in some series but averaging approximately 30 to 40% of patients in most studies ([516], [552], [553]). The most common site of thrombosis is extremity deep vein thrombosis, but occasionally, unusual sites are involved, such as the axillary, retinal, and hepatic veins and cerebral venous sinus thrombosis ([551], [554]). Cerebral thrombosis, often heralded by repeated transient ischemic attacks, is a common arterial lesion ([555]). Mesenteric artery occlusion, adrenal infarction, gastrointestinal ischemia or ulceration, and subclavian thrombosis with “pulseless” disease also have been described. Multiple cerebral infarcts with dementia in addition to coronary occlusions have occurred in unusually young age groups ([556]). A paradoxic syndrome of cerebral infarction with concurrent severe thrombocytopenia and bleeding has been reported in several cases ([555]). Antibodies to ß $_2$gpI are highly associated with venous

thrombosis (557), and in another study, assays for the LA correlated best with thrombosis, compared with assays for other APAs (558). This association between LA and thrombosis risk has been confirmed in a recent literature review (558a). Another unusual ischemic syndrome associated with APA is avascular osteonecrosis (559).

Thrombocytopenia Moderate immune thrombocytopenia is noted in approximately 50% of patients with lupus inhibitors, but in many cases, it apparently is the result of the underlying disorder (560). Immune thrombocytopenia is no longer considered a clinical event for diagnosis of APS (542). Patients with thrombocytopenia of obscure etiology, including those with idiopathic thrombocytopenic purpura–like syndromes, probably should be screened for the LA and aCL antibodies. When bleeding occurs in patients with aPLs (561), this is generally attributed to coexistent thrombocytopenia, platelet dysfunction (562), prothrombin deficiency (563), or other underlying coagulopathies. Other cytopenias may be associated with APA, including autoimmune hemolytic anemia and leukopenia.

Neurologic Syndromes Various neurologic disorders have been linked with APA, including dementia, migraines, chorea, seizures, transverse myelopathy, Guillain-Barré syndrome, mononeuritis multiplex, transient global amnesia, and myasthenia gravis. Many of these disorders are not associated with ischemia or thrombosis, and the pathologic relationship of these disorders with APA is uncertain. However, in certain cases, immunosuppressive therapy for presumed PAPS may be therapeutically useful (564). In some studies (565), but not others (566), aCL antibodies appear to be an independent risk factor for stroke. Some investigators have noted a relationship between APA, migraine headaches, and subsequent ischemic infarction (567), whereas other investigators have not confirmed this association (568).

Dermatologic Disorders A variety of ischemic-dermatologic syndromes have been associated with aCL antibodies, including livedo reticularis, acrocyanosis (distal cutaneous ischemia, ulceration, gangrene), widespread cutaneous necrosis, and pyoderma gangrenosum–like skin lesions (569). Men with PAPS, in particular, may experience dermatologic problems.

Cardiac Disorders A high incidence of APA is seen in patients with peripheral arterial disease who experience an associated increased risk of early graft thrombosis (570 , 571). This may justify routine testing for APA before reconstructive vascular surgery, with consideration of perioperative antiplatelet agents or anticoagulation. Some reports have noted the presence of APA in survivors of myocardial infarction (572). Other reports have not confirmed this association (573).

Pulmonary Disorders Ischemic and thrombotic pulmonary disease is linked to APA, including pulmonary embolism, pulmonary hypertension, intraalveolar pulmonary hemorrhage, and adult respiratory distress syndrome (574 , 575). The latter syndrome has been reported in patients with CAPS (575).

Obstetric Aspects APAs are associated with obstetric complications (455 , 576 , 577 , 578 and 579), including intrauterine growth restriction, preeclampsia, chorea gravidarum, and, primarily, recurrent spontaneous fetal loss (RSFL) (455). Pregnancy losses in women with aPLs are often caused by fetal death despite normal fetal karyotypes. Spontaneous fetal loss is perhaps most common in the first trimester, but paradoxically, early first-trimester pregnancy losses are relatively less common than in other patients with recurrent fetal loss (580). The international consensus statement listed obstetric criteria for diagnosis of APA: (a) one or more unexplained deaths of a morphologically normal fetus at or beyond the tenth week of gestation; (b) one or more premature births of a morphologically normal neonate at or before the thirty-fourth week of gestation because of preeclampsia, eclampsia, or placental insufficiency; or (c) three or more unexplained consecutive spontaneous abortions before the tenth week of pregnancy (542). There is a significantly increased incidence of elevated APA in women with a history of two or more miscarriages in the first trimester of pregnancy (581). Women with a history of RSFL should be tested for both LA and aCL antibodies (582). Repeat testing after an interval of at least 8 weeks is important because only 66% of LA-positive, 37% of IgG aCL-positive, and 36% of IgM aCL-positive women had a positive test result on repeat evaluation. Laboratory screening for LA is confounded in pregnancy because altered coagulation factor concentrations in normal pregnancy may change the observed normal range of coagulation tests, including the PTT. In two studies, the DRVVT was the most frequently positive test for the LA in this population. Rigorous adherence to diagnostic criteria is particularly appropriate in pregnancy because treatment may require potentially hazardous antithrombotic therapy. Elevated maternal serum levels of a-fetoprotein (583) or human chorionic gonadotrophin (584) are common in women with aPLs and are significantly associated with fetal loss. Maternal APA testing may be appropriate if prenatal screening reveals an elevated human chorionic gonadotrophin level and ultrasonography demonstrates an otherwise normal singleton gestation. It is generally considered not appropriate to screen for APA in asymptomatic pregnancies without a history of RSFL (585). APAs were identified at the first prenatal visit in almost 25% of healthy pregnant women (586). LA appears to be much rarer than aCL antibodies in pregnancy (587). It appears that women with isolated IgM aCL or with low levels of IgG aCL are a distinct group that is not at risk for APA-related complications beyond the risk conferred by their medical histories (588). Although the mechanism by which APA causes recurrent pregnancy loss has not been fully explained, these antibodies may induce intervillous thrombosis and intravillous infarctions, resulting in poor placental perfusion, and have been shown to affect cytotrophoblast tissue *in vitro*. Placental elution studies from patients with a history of RSFL found IgG APA bound directly to placental tissues in patients with positive sera (589). The thrombotic phenomenon may be mediated by aPL antibodies interfering with trophoblastic annexin V (590).

Catastrophic Antiphospholipid-Antibody Syndrome Some patients with APA develop an acute, severe, multiorgan illness (455 , 575 , 591) characterized by diffuse small vessel ischemia and occlusion with extensive tissue damage, including myocardial infarction, limb ischemia, DIC, and a high mortality rate of 50% (592). The patients present with a dramatic illness, often without an obvious precipitating event, that prompts consideration of a wide differential diagnosis including severe lupus vasculitis, thrombotic thrombocytopenic purpura, or severe DIC. The syndrome is defined by clinical involvement of at least three different organ systems with histologic evidence of thrombosis (592). Typically, small vessel thrombotic lesions occur, with common sites of involvement including the kidney, lung, central nervous system, heart, and skin (592). In a larger series of CAPS patients, nearly one-half of the cases had systemic lupus, and 40% had PAPS (593). Precipitating factors for development of CAPS included infections, trauma/procedures, cancer, and subtherapeutic anticoagulation (593). LA activity and, particularly, high aCL antibody titers are usually present. Central nervous system symptoms and hypertension are common, and leukocytosis and a significantly elevated sedimentation rate are often also present. The clinical manifestations of this syndrome can include all the symptoms and signs indicated in Table 60.10.

LABORATORY DIAGNOSIS OF ANTIPHOSPHOLIPID–PROTEIN ANTIBODIESLA and high-titer aCL antibodies have similar clinical implications, although studies suggest a higher thrombotic risk in patients with the LA (558, 558a). In patients with SLE, the LA is the best predictor for both venous and arterial thrombosis. The laboratory should perform both fibrin-based coagulation assays to detect LA and solid-phase ELISA assays for aCL antibodies in patients suspected of having APA. Both antibodies are found in approximately 60% of circumstances, but there is discordance between the two test systems in detecting the remaining cases. A considerable array of phospholipid-responsive laboratory tests, such as the PTT, dilute PTT, kaolin clotting time, and DRVVT, may serve to screen for the LA (460 , 594). LA may be defined as an immunoglobulin (IgG, IgM, IgA, or a mixture) that interferes with one or more of these *in vitro*, phospholipid-dependent coagulation tests. A more recent definition of the LA would be antibodies to ß $_2$gpI or to prothrombin that prolong phospholipid-dependent coagulation assays. Coagulation tests that are phospholipid-independent are not affected by LA. Unless concurrent additional factor deficiencies are present, the standard PT is usually normal because of the large amount of phospholipids in this reagent. No individual test seems to have a universal detection rate; this observation may reflect LA subtypes with distinct activities or the requirement of various cofactors. Comparative studies suggest that activated PTT reagents with reduced levels or different types of phospholipids are more sensitive than routine PTT assays (460 , 595). There are claims that assays based on venom activators of factor X and prothrombin may have particular advantages, such as reduced sensitivity to coagulation factor deficiency, that would be more suitable for analysis of plasmas from patients receiving oral anticoagulants (596). Platelet-poor plasma should be used in these screening assays, particularly if frozen plasma samples are to be tested (597). Table 60.11 indicates some of the clinical and laboratory differences between specific anticoagulant antibodies to particular factors, such as factor VIII and LA. Other nonspecific anticoagulants are uncommon but include the heparinlike anticoagulants discussed in the section Other Acquired Coagulation Disorders. Confirmatory tests for LA based on activated PTT or DRVVT include abnormal mixing studies with normal plasma and correction with mixing using phospholipids, such as lysed washed platelets (platelet neutralization procedure), or with added hexagonal-phase phospholipids (598). A high concentration of liposomes prepared from rabbit brain extracts may achieve the most efficient correction of the defect (599), but this method is not widely used. The College of American Pathologists has published detailed recommendations for lupus anticoagulant testing (599a).

TABLE 60.11. Comparison of Factor VIII Antibodies and Antiphospholipid–Protein Antibodies

Clinical Event or Laboratory Test	Factor VIII Antibodies	Antiphospholipid–Protein Antibodies
Bleeding	Often severe	Uncommon
Thrombosis	Rare	Common
Obstetric complications (abortion and intrauterine fetal death)	Rare	Common
Prothrombin time	Normal	May be prolonged
Thrombin time	Normal	Occasionally prolonged
Thrombocytopenia	Rare	Common
Inhibitory effect in plasma mixtures	Usually time dependent	Often is instantaneous; occasionally, mixing studies show time-dependent inhibition
Prothrombin level	Normal	Occasionally deficient
Factor VIII level	Deficient; one-stage assay curve is aberrant with low-affinity antibodies	Normal when assayed in a dilute system; all one-stage assay curves are aberrant

Anticardiolipin antibodies	Rare	Anticardiolipin antibodies of either IgG or IgM classes are common
Phospholipid or platelet correction of abnormal assay result	No	Usually

Ig, immunoglobulin.

Several clinical points are worth stating. The search for LA or aCL antibodies should not be abandoned even if normal plasma in a mixing study corrects the test patient plasma, particularly in a human immunodeficiency virus–positive population ([600]). It is sometimes important for the clinician to discern the possible effect that heparin in the test patient plasma can have on the confirmatory laboratory assay; satisfactory correction procedures should be resistant to heparin. The ideal test to identify the LA is controversial; some investigators have reported the kaolin clotting time to be the most sensitive test ([595], [601], [602]). On the other hand, some DRVVT assays are more able to identify LA associated with thrombosis ([603]). A subgroup of patients with unexplained thrombosis with antibodies to phosphatidylethanolamine as the only abnormal APA test has been identified ([604]). Optimal detection of the LA requires more than one of the phospholipid-dependent assays described earlier ([605]). This latter suggestion is supported by reports that different phospholipid-dependent coagulation tests detect different populations of LA antibodies ([606]). Table 60.12 summarizes the recommendations of an ISTH consensus group on laboratory diagnosis of LA ([605]). Despite the ISTH recommendations of LA testing, the optimal strategy for evaluating LA is unknown ([607]). One report used decision analysis to determine optimal LA testing strategies ([608]). The preferred strategies identified by this group are shown in Table 60.13; these preferences are based on sensitivities and specificities for each strategy, as well as costs and patient outcomes and preferences ([608]).

TABLE 60.12. Laboratory Diagnosis of Lupus Anticoagulant: ISTH Criteria

Prolongation of at least one phospholipid-dependent coagulation test with the use of platelet-poor plasma (e.g., the activated partial thromboplastin time, dilute prothrombin time, dilute Russell viper venom time, kaolin clotting time)

Failure to correct the prolonged coagulation time by mixing patient and normal plasma

Confirmation of lupus anticoagulant by demonstrating correction of the prolonged coagulation time by addition of excess phospholipids or freeze-thawed platelets

Exclusion of alternative coagulopathies using specific assays (e.g., factor VIII antibodies)

Diagnostic criteria from Levine JS, Branch DW, Rauch J. The antiphospholipid syndrome. N Engl J Med 2002;346:752–763; and Brandt JT, Triplett DA, Alving B, et al. Criteria for the diagnosis of lupus anticoagulants: an update. On behalf of the Subcommittee on Lupus Anticoagulant/Antiphospholipid Antibody of the Scientific and Standardisation Committee of the ISTH. Thromb Haemost 1995;74: 1185–1190.

TABLE 60.13. Lupus Anticoagulant Testing Strategies Based on Decision Analysis

Patient Group	Least Costly Strategy	Greatest Patient Utility Strategy
Healthy people with a prolonged activated partial thromboplastin time	No testing; assume all are negative	No testing; assume all are negative
Systemic lupus erythematosus patients	No testing; assume negative *or* TTI alone	TTI?DRVVT?confirmatory DRVVT
Patients with prior thrombosis or fetal loss	No testing; assume negative *or* TTI alone *or* confirmatory DRVVT alone	No testing; assume all are negative

DRVVT, dilute Russell viper venom time; TTI, tissue thromboplastin inhibition test.

Strategies from Segal JB, Lehmann HP, Petri M, et al. Testing strategies for diagnosing lupus anticoagulant: decision analysis. Am J Hematol 2002;70:195–205.

aPLs may also be detected by ELISA or by radioimmunoassay ([609]). Commercial ELISA systems are reasonably well standardized. The aCL-antibody assay used to improve sensitivity and specificity has undergone several modifications ([610]). Using anti-ß $_2$gpI–dependent assay systems is useful to discriminate between transiently positive aCL antibodies that are associated with infection, which characteristically do not have a ß $_2$gpI cofactor requirement, and those aCL antibodies associated with an increased risk of thrombosis ([611]). Definitional standardization of the criteria for clinical and laboratory APA have been published ([455], [542], [605]). For the diagnosis of APS, in addition to a clinical history (e.g., at least one venous or arterial thrombosis, pregnancy morbidity/mortality), positive laboratory tests for LA or aCL antibodies (in medium or high titer) should be found on two occasions at least 6 weeks apart (Table 60.9). It is recommended that aCL antibodies be measured by a standardized ELISA for ß $_2$gpI-dependent antibodies ([542]). Measurement of ß $_2$gpI antibodies is not recommended for diagnosing APS at this time ([542]). Although consensus criteria require persistence of the laboratory abnormality for at least 6 weeks, in clinical practice, a functional definition taking into account the number of clinical manifestations and the titer of aCL antibodies on even a single occasion may help categorize patients as having definite, probable, or doubtful APS ([609]) and may direct immediate treatment options. Even if the patient is asymptomatic, lupus inhibitors should always be identified correctly when discovered, even though costly and time-consuming laboratory study is required. If the cause for a prolonged PTT is not identified, the necessity for definitive laboratory evaluation almost invariably arises again, often in the context of an emergency. This may result in the unnecessary use of blood products and a delay of required surgical procedures.

TREATMENT OF ANTIPHOSPHOLIPID–PROTEIN ANTIBODY SYNDROME The optimal treatment of patients with APA syndrome has not been defined ([610]). Depending on the clinical symptoms, patients with APA may need no treatment or may need anticoagulant or immunosuppressive therapy. Although spontaneous remissions are uncommon and aCL antibodies and LA can be associated with life-threatening thromboembolic events, only 10 to 15% of asymptomatic patients with APA develop these complications. Based on the uncertainty of predicting when thrombotic events might occur, as well as the risks of anticoagulation, most investigators do not treat asymptomatic patients prophylactically, with the possible exception of short-term intervention when additional thrombophilic hazards such as immobilization or surgery are anticipated. Patients with significant thrombotic events (e.g., deep vein thrombosis, arterial ischemia, or fetal loss) are appropriate candidates for antithrombotic therapy. Although retrospective in design and somewhat arbitrary in its partition of INR values, a particularly useful study ([612]) of secondary prevention of thrombosis in patients with antiphospholipid–antibody syndrome resulting from a variety of disorders suggested that high-intensity warfarin therapy, achieving an INR value at least equal to 3, with or without a low dose (75 mg) of aspirin daily, was considerably more effective than warfarin treatment at a lower intensity with or without low-dose aspirin, or treatment with aspirin alone, in preventing recurrent thrombotic events. Although bleeding complications were increased significantly by higher-intensity therapy, long-term persistent higher-intensity anticoagulation therapy was recommended for most patients ([612]). Long-term treatment with oral anticoagulation therapy is advised because of the high rate of recurrence even if the venous or arterial occlusion occurred many years previously ([613], [614]). Patients receiving oral anticoagulants had no recurrence over 8 years, whereas patients in whom anticoagulant drugs had been discontinued had a 50% probability of a recurrent venous thromboembolic episode after 2 years and an almost 80% probability of recurrence after 8 years ([615]). This strategy is supported by a study that found that APS patients with thrombosis benefited from prolonged oral anticoagulation because persistent elevation of aCL levels predicted an increased risk of thrombosis recurrence and death ([616]). The bleeding risks of high-intensity oral anticoagulation in these patients appear to be similar to patients treated with standard low-intensity oral anticoagulation ([617]). Many investigators follow this approach, unless all laboratory evidence of LA and aCL in patients in whom high titers were initially detected or in whom a thrombotic risk was attributed to APA has been continually absent for at least 6 months; no other thrombophilic risk is present; and close surveillance is feasible. The optimal intensity of oral anticoagulation for APS patients is the subject of an ongoing study ([618]). Patients with the uncommon LA-hypoprothrombinemia syndrome who either have bleeding or need surgery may benefit from steroid therapy or intravenous IgG ([619]). Patients with the LA and acute thrombosis pose difficulty in terms of monitoring heparin anticoagulation. The usually prolonged PTT value seen with the LA renders this test unreliable. These patients can be monitored using heparin assays, which are now available by automated methodology (see Chapter 61). Alternatively, patients can be treated using a low-molecular-weight heparin, such as enoxaparin or tinzaparin, without the necessity for laboratory monitoring (see Chapter 61). In those patients with an LA and hypoprothrombinemia, or an LA that affects the PT, the use of the INR to monitor anticoagulation has been questioned. These patients may require monitoring with a test that is insensitive to the LA, such as a prothrombin-proconvertin assay or a chromogenic factor X assay ([620]). Corticosteroid use often diminishes or abolishes the coagulation abnormalities and immune thrombocytopenia of APA syndrome within a short time. However, for most patients, the role of steroids, other immunosuppressive agents, or aspirin is uncertain. Although immunosuppression with cyclophosphamide in pulse form is effective in reducing elevated antibody levels, there is often a rapid rebound to pretreatment levels shortly after discontinuation of the therapy. Consequently, additional therapies with aspirin or steroids or more aggressive immunosuppression are not used unless recurrent thrombotic or ischemic events are seen despite high-intensity warfarin therapy. High-dose

corticosteroid therapy has equivocal efficacy and considerable toxicity and is reserved for treatment of underlying comorbid conditions such as active lupus and not for the laboratory phenomena of the antiphospholipid-antibody syndrome itself. In patients with CAPS who experience multisystem involvement, intensive treatment with corticosteroids, immunosuppression, intravenous IgG, or plasmapheresis may be useful ([455], [592]). In one literature analysis of CAPS therapy, the highest response to therapy occurred in patients treated with anticoagulation and steroids (64%) ([593]). Immune thrombocytopenia and autoimmune hemolytic anemia in patients with APA are treated similarly as patients without APA.
Obstetric Treatment Because the risk of pregnancy loss in women with APS and prior pregnancy loss may exceed 60%, a history of recurrent fetal loss is an indication for treatment during pregnancy. Antiplatelet agents such as aspirin 80 mg/day ([621]), low-dose immunosuppressive agents such as prednisone 15 to 30 mg/day, or anticoagulants (heparin or low-molecular-weight heparin) have all been used in an attempt to improve pregnancy outcome ([455]). Several randomized studies have provided information about useful treatment strategies in pregnancy-associated APS (reviewed in reference [455]). Intravenous IgG is of no benefit in these patients, and heparin is more effective than aspirin. Heparin or low-molecular-weight heparin is the treatment of choice; pregnant patients without a history of thrombosis benefit from heparin in doses of 10,000 to 20,000 U daily in divided doses, whereas pregnant patients with a history of thrombosis should receive therapeutic anticoagulation, preferably with low-molecular-weight heparin ([455]).

Transfusion-Associated Coagulation Abnormalities

The administration of blood products in a volume greater than 1.5 times the patient's estimated blood volume or replacement of total blood volume in less than 24 hours constitutes massive blood transfusion ([622]). Dilutional coagulopathy occurs when replacement therapy consists of crystalloid and packed red cells. Some authors recommend using whole blood to minimize this coagulopathy ([623]), whereas others recommend fresh frozen plasma ([624]). Platelet transfusion may be less important because platelets can be mobilized from reserve sites. One retrospective study observed that significant thrombocytopenia did not develop unless patients were given 20 or more units of red blood cell products, and that transfusion of more than 12 units of red blood cell products consistently prolonged the PT and PTT ([625]).

Some believe that clinical bleeding in patients receiving massive transfusion results less from the dilutional coagulopathy and more often is a result of DIC, which may be seen in 30% of such patients ([626]). Hypoperfusion, not transfusion, is thought to be of primary importance for these cases, and the occurrence of DIC relates more to the duration of hypovolemia than to the absolute volume lost or replaced ([627]). Obviously, coexisting diseases such as liver dysfunction, renal disease, and others may contribute to hemostatic impairment in patients receiving massive transfusion. The use of point of care monitoring may reduce use of blood products in the operating room setting ([628]).

Previous guidelines recommended routinely using platelets and plasma based on the quantity of blood transfused. More recent guidelines suggest using the basic hemostasis screening tests to monitor the necessity of using platelets or plasma replacement ([629]). An increase in the PT and PTT to more than 1.8 times the upper limit of normal may justify the use of fresh frozen plasma (4 units for an adult). If bleeding is present and the platelet count is less than 50,000/µl, 6 to 8 units of platelets should be given for an adult patient ([629]). DIC panels should be done to identify whether this entity is present and to determine whether fibrinogen replacement with cryoprecipitate is necessary.

Bleeding Associated with Extracorporeal Circulation

Defective hemostasis with cardiopulmonary bypass is associated with multiple contributory causes, including hemodilution of coagulation factors, inadequate neutralization of heparin, acquired platelet dysfunction, and thrombocytopenia. These latter two defects are further discussed in Chapter 58. In general, extracorporeal circulation–induced hemostatic defects may be ascribed to activation of platelets and coagulation proteins by artificial surfaces.

Platelet dysfunction (acquired storage pool defect) is considered the major hemostatic insult induced by bypass ([630]). Although DDAVP has been shown to reduce bleeding and transfusion requirements in these patients ([631]), subsequent trials suggested that the typical “low-risk” patient does not benefit from DDAVP ([632]), and routine DDAVP therapy may be hazardous in older patients with significant vascular disease ([633]). The protease inhibitor aprotinin appears to be useful in reducing blood loss and transfusion requirements in bypass surgery ([634]); this drug is thought to inhibit plasma proteolytic activity induced by cardiopulmonary bypass, reducing the extent of platelet activation. Aprotinin is now available for parenteral use for this indication, especially in high-risk patients. A major toxicity of this drug is hypersensitivity, especially for patients who have previously received the drug. Aprotinin appears to be superior to EACA ([635]). The use of routine prophylactic platelet transfusions has no apparent benefit ([636]).

Drug-Induced Coagulation Abnormalities

Broad-spectrum antibiotics, such as the ß-lactam antibiotics, may induce a coagulopathy by inhibition of vitamin K synthesis by gut bacteria and direct inhibition of essential carboxylation reactions ([28]). A number of antibiotics may also inhibit platelet function (see Chapter 58).

L-asparaginase produces hypofibrinogenemia and deficiency of other coagulation factors ([637], [638]). Mithramycin may induce a coagulopathy as a result of deficient coagulation protein levels and platelet dysfunction ([639]). A number of cancer chemotherapeutic agents impair fibrin cross-linking *in vitro* ([640]). Hematin produces a complex coagulopathy ([641]). Valproic acid therapy has been associated with acquired vWD ([642]). Anticoagulant therapy is discussed in Chapter 61.

Acquired Deficiencies of Single Coagulation Factors

A rare and largely unexplained phenomenon is the development of deficiency of a single coagulation factor during the course of an acquired disorder (Table 60.7). Isolated deficiency of factor X is well documented in patients with primary amyloidosis and amyloidosis associated with multiple myeloma ([643], [644]). Factor X levels in these patients do not rise even after massive replacement therapy, and the findings from studies using ^{131}I-labeled factor X suggest that this proenzyme is bound to subendothelial amyloid fibrils in blood vessels ([645]). A combined deficiency of factors IX and X in amyloidosis also has been reported ([646]). In many patients, the hemostatic defect is complicated by other abnormalities, such as vascular infiltration, liver disease, high levels of antithrombins, and azotemia with platelet dysfunction ([647]). Splenectomy abolished the factor X deficiency and produced complete remission of bleeding in several cases ([648]), presumably because of extensive amyloid infiltration in the splenic vasculature. Chemotherapy with melphalan and prednisone may resolve factor X deficiency in amyloidosis ([649]). High-dose chemotherapy with stem cell transplantation is also effective therapy ([650]). Factor X deficiency has also been associated with upper respiratory tract infections ([446]).

Hypoprothrombinemia has been reported as an isolated finding ([651]), most commonly in association with LAs, as discussed previously. Deficiencies of prothrombin, factors IX and XII, plasminogen, and antithrombin have been reported in some patients with the nephrotic syndrome ([652], [653], [654], [655] and [656]), presumably as the result of massive protein loss in the urine. In one patient with Sheehan syndrome, a selective deficiency of factor IX responded to treatment with corticosteroids and thyroid replacement ([657]). Isolated deficiency of factor IX in several patients with Gaucher disease also has been documented ([658]). Acquired factor VII deficiency has been reported with aplastic anemia ([659]) and liposarcoma ([660]).

Factor XIII deficiency has been associated with chronic myelocytic leukemia and with various forms of acute leukemia ([661]). Particularly low levels of this factor, which bear no clear relationship to the presence or absence of DIC, have been demonstrated in patients with acute promyelocytic leukemia. Factor XIII deficiency has also been associated with inflammatory bowel disease ([662]), and isoniazid-induced antibodies to factor XIII have been reported ([433], [434], [663]). Factor XII deficiency has been described in association with chronic myelocytic leukemia ([664]). Factor XI deficiency has been linked to Gaucher disease ([665]) and Ehlers-Danlos syndrome ([666]). Factor V deficiency has been reported in chronic myeloid leukemia and in celiac disease. Acquired vWD was discussed earlier in the section von Willebrand Factor.

Other Acquired Coagulation Disorders

Heparinlike anticoagulants have been reported in patients with hematologic malignancies [e.g., plasma cell dyscrasias ([667]) or leukemias ([668], [669]) or solid tumors ([670])]. A prolonged thrombin time and normal reptilase clotting time are typically seen in these patients. Significant clinical bleeding may occur with heparinlike

anticoagulants; a titrated protamine sulfate infusion may be helpful in these patients.

Malignancy may also be associated with other inhibitors of coagulation, including FDPs and paraproteins, dysfibrinogen-emias, and specific antibodies to coagulation factors (discussed earlier). A monoclonal antithrombin antibody associated with bleeding has been reported in a patient with myeloma ([671]).

Thrombosis and Antithrombotic Therapy

> This humour…immediately congeals not only outside the body but actually contained in its own surroundings: and this congealing of itself, we see terminate in the *thrombus* for by this term the Greeks name the congealed blood.
>
> Galen, C Black bile. Corpus medicorum Graecorum Quae Exstant V: 106, Leipzig, Cnoblock, 1823

The term *thrombosis* refers to the formation, from constituents of the blood, of a mass *within* the venous or arterial vasculature of a living animal. Hemostatic thromboses, namely self-limited and localized thromboses that prevent excessive blood loss, represent the body's natural and desired response to acute vascular injury. Pathologic thromboses such as deep venous thrombosis (DVT), pulmonary embolism (PE), coronary arterial thrombosis leading to myocardial infarction (MI), and cerebrovascular thrombotic occlusion represent the body's undesired response to acute and chronic perturbations of the vasculature, blood, or both. The terms *coagulated blood* and *clot* are not synonymous with thrombosis and refer to the formation of a solid mass of blood components *outside* of the vascular tree. Examples of clots include soft tissue, body cavity (e.g., peritoneal), and visceral hematomas. Coagulated blood best describes clots formed *ex vivo*.

