PAS reacts primarily with glycogen. ALL lymphoblasts often have prominent PAS staining in the form of coarse granules or blocks (Fig. 77.3A). Myeloblasts may also be positive, so the stain is of limited utility in diagnosis of acute leukemia. Maturing neutrophils are diffusely PAS positive. Monocytic precursors may show prominent granular PAS staining. Erythroid precursors are normally PAS negative. A coarsely granular staining pattern may be seen in pronormoblasts and basophilic normoblasts in myelodysplastic syndrome (MDS)-related AML (Fig. 77.8B). Diffuse PAS staining may be present in later stage erythroid precursors in MDS and MDS-related AML. Megakaryoblasts may show some PAS staining.

Other enzyme stains, such as acid phosphatase, are not useful in diagnosis of acute leukemia.

Electron Microscopy

Ultrastructural studies have contributed substantially to the understanding of the cellular morphology of the acute leukemias ([13], [21], [22] and [23]) but have been supplanted by immunophenotyping and genetic studies for clinical diagnosis and characterization of patient material.

Immunophenotyping

Immunophenotyping greatly facilitates diagnosis of the acute leukemias ([24], [25], [26], [27], [28], [29], [30] and [31]). The antibodies used recognize surface and cytoplasmic antigens expressed by human hematopoietic cells and their leukemic counterparts (Table 77.1). Most of the antigens are lineage associated, rather than lineage specific, but expression of groups of antigens is accurate in assignment of lineage. In difficult cases, a limited number of cytoplasmic antigens are currently considered lineage specific [cytoplasmic CD22 (cCD22) or cCD79a for B differentiation, cCD3 for T, cCD41 or cCD61 for megakaryoblastic, and cMPO for myeloid]. With immunophenotyping, morphology, and cytochemical tests, the lineage of differentiation (ALL or AML) can be reproducibly identified in more than 95% of acute leukemias, and ALL can be further subclassified based on T versus B precursor differentiation ([32], [33], [34], [35], [36] and [37]).

TABLE 77.1. Immunologic Markers Commonly Used in Classification of Acute Leukemia

Lineage	Antigen
B cell	CD19, CD20, CD22, CD79a, cCD22*, cCD79a*
T cell	CD1, CD2, CD3, CD4, CD5, CD7, CD8, cCD3*
Lymphoid	TdT
Myeloid	CD13, CD33, CD11b, CD15, CD4(CD2 $^-$), CD117, cMPO*
Monocytic	CD14, CD11b
Erythroid	Glycophorin A
Megakaryocytic	CD41, CD61, cCD41*, cCD61*
Lineage-independent antigens	
HLA class II	HLA-DR
Leukocyte common antigen	CD45
Stem cell antigen	CD34
Common acute lymphoblastic leukemia antigen	CD10

NOTE: Antigens marked with an asterisk are currently considered lineage specific.

Immunophenotyping is usually performed by flow cytometry and interpreted in the context of panels of antibodies (Table 77.1) ([38], [39]). Paraffin immunohistochemistry on tissue sections can partially substitute for flow cytometry if a cell suspension is not available (i.e., dry tap and extramedullary sites), but the panel of available antibodies is limited and interpretation is more difficult ([40], [41]).

The immunophenotypic characteristics of leukemic cells are generally not unique to leukemia but reflect normal differentiation stages of cells sometimes with asynchronous antigen expression ([32], [42], [43], [44] and [45]). A discussion of lymphoid differentiation appears in Chapter 18, Chapter 19 and Chapter 20 and myeloid differentiation in Chapter 13. This discussion considers only use of myeloid and lymphoid differentiation antigens that are pertinent to the classification of acute

leukemias.

B-CELL MARKERS The B-cell antigen receptor complex consists of an antigen-recognition structure [membrane immunoglobulin (Ig)] and two associated proteins, Ig-a and Ig-ß. In addition to the antigen receptor complex, B cells express a variety of other cell-surface proteins useful for diagnostic purposes. Some of these molecules function as receptors for signals that trigger B-cell maturation and activation; others, such as CD10 (common ALL antigen, a neutral endopeptidase), have cell-surface enzymatic activity ([46]). Antigens are expressed in an orderly sequence that reflects maturation ([47]). The earliest B precursor expresses nuclear terminal deoxynucleotidyl transferase (TdT) and class II HLA-DR antigens (neither lineage specific). CD19 and cytoplasmic CD22 appear early and are expressed in virtually all cases of B-precursor ALL. The same is true for CD79a (mb-1), the Ig-a portion of the B-cell antigen complex ([48]). Other antigens less useful for recognition of B-precursor blasts in ALL are CD20, cytoplasmic Ig (cIg), and surface Ig (sIg). Expression of TdT coincides with Ig heavy chain gene rearrangement. Expression of CD10 and CD19 precede rearrangement of Ig light chain. Precursors that are CD10, CD19, CD34, and TdT positive are designated early pre-B; their normal counterpart constitutes less than 1% of nucleated marrow cells. This phenotype accounts for approximately two-thirds of B-precursor ALL ([49]). The next stage, pre-B, has CD20 expression, cIg, and absence of sIg ([50]). Rearrangement of ? light chain follows, then ? ([51] , [52] , [53] and [54]). Light chain gene rearrangement, in contrast to the heavy chain, is more lineage restricted, but light chain rearrangement has been reported in some cases of T-lymphoblastic disease ([55] , [56]). A transitional stage may follow in which the lymphoblasts express cIg and sIg without ? or ? light chains ([57]). The last acute leukemic stage, the B-cell stage, has surface Ig, has often lost CD10, and is typically TdT negative; this stage corresponds to a leukemic phase of Burkitt lymphoma and is a counterpart of a germinal center cell rather than a marrow cell ([58] , [59] and [60]). The frequency of B-cell–specific or B-cell–associated antigen expression in ALL is summarized in Table 77.2 ([34]).

TABLE 77.2. Relative Frequency of B-Lymphoblastic Antigen Expression in Precursor B Acute Lymphoblastic Leukemia

Antigen	Cases Positive (%)
Ia/HLA-DR	99.8
CD19	98
CD24	97
CD10 (common acute lymphoblastic leukemia antigen)	92
CD9	90
CD22	74
CD34	64
CD20	36
CD21	4

Adapted from Borowitz MJ. Immunological markers in childhood acute lymphoblastic leukemia. Hematol Oncol Clin North Am 1990;4:743–765.

Hematogones are early B-lineage cells that comprise up to 5% of nucleated cells in normal marrow. Their number may increase in adults or children after chemotherapy, stem cell transplantation, or with cytopenias of multiple causes ([58] , [59]). Their immunophenotype (TdT, CD19, CD10, CD34 positive) is similar to B-precursor ALL ([60]).

T-CELL MARKERS T cells are recognized with monoclonal antibodies and by rearrangement of the T-cell receptor (TCR) genes ([61] , [62] and [63]). TCR genes rearrange during T-cell differentiation to form a functional antigen with immunologic diversity. Two types of heterodimeric TCR are expressed on peripheral blood T cells. Receptors composed of a and ß subunits are expressed on most T cells, those composed of ? and d subunits on a small fraction ([64]). Both types of TCR are noncovalently associated with CD3, a complex of proteins involved in signal transduction. Rearrangement of the TCR-d gene is followed by relatively synchronous rearrangement of the ? and ß genes, followed by a gene rearrangement. The TCR-d gene is usually modified in T-precursor ALL, but the ?, ß, and a genes may remain in germ-line configuration ([65] , [66] and [67]). The TCR genes may also be rearranged in B-lineage ALL ([62] , [67] , [68] , [69] and [70]) and AML ([71]). Thymic stem cells are thought to arise from precursors in the marrow ([45]). The putative thymic precursor expresses nuclear TdT and membrane CD7. Some myeloid cells, but none of B-cell lineage, also express CD7 ([72]). Prethymocytes also express cytoplasmic CD3 ([73]). Rearrangement of the TCR-ß gene follows expression of CD7 ([74]). CD2, CD5, and CD7 antigens are expressed early and persist through T-cell development. CD2 is the sheep erythrocyte rosette receptor. CD4 and CD8 are expressed as T cells mature in the thymus, and CD3 is present on the cell surface in more differentiated cells. CD2 and CD7 are expressed in 5 to 30% of AML ([75] , [76]). Most cases of T-ALL are HLA-DR negative, whereas most AML cases, except APL, are HLA-DR positive.

MYELOID LINEAGE Many surface antigens expressed by myeloid cells have been identified, some of which are listed in Table 77.1. Several antigens are expressed by both neutrophils and monocytes, whereas others are expressed by monocytes alone. Red cell precursors and platelets, as well as monocytes, express CD36. Other red cell and megakaryocyte antigens include glycophorin A and CD41 and CD61, respectively. CD33 is expressed on normal myeloblasts, promyelocytes, myelocytes, and monocytes as well as on approximately 80 to 90% of AML blasts ([25] , [77]). CD13 shows a similar distribution to CD33 in normal cells and is present in approximately 70 to 80% of AML. Monoclonal antibodies to CD11b, CD14, and CD36 react primarily with monocytic variants. CD11b is expressed in 5 to 10% of ALL, but CD14 is present in less than 1%. HLA-DR is expressed by 80% of AML; of the approximately 20% that are negative, most are APL. CD4 positivity in the absence of CD2 staining is a useful marker of myeloid lineage seen in 65% of AMLs ([78]). CD15 is more associated with differentiated leukemias. Glycophorin A is expressed in erythroblasts but not until the colony-forming unit erythrocyte stage. CD41 (platelet glycoprotein IIb/IIIa) and CD61 (platelet glycoprotein IIIa) are present on megakaryoblasts ([79]). APL usually lacks CD34 and HLA-DR. CD2 is expressed in microgranular APL ([80]). CD56, the neural cell adhesion molecule, is an antigen expressed on natural killer cells and a subset of T cells often with cytolytic features. CD56 has been detected in 13 to 41% of AMLs ([81] , [82] and [83]). CD56 expression is associated with monocytic differentiation, t(8;21), and trisomy 8 ([81]). Correlation with extramedullary location has been reported by some ([83]) but not by others ([81]). CD56 expression has been noted in a subset (approximately 5%) of AML with cytologic features of M3v ([84]). These myeloid/natural killer cell leukemias are HLA-DR and CD34 negative, CD33, CD13, CD56, and CD11a positive, and CD16 negative. Analysis for t(15;17) and PML/RARa has been negative in some cases ([84]) and positive in others ([85]).

LINEAGE-INDEPENDENT MARKERS CD10 (common ALL antigen) is present on B-precursor (>90%) and T-precursor ALL (10 to 40%), AML (1 to 5%), and mature neutrophils ([36] , [47]). CD34 is a marker of primitive progenitor cells; it is seen in 40 to 60% of AML and 70 to 80% of B-precursor ALL ([86] , [87]). HLA-DR is present on B cells, monocytes, and activated T cells; most acute leukemias are HLA-DR positive with the exception of T-ALL and APL. CD45, leukocyte common antigen, is present on all hematopoietic cells except erythrocytes and platelets ([88]); most leukemic blasts express CD45, but it is absent in some cases ([89]).

Aberrant Antigen Expression in Acute Leukemia

Myeloid antigen expression (e.g., CD13, CD33, CD14, and CD15) is seen in 5 to 40% of adult and childhood ALL ([28] , [90] , [91] , [92] , [93] and [94]), higher in adults in most series. Some of the most commonly expressed myeloid-associated antigens are CD13 (6 to 16%) and CD33 (3 to 10%). In most ALL series, myeloid antigen expression has no significant independent effect on outcome ([94]). CD15-positive B-precursor ALL associates with 11q23/MLL rearrangements; other myeloid antigen–positive ALLs associate with t(9;22) ([90] , [95]). CD4 is normally present on monocytes.

Lymphoid antigen expression is seen in 20 to 30% of AML. The most commonly expressed lymphoid-associated antigens are TdT (5 to 15%), CD7 (11 to 28%), CD2 (5 to 21%), and CD19 (3 to 14%). Others include surface CD3 (1%), CD10 (1 to 5%), and CD20 (6%) ([25] , [77] , [79] , [96] , [97]). Lymphoid antigen expression in AML correlates with neither TdT positivity nor presence of gene rearrangements ([96] , [97]). AML with t(8;21) frequently expresses CD19 and CD56, and CD2 expression is frequent in the microgranular variant of APL ([96]). AML with lymphoid antigen expression or lymphoid gene rearrangement more often has t(9;22) or 11q23 rearrangements ([98]). Lymphoid antigen expression in AML has no consistent prognostic significance beyond karyotypic associations ([25] , [96] , [99]).

Enzyme Markers

The DNA polymerase TdT participates in rearrangement of Ig genes by inserting nucleotides at recombination junctions ([100]). It can be detected in individual cells by immunofluorescence or immunohistochemistry. TdT exists in high concentration in normal cortical thymocytes and in a small percentage of normal bone marrow cells, but not in blood lymphocytes. Expression is common in ALL, especially in blasts that are CD10 positive or of early B- or T-cell origin ([101] , [102]). Enzyme activity is usually absent in B/Burkitt ALL ([103]). TdT-negative ALL has been described in a small group of patients with high tumor burden and a poor response to therapy ([104] ,

[105]). In a small percentage of AML, blasts are TdT positive ([106], [107] and [108]).

Genetic Abnormalities

The known genetic abnormalities in the acute leukemias are discussed in detail in the preceding chapter. Presumably, genetic alterations are present and causative in all acute leukemias. The known abnormalities have led to an understanding of at least some of the events that transform precursor stem cells into acute leukemia, are now used in subclassification of the acute leukemias, and are increasingly the targets of directed therapy aimed at specific molecular genetic abnormalities in subsets of leukemia. This trend will continue and expand for the foreseeable future. It is imperative that new cases of acute leukemia receive thorough cytogenetic and directed molecular genetic evaluation to obtain sufficient information for accurate classification and appropriate direction of treatment.

FRENCH/AMERICAN/BRITISH PHENOTYPIC DESCRIPTIONS

The acute leukemias mimic substantially the differentiation tree of hematopoietic/lymphoid cells. This capacity formed the basis for a morphologic/cytochemical classification system that evolved over the twentieth century, commencing with the description of myelomonocytic leukemia by Naegli in 1900. In an important effort, in 1976 a group of French, American, and British investigators standardized this classification, with several subsequent modifications ([16], [109], [110], [111], [112], [113] and [114]) (Fig. 77.2, Fig. 77.3, Fig. 77.4, Fig. 77.5, Fig. 77.6, Fig. 77.7, Fig. 77.8 and Fig. 77.9). As treatment results for leukemia improved and the underlying genetic basis of leukemic transformation was elaborated in ensuing decades, comparisons with the FAB classification concluded that this historical classification approach had little predictive value for treatment outcome and compared poorly with biologic data. It is therefore of no continuing use as a clinical classification of disease per se, but it remains a useful shorthand descriptor for the varying morphology of acute leukemia and is described below for this purpose.

Acute Lymphoblastic Leukemia

There are three FAB subtypes of blasts in ALL. Two are distinguished on the basis of size, nuclear shape, nucleoli, and amount of cytoplasm (Fig. 77.2) ([109]). L1 blasts are small with little cytoplasm, a regular nucleus, and small, inconspicuous nucleoli. L2 blasts are larger with irregular nuclear membranes, finer chromatin, one or more distinct nucleoli, and more abundant cytoplasm. L2 blasts are more common in adults (67% of adult cases), and L1 blasts are more common in children (79% of pediatric cases) ([115], [116]). These two subgroups have no current clinical significance beyond recognition by the morphologist as ALL. L2 blasts can be confused with myeloblasts; reliable differentiation requires cytochemical stains and immunophenotyping (Fig. 77.3 and Fig. 77.4) ([24]). The third type, L3 blasts, the leukemic counterpart of Burkitt lymphoma, are large regular cells with round to oval nuclei, fine or slightly coarse nuclear chromatin, prominent nucleoli, and intensely basophilic, often vacuolated, cytoplasm; the vacuoles are lipid and negative with PAS staining. Azurophilic granules are seen in 10% of L1 and L2 ALL ([8], [9] and [10]) (Fig. 77.2D), usually larger than granules in myeloblasts, often with a halo. The granules are negative for MPO, may be faintly PAS positive, are often positive for SE and NSE, and may stain weakly with SBB ([9]).

Acute Myeloid Leukemia

FAB variants of AML are based on cell lineage and degree of differentiation (Fig. 77.4, Fig. 77.5, Fig. 77.6, Fig. 77.7, Fig. 77.8 and Fig. 77.9). Three have granulocytic differentiation and differ from one another in extent of maturation (M0: undifferentiated by light microscopy; M1: poorly differentiated with demonstrable SBB/NSE positivity; M2: more differentiated). M3 (APL) demonstrates dysplastic promyelocytic morphology (M3h: hypergranular promyelocytes with a reddish color shift of granules, Auer rods, and faggot cells; M3v with inapparent or fine granules with light morphology, intense SBB/MPO positivity, and characteristic grooved bilobed nuclei; and M3a, less hypergranular blasts lacking features of M3h of M3v). M4 has both granulocytic and monocytic differentiation, a subtype having dysplastic eosinophils (M4Eo). M5 has monocytic differentiation with NSE positivity, predominantly blasts (M5a) or with differentiation to promonocytes and monocytes (M5b). M6 has myeloblasts with background dysplastic erythroid precursors, or in uncommon cases is comprised of erythroblasts. M7 has megakaryoblastic differentiation with surface blebs, binucleation, a clumping tendency of blasts, and ANA positivity with NaF resistance; it typically also has associated reticulin fibrosis. M0, M1, and M2 account for approximately 50% of AML; M4 for 25%; M3 for 10%; M5a and M5b for 10%; M6 for 5%; and M7 for 3 to 5% ([117], [118]). The exact distribution varies somewhat with age.

DIFFERENTIAL DIAGNOSIS OF ACUTE MYELOID LEUKEMIA AND ACUTE LYMPHOBLASTIC LEUKEMIA

Separation of AML and ALL remains of fundamental importance for treatment of acute leukemia. It is based on a combination of morphology, cytochemistry, and immunophenotyping. With the exception of Auer rods and dysplastic promyelocytes, morphology alone is insufficient for reliable separation of the two entities, even in expert hands. Cytochemistry and immunophenotyping are somewhat redundant for diagnosis of leukemia. When offered on site, immunophenotyping is frequently available before cytochemistry. Immunophenotyping instrumentation is in increasingly widespread use, but rapid immunophenotyping is still not readily available in many areas of the world. Cytochemistry can contribute only negative information for diagnosis of ALL. Nevertheless, cytochemistry still contributes valuable information in some subsets of AML, is still useful for separation of AML and ALL in conjunction with immunophenotyping (or if immunophenotyping is unavailable), and is of great help for recognition of biphenotypic leukemias, in which small subsets of blasts with myeloid differentiation may be overlooked with immunophenotype gating.

WORLD HEALTH ORGANIZATION CLASSIFICATION OF THE ACUTE LEUKEMIAS

In 2001, a group convened by the World Health Organization (WHO) published a new classification of hematopoietic and lymphoid neoplasms, including the acute leukemias ([119]) (Table 77.3). The directive for the classification was that it be up to date, incorporate genetic and immunophenotypic as well as morphologic information, and that it also be usable throughout the world, not just in Western academic medical centers. The AML classification includes four groups: AML with recurrent cytogenetic abnormalities, AML with multilineage dysplasia, therapy-related AML and MDS, and AML not otherwise specified, the latter being a modification of the FAB AML classification. The WHO classification does not group the acute lymphoid leukemias together, but separates them under three broader categories of lymphoid disease: precursor B-cell and precursor T-cell neoplasms, and mature B-cell neoplasms. Additionally, in each case it lumps predominantly leukemic disease with predominantly lymphomatous disease, based on similar biologic and genetic characteristics of disease rather than clinical presentation. Burkitt leukemia (previously L3/B-ALL) is lumped with Burkitt lymphoma and placed biologically correctly under mature B-cell neoplasms. However, because of its similarity to, and differential diagnostic problems with, precursor B-cell and T-cell ALL, Burkitt leukemia/lymphoma is also discussed in this chapter.

TABLE 77.3. Classification of Acute Leukemias

Acute myeloid leukemias
AMLs with recurrent cytogenetic abnormalities
AML with t(8;21)(q22;q22), *(AML1/ETO)*
AML with inv(16)(p13q22) or t(16;16)(p13;q22), *(CBFß/MYH11)*
Acute promyelocytic leukemia (AML with t(15;17)(q22;q12), *(PML/RARa)*
AML with 11q23 *(MLL)* abnormalities
AML with multilineage dysplasia
With prior myelodysplastic syndrome
Without prior myelodysplastic syndrome
AML and myelodysplastic syndrome, therapy related
Alkylating agent related
Topoisomerase II inhibitor related
AML, not otherwise categorized
AML, minimally differentiated
AML without maturation
AML with maturation

Acute promyelocytic leukemia lacking RARa rearrangement
Acute myelomonocytic leukemia
Acute monoblastic and monocytic leukemia
Acute erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Acute lymphoblastic leukemias
Precursor B-lymphoblastic leukemia/lymphoma [a]
Precursor T-lymphoblastic leukemia/lymphoma [a]
Burkitt lymphoma/leukemia [b]
Acute leukemias of ambiguous lineage
Biphenotypic acute leukemia
Undifferentiated acute leukemia

AML, acute myeloid leukemia.

[a] Listed in World Health Organization (WHO) classification under precursor B-cell and T-cell neoplasms.

[b] Listed in WHO classification under mature B-cell neoplasms.

Modified from the World Health Organization Classification of Tumours, Pathology and Genetics: Tumours of Haematopoietic and Lymphoid Tissues.

Acute Myeloid Leukemia

ACUTE MYELOID LEUKEMIA WITH RECURRENT CYTOGENETIC ABNORMALITIES Acute myeloid leukemias with recurrent cytogenetic abnormalities are characterized by recurring balanced translocations and inversions; have an approximately flat incidence throughout life after infancy, with median age in the 30s; lack multilineage background dysplasia; tend to have polyclonal background and remission hematopoiesis; tend to respond favorably to cytotoxic chemotherapy; and are unrelated pathogenetically to MDS ([120], [121] and [122]). They comprise approximately 85% of AML in young patients but only a small percent of cases in the elderly. Four specific groups are recognized in the classification, but others exist in smaller numbers. Each has morphologic correlates, though none are exact. All may be caused in a minor percent of cases by insertional events rather than translocations, and thus be cytogenetically inapparent, requiring fluorescence *in situ* hybridization or reverse transcriptase-polymerase chain reaction analysis for recognition. If these genetic abnormalities are encountered in a patient with symptomatic myeloproliferative disease, this diagnosis should be made regardless of the blast percent in peripheral blood or marrow ([122]).

- AML with t(8;21)(q22;q22);(*AML1/ETO*). Most typically, AML with differentiation (FAB M2 morphology). Blasts typically have prominent secondary granulation, an orange color to the Golgi zone with Wright-Giemsa staining, frequent Auer rods, and in some cases large granules similar to Chédiak-Higashi anomaly. Approximately 10 to 15% of AML.
- AML with inv(16)(p13q22) or t(16;16)(p13;q22);(*CBFb/MYH11*). Typically, AML with myelomonocytic differentiation and dysplastic eosinophils (FAB M4Eo morphology). The dysplastic eosinophils contain large purple granules, and may be positive for SE and PAS (normal eosinophils are negative). Other morphology is frequent, including lack of dysplastic eosinophils and M2 or M5 morphology. Approximately 6 to 8% of AML.
- APL (AML) with t(15;17)(q22;q12)(*PML/RAR*a) and variants. High correlation with M3h or M3v (approximately 20% of cases) morphology; however, 2 to 3% of cases have M1 or M2 morphology. The uncommon variant translocation t(11;17)(q23;q12) (*PLZF/RAR* a) usually has M3a morphology. Other translocation variants are t(5;17)(q32;q12) and t(11;17)(q13;q12). Approximately 8 to 10% of AML.
- AML with 11q23 (*MLL*) abnormalities. Numerous translocation partners have been identified, the most frequent being t(9;11)(p21;q23);(*MLL/AF9*). Most frequently, AML with FAB M5 morphology, but there is considerable variation from case to case, including M2, M4, and M7 morphology. Approximately 5 to 8% of AML.

ACUTE MYELOID LEUKEMIA WITH MULTILINEAGE DYSPLASIA MDS-type dysplastic features should be present in at least two cell lines ([120]). AML leukemias with multilineage dysplasia are characterized by cytogenetic abnormalities shared with MDS; an exponentially increasing incidence with advancing age (similar to MDS), with median age in the 70s; tend to have multilineage background dysplasia; tend to have clonal background and remission hematopoiesis; respond poorly to cytotoxic chemotherapy, with resistant disease and sensitive background hematopoiesis; and are related pathogenetically to MDS ([121]). Cytogenetic abnormalities include -7/del(7q), -5/del(5q), +8, +9, +11, del(11q), del(12p), -18, +19, del(20q), +21; less frequently, t(2;11), t(1;7), t(3;3)(q21;q26), and inv(3)(q21q26). If these genetic abnormalities are encountered in a patient with AML and absent one of the recurring translocations found in the first category (AML with recurring cytogenetic abnormalities), this diagnosis should be made ([122]). Cases with a history of MDS should also be placed in this category. AML with multilineage dysplasia comprises approximately 15% of AML in young patients, and the vast majority of cases in the elderly. Further subclassification of this category is uncertain at this time, but may be based on specific genetic abnormalities (e.g., -7, +8) and the complexity of abnormalities.

ACUTE MYELOID LEUKEMIA, THERAPY RELATED Some cytotoxic chemotherapy and radiation therapy are leukemogenic. Two patterns of therapy-related leukemia have been identified ([120]).

- Alkylating agent–related AML. Agents that cause interstrand cross-link DNA damage, such as alkylating agents, and radiation cause secondary leukemia morphologically and genetically similar to AML with multilineage dysplasia. Peak incidence is approximately 5 years after exposure. It is often preceded by MDS.
- Topoisomerase II inhibitor–related AML. Inhibitors of topo-isomerase II cause an increased incidence of the recurring translocations seen in the first category (AML with recurring cytogenetic abnormalities). The distribution of translocations varies with the agents used. Epipodophyllotoxins cause predominantly 11q23/MLL–type translocations, and to a lesser extent 21q22/AML1 translocations. Anthracyclines and complex therapeutic regimens are associated with an increased incidence of all translocations found in the first category. Peak incidence is earlier than for alkylating agent–related disease.

ACUTE MYELOID LEUKEMIA NOT OTHERWISE CATEGORIZED AML cases should be placed in one of the first three categories if possible, rather than in four ([120]). If placement in the first three categories is not possible for technological reasons or because of nondefinitive data, the modified FAB-type classification below is retained, with the understanding that treatment decisions will be based on other parameters than this classification, such as patient age.

- AML, minimally differentiated (FAB M0). No myeloid differentiation with Romanovsky morphology and cytochemistry, with differentiation confirmed by immunophenotyping or other means (e.g., electron microscopy).
- AML without maturation (FAB M1). Minimal myeloid differentiation confirmed by morphology and cytochemistry.
- AML with maturation (FAB M2). Maturing myeloid precursors beyond blasts comprise at least 10% of marrow cells.
- APL lacking an RARa translocation. Although not included in the WHO classification, APL occurs lacking an RARa translocation; it usually has M3a morphology, and has treatment response and course similar to other non-t(15;17) AML. It does not respond to all- *trans*-retinoic acid therapy.
- Acute myelomonocytic leukemia (FAB M4). Mixed myeloid and monocytic differentiation in blasts demonstrated by morphology, cytochemistry, and immunophenotyping.
- Acute monoblastic leukemia (FAB M5a and M5b). Monoblastic differentiation predominates (>80% of myeloid cells), demonstrated by morphology, cytochemistry, and immunophenotyping, with minimal further differentiation (M5a) or differentiation to promonocytes and monocytes (M5b).
- Acute erythroid leukemia.
  - Erythroleukemia (erythroid/myeloid). Myeloblastic leukemia with a major background component of maturing erythroid precursors.
  - Pure erythroid leukemia. Neoplastic proliferation of erythroid precursors with no myeloblastic component.
- Acute megakaryoblastic leukemia (FAB M7). Megakaryoblasts are characterized by surface blebs resembling budding platelets, a tendency to clump together, binucleation, ANA positivity partially resistant to NaF inhibition, and cytoplasmic immunopositivity for CD41 or CD61. Factor VIII expression is insensitive for diagnosis. Often associated with reticulin fibrosis of marrow. A variant in infants has t(1;22)(p13;q13) and presents with abdominal organomegaly.
- AML/transient myeloproliferative disorder (TMD) in Down syndrome (DS) variant of acute megakaryoblastic leukemia. DS patients have a striking increased

incidence of AML younger than the age of 3 years; most is acute megakaryoblastic leukemia, but has an excellent prognosis with appropriate therapy. A similar but spontaneously remitting process (TMD) also occurs in DS, especially in the neonatal period. A substantial percent of patients with TMD later develop acute megakaryoblastic leukemia.
- Acute basophilic leukemia. Rare leukemia with predominant basophilic differentiation.
- Acute panmyelosis with myelofibrosis (acute myelofibrosis). Rare disorder characterized by rapidly progressive marrow fibrosis.
- Myeloid sarcoma. A tumor mass of myeloblasts may occur in association with other subtypes of AML, but rarely an isolated tumor mass is the first presenting manifestation of AML, with no discernible marrow disease.

COMMENTS ABOUT ACUTE MYELOID LEUKEMIA CLASSIFICATION The first three categories in the preceding AML classification are ultimately based on pathogenesis of disease ([121]). The fourth category is morphologic and descriptive. Thus, the classification is inconsistent in its premises. Several factors were important in dictating this inconsistency. If the second category, AML with multilineage dysplasia, is viewed as a surrogate for MDS-related disease, then most cases of AML appear to fall into the first two categories. However, there is no way currently to definitively assign all cases in these two categories. Because of this, it is also possible that there are other pathogenetic categories, as yet undescribed, encompassing small numbers of patients. Finally, the classification is intended for worldwide use, yet requisite technology for recognition of these categories of disease is not universally available. Therefore, the fourth category was necessary. If possible, given technological limitations, cases should be assigned in the first three categories, with fallback to the fourth group only if this is not possible.
Differential Diagnosis of Myelodysplastic Syndrome versus Acute Myeloid Leukemia with Multilineage Dysplasia Traditionally, a 30% blast threshold in marrow has been used to separate AML and MDS. The proposal by the WHO working group to lower this threshold to 20% has stirred controversy. Rather than using variation of blast percent around a threshold, diagnosis of AML is better reserved for disease characterized by blast proliferation and tumor burden (AML), as opposed to ineffective hematopoiesis (MDS). Cases of MDS-related disease with blasts in the 20 to 35% range may behave as either AML or MDS clinically, and comparison to a fixed threshold cannot reliably discriminate between the two possibilities. When possible, it is advisable to delay definitive therapeutic intervention for several weeks in such cases and repeat a marrow examination to document the rate of rise of the blast percent. If the rise is gradual, persistent MDS is the better diagnosis; if rapid, AML should be the diagnosis ([123]) (Fig. 77.10).

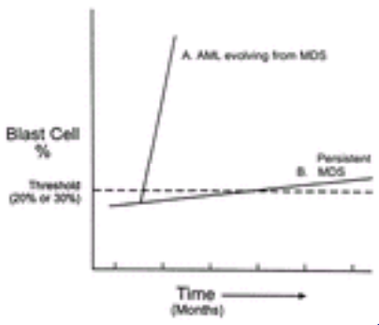

Figure 77.10. In myelodysplastic syndrome (MDS)-related disease with a marrow blast percent from 20 to 35%, diagnosis of acute myeloid leukemia (AML) is best done with serial marrow examination. AML should show a rapid rise in blast percent, whereas persistent MDS has a stable blast percent or a slow rise. (Adapted from Head DR. Proposed changes in the definitions of acute myeloid leukemia and myelodysplastic syndrome: are they helpful? Curr Opin Oncol 2002;14:19–23.)

FLT-3 To transform blasts to grow *in vivo* as acute leukemia appears to require at least two genetic events, one to block differentiation and a second to drive proliferation. As discussed in the preceding chapter, the genetic defects in AML with recurrent cytogenetic abnormalities all appear to block differentiation. Flt-3 is a member of the platelet-derived growth factor family of membrane receptors with cytoplasmic tyrosine kinase domains. Internal tandem duplications and point mutations that lead to constitutive activation of flt-3 are found in a percent of most subtypes of AML with recurrent cytogenetic abnormalities, as well as in some cases of AML with multilineage dysplasia, and appear to drive blast proliferation. Flt-3 is thus an example of an additional set of mutations that appear to cooperate in leukemia pathogenesis with genetic errors that block differentiation. Specific inhibitors of flt-3 activity are under development. Their clinical use will require identification and reporting of such defects. There is no provision as yet to incorporate this information as part of the WHO classification, but when available such information should become part of the complete descriptive pathologic report of a case.

Acute Lymphoblastic Leukemia

PRECURSOR B-LYMPHOBLASTIC LEUKEMIA/LYMPHOMA Precursor B-lymphoblastic leukemias and lymphomas have demonstrable B-lineage differentiation in blasts by immunophenotyping ([124]). The most commonly used antibodies are for CD19, CD20, CD22, and CD79a. In difficult or ambiguous cases, cCD22 and cCD79a are considered lineage specific for B differentiation. They are also usually positive for CD10, HLA-DR, and TdT, and may be positive for CD34. They may have FAB L1, L2, or mixed blast morphology. The leukemias and lymphomas presumably differ in homing mechanisms for marrow versus lymph nodes, but share immunophenotype, genetic abnormalities, and response to therapy. They may be further subclassified by genetics into good risk [t(12;21)(p13;q22), hyperdiploidy >50], poor risk [t(9;22)(q34;q11.2), and average risk] groups.
PRECURSOR T-LYMPHOBLASTIC LEUKEMIA/LYMPHOMA Precursor T-lymphoblastic leukemias and lymphomas have demonstrable T-lineage differentiation in blasts by immunophenotyping ([125]). The most commonly used antibodies are for CD2, CD3, CD5, and CD7. In difficult or ambiguous cases, cCD3 is considered lineage specific for T differentiation. They are usually positive for TdT, negative for HLA-DR, and may express CD34. They may have FAB L1, L2, or mixed blast morphology. The leukemias and lymphomas presumably differ in homing mechanisms for marrow versus lymph nodes, but share overlapping immunophenotypes, genetic abnormalities, and response to therapy. A large number of recurring translocations have been described, but currently are not used for subclassification of cases for treatment purposes.
BURKITT LYMPHOMA/LEUKEMIA Burkitt lymphomas and leukemias are not technically precursor lymphoid neoplasms, but rather are derived from follicular center cells (small noncleaved lymphocytes). In the WHO classification, they are classified as mature B-cell neoplasms ([126]). However, because of similarities to, and differential diagnostic problems with, precursor B- and T-lymphoblastic disease, they are included here. Blasts have FAB L3 morphology, express clonal sIg, and are positive for CD19, CD20, CD22, and HLA-DR. They may express CD10, but are TdT negative. They have dysregulation of MYC by translocation into the promoter region of an Ig gene; most commonly, t(8;14)(q24;q32) (IgH) and less frequently t(2;8)(q11;q24) (? light chain) or t(8;22)(q24;q11) (? light chain). In pediatric disease, the genetics, L3 morphology, and clonal sIg are found together in most cases, but of the three the translocation is the most reliable marker, and morphology second. Clonal sIg is found in a small percent of cases of precursor B-lymphoblastic leukemia/lymphoma, a small percent of Burkitt lymphoma/leukemia is sIg negative, and occasional Burkitt-like cases lack typical FAB L3 morphology.

Acute Leukemia of Ambiguous Lineage

There are two categories of acute leukemia of ambiguous lineage; cases with apparent differentiation to more than one lineage, usually T/myeloid or B/myeloid (biphenotypic acute leukemia), and cases with no discernible further differentiation beyond hematopoietic stem cells using current techniques (undifferentiated acute leukemia) ([127]).

BIPHENOTYPIC ACUTE LEUKEMIA Two morphologic populations of blasts are usually present; large blasts demonstrating differentiation as myeloblasts (SBB and MPO positive, often with Auer rods) and smaller blasts with FAB L1 lymphoblast morphology. The latter may have hand-mirror morphology. The blasts express a mixture of T and myeloid or B and myeloid antigens. Antigen expression may differ or overlap between the two morphologic populations. T/myeloid cases have no specific genotype, although both sets of blasts appear to share the same genotype. B/myeloid cases often have t(9;22)(q34;q11.2) or 11q23 translocations ([128]). Biphenotypic acute leukemia comprises 1 to 2% of acute leukemia cases ([129]).
UNDIFFERENTIATED ACUTE LEUKEMIA Blasts usually have FAB L2 morphology and lack any evidence of lineage differentiation. The incidence of this group is low but varies partially with the sophistication of techniques used to demonstrate lineage differentiation.

SUMMARY

Acute leukemia is a marrow-based neoplasm arising in stem cells and composed predominantly of minimally or partially differentiated hematopoietic/lymphoid precursors. It is broadly classified into myeloid and lymphoid cell types, and currently subdivided using a combination of biologic, genetic, and pathogenetic features. Optimal diagnosis and classification require a variety of sophisticated immunophenotyping, cytogenetic, and molecular biologic techniques, when possible best performed in tertiary referral centers. The WHO classification forms the basis for current classification and treatment. The understanding of the pathogenesis of these diseases will continue to evolve rapidly, will result in further dramatic innovations in treatment targeted to specific genetic aberrations ([130]), and will predictably require further evolution of classification in the coming years.

ACKNOWLEDGMENT

The author wishes to thank M.C. Kenney and I.N. Lukens for photomicrographs used in this chapter.

Acute Lymphoblastic Leukemia in Adults

Acute lymphoblastic leukemia (ALL) is a neoplastic disorder that is rapidly fatal if untreated. In children, ALL is the most common leukemia, and considerable advances have resulted in most being cured of their disease. Similar progress in the treatment of ALL in adults has lagged behind. However, recent progress in understanding the molecular basis of the disease has led to improved prognostic stratification and may result in more rational, risk-adapted therapeutic approaches as well as the development of novel therapies.

The clinical onset of ALL is rarely insidious, and presenting signs and symptoms reflect bone marrow as well as extramedullary involvement by leukemia. Examination of the peripheral blood smear is often sufficient to establish the diagnosis of ALL, but additional clinical and laboratory tests are essential for formulating a treatment plan and provide important prognostic information. Current therapy for adults involves a scheduled sequence that starts with remission induction chemotherapy, followed by one or more cycles of intensification, prophylaxis of the central nervous system (CNS), and prolonged maintenance lasting 2 to 3 years. With this multiagent, multicycle approach, between 25 and 40% of adults with ALL are cured of their disease. Modifications to this general scheme, based on an appreciation of the high risk for disease relapse, have improved outcome for adult ALL patients who have the mature B-cell phenotype as well as those with the Philadelphia (Ph) chromosome. Age remains a significant limitation to treatment intensity as one-third of adults with ALL are over the age of 60 years.

Most adult patients with ALL experience relapse of their disease. Successful treatment options for relapsed or refractory ALL are few.

HISTORICAL BACKGROUND

Only a few decades ago, ALL was an incurable disease in all but a small minority of patients. Progress in the treatment of pediatric ALL has been substantial. This is clearly illustrated in the results reported from a series of successive clinical protocols from St. Jude Children's Research Hospital ([1], [2]). Sequential treatment modifications in successive cohorts of children show a steady improvement in survival outcome as shown in Figure 78.1A. The initial clinical trials from 1962 to 1969 introduced multiagent chemotherapy regimens into pediatric ALL therapy. This proved superior to single agent therapy, but, still, few children experienced long-term survival. The next era, from 1967 to 1979, saw effective prevention of leukemia relapse in sanctuary sites in the CNS through the use of cranial irradiation and intrathecal chemotherapy. Intensification of postremission therapy with administration of non–cross-resistant drugs was responsible for improving survival in subsequent cohorts. With further refinements, as well as general improvement in supportive care, approximately 85% of children with ALL are now cured of the disease.

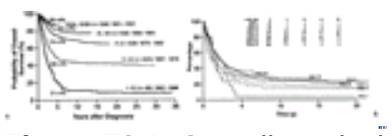

Figure 78.1. Overall survival in successive acute lymphoblastic leukemia patient cohorts. **A:** Childhood acute lymphoblastic leukemia patients treated at the St. Jude Children's Research Hospital ([2]). **B:** Adult acute lymphoblastic leukemia patients treated by the UKALL collaborative study group ([3]).

The success demonstrated in the pediatric ALL trials led to similar approaches in the treatment of adults. As shown in Figure 78.1B, outcomes in consecutive cohorts of adults with ALL treated by a collaborative study group gradually improved as treatment was intensified and extended. Compared with the success in treating childhood ALL, however, the degree of improvement is only modest. The British Medical Research Council initiated the United Kingdom Acute Lymphoblastic Leukemia (UKALL) trials in 1971 ([3]). The first trial, UKALL I, evaluated CNS prophylaxis but only enrolled 16 adults. Subsequent trials examined both the addition of active agents and more sustained intensive postremission therapy, and participation of adult patients progressively expanded. Survival for adults with ALL was still only 20% at the time the UKALL IX trial opened for patient accrual in 1980. It was the first trial in the series to enroll adults separately from children. UKALL IX and the subsequent trial, UKALL XA, saw further, although minor, incremental improvement in the survival rate but provided important systematic analyses of prognostic indicators based on clinical, immunophenotypic, and cytogenetic characteristics. The results from this trial are representative of outcomes expected with current therapy. The complete remission (CR) rate was 88%, disease-free survival at 5 years was 28%, and overall survival at 5 years was 34% ([4]). The current generation study, UKALL XII, opened for accrual in 1993. This study, along with efforts from many other collaborative study groups, will prospectively evaluate what may be the best approach to improving outcome for adults with ALL, tailored postremission therapy adapted individually to each patient on the basis of anticipated relapse risk.

PATHOPHYSIOLOGY

The cause of ALL is essentially unknown, and few clues can be derived from epidemiologic studies. The molecular pathogenesis of ALL is reviewed in Chapter 76. Points relevant to adult ALL concerning these issues are briefly highlighted here.

Epidemiology

The overall age-adjusted incidence of ALL in the United States based on the most recent National Cancer Institute report is 1.4 in 100,000 ([5]). The incidence of ALL in blacks is approximately one-half the incidence rate in whites. There is a slight male predominance with a male to female ratio of 1.3:1.0. The majority of the

approximately 4000 new cases each year in the United States are diagnosed in persons younger than 15 years old with a peak between the ages of 2 and 5 years ([6]). A bimodal age-specific incidence pattern then ensues with a continuously decreasing incidence rate through young adulthood until age 50 when the incidence rate again rises (Fig. 78.2). A second minor peak observed in those over the age of 80 years was less pronounced during the most recent observation period between 1995 and 1999. Geographic differences in the incidence of ALL are reflected by higher rates in North America and Europe and lower rates in African and Asian populations ([7]).

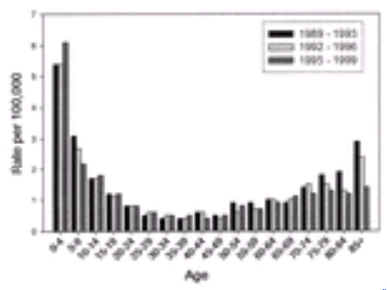

Figure 78.2. Age-specific incidence rates for acute lymphoblastic leukemia by observation period. Data are based on Surveillance, Epidemiology, and End Results Program Cancer Statistics Review. (Data from Ries LAG, Eisner MP, Kosary CL, et al., eds. SEER Cancer Statistics Review, 1973-1999. Bethesda, MD: National Cancer Institute, 2002.)

Etiology

The cause of ALL in adults is largely unknown ([8]). Inherited factors and genetic predisposition syndromes are more relevant to childhood ALL. Survivors of the nuclear fallout from the atomic bombing in Hiroshima and Nagasaki have an overall relative risk of 9.1 for ALL, greater among those exposed in childhood, with the peak incidence occurring 6 to 7 years after radiation exposure ([9]). Somewhat more relevant to adult ALL is the association between occupational exposure to low-dose ionizing radiation among nuclear workers in the United States and Europe and a slightly increased risk for leukemia, although findings were inconsistent across populations ([10] , [11] and [12]).

Among chemical environmental exposure, high level benzene exposure that occurred before contemporary occupational standards is generally accepted as a cause of bone marrow aplasia, chromosome damage, and leukemia ([13] , [14]). Cigarette smoking was linked to a small increase in risk for ALL among persons older than 60 years in one report ([15]). Secondary acute leukemias occurring after exposure to chemotherapeutic agents are usually myeloid, although rare cases of therapy-related ALL have been observed ([16] , [17] and [18]).

Molecular Pathogenesis

Molecular abnormalities can be grouped according to the functional consequence of oncogenic mutation. Acquired constitutive activation of the ABL protein kinase by rearrangement with the *BCR* gene is an example of a mutation that confers a proliferative advantage ([19]). The fusion gene is the consequence of the t(9;22)(q34;q11) balanced chromosomal translocation, which is the most common cytogenetic abnormality in adult ALL. ABL is a nonreceptor tyrosine protein kinase that enzymatically transfers phosphate molecules to substrate proteins, thereby activating downstream signal transduction pathways important in regulating cell growth and proliferation ([20]). Other gene rearrangements result in loss- or gain-of-function mutations involving transcription factors that are important for normal hematopoietic development ([21]). An example is the t(12;21)(p13;q22) chromosomal translocation, which juxtaposes the *TEL* and *AML1* genes ([22]). Excluding numerical aberrations, *TEL- AML1* is the most frequent cytogenetic abnormality in childhood ALL, although it is uncommon in adults. Another general mechanism of cancer formation involves loss or inactivation of tumor-suppressor genes, many of which have key regulatory functions in controlling cell cycle progression ([23]). Examples are p16(*INK4A*) and *p15*(*INK4B*). Stock et al. investigated the incidence of cell cycle regulatory gene abnormalities in adult patients with *de novo* ALL treated by the Cancer and Leukemia Group B (CALGB) study group ([24]). Deletions, microdeletions, and gene rearrangements involving *p16*(*INK4A*) and *p16*(*INK4B*) were common occurrences. Even more frequent was aberrant expression of *Rb* and *p53*, two other tumor–suppressor genes. Concurrent abnormalities involving two or more of these genes were found in one-third of adult ALL patients.

CLINICAL FEATURES

Although the clinical presentation is variable and may develop insidiously, virtually all adults diagnosed with ALL present with symptoms of only a few weeks duration. The symptoms generally reflect bone marrow failure or involvement of extramedullary sites by leukemia (Table 78.1). Up to one-half of patients with ALL have fever or documented infections. One-third have bleeding symptoms at diagnosis, which is less frequent than in patients presenting with acute myeloid leukemia. Severe hemorrhage is uncommon ([25]). Fatigue, lethargy, dizziness, or even dyspnea and cardiac angina may reflect anemia in adults with ALL. Marrow expansion by leukemic blasts may produce bone pain and arthralgias, but marrow necrosis is much less frequently found in adults as compared with children who have ALL ([26]). Approximately one-half of adult patients have hepatomegaly, splenomegaly, or lymphadenopathy at diagnosis that can be appreciated on physical examination. Mediastinal masses are detected by chest radiographs or computed tomography scans primarily in patients with T-lineage ALL, who also frequently have pleural involvement and may complain of chest pain ([27]). The fewer than 10% of ALL patients who have CNS involvement infrequently present with referable symptoms, such as headache, vomiting, neck stiffness, alteration in mental status, and focal neurologic abnormalities. Other sites of extramedullary involvement include testis, retina, and skin, although virtually any organ can be infiltrated by leukemic blast cells.

TABLE 78.1. Clinical Findings at Diagnosis in Adults with Acute Lymphoblastic Leukemia

Findings	Patients (%)
Male	59–63
Symptoms	
Fever/infection	3–56
Bleeding	33
Lymphadenopathy	40–57
Hepatomegaly	24–47
Splenomegaly	31–56
Mediastinal mass	10–15
Central nervous system leukemia	1–7
Other organ involvement	
Pleura	2.9
Pericardium	1.0
Retina	1.0
Skin	0.6
Tonsils	0.6
Testis	0.3

NOTE: Data are based on collaborative trials reported by the CALGB (n = 197; reference [53]); MRC (n = 617; reference [59]); GIMEMA (n = 778; reference [64]); and GMALL (n = 1273; reference [28]).

LABORATORY FEATURES

In addition to a complete medical history and physical examination, patients with ALL should have a battery of diagnostic laboratory tests to confirm the diagnosis, subcategorize the patient's disease for prognostic classification, and plan for appropriate therapy (Table 78.2). These studies include a complete blood count with examination of the peripheral blood smear, electrolyte measurements, creatinine, hepatic enzymes, uric acid, calcium, and albumin. Therapy-related declines in anticoagulation factors, including fibrinogen, occur with L-asparaginase, a drug commonly used in the treatment of ALL, and baseline levels should therefore be obtained. A mediastinal mass may be detected with a chest radiograph. A lumbar puncture for examination of the CSF to assess for leukemic involvement should be performed if patients present with neurologic symptoms. A bone marrow examination is mandatory and should include a complete cytogenetic assessment and immunologic phenotyping. Morphologic, cytogenetic, and immunophenotypic characteristics of ALL are detailed in Chapter 77. This section emphasizes features pertinent to adults diagnosed with the disease.

TABLE 78.2. Diagnostic Approach for Adult Acute Lymphoblastic Leukemia

Medical history
Physical examination
Laboratory studies
Complete blood count, peripheral smear, coagulation studies, fibrinogen level, serum chemistry, ABO and Rh blood group, HLA typing
Chest radiograph or computed tomography
Lumbar puncture
Bone marrow aspiration and biopsy
Cytochemical stains, cytogenetic analysis, immunophenotype analysis, *BCR-ABL* molecular analysis

Routine Laboratory Evaluation

Routine laboratory evaluation reveals that a substantial number of adult patients with ALL have normal or only modestly elevated white blood cell (WBC) counts at the time of diagnosis (Table 78.3). Hyperleukocytosis (>100,000 × 10^6/L) occurs in approximately 15% of patients and may exceed 200,000 × 10^6/L. Some degree of anemia is present in the majority of adults. Approximately one-third of patients have a platelet count less than 25,000 × 10^6/L, which is approximately the same proportion that present with bleeding symptoms. Circulating leukemic blasts may not be evident on examination of the peripheral smear in a significant number of patients. Coagulation parameters are typically normal, and disseminated intravascular coagulation is rarely observed ([28]). Metabolic abnormalities, including hyperuricemia, can occur, especially in patients with rapidly dividing leukemia cells and high tumor burden.

TABLE 78.3. Laboratory Findings at Diagnosis in Adults with Acute Lymphoblastic Leukemia

Laboratory Finding	Patients (%)
White blood cell count (×10^6/L)	
<10,000	41
<30,000	66
50,000–100,000	10–13
>100,000	14–16
>200,000	6
Hemoglobin (g/dl)	
<5	11
<10	55–62
=10	38–45
Platelet (×10^6/L)	
<25,000	30
<50,000	41–55
=50,000	48–59
>150,000	15
Blast cells in peripheral blood	
Present	92
None	8
Blast cells in bone marrow (%)	
<90	28–29
=90	71–72
100	7

NOTE: Data are based on collaborative trials reported by the CALGB (n = 197; reference 53); MRC (n = 617; reference 59); GIMEMA (n = 778; reference 64); and GMALL (n = 1273; reference 28).

Lumbar Puncture

A lumber puncture is often performed at the time of diagnosis to examine the cerebrospinal fluid (CSF). CNS involvement is traditionally defined as greater than 5 WBC/µL of CSF with morphologically unequivocal leukemic blasts on the cytocentrifuged specimen ([29]). Patients at risk for bleeding complications due to thrombocytopenia should be transfused to an adequate platelet count before the procedure. Whether to perform a lumbar puncture in patients with a high circulating blast count is controversial. This is due to concerns of iatrogenic “seeding” of the CNS with leukemic cells. Studies in pediatric ALL have shown that when the procedure is complicated by a traumatic tap, the finding of blast cells in the CSF occurs more frequently in children with higher presenting WBC count ([30]). Among the patients who had traumatic lumbar punctures, those with leukemic blasts in the CSF were more likely to have subsequent CNS relapse.

Bone Marrow Evaluation

All patients with ALL should undergo a bone marrow aspiration and core biopsy procedure. The specimens must be submitted for histologic, cytogenetic, and immunophenotypic analysis. Morphologically, the marrow space is usually densely packed with leukemic blasts, which account for greater than 90% of nucleated cells in most adult ALL patients. As a result, the marrow biopsy sections are generally hypercellular, and, in 7% of adult patients with ALL, the normal marrow is completely replaced by leukemic blasts. This may prevent a successful aspiration, and a touch imprint of the biopsy tissue then becomes useful in evaluating cytologic features.

Although increased reticulin deposits are common, marrow fibrosis is rarely present ([31], [32]).

CYTOGENETICS Historically, poor chromosomal morphology in ALL made banding studies challenging, and karyotypic abnormalities were not reliably detected in early studies ([33]). The implementation of modern metaphase spreading, banding, and molecular cytogenetic techniques now reveals prognostically significant abnormal karyotypes in the majority of adult patients with ALL ([34]). These molecular techniques include fluorescent *in situ* hybridization using chromosome- and gene-specific probes for gene rearrangements that are difficult to identify, such as the t(12;21) chromosomal translocation ([35]). Application of these sensitive methods has revealed, for instance, that the t(12;21) translocation is much less common in adults with ALL than in children ([36], [37]). Other age-related differences include fewer occurrences of numerical chromosome abnormalities and a higher incidence of the Ph chromosome in adults (Table 78.4).