Thrombosis of the veins and arteries, together with complicating embolic phenomena, is perhaps the most important cause of sickness and death in the developed countries of the world at the present time. Deaths from MI and thrombotic stroke consistently represent the major causes of death in the United States, numbering more than 800,000 people annually (more than one-third of all deaths) in a recent report ([1]). Venous thromboembolic disease is the third most common cardiovascular disease, after atherosclerotic heart disease and stroke. It has been estimated that between 500,000 and 2 million venous thromboembolic events (VTE) including calf vein thrombosis, proximal DVT (e.g., lower extremity and pelvic veins), and PE occur annually in the United States alone ([2]). The incidence of pathologic thrombosis, prevalence of disorders that predispose to thrombosis, and morbidity and mortality associated with thrombotic events all reflect the magnitude of the importance of the study of thrombotic mechanisms and development of effective antithrombotic therapies.

In this chapter, the pathophysiology of arterial and venous thrombosis and mechanisms of action of antithrombotic pharmacologic agents including antiplatelet drugs, anticoagulants, and fibrinolytic agents are summarized and discussed. Inherited conditions that predispose an individual to thrombosis, also termed *hypercoagulable states*, and the management of venous thromboembolic disease are covered. The management of arterial thrombotic events is beyond the scope of this chapter, and the reader is referred to several excellent recent review articles ([3], [4], [5] and [6]).

PHYSIOLOGY AND PATHOPHYSIOLOGY OF THROMBOSIS

The human hemostatic system consists of multiple independent, yet integrally related, cellular and protein components that function to maintain blood fluidity under normal conditions and promote localized, temporary thrombus (hemostatic thrombus) formation at sites of vascular injury. A normal hemostatic system is the human physiologic defense against exsanguination. An abnormal hemostatic system can result in pathologic bleeding, vascular thrombosis, or both.

The hemostatic system is comprised of six major components: platelets, vascular endothelium, procoagulant plasma protein “factors,” natural anticoagulant proteins, fibrinolytic proteins, and antifibrinolytic proteins. Each of these six hemostatic components must be present in fully functional form, in adequate quantity, and at the proper location to prevent excessive blood loss after vascular trauma and, at the same time, to prevent pathologic thrombosis. The hemostatic system is highly regulated and maintains a delicate balance between a prohemorrhagic state and a prothrombotic state. Any significant acquired or congenital imbalance in the hemostatic “scales” can lead to a pathologic outcome.

Normal hemostasis in response to vascular injury can be divided into two major processes of equal importance known as *primary* and *secondary hemostasis*. *Primary hemostasis* comprises the reactions needed to form a platelet plug at a site of vascular damage, whereas *secondary hemostasis* comprises a series of reactions (coagulation cascade) needed to generate cross-linked fibrin required to stabilize the platelet plug and form a durable thrombus. Natural anticoagulants [antithrombin (AT) and activated protein C] function to confine thrombus formation to the sites of vascular injury and limit thrombus size to prevent vessel occlusion and flow interruption in the affected vessel. The activity of AT is greatly enhanced by endothelial cell heparan sulfate and pharmacologic heparins. The function of activated protein C (APC) is enhanced by its cofactor, protein S. Physiologic fibrinolysis is initiated by endothelial cell–derived tissue-type plasminogen activator (t-PA), which converts plasminogen to plasmin. Plasmin can degrade cross-linked fibrin, limit thrombus size, and help dissolve a thrombus once the vascular injury has been repaired. The fibrinolytic system is regulated and localized by antiplasmin and plasminogen activator inhibitor (PAI)-1. Details of the hemostatic mechanisms and

endothelial cell regulation of hemostasis are given in Chapter 21 and Chapter 22.

Specific alterations in the quantitative and qualitative status of any hemostatic cellular or protein element can lead to pathologic thrombosis. A marked increase in the platelet count (thrombocytosis) and accentuated platelet aggregation ["sticky platelet syndrome" (SPS)] are associated with thromboembolic events. Elevated levels of procoagulant factors such as factor VIII, fibrinogen, factor IX, factor XI, and factor VII, as well as factor V resistance to inactivation by activated protein C, are recognized risk factors for vascular disease and thrombosis. Deficiency of a natural anticoagulant protein such as protein C, protein S, and AT is associated with venous thromboembolic disease. Deficiency of a fibrinolytic cascade component, such as t-PA or plasminogen, and excess plasma levels of the fibrinolytic inhibitor PAI-1 have been linked to hypercoagulability and thrombosis. Deficient endothelial cell production of thrombomodulin or release of t-PA may be associated with a thrombotic tendency. It is the net balance between the participating and, at times, opposing groups of proteins and not the level of any individual factor that is most critical to hemostatic regulation.

VIRCHOW TRIAD

In the mid-nineteenth century (1854), German pathologist Rudolph Virchow postulated that vascular obstruction was precipitated by, and thrombosis resulted from, three interrelated factors: (a) "decreased blood flow" (stasis of blood flow), (b) "inflammation of or near the blood vessels" (vascular endothelial injury), and (c) "intrinsic alterations in the nature of the blood itself" (hypercoagulability) ([7]). Many students of coagulation medicine, though, do not realize that Virchow actually recognized his "triad" as being the result of vascular occlusion—not necessarily as the original precipitant of vascular thrombosis. Nonetheless, the vascular, rheologic, and hematologic aspects of thrombosis known as Virchow triad remain relevant and instructive today (Fig. 61.1).

Figure 61.1. Pathophysiology of thrombosis. Factors implicated in the pathogenesis of arterial thrombosis (*left*) and venous thrombosis (*right*) are depicted. Examples of disorders leading to platelet activation and arterial thrombosis include the myeloproliferative disorders, heparin-associated thrombocytopenia/thrombosis syndrome, thrombotic thrombocytopenic purpura, and certain platelet polymorphisms. Examples of disorders leading to venous thrombosis in the category of deficiency of physiologic inhibitors include the inherited disorders, factor V Leiden, proteins C and S deficiencies, and AT deficiency. Many patients with thrombosis may have more than one of the risk factors listed. Estrogen therapy is a risk factor for venous thrombosis; its use is associated with activation of coagulation.

Abnormalities of Blood Flow

Arterial thrombosis initially occurs under conditions of rapid blood flow (high shear stress), a condition in which von Willebrand factor (vWF) is critical for platelet adhesion ([8]). Arterial thrombi usually are composed of tightly coherent masses of platelets, which contain small amounts of fibrin and a few erythrocytes and leukocytes. These thrombi are the classic "white thrombi," which resemble, in many respects, normal hemostatic plugs. As arterial thrombi enlarge, progressive or intermittent deposition of new layers of platelets and fibrin produces the characteristic lines of Zahn; partial or complete obstruction of blood flow may produce a "tail" of "red thrombus." The most serious consequences of arterial thrombosis are vascular occlusion with resultant ischemia and infarction of tissue and distal thrombus embolization.

Hypertension, turbulent blood flow at arterial branch points and at sites of focal atherosclerosis, and hyperviscosity may be contributory factors in certain forms of arterial thrombosis. Causes of plasma hyperviscosity that can precipitate thrombosis and exacerbate ischemia include acute myeloid leukemia, myeloproliferative syndromes such as polycythemia rubra vera, cryoglobulinemia and the plasma cell dyscrasias, including multiple myeloma and Waldenström macroglobulinemia. Immunoglobulin (Ig) paraproteins produced by plasma cell dyscrasias can increase viscosity, promote red blood cell agglutination, and, in select cases, induce a natural anticoagulant deficiency ([9]).

Venous thrombosis typically develops under conditions of slow blood flow (low shear stress) and is augmented by further retardation and stagnation of flow caused by the developing thrombus itself. Right-sided heart failure, preexistent venous thrombosis, extrinsic vascular compression by tumor, and chronic venous insufficiency all promote venous stasis, blood pooling, and a concentration of procoagulant factors ([10]). The anatomic structure of venous valves results in retrograde eddy currents, which produce pockets of stasis even in normal veins ([11]). The venous arcades in the soleus muscles of the calves may represent another site of physiologic venous stasis. These structures may enlarge and lose vascular tone with aging ([12], [13]). These facts may partially explain why DVT most commonly occurs in the valve cusps and veins of the pelvis and lower extremities.

Venous thrombi are composed of large amounts of fibrin containing numerous erythrocytes. In these loose, friable masses (the red thrombus), the platelets and leukocytes are enmeshed in random fashion. Venous thrombi resemble blood clots formed *in vitro*, and they usually produce significant obstruction to blood flow from the outset, but their most serious consequence is embolization. Blood flow obstruction secondary to venous thrombosis itself promotes the further formation of thrombus. Results of studies of clots formed in a thromboviscometer at varying rates of shear suggest that the differences in the structure of venous and arterial thrombi may be mainly the result of the velocity of blood flow. The many and complicated rheologic factors that may be involved in thrombosis have been reviewed ([14]).

Vascular Injury

Permanent and transient vascular injuries play major roles in the development of arterial thrombosis. Intraluminal vascular endothelial cell injury, atherosclerotic plaque rupture, hyperhomocysteinemia, arterial outflow obstruction, aneurysm formation, and vessel dissection are among the recognized risk factors for arterial thrombosis ([15], [16]). Arterial thrombosis usually begins with platelet adhesion to an abnormal vascular endothelial surface or exposed subendothelial constituent such as collagen. The adherent platelets become activated, leading to the release of a- and dense granule contents ([15]). Platelet-dense granules (dense bodies) release adenosine diphosphate (ADP), adenosine triphosphate, calcium, and serotonin into the surrounding milieux, resulting in the recruitment and activation of additional platelets ([15], [17]). This release reaction and platelet synthesis of thromboxane A_2 (TxA_2) and other agonists induce the aggregation of more platelets and enlargement of the temporary platelet plug. In addition to the recruitment of additional platelets, the original nidus of adherent platelets provides a phospholipid surface rich in phosphatidylserine to support and concentrate the generation of thrombin and fibrin necessary to reinforce and stabilize the platelet plug.

New insights into arterial thrombus formation have been gleaned from experiments using confocal and wide-field microscopy to image real-time thrombus formation in live-mouse cremaster muscle arterioles ([18]). Thrombosis is precipitated by laser-induced endothelial injury. These experiments demonstrated that the initiation of blood coagulation *in vivo* involves the initial accumulation of tissue factor (TF) on the upstream and thrombus–vessel wall interface of the developing thrombus. The TF is biologically active and is associated with intrathrombus fibrin generation. TF density is highest at the thrombus–vessel wall interface and is eventually observed throughout the thrombus. Leukocyte rolling is noted approximately 2 minutes after endothelial cell injury and correlates with P-selectin expression on the outer aspect of the thrombus. Minimal TF and fibrin are detected in platelet thrombi formed in mice lacking P-selectin or the P-selectin ligand, PSGL-1.

In venous thrombosis, the luminal surface of the vessel wall is usually histologically normal, and factors extrinsic to the vessel appear to have a major pathophysiologic role. Exceptions to this generalization are direct venous trauma, extrinsic venous compression, and vascular endothelial cell injury due to the toxic effect of cancer chemotherapy and excess levels of homocysteine ([16]). A limited quantity of activated platelets likely serve as a phospholipid surface to support local thrombin and fibrin formation. A generalized reduction in venous tone may be an important pathophysiologic factor in venous thrombosis in pregnant women and in women taking oral contraceptives ([19]).

Abnormalities of the Blood: Hypercoagulability

The term *hypercoagulable state* and its synonym *thrombophilia* refer to any inherited or acquired abnormality of the hemostatic system, which places an individual at increased risk for venous or arterial thrombosis (or both). Blood from patients with active thrombosis or with a hypercoagulable state may clot at an abnormally rapid rate *in vitro* ([20]). The concept of hypercoagulability has gained widespread acceptance, and it is generally appreciated that these hemostatic changes are important in the pathogenesis of thrombosis, and that testing for these disorders may be helpful in patient management ([3], [21], [22] and [23]).

PLATELET ABNORMALITIES Although platelets may be incorporated into virtually any thrombus, they appear to be pathogenetically most important in arterial thrombosis. The relative lack of use of antiplatelet agents for the primary and secondary prevention of VTE indirectly supports this notion. Increased platelet turnover (shortened platelet survival, compensated platelet destruction) occurs in vascular disease and thrombosis, including arterial and venous thrombosis, coronary artery disease, vasculitis, hyperhomocysteinemia, and valvular heart disease ([24], [25], [26], [27], [28], [29] and [30]). Increased platelet turnover can also be seen in patients with risk factors for vascular disease, including those who use tobacco and those with hyperlipidemia ([31], [32]). The increased platelet turnover and activation can reflect thromboembolic disease and also probably contribute to an exacerbation of thrombotic events. As a consequence of platelet–vessel wall interactions in patients with vascular disease, platelet adhesion, activation, and aggregation occur, resulting in acquired storage pool disease and the presence in the blood of platelet granule-derived proteins such as platelet factor-4 and ß-thromboglobulin ([33], [34]). Although elevated blood levels of these proteins indicate increased platelet turnover, improper blood collection technique may artifactually result in abnormal levels, and the clinical use of such testing is uncertain. Vascular endothelium possesses multiple antiplatelet properties that may be important in preventing platelet adhesion, promoting vasodilation, and inhibiting platelet aggregation ([35], [36], [37] and [38]). However, interruption of endothelial cell prostacyclin synthesis by aspirin does not result in a net thrombotic tendency. The potential role of hyperactive platelets in patients with thrombosis, as well as the use of platelet function testing in this setting, is somewhat controversial. SPS is an autosomal-dominant disorder characterized by *in vitro* platelet hyperaggregability in response to ADP and epinephrine ([39]). Up to 21% of people with unexplained arterial occlusive events and many with recurrent arterial thrombotic events have SPS. Clinical events associated with SPS appear to follow bouts of emotional stress. Aspirin therapy at a dose as low as 81 mg daily normalizes the *in vitro* aggregation defect in the majority of patients. Because of the importance of vWF in mediating platelet adhesion to subendothelium, the role of vWF in human vascular disease has been a topic of investigation. Pigs affected with von Willebrand disease (vWD) are resistant to atherosclerosis; however, a human autopsy study found that severe vWD did not protect against atherosclerosis ([40], [41]). On the other hand, there was no pathologic evidence for arterial thrombosis in the autopsy study ([41]). An association between elevated plasma vWF levels and recurrent MI has been demonstrated, and vWF antigen is an independent predictor of coronary artery disease ([42]). Platelet polymorphisms have been evaluated as risk factors for arterial thrombosis. These include polymorphisms for glycoprotein (gp) IIIa (Pl ^{A2}), gpIa (807 T allele), and gpIba ([43]). The Pl ^{A2} polymorphism is linked with coronary artery disease; Pl ^{A2}-positive platelets exhibit a lower threshold for activation and also have variable aspirin sensitivity ([43]).

COAGULATION ABNORMALITIES Coagulation disorders that can contribute to hypercoagulability can be divided in three risk factor categories: situational, inherited, and acquired ([21], [44], [45] and [46]). Situational risk factors represent well-defined, transient clinical circumstances that are associated with increased thrombosis risk both while they are present and for a short period after they have resolved. Examples include surgery, prolonged immobilization, oral contraceptive pill (OCP) use, hormone replacement therapy (HRT), pregnancy, cancer chemotherapy, and heparin-induced thrombocytopenia (HIT). Inherited risk factors represent genetic mutations and polymorphisms that result in deficiency of a natural anticoagulant (e.g., protein C, protein S, or AT), procoagulant factor accumulation (e.g., prothrombin G20210A or the thermolabile variant of the enzyme methylenetetrahydrofolate reductase), or coagulation factor resistance to inactivation by a natural anticoagulant (i.e., factor V G1691A, also known as *factor V Leiden*). These conditions are characterized by a disruption in the normally highly regulated coagulation mechanism resulting in greater thrombin generation and an increased risk of clinical thrombosis. Acquired risk factors result either from medical conditions or from nonfamilial hematologic abnormalities that interfere with normal hemostasis or blood rheology. Examples include cancer, inflammatory bowel disease, nephrotic syndrome, vasculitis, antiphospholipid antibodies, myeloproliferative syndromes, paroxysmal nocturnal hemoglobinuria, and hyperviscosity syndromes. These acquired risk factors are distinct from situational risk factors by the fact that they represent alterations in hemostatic homeostasis as a result of disease or, for the most part, nonreversible processes. In contrast, situational risk factors result from either a therapeutic intervention or an adverse reaction from such an intervention. Hyperhomocysteinemia and increased factor VIII functional activity are examples of thrombosis risk factors that can be acquired in nature or have a genetic predisposition ([30], [47]). Age defies categorization but remains the single most predictable risk factor for thrombosis. The estimated baseline annual age-associated risk of VTE is 1 in 10,000 people younger than 40 years of age, increasing to 1 in 100 people older than 75 years of age ([48], [49] and [50]). Recent reports have focused on elevated levels of various coagulation factors, particularly fibrinogen and factors V, VII, VIII, X, and XI, that have been documented in patients with thrombosis and prethrombotic disorders, including pregnancy and estrogen-containing contraceptive use ([51]). Fibrinogen and factors V and VIII are acute-phase reactants, and their plasma levels may rise in patients with virtually any disorder associated with tissue damage or inflammation, including most thrombotic processes. Whether increased because of a genetic factor or an acute-phase reaction, excess procoagulant factor concentrations may tilt the hemostatic scales in favor of hypercoagulability and may be associated with an increased risk of thrombosis. Epidemiologic studies have identified elevated plasma levels of fibrinogen and factor VII activity as independent risk factors for cardiovascular disease ([52], [53] and [54]).

FIBRINOLYTIC ABNORMALITIES Abnormal fibrinolysis has also been linked to vascular disease. Low fibrinolytic activity (measured by dilute clot lysis) was a significant determinant of coronary artery disease in the Northwick Park Heart Study, and elevated PAI-1 activity was associated with major ischemic events in another study ([55], [56]). In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations ($p = .02$) and PAI-1 activity ($p = .001$) ([57]). Defects in endogenous fibrinolytic capacity have also been found in young patients with severe limb ischemia or unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59% ([58]). Excess PAI-1 resulting in impaired endogenous fibrinolysis has also been associated with venous thrombosis in select cases ([59]). One must appreciate that elevated levels of coagulation zymogens not only occur in a number of medical disorders as a result of an acute-phase response; certain coagulation proteins may also have predictive importance when elevated in cardiovascular disease. Fibrinogen, factor VII, PAI-1, and vWF appear to be particularly useful in this regard.

ACTIVATION OF COAGULATION

Mechanisms leading to activation of coagulation in patients with thrombosis have been proposed. TF is thought to be the primary initiator of *in vivo* coagulation ([60]). In the absence of TF expression, endothelial cells actively maintain thromboresistance. TF may be expressed in trace amounts during various physiologic processes, such as during normal parturition and after even minimal trauma, including minor head injuries. Immunologic injury of endothelium may lead to the exposure of TF ([61]). Antibodies formed to exogenous heparin may bind to heparan sulfate on the endothelium, resulting in cell injury, the expression of TF, and the initiation of coagulation ([62], [63]). In a similar manner, endothelial cells may be induced to express TF by interleukin-1, homocysteine, tumor necrosis factor, and endotoxin ([64], [65], [66] and [67]). TF antigen expression by endothelium has been demonstrated in pathologic primate and human tissues ([68], [69] and [70]). Activation of coagulation may also occur on monocytes, and platelets can be activated to mediate factor Xa–catalyzed prothrombin conversion to thrombin ([71], [72]). Deficient hepatic clearance of activated coagulation factors may represent an important thrombogenic factor in premature infants and in patients with liver disease, especially after administration of prothrombin complex concentrates that contain trace amounts of activated vitamin K–dependent coagulation factors.

Various other mechanisms may be responsible for low-grade *in vivc* coagulation under certain conditions. Adenocarcinoma tumor cells can directly promote thrombin generation by producing TF, expressing the coagulation factor X activator known as *cancer procoagulant*, or displaying surface sialic acid residues that can support nonenzymatic factor X activation ([73], [74]). Tumor cells can also indirectly promote thrombin generation by eliciting TF expression by monocytes and endothelial cells. Selected tumors may mediate an accentuation of platelet activation and accumulation, whereas other tumor cells may express surface phospholipid species such as phosphatidylserine, which can support prothrombin and factor X activation ([75]).

Kinetic studies have been performed in an attempt to demonstrate accelerated catabolism of coagulation factors in hypercoagulable states. The turnover of fibrinogen is accelerated in patients with major venous thrombosis and in diabetics with hyperglycemia, but not in patients with small thrombotic lesions ([76], [77]). The turnover of radioiodinated prothrombin is normal, even in the setting of major thrombosis ([78]).

A laboratory picture similar to that described in the hypercoagulable state may also be seen in patients with nonovert (compensated or chronic) disseminated intravascular coagulation (DIC) ([79]). In such patients, the prothrombin time (PT) and the activated partial thromboplastin time (aPTT) may be shortened because of the presence of traces of thrombin or other activated coagulation factors. These activated factors affect one-stage, but not two-stage, clot endpoint coagulation assays. High levels of factor V and factor VIII activity may reflect the presence of thrombin-activated forms of these factors in the circulation. Pregnancy, which can be regarded as a hypercoagulable state, has also been described as a physiologic form of nonovert DIC by some clinicians ([80]). Pregnancy increases the risk of venous thromboembolism approximately fivefold among the general population, and female patients who have experienced prior venous thrombosis have a threefold risk of

venous thrombosis during pregnancy ([81]). The use of estrogen-containing oral contraceptives and estrogen HRT is clearly associated with an increased risk of venous thromboembolism ([82]). A prospective study of these patients indicates that estrogens induce activation of coagulation as well as reduction in levels of natural anticoagulants such as AT and protein S ([83]). However, many patients who experience venous thromboembolism while taking oral contraceptives have a common inherited thrombotic disorder, APC resistance (APC-R), or prothrombin G20210A ([84]). Another report indicated that oral contraceptives induced “acquired activated protein C resistance” in females ([85]). The relative risk of venous thromboembolism in postmenopausal women using estrogen replacement is 2.14, and the risk is highest during the first year of use ([86]). Table 61.1 summarizes acquired etiologies predisposing one to thrombosis.

TABLE 61.1. Acquired Disorders Predisposing to Thrombosis

Vascular disorders
Atherosclerosis
Diabetes
Vasculitis
Prosthetic materials (grafts, valves, indwelling vascular catheters)
Abnormal rheology
Stasis (immobilization, surgery, congestive heart failure)
Hyperviscosity (polycythemia vera, Waldenström macroglobulinemia, acute leukemia, sickle cell disease)
Other disorders associated with hypercoagulability
Cancer (Trousseau syndrome)
Cancer chemotherapeutic agents, thalidomide
Oral contraceptives, estrogen therapy, selective estrogen receptor modulators
Pregnancy
Infusion of prothrombin complex concentrates
Nephrotic syndrome
Myeloproliferative disorders
Paroxysmal nocturnal hemoglobinuria
Inflammatory bowel disease
Thrombotic thrombocytopenic purpura
Disseminated intravascular coagulation
Antiphospholipid antibody syndrome
Heparin-induced thrombocytopenia/thrombosis
Human immunodeficiency virus infection

INHERITED THROMBOTIC DISORDERS

Several recent monographs and reviews have covered the topic of inherited thrombotic disorders in detail ([3], [21], [22], [46], [51], [87], [88]). Table 61.2 summarizes the prevalence of selected inherited and acquired hypercoagulable states in different populations, whereas Table 61.3 summarizes the clinical presentations of venous thrombosis that may be suggestive of particular hypercoagulable states. Many patients who experience thrombosis are found to have a combination of defects, for example, APC-R plus use of oral contraceptive agents ([84]), or a combination of inherited defects ([88]). Although people with inherited hypercoagulable states are at a greater risk for developing a thrombotic event than those without such disorders, not all people with a well-defined hypercoagulable state develop an overt thrombosis, and not all people with thrombosis have an identifiable hypercoagulable state. Testing for an inherited hypercoagulable state is likely to uncover an abnormality in more than 60% of patients presenting with idiopathic (i.e., spontaneous or unprovoked) venous thrombosis ([22], [88]). Although the remaining 30 to 40% have unremarkable test results, this does not imply a true absence of a hypercoagulable state. Some of these individuals may have an acquired condition such as cancer or antiphospholipid antibodies, whereas others may have a disorder or genetic defect that has not yet been discovered or characterized.

TABLE 61.2. Prevalence of Selected Inherited and Acquired Hypercoagulable States in Different Patient Populations

Hypercoagulable State	General Population (%)	Patients with First Venous Thromboembolism (%)	Thrombophilic Families (%)
Factor V Leiden	3–7 [a]	20	50
Prothrombin G20210A	1–3	6	18
Protein C deficiency	0.2–0.4	3	6–8
Protein S deficiency	N/A	1–2	3–13
Antithrombin deficiency	0.02	1	4–8
Mild hyperhomocysteinemia	5–10	10–25	N/A
Elevated factor VIII	11	25	N/A
Lupus anticoagulant	0–3	5–15	N/A

N/A, not available or unknown.

[a] Prevalence as high as 15% in northern Europe.

TABLE 61.3. Clinical Presentations of Venous Thromboembolism That May Suggest Certain Hypercoagulable States

Venous Thromboembolism Presentation	Hypercoagulable State
Cerebral vein thrombosis in women using oral contraceptives	PT G20210A mutation
Cerebral vein thrombosis in general	Paroxysmal nocturnal hemoglobinuria, essential thrombocythemia, antiphospholipid antibodies, antithrombin deficiency, PT G20210A mutation
Intraabdominal vein thrombosis (inferior vena cava, renal vein, portal vein, mesenteric and hepatic veins)	Antiphospholipid antibodies, paroxysmal nocturnal hemoglobinuria, myeloproliferative syndromes, cancer, antithrombin deficiency
Warfarin skin necrosis	Protein C, protein S deficiencies
Unexplained recurrent fetal loss	Antiphospholipid antibodies; factor V Leiden
Recurrent superficial thrombophlebitis	Factor V Leiden, polycythemia vera, protein C, protein S, or antithrombin deficiency
Migratory superficial thrombophlebitis (Trousseau syndrome)	Adenocarcinoma (particularly of the gastrointestinal tract)
Neonatal purpura fulminans	Homozygous protein C or protein S deficiency

PT, prothrombin.

Antithrombin Deficiency

AT, formally known as *AT-III*, deficiency was first described by Egeberg in 1965 ([89]). AT, a serine protease inhibitor, regulates coagulation by inactivating thrombin and other procoagulant enzymes, including factors Xa, IXa, XIa, and XIIa. Like most inherited thrombotic disorders, AT deficiency is inherited as an autosomal-dominant disorder ([90] , [91]). A blood bank survey reported that 1 in 600 people have AT deficiency ([92]). The interactions of unfractionated and low-molecular-weight heparin (LMWH) with AT are discussed in the section Heparin.

PATHOPHYSIOLOGY AND GENETICS Patients with AT deficiency may have either type I (quantitative deficiency) or type II (qualitative abnormality) disease. Type I AT-deficient patients usually have concordant reductions in AT measured by both immunologic and functional assays. Type II patients have reduced functional AT activity associated with normal amounts of AT protein. Plasma concentrations of the thrombin activation peptide, prothrombin fragment 1+2, are elevated in patients with AT deficiency, indicating persistent activation of coagulation as a result of deficient neutralization of factor Xa in these patients ([93]). The genetic basis for type I AT deficiency is either deletion of a gene segment or the occurrence of point mutations or deletions, resulting in a nonsense mutation and an incomplete protein. The genetic basis for type II AT deficiency is the occurrence of point mutations that do not impair synthesis of the protein, but that result in a dysfunctional protease inhibitor. A summary of AT mutations (greater than 100) has been reported ([94]). In general, mutant AT molecules exhibit deficient heparin binding, deficient protease inhibition, or both.

CLINICAL ASPECTS AT deficiency is manifested primarily by recurrent venous thromboembolism ([90] , [91]). Almost every vein site has been reported to be involved with thrombosis in AT-deficient patients, including unusual sites such as mesenteric vessels ([95]). Thrombosis may occur in the absence of precipitating factors or may result from events such as pregnancy, estrogen use, trauma, or surgery. AT deficiency can result in heparin resistance manifesting as a normal to minimally increased aPTT in patients receiving large doses of heparin ([96]). However, most patients with AT deficiency do not exhibit heparin resistance, and most cases of heparin resistance are not due to AT deficiency. In family studies, venous thrombosis occurred in 85% of AT-deficient relatives before 55 years of age ([96]). The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 40-fold ([97] , [98]). An annual absolute risk of venous thrombosis of 27.5% has been reported in women carriers of AT deficiency who also use OCPs ([99]). Early studies reported pregnancy-related venous thrombosis rates as high as 70% for AT-deficient women ([100] , [101]). Most AT-deficient patients are heterozygotes and possess approximately 50% of normal activity levels. Although homozygotes have been reported in consanguineous kindreds, in general, homozygous type I AT deficiency is believed to be fatal *in utero* ([102]).

LABORATORY DIAGNOSIS Results of the PT and aPTT are normal in AT-deficient patients. A variety of commercial assays are available to measure AT levels, including functional and immunologic assays. Functional assays are preferable because they detect both type I and type II patients. One report found that approximately 40% of patients with AT deficiency had type II disease ([103]). Functional assays for AT measure heparin cofactor activity using a chromogenic substrate method to quantitate thrombin or factor Xa neutralization ([104]). A potential disadvantage of functional AT assays is that plasma AT levels may be overestimated because of the presence of heparin cofactor II (HCII) in the sample. The use of bovine thrombin and a low heparin concentration (3 U/ml) in the assay system can minimize this problem ([105]). Immunologic assays for AT use Laurell rocket immunoelectrophoresis, microlatex-particle immunoassay, radial immu-nodiffusion, or enzyme-linked immunosorbent assay (ELISA) methods ([106]). Ideally, patients should be evaluated for AT deficiency at a time when they are not receiving therapeutic heparin or oral anticoagulants, because heparin depresses AT levels, whereas long-term warfarin therapy increases plasma AT levels in some patients ([91] , [107]).