TABLE 78.4. Chromosomal Abnormalities at Diagnosis in Acute Lymphoblastic Leukemia

Chromosomal Abnormalities	Patients (%)	
	Adults	Children
Normal karyotype	16–34	9
Numerical abnormalities		
Hypodiploid	4–9	1
Hyperdiploid (>50 chromosomes)	2–9	25
Structural abnormalities		
t(9;22)	11–30	4
t(4;11)	3–7	6
t(10;14)	4–6	4
t(8;14)	4	2
t(1;19)	3	5
9p abnormality	5–16	7–13
6q abnormality	2–6	4–6
12p abnormality, including t(12;21)	4–5	22

NOTE: Data on adult acute lymphoblastic leukemia are from the Third International Workshop on Chromosomes in Leukemia (n = 329; reference [80]) and from collaborative trials reported by the CALGB (n = 256; reference [55]), MRC (n = 350; reference [82]), and GFCH (n = 443; reference [81]). Data on childhood acute lymphoblastic leukemia and t(8;14) are from reference [2].

Because of the profound prognostic implication of the Ph chromosome, molecular testing for the *BCR-ABL* gene rearrangement should be performed for all patients diagnosed with ALL ([38]). The Ph chromosome was originally identified in a patient with chronic myeloid leukemia, in whom the *BCR* and *ABL* genes juxtaposed within the so-called major breakpoint region ([19]). This transcribes a 7-kb messenger RNA that is expressed as a 210-kd fusion protein, or p210 $^{bcr\text{-}abl}$. In ALL, a variant breakpoint location, which results in the smaller p190 $^{bcr\text{-}abl}$ oncoprotein, is commonly found ([39]). A polymerase chain reaction (PCR)–based laboratory test capable of detecting both the p210 $^{bcr\text{-}abl}$ and p190 $^{bcr\text{-}abl}$ gene transcripts is now readily available to most clinicians.

IMMUNOPHENOTYPE The primary basis of initial treatment strategies for ALL depends on antigenic parameters, and, hence, all patients should have their leukemic blasts characterized by immunophenotypic analysis. By current World Health Organization classifications, approximately 70% of adult ALL cases are precursor B-cell ALL, 25% are precursor T-cell ALL, and 5% are mature B-cell (Burkitt cell) ALL ([40], [41]). Compared with adults, children less often present with T-lineage ALL. There is also a slightly higher incidence of myeloid antigen expression in adult ALL patients, with reported incidences ranging from 15 to 54% compared with 4 to 35% in children ([42], [43]). Commonly detected myeloid antigens include CD13, CD15, and CD33. Rare cases with coexpression of multiple lymphoid and myeloid antigens may be considered acute biphenotypic leukemia according to criteria suggested by a European group ([44]). The clinical course appears to be poor; however, there is no uniform consensus on whether to manage these cases as acute myeloid or lymphoid leukemia ([45]). The Royal Marsden Hospital group identified 25 acute biphenotypic leukemia patients whom they treated over a 7-year period ([46], [47]). The patients variably underwent remission induction with ALL-like regimens, AML-like regimens, or hybrid regimens containing elements of both with equal success, except for an excess of treatment-related mortality with the latter. Overall survival was 39.4% at 2 years. They observed a high incidence of the Ph chromosome (41%), which partially accounted for the unfavorable outcome and emphasized the importance of aggressive risk-adapted therapy for these cases.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ALL in adult patients is rarely difficult. Most commonly, patients are diagnosed after an acute symptomatic presentation. ALL can be distinguished from the lymphocytosis, lymphadenopathy, and hepatosplenomegaly associated with viral infections and lymphoma by finding leukemic blasts in peripheral blood or bone marrow specimens. This is followed by definitive diagnosis with immunophenotypic studies.

Difficulty may arise when patients present with an antecedent or overlapping period of pancytopenia before developing ALL, as has been sporadically reported ([48], [49], [50] and [51]). It may be impossible to distinguish “aleukemic” pancytopenic ALL from aplastic anemia based on examination of the peripheral blood smear. Bone marrow evaluation and vigilant watch of the patient's clinical course are mandatory in these instances.

Patients in lymphoid blast crisis of chronic myeloid leukemia are usually initially diagnosed in the chronic phase. Characterization of the breakpoint region for Ph-positive ALL patients is of no use in distinguishing *de novo* ALL from chronic myeloid leukemia lymphoid blast crisis, as both p190 $^{bcr\text{-}abl}$ and p210 $^{bcr\text{-}abl}$ are found in even distribution in patients with Ph-positive ALL ([52]).

PROGNOSTIC FACTORS

Many clinical and biologic characteristics previously identified as prognostic factors for adult patients with ALL have lost predictive value as therapy has evolved and become more intensive. In contrast, age, WBC count at presentation, and initial response to therapy have remained strong predictors of outcome, as have immunophenotypic and cytogenetic features (Table 78.5). As noted above, the laboratory tests providing this information must be obtained for all patients who are diagnosed with ALL. New tests based on an assessment of the response to therapy, such as detection of minimal residual disease, may add refinement to known prognostic subtypes.

TABLE 78.5. Prognostic Factors for Remission Duration in Adults with Acute Lymphoblastic Leukemia (ALL)

Patient Features	Prognostic Factor
Age (yr)	
<30	Favorable
=30	Unfavorable
White blood cell count (×10^6/ml)	
<30,000	Favorable
=30,000 (>100,000 for T cell)	Unfavorable
Immunophenotype	
T-cell ALL	Favorable

Mature B-cell ALL; early T-cell ALL	Unfavorable
Cytogenetics	
12p abnormality; t(10;14)(q24;q11)	Favorable
Normal; hyperdiploid	Intermediate
t(9;22), t(4;11), t(1;19), hypodiploid, -7, +8	Unfavorable
Response to therapy	
Complete remission within 4 wk	Favorable
Persistent minimal residual disease	Unfavorable

Clinical Features

Advanced age and high WBC count at the time of diagnosis have held up as significant adverse prognostic factors in all modern adult ALL multicenter collaborative trials ([4], [53], [54], [55], [56], [57], [58], [59], [60], [61], [62], [63], [64] and [65]). Both advanced age and high WBC count were each inversely correlated with more frequent occurrences of CR, longer duration of CR, or better overall survival in either the majority or all of the collaborative studies. Advanced age was variably defined as greater than 30 or 35 years. When included in multivariate analysis as a continuous variable, increasing age predicted worse outcome across the entire age range, making it difficult to choose a cut-off separating standard-risk from high-risk patients. The cut-off for high WBC count was either 30,000 × 10^6/L or 50,000 × 10^6/L. In the trial conducted by the CALGB study group, patients with advanced age (30 to 59 years) and high WBC count had an overall survival of 39% and 34%, respectively, compared with 69% and 59% for patients without these adverse prognostic factors ([53]).

Laboratory Features

IMMUNOPHENOTYPE The major immunophenotypic feature with prognostic value and therapeutic importance is the mature B-cell ALL subclassification. Mature B-cell ALL is characterized by expression of surface immunoglobulin, either kappa or lambda, in addition to other markers common to B-lineage ALL, including CD10, CD19, CD20, and CD22 ([44]). These patients respond poorly to standard ALL therapy, and outcome was dismal until brief, dose-intensified treatment programs were established as standard therapy ([66], [67]). The substantial improvement in survival that resulted has negated the adverse prognostic value of this feature if patients are optimally managed. T-cell ALL is another formerly unfavorable prognostic feature that, due to changes in treatment approach, is no longer a poor risk feature ([68]). In fact, with many modern treatment programs, the T-cell immunophenotype has become prognostically favorable ([53], [58], [69]). High WBC count does not adversely affect outcome in T-cell ALL if the greater than 30,000 × 10^6/L cut-off is used; however, a higher threshold (>100,000 × 10^6/L) may still identify patients who will have inferior survival ([56], [57]). Additionally, more detailed examination of prospective immunophenotypic data collected by the CALGB identified a subset characterized by expression of fewer than three T-cell markers that had an unfavorable prognosis ([70]). Leukemic blasts from these patients also infrequently expressed mature T-cell surface markers such as CD1, CD2, CD3, CD4, and CD8, and, hence, would be consistent with the “early” T-cell ALL immunophenotype also reported to be unfavorable by the German study group ([71], [72]). Other immunophenotypic markers have variably been shown to have prognostic value but are less well established. CD34 is expressed more frequently in adults with B-lineage ALL and was reported to adversely affect outcome by the CALGB ([70]). However, CD34 expression overlapped with both a high WBC and the presence of the Ph chromosome, and findings from other smaller series have yielded conflicting results ([73], [74], [75], [76] and [77]). From recent series, expression of myeloid antigen markers was slightly more frequent in B-lineage ALL than in T-lineage ALL but had no prognostic value in either instance ([54], [70], [78]).

CYTOGENETICS Unfavorable cytogenetic abnormalities in adult ALL include t(9;22), t(4;11)(q21;q23), t(1;19)(q23;p13), and a hypodiploid karyotype. Translocations involving chromosomal band 14q11 and abnormalities of the short arm of chromosome 12, including t(12;21), are favorable cytogenetic abnormalities. Results from collaborative studies providing karyotypic data generally indicate disease-free survival rates less than 25% for patients with unfavorable abnormalities, as opposed to greater than 75% for those with favorable cytogenetic findings ([52], [55], [79], [80], [81], [82] and [83]). Additional reports from single institutions have provided similar outcome data ([84], [85]). Cytogenetic findings commonly identified in adult ALL with an intermediate prognosis include normal karyotype, hyperdiploidy, and abnormalities at 6q or 9p. The t(8;14)(q24;q32) and other *MYC* gene rearrangements are associated with the mature B-cell ALL subtype and are not prognostically unfavorable markers with optimal treatment. Adult Ph-positive patients achieve CR rates comparable to Ph-negative ALL patients, but the remissions are short and survival poor with standard therapy. The most frequent translocation in adults involving the *MLL* gene, located at chromosome band 11q23, is t(4;11) and is also associated with poor survival ([83]). The t(1;19) translocation results in the *E2A*- *PBX* gene rearrangement, and patients with this abnormality were found to have a 3-year disease-free survival rate of only 20% ([81]). Patients with hypodiploidy ranging from 30 to 39 chromosomes have a disease-free interval of only 2 to 4 months from the start of treatment ([81]). Deletions and translocations involving 12p include the *TEL*- *AML1* gene rearrangement. *TEL* gene rearrangements are much less frequent in adults than in children but are prognostically favorable in both. Translocations involving the *TCR*-a and -d genes at chromosome 14q11 most frequently result in rearrangement with the *HOX11* gene at 10q24 ([86]). Adult ALL patients with t(10;14)(q24;q11) experience long survival, but this may reflect an association with T-cell ALL subtypes ([55], [81]).

Response to Therapy

Response to therapy can be assessed by determination of time to attainment of CR, quantitation of early leukemic blast clearance, or detection of minimal residual disease. These measurements provide a direct assessment of biologic susceptibility to antileukemic agents, and, as such, prognostic factors based on them have inherently high heuristic power. In addition, prospective evaluation of their utility as predictors of outcome in clinical trials has established that they also have high explanatory power. However, virtually all of the clinical studies measuring these outcomes have been performed in pediatric ALL. Modest variation in results among pediatric studies, likely a reflection of differences in the techniques used to measure treatment response, further limit the adoption of these methodologies for practical patient management in adults. Nonetheless, a survey of current results suggests that such assessments of response to therapy may become crucial prognostic factors. These should aid in refining prognostic models with the goal of improving outcome with risk-adapted therapy.

EARLY COMPLETE REMISSION Failure to achieve CR within 4 weeks of starting treatment or after one course of induction chemotherapy is an unfavorable prognostic factor in most adult ALL studies ([53], [65]). When significant, early CR held predictive value for standard ALL programs as well as for newer, dose-intensified treatment protocols ([4], [57], [69], [87], [88] and [89]). Patients requiring greater than 4 weeks to achieve CR were at least twice as likely to relapse, depending on the study. In one study, patients who did not achieve CR by week 4 of induction had a 5-year disease-free survival of 0% as compared with 46% for the remainder of the complete responders ([69]). In this study, the number of weeks required to achieve CR was only marginally worse than the Ph chromosome as an unfavorable variable.

EARLY LEUKEMIC BLAST CLEARANCE Evaluation for persistence of leukemic blasts at even earlier time points, between days 7 and 21 of induction, has been firmly established as an important prognostic indicator for outcome in pediatric ALL ([90], [91] and [92]). Early persistence of leukemic blasts at 7 days after starting induction is thought to represent corticoste-roid resistance ([93]). In contrast, persistence at time points after 21 days is considered a reflection of cytotoxic chemotherapy resistance. Numerous prospective studies in pediatric ALL have shown that a substantial unfavorable influence on outcome is associated with the morphologic detection of blood or marrow leukemic blasts persisting during induction therapy at day 7, day 21, or at other time points in between. Persistence of leukemia was usually defined as the finding of greater than 1000 × 10^6/L blast cells in a peripheral blood sample or leukemic blasts greater than 5% of normal cells in a marrow specimen. Although pediatric protocols already incorporate early treatment response assessment by a day 7 or day 14 bone marrow examination into risk classification, similar data in adult ALL are only beginning to appear ([94]). Results from the few studies reported thus far agree with findings from the pediatric experience. Sebban et al. prospectively evaluated persistence of marrow blasts, defined as greater than 5% of nucleated cells, at day 15 of induction for influence on outcome ([88]). Among 437 adult ALL patients, one-third were found to have persistent blast cells. These patients were less likely to achieve CR after 4 weeks of therapy. Even among only the patients who achieved CR within 4 weeks, an otherwise favorable feature, those who had persistent blasts at day 15 fared significantly worse. Among all complete remitters, the 5-year disease-free survival was 34% for those who cleared marrow blasts at day 15, compared with 19% for those who did not. Annino et al. and the Italian collaborative study group evaluated the early corticosteroid response by giving a 7-day course of prednisone immediately before induction ([64]). The preinduction response was previously shown to have strong prognostic value in pediatric ALL ([95], [96]). In the adult ALL study, prednisone response was defined by reduction of peripheral blood blasts to less than or equal to 1000 × 10^6/L. Lack of a prednisone response was found to negatively affect overall survival, as it did in the pediatric ALL studies, and, among CR patients, it also adversely influenced remission duration.

MINIMAL RESIDUAL DISEASE *Minimal residual disease* refers to the postremission persistence of leukemia that cannot be detected by histomorphologic assessment. Immunophenotypic, cytogenetic, or molecular techniques can be used to detect minimal residual disease ([97]). Samples from peripheral blood are

generally one log $_{10}$ less sensitive than bone marrow but may have comparable sensitivity in T-lineage ALL ([98], [99] and [100]). Fluorescence *in situ* hybridization is better than conventional banding analysis for detecting chromosomal translocations and numerical abnormalities, but both are limited by low sensitivity ([101], [102], [103] and [104]). The most sensitive assays for detecting minimal residual disease are based on PCR techniques, which can detect one leukemic blast in up to 10 ^{6} normal cells. PCR targets using fusion gene transcripts such as *BCR-ABL*, *TEL-AML1*, *MLL-AF4*, and *E2A-PBX* are relatively standardized, but each alone can only be used for patient subsets ([105], [106]). PCR targets based on immunoglobulin and T-cell receptor gene rearrangements can be used to detect minimal residual disease in theoretically all patients but lose sensitivity if consensus rather than patient-specific primers are used ([105], [107]). Generating patient allele-specific primers requires DNA sequencing capability, and accurate quantitation is difficult without *real-time* PCR analyses. Flow cytometry, used in 4-color combinations and taking advantage of new reagents, can unambiguously distinguish one leukemic blast among more than 10 ^{4} normal cells in 90% of all patients ([108], [109]). This level of sensitivity is sufficient for prognostically significant minimal residual disease detection ([110]). Additionally, flow cytometry is rapid, reliable, and allows accurate quantitation, and the technical requirements for the assay are already in place at most centers. Information from ongoing pediatric ALL trials using PCR and flow cytometry in tandem may help determine the role of each for evaluating minimal residual disease ([111]). Many studies evaluating the prognostic utility of minimal residual disease detection have been reported ([90], [105], [112]). Virtually all were conducted in children with ALL. Three of the pediatric studies stand out for having large patient numbers, inclusion of both B- and T-lineage ALL, and for including patients with poor risk features ([110], [113], [114]). The European studies were multicentered and used PCR detection of patient-specific antigen receptor gene rearrangement, whereas Coustan-Smith et al. used multicolor flow cytometry in an unselected patient cohort treated at the St. Jude Children's Research Hospital. Minimal residual disease was determined at the end of induction and at various time points thereafter. The testing was technically challenging, as 1254 of 1914 (66%) combined patients treated during the study period did not have suitable PCR targets, did not have serial PCR performed, or did not have an immunophenotype suitable for minimal residual disease assessment. Nonetheless, all three studies demonstrated an unfavorable influence of persistent minimal residual disease on relapse-free survival. By multivariate analyses in the St. Jude study, sequential detection of persistent minimal residual disease remained a poor prognostic marker after controlling for age, WBC count, and adverse cytogenetics including the Ph chromosome and *MLL* gene rearrangement ([110]). Detection of minimal residual disease during maintenance therapy tended to have the strongest positive predictive value for relapse. Conversely, absence of minimal residual disease at the end of induction negated the unfavorable influence of persistent leukemic blasts at day 7 as a prognostic factor. Issues related to technique remain to be resolved. For instance, threshold values of minimal residual disease were suggested to be prognostically significant by the clinical studies ([113], [114]). Quantitation of leukemia-specific residual disease with the PCR assay, however, is technically demanding, and little is mentioned about efforts to ensure standardization of assay sensitivity between testing facilities. Quantitative real-time PCR may aid substantially in this regard ([115]). Efforts to study the predictive value of minimal residual disease in adult ALL have been considerably more limited, but the findings have been similar ([116], [117] and [118]). Mortuza et al. reported results for 66 Ph-negative adult B-lineage ALL patients treated at a single institution, for whom minimal residual disease was assessed with PCR using consensus immunoglobulin heavy chain gene primers ([116]). Detection of residual leukemia at the 10 $^{-3}$ level, the limit of sensitivity of the assay, independently correlated with inferior disease-free survival. Ongoing prospective minimal residual disease assessment in trials being conducted by major cooperative groups will help clarify the extent to which the substantial pediatric data can be extrapolated to adult ALL ([119], [120]).

PRIMARY THERAPY

Current management strategies for adult patients with ALL require a careful assessment of relapse risk at the time treatment is initiated. Most adult ALL patients have the precursor B-cell or T-cell subtype and can be managed with established treatment programs that start with remission induction, followed by blocks of intensification, CNS relapse prophylaxis, and prolonged maintenance therapy. With modern multiagent regimens, up to 90% of patients achieve CR, and 25 to 40% can be cured. The disease-free survival figure obviously needs improvement, and, hence, therapy should be tailored for patients who have an adverse prognostic profile. Risk-adapted therapy has proven remarkably effective for certain poor-risk groups, such as brief dose-intensive protocols for adult patients with mature B-cell ALL. Other patient groups known to have high risk for disease relapse should undergo allogeneic bone marrow transplantation (BMT) in first remission, given an available donor and eligibility status. Considerable clinical data suggest that this strategy has been effective, particularly with Ph-positive patients. Elderly ALL patients pose special treatment considerations, which are discussed in this chapter. General issues relating to supportive care of the patient with leukemia are discussed in Chapter 75.

General Principles

On presentation, certain pretreatment considerations should be attended to before initiating therapy. Leukemia therapy is guided by an estimate of relapse risk, although there is no formal risk assessment tool for adult ALL. In reviewing the list of agents used to induce remission and protect against relapse, it can be appreciated that the individual superiority of one drug over another in many instances has not been established. Complicating management decisions are similarly conflicting outcome results for BMT in first remission for high-risk patients, although the general consensus is that allogeneic BMT from a sibling donor is best therapy.

PRETREATMENT CONSIDERATIONS Attention should be paid to metabolic, infectious, and hematologic matters before starting leukemia-specific therapy. Hyper-uricemia, hyperphosphatemia, and secondary hypocalcemia may be pronounced with high leukemic cell burden and require intravenous hydration, alkalinization, and administration of allopurinol. In addition to myelosuppression during intensive treatment blocks, ALL therapy suppresses cell-mediated immunity, and some protocols have provisions for prophylaxis against herpesvirus and *Pneumocystis carinii* infections ([87]). The clinical consequences of hyperleukocytosis (=100,000 × 10 ^{6}/L) in adult ALL patients are not well understood. Patients with *MLL* gene rearrangements and the mature B-cell ALL subtype are at higher risk for hyperleukocytosis at presentation ([52]). In children, pronounced hyperleukocytosis involving lymphoid blasts are better tolerated than myeloid blasts, as reflected by fewer complications attributable to leukostasis or hemorrhage ([121]). In one series, leukapheresis for pediatric ALL patients having blast counts greater than or equal to 200,000 × 10 ^{6}/L led to outcomes equivalent to those for children who did not have this degree of hyperleukocytosis ([122]). A similar policy is reasonable for adult ALL patients. Alternatively, immediate administration of prednisone or vincristine can rapidly reduce the circulating blast count. In an adult series, the WBC count dropped from greater than 100,000 × 10 ^{6}/L to less than 1000 × 10 ^{6} in 39% of patients given a 7-day course of prednisone immediately preceding remission induction chemotherapy ([64]).

RISK ASSESSMENT MODEL There are no useful clinical staging or prognostic scoring systems for adult ALL patients as there are for other hematologic malignancies, and there are no agreed-on uniform risk criteria as there are for pediatric ALL ([123], [124], [125], [126] and [127]). A prognostic model based on CALGB data suggested an additive effect of multiple adverse prognostic features on outcome, and, conversely, those without any poor prognostic factors did exceptionally well with few relapses ([53]). Others have described similar analyses ([57], [69]). Based on these models and the current clinical evidence, a general framework for risk assessment may consider placing adults with ALL in high-risk and standard-risk prognostic categories (Fig. 78.3). All patients with at least one established poor prognosis factor based on clinical, immunophenotypic, or cytogenetic features and morphologic response to induction therapy should be considered at high risk for relapse. Adding response to therapy, based on early blast clearance and minimal residual disease detection, as a risk criterion for adapting therapy awaits prospective validation of these prognostic factors in adult ALL studies.

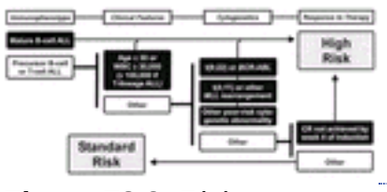

Figure 78.3. Risk assessment for adult acute lymphoblastic leukemia (ALL). Clinical, immunophenotypic, and cytogenetic features may be combined with the initial response criteria to classify patients at high risk or low risk for disease relapse. CR, complete remission; WBC, white blood cell.

REMISSION INDUCTION The goal of remission induction therapy is hematologic CR, as defined by the eradication of morphologically detectable leukemia cells in blood and bone marrow and the return of normal hematopoiesis. Remission induction chemotherapy for adults with ALL is most commonly built around a backbone of vincristine and prednisone. Remission induction with these two drugs in combination produces CR in approximately one-half of patients with *de novo* ALL. The CR rate improves to 70 to 85% when an anthracycline is added, which was proven in a landmark CALGB trial to be superior to vincristine and prednisone alone ([128]). Induction failures are evenly divided between refractory disease and toxicity-related mortality ([4], [53], [56], [64], [69]). The efficacy of various anthracyclines in adults has been similar, including daunorubicin, doxorubicin, zorubicin, and mitoxantrone ([68], [129], [130] and [131]). Many alterations to the basic induction regimen have been evaluated ([72], [132], [133], [134] and [135]). A critical evaluation of the individual merits of these modifications is challenging. Improvement to CR rates that already exceed 80% would be difficult to detect at a satisfactory level of significance. Modern treatment protocols are complex, and it is difficult to attribute outcome results to any one component or to make comparisons of significant findings between any two trials. For example, most modern induction protocols also incorporate L-asparaginase, cyclophosphamide, or both, although neither has been proven by controlled trials to be beneficial in adult ALL when added to initial induction regimens. The one

randomized trial with L-asparaginase found no improvement in frequency or duration of CR with the addition of L-asparaginase to doxorubicin, vincristine, and prednisone during induction ([136]). Nonetheless, L-asparaginase has a mechanism of action that is close to being ALL-specific and causes minimal myelosuppression, and efficacy data can be found in the pediatric ALL experience ([137]). An Italian Gruppo Italiano Malattie Ematologiche dell' Adulto (GIMEMA) trial randomized adult ALL patients to induction with daunorubicin, vincristine, prednisone, and L-asparaginase with or without cyclophosphamide ([64]). The rate and durability of remission, as well as overall survival, did not differ between the two randomized treatment groups or for any subtype analyzed. In contrast, other studies have suggested a benefit with the inclusion of cyclophosphamide during induction, especially for patients with T-cell ALL, and, conversely, worse outcome with its omission ([53] , [138]). Dose-intensified anthracycline and high-dose cytarabine induction regimens are being evaluated as alternatives to traditional induction protocols. These treatment programs were intended to improve outcome by inducing rapid reduction of leukemic cell mass to achieve early CR ([139]). Todeschini et al. generated considerable interest with reports from two sequential trials showing that dose escalation of daunorubicin to 225 mg/m ^{2} and, subsequently, to 270 mg/m ^{2} significantly improved disease-free survival ([140] , [141] and [142]). Multicentered implementation of this protocol by the GIMEMA group, however, failed to reproduce the earlier experience based on an interim analysis of 460 of 501 total patients enrolled ([143]). Weiss et al. investigated a different approach using high-dose mitoxantrone given with high-dose cytarabine during induction ([144] , [145]). Compared with historical controls, this regimen yielded an improvement in the remission rate as well as the time to CR and is currently being explored in an expanded randomized trial at six study sites in the United States. Patients with mature B-cell ALL have poor initial responses to these conventional regimens and require special dose-intensified remission induction programs that are discussed below ([66] , [67] , [146] , [147]). Granulocyte colony-stimulating factor started after completion of the first few days of ALL induction chemotherapy did not improve CR rates in randomized trials. It did shorten the duration of neutropenia by 5 to 6 days and appears to decrease the incidence of associated complications, particularly infections ([54] , [148] , [149] and [150]).

INTENSIFICATION THERAPY Postremission intensification or consolidation therapy after the attainment of CR is standard treatment for adult patients with ALL. This therapy refers to the administration of non–cross-resistant drugs aimed at eliminating residual leukemia to prevent relapse as well as the emergence of drug-resistant cells. Variably myelosuppressive doses of different drugs are given according to various schedules depending on the protocol. Due to the heterogeneity of approaches, it is difficult to assess the effect of any individual drug, and only a general assessment of the overall value of intensification can be made. A randomized trial in childhood ALL clearly demonstrated that administration of both early (given immediately after CR) and late (week 20) intensification therapy was better than either early or late intensification alone and better than no intensification at all ([151]). Two other pediatric trials confirmed the benefit of intensification ([152] , [153]). Results from comparative trials in adults have been less clear and again highlight the difficulty of comparing findings from discordantly designed studies. The childhood study was conducted by the British UKALL study group, which also enrolled adult patients in a concurrent trial using essentially identical treatment regimens ([4]). There was a significant decrease in relapse incidence for patients who received the early intensification block, but this was not reflected by a statistically significant improvement in disease-free survival, possibly due to an increased number of deaths during remission. Likewise, two GIMEMA studies randomizing adult ALL patients to intensive versus standard consolidation and maintenance saw no advantage in disease-free survival for intensified postremission treatment ([63] , [64]). No benefit was observed with extending consolidation started early in the postremission period from 1 month to 4 consecutive months ([154]). Adding two myelosuppressive consolidation courses patterned after acute myeloid leukemia, “3 + 7” cytarabine and daunorubicin, to maintenance alone made no difference in the duration of remission ([155]). Last, very late intensification given at 6 months or 11 months after CR, in two separate trials, led to no reduction in relapse compared with standard postremission therapy alone ([156] , [157]). In contrast, clinical data from nonrandomized trials provide evidence that adult ALL patients benefit from intensification ([53] , [56] , [57]). In the CALGB study, patients who achieved CR received two blocks of early intensification in addition to an 8-week late intensification therapy ([53]). The reported medians of remission duration and survival, 29 months and 36 months, respectively, were substantially better than those observed in prior CALGB trials that did not use intensification blocks. Outcomes better than historical comparison groups were reported by German Multicenter Acute Lymphoblastic Leukemia (GMALL) studies that consolidated remission patients with a late “re-induction” of drugs identical to initial therapy given 21 weeks after starting treatment ([56] , [57]).

MAINTENANCE THERAPY Like postremission intensification, the value of long-term, continuous maintenance therapy for adult ALL has not been established by randomized trials as it has for pediatric ALL ([158]). Patterned after the childhood ALL experience, maintenance therapy usually consists of daily 6-mercaptopurine and weekly methotrexate for a total treatment period of 2 to 3 years. There is no information from adult ALL trials regarding the proper duration of maintenance therapy, but children who receive less than 18 months of therapy have worse outcome. The addition of monthly pulses of vincristine and prednisone reduced relapses in controlled childhood ALL studies and has been adopted in some adult maintenance therapy regimens. From a mechanism-of-action perspective, it may be that long-term drug exposure is required to eradicate residual slowly dividing or drug-resistant ALL clones ([159]). This could explain why maintenance is not necessary for optimally treated patients with mature B-cell ALL, which is a highly mitotically active leukemia ([2] , [66] , [67] , [146] , [147]). Relatively strong evidence that adult ALL patients benefit from maintenance therapy comes from a number of studies showing inferior outcome when prolonged maintenance was completely omitted ([129] , [160] , [161] and [162]). The CALGB study was intended to evaluate the efficacy of mitoxantrone during induction and consolidation given over a 7- to 9-month period without maintenance ([129]). Patient accrual on this trial was terminated at interim analysis because the median duration of remission (11 months) was much shorter than in previous protocols. Similarly, another American cooperative study group investigated high-dose cytarabine intensification followed by 8 cycles of multiagent consolidation ([161]). Without maintenance, the median duration of remission was 10 months, and the disease-free survival at 4 years was only 13%.

CENTRAL NERVOUS SYSTEM THERAPY CNS prophylaxis is essential in the treatment of ALL. Approximately one-third of adult patients will eventually have CNS involvement at relapse without prophylactic therapy ([163] , [164]). The advantage of CNS prophylaxis in adult ALL was established by the Southeastern Cancer Group in a randomized trial comparing cranial irradiation plus intrathecal methotrexate versus no prophylaxis ([165]). CNS prophylaxis may involve combinations of intrathecal chemotherapy, cranial irradiation, and systemic administration of drugs with high CNS bioavailability, such as high-dose methotrexate and high-dose cytarabine. Although the best combination of modalities and the preferred timing have not been established in controlled trials, a number of different approaches have all proved equally effective. Intrathecal chemotherapy alone or high-dose chemotherapy alone, however, has been associated with poor protection from CNS relapse ([166] , [167]). On the other hand, more aggressive approaches combining all three modalities do not yield clearly superior results ([56]). Cranial irradiation between 1800 and 2400 cGy plus intrathecal methotrexate started after achievement of CR has been used as CNS prophylaxis in several studies with CNS relapse rates between 0 and 11% ([53] , [60] , [69] , [138]). Similar results were achieved in other studies that were able to omit cranial irradiation by starting intrathecal chemotherapy concurrent with induction and incorporating high-dose methotrexate, high-dose cytarabine, or both ([63] , [87] , [155]). Adult ALL patients with CNS involvement at diagnosis require additional CNS-directed therapy. Up to 10% of adults present with CNS leukemia at the time of diagnosis ([53] , [57] , [131] , [167]). Patients with mature B-cell ALL are at high risk for both CNS disease at presentation and subsequent CNS relapse ([66] , [67]). The treatment of CNS leukemia has generally involved early and repeated dosing of intrathecal chemotherapy started during induction therapy ([57] , [69] , [87]). Kantarjian et al. gave twice weekly alternating intrathecal methotrexate and cytarabine until the CSF showed no leukemic blasts, followed by the standard intrathecal prophylaxis regimen ([87]). Linker et al. gave intrathecal methotrexate injections weekly for 10 weeks, then monthly for the remainder of the first year ([69]). The cranial irradiation dose was also increased to 2800 or 3000 cGy when included as CNS prophylaxis during the treatment protocol ([57] , [69]). With either approach, the presence of CNS leukemia did not adversely affect subsequent outcome.

BONE MARROW TRANSPLANTATION Allogeneic BMT in first remission improves outcome for adult ALL patients with high-risk features and should be pursued for all eligible patients. Outcome data from most uncontrolled individual trials indicate disease-free survival between 40 and 60% with matched sibling allogeneic BMT ([168] , [169] , [170] , [171] , [172] and [173]). Some centers reported exceptionally impressive results. In a transplant study performed by Stanford University and the City of Hope National Cancer Center, high-risk inclusion criteria were defined as age greater than 30 years, a WBC count greater than 25,000 × 10 ^{6}/L, failure to achieve CR within 6 weeks of starting induction, or the presence of unfavorable cytogenetic abnormalities. Blume et al. initially reported a disease-free survival rate of 63%, which held up at 61% with longer follow-up of an expanded patient cohort, as reported by Chao et al. ([168] , [169]). Registry data from the International Bone Marrow Transplant Registry (IBMTR) provide additional information. Registry data are useful in limiting the influence of selection bias and heterogeneity between patient groups at different institutions, especially when based on large patient numbers. Reporting on 243 adult patients with high-risk ALL undergoing sibling donor allogeneic BMT, the 5-year estimate of disease-free survival was 39% ([174]). Treatment-related mortality (37%) exceeded disease relapse (30%) as the cause of treatment failure. In additional analyses by the IBMTR, patients were found to be half as likely to relapse if they developed either acute or chronic graft-versus-host disease ([175]). Others have also described similar evidence for a significant graft-versus-leukemia effect, which may have contributed to the relatively low relapse rate ([176]). Several comparisons of IBMTR data with outcome after standard therapy have been reported ([177] , [178] and [179]). In these indirect comparisons with historical control groups, allogeneic BMT in first CR proved superior for survival due to protection from relapse. Only one study providing controlled outcome data for allogeneic BMT versus standard therapy has been completed, and long-term results were recently reported ([61] , [62] , [131]). The French Leucémie Aiguë Lymphoblastique de l'Adulte (LALA) study group genetically randomized adult patients with ALL to sibling donor allogeneic BMT in first CR versus consolidation and maintenance chemotherapy, regardless of risk category. Risk categorization was based on criteria set by the German study group ([57] , [58]). Allogeneic BMT was found to be significantly superior to standard therapy but only for high-risk patients. Disease-free survival at 10 years for these patients was 44% with allogeneic BMT versus 11% for conventional therapy. For standard-risk patients, disease-free survival with allogeneic BMT was similar (49%) but no better than conventional therapy (43%). The preliminary results of an Italian multicenter randomized trial evaluating a similar study design also appeared to favor allogeneic BMT over standard chemotherapy only for high-risk patients ([180]). Allogeneic BMT from unrelated donors for adults in first CR can be successfully performed. Various individual trials have been reported, but the most relevant outcome results are recently updated registry data from the National Marrow Donor Program ([181] , [182] and [183]). Sixty-four patients with high-risk features, including the t(4;11) and t(1;19) translocations, received matched unrelated donor allogeneic BMT in first remission. Transplant-related mortality was 54%,

but relapse at 4 years was only 19%, and only 1 of 17 patients surviving beyond the first year had relapsed at the time of last follow-up. The role for autologous BMT as an option for postremission therapy in high-risk ALL patients is difficult to evaluate. The French LALA group performed a trial, parallel to the allogeneic BMT study, that randomly assigned patients younger than 50 years who did not have a matched sibling donor to autologous BMT versus standard therapy, once again regardless of disease risk ([62], [131]). Conventional therapy was found to be equivalent to autologous BMT for standard-risk patients. For high-risk patients, autologous BMT and conventional therapy both proved equally ineffective, with 10-year disease-free survival rates of 10% and 16%, respectively. Patients on the BMT arm were transplanted after three consolidation courses, and the autografts were purged with monoclonal antibodies and complement or mafosfamide. Many autologous transplant studies compare individual trials with registry data and report significantly better results. These trials differ considerably from one another and from the French randomized study with respect to timing of transplant, purging method, intensity of preparative regimen, and whether posttransplant maintenance therapy is given ([184], [185]). Taken together, disease-free survival for autologous BMT in first CR from individual trials ranges from 26 to 65%, a wide degree of variability likely reflecting the above considerations ([173], [186]). In some studies, transplant-related mortality approached 20% and seems high relative to contemporary experience with autologous BMT ([187], [188] and [189]). A trial genetically randomizing adult patients in first CR to sibling donor allogeneic versus autologous BMT found the former superior by a substantial margin ([190]). These results suggest that sibling donor and, probably, matched unrelated donor allogeneic BMT is preferable to autologous BMT in first CR.

Adult Precursor B-Cell and T-Cell Acute Lymphoblastic Leukemia

Adult ALL patients with the precursor B-cell or T-cell immunophenotype should enter into chemotherapy treatment programs that start with multiagent remission induction chemotherapy. Prophylaxis against CNS relapse is indicated for all patients. Standard-risk patients who achieve remission, who are the majority, should continue with intensification and maintenance therapy. Patients at high risk for relapse are best managed with allogeneic BMT in first CR.

Modern adult ALL treatment regimens that have been established by major collaborative study groups are illustrated in Figure 78.4 ([4], [53], [56], [57], [64]). Clinical outcome results from these trials, which were conducted by American, German, British, and Italian study groups, are summarized in Table 78.6. Almost all modern multiagent, multiphasic adult ALL treatment protocols are variations on the basic treatment theme ([65], [68], [69], [131], [136], [155], [191], [192]). Two exceptions are the GMALL B-NHL 86 and hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) protocols, which are brief, intensive treatment regimens that have improved outcome for adult mature B-cell ALL. They are discussed later in this chapter ([66], [67]).

Figure 78.4. Established treatment protocols for adult acute lymphoblastic leukemia (ALL). Protocols for patients with precursor B-cell or T-cell ALL shown are adapted from **(A)** CALGB 8811 trial ([53]); **(B)** GMALL 02/84 trial ([56]); **(C)** UKALL XA trial ([4]); and **(D)** GIMEMA 0288 ([64]). TABLE 78.6. Multicenter Trials in Adults with Acute Lymphoblastic Leukemia

Trial	Treatment Period	Patients (no.)	Median Age (yr)	Complete Remission (%)	Median Remission Duration (mo)	Overall Survival	Disease-Free Survival	Reference
GMALL 01/81	July 1981–June 1983	368	25	74	24.3	33% (11 yr)	35% (10 yr)	57, 58
GMALL 02/84	July 1983–June 1987	562	28	75	27	36% (5 yr)	39% (7 yr)	56
CALGB 8811	Sept. 1988–June 1991	197	32	85	29	36 mo	46% (3 yr)	53
MRC-UKALL XA	April 1985–Dec. 1992	618	>15	82	—	27 mo	28% (5 yr)	4
GIMEMA 0288	Jan. 1988–April 1996	794	28	82	29	26 mo	29% (9 yr)	64

The remission induction regimens are built around the four-drug combination of vincristine, prednisone, L-asparaginase, and an anthracycline, most commonly daunorubicin. The American CALGB 8811 and Italian GIMEMA 0288 protocols added cyclophosphamide to the induction regimen. For those who achieve remission, induction is followed by various intensification or consolidation treatment blocks, generally completed within 6 months of starting treatment. Prolonged maintenance with 6-mercaptopurine and methotrexate is continued for a total of 2 years of scheduled therapy. Intermittent pulses of vincristine and prednisone are also given during maintenance in the CALGB, GIMEMA, and the British UKALL protocols. Cranial irradiation is administered early in the German GMALL treatment program, during interim maintenance in the CALGB and UKALL programs, and omitted in the GIMEMA trial.

The CALGB 8811 trial was conducted between September 1988 and June 1991 at 25 institutions in the United States. Larson et al. reported the results of this study, which showed an 85% CR rate, median remission duration of 27 months, and disease-free survival of 46% but with relatively short median follow-up of 43 months ([53]). Six percent failed therapy due to death during induction, and an additional 7% due to refractory disease. Intensification of standard induction with cyclophosphamide was felt to contribute to favorable outcome with T-cell ALL but contributed to myelosuppression, requiring dose reduction in patients older than 60 years and hospital stays averaging 26 days during the induction phase. Prospective karyotype and immunophenotypic data were collected from patients on this and subsequent CALGB protocols for analysis of prognostic markers and were reported separately ([55], [70]).

The German GMALL 02/84 trial evaluated sequential blocks of intensive induction and consolidation therapy that extended for nearly a year before beginning maintenance. CNS therapy was aggressive and incorporated intrathecal chemotherapy and cranial irradiation, as well as systemic high-dose cytarabine and methotrexate. International application of this treatment protocol confirmed the high CR rate and disease-free survival of 39% that was reported by Hoelzer et al. ([56], [57], [166], [190], [193], [194] and [195]).

The British UKALL XA trial was designed to evaluate the benefit of postremission therapy with early and late intensification blocks, and results were reported by Durrant et al. ([4]). CR was achieved in 88% of adult patients, and disease-free survival at 5 years was 28%. As previously mentioned, there was a reduction in relapse for patients randomized to receive the early intensification block, but this did not lead to a superior disease-free survival rate. Additional analyses of this patient cohort describing clinical, immunophenotypic, and cytogenetic prognostic factors were detailed in separate reports ([59], [82]).

The GIMEMA 0288 trial tested the prognostic value of response to preinduction prednisone and the efficacies of cyclophosphamide inclusion during induction followed by intensification of postremission therapy. An 82% CR rate was observed in 794 adult patients with ALL, which was not better among patients randomized to receive cyclophosphamide during induction ([64]). The response to prednisone was shown to have prognostic significance. Prednisone responders had an overall survival rate of 33% at 8 years compared with 17% among nonresponders. The disease-free survival rate was 29%, which was no better for patients who were

randomized to an additional eight-drug consolidation after intensification, as opposed to proceeding directly to maintenance therapy.

Adult Mature B-Cell Acute Lymphoblastic Leukemia

The mature B-cell phenotype is found in 5% of adult ALL cases, and most are not cured with conventional ALL regimens such as those just described. Diagnosis is made by morphologic and immunophenotypic features, as has been discussed. Compared with other ALL subtypes, there is a more pronounced male predominance and higher incidence of extramedullary disease, including CNS involvement ([196], [197] and [198]). As is the case with other high-grade malignancies, the blast cells have a rapid doubling time, and vigorous supportive care must be pursued to prevent or treat tumor lysis syndrome ([199]). The high proliferative rate exhibited by the leukemic cells served as the rationale for a treatment strategy based on repeated administration (hyperfractionation) of high-dose cyclophosphamide plus methotrexate, also given at high dose, which proved highly successful in pediatric studies ([146], [200]).

Studies performed by German, French, and American groups have established that these brief, cyclical, dose-intensive protocols are the preferred approach to treating adult patients with mature B-cell ALL ([66], [67], [201]). Adapted from the pediatric regimens, the B-NHL 86 protocol used by the German study group and the hyper-CVAD treatment program evaluated at the M.D. Anderson Cancer Center are illustrated in Figure 78.4. Both use alternating blocks of intensive chemotherapy given monthly for a total of 6 or 8 months without subsequent maintenance. The hyper-CVAD regimen rotated fractionated high-dose cyclophosphamide with high-dose methotrexate. The B-NHL 86 protocol gave high-dose methotrexate with every treatment block and alternated cyclophosphamide with ifosfamide. CNS prophylaxis with intrathecal chemotherapy was started early, but cranial irradiation was omitted in the hyper-CVAD protocol. Similar outcome was reported by both studies (Table 78.7). Remarkably similar results were also reported by the CALGB, which implemented the German protocol in a study involving 24 adult patients, with the exception that excess neurotoxicity was reported by the CALGB ([202]).

TABLE 78.7. Dose-Intensive Therapy in Adults with Mature B-Cell Acute Lymphoblastic Leukemia

Trial	Year	Patients (no.)	Median Age (yr)	Complete Remission (%)	Induction Death (%)	Overall Survival (%)	Disease-Free Survival (%)	Reference

CALGB 9251	2001	24	45	75	4	44 (3 yr)	53 (3 yr)	202

There are currently no effective treatment options for mature B-cell ALL patients who have refractory or relapsed disease. From the recent studies, predictors for relapse were high WBC count (>50,000 × 10^6/L), severe anemia, older age, and poor performance status ([66], [67], [201]). In the report by Thomas et al., nine patients relapsed in CR, for whom the median remission duration was only 7 months. Progression after relapse was rapid, with two deaths occurring before treatment could be initiated. The remaining patients were resistant to salvage therapy that included retreatment with hyper-CVAD. After relapse, the median survival for the group was 1 month.

Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia

Ph-positive ALL accounts for at least 20% of adult cases ([52], [203], [204]). Patients tend to be older and have a higher WBC count and are more likely to present with hepatosplenomegaly and lymphadenopathy. Virtually all have the precursor B-cell immunophenotype. Most achieve CR with standard ALL induction chemotherapy, but few are long-term survivors due to relapse. The median duration of survival ranges from 8 to 16 months, and disease-free survival did not exceed 10% ([55], [80], [81] and [82], [205]). Incorporation of maintenance therapy to the hyper-CVAD regimen yielded interesting results for subtypes of adult ALL other than mature B-cell ALL but had no impact on survival for the 32 Ph-positive patients in the series reported by Kantarjian et al. ([87]).

Patients with Ph-positive ALL should undergo allogeneic BMT in first CR. Results vary from center to center, but 30 to 65% of Ph-positive patients can expect long-term survival with allogeneic BMT ([206], [207], [208] and [209]). Registry data from the IBMTR show rates at 2 years of 38% for disease-free survival and 34% for relapse ([210]). There are no comparative trials, but a large retrospective review of children who were Ph-positive, an equally unfavorable marker in pediatric ALL, suggested that allogeneic BMT substantially improved survival compared with chemotherapy alone ([211]). Too few Ph-positive adult ALL patients have been treated with autologous BMT in first CR to properly assess the value of this approach.

Acute Lymphoblastic Leukemia in Elderly Patients

One-third of adults diagnosed with ALL are older than 60 years according to United States prevalence data ([5]). Advanced age is itself an adverse prognostic factor for ALL, and survival decreases continuously with increasing age. Although older age is independently predictive of inferior outcome, a number of factors can be identified that may account for the poor prognosis ([212], [213], [214], [215] and [216]). Elderly ALL patients tend to have worse performance status, in part, reflecting comorbid medical conditions. As a result, these patients have limited tolerance for intensive therapy, which may contribute to a high rate of treatment-related mortality. Additionally, aspects reflecting the underlying biology of the leukemia likely have an influence as well. Elderly patients are more likely to be Ph-positive, be underrepresented in the favorable T-cell subgroup, and have disease refractory to standard chemotherapy drugs used to treat ALL.

At present, there is no satisfactory approach for managing elderly patients with ALL. Several groups have described treatment outcome for these patients, and the results are summarized in Table 78.8. Elderly ALL patients given no therapy may not survive more than a few weeks ([217]). Palliative therapy, usually moderate-dose prednisone and intermittent vincristine, has been used ([218]). Modest responses were observed, with survival extending to a few months. A retrospective review of one cooperative group member institution's 13-year experience revealed that only one-half of their ALL patients older than 60 years were enrolled in their active study protocol ([213]). In these instances, risk-adapted therapy often meant limiting treatment intensity on a case-by-case basis. Many of these elderly patients were given ad hoc induction regimens of variably dosed vincristine and prednisone, with or without a third drug ([219], [220] and [221]). Complete responses were reported in up to 40%, but median survival remained only several months. Several groups uniformly treated fairly large cohorts (40 to 60) of elderly patients with “age-adjusted” chemotherapy programs ([222], [223] and [224]). Impressive CR rates were sometimes observed, and median survival extended to 12 to 14 months. The patient numbers were still small, and it is difficult to evaluate the influence of patient selection bias, as conflicting results have been reported by the same institution treating patients with essentially the same protocol ([222], [223]). Data from major collaborative groups treating selected, elderly ALL patients suggest that up to one-half may achieve CR with intensive therapy ([225], [226]). Resistant disease and toxic deaths were frequent, but a median survival of 10 months may be reasonably expected.

NA, not applicable.

At present, there is little reason to be optimistic about improving outcomes in elderly patients with ALL. The accumulated literature is still sparse, and much remains to be learned about treating these patients. Improvements in supportive care have certainly benefited elderly patients undergoing therapy. Some study centers are likely to evaluate newer, less toxic therapies, such as monoclonal antibodies or small molecule-based targeted approaches. Elderly patients should be referred for such investigational protocols whenever practical.

SALVAGE THERAPY

The prospect of salvage therapy for refractory or relapsing disease will eventually have to be considered for most adult ALL patients. Primary resistance to induction chemotherapy reported by collaborative trials ranges from 8 to 15% ([4], [53], [56], [64], [65], [69]). Although most patients achieve a first CR, only 20 to 40% become long-term survivors, and the principal cause of treatment failure is disease relapse. Although a second or salvaged CR can be obtained for a slight majority with chemotherapy, the durability of remission is likely short unless an allogeneic BMT is subsequently performed, and, even then, remission duration is limited for most patients.

Recent studies yield some insight into the biologic and clinical features of disease relapse in adult ALL patients. Thomas et al. reviewed the presenting characteristics at relapse in patients referred for therapy at a single institution over a 17-year period ([227]). The duration of CR was less than 1 year in 61%. Essentially all patients had marrow relapses, although one-third had concurrent extramedullary involvement, including CNS leukemia in 16%. In other studies, the cytogenetic, immunophenotypic, and molecular changes at relapse compared with initial presentation were examined ([228], [229]). Clonal cytogenetic changes were the most common finding. One-half of the cytogenetic findings were believed to represent clonal evolution, and the remainder were karyotypic changes. Two entirely different abnormal karyotypes were never found. Immunophenotypic changes were twice as likely in patients with T-cell versus B-cell ALL and were marked by gain or loss of one or two antigens but no complete shift from B- to T-lineage ALL, or vice versa. Neither the presence of a karyotypic shift nor an immunophenotypic shift adversely influenced survival from the time of relapse.

Chemotherapy

Reinduction of remission, or attainment of a first CR for refractory patients, can be expected in slightly more than one-half of patients with salvage chemotherapy. However, in the majority, remissions do not extend beyond 3 to 6 months, and long-term survival is well below 10% whether or not postremission therapy is given. The numerous reports describing generally single-institution studies involving small numbers of patients have been exhaustively catalogued in excellent reviews ([230], [231] and [232]). In general, single-agent chemotherapy is inferior to multiagent protocols. Two or three drugs have been added to L-asparaginase or an anthracycline with good responses, but the best results are produced by combinations based on intermediate- to high-dose cytarabine. In one of the larger patient series, doxorubicin combined with vincristine and dexamethasone induced CR in 39% of 64 refractory patients ([233]). Treatment failure was due to resistant disease in 41%, whereas induction mortality was only 6%, reflective of an inverse correlation between toxicity-related death and antileukemic activity.

Much more extensively studied have been salvage regimens based on high-dose cytarabine, which produce CR rates that vary widely but have occasionally exceeded 70%. Additional drugs have included an anthracycline, mitoxantrone, and fludarabine. The hyper-CVAD regimen, which incorporates doxorubicin and high-dose cytarabine in addition to fractionated cyclophosphamide, was used to salvage 66 relapsed patients and induced remissions in 44% ([234]). Hiddemann et al. reported a 50% CR rate in 24 refractory patients with the mito-xantrone and high-dose cytarabine two-drug combination ([235]). Other studies with these two drugs have reported CR rates of 17 to 80%. Fludarabine is a purine analog that enhances bioavailability of the active metabolite of cytarabine, and, as a salvage regimen, the combination yields CR in 30 to 83%, with the higher response rates reported when cytarabine was used at high rather than intermediate dose ([236], [237] and [238]).

In a large single-institution review, Thomas et al. described treatment outcome for 314 adult patients with relapsed or refractory ALL who received various salvage therapy regimens. Overall CR was achieved in 31% ([227]). Patients with long first remissions received the customary front-line study salvage regimen, which varied depending on the study period, whereas patients resistant to or relapsing on therapy were treated with new drug combinations. This approach to treatment regimen selection, based on timing of relapse and prior induction programs, can be regarded as reasonable recommendations for all adult ALL patients requiring salvage therapy. Patients with primary refractory disease and those with relapsed disease were found to achieve CR equally well. Death occurred without achieving remission in 21%. Patients with long first CR duration (>2 years) were more likely to achieve CR and have longer durations of second remission, a finding confirming observations made by other investigators ([239], [240]). For the entire group, the median durations of remission and survival from the start of salvage therapy were 6 months and 5 months, respectively.

Bone Marrow Transplantation

Given the dismal outlook, allogeneic BMT should be attempted for all eligible adult ALL patients as soon as possible after second or salvaged remission is achieved. The logistics may be difficult given the narrow window before impending relapse. This was examined by Davies et al., who describe finding matched related donors for only 35% of 115 consecutive relapsed ALL referrals to a single institution over a 2-year period ([241]). An unrelated marrow donor search was initiated in most of the remainder, which was successful in another one-third but required a median of 10 weeks before a donor was identified. Overall, allogeneic BMT was not performed in the majority of the patients, and the reason in 19% was death before transplant despite all efforts to expedite BMT. This point was highlighted by a study at 12 GIMEMA institutions, which reinduced CR in 56% of adult ALL patients in first relapse with a combination of idarubicin and intermediate-dose cytarabine ([242]). This was to be followed by a scheduled BMT that could not be performed in 44% due to relapse and in another 26.5% due to persistent infection acquired during induction.