TREATMENT Some AT patients may experience heparin resistance, requiring the administration of AT by using virally inactivated, plasma-derived AT concentrates or fresh frozen plasma. A transgenic AT concentrate has been developed and is currently in clinical trial. Supplemental AT may make it easier to achieve therapeutic anticoagulation with heparin in these patients. Patients with recurrent thrombosis should receive long-term warfarin therapy at a dosage to maintain an international normalized ratio (INR) value of 2.0 to 3.0 (discussed in the section Warfarin). Patients with a single thrombotic event should receive at least 3 to 6 months of warfarin therapy and, because of an increased recurrence rate, should be considered for long-term therapy beyond 6 months. Patients with massive venous thrombosis or PE may be candidates for thrombolytic therapy. AT-deficient patients who become pregnant or who will undergo general surgery should be considered for anticoagulant prophylaxis, including AT concentrate administration ([108]). Most asymptomatic patients should not be treated. The avoidance of estrogens should be considered in AT-deficient patients.

ACQUIRED ANTITHROMBIN DEFICIENCY AT deficiency is also associated with numerous disorders, including DIC, liver disease, nephrotic syndrome, preeclampsia, and is seen in patients taking oral contraceptive agents and during pregnancy ([109] , [110] , [111] and [112]). Although logic would suggest that correction of AT deficiency might be clinically useful in disorders such as DIC or liver disease, there are no conclusive data supporting AT replacement therapy outside the setting of prophylaxis of high-risk patients, such as pregnant, AT-deficient patients ([113]).

Heparin Cofactor II Deficiency

HCII is another heparin-dependent thrombin inhibitor, differing from AT in that a glycosaminoglycan other than heparin, dermatan sulfate, catalyzes this inhibitor of coagulation ([114]). HCII deficiency is inherited as an autosomal-dominant trait. Although there have been anecdotal studies of thrombosis associated with HCII-deficient kindreds, a larger study has concluded that HCII deficiency by itself may not be an inherited risk factor for thrombosis ([115] , [116] and [117]). Commercial assays to measure HCII levels are available, but the clinical use of such assays in routine evaluation of patients for inherited thrombosis is uncertain.

Protein C Deficiency

Protein C is a vitamin K–dependent plasma protein that, when activated by the thrombin-thrombomodulin complex to activated protein C, inactivates factors Va and VIIIa to inhibit coagulation ([118]). APC also possesses profibrinolytic activity that results from neutralization of PAI-3 activity ([119]). Inherited deficiency of protein C and its association with thrombosis were first described by Griffin and co-workers in 1981 ([120]). Protein C deficiency was believed to be inherited in an autosomal-dominant pattern with incomplete penetrance. Recent studies have suggested that protein C deficiency may be an autosomal-recessive disorder and that coinheritance of another defect (particularly factor V Leiden) results in a high degree of penetrance that appears as dominant inheritance in double-heterozygous carriers ([121] , [122]).

PATHOPHYSIOLOGY AND GENETICS As with AT deficiency, patients with protein C deficiency may have type I (quantitative deficiency) or type II (qualitative abnormality) disease. Most patients are heterozygotes with approximately 50% of normal protein C levels. A hypercoagulable state can be demonstrated in nonanticoagulated protein C–deficient patients using activation peptide (fragment 1+2) assays ([123]). In type I protein C deficiency, more than half of the gene mutations identified are missense mutations. Point mutations affecting protein function appear to be common in patients with type II protein C deficiency. A 1995 review of protein C mutations identified 16 distinct mutations in type II protein C deficiency ([124] , [125]). More than 160 different gene abnormalities have been associated with both types of protein C deficiency ([94] , [126]). An updated summary of protein C mutations is available at www.ISTH.org. Despite the clear association of protein C deficiency with thrombosis in large epidemiologic studies, there are also definitive data indicating that many protein C–deficient patients are asymptomatic ([127]). For example, one report found that heterozygous protein C deficiency occurred in approximately 1:250 subjects, whereas a large Scottish study estimated the prevalence to be approximately 1:500 ([121] , [128]). No patient in either study had a history of symptomatic venous thrombosis. These findings indicate that additional risk factors—acquired, genetic, or both—are necessary to provoke thrombosis in heterozygous protein C–deficient patients. Indeed, in one study, up to 20% of symptomatic protein C–deficient patients also had APC-R, supporting the concept that many patients with recurrent thrombosis have more than one risk factor ([122]).

CLINICAL ASPECTS Three clinical syndromes are associated with protein C deficiency: venous thromboembolism in heterozygous adults, neonatal purpura fulminans in homozygous newborns, and warfarin-induced skin necrosis in certain heterozygous adults. The predominant clinical symptom of protein C–deficient patients is recurrent venous thromboembolism, although arterial thrombotic events, including stroke, have been reported ([129] , [130]). As mentioned above, many patients are found to have risk factors other than inherited protein C deficiency on investigation, such as APC-R, use of oral contraceptive agents, and pregnancy. Protein C deficiency has been linked to fetal loss ([131]). Neonatal purpura fulminans is seen in homozygous newborns of heterozygous parents. These children develop DIC at birth, associated with extensive venous or arterial thrombosis (or both) and very low levels of protein C (<5% of normal) ([132]). Warfarin-induced skin necrosis is an unusual syndrome seen in certain patients with heterozygote protein C deficiency ([133]). Most patients who develop this syndrome have received large doses of warfarin in the absence of concomitant overlapping therapeutic parenteral anticoagulation. The basis for this syndrome is that warfarin therapy, especially in large loading doses, reduces protein C levels more rapidly than the vitamin K–dependent procoagulant factors, leading to exacerbation of the basal hypercoagulable state and thrombosis. In family studies, venous thrombosis occurred in 50% of protein C–deficient relatives of affected probands before 40 years of age ([134]). The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 31-fold ([97] , [98]). As stated above, other studies did not detect an increased thrombosis risk in carriers of protein C deficiency. Differences in risk between family- and population-based studies can be in part explained by greater difficulty in obtaining reliable population-based estimates due to the overall low prevalence of this and other natural anticoagulant deficiencies. In studies of

unselected patients with venous thrombosis, the odds ratio of having protein C deficiency is increased six- to ninefold compared to controls ([46], [134], [135] and [136]). An annual absolute risk of venous thrombosis of 4.3% has been reported in women carriers of a natural anticoagulant deficiency such as protein C deficiency who also use OCPs ([99], [137]). Protein C activity less than 0.68 U/ml, measured at the time of thrombosis in individuals without a known hypercoagulable state, has been associated with increased rates of recurrent venous thrombosis ([138]).

LABORATORY DIAGNOSIS Patients with heterozygous protein C deficiency have normal PT and aPTT values, whereas patients with homozygous protein C deficiency have abnormal coagulation tests consistent with DIC. Because both type I and type II disorders may occur, functional assays are suggested to optimize identification of affected patients. The most commonly used commercial assay uses a snake venom activator (Protac) in a chromogenic substrate or clot-based assay ([139]). The limitations of Protac-based assays have been reviewed ([139]). Some investigators prefer the clot endpoint-based assay, because it measures complete function of the protein C molecule, including those patients with abnormal protein C molecules that possess normal activity by a chromogenic substrate assay. However, therapeutic heparin levels affect the clot-based assay. A College of American Pathologists' consensus conference on thrombophilia recommends use of the chromogenic substrate assay ([140]). A recent report indicated that measurement of the protein C to protein S antigen ratio was useful in identifying carriers of protein C deficiency ([141]). Protein C levels can also be measured by immunologic methods, including Laurell rocket immunoelectrophoresis and ELISA ([139]). However, immunologic assays may not detect type II patients and may overestimate protein C levels in warfarin-treated patients. Immunologic assays may be more useful in evaluating patients with homozygous deficiency and DIC. Age-related changes occur with protein C levels ([142]). Consequently, it is important to consider this when testing younger patients (<30 years); otherwise, normal subjects may be misclassified as protein C–deficient. A common problem faced by laboratories is measuring protein C levels in patients taking oral anticoagulants. Many clinicians forget that protein C is a vitamin K–dependent molecule, and that otherwise hemostatically normal people taking warfarin may have low protein C levels. Griffin and co-workers suggested that protein C data be normalized against the level of another vitamin K–dependent protein to distinguish inherited protein C–deficient patients from normal subjects taking warfarin ([120]). One author reported that using a ratio between protein C and prothrombin optimally categorized patients ([143]). However, for this method to be useful, patients must be stably anticoagulated for at least 2 weeks, and the laboratory must obtain plasma samples and reference ranges from patients taking warfarin for reasons other than recurrent thrombosis. The consensus conference did not recommend assaying protein C levels in patients on oral anticoagulants ([140]).

TREATMENT Many patients with protein C deficiency are asymptomatic, especially those identified in screening studies. Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures, such as surgery. Symptomatic protein C–deficient patients should be anticoagulated with heparin and then considered for long-term secondary prophylaxis with warfarin at an INR of 2.0 to 3.0. Those patients with a single thrombotic event should receive at least 3 to 6 months of warfarin. The American College of Chest Physicians' Consensus Conference on Antithrombotic Therapy does not recommend indefinite anticoagulation for protein C–deficient patients with a single uncomplicated thrombotic event ([144]). Patients with more than one thrombotic event, or patients with a single life-threatening thromboembolic event, should be considered for long-term anticoagulation. Patients with massive thrombosis or PE may be candidates for thrombolytic therapy. Infants with neonatal purpura fulminans should be treated with protein C replacement therapy. Protocols using a purified protein C concentrate or prothrombin complex concentrates have been described ([145], [146]). Use of the purified concentrate normalizes activation of coagulation in these homozygous patients ([147]). The role of replacement therapy using the recently approved recombinant APC concentrate in patients with protein C deficiency remains to be determined.

ACQUIRED PROTEIN C DEFICIENCY Because protein C is a vitamin K–dependent protein, any disorder associated with vitamin K deficiency may result in protein C deficiency, including warfarin use, liver disease, and malnutrition ([148]). Protein C levels are also reduced in DIC, presumably reflecting thrombin activation of the zymogen and consumption of APC ([149]). Protein C levels may also be reduced in renal disease, especially the nephrotic syndrome ([150]).

Protein S Deficiency

Protein S is a vitamin K–dependent plasma protein that facilitates the anticoagulant activity of activated protein C. Protein S deficiency in association with inherited thrombotic disease was first described by two groups in 1984 ([151], [152]). As with AT and protein C deficiencies, protein S deficiency is inherited as an autosomal-dominant trait. A recent large epidemiologic study found that protein S deficiency may not be a true risk factor for thrombosis, and others have reported that many patients with a previous diagnosis of protein S deficiency actually have APC-R ([127], [153], [154]). This diagnostic error results from interference in the functional protein S assay of patients with the inherited disorder, APC-R, and misclassification of patients. These patients have a “pseudo” protein S deficiency, often display a type II deficiency pattern, and have protein S activity levels that correlate with the APC ratio. Based on these reports and the high incidence of APC-R in the general population, the true importance of protein S deficiency in inherited thrombosis is uncertain ([153], [154] and [155]).

PATHOPHYSIOLOGY AND GENETICS As described for AT and protein C deficiencies, patients with protein S deficiency may have quantitative or qualitative disorders. Under normal circumstances, protein S exists in plasma in two forms: bound to C4b-binding protein (60% of total protein S) and free (40% of total). Because only free protein S has cofactor activity, a revised classification system has been proposed for protein S deficiency ([156]). Type I protein S deficiency is a quantitative disorder in which protein S functional activity, total antigen, and free antigen levels are equally reduced to approximately 50% of normal. Type IIa protein S deficiency is a deficiency of free protein S with preserved normal levels of total protein S. In type IIb protein S deficiency, the levels of both total and free protein S antigen are normal. Apparent type IIb protein S deficiency has been described in patients with APC-R ([155]). An acquired type IIa protein S deficiency may result from excess levels of C4b-binding protein or the presence of free protein S inhibitory and clearing autoantibodies. More than 100 different mutations have been identified in the gene that codes for protein S ([94]). A full listing of protein S gene mutations and polymorphisms can be found at www.ISTH.org. As with protein C deficiency, many patients with protein S deficiency and thrombosis have additional risk factors. In one study, among patients with protein S deficiency, approximately 40% also had APC-R; of family members with thrombosis, 72% had both defects, whereas less than 20% of patients with single defects experienced thrombosis ([157]).

CLINICAL ASPECTS Like AT and protein C–deficient patients, most patients with protein S deficiency and thrombosis have experienced venous thromboembolism ([151], [152]). However, unlike most other inherited thrombotic disorders, up to 25% of patients with protein S deficiency may experience arterial thrombosis including stroke ([158]). As mentioned previously, many patients with protein S deficiency and thrombosis have other risk factors, including APC-R, estrogen use, or pregnancy ([157]). Neonatal purpura fulminans, fetal loss, and warfarin-induced skin necrosis have also been associated with protein S deficiency ([131], [159]). In family studies, venous thrombosis occurred in 100% of protein S–deficient relatives of affected probands by 70 years of age ([160]). The estimated lifetime increased relative risk of thrombosis has been reported to be as high as 36-fold for protein S deficiency ([97], [98]). As mentioned above, other studies including the Leiden Thrombophilia study cast doubt on the association between thrombosis and protein S deficiency alone.

Laboratory Diagnosis Patients with heterozygous protein S deficiency have normal PT and aPTT values. The laboratory diagnosis of protein S deficiency is complicated by four factors: the levels of C4b-binding protein, the coexistence of APC-R in certain patients, elevated factor VIII activity levels, and warfarin therapy. C4b-binding protein is an acute-phase reactant protein S–binding protein, often elevated in thromboembolism, resulting in reduced free protein S levels from the patient's true baseline. Consequently, measurement of protein S levels in patients with acute thrombosis may yield misleading results. Similarly, false-positive results may be seen when functional protein S assays are performed on patients who have APC-R or factor VIII activity levels greater than or equal to 250% ([155]). Patients should not be assumed to have protein S deficiency (diagnosed by functional assay) until APC-R has been excluded. Lastly, because protein S is a vitamin K–dependent protein, warfarin therapy and vitamin K deficiency pose the same difficulty as described for patients evaluated for protein C deficiency. Protein S levels may also be decreased in the setting of pregnancy, but not necessarily associated with thrombotic events. Both functional and immunologic assays are commercially available to quantitate plasma protein S levels. Functional assays may be PT- or aPTT-based, measuring inhibition of factor Va by APC ([161]). These assays have the advantage of measuring free protein S activity. Immunologic assays to measure either total (free plus C4b-binding protein-bound) or free protein S levels are available ([162], [163]). Immunologic assays may be useful in evaluating patients who have coexisting APC-R. Total protein S levels are measured by Laurell rocket immunoelectrophoresis or ELISA. In the interpretation of immunologic assays, one should consider the report that the mean plasma level of protein S antigen in males is higher than it is in females ([163]).

TREATMENT Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures, such as surgery. Symptomatic protein S–deficient patients should be anticoagulated as described for protein C–deficient patients. Those patients with recurrent thrombosis, or patients with a single life-threatening thromboembolic event, should be considered for long-term anticoagulation. Protein S concentrates are under development.

Activated Protein C Resistance (Factor V Leiden)

Before 1993, most patients with idiopathic venous thrombosis evaluated for inherited thrombosis were not given a diagnosis, because AT, protein C, and protein S deficiencies together were found in less than 20% of patients. In 1993, Dahlback and colleagues from Sweden postulated that certain patients with recurrent thrombosis might have additional abnormalities of the protein C pathway, resulting in a hypercoagulable state ([164]). They found that addition of APC to plasma obtained from patients with recurrent thrombosis did not prolong the aPTT to the same degree as that seen when APC was added to normal plasma ([164]). These patients did not have any previously recognized inherited thrombotic disorder. The term *APC resistance* was used for these patients. Other investigators then used the aPTT-based APC screening test to examine other populations for this phenotype. APC-R was found in 20 to 60% of patients with recurrent thrombosis ([165], [166] and [167]

). Like other inherited thrombotic disorders, APC-R was inherited in an autosomal-dominant manner.

PATHOPHYSIOLOGY AND GENETICS Dominant inheritance renders the factor Va heavy chain partially (but not completely) resistant to inactivation by APC. APC inactivates factor Va in an orderly and sequential series of cleavages, first at Arg506, and then at Arg306 and Arg679 ([168], [170]). Although the affected factor V cleavage site in APC-R is not directly responsible for complete inactivation of factor Va, APC cleavage at this site is necessary for subsequent proteolytic events. This "partial resistance" is explained by the fact that cleavage of factor Va by APC at Arg306 continues to occur, albeit at a slower rate ([171]). In fact, factor V Arg506Gln (factor V Leiden) is inactivated ten times slower than normal factor Va. This provides a pathophysiologic explanation for why factor V Leiden, although common, is a relatively weak risk factor for VTE. Because factor Va functions as a cofactor in the conversion of prothrombin to thrombin, the mutation results in greater amounts of factor Va available for coagulation reactions, "shifting" the hemostatic balance toward greater thrombin generation ([21], [94]). APC-R due to factor V Leiden is the most common inherited predisposition to hypercoagulability in Caucasian populations of northern European background ([21]). Factor V Leiden follows a geographic and an ethnic distribution: The mutation occurs most frequently in northern and western Europe (the highest prevalences of 10 to 15% have been reported in Cyprus, Sweden, and Turkey) but is rare in the Asian and African continents as well as in ethnic groups from Asian descent, such as Inuit Eskimos, Amerindians, Australian Aborigines, and Polynesians ([172]). In the United States, factor V Leiden is most commonly seen in Caucasians (6.0%), with lower prevalences in Hispanics (2.2%), African and Native Americans (1.2%), and Asian Americans (0.45%) ([173]). Factor V Leiden accounts for 92% of cases of APC-R, with the remaining 8% of cases due to pregnancy, oral contraceptive use, cancer, selected antiphospholipid antibodies, plasma glucosylceramide deficiency, and other factor V point mutations ([21], [174], [175] and [176]). Therefore, the terms *factor V Leiden* and *APC-R* should not be considered synonymous; in fact, APC-R is an independent risk factor for VTE even in the absence of factor V Leiden ([177]). It is estimated that the mutation arose in a single Caucasian ancestor some 21,000 to 34,000 years ago—well after the evolutionary separation of non-Africans from Africans (approximately 100,000 years ago) and of Caucasoid (white Caucasians) from Mongoloid (Asians) subpopulations (approximately 60,000 years ago) ([178]).

CLINICAL ASPECTS Heterozygous carriers of factor V Leiden have a two- to tenfold increased lifetime relative risk of developing VTE ([97], [137], [179], [180], [181], [182], [183] and [184]). This risk is further increased in combination with pregnancy (9-fold), OCP use (36-fold), and HRT (13- to 16-fold) ([185], [186], [187] and [188]). Venous thromboembolism is the most common clinical symptom of APC-R in patients who experience thrombosis. In general, there is a notable lack of association of APC-R with arterial thrombosis ([182]). Another clinical association with APC-R is recurrent miscarriage, with one study reporting that 20% of patients with second trimester pregnancy loss have APC-R ([131], [189]). Factor V Leiden does not appear to be a cause of recurrent pregnancy loss occurring late in the first trimester ([189], [190]). Neonatal purpura fulminans has been reported in a patient with factor V Leiden who did not have proteins C or S deficiency ([191]). APC-R is also a common inherited risk factor for cerebral venous thrombosis ([192]). The factor V Leiden mutation has also been identified in children who experience thrombosis ([193]). However, this mutation does not appear to play a major role in the hypercoagulability of cancer ([194]). An intriguing report has demonstrated that the factor V Leiden mutation is a risk factor for MI in young women; the combination of factor V Leiden with smoking increased the risk of MI more than 30-fold ([195]). Factor V Leiden has also been associated with MI in individuals with coronary artery thrombosis in the absence of evidence of underlying fixed atherosclerotic lesions ([196]). There are conflicting data on the role of factor V Leiden heterozygosity as an independent risk factor for VTE recurrence ([197], [198]). Two studies ("positive studies") have found an increased risk of VTE recurrence compared to control subjects, with relative risk of 4.1 and 2.4, respectively. Six other studies ("negative studies") have found no such association ([199], [200], [201], [202], [203] and [204]). The positive studies by Ridker et al. and Simioni et al. were prospective but included a small number of patients with factor V Leiden heterozygosity (14 and 41, respectively) ([197], [198]). The Physicians' Health Study (by Ridker et al.) included only men ([197]). Among the negative studies, four were prospective, and two were retrospective ([199], [200], [201], [202], [203] and [204]). Three of the prospective studies and the large retrospective cohort study by De Stefano et al. each included 80 to 112 patients with factor V Leiden heterozygosity ([199], [200], [202], [204]). The two positive studies and three of the negative studies had a patient follow-up period of 4 or more years ([197], [198], [200], [202], [204]). The study by Simioni et al. and two of the negative studies did include some patients in whom the diagnosis of VTE recurrence was made on clinical grounds alone, without objective imaging assessment ([198], [200], [204]). When only objectively confirmed cases of VTE recurrence were analyzed, the negative study by Lindmarker et al. showed a nonstatistically significant trend toward more VTE recurrence in individuals heterozygous for factor V Leiden compared to noncarriers (16.1% vs. 12.4%). One positive study and three of the negative studies also included patients with upper-extremity and distal lower-extremity (calf) DVT, whereas the positive study by Simioni et al. had the greatest proportion of patients with proximal lower-extremity DVT (>90%). A recent reevaluation of the study by Simioni et al. did confirm the original study findings of increased relative risk of recurrent VTE in heterozygous carriers of factor V Leiden ([205]). Additional data from recently completed large-scale prospective trials will hopefully clarify the question of whether factor V Leiden heterozygosity is a risk factor for VTE recurrence. One study, the PREVENT trial, demonstrated equivalent rates of recurrent VTE in patients with and without factor V Leiden ([499]).

Homozygous carriers of the factor V Leiden mutation are estimated to have an 80-fold increased lifetime relative risk of VTE ([181]). A more recent estimate, derived from a pooled analysis of a larger population, has confirmed an increased risk of VTE but of lower magnitude (tenfold) ([184]). The discrepancy is likely due to the very low prevalence of factor V Leiden homozygosity found in the healthy controls from the general population ([181], [184]). Most homozygous carriers present with VTE before 40 years of age, but some can live thrombosis-free until the sixth or seventh decade of life or even remain asymptomatic for life ([206], [207]). The majority of VTE is situational, and women appear more likely to develop VTE than men, suggesting an important role of OCP use and pregnancy in triggering thrombosis ([206], [207] and [208]). Based on data from the first prospective Duration of Anticoagulation trial, the risk of VTE recurrence is significantly increased in homozygous factor V Leiden carriers (36.4% at 48 months) when compared to heterozygous carriers (16.1%) and controls (12.4%) ([200]).

LABORATORY DIAGNOSIS APC-R has only been recognized as a disease entity since 1993, but the intense interest in this common inherited thrombotic disorder has focused substantial attention on laboratory methods for its diagnosis. Laboratory aspects of its discovery have been reviewed by Dahlback ([209]). The disorder can be evaluated by coagulation assays that have as their basis inhibition of factor Va by APC and prolongation of the clotting time. Typically, APC is added to patient plasma, and a clotting assay is performed (usually the PTT), with results expressed as a ratio:

$$\frac{\text{Patient aPTT + APC}}{\text{Patient aPTT – APC}}$$

Reference ranges are established for normal patients with and without addition of APC. Affected patients with mutant factor V have clotting times prolonged to a lesser extent (lower ratio) than normals. Alternatively, a DNA test can be done to specifically look for the Arg506Gln mutation; this highly conserved point mutation is present in most patients with APC-R. With properly collected plasma samples, the APC-R clotting test can correctly classify nearly 100% of patients, when normalized to a control plasma pool ([210]). However, most laboratories do not use a normalized assay, relying instead on commercial APC-R assay kits, some of which cannot reliably distinguish between normals and patients with factor V Leiden. Predilution of the patient sample with factor V–deficient plasma has improved the performance characteristics of most currently available commercial assays ([211]). These disadvantages of routine clotting assays have led to the development of alternative methods to diagnose APC-R. Samples from patients with baseline abnormal coagulation studies (e.g., anticoagulant therapy, lupus anticoagulants, liver disease) yield uninterpretable results. A TF-dependent factor V assay has been described that is useful in patients taking oral anticoagulants or with the lupus anticoagulant ([212]). The polymerase chain reaction test for factor V Leiden uses the restriction enzyme *Mnl*I to digest a 267–base pair amplified fragment of patient DNA ([169]). Consensus recommendations on methodologies to assay for factor V Leiden have been presented ([213]).

TREATMENT Therapy of venous thromboembolism in patients with APC-R is similar to that described for patients without an identified hypercoagulable state. Long-term secondary prophylaxis is not necessary for heterozygotes unless they experience more than one thrombotic event or experience life-threatening thromboembolism. Asymptomatic patients with APC-R should not be treated, but female patients with this disorder should be informed about the additional thrombotic risk associated with oral contraceptive use, pregnancy, and HRT ([85], [214]). Prophylaxis for high-risk situations, such as surgery, should be given. Unresolved questions in this area include whether female patients should be screened for APC-R before initiating estrogen therapy and whether asymptomatic pregnant females with APC-R should receive anticoagulant prophylaxis.

Prothrombin Mutations

The prothrombin G20210A mutation is the second most common inherited predisposition to hypercoagulability ([21]). Heterozygous prothrombin G20210A has been found in 18% of probands of thrombophilic families, 6% of unselected patients with deep vein thrombosis, and 2% of normal Caucasian individuals ([21], [215]).

More recently, a novel single-point mutation of the prothrombin gene at position 20209 has been reported in four unrelated patients, two of whom had a history of VTE and one of whom had a history of stroke ([216]). Although the clinical significance of the PT C20209T mutation is unknown, it may be underrecognized because it is not detected by the polymerase chain reaction/digestion assay commonly used for prothrombin gene mutation testing ([215], [216]). Interestingly, all four reported individuals with PT C20209T were African-Americans. Two additional African-American patients with this mutation have been identified by the same group of investigators.

PATHOPHYSIOLOGY AND GENETICS Prothrombin G20210A is a single-point mutation (G-to-A substitution at nucleotide 20210) in the 3' untranslated region of the prothrombin gene ([21], [215]). This autosomal-dominant mutation appears to result in elevated concentrations of plasma prothrombin ([215]). In fact, the VTE risk

increases as the plasma prothrombin level increases, with levels greater than 115 IU/dl leading to a 2.1-fold increased relative risk of VTE ([215]). The G20210A mutation leads to a “gain of function” of the prothrombin gene, perhaps by resulting in an altered polyadenylation pattern in mutant prothrombin mRNA ([217]). An *in vitro* study of thrombin generation found that increasing prothrombin levels to 150% of normal resulted in enhanced thrombin activity ([218]). The mutation appears to follow a geographic and ethnic distribution, with the highest prevalence occurring, unlike factor V Leiden, in Caucasians from southern Europe (3%) ([218]). This prevalence is nearly twice that observed in northern Europe (1.7%) ([219]). Similar to factor V Leiden, the prothrombin G20210A mutation is also found in the Middle East and Indian regions, but it is virtually absent in individuals of Asian and African backgrounds ([219]). These distributions provide support to the estimate that both mutations (factor V Leiden and prothrombin G20210A) originated relatively recently in the European founding population, after the evolutionary divergences of subpopulations. A recent evaluation of patients in Northeast Ohio who underwent hypercoagulability evaluations revealed an equivalent prevalence of prothrombin gene mutations in whites and blacks ([216]).

CLINICAL ASPECTS Heterozygous PT G20210A is associated with a two- to sixfold increased lifetime relative risk of VTE ([46] , [207] , [215] , [220]). The risk appears to be further increased in combination with pregnancy (15-fold) and OCP use (16-fold) ([185] , [221]). The relative risk of cerebral vein thrombosis is increased 10-fold in women with this mutation who are not on OCPs, as opposed to 150-fold in pill users ([222]). Homozygosity for PT G20210A has an estimated population prevalence of 0.014%, and homozygous carriers appear to have greater predisposition to develop early (before 40 years of age) idiopathic recurrent VTE than heterozygotes ([215] , [223] , [224]). The role of PT G20210A as a risk factor for VTE recurrence is less controversial than it is for factor V Leiden, but data are also somewhat conflicting. Simioni et al., reevaluating a prospective study from 1997, retrospectively determined patients' PT G20210A mutation status and found that the hazard ratio of VTE recurrence was 2.4 ([205]). However, three prospective studies, which each included 28 to 52 patients, found no increased risk of recurrent VTE in heterozygous PT G20210A carriers ([200] , [225] , [226]). A fourfold increased risk of MI has been demonstrated, particularly in young women carriers of this mutation. A large case-control study of more than 14,000 men, though, revealed no increased risk of stroke or MI associated with this abnormal prothrombin gene. The reasons for this apparent male/female disparity are unknown ([195] , [227]).