Even if a patient is transplanted, the available data suggest that few will be effectively salvaged with allogeneic BMT. Outcome reported from individual trials indicates long-term disease-free survival in 15 to 45% after sibling donor allogeneic BMT in second or greater CR ([171], [243], [244]). Registry data from the IBMTR show a 5-year disease-free survival estimate of 26% ([245]). Unlike allogeneic BMT for adult ALL in first remission, however, relapse (52%) outranked treatment-related mortality (36%) as the cause of treatment failure.

Allogeneic BMT for active disease appears to yield inferior results. Results for individual trials reporting sibling-donor allogeneic BMT for untreated refractory or relapsed disease indicate disease-free survival of 12 to 43% ([244], [246]). The IBMTR reported a 4-year disease-free survival of 13% with 71% of patients relapsing ([245]).

Unrelated donor BMT is associated with a very high transplant-related mortality, compounding the difficulties of finding a matched donor. Based on registry data from the National Marrow Donor Program, transplant-related mortality was 75% for patients transplanted in second or greater CR and 64% for patients transplanted in relapse ([181]). Recent advances in histocompatibility antigen matching based on molecular typing techniques may improve outcome by selecting better-matched donors ([247]).

A benefit from autologous BMT for patients in second or subsequent CR is difficult to determine. There are many individual studies, generally with short follow-up, reporting disease-free survival ranging from 10 to 31% ([182], [187], [248], [249] and [250]). Almost all failures are due to treatment relapse, however, and no study has demonstrated a disease-free survival plateau. Based on the available data, it appears that, as compared with standard therapy, remissions may be extended with autologous BMT for select patients. On that basis, autologous BMT can be considered an option in the salvage setting, particularly as part of an investigational

protocol when available.

SUMMARY AND FUTURE DIRECTIONS

Considerable progress has been made in the management of ALL in adult patients. Multiagent induction chemotherapy induces CR in over 85% of adult ALL patients. With the institution of postremission therapy and prophylaxis against CNS relapse, up to 40% may be cured of the disease. There is no compelling reason to believe, however, that further modification of modern multiagent regimens with the addition of currently available chemotherapy drugs will lead to a substantial improvement in outcome for these patients.

On the immediate horizon is the prospect of tailored therapy adapted for each individual patient on the basis of anticipated relapse risk. This approach has proved to be remarkably successful for two adult ALL subgroups, namely, those with mature B-cell ALL and those with Ph-positive ALL. Ongoing prospectively randomized trials will establish the role of risk-adapted therapy for patients with high-risk features according to other criteria. Ongoing trials will also help define the role of new technologies, such as minimal residual disease assessment, in refining and improving the ability to accurately evaluate relapse risk.

The success with improving outcome for Ph-positive ALL, while satisfying, highlights the fact that, at present, the only viable intervention for intensifying therapy for high-risk patients is allogeneic BMT. Newer approaches with allogeneic BMT using dose-attenuated nonmyeloablative recipient conditioning are promising and can extend the procedure to patients who might otherwise not be eligible for conventional transplantation. Clinical outcome data are not mature, however, and, at present, the procedure is still investigational.

Targeted therapy, such as monoclonal antibodies directed against surface antigens expressed by malignant cells, has proven extremely effective for other lymphoproliferative disorders. Targeted molecular therapy, such as the small molecule inhibitor of the *BCR-ABL* tyrosine kinase, is beginning to significantly affect care of patients with chronic myeloid leukemia. The addition of both approaches can be immediately evaluated for adult patients with ALL. Additional state-of-the-art novel therapies, based on a progressive understanding of the biology of the disease and the mechanisms of drug resistance, are needed and remain to be developed.

Acute Myeloid Leukemia in Adults

The terms *acute myeloid leukemia* (AML), *acute myelogenous leukemia*, and *acute nonlymphocytic leukemia* (ANLL) refer to a group of marrow-based neoplasms that have clinical similarities but distinct morphologic, immunophenotypic, and cytogenetic features. AML should be distinguished from acute lymphoblastic leukemia (ALL) (Chapter 77) and may follow myelodysplasia (MDS) (Chapter 83). AML occurs at any age but is more common in adults, with increased frequency as age advances. Clinical features are similar at all ages and are the result of replacement or suppression of normal marrow elements by malignant blasts, generally resulting in impaired hematopoiesis manifested by cytopenias. Chapter 81 addresses the diagnosis and therapy of AML in children.

The malignant cell in AML is a blast that most often shows myeloid or monocytic differentiation. In approximately 5 to 10% of patients, blasts have erythroid or megakaryocytic differentiation; for this reason, *ANLL* has been considered a more precise term, but *AML* is used more commonly and is the recommended term ([1]). The myeloid blast can be identified by the presence of Auer rods or by Sudan black, myeloperoxidase (MPO), chloroacetate esterase, or nonspecific esterase positivity on cytochemical stains. In addition to morphology and cytochemical evidence of lineage, flow cytometry is used to classify acute leukemia based on the presence of myeloid and lymphoid antigens ([1] , [2]). Surface marker analysis has shown that AML is heterogeneous and may have patterns of antigen expression varying from those seen on stem cells to those present on more mature myeloid cells. Expression of lymphoid antigens is not uncommon in subtypes of AML. Biphenotypic or mixed lineage features have been described in 5 to 20% of acute leukemias. Electron microscopy may also be used to identify and subclassify AML ([3]).

The pathogenesis of AML is uncertain, but chromosome abnormalities are present in most patients ([4]). Cytogenetic translocations result in the formation of fusion proteins, which are a common pathway in leukemogenesis. New diagnostic tools, including fluorescence *in situ* hybridization, polymerase chain reaction (PCR), comparative genomic hybridization, and microarray analysis have improved the sensitivity of detection of genetic abnormalities and the ability to subclassify AML and to detect minimal residual disease. Because of the importance of cytogenetics in diagnosis and prognosis in AML, the World Health Organization (WHO) has incorporated cytogenetic findings into a new classification. Genetic syndromes and toxic exposures contribute to the pathogenesis in some patients.

Advances in therapy have changed the cure rates in AML from less than 20% in 1960 to 1980 to 40 to 70% for selected groups in the 2000s. In fact, the cure rate of acute promyelocytic leukemia (APL) is more than 70% with the addition of all- *trans*-retinoic acid (ATRA) to chemotherapy (Chapter 82). For other types of AML, the highest cure rates have resulted from allogeneic stem cell transplantation (alloSCT) in first remission; however, the improved survival in patients receiving high-dose cytosine arabinoside (ara-C) chemotherapy has kept the question of what is the best initial therapy in AML unanswered. In this chapter, epidemiologic, clinical, biologic, and cytogenetic features of adult AML are addressed in the context of therapeutic principles and prognosis.

HISTORICAL PERSPECTIVE

Virchow recognized leukemia as a distinct disease in 1845 when he used the term *weisses Blut* to describe the findings in an autopsy in which the ratio of red corpuscles to “colorless (in mass white)” was reversed ([5] , [6]). He used the term *leukämie* for the first time in 1847 and, subsequently, described lymphatic and splenic forms ([7]). Friedreich recognized acute and chronic types in 1857 ([8]), and Neumann in 1868 identified the bone marrow as the origin of leukemia and used *myelogenous* as a provisional term that has been validated over time ([5] , [9]). In 1876, Mosler introduced bone marrow puncture as a method to diagnose leukemia ([10]).

At the beginning of the twentieth century, Naegli distinguished acute myelomonocytic leukemia (AMMoL) from acute myeloblastic leukemia ([11]); and Erhlich used morphology and aniline dyes to diagnose and categorize leukemia ([12]). During the first half of the century, most of the subcategories of AML were identified by light microscopy with the aid of cytohistochemical stains and were described based on the resemblance to normal hematopoietic precursors. Reschad and Schilling described acute monoblastic leukemia in 1913 ([13]); DiGugliemo described acute erythroleukemia in 1917 ([14]); Von Boros and Karenyi described acute megakaryocytic leukemia (AMgL) in 1931 ([15]); and Hilstad described APL in 1957 ([16]). The morphologic approach to AML culminated in the development of standard criteria beginning in 1976 by the French/American/British (FAB) working group, in what became known as the FAB classification of AML ([17]). Modifications of the FAB classification were made with recognition of new morphologic subsets of AML, such as minimally differentiated disease with myeloid antigen expression ([18]).

Nevertheless, the weaknesses of the FAB classification include interobserver variability, the failure to incorporate cytogenetic data into diagnosis, and poor correlation with clinical outcome. The recognition of the Philadelphia chromosome in chronic myeloid leukemia (CML) by Nowell and Hungerford in 1960 was the first

demonstration of a recurring chromosomal abnormality ([19]). In the latter half of the twentieth century, numerous cytogenetic abnormalities, including specific translocations, were identified in subtypes of AML and have led to changes in classification, as proposed in 1997 by the WHO ([20] , [21]). The WHO subdivides AML into true *de novo* AML occurring predominantly in young to middle-aged adults with recurring cytogenetic translocations or inversions and MDS-related AML occurring in elderly adults often with complex chromosomal abnormalities ([21] , [22]). The WHO recognizes therapy-related AML and retains the morphologic subcategories of the FAB in cases not otherwise classified ([21] , [22]). The category of acute leukemia of ambiguous lineage is also added.

EPIDEMIOLOGY

Findings in epidemiologic studies suggest that environmental, occupational, and genetic factors play a role in the pathogenesis of AML ([23] , [24] and [25]). Incidence rates are greater in developed countries and in industrialized cities. Studies reveal an increased risk for Eastern European Jews and a decreased risk for Asian populations ([24]). The overall annual incidence is 3.4/100,000 ([26]). The incidence of AML increases with age, with a median of 68 years ([26]). It is less than 1/100,000/year for persons younger than 30 years of age, but it reaches 17/100,000 for persons 75 years of age; the incidence is higher in males than in females and in whites than in blacks (Fig. 79.1) ([26] , [27]). There is an increasing incidence of AML in the elderly, which is probably related to improved diagnosis, the recognition of AML after MDS, and longer life expectancy, resulting in increased environmental exposures ([28]). AML accounts for less than 15% of cases of leukemia in children younger than 10 years of age and 25 to 30% of cases between 10 and 15 years of age ([25] , [26]); in adults, AML accounts for 80 to 90% of cases of acute leukemia. Paradoxically, congenital leukemia is usually AML rather than ALL and is often monocytic, with a high incidence of extramedullary disease, particularly involving the skin and the central nervous system (CNS).

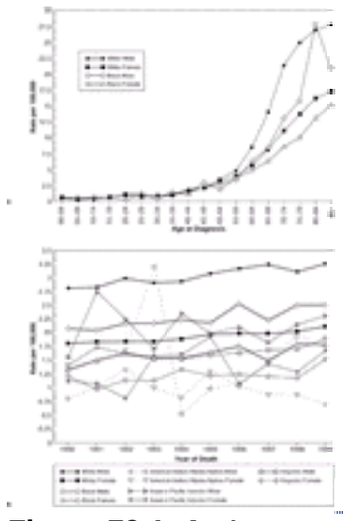

Figure 79.1. A: Age-specific incidence rates for acute myeloid leukemia (AML) by race (black/white) and sex for nine areas evaluated by the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute, 1973–1999. **B:** Age-adjusted mortality rates for AML by expanded race and sex by the SEER program, 1990–1999. Males predominate over females among all races, with the highest rate in white males (3.27/100,000 in 1999) and the lowest rate in Native-American/Alaskan females (0.73/100,000 in 1999). (Adapted from Ries LAG, Eisner MP, Kosary CL. SEER cancer statistics review, 1973–1999. Bethesda, MD: National Cancer Institute, 2002.)

Genetic factors are implicated in the pathogenesis of AML by virtue of its high incidence in patients with syndromes characterized by chromosomal abnormalities or instability or defective DNA repair ([29]). These disorders can be separated into congenital defects and marrow failure syndromes (Table 79.1) ([30]). They are usually recognized in childhood AML discussed in Chapter 81. Children with Down syndrome (trisomy 21) may have a transient leukemoid reaction and are also at a 20 times greater risk for development of acute leukemia, with a similar ratio of ALL to AML (4:1) as in other children ([30] , [31] and [32]). Acute leukemia in Down syndrome tends to occur 2 to 3 years earlier than the median age of 5 to 6 years in other children, and children with Down syndrome and AML often have acute megakaryoblastic leukemia (FAB M7) ([30] , [31] and [32]). Bloom syndrome is a rare autosomal-recessive disorder with excessive chromosomal breakage, including quadriradial formation and increased sister chromatid exchanges. Like the other syndromes with defective DNA repair, ataxia telangiectasia and xeroderma pigmentosum, Bloom syndrome is characterized by unique clinical features (telangiectatic erythema, photosensitivity, growth retardation, and immunodeficiency with or without mental retardation) and a predisposition to a variety of cancers ([33]). The gene for Bloom syndrome has been localized to chromosome 15q26.1 and encodes a protein with helicase activity that is central to DNA repair ([33]). Infantile monosomy 7 syndrome is a unique myelodysplastic syndrome of childhood that overlaps with juvenile CML and can evolve into aplastic anemia or AML ([34] , [35] and [36]). Both Klinefelter syndrome (XXY) and Turner syndrome (XO) are rarely associated with AML ([37] , [38]).

TABLE 79.1. Genetic Disorders Implicated in the Pathogenesis of Acute Myeloid Leukemia

Congenital Defects	Marrow Failure Syndromes
Down syndrome	Fanconi anemia
Bloom syndrome	Dyskeratosis congenita
Monosomy 7 syndrome	Shwachman-Diamond syndrome
Klinefelter syndrome	Amegakaryocytic thrombocytopenia
Turner syndrome	Blackfan-Diamond syndrome
Neurofibromatosis	Kostmann agranulocytosis
Congenital dysmorphic syndromes	Familial aplastic anemia

Neurofibromatosis has unique phenotypic features (café-au-lait patches, benign neurofibromata, freckling in intertriginous areas, skeletal abnormalities) and abnormalities of a specific gene, NF1, on the long arm of chromosome 17 at 17q11.2, which acts as a tumor-suppressor gene ([30] , [39]). Patients with neurofibromatosis have a predisposition to cancer, including malignant nerve sheath tumors, optic nerve gliomas, and myeloid leukemias, which tend to develop in the second decade of life ([40] , [41]). Other rare congenital syndromes associated with acute leukemia have unique dysmorphic features, usually in conjunction with a specific cytogenetic abnormality. Rubinstein-Taybi (broad thumbs and great toes, mental retardation, abnormal facies) is associated with breakpoints on chromosome 16p13.3 ([30] , [42]); Treacher-Collins syndrome (mandibulofacial dysostosis) has been associated with abnormalities of chromosome 5q31-34 ([30] , [43]), and Klippel-Feil syndrome (fusion of cervical vertebrae) and Goldenhar syndrome (hemifacial microsomia, radial defects) have autosomal-dominant inheritance. The latter is associated with abnormalities of chromosome 7 ([30] , [44]).

Marrow failure syndromes are addressed in Chapter 44 and Chapter 83 and include disorders listed in Table 79.1. Fanconi anemia (FA) is the most common disorder and also confers the highest risk of developing AML (approximately 9% risk) ([30] , [45] , [46]). FA was first described in 1927 ([45]); its association with leukemia was not reported until more than 30 years later ([47]). FA is an autosomal-recessive disorder with a slightly higher incidence in males ([30]). Four-fifths of cases are diagnosed between the ages of 2 and 13 years, with a median age of 7 years at diagnosis ([30] , [48]). Clinical factors are variable but often include café-au-lait spots, skeletal abnormalities with absent thumbs, short stature, microcephaly, mental retardation, and renal abnormalities ([30] , [48]). The cells in FA tend to exhibit spontaneous chromosome breaks. Karyotypes of bone marrow cells are often abnormal; monosomy 7 and rearrangements involving chromosome 1 are the most common findings ([47] , [48]). The diagnosis of FA can be confirmed by an increased frequency of chromosome breaks when the cells are exposed to clastogens such as mitomycin C or diepoxybutane ([30] , [46]). The best survival in FA is with marrow transplantation, but the preparative regimens must be modified because of excess toxicity in these

patients (Chapter 25).

Dyskeratosis congenita (Zinsser-Cole-Engman syndrome) is predominantly X-linked, with approximately one-half of patients developing marrow aplasia at a mean age of 10 years ([30]). Shwachman-Diamond syndrome is autosomal recessive, with pancreatic insufficiency, skeletal abnormalities, and a median age of onset for leukemia of approximately 8 years ([30] , [49]). Amegakaryocytic thrombocytopenia, which may be X-linked, and Blackfan-Diamond syndrome, a constitutional pure red cell aplasia, rarely precede AML ([30]). Patients with Kostmann syndrome and other congenital neutropenias have been treated with growth factor support, and data indicate that this intervention may promote leukemogenesis ([50]). Familial aplastic anemia may precede AML in a minority of cases. Acquired diseases with an increased risk for developing AML include myelodysplastic syndromes (Chapter 83), chronic myeloproliferative disorders (Chapters 84 to 87), aplastic anemia (Chapter 44), and paroxysmal nocturnal hemoglobinuria (Chapter 37).

Familial studies have demonstrated an increased risk of leukemia in family members of patients with leukemia but may be flawed by biases in reporting and methodologic weaknesses. No consistent mendelian pattern has been identified in most reports; however, the Li-Fraumeni syndrome, described in 1969, is an autosomal-dominant cancer family syndrome with an increased risk for sarcomas, breast cancer, and other neoplasms, including leukemia, caused by mutations in the p53 gene ([51] , [52]). The risk of familial leukemia may be increased with consanguinity or inherited chromosomal instability syndromes (e.g., FA). It is probably caused by one of two factors: a genetic predisposition within a family or a common environmental exposure ([30]). Constitutional chromosome abnormalities associated with AML include t(7;20) ([53]) and t(3;6), both of which are rare ([54]). Anticipation (onset at earlier age with each generation) has been recognized in rare autosomal-dominant AML; possible candidate genes are located at 21q22, 11q23, or 16q22 ([55]).

The classic method for determining inheritability of a disease is through twin studies and evaluation of human lymphocyte antigen (HLA) associations ([30]). Leukemia in twins was first reported in 1928, and further studies have demonstrated an increased risk in monozygotic twins ([56]). The clinical presentation is atypical, with leukemia usually occurring before 2 years of age, indicating the probability of an intrauterine event ([57]). Transfer of leukemia cells from one twin to the other through a common placental blood vessel is generally accepted as the explanation for neonatal leukemia in monozygotic twins ([30]). Although there are conflicting data about the risk of leukemia in association with specific HLA types, there is a suggestion of nonrandom genetic associations between HLA-C locus alleles and acute leukemia ([23] , [30]). Prospective studies of HLA associations using molecular genetic analysis in selected populations are needed to identify whether HLA typing can be used as a surrogate marker for risk of leukemia ([30]).

Environmental factors have also been implicated in the pathogenesis of AML (Table 79.2) ([5]). A possible link between solvents and leukemia was suggested by Vigliani ([58]) and confirmed by observations by Aksoy in shoe factory workers ([59] , [60]). Similar increases in incidence of leukemia have been reported in workers involved in organic synthesis and in rubber and paint manufacturing ([61] , [62]). Benzene is a solvent that can be absorbed through the skin and lungs and can accumulate in the body fat and neurologic tissues ([60]). Toxicity is related to cumulative dosage, and the risk of leukemia was high before safety controls were put into place in the workplace ([60]). Chromosome damage can occur at 1 to 10 ppm, and leukemogenic risk is considerable at 124 to 200 ppm ([60] , [63]). In surveys of factories in China, the leukemogenic risk was four to seven times higher in workers exposed to benzene than in the general population, and the average latency was 11.4 years ([60] , [62] , [64]). A dose response pattern was suggested with the highest risk in Chinese workers exposed at constant levels of 25 ppm or higher ([64]).

TABLE 79.2. Environmental Factors Contributing to Acute Myeloid Leukemia

Solvents (benzene)
Smoking
Ionizing radiation
Atomic bomb exposure
Nuclear power exposure
Medical radiation
Nonionizing radiation (?)
Chemotherapy
Alkylating agents
Topoisomerase II inhibitors
Other drugs
Chloramphenicol
Phenylbutazone

Smoking has been weakly associated with leukemia. Metaanalyses have estimated a relative risk for AML of 1.3 to 1.5 in smokers ([65] , [66]). This association could be partially caused by exposure to benzene in cigarettes ([60]). Tobacco smoke also contains other potentially leukemogenic chemicals, including urethane, nitrosamines, and radioactive compounds ([60]). Studies from the American Cancer Society, the Veterans Administration, and Seventh Day Adventists have identified an increase in the incidence of myeloid leukemia in smokers ([67] , [68]). The risk of developing AML is two to three times higher in male smokers who have exceeded 20 pack-years ([60] , [67] , [69]). Smokers of more than 40 cigarettes/day who develop AML have an increased incidence of unfavorable cytogenetic abnormalities, including -7/7q- and -5/5q- ([60] , [70]).

The leukemogenic effect of ionizing radiation was established in the early twentieth century: Roentgen discovered X rays in 1895; the first cancer was reported on the hand of a radiologist in 1902; and leukemia caused the death of Marie Curie in 1934 ([71]). Subsequently, an increased prevalence of leukemia was recognized in radiologists in the 1940s ([72]). Atomic bombs were released over Hiroshima and Nagasaki in 1945; the first report of leukemia appeared in 1952 ([73]), and long-term follow-up has indicated a latency period of 5 to 21 years ([60] , [74] , [75]). The primary carcinogenic effects of ionizing radiation are breaks in double-stranded DNA. The risk of leukemia correlates with radiation dosage and age at exposure, with a more rapid peak early in life (<15 years), as well as a more rapid decline than in those exposed at older ages (Fig. 79.2) ([60] , [76]). Fallout from atomic tests and exposure to nuclear reactors have been a concern in the second half of the twentieth century. Whereas little radioactivity was released into the environment at Three Mile Island, there was extensive exposure to radioactivity after Chernobyl ([77]). Although there are conflicting data on the impact of Chernobyl, there does appear to be an increased risk of leukemia associated with isolated events in which large amounts of radiation have been released into the atmosphere ([77] , [78] , [79] and [80]).

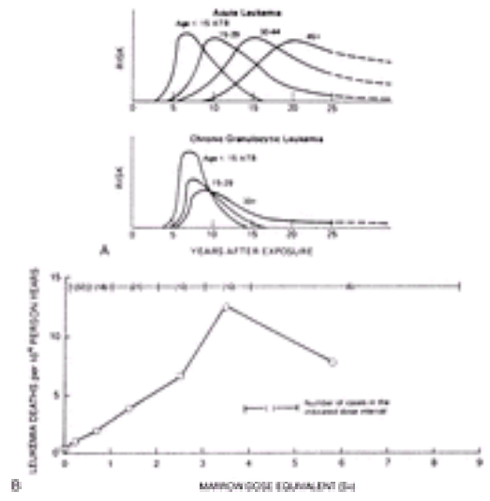

Figure 79.2. Risk of leukemia among atomic bomb survivors. **A:** Effect of age at exposure and the temporal pattern of developing leukemia according to cell type (acute vs. chronic granulocytic leukemia). [From Okada S, Hamilton HB, Egami N, et al., eds. A review of thirty years of Hiroshima and Nagasaki atomic bomb survivors. J Radiation Res 1975;16(Suppl):1–164.] **B:** Dose-response relationship among atomic bomb survivors. The leukemic risk increased with radiation dose except that a downturn was suggested after 4 Gy, possibly caused by killing of stem cells ([56]). ATB, at time of bomb. Radiation used for medical purposes was leukemogenic in the early twentieth century, when the carcinogenic effects of radiation were less well known. Diagnostic radiology, radiotherapy for benign and malignant diseases, and radionuclide exposure have been associated with leukemia ([77]). Although diagnostic radiographs are no longer considered to be associated with an increased risk, most studies of exposure during pregnancy have shown an increased risk of childhood leukemia ([77], [81]). Smith and Doll reported a fivefold increased risk of leukemia in patients with ankylosing spondylitis receiving a single dose of pelvic radiation; the risk peaked 3 to 5 years after radiotherapy ([82]). A twofold increased risk has been reported after pelvic radiation for menorrhagia, a treatment commonly used during the 1930s and 1940s ([83]). Small increases in risk have also been reported after radiation for tinea capitis ([84]) and peptic ulcer disease ([85], [86]).

Although radiation therapy is less leukemogenic than chemotherapy, leukemia has followed radiation and radioisotope therapy given for a variety of cancers. The risk of leukemia (latency period of 2 to 11 years) is approximately two times higher in patients who have received either radium implants or external beam radiation for cervical, ovarian, or endometrial cancer ([60], [86], [87]). Similarly, a twofold increase in risk has been reported in breast cancer patients receiving adjuvant radiotherapy compared to a tenfold increase in risk after chemotherapy; combined radiation and chemotherapy resulted in a 17-fold risk ([77], [88]). Radiation therapy has been associated with only a small increase in risk of leukemia in patients with Hodgkin and non-Hodgkin lymphomas, unless the radiation is extensive and encompasses a large volume of bone marrow ([89], [90] and [91]). Although there has been no increase in the risk of leukemia in patients treated with radioactive iodine (^{131}I) for hyperthyroidism, there have been reports of an increased incidence of leukemia in patients receiving higher ^{131}I dosages for thyroid cancer ([92]). In a randomized clinical trial, radioactive phosphorus (^{32}P) administered to patients with polycythemia vera resulted in a 6% incidence of leukemia, compared to a 1% incidence after phlebotomy alone and an 11% incidence in patients treated with chlorambucil ([93]). Thorotrast, a radioactive contrast agent containing thorium (^{232}Th), has also been associated with an increased risk of leukemia ([94]).

Radon, cosmic radiation, and nonionizing radiation have been implicated as possible etiologic factors in AML but are unlikely to contribute a major risk. Although radon exposure has been linked to AML in some studies ([95]), there has been no association in other studies ([96]); moreover, there has not been an increased incidence of leukemia in underground miners who are exposed to large amounts of radon ([97]). Cockpit crew members with a long flying history were observed to have an increased risk of AML, suggesting a possible leukemogenic role for cosmic radiation ([98]). Nonionizing radiation from the electromagnetic fields of household appliances and electrical power lines has generated public concern, but there are insufficient data to confirm any link to acute leukemia ([77]).

Drugs have been linked to AML, with the most convincing evidence pertaining to the antineoplastic agents, particularly alkylating agents and topoisomerase II inhibitors ([99], [100]). Alkylating agents cause point mutations, which result in activation of oncogenes such as RAS, as well as chromosomal deletions and unbalanced translocations involving chromosomes 5 and 7 ([99], [101]). Topoisomerase II inhibitors result in loss of a critical enzyme involved in DNA replication, leading to balanced chromosomal translocations involving 11q23 or 21q22, with the formation of chimeric fusion genes ([102]). Most therapy-related leukemias occur 3 to 10 years after initial therapy, with a longer latency for alkylating agents (5 to 9 years) than for topoisomerase II inhibitors (6 months to 5 years) ([99]). A third syndrome of therapy-related leukemias has been described in patients who develop AML with prognostically favorable cytogenetics, including t(15;17) and inv(16). These patients have received either alkylating agents or topoisomerase II inhibitors often with radiation, have a short latency period (22 to 29 months, median), and have chemosensitivity similar to that of *de novo* patients ([103]). Therapy-related ALL has also been described and usually involves an 11q23 translocation ([104]).

The best described and most common therapy-related leukemias are associated with alkylating agents. The most extensively studied disease is Hodgkin lymphoma ([101], [105], [106], [107], [108], [109] and [110]), but leukemia has occurred after therapy of multiple neoplasms treated with alkylating agents, including breast cancer ([100], [111]), multiple myeloma ([112]), ovarian cancer ([113]), and non-Hodgkin lymphoma. Similarly, MDS or acute leukemia may develop in myeloproliferative disorders, particularly polycythemia rubra vera, as well as nonneoplastic disorders such as collagen vascular diseases treated with alkylating agents. With the increased use of autologous transplants as salvage therapy for hematologic neoplasms, secondary MDS and AML are being recognized and are associated with a poor prognosis ([114]). In Hodgkin lymphoma, radiation can be a contributing factor, but the risk in patients who have received radiation only is usually less than 1.0%, compared to 1.5 to 5.0% for those who received both types of therapy, particularly when chemotherapy is administered as salvage therapy for relapse after radiation ([115], [116]). The risk of leukemia after Hodgkin lymphoma ranges from an 11- to a 136-fold increase over that in the normal population ([116]).

The time of leukemia onset after alkylating agent exposure has ranged from 1 to 28 years and is most commonly in the 5- to 9-year range ([100], [117]). The risk is greater and the latency is shorter in older patients with Hodgkin lymphoma (>50 years of age) ([100], [107]). Splenectomy has been suggested as a contributing factor to leukemia in some, but not all, studies ([107], [117]). Elevation in the mean corpuscular volume may be an early sign of development of myelodysplastic changes, and up to two-thirds of patients who develop leukemia have a preceding myelodysplastic phase that lasts approximately 6 months ([100]). In secondary MDS, there may be more hypoplasia and fibrosis than are observed in *de novo* MDS ([117]). When there is evolution to acute leukemia, Auer rods are rare, and assignment of FAB subtype is difficult ([100]). Clonal cytogenetic abnormalities are often complex; the most common single abnormality is monosomy 7(-7), followed by del(5q) and -5 ([100], [116], [117] and [118]).

Topoisomerase II inhibitors, particularly etoposide and teniposide, were recognized as leukemogenic agents in survivors of lung cancer ([119], [120]), germ cell cancer ([121], [122], [123] and [124]), acute lymphocytic leukemia ([125], [126]), neuroblastoma ([127]), and osteosarcoma ([128]) in the 1980s. Large cumulative dosages and prolonged courses have been implicated as increasing the risk of leukemia. The latency period was short, with most cases occurring between 6 months and 5 years after initial therapy. There was no myelodysplastic phase, and the majority of cases were myelomonocytic (FAB M4) or monoblastic (FAB M5). The cytogenetic abnormality usually consists of a translocation involving 11q23 or, less commonly, 21q22 ([99], [100], [117]). Patients with AML and 11q23 abnormalities after topoisomerase II inhibitors tend to be chemosensitive but are rarely long-term survivors because of a high relapse rate ([117]).

Other drugs and chemicals as well as parental and occupational exposures have been suggested as leukemogenic ([24], [117]). Maternal alcohol consumption during pregnancy has been associated with an increased risk of AML, particularly in young children ([129]). Additionally, it has been suggested that maternal exposure to topoisomerase II inhibitors in the environment [flavonoids, catechins, caffeine, quinolones, thiram (agricultural fungicide), and podophyllin (used to treat genital warts)] may be associated with an increased risk of infant leukemia with abnormalities involving the mixed lineage leukemia (MLL) gene at chromosome band 11q23 ([24], [130], [131]). Antibiotics, including chloramphenicol ([132], [133]) and analgesic agents, including phenylbutazone and derivatives such as sulfinpyrazone ([134]), have been associated with marrow suppression, aplastic anemia, agranulocytosis, and, more rarely, AML ([5]). The leukemia tends to follow marrow suppression, similar to what

is seen with benzene and radiation-induced leukemia ([117], [132]). Chloroquine, methoxypsoralen, and lysergic acid diethylamide have also been reported to be associated with AML ([24]). AML has been reported in workers exposed to rubber, paint, embalming fluids, pesticides, ethylene oxide, gasoline, poultry, and electrical wiring ([24], [117]); however, many of these associations are difficult to substantiate because of small numbers and problems in epidemiologic reporting.

CLINICAL PRESENTATION

Symptoms related to AML are caused by failure of normal hematopoiesis, resulting in anemia and increased risk of infection and bleeding (Chapter 72). The most common complaint is nonspecific fatigue or malaise that usually has been present for several months. Pallor and weakness are caused by anemia. Fever is common and is the presenting feature in 15 to 20% of patients; it is often associated with sweats and results from infection secondary to neutropenias or from leukemia itself. Hemorrhagic signs and symptoms, including petechiae, epistaxis, and easy bruising, may be found in up to one-half of patients at diagnosis and correlate with the severity of thrombocytopenia or the presence of disseminated intravascular coagulation (DIC), most commonly observed in APL. Up to 50% of patients experience weight loss, but it is usually not severe. Bone pain occurs in less than 20% of patients. Although organomegaly and adenopathy have been reported in up to one-half of patients with AML, these signs are more common in ALL.

Leukemia skin infiltration, or leukemia cutis, occurs in up to 13% of patients with AML during the course of the disease and is associated with involvement of other extramedullary sites, including the CNS ([135]). The lesions are often violaceous and nodular and are more common in patients with a monocytic component to the AML (Fig. 79.3). The skin lesions may precede the diagnosis of AML. They are radiosensitive, but patients should usually be treated with systemic chemotherapy ([135]). Gum infiltration is also characteristic of acute monocytic leukemia (AMoL) (Fig. 79.4). Approximately one-half of children with congenital leukemia have gray-blue nodular skin lesions whose appearance is reminiscent of a blueberry muffin ([136]). Benign skin lesions associated with AML include Sweet syndrome ([137]) and pyoderma gangrenosum ([138]); these are generally painful and responsive to steroids.

Figure 79.4. Swollen and spongy gums in a patient with acute leukemia. See Color Plate. (Courtesy of Dr. Stuart Salmon, Division of Hematology/Oncology, Vanderbilt University Medical Center.)

The incidence of CNS disease at diagnosis is difficult to determine because lumbar puncture is not always performed ([139], [140], [141], [142], [143] and [144]). Meningeal disease has been reported to develop in 5 to 20% of children ([142], [143]) and up to 16% of adults ([144]) with AML. The increased use of HiDAC lessens the risk of CNS leukemia in AML, as evidenced by a 2.2% incidence in a review of 410 patients from a single institution ([145]). CNS disease is associated with young age (<2 years), hyperleukocytosis, and the AMoL variants ([139], [140]). It is often asymptomatic but may be associated with headache or cranial nerve palsies, particularly V and VII. Ocular involvement may result in blindness and suggests meningeal involvement. Intracerebral masses rarely coexist with leukemia meningitis but have been reported in FAB M4Eo in association with inv(16)(p13q22) ([141]). Prophylactic CNS therapy is not given routinely to patients with AML; however, some clinicians advocate prophylaxis, particularly in children and in patients with AMoL or with white cell counts greater than 100,000 cells/mm ^{3} ([143]).

Myeloid (granulocytic) *sarcoma*, or *myeloblastoma*, is an extramedullary tumor that occurs in 2 to 14% of cases of AML ([146], [147], [148], [149], [150] and [151]). These tumors are called *chloromas* because some appear green or turn green in dilute acid secondary to expression of MPO ([149], [150] and [151]). The tumors are usually localized; they often involve bone, periosteum, soft tissues, lymph nodes, or skin. Common sites are the orbit and the paranasal sinuses, but other sites reported include the gastrointestinal tract, genitourinary tract, breast, cervix, salivary glands, mediastinum, pleura, peritoneum, and bile duct ([147], [151]). Granulocytic sarcomas may occur at diagnosis of AML or may precede the diagnosis; they have also been seen in association with myelodysplastic syndromes or myeloproliferative disorders and usually predict transformation to acute leukemia ([150], [151]). The diagnosis may be missed but should be suspected if eosinophilic myelocytes are present in hematoxylin and eosin–stained biopsy sections. Imprint preparations can be helpful. The diagnosis can be made if Auer rods are detected or if myeloid origin is confirmed by cytochemical or immunohistochemical methods ([149]). Although granulocytic sarcomas are radiosensitive, systemic chemotherapy is warranted in most cases ([149]). Testicular infiltration is less common in AML than in ALL, with an incidence of 1 to 8%; the management of testicular involvement includes bilateral testicular irradiation and systemic chemotherapy ([151], [152] and [153]). Neutropenia is common in patients with granulocytic sarcoma; the marrow may be hypocellular and often reveals increased blasts.

Other organ systems may be involved with AML. Cardiac abnormalities are usually related to electrolyte imbalances, particularly hypokalemia, but may result from direct involvement of the conduction system or infiltration of vessel walls ([151], [154]). Pulmonary symptoms occur in patients with leukostasis, infections related to neutropenia, or hemorrhage due to thrombocytopenia ([151]). Gastrointestinal symptoms also include infections, particularly perirectal abscesses and typhlitis, a necrotizing colitis related to leukemia infiltration of the bowel wall. Management of typhlitis is controversial and has included supportive care with antibiotics and nasogastric suction as well as surgical intervention ([155], [156]). Obstructive jaundice has occurred secondary to granulocytic sarcoma, and patients with AML rarely present with hepatic failure ([151], [157]).

LABORATORY FINDINGS

Blood counts vary widely among patients with AML ([158]). The leukocyte count is elevated in more than one-half of patients but is more than 100,000 cells/mm ^{3} in less than 20%. Blasts usually are identified on peripheral smear; Auer rods and Phi bodies are considered pathognomonic of AML. *Phi bodies* are fusiform or spindle-shaped rods similar to Auer rods and require special stains for hydroperoxidases ([159]). Aleukemic leukemia (no blasts in the peripheral smear) is rare, particularly if buffy coat smears are examined.

Cytopenias result from hematopoietic failure and contribute to symptoms and signs. Neutropenia is present in most AML patients. Galton et al. indicated that a normal neutrophil count is more common in patients with monocytic variants of AML and suggested that a correlation exists between the normal neutrophil count and maturation of the leukemia cells in AMoL ([160]). Giant lysosomes are rarely noted in neutrophils of patients with AML; their presence has been called a *pseudo–Chédiak-Higashi syndrome* ([161]). Anemia is common in AML and is predominantly normochromic and normocytic. Nucleated red cells and reticulocytopenia are often present. Erythroid precursors in the marrow are often megaloblastic, particularly in acute erythroleukemia or in AML that has evolved from a myelodysplastic syndrome. Thrombocytopenia, which may be severe at diagnosis, can be associated with DIC. Thrombocytosis is rarely identified, but large bizarre platelets may be

found; megakaryocytes are usually decreased in number and may have abnormal nuclear morphology, including monolobate and hyperlobate forms.

DIC is more common in AML than in ALL; it is most common in APL, as initially described by Hillstad (Chapter 82) ([16], [162]). The cause of DIC is thought to be release of tissue factor–like procoagulants from the azurophilic granules within the leukemia cells. DIC is typically seen at presentation or during induction chemotherapy for APL ([163], [164]). Other mechanisms such as excessive fibrinolysis and secretion of interleukin (IL)-1 by the leukemia cells may contribute to bleeding in these patients ([165], [166]). DIC is manifested clinically by diffuse oozing of blood and is characterized by thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, and deficiency of coagulation factors, including factor V and factor VIII ([167]).

Hyperuricemia has been noted in up to 50% of patients with AML and can also be associated with tumor lysis, although the latter is more common in ALL ([168]). Appropriate hydration and administration of allopurinol can prevent complications of tumor lysis, which may occur during induction chemotherapy, most often in the setting of hyperleukocytosis. Serum lactate dehydrogenase levels may be elevated, particularly in monocytic (M4/M5) subtypes, but to a lesser degree than is observed in ALL ([169]).

Levels of lysozyme are elevated, particularly in variants of AML with a predominantly monocytic component, including AMoL and AMMoL. Excess lysozyme (muramidase) may cause proximal renal tubular damage, which results in hypokalemia. Pickering et al. recorded hypokalemia in 12 of 50 patients with AML; all 12 had either AMoL or AMMoL, and 10 had lysozymemia ([170]). Other factors that can contribute to hypokalemia in AML include potassium uptake by rapidly proliferating cells, as well as drugs, particularly antibiotics and diuretics. Hyperkalemia can occur in association with hyperuricemia and tumor lysis. Patients with AML may have hypercalcemia ([171]), but hypocalcemia is more common and may rarely be caused by acceleration of bone formation by leukemia cells ([172]).

Hyperleukocytosis, arbitrarily defined as a blood blast count greater than 100,000/mm ^{3}, is rare in AML without a monocytic component; it occurs more commonly in cases of AMoL and AMMoL ([150], [173], [174]). Hyperleukocytosis is associated with leukostasis in the lung, CNS, or genitourinary tract ([175], [176]). Pulmonary leukostasis is manifested by dyspnea, tachypnea, rales, interstitial infiltrates, and respiratory failure and is associated with a poor prognosis ([176], [177] and [178]). Symptoms of CNS leukostasis are headaches and blurred vision. Fatal intracerebral hemorrhage may occur ([139]). Priapism, enlarged kidneys, hyperuricemia, and renal failure are features of genitourinary involvement ([151]). Cardiovascular involvement may result in congestive heart failure and myocardial infarction ([151], [176]). Spurious laboratory data associated with hyperleukocytosis include a falsely elevated platelet count (because white cell fragments are counted as platelets), pseudohypoxemia caused by oxygen consumption by leukemia cells, falsely prolonged coagulation tests, pseudohyperkalemia, and pseudohypoglycemia ([179], [180] and [181]). Artifactual lowering of the PO_2 and glucose may be averted by placing blood samples on ice and performing the tests without delay ([150]).

Hyperleukocytosis is associated with a less favorable prognosis because of its association with CNS hemorrhage, respiratory failure, CNS involvement, and a higher relapse rate ([139], [175], [182], [183]). Therapeutic options to decrease the risks of leukostasis in patients with hyperleukocytosis include leukapheresis, administration of large doses of hydroxyurea, and immediate initiation of induction chemotherapy ([150], [174], [183]). Red cell transfusions should be minimized initially because increases in blood viscosity may worsen leukostasis. However, platelet transfusions are needed to decrease the risk of hemorrhage, because leukapheresis exacerbates thrombocytopenia. No controlled clinical trials have defined the optimal management of hyperleukocytosis. Leukapheresis is advocated if symptoms of leukostasis are present ([178]). Moreover, leukapheresis is advocated to decrease the risk of leukostasis in patients with hyperleukocytosis, as the onset of leukostasis may be abrupt, and, once initiated, it may be fulminant and irreversible ([150]). Recent studies suggest leukapheresis is associated with decreased early mortality and improved complete remission (CR) rates, but not with improved survival ([182], [183]). Because leukapheresis is only a temporary measure to decrease the risk of leukostasis, chemotherapy should also be initiated as rapidly as possible ([150]).

BIOLOGIC FEATURES

AML is a marrow-based neoplasm composed of immature or blast cells, the nonlymphoid differentiation of which can be demonstrated by morphology, cytochemical and immunologic studies, and electron microscopy ([184], [185]). Cytogenetic analysis ([186]), isoenzyme studies ([187]), and restriction fragment length polymorphism analysis ([188], [189]) have confirmed the clonal nature of AML. The neoplastic cells in AML, in contrast to CML, usually show only limited maturation, presumably because of abnormalities in the regulation of growth and differentiation that inhibit the cells from becoming fully differentiated and functionally competent. Cells appear to be blocked or “frozen” in early stages of maturation. Glucose-6-phosphate dehydrogenase analysis of leukemia cells from female heterozygotes demonstrates clonal abnormalities in either a single cell line or more than one cell line (e.g., myeloid and erythroid or myeloid and megakaryocytic), indicating that the leukemia events can involve either restricted lineage or multipotential stem cells ([190], [191], [192], [193] and [194]). The former pattern is more common in patients younger than 45 years of age, whereas the latter has been identified primarily in patients older than 60 years of age ([187], [194]).

AML is a complex and heterogeneous disease in all respects (cytologic features, stage of differentiation, antigen expression, chromosome abnormalities, gene expression, growth regulation, and response to treatment). Prior classification systems are inadequate because they do not reflect this biologic heterogeneity. Recently, the WHO has attempted to develop an improved classification system ([20], [21] and [22]). The development of *in vitro* bone marrow culture systems, the recognition of specific oncogenes, and the increasing sophistication of clinical and research techniques should allow improved classification of AML, along with more effective means of therapy. The next section is a brief overview of the characteristics of leukemia colony growth, response to soluble factors, cell growth parameters, and gene expression.

Colony Assays and Growth Factors

In vitro colony assays have been useful in studying growth and differentiation of normal and neoplastic cells ([195], [196], [197] and [198]). Murine multipotent progenitor cells can be identified as colony-forming units spleen. In mice and humans, a progenitor cell common to granulocytes, erythrocytes, monocytes, and megakaryocytes (colony-forming unit granulocyte-erythrocyte-monocyte-megakaryocyte) is similar to colony-forming unit spleen but has little or no self-renewal capacity, suggesting that the colony-forming unit granulocyte-erythrocyte-monocyte-megakaryocyte is at a later point in differentiation. Cells that have undergone further differentiation are committed to one or two lineages. These include burst-forming unit erythroid, colony-forming unit erythroid, colony-forming unit granulocyte-monocyte (CFU-GM), or colony-forming unit megakaryocyte. Leukemia cells also form clusters or colonies; early clonogenic assays measuring leukemia cell growth in leukocyte feeder layer systems varied from 30 to 98% cloning efficiency ([199], [200] and [201]). Moore et al. described five patterns of growth: no growth, small clusters, large clusters, an abnormally high ratio of clusters to colonies, and rare colonies with normal cluster to colony ratio ([202], [203]). No growth, large clusters, and an abnormally high ratio of clusters to colonies are associated with a poor response to chemotherapy; however, subsequent studies suggest different prognostic correlations, with a favorable response for no growth and small cluster growth and an unfavorable prognosis for the large cluster growth ([201], [204], [205]). The use of improved culture systems with the addition of soluble factors has shown a higher yield, with growth of clonogenic cells in 80 to 90% of cases ([206], [207]). The *in vitro* growth pattern of leukemia cells is a parameter that is not used clinically at present.

Leukemia cells, like normal cells, generally require growth factors for survival and proliferation ([208], [209]). Early studies showed improved colony growth with the addition of phytohemagglutinin or phytohemagglutinin-conditioned medium from peripheral blood leukocytes. In recent years, numerous growth factors for hemopoietic cells have been identified, and many have been cloned. These factors include granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), multiple ILs, Steel factor (KIT ligand), thrombopoietin (TPO) (c-mpl ligand), erythropoietin, and Fms-like tyrosine kinase 3 (FLT-3)/FLT-3 ligand ([210], [211], [212], [213] and [214]). Growth factor action is complex; it may be restricted or may affect multiple lineages at multiple stages of differentiation. Growth factors may act synergistically with each other and with other soluble substances. These factors may be supplied exogenously in a paracrine fashion by stromal cells, or, in the case of leukemia cells, autocrine growth factor production may be present ([215]). Transfection of normal mouse marrow cells with the IL-3 gene also produces autonomous growth ([216]). The effect of growth factors is predominantly proliferative, although G-CSF can induce differentiation ([217]), and FLT-3 ligand can prevent apoptosis of AML cells ([218]). The antiapoptotic effects of FLT-3 ligand are augmented when it is combined with G-CSF or GM-CSF and correlate with low bax and high bcl-2 levels ([218]).

Numerous other growth factors may be important in leukemogenesis and may have an impact on therapy. Steel factor (also known as *KIT ligand* and *stem cell factor*) is a restricted growth factor that cannot drive hematopoietic progenitor cells into cell cycle but may play a role in chemotherapy resistance by preventing apoptotic cell death ([219]). Inhibitory factors include transforming growth factor (TGF)-ß1 and tumor necrosis factor (TNF), but their effects are often difficult to interpret because of their induction of other regulatory molecules ([220], [221]). TGF-ß1 suppresses growth factor–dependent colony formation in normal and *de novo* AML cells; however, it

does not inhibit colony formation in AML after MDS because of a reduction in TGF-ß1 binding sites on AML cells arising from MDS ([222]). Theoretically, this loss of TGF-ß1 inhibition results in dysregulation of proliferation and could contribute to the chemoresistance of MDS-related AML.

Coculture experiments indicate that normal CFU-GM are inhibited by leukemia blasts ([223]). Inhibition correlates at least in part with the production of a soluble factor with leukemia inhibitory activity produced by small, nonadherent, light-density cells isolated from patients with several types of leukemia ([224] , [225]). Leukemia inhibitory activity is cytotoxic to normal CFU-GM in the S-phase of the cell cycle, but CFU-GM from the marrow of patients with AML are resistant, possibly because of a shift of CFU-GM out of cycle. A second distinct substance, leukemia-associated inhibitor, has also been described and is produced by Fc receptor–positive medium-density cells ([226] , [227]). Leukemia-associated inhibitor reversibly inhibits S-phase CFU-GM and reduces the tritiated thymidine labeling index of leukemia blasts ([227]). A long-term culture system simulates the microenvironment of marrow and includes stromal fibroblasts, endothelial cells, and macrophages—all of which can produce cytokines affecting leukemia growth ([228]). Increased bone marrow vascularization measured by microvessel density occurs in AML and correlates with vascular endothelial growth factor (VEGF) and VEGF receptor levels on AML blasts ([229]). Understanding the microenvironment and the diverse effects of growth factors and inhibitors on leukemia cells should lead to improved therapy.

Cell Growth Studies

Multiple parameters, including a decreased thymidine labeling index, a lower mitotic rate, and a low proportion of cells in S and G_2 + M phases in DNA cell cycle analysis, indicate that leukemia cells often proliferate more slowly than their normal counterparts ([230]). One explanation for these findings is the existence of proliferative and nonproliferative pools of neoplastic cells. Autoradiographic and ultrastructural studies show that most labeled, proliferative blasts are large, whereas small blasts are not proliferating ([231] , [232] , [233] and [234]). When large marrow blasts divide, they give rise predominantly to small nondividing cells that are released preferentially into the peripheral blood ([233] , [235]). The small blasts are capable of reentering the cycle and transforming into larger cells to replenish the proliferative compartment. An increase in cell mass is seen when the number of small cells reentering the cycle outnumbers those lost to cell differentiation and death.

Investigators have attempted to correlate kinetic parameters (e.g., percentage S-phase, total cycling time, and cell production rate), measured by flow cytometric analysis, *in vitro* uptake of tritiated thymidine, or *in vivo* bromodeoxyuridine infusion, with attainment of remission and remission duration ([230] , [236] , [237] , [238] , [239] , [240] and [241]). The results have been conflicting. Leukemias with a high percentage of cells in S-phase often are more responsive to chemotherapy, but some patients with rapidly cycling leukemias not only achieve marrow aplasia quickly after chemotherapy, but also have rapid repopulation of the marrow by leukemia blasts ([238]). Patients whose leukemia cells have low levels of proliferative activity have better survival than those with high levels ([205] , [230]). The presence of longer S-phases and total cycling times in relapsed rather than in newly diagnosed AML suggests that resistance to chemotherapy may result from selection of slowly cycling clones ([239]). Recent data correlate a lower CR rate with the presence of increased AML cells in G_0-phase at day 9 after the start of chemotherapy ([241]).

Leukemogenesis

Leukemogenesis is a heterogeneous, multistep process that results in a block of differentiation, increased proliferation, and inhibition of apoptosis through genetic dysregulation. There is evidence for at least a “two-hit” model of leukemogenesis ([242]). Fusion genes [AML1/ETO, CBF/SMMHC, and promyelocytic leukemia (PML)/retinoic acid receptor (RAR)-a] involved in specific structural chromosomal abnormalities [t(8;21), inv(16), and t(15;17), respectively] impair differentiation and apoptosis, whereas another class of genetic changes, mutations in FLT-3 and N-RAS, promotes proliferation. Neither class of genetic changes is sufficient to cause leukemia by itself, and genetic changes may be mutually exclusive in that two translocations or inversions or two genetic mutations rarely occur in the same case of leukemia ([242] , [243]).

Supporting evidence for the cooperation of the two classes of mutations in leukemogenesis stems from the finding of FLT-3 gene mutations in 30 to 40% of APL patients ([242] , [244]). FLT-3 mutations are predominantly small tandem duplications within the gene, resulting in the duplication of amino acids within the juxtamembrane domain of the receptor. These duplications cause loss of autoinhibition and result in constitutive tyrosine kinase activity ([242]). FLT-3 mutations are also commonly found in cases of AML patients with normal cytogenetics and likely represent “second-hit” genetic changes that impair hematopoiesis ([242]). FLT-3 mutations in these patients are associated with a poor prognosis (see section Prognosis).

A common component of leukemogenesis and drug resistance is inhibition of apoptosis. There are two pathways for apoptosis, both of which result in caspase activation: (a) the receptor-mediated pathway, which involves the TNF family of death receptors, and (b) the mitochondrial-mediated pathway regulated by the bcl-2 family of proteins ([245]). Resistance to apoptosis is often mediated by aberrant genes; BCR-ABL, fusion genes resulting from MLL translocations, and PML/RAR-a all inhibit apoptosis ([245]). The tyrosine kinase inhibitor STI 571 (Gleevec, Novartis) serves as the model for specifically targeting a gene blocking apoptosis. Classic chemotherapy kills malignant cells through activation of apoptosis; however, resistance often develops in the apoptotic pathways. Ongoing investigations are directed at developing new agents to target the molecular biologic processes involved in preventing apoptosis of leukemia cells.

CLASSIFICATION OF ACUTE MYELOID LEUKEMIA

The WHO classification of acute leukemias and MDS has evolved away from the FAB classification, which is based on morphology, to include not only morphology, but also clinical, immunophenotypic, and cytogenetic features ([20] , [21]). There are five major categories recognized by the WHO: (a) AML with recurrent genetic abnormalities; (b) AML with multilineage dysplasia; (c) AML and MDS, therapy related; (d) AML not otherwise categorized; and (e) acute leukemia of ambiguous lineage (Table 79.3). In the WHO, the refractory anemia with excess blasts in transformation (20 to 30% blasts) category of MDS has been eliminated based on evidence that the survival pattern of patients with marrows with 20% or more blasts is similar to those of patients with marrows with 30% or more blasts ([246]).