LABORATORY DIAGNOSIS The prothrombin G20210A mutation can only be reliably and routinely identified using molecular biologic techniques. Measurements of functional prothrombin activity do not sufficiently differentiate between carriers and noncarriers of this gene mutation ([21]). Testing can accurately be performed despite concomitant treatment with any form of anticoagulation. Detection of the C20209T mutation was performed using rapid polymerase chain reaction with fluorescent hybridization probes, analysis for abnormal melting curves, and direct gene sequencing ([216]).

TREATMENT Treatment paradigms for patients with prothrombin G20210A heterozygosity parallel those for heterozygous factor V Leiden.

Hyperhomocysteinemia

Homocysteine is a sulfhydryl amino acid formed during the conversion of methionine to cysteine. Hyperhomocysteinemia has been identified as an independent risk factor for stroke, MI, peripheral arterial disease, and venous thrombotic disease ([228] , [229] and [230]). Even mild to moderate hyperhomocysteinemia is a significant risk factor for vascular disease. Hyperhomocysteinemia results when homocysteine metabolism is deranged. Homocysteine is normally metabolized by either cystathionine ß-synthase (CBS)–mediated transsulfuration to cystathionine or methylene tetrahydrofolate reductase (MTHFR)–dependent remethylation to methionine ([231] , [232]). Mutations and deficiencies of the enzymes and essential vitamin cofactors (B $_6$, B $_{12}$, and folate) involved in these metabolic pathways can result in an accumulation of homocysteine.

PATHOPHYSIOLOGY AND GENETICS The amino acid homocysteine is normally metabolized via the transsulfuration pathway by the enzyme CBS, which requires vitamin B $_6$ as cofactor, and via the remethylation pathway by the enzymes MTHFR, which is folate dependent, and methio-nine synthase, which requires vitamin B $_{12}$ as cofactor ([231] , [232]). Inherited severe hyperhomocysteinemia (plasma level >100 µmol/L), as seen in classic homocystinuria, may result from homozygous MTHFR and CBS deficiencies and, more rarely, from inherited errors of cobalamin metabolism ([231] , [232]). Inherited mild to moderate hyperhomocysteinemia (plasma level >15 to 100 µmol/L) may result from heterozygous MTHFR and CBS deficiencies but most commonly results from the thermolabile variant of MTHFR (tlMTHFR) that is encoded by the C677T gene polymorphism ([231] , [232]). This single-point mutation (C677T) is in the coding region for the MTHFR binding site (exon 4) leading to substitution of a valine for an alanine, resulting in the thermolabile enzyme. Acquired hyperhomocysteinemia may be caused by folate deficiency, vitamins B $_6$ and B $_{12}$ deficiencies, renal insufficiency, hypothyroidism, type II diabetes mellitus, pernicious anemia, inflammatory bowel disease, advanced age, climacteric state, carcinoma (particularly involving breast, ovaries, or pancreas), and acute lymphoblastic leukemia, as well as methotrexate, theophylline, and phenytoin therapy ([231] , [232]). The precise mechanisms underlying the thrombogenicity of homocysteine remain unclear. Several diverse mechanisms have been proposed including endothelial cell desquamation, low-density lipoprotein (LDL) oxidation, promotion of monocyte adhesion to endothelium, and factor V activation and promotion of thrombin generation ([16]). Homocysteine also enhances platelet aggregation and adhesiveness as well as turnover, presumably as a result of endothelial cell injury ([233]). A recent study found that moderate hyperhomocysteinemia does not impair the activation of protein C by thrombin and does not impair the inactivation of factor Va by APC ([234]). A novel mechanism of hyperhomocysteinemia resulting from DNA hypo-methylation has been proposed (234a). Severe homocysteinemia usually results from homozygous CBS deficiency. The incidence of this disorder is approximately 1:335,000 live births. Classic symptoms for homozygous patients include premature vascular disease and thrombosis, mental retardation, ectopic lens, and skeletal abnormalities ([235]). Recently, heterozygous homocysteinemia has been recognized as a disease entity; this disorder may affect 0.3 to 1.0% of the general population ([235]).

CLINICAL ASPECTS Heterozygous carriers of the tlMTHFR mutation have normal plasma homocysteine levels unless folate levels are reduced ([236]). More important, the majority of case-control studies have not demonstrated an increased VTE risk in homozygous carriers of the tlMTHFR, and the majority of individuals with hyperhomocysteinemia do not have the tlMTHFR polymorphism. Thus, characterization of the tlMTHFR polymorphism is not useful to determine an individual's VTE risk. VTE risk is most closely related to elevated fasting plasma homocysteine levels, regardless of etiology. Hyperhomocysteinemia (plasma level >18.5 µmol/L) has been associated with a two- to fourfold increased VTE risk ([237] , [238]). Interestingly, in the Physicians' Health Study, hyperhomocysteinemia (plasma level above the ninety-fifth percentile; 17.2 µmol/L) did increase the risk of idiopathic VTE (relative risk, 3.4) but not the risk of all (situational and idiopathic) VTE ([183]). The cumulative probability of VTE recurrence 2 years after discontinuation of anticoagulation has been shown to be higher in patients with persistent hyperhomocysteinemia (plasma levels above the ninety-fifth percentile) than in controls (19.2% vs. 6.3%; relative risk, 2.7; p = .009) ([239]). The majority of reports linking hyperhomocysteinemia to thrombosis have focused on venous thromboembolic disease. The link between hyperhomocysteinemia and peripheral arterial thrombosis has been less well studied. Kottke-Marchant et al. compared 23 patients with documented arterial peripheral thrombosis to age- and sex-matched controls ([240]). Elevated homocysteine levels (>13 µm) conferred an odds ratio of 7.8 for thrombosis. Elevated homocysteine levels were found in 73% of cases versus 28% of controls. Only smoking and homocysteine level were independent risk factors for arterial thrombosis. Currie et al. evaluated homocysteine and cardiovascular risk factors in 66 adult patients with vascular disease. Hyperhomocysteinemia was identified in 29% of patients and was an independent risk factor for the failure of vascular procedures (p = .006) ([241]).

LABORATORY DIAGNOSIS The initial step in the evaluation of the patient with suspected hyperhomocysteinemia involves measurement of fasting total plasma homocysteine (the sum of nonprotein bound and protein bound) ([231]). Many laboratories report homocysteine values in reference to published “normal” ranges such as 5 to 15 µm/L, but, ideally, a local, laboratory specific normal range should always be established. A normal value in the nonfasting setting does not normally require repeating. Under ideal laboratory circumstances, patients with a normal fasting value should undergo repeat testing after an oral methionine challenge. Testing 2 to 8 hours after an oral methionine load (100 mg/kg) increases the sensitivity of detecting occult vitamin B $_6$ deficiency and obligate heterozygotes for CBS deficiency ([242]). A separate normal range for post–methionine loading homocysteine levels should be used. Vitamin B $_{12}$ and folate deficiency do not affect post–methionine loading homocysteine values. In patients found to have elevated levels of homocysteine, testing for vitamin B $_{12}$ deficiency is advocated to avert missing subclinical deficiency before beginning oral folic acid therapy. Metho-dologies to measure homocysteine levels have been reviewed ([16] , [243]).

TREATMENT Thrombotic events in homocysteinemic patients should be treated as described for other inherited disorders. An additional treatment strategy is to lower plasma homocysteine levels, hopefully alleviating the risk factor for thrombosis. Folic acid supplementation is the mainstay of effective hyperhomocysteinemia therapy ([231] , [244]). A recent metaanalysis of 1114 patients enrolled in 12 randomized studies of vitamin supplementation to lower homocysteine levels demonstrated a 25% reduction in homocysteine levels with similar effects across a dosage range from 0.5 to 5.0 mg daily ([245]). The usual recommended dose is 0.4 to 1.0 mg daily. Whether patients unresponsive to one dose benefit from an escalation in dose is unclear. Because patients with subclinical vitamin B $_{12}$ deficiency may be prone to developing peripheral neuropathy if they receive folic acid supplementation alone, additional treatment with 0.5 mg/day of oral vitamin B $_{12}$ has been advocated ([244]). In the same metaanalysis, an additional 7% reduction of homocysteine levels was noted with vitamin B $_{12}$ supplementation ([245]). Vitamin B $_{12}$ administration results in normalization of homocysteine levels in B $_{12}$-deficient individuals. Oral supplementation of vitamin B $_{12}$ may be insufficient in patients with pernicious anemia or other malabsorption syndromes. In these patients, a monthly intramuscular injection of 200 to 1000 µg of vitamin B $_{12}$ is considered adequate replacement. Vitamin B $_6$ supplementation did not appear to have any effect on homocysteine levels. However, in patients with vitamin B $_6$ deficiency, replacement doses of 10 to 50 mg daily are typically recommended. Betaine, a nutritional supplement derived from beets, functions as an alternative methyl donor in the remethylation of homocysteine to methionine. Betaine has been used in individuals with homocystinuria and may facilitate homocysteine reduction in individuals not responsive to folate and vitamin B $_6$

([246]).

Increased Factor VIII Activity

It is now appreciated that elevated levels of procoagulant coagulation factors, in addition to deficiencies of natural anticoagulant proteins, are risk factors for VTE. Factor VIII levels greater than 1.5 IU/ml (150%) are associated with a threefold and a sixfold greater relative risk of VTE when compared to levels below 1.5 IU/ml (150%) and below 1.0 IU/ml (100%), respectively ([247]). VTE risk is increased 11-fold with levels greater than 200%, but it does not appear to be accentuated by concomitant OCP use ([248] , [249]). Elevated activity levels of factor VIII associated with VTE risk seem to be persistent and not solely attributable to acute-phase response ([250]). Transiently elevated factor VIII levels associated with acute-phase protein release, though, may in part explain the hypercoagulability associated with inflammatory disorders such as inflammatory bowel disease and cancer. Individuals with plasma factor VIII activity greater than 234% (above the ninetieth percentile cut-off point for the study population) have a 6.7-fold increased relative risk of recurrent VTE compared to those with activity levels of less than 120% ([47]).

Because factor VIII is indeed an acute-phase reactant and its levels can be affected by many factors, including blood type and vWF concentration, determination of the true meaning of an elevated factor VIII level in an individual patient with VTE is challenging. In the study by Koster et al., in which blood samples for factor VIII activity were obtained a minimum of 6 months after the VTE, it was impossible to completely distinguish between inherited elevation and postthrombotic, transient elevation of factor VIII ([207] , [247]). Nonetheless, the fact that an increased factor VIII level is prevalent in persons with VTE may, in fact, imply that elevated factor VIII is not only frequent, but also an important risk factor for VTE ([207]). The College of American Pathologists' consensus conference recommendations are to not routinely measure factor VIII levels in patients with venous or arterial thrombosis ([251]).

Impaired Endogenous Fibrinolysis

The endogenous fibrinolytic system is comprised of plasminogen, plasminogen activators (PAs), and antifibrinolytic regulatory proteins. Intravascular plasminogen is converted to the active fibrinolytic enzyme plasmin primarily by t-PA derived from vascular endothelial cells and by urokinase-type plasminogen activator (u-PA) from leukocytes. The principal physiologic inhibitor of t-PA is PAI-1, whereas plasmin itself is inactivated by circulating and thrombus-bound a $_2$-antiplasmin. Decreased endogenous fibrinolytic activity as a result of qualitative and quantitative abnormalities of plasminogen, an inadequate release of t-PA in response to vascular injury, and excessive production of PAI-1, such as is found in inflammatory and malignant diseases, can result in impaired endogenous fibrinolysis and accumulation of pathologic thrombus ([252]).

Abnormal fibrinolysis was previously thought to account for a large proportion of patients with inherited thrombosis. However, the discovery of APC-R as a common inherited disorder and a literature review that concluded that a causal relationship between abnormal fibrinolysis and inherited thrombosis had not been clearly demonstrated have diminished enthusiasm for routinely evaluating patients with recurrent thrombosis for abnormal fibrinolysis ([253]).

PLASMINOGEN DEFICIENCY Quantitative and qualitative abnormalities of plasminogen have been reported in patients with recurrent venous thrombosis ([254] , [255]). Quantitative deficiency is inherited as an autosomal-dominant disorder, whereas qualitative plasminogen defects (dysplasminogenemia) are usually inherited as autosomal-recessive disorders. Dysplasminogenemia is more common in Japanese subjects, and a single mutation accounts for more than 90% of cases in this population ([256]). One report has suggested that quantitative plasminogen deficiency may not be a risk factor for thrombosis ([257]). Optimal assays for plasminogen deficiency use a functional chromogenic substrate assay to detect type I and type II patients; in this assay, streptokinase (SK) is added to the plasma sample, and the SK-plasminogen complex formed hydrolyzes a synthetic substrate ([258]).
TISSUE PLASMINOGEN ACTIVATOR DEFICIENCY Defective synthesis or release of t-PA from the vessel wall represents a potential mechanism for thrombosis. Plasma t-PA activity is unstable, and for accurate assays, citrated plasma samples must be immediately acidified and red blood cells removed ([259] , [260]). Addition of a platelet activation inhibitor to the blood collection tube may help reduce the release of platelet-derived PAI-1, which can interfere with t-PA activity quantification. A plasminogen-chromogenic substrate assay is used to measure t-PA activity; t-PA antigen can be measured by ELISA using citrated plasma.
INCREASED PLASMINOGEN ACTIVATOR INHIBITOR-1 LEVELS Increased levels of PAI-1 have been associated with venous or arterial thrombosis. Plasma PAI-1 activity is measured in citrated plasma using a back-titration method with single-chain t-PA ([261]). Because blood fibrinolytic activity exhibits a diurnal rhythm (decreased fibrinolysis in the morning as a result of peak PAI-1 levels; increased fibrinolysis in the evening as a result of low PAI-1 levels), plasma samples should be obtained at standardized times, such as between 8:00 and 9:00 a.m. ([262]). Additionally, because fibrinolytic component levels can be affected by acute-phase changes, patients should not be evaluated for abnormal fibrinolysis until 2 to 3 months after an acute thrombotic event. In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations (p = .02) and PAI-1 activity (p = .001) ([57]). Elevated levels of PAI-1 may effectively reduce t-PA activity levels, thereby blocking the activation of plasminogen to plasmin and inducing impaired fibrinolysis that may ultimately lead to thrombosis. Theoretically, markedly elevated levels of PAI-1 might also impair attempts at pharmacologic thrombolysis in the setting of acute arterial and venous thrombosis ([263]). Defects in endogenous fibrinolytic capacity have also been found in young patients with unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59% ([264]). Similar defects have been detected in individuals with recurrent venous thrombosis. It has been noted that patients who have undergone major surgical procedures might experience a transient “fibrinolytic shutdown” due to elevated PAI-1 levels as part of an acute-phase response ([265]). Avoidance of obesity and associated insulin resistance, correction of hypertriglyceridemia, cessation of smoking, and exercise may improve the innate fibrinolytic status ([57] , [266] , [267]). Treatment of hypertension with angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists has been associated with significantly reduced PAI-1 production ([268] , [269]). The lipid-lowering agent gemfibrozil has also been shown to decrease the PAI-1 synthesis rate ([270]). Modest alcohol consumption and hormone replacement treatment in postmenopausal women also seem to be beneficial ([271] , [272]).

Dysfibrinogenemia

The clinical and biochemical aspects of dysfibrinogens are reviewed in Chapter 59. In general, dysfibrinogens associated with thrombosis have as their molecular defect generation of an abnormal fibrin resistant to fibrinolysis. An updated summary of dysfibrinogen molecular abnormalities is presented at www.ISTH.org. Dysfibrinogenemia as a cause of inherited thrombosis is uncommon.

Certain patients with dysfibrinogenemia may have a prolonged PT; more typically, these patients are detected by prolonged thrombin and reptilase times, suggesting a defect in the conversion of fibrinogen to fibrin ([273]). Confirmation of a dysfibrinogen can be done by simultaneous measurement of functional and immunologic fibrinogen levels. Typically, immunologic levels are found to be higher than levels measured by functional assay. Published guidelines in the healthy population indicate that for fresh plasma samples, the ratio of immunologic to functional fibrinogen ranges from 1.12 to 1.65; ratios greater than 1.65 are suggestive of dysfibrinogenemia ([274]).

Another potentially useful test to evaluate patients for dysfibrinogenemia is the fibrinogen lysis time. This test requires partial purification of the patient's fibrinogen, followed by clotting and lysis in a standardized assay ([275]). Dysfibrinogens may also result in a false-positive test for fibrin(ogen) degradation products (FDPs) as assayed by latex agglutination, because residual fibrinogen remains in serum after clotting and is detected by the antibody-coated latex beads. An algorithm for the laboratory diagnosis of dysfibrinogenemia has been reported ([276]).

Thrombomodulin Deficiency

Thrombomodulin complexed with thrombin is required to activate protein C. In theory, thrombomodulin deficiency should result in hypercoagulability. A number of mutations in the thrombomodulin gene have been identified in patients with venous thrombosis and their families ([277]). Routine laboratory testing for this disorder is not yet available, but an Italian study of thrombosis patients indicated that thrombomodulin deficiency is not a common cause of thrombosis ([278]). However, thrombomodulin gene mutations have been linked to myocardial infarction ([279]). In the prospective Atherosclerosis Risk in Communities study, soluble thrombomodulin levels had a graded, inverse association with, and were a good predictor of, coronary artery disease ([280]). The levels correlated in their extreme quartiles with the coagulation activation marker prothrombin fragment 1+2 ([280]).

Lipoprotein (a)

Lipoprotein (a) [Lp(a)] is a lipoprotein moiety similar to LDL cholesterol in core lipid composition and in the fact that it has apolipoprotein (apo) B–100 as a surface apolipoprotein. In addition, Lp(a) has a unique glycoprotein, apo(a), which is bound to apoB-100. Apo(a) is structurally similar to plasminogen but lacks fibrinolytic activity ([281]). Lp(a) has both atherogenic and thrombogenic properties. Its thrombogenic effect is derived from stimulation of PAI-1 synthesis, promotion of intercellular adhesion molecule-1 expression by vascular endothelium, inhibition of both plasminogen and t-PA binding to fibrin, inhibition of plasminogen activation by t-PA, and competition with plasminogen for binding sites on endothelial cells and fibrin ([282]). The cumulative effect is impaired activation of plasminogen to plasmin at the vessel wall, inhibition of fibrinolysis, and increased risk for thrombosis.

The exact mechanisms that control Lp(a) levels are unknown, but genetic factors that regulate hepatic synthesis of apo(a) are likely important. One's plasma Lp(a) level is stabilized during infancy and maintained throughout life ([283]). Plasma concentrations greater than 20 mg/dl seem to increase the risk of coronary artery disease, peripheral arterial occlusive disease (PAOD), and stroke ([282]). Lippi et al. evaluated Lp(a) in 68 patients subjected to vascular and endovascular surgery ([284]). Significant restenosis or reocclusion occurred in 23 (34%) patients. Lp(a) concentrations were significantly higher in those with restenosis and reocclusion compared with those in the no restenosis group. Occlusive complications were unlikely to occur in patients with Lp(a) concentrations below 5 mg/dl ([284]). Different isoforms of the apo(a) component of Lp(a) have different atherogenic potential and possibly different thrombogenic potential.

There are, as yet, no definitive studies demonstrating that reduction of elevated Lp(a) levels reduce the risk of atherosclerotic vascular occlusion or arterial thrombosis. Because a significant component of Lp(a) excess cardiovascular risk appears to be related to concomitant LDL cholesterol excess, measurement of Lp(a) as a general screening test is not currently recommended ([285]). Measurement of Lp(a) should be considered mainly in individuals with atherosclerosis in the absence of classic risk factors, rapidly progressive atherosclerotic lesions despite aggressive risk factor modification, and individuals with acute arterial thrombosis ([283], [285], [286]). Because it is an acute-phase reactant, an elevated Lp(a) level must be carefully interpreted if drawn shortly after surgery, acute thrombosis, or acute coronary syndromes ([287]).

Patients with elevated Lp(a) benefit most from aggressive LDL cholesterol lowering. Current National Cholesterol Education Program guidelines recommend achievement of a target LDL level less than 100 mg/dl in individuals with peripheral arterial disease ([288]). Although hepatic 3-methylglutaryl coenzyme A reductase inhibitors (“statins”) may be the ideal agents for LDL lowering and atherosclerotic plaque stabilization, this class of drug does not appreciably lower Lp(a) levels themselves ([289]). Nicotinic acid (niacin), usually in high doses, is the first-line pharmacologic therapy to lower Lp(a) levels. Reductions up to 38% have been reported ([290]). Because nicotinic acid therapy may be poorly tolerated, a gradual escalation in dose and pretreatment with aspirin are recommended. In women, estrogen replacement therapy can lower Lp(a) levels by as much as 50% ([286]). The goal of therapy for Caucasian populations is to reduce Lp(a) levels to less than 30 mg/dl ([285]).

Combined Defects

Compound heterozygosity for two different natural anticoagulant deficiencies is extremely rare due to the low prevalence of each individual defect. The phenotypic presentation of such compound heterozygotes does not appear to be as severe as it is for the homozygous forms of each deficiency, with the rarely reported patient presenting with VTE of early onset (in the teenage years) ([97], [207]). Because factor V Leiden is the most common inherited thrombophilia, double heterozygosity for factor V Leiden and a natural anticoagulant deficiency have been described in some families ([122], [291]). In families harboring factor V Leiden and protein C deficiency, 73% of compound heterozygotes reported a history of VTE, compared with 31% and 13% of relatives with protein C deficiency only and factor V Leiden only, respectively ([122]). In families with factor V Leiden and AT deficiency, 92% of double-heterozygous carriers had a history of VTE, as opposed to 57% and 20% of individuals with AT deficiency only and factor V Leiden only, respectively ([291]).

Although it is clear that VTE is more frequent in double-heterozygous carriers from thrombophilic families as described above, evaluation of a true interaction and estimation of VTE risk cannot be determined due to lack of power ([184], [207]). However, combined heterozygosity for both factor V Leiden and prothrombin G20210A mutations, which is estimated to occur in 1 in 1000 persons, does appear to be associated with an increased relative risk of both first and recurrent VTE ([184], [204], [292]). In a pooled analysis of eight case-control studies including more than 2000 patients with VTE, a 2.2% prevalence for the combined mutations was found in patients ([184]). Twelve percent of patients with factor V Leiden were also heterozygous for PT G20210A, and 23% of patients with PT G20210A were also heterozygous for factor V Leiden ([184]). Double heterozygosity was associated with a 20-fold increased relative risk of VTE ([184]). The risk of recurrent VTE for heterozygous carriers of both factor V Leiden and PT G20210A also appears to be increased (2.6-fold) ([204]).

The prevalence of factor V Leiden carriership in combination with acquired hypercoagulable states has also been studied. Factor V Leiden appears to increase the risk of VTE in patients with antiphospholipid antibodies but is not a prerequisite for the development of VTE in those patients ([207], [293]). The interaction between factor V Leiden and hyperhomocysteinemia has been a matter of interest since the observation, not corroborated by further studies, that factor V Leiden appeared to be a prerequisite for VTE in individuals from families with classic homocystinuria ([294]). Nonetheless, two studies on the interaction between mild to moderate hyperhomocysteinemia and factor V Leiden have yielded somewhat different findings. Den Heijer et al. found that the risk of VTE associated with the combination of conditions (twofold) did not exceed the risk associated with each condition alone (9.5-fold for factor V Leiden, 2.2-fold for hyperhomocysteinemia) ([237]). However, in the large Physicians' Health Study, the concomitant presence of both conditions did appear to be synergistic ([183]). The relative risks of 21.8 and 9.7 for idiopathic VTE and all VTE (situational and idiopathic), respectively, far exceeded the risk of VTE associated with each condition alone ([183]). Thus, it is uncertain whether the interaction between factor V Leiden and hyperhomocysteinemia is, in fact, synergistic. Because both studies used the ninety-fifth percentile cut-off point for plasma homocysteine levels, the discrepancies in the reported relative risks (2.0 and 21.8 in the Dutch and the American study, respectively) could have resulted from the small number of patients with both conditions ([183], [207], [237]). In the Physicians' Health Study, only four patients and two controls had the combined defects ([183]).

Inherited Risk Factors in Childhood Venous Thrombosis

Many of the common inherited thrombotic disorders described in adult patients have been linked to pediatric thrombosis. A prospective European study identified a single genetic risk factor in 54% of pediatric thrombosis patients ([295]). Common defects identified were factor V Leiden (32%), protein C deficiency (9%), protein S deficiency (6%), prothrombin gene mutation (4%), and AT deficiency (3%) ([295]). In most patients, thrombosis is precipitated by superimposed nongenetic risk factors that included central venous catheters, cancer, sepsis, immobility, surgery, trauma, or use of oral contraceptives ([296]). For neonatal patients with thrombosis, the most significant factor associated with thrombosis is the presence of a central venous catheter ([297]). In children with recurrent thrombosis, the factor V Leiden mutation is present in most patients ([298]). Homozygous deficiencies of protein C or protein S are causal in neonatal purpura fulminans ([132], [159]). When pediatric patients are evaluated for protein C, protein S, or AT deficiency, pediatric reference ranges are mandatory because age-related changes occur in the levels of these proteins.

A consensus panel of the International Society on Thrombosis and Haemostasis has recommended that pediatric patents with thrombosis be routinely tested for inherited and acquired disorders in a comprehensive fashion ([299]). However, many of the suggested tests are not recommended by the College of American Pathologists' consensus panel, and there are no data to indicate that patients with a genetic predisposition to thrombosis—children or adults—should be treated differently (299a) (discussed in the following section).

Perspective on Laboratory Testing for Inherited Thrombotic Disorders

Mounting interest in hypercoagulability, increased availability of hypercoagulable state test “panels,” and enhanced ability to identify an abnormality in tested patients have prompted widespread testing of thrombosis patients. Testing for acquired and inherited hypercoagulable states uncovers an abnormality in more than 50% of patients presenting with an initial VTE but may have minimal actual impact on management in most of these patients ([21], [97], [300], [301]). Such laboratory screening should be reserved for patients for whom the results of individual tests significantly impact the choice of anticoagulant agent, intensity of anticoagulant therapy, therapeutic monitoring, family screening, family planning, prognosis determination, and most of all, duration of antithrombotic therapy. Testing “just to know” is neither cost effective nor clinically appropriate. Table 61.4 lists situations in which hypercoagulable state testing should be considered, but not necessarily performed, unless

an *a priori* use of the test results has been determined. Table 61.5 lists potential elements of an initial battery of tests to detect a defined hypercoagulable state.

TABLE 61.4. Clinical Circumstances in Which Selected Hypercoagulable State Testing May Be Considered

Idiopathic VTE
VTE in unusual sites
Recurrent VTE (especially if idiopathic)
VTE at young age (<45 yr)
VTE in the setting of a strong family history of VTE
Unexplained recurrent pregnancy loss
Family members of VTE patients with known inherited hypercoagulable states

VTE, venous thromboembolism.

TABLE 61.5. Screening Laboratory Evaluation for Patients Suspected of Having a Hypercoagulable State

Activated protein C resistance (diluting patient plasma with factor V–deficient plasma)
Prothrombin G20210A mutation testing by polymerase chain reaction
Activity assays for antithrombin, protein C, and protein S [a]
Activated partial thromboplastin time, mixing studies, and dilute Russell viper venom time [a]
Fasting total plasma homocysteine level
Anticardiolipin antibody testing by enzyme-linked immunosorbent assays
Factor VIII activity [a]

[a] Assays should not be done at the time of acute thrombosis or while the patient is anticoagulated.

Patients should be considered for evaluation of these disorders if they are young (<45 years of age) with recurrent thrombosis, or if they have had a single thrombotic event and have a positive family history ([22], [88]). This recommendation is based on the fact that, with the exception of hyperhomocysteinemia and qualitative abnormalities of plasminogen, inherited thrombotic disorders, especially the five most common (APC-R, prothrombin G20210A, protein C deficiency, protein S deficiency, and AT deficiency), are autosomal-dominant disorders, and most patients with these disorders have supportive family histories ([22]). Patients without a family history of thrombosis should be evaluated for common acquired etiologies for thrombosis, including malignancy, myeloproliferative disorders, and antiphospholipid antibodies ([22], [88]). Because thrombosis may induce an acute-phase response that may affect functional coagulation assays, testing is ideally done when the patient has fully recovered from the acute event and is not receiving anticoagulants ([22]). Functional assays are preferred over immunologic assays, so that both type I and type II disorders can be detected. An important exception to this recommendation is APC-R, which can be screened for using a DNA test that is not affected by acute-phase responses or anticoagulant therapy ([22]). Diagnosis of protein C or S deficiency in patients already anticoagulated with warfarin can be facilitated by parental testing, testing symptomatic family members not receiving anticoagulation, referral to a reference laboratory that has standardized assays for these natural anticoagulants in anticoagulated patients, or temporary cessation of warfarin therapy (minimum of 3 to 4 weeks) ([22], [88]). Patients with arterial thrombosis should be considered for testing for hyperhomocysteinemia, Lp(a), and, possibly, protein S deficiency ([3]).

In addition to a positive family history of thrombosis, other clinical features may suggest inherited thrombosis, including recurrent spontaneous thromboses, thrombosis in unusual sites (mesenteric vein), thrombosis at an early age, heparin resistance (suggestive of AT deficiency), warfarin-induced skin necrosis and neonatal purpura fulminans (suggestive of protein C or protein S deficiency), and thrombosis occurring with estrogen therapy or pregnancy (suggestive of APC-R or prothrombin G20210A) ([22]). The presence of these clinical events may justify laboratory evaluation of these patients. Even in situations in which the relative risk of thrombosis and recurrent thrombosis is increased, the absolute risk for a particular patient may not warrant the risks of chronic anticoagulation. Thus, one should always assess the pretest use of hypercoagulable state testing before embarking on an expensive investigation.

A more fundamental question is whether routine laboratory testing for inherited thrombotic disorders will change treatment (intensity or duration of anticoagulation). This is a controversial subject because the available data do not support the contention that patients with an inherited thrombotic disorder should be managed differently than patients without such a disorder ([301]). At a minimum, physicians electing to test patients should inform them of the pros and cons of testing ([302]).

There are two thrombotic risk factors that may influence treatment strategy: the presence of antiphospholipid antibodies (discussed in Chapter 60) and hyperhomocysteinemia. Patients with antiphospholipid antibodies may require a higher intensity of oral anticoagulation, and many patients with homocysteinemia respond to vitamin therapy to resolve this thrombosis risk factor. Table 61.6 summarizes the clinical laboratory testing recommendations made by the College of American Pathologists' Consensus Conference on Thrombophilia ([302]).

TABLE 61.6. Summary of the College of American Pathologists' Recommendations on Laboratory Testing for Inherited Thrombosis

Thrombotic Disorder	Who Should Be Tested?	Test Method(s)	Comments
FVL	First VTE at age <50 yr Recurrent VTE First unprovoked VTE First VTE, unusual site First VTE, positive family history First VTE related to pregnancy or hormonal therapy Unexplained second or third trimester pregnancy loss	APC-R assay using factor–V deficient plasma *or* DNA-based assay	Patients with relatives who are known to have FVL should be tested directly with DNA-based assays. Patients with positive APC-R assays should have confirmatory DNA tests.
Prothrombin gene mutation	As above	DNA-based assay	Prothrombin activity assays should not be used.
Homocysteinemia	Arterial vascular disease; controversial for VTE	High-performance liquid chromatography or immunoassays	Genotyping for methylenetetrahydrofolate reductase mutations is not recommended. Fasting may not be necessary. Proper sample processing is necessary. Testing in VTE patients may be appropriate to identify and treat affected patients with vitamins.

PC deficiency	Infants with neonatal purpura fulminans VTE patient from a family with known PC deficiency Asymptomatic female from a known PC-deficient family before hormonal therapy	Chromogenic substrate assays preferred Functional assays are useful Immunologic assays are discouraged	Avoid testing during acute thrombosis or anticoagulant therapy. Exclude causes of acquired PC deficiency. Consider age-dependent reference ranges.
PS deficiency	Patient with VTE from a family with known PS deficiency	Functional assay *or* immunoassay for free PS Total PS antigen assays not recommended	Abnormal functional assay results should be confirmed with an immunoassay for free PS. Exclude acquired causes of PS deficiency. Avoid testing during acute thrombosis, anticoagulant therapy, and pregnancy. Consider age- and gender-dependent reference ranges.
AT deficiency	Patient with VTE from a family with known AT deficiency Asymptomatic female from a known AT-deficient family before hormonal therapy	Chromogenic substrate assays preferred AT antigen assays not recommended	Exclude acquired causes of AT deficiency. Avoid testing during acute thrombosis or anticoagulant therapy.
Elevated factor VIII levels	Controversial	Factor VIII activity assay	Test 6 months after thrombosis. Avoid anticoagulant therapy.
Dysfibrinogenemia	Not recommended		
Heparin cofactor II	Not recommended		
Factor XIII polymorphisms	Not recommended		
Plasminogen activator inhibitor-1	Not recommended		
Plasminogen deficiency	Test in non-DVT patients with ligneous conjunctivitis		

APC, activated protein C; AT, antithrombin; FVL, factor V Leiden; PC, protein C; PS, protein S; VTE, venous thromboembolism.

Laboratory Testing for the Prethrombotic State

Levels of fibrin degradation products, including cross-linked fibrin degradation products (D-dimer), are usually increased in the presence of acute venous thromboembolism. Absence of an elevated level of D-dimer in patients undergoing an evaluation for acute DVT or PE has an excellent negative predictive value for thrombosis ([303]). Recently, D-dimer measured 3 months after oral anticoagulation for DVT treatment was discontinued has been shown to have a negative predictive value of 95.6% for VTE recurrence. It has also been recently shown that baseline elevations of D-dimer are strongly and positively related to the occurrence of future venous thrombosis ([303a]). Plasma levels of fibrinopeptide A can be increased in venous thrombosis patients, but this assay has the disadvantage of requiring rigorous attention to specimen collection to avoid an activated plasma sample ([304]). The activation peptide generated when prothrombin is cleaved to form thrombin, prothrombin fragment 1+2, is a sensitive measure of thrombin formation ([305]). Other markers of activation of coagulation include thrombin-AT complex and plasmin-antiplasmin complex.

One active area of investigation is combining a sensitive D-dimer assay with clinical criteria to exclude venous thromboembolism ([306]) or risk of recurrent venous thromboembolism ([307]). Figure 61.2 depicts one strategy algorithm to incorporate D-dimer testing in thrombosis evaluation.

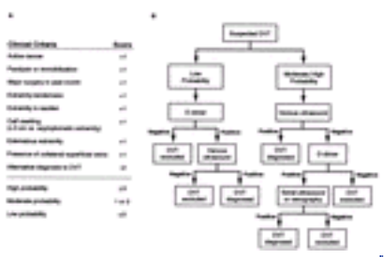

Figure 61.2. Algorithm for excluding deep vein thrombosis (DVT) using clinical criteria, D-dimer testing, and venous ultrasound. Clinical criteria are based on those of Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. Lancet 1997;350:1795–1798. D-dimer methods are similar to those described by Hirsh J, Lee AY. How we diagnose and treat deep vein thrombosis. Blood 2002;99:3102–3110. **A:** Based on clinical criteria fulfilled by the patient, the cumulative score is tallied. High probability is a score greater than or equal to 3, moderate probability is 1 or 2, low probability is less than or equal to 0. **B:** The probability score is used with D-dimer assay and ultrasound to determine which patients may be excluded from DVT testing.

ANTITHROMBOTIC THERAPY

Arterial and venous thrombotic events combined, including acute coronary syndromes, stroke, peripheral arterial thrombosis, DVT, and PE, are likely responsible for more morbidity and mortality than any other condition in the developed world.

Coronary artery occlusive disease was responsible for more than 500,000 deaths in the United States alone in 1999 (one of every five total deaths), and it is estimated that 1.1 million Americans had a new or recurrent MI in 2002 ([308]). Acute limb ischemia secondary to peripheral arterial thrombosis and thromboembolism involving native and prosthetic vessels is a relatively uncommon, but ominous form, of vascular accident. National databases suggest a rate of 16 events annually per 100,000 population ([309]). Outcomes are inferior if treatment is delayed, and the incidence appears to steadily increase with patient age ([310]). In a similar fashion to coronary artery thrombosis, acute peripheral arterial thrombosis typically develops at sites of preexistent atherosclerotic PAOD. PAOD has been diagnosed in as many as 17% of men and 20% of women older than 55 years of age and is highly predictive for the coexistence of coronary and cerebral vascular disease. It has been estimated that PAOD progresses to critical limb ischemia in 15 to 20% of patients ([311] , [312]).

Acute VTE, including DVT and PE, is a common, potentially life-threatening, often preventable vascular condition associated with trauma, major surgery, advanced congestive heart failure, pregnancy, HRT, malignancy, and inherited hypercoagulability ([313]). Proximal lower-extremity DVT can result in venous limb gangrene (phlegmasia cerulea dolens), chronic stasis changes related to the postthrombotic syndrome, and symptomatic PE. PE in its most severe presentation can result in pulmonary hypertension, right-sided heart failure, cardiopulmonary collapse, and death.

A common feature of the management of *all* thromboembolic vascular diseases is the use of antithrombotic agents. Antithrombotic agents, including antiplatelet drugs, anticoagulants, and thrombolytic agents, are used to prevent thrombotic events, prevent or mitigate the complications of thrombotic events, and restore vascular patency to prevent loss of tissue, organ, and limb function, as well as life. Based on the pathologic basis of thrombosis involving different vascular beds, drugs that inhibit platelet activation and aggregation play a primary role in arterial disease management, whereas drugs that inhibit thrombin and fibrin generation play a primary role in venous disease management. The following sections describe the pharmacodynamics, pharmacokinetics, and clinical uses of select antithrombotic agents.

Antiplatelet Drugs

Given the important role of platelets in mediating arterial thrombosis and the significant morbidity and mortality of arterial thrombotic disorders, the safety and efficacy of antiplatelet drugs have been evaluated in numerous primary and secondary prevention trials. A 1988 metaanalysis indicated that antiplatelet treatment reduced overall mortality from vascular disease by 15% and that nonfatal vascular events were reduced by 30% ([314]). A 1995 update on this subject supports the original observation of the efficacy of antiplatelet therapy ([315]). The American College of Chest Physicians' consensus conference has summarized the status of clinical trials with aspirin and other antiplatelet drugs ([316]).

Numerous potential targets exist for antiplatelet therapy (Fig. 61.3). Platelet cyclooxygenase (COX) is the target of acetylation and irreversible inactivation by aspirin ([317]). ADP-induced platelet aggregation can be selectively inhibited by the thienopyridines ticlopidine and clopidogrel ([318] , [319]). Inhibitors to thromboxane synthetase and the TxA_2 receptor (ridogrel) have been studied ([320]). Infusion of prostaglandin E_1 or stable analogs of prostacyclin (Iloprost) increase platelet cyclic AMP concentrations, inhibiting platelet activation ([316]). Dipyridamole alters platelet function, in part, by inhibition of cyclic nucleotide phosphodiesterase to increase platelet cyclic AMP levels ([316]). Other potential targets for antiplatelet therapy include the platelet membrane receptor, gpIb, mediator of platelet adhesion, and inhibitors to thrombin, the most potent stimulus to platelet activation ([317]). Interference with fibrinogen-mediated platelet aggregation by anti–gpIIb-IIIa antibodies and peptides is well established ([321]).

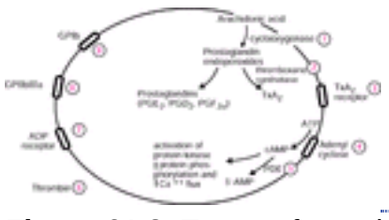

Figure 61.3. Targets for antiplatelet agents. This diagram summarizes certain aspects of platelet function relevant to antiplatelet therapy. Platelet metabolic pathways, membrane receptors, and enzymes are depicted with specific therapeutic targets enumerated. Four target categories for antiplatelet drugs are the arachidonic acid pathway that regulates production of prostaglandins (PGs) and thromboxanes, the cyclic–adenosine monophosphate (AMP) mechanism that modulates important metabolic events, platelet membrane glycoproteins (GPs) that act as receptors for platelet agonists, and thrombin, a key stimulus to platelet activation. Specific targets for antiplatelet therapies include the following: (*1*) Cyclooxygenase is the target of acetylation and irreversible inactivation by aspirin, as well as reversible inactivation by the nonsteroidal antiinflammatory agents; (*2*) inhibitors to thromboxane synthetase such as dazoxiben and imidazole analogs prevent generation of thromboxane A_2 (TxA_2); (*3*) an example of a TxA_2 receptor antagonist is BM 13177; (*4*) infusion of PGE_1 or stable analogs of prostacyclin (Iloprost) increases platelet concentrations of cyclic AMP (cAMP) via stimulation of adenylate cyclase; (*5*) dipyridamole increases platelet cAMP concentrations by inhibition of cyclic nucleotide phosphodiesterase (PDE); (*6*) because thrombin is the most potent stimulus to platelet activation, inhibitors of thrombin (heparin, argatroban, lepirudin, and bivalirudin) may be important agents in preventing platelet-dependent thrombosis; (*7*) ticlopidine and clopidogrel inhibit platelet activation by inhibition of adenosine diphosphate (ADP)–induced aggregation; (*8*) monoclonal antibodies or peptides directed against the GPIIb-IIIa complex inhibit fibrinogen binding to platelets and subsequent platelet aggregation; and (*9*) inhibitors to the von Willebrand factor receptor (GPIb) are being developed to prevent platelet adhesion. ATP, adenosine triphosphate. (Reproduced and modified from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599.)

ASPIRIN Aspirin (acetylsalicylic acid) is the prototypical antiplatelet drug, exerting its antithrombotic action by irreversibly inactivating (by acetylation) the COX activity of platelet prostaglandin H synthase-1 (COX-1) and prostaglandin H synthase-2 (COX-2) ([322]). This COX inhibition leads to the prevention of TxA_2 synthesis and impairment of platelet secretion and aggregation ([323]). A variety of nonsteroidal antiinflammatory drugs can inhibit TxA_2-dependent platelet function via competitive, reversible inhibition of COX-1. A lesser degree of COX-1 inhibition may explain why long-term use of nonaspirin nonsteroidal antiinflammatory drugs is not protective against first MIs in postmenopausal women ([324]). Aspirin is the least expensive, most widely studied, and most widely used antiplatelet drug. Aspirin (when not enteric coated) is rapidly absorbed from the upper gastrointestinal tract; plasma salicylate concentrations peak within 1 hour of ingestion. The effects of aspirin on platelet function occur within 1 hour and last for the duration of the affected platelets' lifespan (approximately 1 week). The toxicity of aspirin is dose related, explaining why clinical studies have focused on finding the lowest effective antithrombotic dose of the drug. Toxicities include gastrointestinal discomfort and blood loss and the risk of systemic bleeding. Clinical trials suggest that aspirin doses as low as 75 mg/day or 30 mg/day are antithrombotic ([325] , [326] , [327] and [328]). In addition to reducing aspirin toxicity, lower aspirin doses also inhibit vascular endothelial cell prostacyclin production to a lesser extent, because inhibition of endothelial cell COX is of shorter duration and requires higher aspirin doses than does platelet COX ([329]). The inhibitory effects of chronic low-dose aspirin administration are cumulative ([330]). However, even when taken chronically in large doses, aspirin is not believed to be thrombogenic ([331]). The 2001 consensus conference statement on antiplatelet therapy indicates that aspirin has been convincingly demonstrated to be effective in treatment of the following thrombotic disorders: stable and unstable angina, acute MI, transient ischemic attack and incomplete stroke, stroke after carotid artery surgery, atrial fibrillation, and prosthetic heart valves (in combination with warfarin) ([315] , [316]). The minimum effective aspirin dose for these indications is 75 to 325 mg/day. Aspirin has also been shown to reduce mortality post–coronary artery bypass surgery and to be effective for primary prevention of cardiovascular events ([332] , [333] and [334]). A summary of 142 trials indicated that for patients with acute MI or stroke, aspirin prevents 35 to 40 events/1000 patients treated (secondary prevention). In contrast, when used in primary prevention, aspirin prevents four events per 1000 subjects treated ([316]). It is recommended that all patients with acute MI and unstable angina receive 75.0 to 162.5 mg of non–enteric coated aspirin to chew and swallow as soon as possible ([316]). Aspirin in this dosage should be continued indefinitely. Aspirin should be considered for primary prevention in men and women older than 50 years of age who have at least one major risk factor for coronary artery disease ([316]). Aspirin may modify the natural history of intermittent claudication from lower extremity arteriosclerosis. Because these patients are at high risk for future cardiovascular and cerebrovascular atherothrombotic events, life-long aspirin therapy is recommended ([315] , [316]). Similar therapy is advisable after peripheral arterial bypass surgery and carotid endarterectomy ([315] , [316]). The Pulmonary Embolism Prevention trial was a large-scale, double-blind, multicenter study of 13,356 patients undergoing surgery for hip fracture and an additional 4088 patients undergoing elective knee or hip arthroplasty ([335]). Patients were assigned to a regimen of 160 mg of aspirin or placebo once daily for 5 weeks, with the first dose given before surgery. Other forms of prophylaxis were allowed, and 40% of patients received unfractionated heparin (UFH) or LMWH in addition to the aspirin. The study demonstrated that aspirin reduces the incidence of fatal PE (58% risk reduction) and symptomatic nonfatal DVT or PE (36% risk reduction) in patients with hip fracture ([335]). Although beneficial when compared to placebo, aspirin cannot be recommended as first-line VTE prophylaxis in hip fracture patients because the benefit of aspirin is less than with anticoagulants ([336]).

THIENOPYRIDINES Ticlopidine and clopidogrel are structurally related compounds that selectively inhibit ADP-induced platelet aggregation and likely ADP-mediated amplification of the platelet response to other agonists ([337]). A lack of *in vitro* platelet aggregation inhibition suggests that *in vivo* hepatic transformation to an active metabolite is necessary for an antiplatelet effect ([316]). Both agents were initially used as aspirin substitutes in aspirin-intolerant patients. Although more effective than aspirin in reducing stroke rates in people with transient ischemic attacks; more effective than placebo in reducing the combined risk of stroke, MI, and vascular death in patients with thromboembolic stroke; more effective than conventional antianginal therapy in reducing vascular death in patients with unstable angina; and more effective than control therapy in reducing vascular complications in patients with peripheral vascular disease, enthusiasm for ticlopidine has been dampened by associated hematologic complications ([316] , [338]). Ticlopidine has been associated with neutropenia, thrombocytopenia, aplastic anemia, and thrombotic thrombocytopenic purpura ([339] , [340] and [341]). Clopidogrel is rapidly absorbed and extensively metabolized. The plasma half-life of the main systemic metabolite, SR 26334, is roughly 8 hours ([342]). Clopidogrel inhibits ADP-induced platelet aggregation in a dose-dependent fashion with inhibition detectable 2 hours after an oral dose of 400 mg ([342]). On repeated daily dosing of 50 to 100 mg, 25 to 30% inhibition of ADP-induced platelet aggregation is noted on the second day of therapy with 50 to 60% steady-state inhibition noted after 4 to 7 days ([316]). Platelet function returns to normal approximately 7 days after the last dose of clopidogrel. The phase III Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events trial compared clopidogrel to aspirin in patients who had experienced a recent stroke or a recent MI and in those presenting with symptomatic peripheral arterial disease ([343]). A modest difference in efficacy was observed. The annual ischemic event rate for aspirin was 5.83% compared to 5.32% for clopidogrel, with a relative risk reduction of 8.7% (95% confidence interval, 0.3 to 16.5%; $p = .043$) ([341]). The majority of the difference in efficacy occurred in the patients who entered because of symptomatic peripheral arterial disease, with a 23.8% relative risk reduction (95% confidence interval, 8.9 to 36.2%; $p = .0028$) ([343]). The Clopidogrel in Unstable Angina to Prevent Recurrent Events trial has demonstrated an advantage of clopidogrel plus aspirin over aspirin alone in patients with acute coronary syndromes ([344]). Clopidogrel, like ticlopidine, can rarely precipitate thrombotic thrombocytopenic purpura ([345]).

INTEGRIN $a_{IIB}ß_3$ (GLYCOPROTEIN IIB/IIIA) RECEPTOR ANTAGONISTS Because of the multitude of pathways that lead to platelet aggregation, it is not surprising

that the clinical efficacy of the antiplatelet agents described above is only partial. Even combination therapy with clopidogrel and aspirin, resulting in partial inhibition of TxA_2- and ADP-mediated platelet aggregation, leaves platelets susceptible to agonists like thrombin and collagen ([316]). Because expression of functionally active gpIIb/IIIa on platelet surfaces is the final common pathway of platelet aggregation regardless of initial stimulus, it is logical to target this glycoprotein receptor with antiplatelet agents. gpIIb/IIIa is a member of the integrin family of receptors. These receptors recognize the amino acid sequence arginine-glycine-aspartate [Arg-Gly-Asp (RGD)], which represents the cell attachment regulation sequence present in certain adhesive proteins like fibrinogen ([346] , [347]). Inhibitors of fibrinogen binding to gpIIb/IIIa, called the *disintegrins*, include a chimeric monoclonal antibody against the receptor, naturally occurring RGD sequence–containing peptides from snake (pit viper) venoms, synthetic RGD peptides, synthetic Lys-Gly-Asp (KGD) peptides, peptidomimetics, and nonpeptide RGD mimetics ([321] , [348]). Reviews of this subject are available for further details ([349] , [350] and [351]). Three parenteral gpIIb/IIIa inhibitors have been extensively studied, primarily in the settings of percutaneous coronary intervention (PCI), unstable angina, and non–Q-wave MI. These are abciximab, eptifibatide, and tirofiban ([316]). Abciximab (c7E3 Fab) is a chimeric Fab fragment of human and murine protein that binds to gpIIb/IIIa. Abciximab is unique among the gpIIb/IIIa antagonists because it also blocks the $a_v ß_3$ receptor ([352]). Eptifibatide is a synthetic cyclic heptapeptide with a KGD sequence that is more specific for gpIIb/IIIa than the RGD sequence ([316] , [348]). Tirofiban is a synthetic peptidomimetic based on the RGD sequence ([353]). Oral gpIIb/IIIa inhibitors have been generally unsuccessful. The reader is referred to an excellent review that covers the use of the oral agents ([354]).

Anticoagulant Drugs

Anticoagulant drugs are ubiquitous in medical and surgical practice. Anticoagulants are used to prevent and treat thrombosis. Short-term anticoagulation is usually provided in the form of an intravenous infusion or subcutaneous injection. More chronic anticoagulation is facilitated by the use of oral agents. Each agent has its strengths and weaknesses. A current trend toward the development of narrow-spectrum (single protein target) anticoagulants (e.g., fondaparinux and ximelagatran) to supplant more broad-spectrum anticoagulants (e.g., heparin and warfarin) is likely to continue.

HEPARIN Heparin is a naturally occurring, highly sulfated glycosaminoglycan normally present in human tissues (Fig. 61.4). McLean first isolated heparin from ox liver and identified its anticoagulant properties ([355]). Commercial UFH is obtained from either bovine lung or porcine intestinal mucosa and consists of a heterogeneous mixture of polysaccharides (glycosaminoglycans) with molecular weights ranging from 4000 to 30,000 daltons (d), with a mean molecular weight of approximately 15,000 d (approximately 45 saccharide units). UFH molecules possessing anticoagulant activity constitute approximately one-third by weight of commercial heparin products ([356]). Sodium and calcium salts of heparin are available, and most commercial heparin preparations have specific activities of approximately 150 U/mg. Heparin structure consists of alternating residues of uronic acid and glucosamine that are variably sulfated ([357]). Sulfation of residues in heparin is a major determinant of the anticoagulant activity of a given heparin preparation; the heparin molecules with anticoagulant activity exhibit high-affinity binding to AT. Vascular endothelium synthesizes and expresses a related glycosaminoglycan, termed *heparan sulfate*.

Figure 61.4. Structure of the common active saccharide moieties found in commercial unfractionated heparin. These polymeric structures are termed *glycosaminoglycans*. From left to right, the saccharide structures are 2-deoxy-2-sulfamino-a-D-glucose-6-sulfate; a-L-iduronic acid-2-sulfate; 2-acetamido-2-deoxy-a-D-glucose; ß-D-glucuronic acid; and a-L-iduronic acid. (Reproduced from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599, with permission.)

UFH molecules contain a randomly distributed unique pentasaccharide sequence that binds to AT. Once bound to UFH, the natural anticoagulant effect of AT is potentiated resulting in the accelerated binding and inactivation of serine proteases, in general, and factor Xa and thrombin, in particular ([358] , [359]). The inhibition of these factors has an impact on the common pathway of coagulation resulting in decreased formation of thrombin and fibrin. Heparin's interaction with AT is thought to occur as follows and is depicted in Figure 61.5 . A ternary complex with heparin, thrombin, and AT first occurs; this association permits inactivation of thrombin by the active site inhibitor domain of AT. Lastly, heparin dissociates from the AT-thrombin complex to subsequently catalyze additional AT-mediated reactions ([360]). A synthetic pentasaccharide (fondaparinux) described later contains only the AT binding sequence and promotes factor Xa inhibition substantially but has minimal effect on thrombin inhibition ([361]). In this case, only the conformational change induced by the pentasaccharide is necessary for factor Xa inhibition to occur. Oligosaccharides of greater length (at least 18 residues) are necessary for enhancement of thrombin inhibition by AT. It is likely that in this latter case, a ternary complex between ATIII, thrombin, and heparin forms to mediate protease inhibition ([362]). These observations form the basis for the development and clinical use of LMWHs in the prophylaxis and treatment of thrombosis; these drugs, like the synthetic pentasaccharide, primarily inhibit factor Xa and have a lesser effect on inhibition of thrombin. *In vitro* experiments suggest that UFH exerts its major anticoagulant effect by promoting AT suppression of thrombin-dependent amplification reactions ([363]).

Figure 61.5. Inhibition of thrombin activity by the heparin (H)–antithrombin (AT) mechanism. Reaction *1* indicates that in the absence of heparin catalysis, AT can irreversibly inactivate thrombin (T), albeit in an inefficient manner. In the presence of H, a conformation change occurs in the AT molecule, and heparin also acts as a template to bind both AT and T, promoting rapid inactivation of coagulation (reaction *2*). In reaction *3*, heparin is released from the AT-T complex and is available to catalyze subsequent reactions. Inhibition of factor Xa by AT-H does not require binding of heparin to the factor Xa molecule.

In addition to its anticoagulant activity, heparin possesses other unrelated biologic effects ([364]). Heparin hydrolyzes triglycerides from chylomicrons and very-low-density lipoproteins by release of endothelial cell lipoprotein lipase into the blood ([365]). Heparin can also activate platelets, suppress cell-mediated immunity, and affect metabolism of aldosterone and thyroxine. Heparin is active when given parenterally, either intravenously or subcutaneously. Because of its highly charged nature and inability to cross biologic membranes alone, oral use of heparin has historically been viewed as impossible. Recently, delivery systems have been developed that make oral heparin a reality. These delivery systems use synthetic amino acids such as sodium N-(8[2-hydroxybenzoyl]amino) caprylate or sodium N-(8[2-hydroxybenzoyl]amino) caprylate derivatives to facilitate oral heparin gut absorption ([366]). When sufficient amounts of heparin are orally administered, a prophylactic intensity of anticoagulation can be achieved. The half-life of heparin varies with the dosage given, with the half-life increasing with increasing dosage ([367]). A 100-U/kg intravenous dose is cleared with a half-life of approximately 1 hour. The clearance of heparin is also affected by the extent of thromboembolism, with extensive thrombosis decreasing heparin half-life ([368]). Heparin is cleared by the reticuloendothelial system and metabolized by the liver, and metabolic products are excreted in the urine. The anticoagulant effect of heparin is also altered by its nonspecific binding to plasma proteins and cells ([369]). Given these numerous variables affecting the plasma half-life of heparin, therapeutic use of this drug requires close laboratory monitoring to ensure attainment of a therapeutic effect and regulation of heparin levels within a range that minimizes the bleeding risk. These pharmacokinetic disadvantages of standard heparin are not shared by the LMWHs and are major reasons for the ever-increasing clinical use of the newer drugs. An additional challenge to the use of heparin to prevent and treat thrombosis is heparin resistance. “True” heparin resistance manifests as inadequate anticoagulant and antithrombotic responses from what would otherwise be perceived as an adequate, and probably weight-based, dose of heparin. Some have deemed a requirement of greater than 35,000 units of heparin per 24-hour period, regardless of patient weight, to reflect this form of heparin resistance ([370]). With true heparin resistance, both a measurement of anticoagulant activity like the aPTT and a measurement of antithrombotic activity like the anti–factor Xa activity assay demonstrate inadequate degrees of heparin activity. True heparin resistance most likely results from the nonspecific binding of heparin to mononuclear white cells, vascular endothelial cells, and acute-phase proteins such as histidine-rich glycoprotein, vitronectin, and platelet factor-4, resulting in an inadequate quantity of free or AT-bound heparin ([369]). Another potential cause of heparin resistance is compensated DIC-associated AT deficiency as can be seen in cancer patients. Patients can also manifest an “apparent” heparin resistance characterized by dissociation between the aPTT and heparin assays ([370]). In these patients, the aPTT may be normal or near normal, whereas the anti–factor Xa activity assay reveals a therapeutic heparin activity level between 0.3 and 0.7 IU/ml. Simply escalating the dose of heparin to achieve the desired aPTT without checking a heparin assay may result in a pronounced bleeding risk. Dissociation between the aPTT and heparin concentration likely reflects elevated levels of factor VIII that can shorten the *in vitro* aPTT without affecting the antithrombotic actions of the drug. Table 61.7 illustrates an example of a weight-based nomogram for using UFH. This assumes that the hospital laboratory has calibrated the aPTT values such that an aPTT range from 1.5 to 2.5 times the mean laboratory control aPTT is equivalent to plasma heparin levels of 0.3 to 0.7 U/ml, as measured by anti–factor Xa activity ([369]).

TABLE 61.7. Weight-Based Nomogram of Unfractionated Heparin (UFH) in Treatment of Venous Thromboembolism

Initial UFH bolus	80 U/kg
Initial UFH infusion rate	18 U/kg/hr

Check aPTT after 6 hr of IV infusion; modify infusion rate as follows:	
If aPTT <1.2 × control, repeat bolus (80 U/kg) and increase infusion rate by	4 U/kg/hr
If aPTT is 1.2–1.5 × control, repeat bolus (40 U/kg) and increase infusion rate by	2 U/kg/hr
If aPTT is 1.5–2.3 × control, no change	—
If aPTT is 2.3–3.0 × control, decrease infusion rate by	2 U/kg/hr
If aPTT >3 × control, hold infusion for 1 hr, then decrease infusion by	3 U/kg/hr

aPTT, activated partial thromboplastin time.