TABLE 79.3. Classification of Acute Myeloid Leukemia (AML)

AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22); (AML1/ETO)
AML with abnormal bone marrow eosinophils inv(16)(p13q22) or t(16;16)(p13;q22); (*CBFß/MYH11*)
Acute promyelocytic leukemia (AML with t(15;17)(q22;q12) (*PML/RAR*-a) and variants
AML with 11q23 (mixed lineage leukemia) abnormalities
AML with multilineage dysplasia
After a myelodysplastic syndrome or myelodysplastic syndrome/myeloproliferative disorder
Without antecedent myelodysplastic syndrome
AML and myelodysplastic syndromes, therapy-related
Alkylating agent–related
Topoisomerase type II inhibitor–related (some may be lymphoid)
Other types
AML not otherwise categorized
AML minimally differentiated
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic and monocytic leukemia
Acute erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia

Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Acute leukemia of ambiguous lineage

AML with recurrent genetic abnormalities includes AML with t(8;21)(q22;q22), inv(16)(p13;q22) or t(16;16)(p13q22), t(15;17)(q22;aq12), or translocations or structural abnormalities involving 11q23. The first three variants occur in younger people and have a more favorable response to therapy. Two clinical subgroups of patients have translocations involving 11q23: AML in infants and therapy-related leukemia usually occurring after treatment with DNA topoisomerase II inhibitors. AML with recurrent genetic abnormalities is discussed in the section Clinicopathologic Syndromes in the context of the FAB morphologic subtype with which the abnormalities correlate.

AML with multilineage dysplasia is associated with unfavorable cytogenetics, including -7/del(7q), -5/del(5q), +8, +9, +11, del(11q), del(12p), -18, +19, del(20q) +21, and, less often, translocations t(2;q11) and t(1;7) and those involving 3q21 and 3q26 ([20], [21]). Abnormalities in the 3q26 region may be associated with increased platelet production. It is more common in older patients and has a poor response to therapy. Dysplasia must be present in 50% or more of the cells of at least two lineages. There is frequent aberrant expression of CD56, CD7, or both.

AML not otherwise categorized includes AML that does not fulfill criteria for the other groups and essentially reflects the morphologic and cytochemical features and degree of maturation used in the FAB classification with the exception that 20% (rather than 30%) or more blasts in the marrow is sufficient for diagnosis of acute leukemia; the abnormal promyelocytes in APL and the promonocytes in AML with monocytic differentiation are also considered blast equivalents. This category includes, in addition, acute basophilic leukemia, acute panmyelosis with myelofibrosis, and myeloid sarcoma (see section Clinical Presentation).

AML and myelodysplastic syndromes, therapy related, are discussed in the section Epidemiology. Acute leukemia of ambiguous lineage is diagnosed when blasts lack sufficient lineage-specific antigen expression to classify them as myeloid or lymphoid and is discussed in the section Immunophenotypic Classification.

Morphologic Subtypes

The FAB classification identified eight subtypes of AML based on morphology and cytochemical staining, with immunophenotypic data in some instances (Chapter 77) ([17], [181], [247], [248], [249] and [250]). Four types (M0, M1, M2, M3) are predominantly granulocytic and differ according to the extent of maturation. M4 is both granulocytic and monocytic, with at least 20% monocytic cells, whereas M5 is predominantly monocytic (at least 80% monocytic cells). M6 shows primarily erythroid differentiation with dysplastic features including megaloblastic changes, and M7 is AMgL identified by the presence of megakaryocyte antigens demonstrated by flow cytometry or immunohistochemistry, the presence of platelet peroxidase, or a demarcation membrane system on ultrastructural studies. Problems with the FAB classification include interobserver variability, lack of definitive criteria for some cases of AML, and poor correlation with survival ([250], [251]). Additionally, correlations with immunophenotyping, cytogenetics, and molecular diagnosis have not been fully defined. There are morphologic subtypes that are not precisely defined by the FAB, including hypocellular AML and mixed lineage acute leukemia ([252], [253], [254] and [255]). Eosinophilic leukemia, basophilic leukemia, and mast cell leukemia are rare, overlap with myeloproliferative disorders, and are also not recognized by the FAB classification. The WHO classification recognizes chronic eosinophilic leukemia with the overlapping hypereosinophilic syndrome, and acute basophilic leukemia and the spectrum of mast cell disease, including mast cell leukemia (Chapter 87) ([21]).

Immunophenotypic Classification

The nonlymphoid derivation of AML is confirmed by the presence of antigens expressed during myelomonocytic differentiation, including CD13 (My7), CD14 (Mo2), CD15 (My1, LeuM1), CD33 (My9), CD117 (c-kit), and MPO; erythroid antigens (glycophorin A, CD71); and megakaryocytic antigens, including CD41 (platelet glycoprotein IIb/IIIa), CD42b (platelet glycoprotein Ib), CD61 (platelet glycoprotein IIIa), and factor VIII antigen ([256]). The stem cell marker CD34 (My10, HPCA-1) is present on blasts in 40 to 65% of cases of AML ([257]). Surface markers in most cases have not correlated well with the FAB classification or with prognosis ([258], [259]). More than 90% of cases of AML express CD33 or CD13, 80 to 90% express HLA-DR, and less than 25% express CD15; CD11b and CD14 are more variably expressed but tend to be present in monocytic (M4/M5) subtypes ([257]). Some antigens have also been associated with morphologic and cytogenetic subsets: CD2 with M4Eo (abnormal 16q22) ([260], [261]); absence of HLA-DR (major histocompatibility complex class II) and of CD34 with M3 [t(15;17)] ([262]); and presence of CD19, CD34, and CD56 with M2 [t(8;21)] ([263], [264]).

The morphologic associations and prognostic significance of surface markers have been variable; antigen expression should be interpreted only in the context of other clinicopathologic features. CD34 is expressed more often in less differentiated subtypes (M0, M1; M5, poorly differentiated) in many series ([265], [266] and [267]); it has also been described as more common in monocytic (M4/M5) than in granulocytic (M1, M2, M3) subtypes ([260]). CD34 is generally a poor prognostic marker, particularly when observed in the elderly, after MDS, or in association with expression of the multidrug resistance gene (MDR-1) ([266], [268], [269]); however, CD34 is also commonly expressed in FAB M2 AML with the t(8;21) chromosomal translocation ([270]) and in FAB M4Eo with inv(16) ([260]), both of which have a favorable prognosis.

Lymphoid antigens are expressed on blasts in 10 to 30% of cases of AML, and their expression has often been implicated as having prognostic significance, but their presence should be interpreted in the context of all available information ([267]). Terminal deoxynucleotidyl transferase (TdT) is a DNA polymerase normally expressed in early lymphoid cells of the bone marrow and the thymus. The reported incidence of TdT positivity in AML varies widely (0 to 55%; average, 18%) in part because of the use of different methods and because of different cut-off values for positivity ([271]). In approximately one-half of studies of adult patients with AML, TdT expression is correlated with a poor prognosis, but usually in the setting of poorly differentiated AML and often in association with CD34 expression ([271], [272], [273] and [274]). Expression of the lymphoid antigens, CD2 (T cell) and CD19 (B cell), has been associated with a good prognosis ([275]), but CD19 expression has also been associated with a poor prognosis ([276]). CD19 is associated with a good prognosis when present in AML with t(8;21) ([275]) and a poor outcome when coexpressed with CD34 in the absence of favorable cytogenetics findings ([276]). CD7, which is present on most mature T and natural killer lymphocytes, is present in 15 to 20% of cases of adult AML and has been associated with a poor prognosis, usually with less differentiated subtypes (M0/M1) and expression of CD34, MDR-1, or TdT ([277], [278]). CD56, a cell-surface glycoprotein identical to the neural cell adhesion molecule, is more commonly observed in patients with AMoL, t(8;21), and trisomy 8 and with expression of CD11b, CD14, and CD19 ([278]). CD56 expression is also present in rare leukemias that have a precursor myeloid/natural killer cell phenotype ([279]). The lymphocyte activation antigens CD25 and CD30 are often observed in AML after MDS ([222]). Immunophenotyping is important in confirming the nonlymphoid nature of the leukemia and in recognizing subsets of AML; its prognostic impact can be interpreted only in the context of other factors and, ideally, in large prospective series.

The WHO classification includes a category of acute leukemias of ambiguous lineage in which blasts lack sufficient evidence to classify as myeloid or lymphoid ([21]). The reported incidence of these unclassifiable acute leukemias is highly variable because of lack of uniform diagnostic criteria, the use of different monoclonal antibody panels, and the failure to recognize the lack of lineage specificity of antibodies ([252], [253], [254] and [255]). Although up to 20% of patients with acute leukemia may have biphenotypic or mixed lineage features as detected by immunologic and molecular genetic techniques, the actual unclassifiable acute leukemia should be less than 4% of AML ([21]).

Acute leukemias of ambiguous lineage are divided into three groups. Undifferentiated acute leukemias, the first group, lack morphologic or immunologic differentiating features. The blasts often express HLA-DR, CD34, and CD38 and may express TdT and CD7. Bilineal acute leukemia, the second group, has two populations of blasts expressing distinct lineage markers of myeloid or lymphoid origin or, less frequently, B- and T-cell lineage. These leukemias may evolve into biphenotypic acute leukemia. In the third group, biphenotypic acute leukemia, blasts coexpress myeloid and lymphoid (B- or T-cell) antigens. Blasts very rarely express myeloid, B-, and T-cell antigens. Leukemia cells may reflect normal early multipotential or pluripotential stem cells that have a limited capacity to express antigens of multiple lineages (“lineage promiscuity”), or the leukemia cell may have aberrant lineage differentiation (“lineage infidelity”) ([253], [280]). Rearrangements of the T-cell receptor or the immunoglobulin chain genes are usually absent in AML with lymphoid antigen expression ([281], [282]), although they have been described, usually in association with karyotypic abnormalities such as t(9;22), 11q23, or 14q32 translocations ([283], [284], [285], [286] and [287]).

The clinical significance and therapeutic implications of biphenotypic antigen expression remain undefined because uniform criteria for the diagnosis of biphenotypic

leukemia have not been established. The expression of at least one cross-lineage marker is common in AML (20 to 30% of cases) and in ALL (5 to 46% of cases). For this reason, the diagnosis of biphenotypic leukemia should be reserved for cases in which there is ambiguity of lineage assignment. Scoring systems have been proposed to more precisely define biphenotypic leukemia ([254], [288]). A morphologic “tip-off” to the presence of a bilineal or biphenotypic acute leukemia is the presence of a mixed population of small blasts resembling lymphoblasts and large blasts. Biphenotypic acute leukemias respond less favorably to therapy than either AML or ALL; their prognosis is usually related to an association with other adverse features ([255]).

Cytogenetics

Nonrandom acquired chromosome abnormalities are present in most patients with AML and correlate with prognosis (Chapter 4). The first descriptions of karyotypic changes in AML occurred in the 1950s; approximately one-half of patients with AML were found to have cytogenetic abnormalities in the 1970s when studies using banding were reported. With technical improvements, recent series have reported abnormal karyotypes in 55 to 78% of adults and 79 to 85% of children with AML ([289], [290], [291], [292], [293], [294], [295], [296], [297], [298] and [299]). Approximately 55% of patients with AML have only a single cytogenetic abnormality (15 to 20% have a gain or loss of a single chromosome as the only change); the remaining 45% have two or more changes ([289]). The most common recurring cytogenetic abnormalities in AML include t(15;17), t(8;21), inv(16), +8, +21, del(5q), -7, -8, 11q23 translocations, and 12p11-13 abnormalities ([296], [297], [298] and [299]).

Correlation of cytogenetics and clinicopathologic data has led to the recognition of distinct subtypes of AML and has helped to identify prognostic groups (Table 79.4) ([236], [290], [291], [296], [297], [298], [299], [300] and [301]). Techniques such as PCR, fluorescence *in situ* hybridization, and comparative genomic hybridization have improved the ability to recognize molecular lesions that involve oncogenes and tumor-suppressor genes and have further defined subtypes of AML (Chapter 76). The best described subtypes of AML have recurring genetic abnormalities, which primarily consist of balanced translocations, occur in younger patients, tend to correlate with morphology, and have a favorable prognosis. These include t(8;21), inv(16) or t(16:16), and t(15;17) and its variants. AML with t(8;21) tends to have blasts with maturation, often with azurophilic granules and occasionally with very large granules (pseudo–Chédiak-Higashi granules) ([21]). AML with inv(16) or t(16;16) usually is associated with monocytic differentiation and abnormal marrow eosinophils ([21], [141]). APL with t(15;17) and its variants are suggested by the presence of hypergranular promyelocytes in association with DIC, but it is also present in a microgranular (hypogranular) subtype (Chapter 82) ([302], [303]). Other cytogenetic abnormalities associated with morphology in AML include translocations of 11q23 with monoblastic features ([21], [304]); t(6;9) and del(12p) with marrow basophilia ([305], [306]); abnormalities of 3q21-26 with abnormal platelets and thrombocytosis ([307], [308]); and t(9;22), 14q32, or 11q23 with MLLs ([274], [275], [304], [309], [310]).

TABLE 79.4. Primary Chromosome Aberrations in Acute Myeloid Leukemia

Type of Rearrangement	Genes Involved	Hematologic Clinical Features	Prognosis
t(1;3)(p36;q21)		Preceded by MDS, M1, M4, dysmegakaryocytopoiesis	Poor
t(1;7)(q10;q10)		Preceded by MDS, M1, M4, genotoxic exposure	Poor
t(1;11)(p32;q23)	AF1p, MLL	M0, M5	Poor
t(1;11)(q21;q23)	AF1q, MLL	M4, M5, infants	Poor
t(1;22)(p13;q13)		M7, thrombocytopenia, hepatosplenomegaly, bone marrow fibrosis	Poor
inv(3)(q21;q26); t(3;3)(q21;q26)	EVI1, ribophorin 1	Preceded by MDS, M1, M4, M6, abnormal megakaryocytopoiesis, thrombocytosis	Poor
t(3;5)(q25, 1;q35)	MLF1, NPM	M6, megakaryocytosis, Sweet syndrome	Intermediate to poor
t(3;21)(q26;q22)	EVI1, MDS1, or EAP; AML1	No FAB preference, genotoxic exposure	Poor
+4		M1, M2, M4; subcutaneous tumors	Poor
5/del(5q)		No FAB preference, genotoxic exposure	Poor
t(5;17)(q35;q12)	NPM, RAR-a	M3	Poor
t(6;9)(p23;q34)	DEK, CAN	Preceded by MDS; M2 and M4, bone marrow basophilia	Poor
t(6;11)(q27;q23)	AF6, MLL	M4 and M5; localized infections	Poor
t(7;11)(p15;p15)	HOXA9, NuP98	M2 with Auer rods	Intermediate
-7/del(7q)		No FAB preference; genotoxic exposure	Poor
+8		M2, M4, and M5; preceded by MDS	Intermediate to poor
t(8;16)(p11;q13)	MOZ, CBP	M5, erythrophagocytosis	Poor
t(8;21)(q22;q22)	ETO, AML1	M2 with Auer rods, eosinophilia, myeloblastoma	Good
t(9;11)(p21-22;q23)	AF9, MLL	M5	Intermediate
t(9;22)(q34;q11)	ABL, BCR	M1 and M2; biphenotypic, rare	Poor
t(10;11)(p11-15;q13-23)	AF10, MLL	M5	Poor
+11	MLL	M1, M2	Poor
t(11;16)(q23;p13)	MLL, CBP	M4, M5, infants	Poor
t(11;17)(q23;q25)	MLL, AF17	M2, M4, and M5	Poor
t(11;17)(q23;q21)	PLZF, RAR-a	M3	Intermediate
t(11;19)(q23;p13)	MLL, ENL, ELL	M4 and M5; biphenotypic	Poor
t/del(11q23)	MLL	M5, biphenotypic, genotoxic exposure	Poor
t/del(12p)		No FAB preference, genotoxic exposure	Poor
i(12)(p10)		Concurrent germ cell tumors	Poor
t(12;22)(p13;q11)	TEL, MN1	Preceded by MDS, M1, M4, M7	Poor
+13		No FAB preference	Poor
t(15;17)(q22;q11)	PML, RAR-a	M3, M3v, DIC	Good
inv(16)(p13;q22), t(16;16) (p13;q22), del(16)(q22)	MYH11, CBFß	M4Eo, central nervous system disease	Good
t(16;22)(p111;q22)	FUS, ERG	No FAB preference	Poor
i(17)(q10)		Preceded by MDS, no FAB preference	Poor
del(20q)		No FAB preference	Poor
+21		No FAB preference	Intermediate
+22		M4	Intermediate

FAB, French/American/British; MDS, myelodysplasia.
NOTE: See Chapter 76 for description of the genes and Mitelman F, Johansson B, Mertens F, eds. Mitelman database of chromosome aberrations in cancer. http://cgap.nci.nih.gov/chromosomes/mitelman.
Adapted from Heim S, Mittelman F. Cancer cytogenetics, 2nd ed. New York: Wiley, 1995:74–75.

Certain chromosomal abnormalities have been associated with MDS and secondary or treatment-related AML. In general, they do not correlate well with specific subtypes of MDS (Chapter 83) ([311], [312], [313] and [314]). Cytogenetic abnormalities have most often been associated with refractory anemia with excess blasts (RAEB)

and RAEB in transformation, which are the subtypes most likely to transform to acute leukemia (314). As noted, RAEB in transformation is now grouped in AML by the WHO. MDS or AML after administration of alkylating agents has a high frequency of involvement of chromosomes 5 and 7 and of complex cytogenetic abnormalities (100 , 116 , 117 and 118). Topoisomerase II inhibitor administration is associated with AMoLs with 11q23 and, less commonly, 21q22 translocations (99 , 100 , 117). As MDS progresses to leukemia, there is often clonal chromosomal evolution. The most common secondary changes involve chromosomes 5, 7, 8, 9, 21, 22, X, and Y (289 , 296).

CLINICOPATHOLOGIC SYNDROMES

The WHO classification (Table 79.3) recognizes four major categories of AML defined by specific genetic abnormalities, prior MDS, prior cytotoxic therapy, and a not otherwise categorized group that retains the morphology-based FAB classification. In addition, acute leukemia of ambiguous lineage is included. In the subsequent paragraphs, clinicopathologic syndromes are briefly described with an emphasis on morphologic, clinical, and genetic features.

Minimally Differentiated Acute Myeloid Leukemia

Although minimally differentiated AML was recognized earlier, criteria for FAB M0 were developed in 1991 (18 , 248 , 315). The blasts in these cases cannot be recognized as myeloid based on morphology and cytochemistry, but immunophenotyping demonstrates myeloid antigens. These cases are agranular and lack Auer rods. By definition, the diagnosis of AML M0 requires less than 3% of MPO-positive and Sudan black B-positive cells but more than 20% of leukemia cells expressing myeloid antigens (CD13, 33, 117) (248 , 315). Of note, lymphoid-associated antigens (CD2, 7, 19) and TdT are commonly expressed in AML M0 (315 , 317). Although no specific cytogenetic abnormality has been associated with AML M0, it often has a complex karyotype with abnormalities of chromosome 5 or 7, similar to MDS and secondary leukemia; trisomies of chromosomes 8 and 13 are also commonly recognized (316 , 317). AML M0 tends to occur in older patients (median age, 60 years), and there is often a stem cell pattern of antigen expression, with CD34 and TdT positivity (318). The CR rate and survival in AML M0 are poor due in part to the association with adverse prognostic factors, particularly unfavorable karyotypes (316 , 317 , 318 and 319).

Acute Myeloid Leukemia without Maturation

AML (FAB M1) is defined by a predominance (>90%) of myeloblasts without evidence of maturation (<10% promyelocytes or other, more mature cells). The presence of Auer rods is variable. At least 3% of the blasts are reactive with Sudan black or MPO. The blasts express myeloid antigens, including CD13, CD14, or CD33. Like AML M0, AML M1 must be distinguished from other types of acute leukemia, including ALL (FAB L2), acute monoblastic leukemia (M5a), acute megakaryoblastic leukemia (M7), and acute basophilic leukemia (21 , 251). AML M1 makes up 10 to 20% of cases of AML (320 , 321) and is more common in adults than in children; the median age is 45 to 50 years (21 , 251). Constitutional symptoms are common, and hepatosplenomegaly and lymphadenopathy occur in up to one-third of patients (21). Approximately one-half of patients present with leukocytosis, and one-fourth have leukopenia; most patients are anemic and thrombocytopenic (21 , 251 , 321). There has been no specific cytogenetic marker associated with AML M1, but it generally is regarded as chemosensitive and prognostically favorable unless adverse features, such as hyperleukocytosis, are present.

Acute Myeloid Leukemia with Maturation and with t(8;21)

The t(8;21)(q22;q22) is reported in 29 to 40% of cytogenetically abnormal cases of AML with maturation (FAB M2) (21 , 251 , 322). Between 5 and 12% of all AML patients have this syndrome; most are children and young adults (300). Clinical features include splenomegaly, an association with chloromas, and, often, anemia and thrombocytopenia at diagnosis. First described in 1973, t(8;21) may be predicted by typical morphology, including prominent Auer rods, marrow eosinophilia with salmon-colored granules, cytoplasmic globules, and vacuoles (Fig. 79.5) (322). Immunophenotypic markers include the presence of myeloid antigens, increased expression of the natural killer cell–associated antigen CD56, and, less commonly, the B-cell antigen CD19 (323). CD34 is also expressed in t(8;21) with coexpression of CD19 and CD56; CD2 and CD7 are usually absent (252 , 270 , 323).

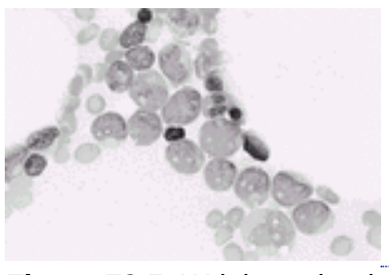

Figure 79.5. Wright-stained marrow smear from acute myeloid leukemia–M2 with t(8;21). Blasts are associated with maturing myeloid elements and numerous eosinophils with salmon-colored granules. See Color Plate.

The two genes involved in t(8;21) are AML1 (also known as RUNX1) at 21q22 and ETO (also called CDR and MTG8) at 8q22 (324 , 325) (Chapter 76). They form a fusion gene on the derivative 8 chromosome that is best recognized by reverse transcriptase PCR (RT-PCR) (326). The fusion transcript can be detected even in patients in long-term remission and, therefore, cannot be used as a marker to predict relapse (326 , 327). The AML1 gene is also involved in t(3;21)(q26;q22), a rare balanced translocation observed in blast crisis of CML and therapy-related AML (328 , 329), in t(12;21) with the TEL gene in ALL (330), and in a variety of other rare translocations seen in patients with AML or MDS, including t(1;21)(p36;q22), t(5;21)(q13;q22), and t(17;21)(q11;q22) (289).

The t(8;21) usually occurs in *de novo* AML and generally predicts an excellent response to chemotherapy, with a high remission rate and a long survival, particularly after HiDAC intensification therapy (331 , 332). However, some patients, particularly children and patients with granulocytosis (>2000 cells/mm ^{3}) or extramedullary disease, have high relapse rates and a poor survival (297 , 333 , 334). Paraspinal masses may result in spinal cord compression with irreversible neurologic sequelae and should be treated with radiation therapy (334). Expression of the CD56 antigen on AML cells with t(8;21) is also associated with a shorter disease-free survival (DFS) (335). For the most part, t(8;21) is regarded as a favorable prognostic factor. These patients are generally not treated with allogeneic transplantation in first remission.

Acute Promyelocytic Leukemia

Between 5 and 10% of patients with AML present with APL, which is characterized by a reciprocal translocation involving chromosomes 15 and 17 (Chapter 82) (336). These patients are usually young, with a median age of 30 to 38 years, although APL rarely occurs before age 10 (251). The disease was recognized in the 1950s and was associated with early mortality often caused by intracranial hemorrhage (162 , 337). Up to 90% of patients present with hemorrhagic manifestations secondary to DIC (251). Leukopenia is usually present in the more common hypergranular APL, whereas leukocytosis tends to occur in the microgranular variant (21 , 251). The leukemia cells characteristically have numerous prominent granules, which may obscure the nucleus along with bundles of Auer rods (“faggot cells”). The microgranular variant of APL, which represents approximately 20% of APL cases, has granules that are small and more difficult to recognize by light microscopy but can be identified by electron microscopy or cytochemical stains (302 , 303). The immunophenotype of APL is distinct from those of other AML subtypes; the myeloid antigens CD13 and CD33 are present, but HLA-DR is absent. The microgranular variant commonly expresses CD34 $^+$ and the T-cell antigen CD2 (262 , 338).

The genes involved in the t(15;17) of APL are the RAR-a gene on chromosome 17q12 and the PML gene, initially called myl, on chromosome 15q22 (339 , 340). Two fusion genes are formed: PML/RAR-a on 15q+ and its reciprocal, RAR-a/PML, on 17q-. The former is found in all patients, and the latter occurs in approximately two-thirds of patients. There are three different genomic breakpoints in the PML gene on chromosome 15: bcr1 (approximately 55% of cases), or long form; bcr2 (approximately 5%), or variable form; and bcr3 (approximately 40%), or short form. Data indicate that the short form is associated with pediatric APL, higher leukocyte counts, the microgranular variant, and a worse prognosis (338 , 341 , 342 and 343). Whereas cells with the long and short forms are responsive to ATRA, cells with the variable form have reduced sensitivity to ATRA and also more commonly have additional cytogenetic abnormalities (344). Other cytogenetic variants of APL involving

fusion of genes with RAR-a include t(11;17)(q23;q11) [promyelocytic leukemia zinc finger (PLZF) gene], t(5;17)(q23;q11) [nucleophosmin (NPM) gene], and t(11;17)(q13;q11) [nuclear matrix–associated (NuMA) gene] ([345], [346] and [347]). APL with t(11;17)(q23;q11) is resistant to ATRA, whereas AML with t(5;17)(q23;q11) is responsive ([344]). Molecular studies using RT-PCR can confirm the presence of t(15;17) in virtually all cases of APL; its absence after therapy appears essential for long-term remission ([347], [348], [349] and [350]).

The therapy of APL dramatically changed with the introduction of ATRA into clinical trials in Shanghai in 1986 ([351], [352]). In early trials using ATRA, patients with t(15;17) had a 95% CR rate ([335], [353], [354] and [355]). ATRA is given orally, usually at doses of 45 mg/m ^{2}/day, and induces hematologic remission without aplasia within 1 to 3 months, but it does not induce a molecular remission, so that chemotherapy remains essential in induction and the postremission phase. There is a body of data indicating that aggressive anthracycline therapy improves the cure rate of APL and that HiDAC may even have a detrimental effect ([356]).