Data based on Raschke RA, Reilly BM, Guidry JR, et al. The weight-based heparin dosing nomogram compared with a “standard care” nomogram. Ann Intern Med 1993;119:874–881.

LOW-MOLECULAR-WEIGHT HEPARINS LMWH is derived from the enzymatic or chemical cleavage of UFH to produce a mixture of low-molecular-weight glycosaminoglycan molecules with a mean molecular weight of approximately 5000 d (approximately 15 saccharide units) ([369]). For example, enoxaparin sodium is produced by benzylation followed by alkaline hydrolysis, dalteparin sodium is produced by controlled nitrous acid depolymerization, and tinzaparin sodium is produced by enzymatic digestion with heparinase. LMWH binds AT via the same pentasaccharide sequence as UFH ([359]). However, due to the predominance of molecules less than 18 saccharide units in length, LMWH has limited AT activity compared to its anti–factor Xa activity. Whereas UFH has an anti–factor Xa to AT activity ratio of 1:1, LMWHs have reported ratios of 1.9:1 to 4.1:1 ([369]). Because of limited thrombin inhibition, LMWH therapy is unable to be monitored using the aPTT. Other differences between LMWH preparations include the degree of TF pathway inhibitor release, degree of sulfation, and degree of stimulated vWF release ([371] , [372] and [373]). These differences form the basis for many medical organizations stating that LMWHs are unique drugs and not therapeutically interchangeable ([144] , [374] , [375]). At low doses, subcutaneous LMWH has 90% bioavailability compared to 30% for UFH. LMWHs have limited nonspecific binding to plasma proteins and platelets, endothelial cells, and macrophages compared to UFH, as well as a predictable clearance and a longer half-life that facilitates once or twice daily administration ([369] , [376]). Unlike UFH, the half-life of LMWH is not dose dependent ([369]). These characteristics make LMWH preferred in settings that may normally result in heparin resistance. These advantages of LMWH allow these drugs to be given subcutaneously, once or twice daily in dosages based solely on body weight, and without the need for laboratory monitoring ([369]). Similar to UFH, absolute contraindications for LMWH include active bleeding, HIT, or a history of HIT, and known sensitivity to LMWH, UFH, or pork products. LMWH is cleared by renal mechanisms; therefore, multiday therapeutic use of LMWH in patients with significant renal insufficiency (creatinine clearance <30 ml/minute) should be avoided ([376]). Reversible elevations of the liver transaminases alanine aminotransferase and aspartate aminotransferase may occur during the administration of LMWH. LMWH does not have the same capacity (approximately 60%) to be reversed after the administration of protamine sulfate ([377]). Table 61.8 summarizes the LMWH products available in the United States and their properties and U. S. Food and Drug Administration (FDA)–approved indications.

TABLE 61.8. Comparison of Low-Molecular-Weight Heparin Products and Pentasaccharides Available or Under Study in the United States

Generic Name, Brand Name, and Manufacturer	Molecular Weight	Factor Xa to Factor IIa Inhibition Ratio	Purification Method	Therapeutic Uses	FDA-Approved Dose or Status for FDA Approval
Low-molecular-weight heparins					
Dalteparin, Fragmin (Kabi 2165), Pfizer	5000 (2000–9000)	2:1.0	Nitrous acid depolymerization	Prophylaxis of ischemic complications of non–Q-wave myocardial infarction or complications of unstable angina	120 units/kg SQ every 12 hr for 5 to 8 days, given concurrently with aspirin 75–165 mg/day PO; do not exceed 10,000 units/dose
				VTE prophylaxis before abdominal surgery	2500–5000 units SQ QD, starting 1–2 hr before surgery
				VTE prophylaxis before hip replacement surgery	Preoperative start, evening before surgery: 5000 units SQ QD
				Treatment of VTE in oncology patients	Phase III
				Prevention of VTE in high-risk medical patients	Phase I PREVENT trial
Enoxaparin, Lovenox, Clexane (PK 10169), Aventis	4500 (3000–8000)	2.7–3.8:1.0	Benzylation and alkaline depolymerization	VTE prophylaxis before knee replacement surgery	30 mg SQ every 12 hr, starting 12–24 hr after surgery
				Prophylaxis of ischemic complications of non–Q-wave myocardial infarction or unstable angina	1 mg/kg SQ every 12 hr, given concurrently with aspirin 100–325 mg/day PO
				VTE prophylaxis before abdominal surgery	40 mg SQ QD, starting 2 hr before surgery
				VTE prophylaxis in medical patients during acute illness	40 mg SQ QD
				VTE prophylaxis before hip replacement surgery	30 mg SQ every 12 hr, starting 12–24 hr after surgery; alternative regimen is 40 mg SQ QD, starting 9–15 hr before surgery
				Inpatient treatment of DVT with/without PE (inpatient therapy) or outpatient treatment of DVT without PE	1 mg/kg SQ every 12 hr, or 1.5 mg/kg SQ QD (at the same time each day); start warfarin when appropriate
				Treatment of VTE in patients 0–11 yr	Phase III
				Treatment of acute myocardial infarction in combination with TNKase	Phase II ENTIRE trial; phase III ASSENT 3 trial
Tinzaparin, Innohep (Novo HLN 1), Pharmion	4500 (3000–6000)	1.8:1.0	Enzymatic depolymerization	Inpatient treatment of DVT with/without PE	175 anti-Xa units/kg SQ QD; start warfarin when appropriate
				Prevention of VTE in oncology patients	Preclinicals
Pentasaccharides					
Fondaparinux, Arixtra (SR-90107a/ORG-31540), Sanofi/Organon	1728	Selective inhibition of factor Xa	Synthetic	Prophylaxis in patients undergoing hip fracture, hip replacement, and knee replacement surgery	2.5 mg SQ QD, starting 6–8 hr after surgery
				Treatment of VTE	MATISSE PE and DVT trials; 5–10 mg SQ QD
				Prevention of VTE in high-risk surgery and medical patients	Phase III study
				Treatment of unstable angina and myocardial infarction	Phase IIb

Idraparinux, Sanofi-Synthelabo/Organon (SanOrg-34006)	Unknown	Selective inhibition of factor Xa	Synthetic	Treatment of cardiovascular disease	Phase III, once-weekly injection
				Prevention and treatment of VTE	Phase IIb (treatment dose is 2.5 mg once weekly)

DVT, deep venous thrombosis; FDA, United States Food and Drug Administration; PE, pulmonary embolism; VTE, venous thromboembolism.

HEPARINOIDS Heparinoids are low-molecular-weight glycosaminoglycans not derived from heparin. Heparinoids include dermatan sulfate and danaparoid sodium. Dermatan sulfate and low-molecular-weight dermatan sulfate act as anticoagulants by activating HCII ([378], [379]). Danaparoid sodium is a glycosaminoglycan mixture derived from porcine intestinal mucosa composed of heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%) ([380]). Danaparoid has an anti–factor Xa activity to AT activity ratio of greater than 22:1 (compared to a 1:1 ratio for heparin), which explains why it is minimally neutralized by protamine sulfate ([380]). The largest collection of clinical experience with danaparoid is provided by Magnani who published an overview of 230 patients treated for HIT ([381]). Danaparoid was associated with a favorable outcome in 92.5% of patients. Of the 15 patients considered to have had unsuccessful outcomes, two patients had bleeding events (one fatal), four developed recurrent thrombocytopenia, five had persistent thrombocytopenia, and four had thromboembolic events. Overall, five patients demonstrated danaparoid cross-reactivity with HIT-IgG (one developed a new thrombosis). Mortality reported as possibly or probably attributed to danaparoid treatment occurred in 3% of patients and included episodes of bleeding, thrombosis, and septic shock. In a recent series, Tardy-Poncet et al. treated 42 patients with either therapeutic intensity (26 patients) or prophylactic intensity (16 patients) danaparoid ([382]). No new thrombotic events were reported, two patients developed major bleeding, and two patients died as a result of HIT with associated paradoxic thrombosis (HITT). Danaparoid may cross-react with 10 to 50% of HIT sera, but *in vivo* cross-reactivity, although reported, has not been commonly observed ([383], [384]). Danaparoid has a relatively long half-life of approximately 24 hours that may make its use less desirable in patients at high risk for developing bleeding or those likely to need surgery. Significant experience exists with the administration of danaparoid by both intravenous and subcutaneous routes. Danaparoid anticoagulation is monitored using an anti–factor Xa activity chromogenic assay calibrated with danaparoid standards. The drug is approved for deep vein thromboprophylaxis after orthopedic surgery at a dose of 750 anti-Xa units twice daily by subcutaneous injection. A common dose for the treatment of active thrombosis in patients with normal renal function is 1500 units as an intravenous bolus followed by 1500 units subcutaneously twice daily. The target therapeutic anti–factor Xa activity is 0.5 to 0.8 U/ml. Danaparoid's potential for cross-reactivity and the longer half-life make it less desirable than a direct thrombin inhibitor (DTI) for the treatment of patients with HIT ([369]). The manufacturer of the drug has discontinued availability of danaparoid in the United States.

PENTASACCHARIDES Fondaparinux is a newly available synthetic pentasaccharide (molecular weight, 1728 d) that causes selective indirect inhibition of factor Xa ([385]). Fondaparinux is administered subcutaneously and does not require therapeutic monitoring. Fondaparinux elimination is prolonged in patients with renal impairment. The reduction in clearance increases as the creatinine clearance decreases. Elimination is also prolonged in patients older than 75 years of age and in those weighing less than 50 kg. Phase III trials comparing fondaparinux with LMWH for the initial management of patients with acute DVT and PE have been completed; the preliminary data indicate that fondaparinux is equivalent to enoxaparin in treatment of venous thromboembolism and equivalent to UFH in treatment of PE ([386]). Fondaparinux is currently FDA-approved for primary thromboprophylaxis in patients with hip fracture undergoing surgery and in those undergoing elective knee and hip joint replacement ([387]). Fondaparinux may result in less HIT than UFH and LMWH. A long-acting pentasaccharide under development, idraparinux, has a half-life of 130 hours, which may facilitate once-weekly dosing for primary and secondary prevention of thromboembolic events ([388]).

DIRECT THROMBIN INHIBITORS Elimination of all heparin exposure is the most essential element in the treatment of HIT. This includes discontinuing heparin intravenous catheter flushes, prophylactic subcutaneous heparin or LMWH, and heparin-coated indwelling catheters. Despite heparin discontinuation and platelet count recovery, patients with isolated, serologically confirmed HIT have up to a 50% risk of developing a confirmed thrombotic event during the 30-day period after heparin cessation ([389]). The persistent prothrombotic tendency associated with HIT and the patient's original indication for heparin therapy warrant use of an alternative anticoagulant agent after heparin cessation (Table 61.9).

TABLE 61.9. Comparison of Direct Thrombin Inhibitors

Drug Profile	Lepirudin (Refludan)	Argatroban (Argatroban)	Bivalirudin (Angiomax)
Derivative	Recombinant hirudin	L-arginine derivative	Synthetic hirudin-based peptide
Action	Direct thrombin inhibitor	Direct thrombin inhibitor	Direct thrombin inhibitor
Clearance	Renal	Hepatic	Renal
Administration	IV (or SC)	IV	IV or SC
Half-life	1.5 hr	40 min	25 min
Monitoring	aPTT or ECT	aPTT	aPTT or ACT
Heparin cross-reactivity	None	None	None
Effect on international normalized ratio	Yes	Yes	Yes
Approved for heparin-induced thrombocytopenia	Yes	Yes	No
Immunogenic	Yes	No	Unknown

ACT, activated clotting time; aPTT, activated partial thromboplastin time; ECT, ecarin clotting time.

Lepirudin Lepirudin is a recombinant hirudin analog that received FDA approval in 1998 for anticoagulant treatment in patients with HIT in the setting of thromboembolic disease to prevent further thrombosis ([390]). Lepirudin differs from native hirudin, found in the saliva of the medicinal leech, in that it lacks sulfation on the tyrosine at position 63 and has a leucine at position 1 rather than isoleucine ([391]). Lepirudin is a potent direct AT that lacks any structural homology with heparin, does not cross-react with heparin, has a short half-life, is able to inactivate clot-bound thrombin, and can be monitored using the ubiquitous aPTT assay or the less readily available ecarin clotting time ([392]). A prospective, multicenter, historically controlled study described lepirudin use in 82 patients with laboratory-confirmed HIT ([393]). Fifty-one HIT patients with thrombosis received 0.4 mg/kg as a bolus followed by a continuous infusion of 0.15 mg/kg/hour; 5 HIT patients with thrombosis receiving thrombolysis received a 0.2-mg/kg bolus followed by a 0.1-mg/kg/hour infusion; 18 patients without thrombosis received a prophylactic infusion of 0.1 mg/kg/hour; and 8 patients undergoing cardiopulmonary bypass received a 0.25-mg/kg bolus and 5-mg boluses as needed. Platelet counts increased rapidly in 88.7% of lepirudin-treated patients with acute HIT. The incidence of the combined endpoint of death, amputation, and new thromboembolic events was reduced by greater than 50% ($p = .014$) in the group that received lepirudin compared with 120 historical controls. Bleeding events and transfusion requirements were no greater in the lepirudin-treated patients ([393]). Current lepirudin dosing recommendations for acute HIT management are 0.4 mg/kg as a bolus followed by 0.15 mg/kg/hour (up to 110 kg). The target aPTT is 1.5 to 2.5 times the median value for the normal range. Monitoring during bypass requires performance of the less readily available ecarin clotting time with a target plasma lepirudin concentration of 2.0 µg/ml ([394]). The activated clotting time (ACT) and point-of-care aPTT assays do not appear to be suitable for lepirudin therapeutic monitoring ([395]). Outpatient subcutaneous lepirudin has been used to treat patients with HIT and thrombosis and patients refractory to other anticoagulant therapy ([396]). The major challenges of lepirudin treatment are the lack of an antidote, the extreme care needed when treating patients with even mild renal insufficiency, and immunogenicity. In the event of lepirudin overdose or lepirudin-induced bleeding, infusions of prothrombin complex concentrates or recombinant factor VIIa may help promote hemostasis ([390]). High flux capillary hemodialysis membranes may facilitate the hemofiltration of lepirudin in some cases ([397]). Partial exchange transfusions, plasmapheresis, and immobilized thrombin affinity columns have also been tried to neutralize the effects of lepirudin ([390]). Marked bolus and infusion rate reductions are necessary in patients with a creatinine clearance of less than 60 ml/minute (serum creatinine >1.6 mg/dl). Lepirudin is to be avoided completely or administered with extreme care in the settings of hemodialysis and acute renal failure and in patients undergoing continuous venovenous hemodialysis even in the setting of a normal serum creatinine. Careful monitoring of both the aPTT and serum creatinine are indicated during lepirudin therapy. Approximately 40% of HIT patients treated with lepirudin develop antihirudin antibodies of the IgG class ([398]). The antibodies seem to be capable of decreasing renal elimination of the drug rather than exerting any *in vivo* neutralizing effect. This paradoxic enhancement of the anticoagulant effect of lepirudin often warrants a significant infusion rate reduction.

Argatroban Argatroban is a synthetic, small-molecule, L-arginine derivative that received FDA approval in June 2000 for prophylaxis and treatment of thrombosis in patients with HIT. Argatroban is a rapid and reversible DTI, in contrast to lepirudin, which is an irreversible thrombin inhibitor. Argatroban is capable of inhibiting both free and fibrin-associated thrombin. Argatroban exerts its antithrombotic effects by inhibiting thrombin-mediated reactions including fibrin formation; activation of coagulation factors V, VIII, and XIII; activation of the natural anticoagulant protein C; and platelet activation ([399]). Like lepirudin, argatroban does not cross-react with heparin. Argatroban is metabolized by the liver with biliary excretion and has a half-life of only 40 minutes. Renal excretion has also been documented; however, renal impairment has been shown to have little adverse effect on drug clearance and half-life. Unlike lepirudin, argatroban does not require dose adjustment in the setting of

renal insufficiency. Dose reduction is required in patients with significant hepatic disease ([399]). Lewis et al. published findings from a large, prospective, historically controlled trial in 2001 ([400]). This study treated 160 patients with HIT alone and 144 patients with HIT and thrombosis with argatroban dosed to maintain an aPTT 1.5 to 3.0 times baseline value. In patients with HIT alone, the combined incidence of death, amputation, and new thromboembolic events was significantly lower in argatroban recipients compared with controls (26% vs. 39%; $p = .014$). In patients with HIT and thrombosis at baseline, the incidence of this combined endpoint was not significantly lower in argatroban recipients compared with controls (44% vs. 57%; $p = .131$). Argatroban recipients also showed significant improvements in platelet count relative to the historical controls. No difference in bleeding events between the argatroban and control groups was noted ([400]). Argatroban is dosed based on patient weight. The recommended starting intravenous infusion rate is 2 µg/kg/minute with a target aPTT of 1.5 to 3.0 times the baseline value. Therapy may also be monitored by whole blood ACT and the ecarin clotting time. Like lepirudin, argatroban prolongs the PT as well as the aPTT. This PT prolongation makes determination of an accurate INR during conversion to oral warfarin therapy a challenge. Holding the infusion of either DTI for several hours before INR determination is prudent. A recent publication showed that argatroban provides adequate anticoagulation with minimal bleeding risk while enabling procedural success in HIT patients undergoing PCI ([401]). Patients were given argatroban 350 µg/kg bolus followed by 25 µg/kg/minute titrated to achieve an ACT of 300 to 450 seconds. This dosing regimen may provide satisfactory anticoagulation during cardiopulmonary bypass and allow intraoperative dose adjustments based on the readily available ACT.

Bivalirudin Bivalirudin is a semisynthetic, bivalent DTI consisting of a dodecapeptide analog of the carboxy-terminal of hirudin ([402]). Bivalirudin has four glycine residues that connect the thrombin exosite 1 and thrombin active-site moieties. Bivalirudin produces only transient inhibition of the thrombin active site. The short half-life of bivalirudin may enhance its safety profile. Bivalirudin is primarily used during PCI in which it has been shown to be at least as effective as heparin with an improved safety profile ([403] , [404] and [405]). Bivalirudin may have a larger role to play in the management of patients with HIT, especially in those requiring cardiac surgery.

Ximelagatran Ximelagatran is a new oral prodrug of the DTI melagatran. Ximelagatran is administered in a fixed-dose fashion, does not require therapeutic monitoring, and has no apparent major food or drug interactions ([406]). Ximelagatran is rapidly absorbed (peak levels in 15 to 30 minutes) and rapidly converted to melagatran (peak levels in 1 to 2 hours). Melagatran is eliminated by the kidney. Ximelagatran-derived melagatran binds to the thrombin active site resulting in inhibition of thrombin-mediated activation of coagulation factors (V, VIII, XIII, and fibrinogen) and platelets ([407]). It is active against free and clot-bound thrombin in an AT-independent manner. Ximelagatran may also enhance endogenous fibrinolysis. Melagatran appears to be nonteratogenic in animals. Phase III trials are currently evaluating oral ximelagatran for the treatment of acute VTE, chronic management of atrial fibrillation, and prevention of VTE in the orthopedic setting. Ximelagatran holds promise as a potential substitute for parenteral agents as well as oral warfarin. Its role in HIT remains to be determined. A standard dose in VTE treatment trials was 24 mg twice daily ([408]).

WARFARIN In the 1920s, cattle developed a bleeding disorder when they were fed spoiled sweet clover. Campbell and Link later identified the active agent as bishydroxycoumarin (dicoumarol) ([409]). Drugs that inhibit the biosynthesis of the vitamin K–dependent coagulation proteins are derived either from 4-hydroxycoumarin or 1,3-indanedione. Although the indanediones are used in Europe, a coumarin derivative, warfarin, is the major oral anticoagulant used in the United States. Warfarin inhibits ?-carboxylation of select glutamic acid residues in the N-terminus of prothrombin and factors VII, IX, and X, as well as the vitamin K–dependent natural anticoagulants, protein C and protein S ([410]). Warfarin inhibits the two enzymes critical for the generation of reduced vitamin K, namely vitamin K epoxide reductase and vitamin K reductase ([411] , [412]). Reduced vitamin K is necessary for catalyzing ?-carboxylation of glutamic acid residues. Inhibition of ?-carboxylation by warfarin leads to synthesis of incomplete, hypofunctional coagulation proteins that are unable to bind to cellular surfaces to mediate coagulation reactions. The effect of warfarin on vitamin K–dependent procoagulant protein production is depicted in Figure 61.6. Details of vitamin K metabolism are presented in Chapter 21.

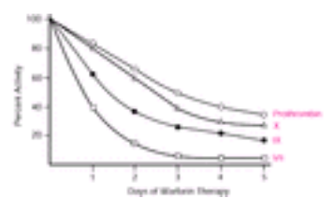

Figure 61.6. Effects of standard warfarin therapy on the plasma vitamin K–dependent procoagulant coagulation proteins. Administration of 5 to 10 mg daily of warfarin results in inhibition of synthesis of functional vitamin K–dependent proteins. The coagulant activity of these proteins in plasma declines as a function of their half-life. Half-lives of factors VII, IX, and X and prothrombin are 6, 24, and 40 and 60 hours, respectively. Although 1 to 2 days of warfarin prolongs the PT assay (because of the rapid decrease in factor VII concentration), therapeutic anticoagulation requires at least 4 to 5 days. (Data from O'Reilly RA. The pharmacodynamics of the oral anticoagulant drugs. Prog Hemost Thromb 1974;2:175–213; reproduced from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599, with permission.)

Commercially available warfarin is a racemic mixture of levorotatory and dextrorotatory forms of the drug. The half-life of warfarin in blood is approximately 36 hours ([413]). Laboratory monitoring of warfarin therapy is best done using functional coagulation tests, such as the PT. Plasma warfarin levels are most useful in evaluating the unusual patient who does not respond to standard warfarin dosages or in whom malabsorption, noncompliance, or inherited drug resistance is an issue ([412] , [414]). Because factor X and prothrombin have half-lives greater than 2 days, reduction of all vitamin K–dependent coagulation proteins into the therapeutic range (approximately 20% of normal) requires 4 to 5 days of therapy ([415]). This is the basis for the “heparin overlap” period of 4 to 5 days during which patients receive therapeutic heparin while waiting to achieve the therapeutic effects of warfarin ([416]). An animal study indicated that depression of both factor X and prothrombin levels by warfarin was important in prevention of hypercoagulability ([415]). Warfarin dosage is influenced by numerous variables, including the patient's dietary stores of vitamin K, liver function, coexisting medical disorders, concurrent medications, and presence or absence of a common cytochrome P-450 2C9 gene mutation ([417] , [418] and [419]). Patients with liver disease, malnutrition, or other factors associated with sensitivity to warfarin should receive lower warfarin dosages. The most common adverse interaction of warfarin use occurs in a patient with marginal dietary vitamin K intake (postoperative state) who is given a broad-spectrum antibiotic, reducing enteric bacterial synthesis of vitamin K, resulting in increased sensitivity to warfarin ([412]). Starting warfarin therapy early after heparin therapy (day 1 or 2) has many advantages, including earlier hospital discharge on adequate oral anticoagulation and potential reduction in the incidence of HIT ([420]). The metabolism of warfarin may be affected by other drugs metabolized by the cytochrome P-450 enzyme complex; drugs that displace albumin-bound warfarin into the circulation; drugs that impair gastrointestinal absorption; and many antibiotics that alter the natural flora of the colon (an endogenous source of vitamin K) ([412]) (Table 61.10).

TABLE 61.10. Drugs and Medical Conditions Affecting Warfarin Potency

Potentiators	Antagonists
Drugs	Drugs
Acetaminophen	Adrenal corticosteroids
Anabolic steroids	Barbiturates
Broad-spectrum antibiotics	Carbamazepine
Chloral hydrate	Chlordiazepoxide
Cimetidine	Cholestyramine
Clofibrate	Efavirenz
Disulfiram	Griseofulvin
Fluconazole	Nafcillin
Indomethacin	Rifampin
Influenza vaccine	Sucralfate
Lovastatin	Trazodone
Metronidazole	Medical conditions
Omeprazole	Excess dietary vitamin K
Phenylbutazone	Inherited resistance to warfarin
Phenytoin	Hypothyroidism
Propranolol	Nephrotic syndrome
Protease inhibitors (except ritonavir)	
Quinine/quinidine	
Salicylates	
Tamoxifen	

Thyroid drugs	
Trimethoprim/sulfamethoxazole	
Medical conditions	
Older age	
Liver disease	
Biliary disease	
Malabsorption	
Congestive heart failure	
Fever	
Hyperthyroidism	
Malnutrition	
Vitamin K deficiency	
Cancer	

Data from the 2003 Physicians' Desk Reference. Montvale, NJ: Thomson Healthcare; and Hirsh J, Dalen JE, Anderson DR, et al. Oral anticoagulants: mechanism of action, clinical effectiveness, and optimal therapeutic range. Chest 2001;119(Suppl):108S–121S.

Certain patients may require very large doses of warfarin (>50 mg/day) to achieve therapeutic anticoagulation; the term *warfarin resistance* has been applied ([414]). Patients who are difficult to anticoagulate with warfarin, either because they exhibit warfarin resistance or because they are very sensitive to the drug and cannot be safely regulated, may be candidates for adjusted-dose subcutaneous heparin or LMWH.

Laboratory Monitoring of Warfarin Therapy The PT assay is useful to monitor warfarin therapy because this assay measures three vitamin K–dependent coagulation proteins—factors VII, X, and prothrombin. The PT is particularly sensitive to factor VII deficiency; with a half-life of 4 to 6 hours, the factor VII level may drop rapidly after only 1 day of warfarin therapy and prolong the PT value. However, because the other vitamin K–dependent proteins have longer half-lives, therapeutic anticoagulation takes 4 to 5 days. There is no advantage to giving larger loading doses of warfarin; this regimen only results in a more rapid drop in factor VII levels, delay in attainment of a stable PT, a precipitous fall in protein C levels, and predisposition to warfarin-induced skin necrosis ([413] , [421] , [422]). To understand current recommendations for monitoring warfarin therapy, it is important to appreciate the concept of the INR, a method that standardizes PT assays ([412] , [423]). An international reference thromboplastin preparation has been adopted by the World Health Organization (WHO). Each new commercial thromboplastin is calibrated against the primary WHO reference preparation. These results are used to calculate the relative sensitivity of the unknown preparation compared with the WHO standard [international sensitivity index (ISI)]. The method to determine the ISI for a particular thromboplastin is depicted in Figure 61.7. By adjusting for the ISI of a particular thromboplastin, an INR, defined as the PT ratio that would have been obtained if the WHO standard thromboplastin had been used, can be determined. The INR is calculated using the following formula: INR = [PT ratio] ^{ISI} (Fig. 61.8).

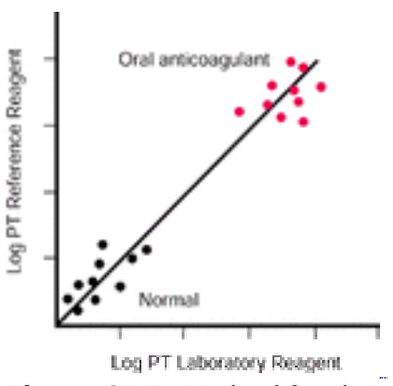

Figure 61.7. Method for determination of an international sensitivity index (ISI) value for a laboratory's thromboplastin preparation. Log prothrombin time (PT) values are determined using a reference thromboplastin reagent and the commercial laboratory thromboplastin reagent on patients receiving stable (2 weeks) oral anticoagulant therapy and a group of normal, untreated volunteers. The best fit line is determined, and the slope of this line multiplied by the ISI of the reference thromboplastin reagent is the ISI value for the commercial thromboplastin reagent. (From Rodgers GM. Laboratory monitoring of anticoagulant and fibrinolytic therapy. In: Kjeldsberg C, McKenna R, Perkins S, et al., eds. Practical diagnosis of hematologic disorders, 2nd ed. Chicago: ASCP Press, 1995:745–755, with permission.)

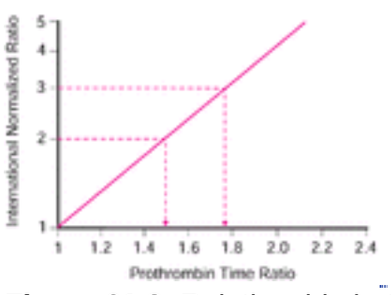

Figure 61.8. Relationship between a patient's prothrombin time (PT) ratio on warfarin therapy and the corresponding international normalized ratio (INR) value. The slope of the line represents the international sensitivity index (ISI) value of the particular thromboplastin preparation used in the laboratory's PT assay. In this example, for low-intensity-warfarin therapy (INR, 2.0 to 3.0), a PT ratio between 1.50 and 1.75 would be required. Thromboplastins with higher ISI values would have slopes greater than that shown and would be less sensitive reagents for the PT assay, whereas thromboplastins with lower ISI values would have slopes less than that shown (more sensitive reagents). (From Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599, with permission.)

The American College of Chest Physicians' consensus panel recommends low-intensity warfarin therapy (INR, 2.0 to 3.0) for all indications except prosthetic mechanical heart valves and prophylaxis of recurrent MI, for which higher-intensity warfarin therapy (INR, 2.5 to 3.5) is suggested ([412]). A summary of recommendations is shown in Table 61.11.

TABLE 61.11. Recommended Therapeutic Range for Warfarin Therapy

Indication	International Normalized Ratio
Low-intensity	2.0–3.0
Prophylaxis of venous thrombosis	
High-risk surgery	
Treatment of venous thromboembolism	
Prevention of systemic embolism	
Tissue heart valves	
Acute myocardial infarction

Prevention of recurrent myocardial infarction	

From Hirsh J, Dalen JE, Anderson DR, et al. Oral anticoagulants: mechanism of action, clinical effectiveness, and optimal therapeutic range. Chest 2001;119[Suppl]:8S–21S, with permission.

Increasing use of the INR format has led to appreciation of its limitations ([426], [427]). These include less accuracy and precision when insensitive (high ISI value) thromboplastins are used, incorrect assignment of an ISI value by the manufacturer, use of a different reagent-instrument combination than that used by the manufacturer, and use of an incorrect control PT value ([428]).

Adverse Effects of Warfarin Therapy

Bleeding A direct relationship exists between the risk of bleeding and the intensity of anticoagulation, with patients receiving higher-intensity (INR >3.0) therapy having a fivefold greater risk of bleeding ([429]). Other major factors contributing to bleeding include coexisting conditions, such as structural gastrointestinal lesions, hypertension, renal disease, and cerebrovascular disease ([430], [431]). Investigation of patients who experience visceral bleeding while on warfarin therapy often results in identification of structural disease ([432]). Highest bleeding rates occur in patients with cerebrovascular disease ([430]). For patients given low-intensity warfarin therapy for prophylaxis of venous thromboembolism, the risk of major bleeding is less than 1%. Antiplatelet medications or other drugs that potentiate warfarin activity are important contributors to bleeding (Table 61.10). Treatment strategy of bleeding in patients receiving warfarin depends on several factors: the duration of expected warfarin therapy, the severity of bleeding, and the extent of INR elevation. Patients with minor bleeding (bruising, microscopic hematuria) and an INR of less than 6.0 can have warfarin withheld until the INR approaches the therapeutic range. Warfarin can then be resumed at a lower maintenance dosage. If patients have visceral bleeding that is not life-threatening and are concluding their warfarin treatment course, their coagulopathy can be reversed with vitamin K, 10 mg, SC or PO. Patients with significant emergent bleeding and who require continued warfarin therapy should be reversed with fresh frozen plasma (four to five units) or prothrombin complex concentrates. If the INR is between 6 to 10 and no clinical bleeding exists, small doses of vitamin K can be given (1 to 2 mg PO or SC), with slow correction toward the therapeutic range within 24 hours. For an INR greater than 10 in patients without bleeding, higher doses of vitamin K can be given (2 to 4 mg, PO or SC) and repeated at 12- to 24-hour intervals, depending on posttreatment INR values. Patients requiring warfarin who are excessively corrected with vitamin K should receive therapeutic heparin or LMWH until oral anticoagulation is reestablished. Failure of vitamin K to correct the coagulopathy suggests that another process is present such as liver disease or DIC. The management of warfarin overdosage and reversal has been reviewed ([433]). Patients who ingest rodenticides that contain long-acting vitamin K antagonists (“superwarfarins”) may require massive daily doses (=100 mg) of vitamin K to correct the coagulopathy, for periods of weeks to months (see Chapter 60). For patients on long-term warfarin therapy who require procedures or elective surgery, bridging therapy with LMWH is acceptable when warfarin is discontinued 4 to 5 days before surgery. Postoperatively, heparin or LMWH is given and continued until a 4- to 5-day overlap period of warfarin has been achieved ([434]). Nonhemorrhagic adverse effects of warfarin therapy include alopecia, gastrointestinal discomfort, rash, and liver dysfunction ([430]). A warfarin embryopathy can occur when pregnant mothers receive warfarin during the first trimester. A bone matrix protein, osteocalcin, is vitamin K–dependent, and in the presence of vitamin K deficiency induced by warfarin, osteocalcin is synthesized in a nonfunctional manner, resulting in fetal bone malformations ([435]). Additional fetal abnormalities have been noted when warfarin is used during pregnancy. Because of these fetal risks, most practitioners avoid warfarin during pregnancy ([436]).

Warfarin-Induced Skin Necrosis Skin necrosis is an unusual but devastating complication of warfarin therapy, occurring within the first week of initiating therapy. Affected patients have usually received large, loading doses of warfarin, perhaps in the absence of therapeutic heparin anticoagulation. Many patients with this syndrome have been found to have heterozygous protein C deficiency ([133]). The basis for this complication is thought to be a warfarin-induced rapid reduction in protein C levels in patients with a preexisting inherited protein C deficiency that results in a hypercoagulable state and thrombosis. Not all heterozygous protein C–deficient patients receiving warfarin experience this complication, and not all patients with this complication have protein C deficiency. Clinically, the skin lesions begin on certain subcutaneous areas of the body (breasts, abdomen, thighs) as erythematous patches ([437]). Lesions progress to blebs followed by demarcated skin necrosis (Fig. 61.9). Skin biopsy reveals generalized thrombosis of skin vessels. This complication may require amputation, plastic reconstructive surgery, or both. The use of standard maintenance doses of warfarin (5.0 to 7.5 mg/day) beginning after patients are therapeutically anticoagulated with heparin may avoid this complication. Patients who experience warfarin-induced skin necrosis should be heparinized, warfarin should be discontinued, and vitamin K should be administered promptly ([133]). Patients experiencing this complication should be screened for protein C deficiency. A few cases of warfarin-induced skin necrosis have been reported in protein S–deficient patients ([438]). A literature review of warfarin-induced skin necrosis found that warfarin therapy could be reinstituted in affected patients; smaller initial doses of warfarin were recommended ([439]).

Figure 61.9. Warfarin-induced skin necrosis. The patient was a 75-year-old female given warfarin in the absence of heparin therapy. An initial area of tenderness over the right calf became erythematous and indurated and then evolved into overt skin necrosis as shown. (From Schleicher SM, Fricker MP. Coumarin necrosis. Arch Dermatol 1980;116:444–445, with permission.)

The “purple toe syndrome” is an uncommon disorder that has been described in patients with underlying atherosclerotic vascular disease who are receiving warfarin therapy ([440], [441] and [442]). These patients present with atheroembolic symptoms including ischemic toes (purple toes), livedo reticularis, gangrene, abdominal pain, or symptoms of renal infarction. Involved visceral organs include the kidneys, pancreas, spleen, and liver. This complication may be difficult to distinguish from warfarin-induced skin necrosis, except that on biopsy, cholesterol emboli are present in the purple toe syndrome, and widespread vascular thromboses are seen in skin necrosis. Treatment involves prompt recognition of the syndrome and discontinuing warfarin therapy ([443]).

Thrombolytic Drugs

The major reaction of the fibrinolytic (plasminogen) system involves the conversion by PAs of the inactive proenzyme, plasminogen, into the active enzyme, plasmin. Plasmin can degrade fibrinogen, fibrin monomers, and cross-linked fibrin (as found in thrombi) into FDPs. These plasmin-mediated reactions generate many species of FDP including unique species of FDP such as fragment X from fibrinogenolysis and cross-linked FDP such as (DD)E- and D-dimer from cross-linked fibrin ([444], [445]). Knowledge of these reactions is necessary to appreciate the mechanisms of action and limitations of commercial PAs.

A common feature of the management of *all* thromboembolic diseases is the desire to restore vascular patency in a timely fashion to prevent loss of tissue, organ, and limb function, as well as life. Acute arterial thrombosis warrants an attempt at immediate thrombolysis, whereas venous thrombosis only warrants such intervention in extreme cases. Recognition of the importance of the endogenous fibrinolytic system in limiting the size of hemostatic thrombi, clearing hemostatic thrombi after vascular repair, and preventing pathologic thrombosis has resulted in the development of pharmacologic fibrinolytic (thrombolytic) agents to facilitate rapid restoration of vascular patency. Most thrombolytic agents are recombinant forms of physiologic PAs. The commercially available PAs differ with regards to plasma half-life, fibrin selectivity, primary clinical usage, primary infusion strategy, and immunogenicity. Currently available PAs and their key characteristics are summarized in Table 61.12.

TABLE 61.12. Properties of Currently Available Thrombolytic Agents

Thrombolytic Agent	Molecular Weight (Daltons)	Plasma Half-Life (Min)	Key Properties
Streptokinase (Streptase)	47,000	20 (drug); 90 (lytic effect)	Complexes with plasminogen to gain activity
Anisoylated plasminogen streptokinase activator complex (Eminase)	131,000	40–90	Streptokinase and plasminogen complex
Urokinase (Abbokinase)	34,000/54,000	15	Direct plasminogen activator derived from fetal kidney cells

Recombinant urokinase	54,000	7	Recombinant high-molecular-weight urokinase
Recombinant prourokinase (ProLyse)	49,000	7	Active after conversion to urokinase
Alteplase (Activase)	65,000	4–8	A recombinant t-PA
Reteplase (recombinant plasminogen activator) (Retavase)	39,000	15	Truncated t-PA with an extended half-life
TNK–recombinant t-PA (TNKase)	65,000	20 (initial); 90–130 (terminal)	A modified t-PA with an extended half-life, enhanced plasminogen activator inhibitor-1 resistance, and greater fibrin specificity

t-PA, tissue-type plasminogen activator.

Most thrombolytic agents are fashioned after endogenous t-PA or urokinase. Traditional thrombolytic drugs include bacteria-derived SK, anisoylated plasminogen SK activator complex, urokinase (two-chain u-PA), and recombinant t-PA (rt-PA). Newer molecules have been and are being developed in an attempt to improve on the traditional agents. Major goals of new thrombolytic agent development include increasing fibrin specificity to theoretically reduce bleeding complications, prolonging initial plasma half-life to facilitate single- or double-bolus administration, reducing sensitivity to inactivation by PAI-1, and improving production efficiency. New thrombolytic agents include mutants of PAs, chimeric PAs, conjugates of PAs with monoclonal antibodies, and novel PAs from animal or bacterial origin.

STREPTOKINASE SK is obtained from cultures of ß-hemolytic streptococci. By itself, SK has no PA activity, but after combining with plasminogen, a complex is formed that is capable of activating other plasminogen molecules to plasmin ([446]). Purified SK has a molecular weight of 47,000 d. SK was the first clinically used thrombolytic agent. It is not fibrin-selective in that its therapeutic use results in systemic fibrin(ogen)olysis and what is termed the *lytic state* from proteolysis of fibrinogen, factors V and VIII, and other plasma proteins ([446]). Platelet function may also be perturbed because plasmin can proteolyze key platelet membrane receptors ([447]). Generation of FDPs also contributes to the significant hemostatic defect of thrombolytic therapy. Although the lytic state predisposes patients to bleeding, the benefit of decreased blood viscosity that results from the lytic state may be clinically important. The half-life of SK is approximately 20 minutes. Because SK is a bacterial protein, it is antigenic, and allergic reactions occur in approximately 6% of patients. Anaphylaxis during SK use occurs in approximately 0.1% of patients ([448]). Patients previously exposed to SK or with previous streptococcal infections may acquire antistreptococcal antibody levels sufficient to neutralize the activity of SK. Therefore, all patients receiving SK should be monitored to ensure attainment of the lytic state. This can be done with the thrombin time assay. SK has been primarily used to treat venous thromboembolism and MI, as well as to treat central venous access device-associated thrombosis.

UROKINASE-TYPE PLASMINOGEN ACTIVATOR In the past, u-PA was obtained from human fetal kidney cell cultures. It is currently produced using nonhuman mammalian tissue cultures. Its molecular weight is 34,000. u-PA is not fibrin-selective, and this drug also produces a lytic state. The half-life of u-PA is approximately 15 minutes. u-PA is used to treat venous thromboembolism, MI, and thrombolysis of clotted catheters.

TISSUE-TYPE PLASMINOGEN ACTIVATOR Currently, t-PA is produced by recombinant technology as a two-chain species, with a molecular weight of approximately 65,000 ([449] , [450]). *In vitro*, t-PA is fibrin-specific, because of its high affinity for fibrin with which it forms a ternary complex with plasminogen. However, with t-PA dosage regimens currently being used, the lytic state is produced ([451]). Consequently, bleeding complications with t-PA are similar to those of SK or u-PA ([452]). The half-life of t-PA is much shorter than that of SK or u-PA, approximately 5 minutes. t-PA is used to treat venous thromboembolism and acute MI ([452] , [453] and [454]) and recently has been approved for use in acute thrombotic stroke ([455] , [456]). Laboratory monitoring of t-PA therapy is usually not recommended.

TISSUE-TYPE PLASMINOGEN ACTIVATOR VARIANTS Recombinant PA (r-PA; reteplase) is a nonglycosylated deletion mutant of wild-type human t-PA comprised of only the kringle 2 and the protease domains of the parent molecule. Lack of the finger domain imparts lower fibrin binding affinity ([457]). Lack of glycosylation, a finger domain, and an epidermal growth factor domain imparts an extended half-life (15 minutes vs. 5 minutes). The longer half-life allows for double-bolus administration. TNK-tPA differs from t-PA by three sets of mutations. The Asn ^{117}?Gln and Thr ^{103}?Asn mutations promote a lower plasma clearance rate and greater fibrin specificity. The Lys ^{296}-His ^{297}-Arg ^{298}-Arg ^{299}?Ala-Ala-Ala-Ala mutation imparts an 80-fold increased resistance to PAI-1 ([458]). The longer half-lives of r-PA and TNK–rt-PA compared with t-PA facilitate bolus administration primarily for acute coronary thrombosis.

Newer Non–Tissue-Type Plasminogen Activator Thrombolytics Recombinant glycosylated prourokinase has a greater stability than recombinant nonglycosylated prourokinase and is rapid acting and safe in the clinical doses used ([459]). Staphylokinase is produced by *Staphylococcus aureus*. It appears to have substantial thrombolytic activity, but it may also be immunogenic ([460]). Vampire bat (*Desmodus rotundus*) salivary PA possesses 85% primary structure homology to human t-PA but lacks a kringle 2 domain. Alfimeprase is a novel thrombolytic based on the snake venom–derived protein, fibrolase. Alfimeprase is not a PA, is neutralized by a $_2$-macroglobulin, and is currently in phase I/II development ([461]).

THROMBOLYTIC THERAPY–ASSOCIATED BLEEDING Bleeding is the most common complication associated with thrombolytic therapy, regardless of the agent. The bleeding stems from plasmin's inability to differentiate between hemostatic and pathologic thrombi. This complication can range from minor bleeding at an intravenous infusion site to life-threatening hemorrhage ([462]). Intracranial hemorrhage is a relatively uncommon but serious complication of thrombolysis in patients being treated for acute MI. The factors that increase the risk for bleeding during thrombolytic therapy are not fully understood. However, Gurwitz and associates used the National Registry for Myocardial Infarction to determine risk factors for this adverse event in individuals treated with t-PA ([463]). Their analysis of 673 patients with intracranial hemorrhage indicated that older age, female sex, black ethnicity, systolic blood pressure greater than or equal to 140 mm Hg, diastolic blood pressure greater than or equal to 100 mm Hg, history of stroke, t-PA dose greater than 1.5 mg/kg, and lower body weight were all significantly associated with an increased risk for intracranial hemorrhage. It is also possible that the properties of the agent used for thrombolysis may contribute to the risk for bleeding complications.

THROMBOLYTIC FIBRIN SPECIFICITY AND HEMORRHAGIC RISK Thrombolytic agents can be characterized along a variety of dimensions, but one that is often mentioned is fibrin specificity ([464]). The ability of a thrombolytic agent (PA) to distinguish between plasminogen in the general circulation and plasminogen bound to fibrin surfaces dictates its fibrin specificity. Activation of fibrin-bound plasminogen results in the generation of fibrin-bound plasmin that is protected from inactivation by a $_2$-antiplasmin. Bound plasmin generates soluble fibrin degradation products; circulating plasmin degrades fibrinogen into FDPs. Fibrin specificity differs from fibrin affinity, which is a measure of how avidly a given agent binds to fibrin, but not its specificity for this molecule ([464]). At present, there is little evidence to support the view that differences in fibrin affinity among PAs are significantly correlated with either the efficacy or safety of these preparations ([465] , [466]). High fibrin specificity is thought to be associated with lower risk for hemorrhagic complications in patients undergoing thrombolytic therapy because of the belief that plasmin generated on the fibrin surface of a thrombus restricts its activity only to that surface. This view is not universally supported by available data from large-scale clinical trials. The relationship between high fibrin specificity and reduced bleeding risk is supported by the results of a recent study ([467]). The results of the Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT)-2 trial, which included 16,949 patients with acute MI, showed that the use of the highly fibrin-specific thrombolytic agent TNK-tPA, compared with rt-PA, was associated with a significantly lower risk for major noncerebral bleeding ([467]). This lower rate of bleeding complications was correlated with a significant reduction in the need for blood transfusions. The ASSENT-2 investigators also reported that TNK-tPA was associated with a significantly lower risk for noncerebral bleeding than the less-specific agent alteplase ([468]). Intracranial bleeding rates were comparable with the two agents. Results from other large-scale studies support the opposing view that high fibrin specificity may actually be associated with increased risk for intracranial bleeding in patients undergoing thrombolytic therapy for acute MI. For example, the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial showed that the risk of intracranial bleeding was slightly higher in 41,021 patients with MIs who received treatment with rt-PA as compared with SK ([469]). These findings are consistent with those from another very large-scale comparison of SK with rt-PA in 20,768 patients with MI [Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico 2 (GISSI-2)], which showed a significantly higher risk of stroke in patients who received the latter, more fibrin-specific agent ([470]). Similarly, the Third International Study of Infarct Survival (ISIS-3) showed that treatment of patients with anisoylated plasminogen SK activator complex was associated with increased risk for intracranial bleeding compared with SK in a large cohort of 41,299 patients who received thrombolytic therapy for suspected MI ([471]). There are a number of potential explanations for the association between high fibrin specificity and increased intracranial bleeding observed in the patients treated in the GUSTO, GISSI-2, and ISIS-3 trials. These include the inability of fibrin-specific agents to distinguish between pathologic thrombi and hemostatic thrombi and the possibility that treatment with fibrin-specific agents resulted in greater degradation of hemostatic fibrinogen and other circulating coagulation factors than SK. Finally, it may be that fibrin-specific therapy resulted in increased production and accumulation of fragment X, and that this enhanced the bleeding risk. PAs once believed to be safer because of their fibrin specificity may actually result in greater bleeding risk by virtue of their generation of the fibrin degradation product (DD)E and fragment X. (DD)E is a cross-linked fibrin degradation product that can bind both plasminogen and t-PA and protect bound plasmin from a $_2$-antiplasmin ([472]). Fragment X is a high-molecular-weight “clottable” FDP, which, when incorporated into a forming thrombus, makes a thrombus more readily lysed ([473]). The sequence of molecular events that can lead to a loss of rt-PA fibrin specificity includes the following: (a) rt-PA and plasminogen bind to a fibrin surface on a pathologic thrombus, resulting in the generation of fibrin-bound plasmin; (b) fibrin-bound plasmin degrades the thrombus, resulting in the formation of fibrin degradation products, such as (DD)E; (c) other rt-PA (via their kringle 2 domains) and plasminogen molecules bind to circulating (DD)E and generate non–fibrin-bound plasmin in the circulation far from the target thrombus; and (d) the circulating plasmin activity degrades circulating fibrinogen and leads to the production and accumulation of fragment X. Hypofibrinogenemia ensues, and hemostatic thrombi that have incorporated fragment X become prone to rapid lysis by circulating and bound plasmin ([474]). Because vampire bat salivary PA lacks a kringle 2 domain, it does not promote the generation of fragment X. This potential for enhanced safety combined with *in vitro* evidence

of enhanced rapidity of clot lysis compared to other thrombolytics makes vampire bat salivary PA an excellent candidate for commercial development ([475]). Fragment X persists in the circulation for as long as 24 hours after an infusion of rt-PA in patients with acute coronary thrombosis. Similar patients given SK have lower circulating levels of fragment X and higher concentrations of smaller degradation products, such as fragment D and fragment E, in their circulation. Bolus administrations of rt-PA may result in less fragment X production than infusions given over several hours. When added to the plasma of healthy dogs, fragment X results in significant lengthening of the thrombin time, and this effect is thought to be due to competition between fragment X and fibrinogen for the fibrinogen binding sites on thrombin ([476]). Unlike in acute MI in which intravenous bolus PA dosing is necessary to rapidly achieve high concentrations of plasmin activity at the site of thrombosis and facilitate rapid lysis of a relatively small thrombus, lysis of larger-diameter and longer peripheral thromboses is best achieved with catheter-directed infusions of PA over several hours to days. Drugs designed for bolus or brief infusion administration to treat acute coronary thrombosis may be associated with an excessive bleeding risk when given by extended continuous infusion. Such infusions may foster the loss of “fibrin specificity” described above, accumulation of fragment X, and increased rates of bleeding.

MANAGEMENT OF VENOUS THROMBOEMBOLIC DISEASE

It has been estimated that between 500,000 and 2 million VTE cases including calf vein thrombosis, proximal DVT, and PE occur annually in the United States alone. It is estimated that up to 50% of DVT and PE is asymptomatic or undetected ([477]). The extremely high incidence of DVT and PE likely reflects inadequate attention to VTE prophylaxis in high-risk surgical and medically ill patients.

The major clinical consequences of extremity DVT include the postthrombotic syndrome (chronic swelling, stasis dermatitis, stasis ulceration, and venous claudication—all secondary to venous insufficiency) and PE. The major clinical consequences of PE include chronic dyspnea, pulmonary hypertension, pulmonary infarction, and death. DVT restricted to the calf veins uncommonly results in clinically important PE and is rarely associated with a fatal outcome. In contrast, inadequately treated DVT involving the popliteal or more proximal leg veins is associated with a 20 to 50% risk of clinically relevant recurrence and is strongly associated with both symptomatic and fatal PE ([478] , [479]). In untreated patients, death from PE occurs most frequently within 24 to 48 hours of initial presentation. All-cause mortality rates in treated patients with PE is as high as 11% at 2 weeks and 17% at 3 months ([477]). Even small PE in patients with emphysema, cardiac disease, or lung involvement with malignancy may result in death. Any VTE in a patient with a contraindication to anticoagulation presents a therapeutic challenge and greater likelihood of adverse outcome. In part, for these reasons, calf DVT, proximal DVT, and PE are considered distinct manifestations of thromboembolic disease.

Calf Deep Venous Thrombosis

It is perceived by many that calf DVT is uncommon and of limited clinical significance. This misunderstanding and underappreciation of the morbidity and mortality associated with calf DVT have resulted in a lack of clear consensus on the optimal management strategy for this thrombotic disease. Contemporary clinical studies have revealed that isolated calf DVT may account for as few as 6.2% of all symptomatic acute DVT and as many as 43.0% of all acute VTE ([479] , [480]). Studies have also demonstrated that, although calf DVT and proximal DVT may be considered separate diseases at their outset, 15 to 25% of calf DVT propagates and converts into proximal DVT ([481] , [482] and [483]). Both symptomatic and asymptomatic calf DVT appear to propagate with an equal frequency ([482]). Such “proximal conversion” renders what was initially a calf DVT just as dangerous as any proximal DVT. Proximal conversion has been shown to occur within the initial 2 weeks after diagnosis in the majority of cases and warrants treatment accordingly ([484] , [485] , [486] and [487]). Despite past reports of inadequate ultrasound sensitivity and specificity for calf DVT, newer imaging hardware and software have made calf DVT diagnosis very feasible by experienced vascular technologists.

Whereas the primary goals of proximal DVT treatment include the prevention of DVT recurrence and PE, the most essential goal of calf DVT treatment should be to prevent early proximal conversion. Current treatment approaches for isolated calf DVT range from identical intensity and duration of anticoagulant therapy as is used for proximal DVT to a complete lack of any pharmacologic therapy at all. Acceptable management, which falls between these extremes, includes serial duplex ultrasound surveillance with therapy begun only in the event of proximal conversion and abbreviated courses of standard anticoagulation. Surveillance consists of noninvasive imaging twice weekly for typically no more than 3 weeks (includes the usual period for proximal conversion). Limitations of serial surveillance include cost, compliance, and convenience. Serial surveillance seems especially prudent in situations such as patients with recent gastrointestinal bleeding for whom the risk of anticoagulation would likely exceed the benefit.

Whereas 6 months of anticoagulation have been shown to be superior to 6 weeks' duration of therapy in patients with proximal DVT, the shorter course of therapy has *not* been shown to be inferior in patients with initial distal thrombosis ([480]). Situational calf DVT (DVT with a clear precipitant such as an inflammatory bowel disease flare and prolonged bed rest) can be safely treated for only 6 weeks assuming the precipitating illness or event has resolved. Inferior vena cava (IVC) filter placement is not recommended for calf DVT in most circumstances.

Proximal Deep Venous Thrombosis

Before selecting an approach to proximal (popliteal vein up to the distal inferior vena cava) DVT management, one must clearly appreciate the goals of therapy. The goals of DVT management include the following: (a) prevention of embolization, (b) prevention of thrombus extension, (c) prevention of early and late recurrence, (d) restoration of venous patency, and (e) prevention of the postthrombotic syndrome. Accomplishment of all five goals should prevent thromboembolic death.

Different treatment strategies accomplish different goals. Supportive care alone (i.e., doing nothing) accomplishes none of these goals. Clinical studies done before the routine use of anticoagulant therapy demonstrated that 20% of patients with untreated DVT died of PE ([488]). Published by Barritt and Jordan in 1960, the landmark study of patients with clinically diagnosed symptomatic PE using heparin followed by oral anticoagulation demonstrated a dramatic mortality reduction in deaths from PE, as well as a reduction in nonfatal recurrence of PE ([489]). Placement of an IVC filter effectively prevents all PE in the short run, but probably at the expense of a greater long-term DVT recurrence rate ([490]). Intravenous, aPTT-adjusted UFH and weight-based LMWH do effectively prevent embolization, extension, and recurrence. LMWHs appear to be slightly, but significantly better, than standard heparin at restoring venous patency and may reduce the incidence of early postthrombotic syndrome. Catheter-directed thrombolytic therapy is the most effective means of completely restoring patency but is associated with excessive bleeding and significant cost. Thrombolysis is best reserved for iliofemoral DVT in the young and those with extensive thrombosis resulting in venous limb gangrene (phlegmasia cerulea dolens).

Several prospective, randomized, controlled trials have demonstrated the efficacy and safety equivalency of UFH and LMWH for the treatment of DVT ([491] , [492] , [493] , [494] and [495]). The major advantage of subcutaneous LMWH is the ability to be self-administered at home without the need for therapeutic monitoring. This translates into a significant reduction in mean hospital length of stay (6.5 days vs. 1.1 days) ([491]). Patients may be started on LMWH in the hospital and then discharged in an “accelerated” fashion to continue their conversion to oral warfarin or may be treated exclusively in the outpatient setting. LMWHs are associated with less osteopenia, less HIT, and less nonspecific protein binding than UFH ([369]). Metaanalyses have demonstrated a survival advantage in those patients with acute DVT who have been treated initially with LMWH versus those treated initially with heparin ([497]). It seems as if this overall survival advantage is derived primarily from a survival advantage imparted to cancer patients with DVT.

The optimal duration of anticoagulation has been widely studied and debated. For idiopathic DVT, 3 months of therapy are better than 4 weeks, and 6 months are better than 6 weeks ([480]). In short, the risk of VTE recurrence is very low as long as therapeutic anticoagulation is continued. It is the 3 to 4% annual risk of major hemorrhage secondary to warfarin that prevents physicians from prescribing long-term anticoagulation with abandon ([498]). Long-term anticoagulation with an attenuated intensity of warfarin therapy may provide ample protection with greatly reduced risk of major bleeding. This latter concept has been reinforced by recently published data indicating that an INR intensity of 1.5 to 2.0 for extended prophylaxis appears to be effective and safe in treating VTE recurrence ([499]). Three to six months of anticoagulation are generally prescribed for individuals with an initial DVT. Recurrent DVT after the completion of a course of anticoagulation usually warrants long-term therapy. Patients with persistent risk factors for thrombosis, such as antiphospholipid antibody syndrome, hyperhomocysteinemia, incurable malignancy, or a deficiency of a natural anticoagulant (protein C, protein S, and AT), usually benefit from long-term therapy. Representative recommended durations of anticoagulation are listed in Table 61.13.

TABLE 61.13. Duration of Anticoagulation in Venous Thromboembolic Disease

Disease	Duration
Situational DVT	6 wk to 3 mo
Idiopathic DVT	6 mo (minimum)
Recurrent idiopathic DVT	12 mo (minimum)
DVT with ongoing risk factors [a]	Long-term/indefinite
Pulmonary embolism	6 mo
Massive pulmonary embolism	Long-term/indefinite
Calf vein DVT	See DVT categories above

DVT, deep venous thrombosis.

[a] For example, malignancy, antiphospholipid antibody syndrome, or natural anticoagulant deficiency.

Pulmonary Embolism

In general, acute PE should be treated in the same fashion as acute DVT. It is actually advisable to start anticoagulation at the time of suspected PE even before diagnostic testing has been performed. LMWHs have been shown to be safe and effective in patients with acute PE treated in hospital ([496], [500]). Outpatient treatment of PE seems reasonable but has not been extensively studied. Placement of an IVC filter at the time of PE diagnosis is usually reserved for those with an absolute contraindication to anticoagulation. Many physicians, however, place filters in patients with underlying cardiac or pulmonary disease who are perceived as being at risk for death should they develop a second PE.

Initial Anticoagulation Therapy

The mainstay of pharmacologic therapy for VTE is anticoagulation. Treatment with heparin or LMWH should be begun as soon as possible, unless an absolute contraindication exists. A delay in achieving a therapeutic intensity of initial parenteral therapy may have a negative impact on a patient's long-term VTE recurrence rate ([501], [502]). Weight-based initial dosing of heparin (80-U/kg bolus followed by 18 U/kg/hour) with subsequent dose adjustments based on a standardized nomogram (Table 61.7) facilitates achieving a therapeutic aPTT ([503]). Several nomograms have been published and their use depends on individual preference. Use of any published nomogram helps facilitate the rapid achievement of therapeutic anticoagulation. Adjusted-dose subcutaneous UFH and intermittent intravenous UFH boluses have also been used effectively in the treatment of VTE ([478]). The therapeutic intensity of UFH is monitored using the aPTT. An aPTT 1.5 to 2.5 times the control aPTT is often considered therapeutic. An aPTT therapeutic range that correlates with an anti-FXa activity level of 0.3 to 0.7 IU/ml is preferred ([144]). The aPTT should be checked every 4 to 6 hours until the aPTT surpasses the minimum of the target range. Fixed-dose boluses and initial infusions are preferred by some and are not necessarily inferior to weight-based dosing ([144]).

Absolute contraindications to the administration of UFH include active bleeding, HIT or a history of HIT, and known sensitivity to UFH or pork products ([144]). Relative contraindications to anticoagulation are listed in Table 61.14. Patients with acute DVT and active bleeding require placement of an IVC filter. It is important to note that active bleeding may be a treatable and transient contraindication to anticoagulation. An IVC filter should not be viewed as an equivalent substitute to anticoagulation in the setting of acute VTE and is certainly not an “insurance policy” against subsequent PE. In patients with filters placed because of bleeding, appropriate anticoagulation should begin as soon as the bleeding source has been properly and completely treated. Because of the significant risk of rebleeding, such a patient should have his or her anticoagulation begun in the hospital. Placement and subsequent removal of a temporary (or retrievable) IVC filter once the contraindication to anticoagulation has passed seems ideal. Placement of an IVC filter because of a “free-floating” DVT may not be necessary in all patients ([504]).

TABLE 61.14. Relative Contraindications to Anticoagulation Therapy

Bacterial endocarditis
Recent organ biopsy or noncompressible arterial intervention site
Recent gastrointestinal or genitourinary bleeding (<10 d)
Thrombocytopenia or marked anemia
History of a bleeding disorder
History of intracranial, spinal, or ocular bleeding
Recent (<2 wk) history of major surgery, stroke, or trauma
Hepatic insufficiency

Patients who are excessively anticoagulated with heparin without serious bleeding can be treated simply by stopping the drug; the short half-life (1 to 2 hours) of heparin ensures rapid return of the aPTT to the therapeutic range. Caution must be used to avoid loss of therapeutic anticoagulation in patients treated for thrombosis. Patients who are excessively anticoagulated and actively bleeding should be considered for reversal of anticoagulation with protamine sulfate. Protamine is given by slow IV infusion, with 1 mg of protamine neutralizing approximately 100 U of heparin ([369]). Because heparin has a short half-life, it is important to give an appropriate protamine dose for the heparin level remaining at that time, so that excess protamine is not administered ([369]). Protamine infusion may be associated with anaphylaxis, and excess protamine may lead to a paradoxic bleeding disorder ([369]).

Nonhemorrhagic heparin-associated toxicities include allergy, osteoporosis, and decreased plasma AT levels ([107], [505]). Patients who are hypersensitive to one heparin preparation (e.g., porcine heparin) can receive another (e.g., bovine heparin), or a LMWH. Osteoporosis results from heparin-induced bone resorption and occurs when patients receive therapeutic dosages of heparin for periods greater than 3 to 4 months ([505]).

Weight-based subcutaneous LMWH is an established standard of care in many communities and hospitals. UFH and LMWH have been demonstrated to be equally safe and efficacious in patients with acute VTE. The choice of which agent to use should be determined for each patient, taking into consideration the individual patient profile including medical history, thrombotic risk factors, bleeding risk, and ambulatory status. Enoxaparin sodium is dosed at 1.0 mg/kg body weight every 12 hours or 1.5 mg/kg once daily. Tinzaparin is dosed at 175 IU/kg once daily ([497], [506]). Dalteparin is dosed at 200 IU/kg (up to 18,000 IU) once daily. At this time, only enoxaparin and tinzaparin are FDA-approved for VTE treatment in the United States.

Patients at increased risk for bleeding should probably be treated initially in an inpatient setting. Such patients include those with active bleeding (including occult stool blood), a history of recent surgery, past gastrointestinal tract or neuraxial bleeding, recent trauma or stroke, concomitant regular nonsteroidal antiinflammatory drug use, thrombocytopenia, and renal insufficiency. Severe renal dysfunction (creatinine clearance <30 cc/minute) results in a 25% or greater reduction in LMWH clearance and thus results in drug accumulation ([369], [376]). LMWH therapy may not be suitable for the morbidly obese ([507]). Most reported clinical trials have enrolled patients weighing less than or equal to 100 kg. Based on a recent pharmacokinetic analysis in obese patients up to 165 kg, tinzaparin can be dosed based on actual weight without dose adjustment ([507]). Monitored heparin therapy is always a choice for the obese patient with acute DVT.

Therapeutic monitoring of LMWH therapy using the anti–factor Xa activity assay is not necessary in most patients. An exact therapeutic range has not been carefully determined, but a consensus panel has recommended a target peak LMWH range of 0.5 to 1.1 U/ml (for twice-daily dosing of a LMWH) ([508]). Adjusting the dose of LMWH based on such testing may not be superior to simple weight-based dosing. In occasional patients with thrombosis, the aPTT assay may not be reliable in monitoring heparin therapy—for example, patients with the lupus anticoagulant and a prolonged baseline aPTT. For these patients, one option would be to use heparin levels that can now be obtained by an automated assay using an anti–factor Xa method. In this instance, the targeted therapeutic range would be 0.35 to 0.7

U/ml. Alternatively, these patients could be given a LMWH, with the dosage determined solely by body weight and no necessity for laboratory monitoring. Patients with marked elevation in factor VIII levels may also be more reliably anticoagulated using LMWH ([370]).

A recently presented abstract demonstrated that fondaparinux is equivalent to enoxaparin for the initial management of DVT and is equivalent to intravenous UFH for the initial management of PE ([386]). Trials evaluating ximelagatran, the oral DTI, in VTE management have recently been completed.

Chronic Phase Anticoagulation

Warfarin therapy can be started as soon as an aPTT greater than 1.5 times control has been achieved with heparin or after an initial weight-based therapeutic dose of LMWH has been given. Bolus dosing of warfarin does not help achieve a stable, target INR faster and may actually delay achievement of a stable INR and prolong hospitalization ([413]). Initial dosing of warfarin with 2.5 to 7.5 mg/day (based on patient weight and nutritional status) seems prudent. Heparin and LMWH therapy must overlap oral warfarin therapy for a minimum of 4 days or, ideally, until a stable, target range (2.0 to 3.0) INR has been achieved ([415] , [416]). Patients with massive DVT or PE may benefit from 7 to 10 days of initial heparin or LMWH therapy. Because of its teratogenic effects, warfarin therapy is contraindicated in pregnancy, so long-term heparin or LMWH is prudent for pregnant patients. LMWH may be preferred in pregnancy, because osteopenia occurs less with LMWH than UFH ([505]).

Warfarin therapy *alone* is contraindicated in the setting of acute thrombosis because of the inherent delay in achieving therapeutic anticoagulation and the theoretical transient exacerbation of hypercoagulability caused by a rapid reduction in protein C levels ([416]). This warfarin-induced paradoxic hypercoagulability may explain warfarin-induced skin necrosis and warfarin-induced limb gangrene in patients with HIT. The INR, not the PT or PT ratio, should be used to monitor warfarin therapy. Monitoring at least every 4 weeks is recommended; patients beginning on warfarin therapy need more frequent monitoring. More frequent monitoring does help maintain the INR within the target range for a greater amount of time ([509]).

The optimal duration of anticoagulation should be determined for each individual patient. Guidelines for the duration of therapy are suggested in Table 61.13. Patients with DVT secondary to a time-limited risk factor such as recent surgery, immobilization, trauma, or pregnancy may be anticoagulated for a short duration of 6 weeks to 3 months, as long as the risk factor has resolved. Patients with a first idiopathic VTE should be anticoagulated for a minimum of 6 months. Patients with recurrent idiopathic VTE (two or more events) or ongoing risk factors, such as malignancy or antiphospholipid antibody syndrome, may require long-term (possibly indefinite) therapy. The predicted long-term bleeding risk must be offset by the long-term benefit before a protracted course of anticoagulation should be prescribed.

All patients anticoagulated with warfarin should be educated regarding maintaining a stable diet. Patients should be encouraged to consume a constant intake of dietary vitamin K and avoid large variations or fluctuations in their diet. Because of the number of pharmacologic interactions that exist between warfarin and other drugs (Table 61.10), patients should be instructed to inform their physician of the addition or withdrawal of any medication during warfarin therapy. In addition, patients should be encouraged to avoid over-the-counter multivitamin supplements or herbal preparations that contain vitamin K or vitamin K analogs and those known to have an impact on warfarin anticoagulation (e.g., ginkgo biloba). The risk of bleeding during therapy should be explained to all patients. It is strongly recommended that patients avoid high-risk activities including contact sports. Patients should be instructed to seek medical attention for severe bleeding or bleeding that is not controlled after 10 to 15 minutes of continuous compression. The appropriate use of protective gear, such as bicycle helmets, should be emphasized. Patients should be instructed to carry a wallet card that identifies their use of an anticoagulant. In addition, they should be encouraged to wear a medical identification bracelet or necklace. Patient instruction is best provided by anticoagulation clinics that specifically focus on anticoagulation monitoring and education. Point-of-care instruments that can reliably monitor a patient's INR values in the hospital or home setting are being increasingly used ([510]).

Catheter-Directed Thrombolysis of Deep Venous Thrombosis

Catheter-directed thrombolytic therapy is usually reserved for patients with extensive DVT involving the IVC or iliac veins and for patients who have signs and symptoms of actual or impending phlegmasia cerulea dolens ([511] , [512] , [513] , [514] , [515] and [516]). Catheter-directed thrombolysis is normally not used for PE because of a lack of demonstrated superiority to peripheral intravenous thrombolytic administration. An initial venogram is performed via a distal vessel, usually a popliteal or foot vein, to fully delineate the extent of the DVT. Access for the vascular access sheath is best accomplished via the popliteal vein, typically using ultrasound guidance to assure nontraumatic, single-puncture catheter placement. A multiside hole catheter is advanced and imbedded within the thrombus. Thrombolytic agent is infused through this catheter. Low-dose heparin (500 units/hour) should be infused through the sheath to prevent sheath thrombosis. Periodic surveillance with venography should be performed to assess resolution of the DVT. As lysis is achieved, the multiside hole catheter may require repositioning to maintain infusion within the thrombus ([511]).

Lytic therapy for DVT carries the same contraindications as for lysis of PE. Active bleeding is an absolute contraindication to the procedure; relative contraindications include those for any anticoagulant. In addition, a history of contrast allergy or renal insufficiency is a relative contraindication to the procedure. Complications are similar to the complications for PE lysis. The main complication associated with the use of lytic agents is bleeding. Access site bleeding is the most common complication. Bleeding in the popliteal space may be particularly significant because the popliteal vein is poorly compressible. Additional complications such as intracranial bleeding are also seen with lytic infusion for DVT lysis. PE, potentially fatal, has been reported in patients undergoing DVT lytic therapy.

Only SK has an approved indication for use in lytic treatment of DVT. Urokinase, rt-PA, r-PA, and TNK–t-PA are not approved for DVT lysis. After the completion of thrombolytic therapy, patients should be anticoagulated with an appropriate parenteral agent (UFH, LMWH, or DTI) and converted to warfarin in the usual fashion. Patients who have a contraindication to lysis may be able to derive some benefit from suction (mechanical) thrombectomy performed at the time of venography/intervention. However, suction thrombectomy should not be attempted in patients with a contraindication to anticoagulation because any benefit from suction thrombectomy would likely be lost without maintenance of therapeutic anticoagulation.

Benefits of DVT thrombolysis include the ability to subsequently diagnose and treat any underlying venous stenosis, venous compression (as in May-Thurner syndrome), or venous webs that may be discovered after thrombolysis ([512] , [513]). The use of angioplasty, stent placement, or both may improve outcomes in these patients ([514]). Use of thrombolysis results in improved venous patency and symptom resolution and a decrease in postthrombotic symptoms and may improve health-related quality of life ([516]).

Thrombolysis for Pulmonary Embolism

Most patients with symptomatic PE should be treated with anticoagulation following the same guidelines for treatment that are applied to DVT. Some patients with PE may derive benefit from thrombolytic therapy to actively degrade the thrombus obstructing the pulmonary vasculature. Clear indications for PE thrombolysis are debated ([517] , [518]). Thrombolysis has been demonstrated to improve survival in patients with massive PE plus shock and is probably indicated in these patients. When compared to anticoagulation alone, thrombolytic therapy results in more rapid thrombus lysis, an early improvement in pulmonary blood flow, and improvement of right ventricular function ([519]). However, these improvements in cardiopulmonary function alone have not resulted in decreased mortality in stable patients without significant hemodynamic compromise. It remains unclear whether patients with PE and evidence of right ventricular dysfunction or elevated cardiac troponin levels (or both) benefit from thrombolysis.

Currently approved drug regimens for PE lysis include the following: SK, 250,000 IU IV bolus over 30 minutes followed by 100,000 IU IV infusion/hour for 24 hours; rt-PA, 100 mg IV infusion over 2 hours; and urokinase, 4400 IU/kg bolus over 10 minutes followed by IV infusion of 4400 IU/kg/hour for 12 hours. Reteplase is not FDA approved for PE management, but when administered as two 10-U boluses separated by 30 minutes, it has been shown to improve pulmonary vascular resistance and blood flow more rapidly than standard-dose rt-PA ([520]). Lytic therapy is contraindicated in patients with an increased risk of bleeding. Active bleeding is an absolute contraindication to therapy. In addition, recent organ biopsy or arterial puncture in a noncompressible site and recent cardiopulmonary resuscitation, uncontrolled hypertension, and pregnancy or recent delivery are relative contraindications. For all patients, the potential benefits of lysis must be weighed heavily against the potential risks of bleeding ([521]).

Major hemorrhage rates have varied between 4 to 22% when used in studies at the currently recommended doses. Extrapolation from acute MI thrombolysis trials supports intracranial hemorrhage rates between 1 to 3%, approximately one-half of which are fatal. There is no benefit to lytic infusion via a centrally placed catheter when compared to peripheral infusion in patients with PE. Many believe heparin should not be administered concomitantly with the lytic agent. An aPTT should be determined at the completion of the lysis; if the aPTT is less than or equal to 2.5 times the control, then heparin infusion should be started/resumed. If the aPTT is greater than 2.5 times the control, the aPTT should be repeated every 4 hours; once it decreases into an acceptable range, the heparin infusion may be initiated. If a

complication of therapy occurs, the lytic agent and any other anticoagulants should be held. Fresh frozen plasma and cryoprecipitate may be used to replete fibrinogen and clotting factors. Consideration should be given to the use of antifibrinolytic agents to reverse excessive fibrinolysis ([517], [518]).

VENOUS THROMBOEMBOLIC DISEASE PREVENTION

If physicians focused more on VTE prophylaxis, much less time would be needed to emphasize methods for VTE diagnosis and treatment. Fatal PE is considered to be the most common preventable cause of hospital death ([522]). Because the clinical diagnosis of venous thromboembolism is unreliable and serial surveillance of all high-risk patients is expensive, widespread use of anticoagulants (or other prophylactic measures) has been recommended ([336]).

It has been shown in a study of general surgery residents that the key to proper prophylaxis is the recognition of risk factors for thrombosis ([523]). Established clinical risk factors include advanced age; prolonged immobility, stroke, or paralysis; prior VTE; active malignancy and its treatment; major surgery, especially that involving the abdomen, pelvis, and lower extremities; trauma, especially involving fracture of the pelvis, hip, or leg; obesity; varicose veins; depressed left ventricular ejection fraction; central venous access devices; inflammatory bowel disease; nephrotic syndrome; pregnancy; estrogen use; and inherited and acquired hypercoagulable states ([336]). Most patients possess multiple risk factors at any given point in time. In patients undergoing general surgery, the number of risk factors, risk of DVT, risk of clinical PE, risk of fatal PE, and the required intensity of prophylactic therapy necessary to mitigate the risk all seem to increase in parallel.

Low-risk general surgery is defined as minor surgery in patients younger than 40 years of age with no additional risk factors ([336]). *Moderate risk* includes minor surgery in patients with additional risk factors, nonmajor surgery in patients 40 to 60 years of age without additional risk factors, and major surgery in patients younger than 40 years of age without additional risk factors ([336]). *High risk* includes nonmajor surgery in patients older than 60 years of age or with additional risk factors and major surgery in patients older than 40 years of age or with additional risk factors ([336]). *Highest risk* includes major surgery in patients older than 40 years of age who have or have had cancer, prior VTE, or a molecular hypercoagulable state; hip or knee arthroplasty; hip fracture surgery; major trauma; or acute spinal cord injury ([336]). Appropriate doses of pharmacologic agents used for thromboprophylaxis are listed in Geerts et al. ([336]).

Not all patients at risk develop a thrombosis, and not all thromboses result in symptoms, morbidity, or death. The benefit of pharmacologic thromboprophylaxis must always be weighed against the bleeding risk. Patients at high risk for bleeding should still receive prophylaxis in the form of an intermittent pneumatic compression device, thromboembolism deterrence stockings, or both. Table 61.14 lists relative contraindications to anticoagulant therapy.

Although the venous thrombosis risk associated with surgical intervention has been appreciated and addressed for some time, appreciation of the risk in the medically ill has lagged behind. A recent study has significantly increased physician awareness of this problem. The MEDENOX (Prophylaxis of Venous Thromboembolism in *Med*ical Patients with *Enox*nantly those immobilized with severe cardiopulmonary disease) have a 14.9% risk of developing DVT within 14 days of admission in the absence of active prophylaxis ([524]). The DVT rate is reduced to 5.5% by the addition of a once-daily dose of LMWH (enoxaparin, 40 mg SC) without a significant increase in bleeding risk. Other studies have demonstrated equivalency between LMWH and heparin 5000 U administered every 8 hours in medical patients with acute cardiac or pulmonary disease ([336]).

Extension of thromboprophylaxis beyond hospitalization has resulted in a reduction primarily in calf vein thrombosis. Whether such therapy has a significant impact on patient morbidity and mortality to a degree that justifies the cost is being questioned. Aspirin is not recommended for venous thromboprophylaxis in any group of at-risk patients because more efficacious methods exist.

Table 61.15 summarizes acceptable approaches to VTE prevention.

TABLE 61.15. Evidence-Based Venous Thromboembolism Prophylaxis Strategies

Setting	Risk Level	Early Ambulation	Low-Dose Subcutaneous Unfractionated Heparin	Low-Molecular-Weight Heparin	PENTA [a]	Adjusted-Dose Unfractionated Heparin	Adjusted-Dose Warfarin	Elastic Stockings	Intermittent Pneumatic Compression	COMBO
General surgery	Low risk	X								
	Moderate risk		X	X				X	X	
	High risk		X	X					X	
	Highest risk									X
Urologic surgery	Low risk (e.g., transurethral resection of the prostate)	X								
	Major, open procedures		X	X				X	X	
	Highest risk									X
Neurologic surgery			X	X					X	
Gynecologic surgery	Brief procedure for benign disease	X								
	Major procedure for benign disease		X	X					X	
	Extensive procedure for malignancy		X	X						X
Orthopedic surgery	Elective hip replacement			X	X	X	X			
	Elective knee replacement			X	X		X			
	Hip fracture surgery			X	X		X			
Trauma				X						
Spinal cord injury	Acute			X						X
	Rehab phase			X			X			
Medically ill			X	X						

COMBO, mechanical prophylaxis combined with low-dose subcutaneous unfractionated heparin or low-molecular-weight heparin; PENTA, low-dose fondaparinux.

[a] Data on fondaparinux in nonorthopedic settings are lacking.

HEPARIN-INDUCED THROMBOCYTOPENIA

HIT, also known as the *white clot syndrome*, is a relatively common, often underrecognized, potentially devastating immune-mediated complication of pharmacologic heparin administration ([525] , [526] and [527]). HITT constitutes the major life and limb-threatening complication of HIT ([525]). The facts that thrombocytopenia is most commonly associated with a bleeding tendency and that heparin is most commonly used to prevent and treat pathologic thrombosis lend to the mystery and underappreciation of HIT(T). The prompt consideration of HIT(T) in patients who develop thrombocytopenia during heparin therapy, with or without new or propagating venous and arterial thromboses, is the cornerstone to appropriate HIT(T) diagnosis. Immediate discontinuation of all forms and routes of heparin exposure constitutes the essential component of HIT(T) treatment. The pathologic basis of HIT(T) is production of antibodies to the heparin–platelet factor-4 complex; subsequently, immune complexes consisting of IgG–heparin–platelet factor-4 bind to platelet Fc receptors, resulting in intense platelet activation, formation of platelet microparticles, thrombocytopenia, and a profound hypercoagulable state ([528]).

HIT usually develops between 5 and 14 days after the commencement of heparin therapy and produces a variable but often profound degree of thrombocytopenia ([529] , [530]). A platelet count fall that begins before day 5 of heparin is not likely to represent HIT except in patients with a recent (within 3 months) heparin exposure ([525]). These patients may experience an abrupt onset of thrombocytopenia on reexposure to heparin as a result of acute platelet activation due to preformed, circulating HIT-associated antibodies.

Although the exact incidence of HIT has not been well established, HIT has been noted to develop in up to 3 to 5% of patients exposed to unfractionated porcine intestine–derived heparin ([389]). Thirty-six to fifty percent of patients with HIT have been noted to develop life- or limb-threatening thromboses ([389]). The thrombotic tendency associated with HIT can last for at least 30 days, and HITT can develop well after the discontinuation of heparin and platelet count recovery. The fact that the thrombocytopenia seen in HIT usually resolves within 3 to 7 days of heparin withdrawal is a useful aid to making the diagnosis of HIT.

Patients exposed to bovine lung–derived UFH have been reported to have a greater likelihood of developing HIT than those exposed to porcine intestine–derived UFH ([531]). HIT(T) appears to occur infrequently, though, as a result of primary LMWH therapy in heparin-naïve individuals ([525]). Warkentin et al. evaluated the incidence of HIT(T) in 665 patients randomized to receive subcutaneous UFH or LMWH for venous thromboprophylaxis after elective hip surgery. HIT was diagnosed in 2.7% (9/332) of patients given UFH versus 0% (0/333) of those given LMWH. HITT developed in 88.9% (8/9) of the patients who developed HIT compared with a thrombosis rate of 17.8% (117/656) in patients without HIT. This study substantiated previous reports of discordance between HIT-IgG formation and the development of clinical HIT. HIT-IgG was detected in 7.8% and 2.2% of patients treated with UFH and LMWH, respectively. These rates of “seroconversion” are considerably higher than the documented HIT rates of 2.7% and 0%, respectively. Such seroconversion has been documented in up to 17% of heparin-treated patients and 8% of LMWH-treated patients ([532]). The difference in seroconversion rate may stem from the fact that LMWHs appear to less readily complex with platelet factor-4 than UFH and, thus, generate less of an immune response.

Thrombosis is the major complication of HIT. Venous thrombosis is more common than arterial thrombosis in HIT patients, especially in those who receive heparin for postoperative DVT prevention ([530] , [533]). Extremity deep vein thrombosis is the most frequently encountered venous thrombotic complication in HIT patients, followed in frequency by PE and cerebral sinus thrombosis ([526]). Most HIT-associated arterial thromboses involve the extremities, but stroke, MI, and renal artery thrombosis related to heparin infusions have been described ([534]). HITT after coronary artery bypass grafting may present as bypass-graft occlusion, left atrial thrombus formation, valvular thrombosis, or PE ([534]). Acute graft occlusion secondary to HIT has been described in vascular surgery patients even after platelet count normalization. It is reasonable to assume that patients with preexisting vascular lesions, intravascular catheters, sepsis, and postoperative venous stasis are particularly susceptible to the thrombotic complications of HIT. Thus, cardiac and orthopedic patients have the highest incidence of HIT.

Other clinical presentations of HIT include heparin-induced skin lesions, heparin “resistance,” and adrenal vein thrombosis leading to hemorrhagic infarction ([535] , [536]). Heparin-induced skin lesions have been observed in approximately 10 to 20% of patients who generate HIT-IgG in response to subcutaneous UFH injections. The skin lesions develop at heparin injection sites and can range from painful, red plaques to overt skin necrosis reminiscent of warfarin-induced skin necrosis. Thrombocytopenia may not develop in the majority of patients with heparin-induced skin lesions, but those who develop skin lesions and thrombocytopenia appear to be at extremely high risk for arterial thrombosis. The thrombocytopenia that develops in HIT is not normally associated with hemorrhagic events, and platelet transfusion may exacerbate the HIT-induced prothrombotic tendency ([527]).

HIT and HITT are primarily clinical diagnoses. HIT(T) should be strongly suspected in any patient who develops thrombocytopenia while receiving heparin in any dose or route of administration. Whereas HIT(T) is usually associated with a platelet count below the lower limits of normal (150,000/μl in most laboratories), the degree of thrombocytopenia is quite variable and may be profound ([525]). The diagnosis should be strongly considered in any patient in whom the platelet count falls below 50% of the baseline value (even if still within the normal range) after the fifth day of heparin treatment. A 30% fall in baseline platelet count combined with any form of thrombosis in a patient receiving heparin should be considered HITT until proven otherwise. Thrombotic events occurring or progressing during therapeutic intensity heparin therapy, even if the platelet count is normal, may constitute a HITT variant ([537] , [538] and [539]). The identification of any platelet-rich “white clot” during surgical thrombectomy or extracorporeal blood circulation should alert health care personnel to the possible existence of HITT.

The currently available *in vitro* diagnostic assays for HIT are either functional assays or immunoassays ([540]). Functional assays detect normal platelet aggregation or platelet activation after exposure to suspected HIT serum and heparin. Functional assays include the platelet aggregation test, the heparin-induced platelet aggregation test, heparin-induced platelet release of adenosine triphosphate detected by lumi-aggregometry, the ^{14}C-serotonin release assay (^{14}C-SRA), heparin-induced platelet microparticle formation detected by flow cytometry, and enzyme immunoassay detection of platelet serotonin release. Immunoassays detect the presence of heparin–platelet factor-4 antibodies using ELISA methodology ([541]).

Traditionally, the ^{14}C-SRA has been considered the “gold standard” for HIT diagnostic confirmation. However, most studies evaluating the diagnostic use of the available functional assays and immunoassays, including studies of ^{14}C-SRA, used a clinical diagnosis of HIT as the true “gold standard.” Additionally, the SRA is tedious to perform, has lengthy turn-around times, and is offered by few laboratories. Therefore, HIT diagnostic assays should be reserved for HIT confirmation and possibly for anticoagulant cross-reactivity testing. In some instances, a HIT test may be used to confirm the absence of circulating functional HIT-IgG before repeat heparin exposure in patients with a questionable past diagnosis of HIT, or if alternate antithrombotic agent use is deemed undesirable. It is our belief that a stereotypical clinical presentation suggestive of HIT should be treated as HIT even in the presence of normal heparin-induced platelet aggregation, ^{14}C-SRA, or ELISA testing. Because of the inherent delay in receiving the results of HIT diagnostic assays and limited availability of such testing at many facilities, HIT management with a DTI (see section Direct Thrombin Inhibitors above) should begin at the earliest clinical recognition of the syndrome.

Warfarin anticoagulation may be desired for long-term therapy but should never be used as the sole alternative anticoagulant in patients with HIT(T). Warfarin has the disadvantage of requiring at least 5 days to achieve full therapeutic effect and has been associated with venous limb gangrene when used alone. Warfarin treatment is the major factor contributing to limb amputation caused by progression of otherwise unremarkable deep vein thromboses to phlegmasia cerulea dolens in patients with HIT ([542] , [543]). The combination of HIT-associated hypercoagulability and warfarin-induced protein C deficiency most likely produces a profound procoagulant state that causes venous limb gangrene. The existence of this syndrome justifies the absolute need for systemic anticoagulation with lepirudin, argatroban, or danaparoid during the initiation of warfarin anticoagulation in patients with HIT(T).

Considering the complexity of HIT diagnosis and treatment, HIT prevention must be emphasized. Patients receiving heparin should have platelet count monitoring at baseline and at least every third day between day 5 and day 14 of heparin exposure. Early oral warfarin anticoagulation initiation in patients receiving heparin therapy for an acute thrombosis or atrial fibrillation should allow the duration of heparin exposure to be kept to a minimum and, hopefully, under 5 days. Appropriate medical record documentation and patient education should help avert heparin reexposure in patients with a history of HIT(T). Reexposure to heparin in patients with past HIT(T) should be delayed at least 3 months, kept to a minimum duration to provide succinct anamnesis, and avoided whenever possible. LMWH may be preferable to UFH for both the treatment and prevention of thromboembolic disease because of the greatly reduced likelihood of instigating HIT(T) ([544]).