ATRA works, in part, through terminal differentiation of APL blasts; its effectiveness is strictly correlated with the expression of the PML/RAR-a fusion transcript (Fig. 79.6) ([335], [347], [348]). ATRA improves DIC parameters often within 48 hours. The main complication associated with ATRA is the retinoic acid syndrome, which occurs in up to one-fourth of patients, particularly in those with high leukocyte counts ([357]). It is characterized by a capillary leak syndrome with fever, respiratory failure, renal impairment, and, in some patients, cardiac failure (Chapter 82). The retinoic acid syndrome can be treated or prevented with high-dose ste-roids or chemotherapy, either hydroxyurea or induction chemotherapy ([357], [358]). The mechanisms by which ATRA prevents DIC are not fully understood but probably relate to protection of endothelium from procoagulants such as tissue factor ([359]).

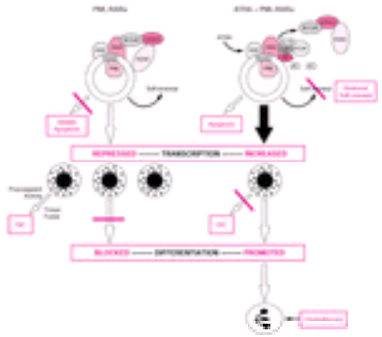

Figure 79.6. Modulation of promyelocytic leukemia/retinoic acid receptor-a (PML/RAR-a) by pharmacologic doses of all- *trans*-retinoic acid (ATRA). On the left, the leukemia model of acute promyelocytic leukemia involves PML/RAR-a interacting with corepressor (CoR) complex and repressing transcription. CoR is composed of three types of proteins: the nuclear receptor corepressor (N-CoR), the mSin3A or mSin3B, and histone deacetylase (HDAC). On the right, pharmacologic dosing of ATRA leads to release of CoR and recruitment of coactivator (CoA) complex, which promotes transcription. CoA is a multiprotein complex and includes the nuclear receptor coactivator (ACTR), the CREB binding protein (CBP)/adenoviral E1A-associated protein p300 (P300), P300/CBP-associated factor (P/CAF), and transcriptional intermediary factor (TIF-1). P/CBF, P/CAF, and ACTR have histone acetylase activity. In the absence of ATRA, RAR/retinoic X receptor (RXR) is associated with CoR, which represses transcription through deacetylation of histones. On binding of ATRA to retinoic acid, CoR is dissociated from RAR/RXR, and CoA binds to the receptor heterodimer, acetylates nucleasomes, and promotes transcription. AC, acetylated histones; DIC, disseminated intravascular coagulation; RARE, retinoic acid response element.

Although APL had a poor prognosis in early reports, in part because of its association with DIC, more recent data indicate an excellent response to therapy, with an overall good prognosis ([335], [336], [355], [360]). The management of the hemorrhagic diathesis associated with APL has always been controversial but has become less so with the use of ATRA, which shortens the period of time for bleeding and lessons the degree of risk ([361]). Heparin had been advocated to control DIC in APL, but no controlled trials are available to prove its efficacy ([361], [362], [363] and [364]). Others have advocated the use of antifibrinolytic agents (e-aminocaproic acid, tranexamic acid, aprotinin) if fibrinolysis is present, as evidenced by a decrease in a $_2$-plasmin inhibitor ([365], [366]), but their efficacy, like that of heparin, has not been verified. If fibrinogen is low, transfusion support with platelets, fresh frozen plasma, and cryoprecipitate is indicated for patients with APL and DIC.

Chinese investigators have also identified arsenic trioxide (As $_2$O $_3$) as effective therapy for APL ([367]). Western studies have confirmed CR rates of 90% in relapsed or refractory APL ([368]). Although the mechanisms have not been completely described, As $_2$O $_3$ at different concentrations induces partial differentiation and apoptosis of APL cells and also causes histone acetylation ([369]). Because As $_2$O $_3$ works by a different mechanism and may be synergistic with other agents, present studies are evaluating its role in APL regimens using ATRA and chemotherapy ([369]). Monoclonal antibodies, HuM 195 and gemtuzumab ozogamicin, have also been effective in APL (*vide infra*) ([370], [371]).

Acute Myelomonocytic Leukemia with Abnormal Eosinophils and Inversion of Chromosome 16

In approximately 5 to 10% of patients with AML, eosinophil precursors with abnormal morphology, cytochemical reactivity, and ultrastructure are present in association with monocytosis and a myeloblastic/monoblastic infiltration in the bone marrow. The median age is 40 to 45 years; organomegaly is common, and leukocytosis is present in most patients with hyperleukocytosis (>100,000 cells/mm ^{3}) in 20 to 25% ([141], [251]). CNS disease and leukemia cutis are common. The immature eosinophils have a monocytoid nucleus and a mixture of eosinophilic and large atypical basophilic granules (Fig. 79.7). Staining with Sudan black, periodic acid-Schiff (PAS), and chloroacetate esterase with nonspecific esterase can identify the neoplastic cell. Well-formed central crystalloids characteristic of eosinophilic granules are absent on ultrastructural examination. By flow cytometry, all cases of AML M4Eo express the panmyeloid marker CD13 and the stem cell antigen CD34, but there is variable expression of other myeloid/monocytic markers, including CD11b, CD11c, CD14, and CD33. There is also frequent expression of the T-lymphoid marker CD2, along with HLA-DR ([261]).

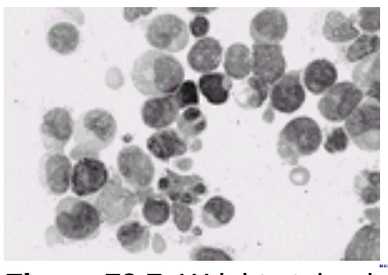

Figure 79.7. Wright-stained marrow smear from patient with M4Eo and an inv(16). Myeloblasts, monoblasts, and abnormal eosinophils with large basophilic granules, as illustrated here, are typically present in this variant. See Color Plate.

The syndrome was first described in 1983 in five patients with a deletion of the long arm of chromosome 16 ([372]). In subsequent reports, almost all patients have had a pericentric inversion of chromosome 16 [inv(16)(p13;q22)], whereas a minority of patients have had a balanced translocation between the two copies of chromosome 16 [t(16;16)(p13.1;q22)] ([373]). Cloning of the 16p and 16q breakpoints has identified the two genes involved: MYH11, which codes for smooth muscle myosin heavy chain, and core-binding factor (CBF) ß (also known as PEBP2ß), which codes for the ß subunit of CBF, a heterodimeric transcription factor involved in murine leukemogenesis and in T-cell receptor gene expression ([374], [375]). CBFa (?PEBP2a), which dimerizes with CBFß to form CBF, is identical to AML1, which binds directly to DNA and is involved in the t(8;21) in AML M2; CBFß does not bind DNA but increases the DNA-binding affinity of AML1. Thus, two of the most prevalent karyotypic abnormalities detected in *de novo* AML, t(8;21) and inv(16), result in the disruption of a single transcription factor, CBF (Chapter 76). CBFß-MYH11 fusion transcripts are detected by RT-PCR in typical AML M4Eo, but also in approximately 10% of patients with AML M4 without eosinophilia ([375], [376] and [377]).

The CR rate of AML with inversion of chromosome 16 to chemotherapy has been higher than for most other subtypes of AML, and its prognosis for DFS is good, so allogeneic transplantation is often considered after relapse rather than as therapy in first remission ([378]). AML with inversion 16 has a higher risk of CNS relapse, but the use of HiDAC intensification therapy decreases the incidence of CNS disease and may serve as CNS prophylaxis ([378]). As with AML/ETO, the absence of CBFß may not be required for prolonged clinical remission ([375]), but residual disease may be monitored by quantitative RT-PCR ([377]).

Acute Monocytic Leukemia (FAB M5a and M5b)

AMoL accounts for 2 to 10% of AML cases ([300], [379]). M5 is subdivided into M5a, poorly differentiated (>80% monocytic cells including monoblasts), and M5b, well differentiated (80% monocytic, predominantly promonocytes and monocytes) ([380]). Patients with M5a tend to be younger (75% <25 years of age) than those with M5b, but both include a wide age range ([251]). Monocytic precursors are recognized by their fluoride-inhibitable nonspecific esterase positivity and expression of CD14 and CD4 (dim expression) but not CD2. Monoblasts may be recognized by staining with antibodies to lysozyme and to CD68 (KP1) ([251]). Cytogenetic abnormalities in M5 are not specific but often consist of chromosome 11 and 9 or 19 translocations. Balanced translocations involving 11q23 occur in both *de novo* and secondary AML, primarily as myelomonocytic (M4) or monocytic (M5) subtypes. The gene involved on chromosome 11 is called *mixed lineage leukemia* and has homology to the *Drosophila trithorax* gene ([381]). More than 25 different partner genes for MLL have been identified ([21]). In t(9;11) and t(11;19), the amino terminus of the MLL gene is fused to either of two homologous genes, AF9 or ENL, from chromosomes 9q21 and 19p13, respectively ([382]).

Extramedullary disease is more common in AMoL than in other subtypes of AML and includes cutaneous lesions, gum infiltration, and CNS disease ([383]); CNS involvement has been reported in 3 to 22% of patients. Leukocytosis is a common finding, present in 10 to 30% of patients. The frequency of DIC is second only to that in APL, and DIC may be exacerbated when therapy begins. Elevated levels of lysozyme are found in more than two-thirds of patients and may contribute to renal insufficiency or proteinuria. Although some disagreement exists about the prognosis of AMoL in relation to other subtypes of AML, results of several studies suggest that AMoL is associated with poor prognostic factors and has a shorter duration of response ([380], [383]). Although 11q23 translocations are often associated with a poor prognosis, t(9;11) is more favorable than the others ([290], [297]).

Erythroleukemia (FAB M6)

Erythroleukemia accounts for less than 5% of cases of AML and is characterized by a prominent component of erythroblasts. Erythroid/myeloid leukemia (M6a) has 50% or more erythroid precursors in the nucleated population and 20% or more myeloblasts in the nonerythroid population. In pure erythroid leukemia (M6b), 80% of the marrow cells are immature erythroids without a significant number of myeloblasts. Erythroid precursors commonly have cytoplasmic vacuolization, nuclear abnormalities, and megaloblastoid features. PAS may stain erythroid elements in a diffuse or globular pattern. Auer rods are present in myeloblasts in up to two-thirds of patients ([251]).

Erythroleukemia usually occurs in patients 50 years of age or older and is more common in men ([380]). Aneuploidy is found in nearly two-thirds of patients, and cytogenetic abnormalities, particularly in association with secondary erythroleukemia, often involve chromosome 5 or 7 ([301], [384]). The presenting complaints are constitutional, including fatigue, malaise, and other complaints related to anemia, but in approximately one-third of patients, bone pain may be a major symptom ([380]). Hypergammaglobulinemia and positive tests for rheumatoid factor, antinuclear antibody, and Coombs may be found in patients with bone pain ([385]). Data are conflicting regarding prognosis in erythroleukemia, but in general, it appears to be less favorable than that of other subtypes of AML. The inferior prognosis is related in part to the associations with older patient age and with secondary leukemia.

Acute Megakaryocytic Leukemia (FAB M7)

AMgL was added to the FAB classification in 1985 and represents 5 to 10% of cases of AML ([251], [380], [386], [387]). Morphologically, AMgL can be confused with the L2 subtype of ALL or with AML M1. Cytoplasmic blebs suggestive of megakaryocyte differentiation may be present on the blasts. Myeloid surface markers CD13 or CD33 may be positive, and CD34 is often absent. The diagnosis depends on the expression of at least one platelet antigen (CD41, CD42b, CD61, or factor VIII–related antigen) on the leukemia cells. The bone marrow may be difficult to aspirate and may have significant fibrosis. AMgL may present as *de novo* leukemia, secondary leukemia after chemotherapy, or transformed myeloproliferative disorders and myelodysplastic syndromes. Cytogenetic abnormalities are heterogeneous but include abnormalities of chromosome 8 and chromosome 21; secondary leukemias usually have abnormalities of chromosomes 5 and 7 ([301], [380]). A subset of AMgL is found in infants who present with extensive organomegaly and have a nonrandom chromosome abnormality, t(1;22)(p13;q13) ([388]). The two genes involved are one twenty-two (OTT), which is related to the *Drosophila* split-end family of proteins, and megakaryocytic acute leukemia (MAL), which is involved in chromatin organization ([389]).

Although data are limited, the clinical presentation of AMgL is not substantially different from that of other subtypes of AML. Fever is common, and organomegaly is noted infrequently. Cytopenias are usually present, but approximately 30% of patients have platelet counts that exceed 100,000/µl ([380]). Platelet function studies usually indicate impaired aggregation responses. Serum lactate dehydrogenase levels are often elevated. Osteosclerotic and osteolytic lesions have been demonstrated radiographically ([380], [390]).

Prognosis in AMgL appears to be poor, although systematic information is limited. Some cases of M7 are probably included in the description of acute myelosclerosis, which was reported in 1979 before the establishment of the criteria for AMgL ([391]). Acute myelosclerosis was associated with a fulminant clinical course and survival of less than 1 year. Patients with AMgL may have either a transient illness, as in neonates with Down syndrome, or a slowly progressive disease that follows a myeloproliferative disorder ([392]). Patients with Down syndrome who develop AML usually have either M6 or M7 subtype and have a good prognosis with therapy (Chapter 81) ([393]).

Other Clinicopathologic Syndromes

Acute panmyelosis with myelofibrosis in the WHO classification has replaced acute myelosclerosis or acute myelofibrosis noted in the section Acute Megakaryocytic Leukemia (FAB M7) ([21]). This is a very rare form of AML and is not well defined. Patients have pancytopenia and constitutional symptoms. There is no or minimal splenomegaly. Marrow is hypercellular with various degrees of hyperplasia of the three cell lineages; clusters of late-stage erythroids may be prominent. Dysplastic changes, including hypolobated megakaryocytes with dispersed chromatin, are present. Clusters of immature cells are present, and the degree of marrow fibrosis is variable. If the proliferative process is predominantly myeloblasts and fibrosis is present, the leukemia should be classified as AML of the appropriate cell types with “myelofibrosis.”

Acute basophilic leukemia is very rare. Cutaneous disease, organomegaly, lytic bone lesions, and symptoms of hyperhistaminemia may be present. Blast nuclei are oval, round, or bilobed, and there are variable numbers of coarse basophilic cytoplasmic granules that on electron microscopy have features of basophils or mast cell granules. The characteristic cytochemical stain is metachromatic positivity with toluidine blue and, in addition, diffuse acid phosphatase positivity and, in some cases, block PAS positivity. Blasts are often negative for Sudan black B, MPO, and nonspecific esterase. Blasts express myeloid antigen CD13, CD33, and CD34 and also HLA-DR; CD9 is usually present. Involvement of 12p or t(6;9), which occurs in some AML with increased basophils, has not been described. Some cases may represent blast crisis of CML or *de novo* Ph^+ acute leukemia, and prognosis is uniformly poor ([394]).

The t(6;9)(p21;q34) is a rare variant of AML (<1%) that was initially described in a young age group (20 to 30 years of age) with basophilia and a poor response to therapy. It is usually of the FAB M2 or M4 subtype and is often preceded by MDS ([395]). The genes involved in this translocation are the DEK gene on chromosome 6p23 and the CAN gene on chromosome 9p34 (Chapter 76).

AML presenting with a normal platelet count or thrombocytosis may involve abnormalities of the long arm of chromosome 3: inv(3)(q21q26) and t(3;3)(q21;q26) ([307], [396], [397] and [398]). The critical gene involved at 3q26 is EVI1 (ecotropic viral integration site 1) ([399], [400]). Clinically, the patients have a young median age and may have preceding MDS. Morphologically, these cases are difficult to subtype and have included M1, M4, and M6 ([252]). Abnormal megakaryocytes are characteristic, and the

prognosis is poor.

More clinicopathologic syndromes of AML are being recognized in conjunction with the discovery of genes involved in specific translocations. For example, AML with t(3;5)(q25.1;q35) has been difficult to subclassify by FAB, but approximately one-fourth of patients have erythroleukemia (M6), and the marrow often has trilineage dysplasia and abnormal megakaryocytes. Unlike patients with inv(3), patients with t(3;5) do not have thrombocytosis, and they may have an increased risk of Sweet syndrome ([401], [402] and [403]). The genes involved in the t(3;5) are the NPM gene on chromosome 5 and a gene named *myelodysplasia/myeloid leukemia factor 1* (MLF1) on chromosome 3 ([404]).

Molecular cloning of translocations in AML continues to identify genes that contribute to leukemogenesis ([405]). The t(5;11)(q35,p15.5) and t(9;11)(p22;p15) result in NUP98/NSD1 and NUP98/LEDGF rearrangements, respectively; both result in fusion gene proteins involving components of the nuclear pore ([406], [407]). New fusion partner genes are being identified in translocations with the MLL gene, usually in secondary or therapy-related leukemias with monocytic features ([408], [409], [410] and [411]). MOZ/p300 and MORF/CBP fusions were cloned in AML with t(8;22)(p11;p13) and t(10;16)(q22;p13), respectively, and contribute to leukemogenesis through transcriptional coactivators and remodeling of chromatin ([412], [413]). Recognition of the genes involved in AML translocations will lead to a better understanding of leukemogenesis and, ultimately, to more specific therapies.

PROGNOSIS

Clinical features, morphology, surface markers, and cytogenetics are combined to describe clinicopathologic syndromes in AML, and prognosis is usually determined by a combination of specific factors (Table 79.5) ([298], [299], [414], [415], [416], [417], [418] and [419]). A single factor cannot reliably predict prognosis but must be correlated with all available information. Age is an important prognostic factor, with elderly and very young (infants <2 years of age) patients having the worst prognoses ([420]). The clinical state of the patient, as reflected in performance status or the serum albumin, affects outcome ([421]). Patients with a preceding bone marrow disorder, including MDS or myeloproliferative syndrome, or with a history of chemotherapy have an inferior response and survival compared to those with *de novo* AML ([422], [423]). The presence of infection or thrombocytopenia has become less important because of improvements in supportive care. Although hyperleukocytosis correlates with a poor prognosis in some series, the correlation is not as strong in AML as it is in ALL ([424], [425]).

TABLE 79.5. Prognostic Factors in Acute Myeloid Leukemia

Factor	Favorable	Unfavorable
Clinical		
Age	<45 yr	<2 yr, >60 yr
ECOG performance status	0, 1	>1
Leukemia	*De novo*	Antecedent hematologic disorder: myelodysplasia, myeloproliferative disorder
Infection	Absent	Present
Prior chemotherapy	No	Yes
Leukocytosis	<25,000/mm ^{3}	>100,000/mm ^{2}
Serum lactate dehydrogenase	Normal	Elevated
Extramedullary disease	Absent	Present
Central nervous system disease	Absent	Present
Cytoreduction	Rapid	Delayed
Morphology		
Auer rods	Present	Absent
Eosinophils	Present	Absent
Megaloblastic erythroids	Absent	Present
Dysplastic megakaryocytes	Absent	Present
FAB type	M2, M3, M4	M0, M6, M7
Surface/enzyme markers		
Myeloid	CD34 $^-$, CD14 $^-$, CD13 $^-$	CD34 $^+$ [a]
HLA-DR	Negative	Positive
Terminal deoxynucleotidyl transferase	Absent	Present
Lymphoid	CD2 $^+$	CD56 $^+$
		Biphenotypic (=2 lymphoid markers)
MDR-1	Absent	Present
Cytogenetics	t(15;17), t(8;21), inv(16)	-7, del(7q), -5del(5q), 3q21 and 3q26 abnormalities, complex karyotype
Molecular markers

FAB, French/American/British.

[a] Except when accompanied by favorable cytogenetics [i.e., FAB-M2 with t(8;21) or FAB-M4Eo with inv(16)].

Favorable morphologic features include Auer rods (M1-M4) and eosinophils (M2 and M4Eo), whereas megaloblastic features that may be seen in erythroleukemia (M6), acute megakaryoblastic leukemia (M7), or AML evolving from MDS are unfavorable ([416], [417], [423]). The eosinophils in M2 show only minor abnormalities such as faint green-blue/yellow granules, whereas in M4Eo, they are dysplastic and often have large, irregular, deeply purple granules (Fig. 79.7); their presence is favorable because of the association with good prognostic cytogenetics—t(8;21) in M2 and inv(16) in M4Eo ([426]). In regard to FAB morphology, results of studies are inconsistent, but they generally indicate that patients with M0, M6, M7, and, possibly, M5 have lower survival rates. Extramedullary disease, common in M5, is also associated with a worse prognosis. The speed of cytoreduction (how quickly aplasia is achieved) also correlates with survival, except in APL (M3), which may be difficult to assess because of the lack of aplasia after ATRA or chemotherapy. Although the usual time of evaluation of the marrow for aplasia is 2 weeks after start of therapy, some studies indicate a better prognosis if aplasia is achieved within the first week ([427], [428]).

The effect of surface markers on prognosis is variable and is interdependent with other factors; moreover, antigen expression often changes at relapse ([405], [429], [430] and [431]). Although CD34 has often been reported as an adverse factor, in some studies, it has had little impact on outcome ([432]). CD34 expression is a poor prognostic factor when coexpressed with CD7 ([278]), but it is probably more important when associated with adverse cytogenetics, including abnormalities of chromosome 5 (-5/5q-) and 7 ([433]), or with the multidrug resistance gene (MDR-1) ([434]). CD34 is also expressed in favorable AML subtypes, including all cases with t(8;21) and inv(16) ([435]). The absence of some markers, including CD34, CD14, and CD13, can be associated with a good prognosis ([265], [419], [429], [434]). Similarly, the lack of HLA-DR reactivity as observed in APL (M3) is associated with a good prognosis. An association between early death (<2 months) and the coexpression of leukocyte function antigens (CD16b and 11c) on leukemia cells has been reported ([436]). CD56, a cell adhesion molecule, has been implicated in the development of extramedullary disease ([335], [437]). The presence of lymphoid markers, particularly when they are multiple, is often associated with a poor prognosis; however, they

have not predicted a poor prognosis when present in children ([438]) or when associated with a good cytogenetic group ([275]).

Cytogenetic subgroups identify prognosis better than any other factor ([290] , [291] , [298] , [299] , [439] , [440] and [441]). Three abnormalities, t(8;21), t(15;17), and inv(16), are regarded as favorable (Fig. 79.8). Even favorable cytogenetics can be associated with an adverse clinical factor surface marker or cytogenetic abnormality. For example, when t(8;21) is associated with extramedullary disease, CD56, or del(9q), the overall prognosis worsens ([334] , [335] , [442]). In early series, patients with t(15;17) did not do well because of hemorrhagic deaths, the number of which has decreased with better transfusion support and with the introduction of ATRA therapy (Chapter 82). The inv(16) has been associated with a high CR rate, but an increased incidence of CNS involvement resulted in an intermediate prognosis in some reports; the use of HiDAC may lessen the risk of CNS disease.

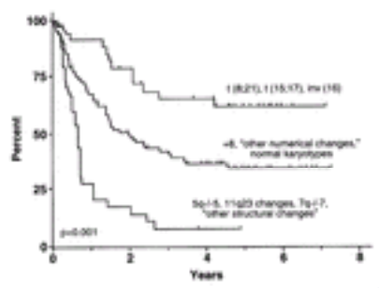

Figure 79.8. Probabilities of continuous complete remission of previously untreated patients with acute myeloid leukemia according to chromosomal groups. (From Dastague N, Payen C, Lafage-Pachitaloff M, et al. Prognostic significance of karyotype in *de novo* adult acute myeloid leukemia. The BGMT group. *Leukemia* 1995;9:1491–1498.)

The main disagreements about prognosis among groups are in the identification of cytogenetic abnormalities that constitute an intermediate risk ([298] , [439] , [441]). Poor cytogenetic groups include those defined by abnormalities of chromosomes 5 and 7, 3q26, and complex karyotypes and often include patients with prior chemotherapy or MDS ([289] , [443]). 11q23 abnormalities are often associated with a poor prognosis but have been considered intermediate risk, especially in young patients with a *de novo* presentation with t(9;11) ([290] , [298]). Trisomy 8 is the most common numerical abnormality in AML and, by itself, may be associated with an intermediate risk, but it often occurs in complex karyotypes that are prognostically unfavorable ([444]). A normal karyotype is generally associated with an intermediate prognosis; however, molecular techniques such as RT-PCR can detect molecular changes in AML with a normal karyotype that may have prognostic significance, including FLT-3 and MLL internal tandem duplications ([244] , [445] , [446]).

Expression of MDR genes has been identified as adverse prognostic markers in AML ([269] , [447] , [448] , [449] , [450] , [451] , [452] and [453]). The best described MDR gene is MDR-1 whose gene product, P-glycoprotein (Pgp), is a 170-kd membrane glycoprotein that functions as a drug efflux pump for naturally occurring substances, including anthracyclines, vinca alkaloids, taxanes, and epipodophyllotoxins ([447] , [453]). Pgp expression can be detected by flow cytometry using specific antibodies such as MRK16 and can be correlated with functional efflux of fluorescent dyes by leukemia blasts ([269] , [449]). Expression of MDR-1/Pgp is more commonly found in older patients, often in conjunction with adverse cytogenetics, and is associated with a lower CR rate ([269] , [449]). Other transport proteins that may confer drug resistance include multidrug resistance–associated protein-1, lung resistance protein (LRP), and breast cancer resistance protein (BRCP) ([449] , [450] , [451] and [452]).

Prognosis in AML may also be assessed by evaluating molecular markers, particularly genes encoding growth factors and their receptors ([453] , [454] , [455] and [456]). The best-studied receptor and its impact on prognosis is FLT-3, also known as stem cell kinase 1 or fetal liver kinase 2 ([454] , [455] , [456] , [457] and [458]). FLT-3 mutations predominantly occur by internal tandem duplication of the juxtamembrane region and, less commonly, through an “activation” loop involving an aspartic acid residue at amino acid position 835 ([458]). They can be detected by genomic PCR amplification and gel electrophoresis in 20 to 34% of patients with AML ([454] , [455] , [456] , [457] and [458]). FLT-3 gene mutations have been associated with higher peripheral blast counts, normal cytogenetics, t(15;17), and FAB M5 disease. Although presence of FLT-3 mutations does not correlate with CR rate, they have predicted relapse and poor survival and may be useful in stratifying patients with normal cytogenetics into risk groups (Fig. 79.9) ([454] , [456] , [458]). RAS mutations occur in 20 to 44% of AML patients but rarely with FLT-3 mutations and have not consistently predicted prognosis ([457] , [459]). Although TP53 mutations are less common than either RAS or FLT-3 mutations, they have been associated with abnormalities in both chromosomes 5 and 7 and a worse overall survival in the elderly ([457]). Increased expression of the protein EVI1 is associated not only with AML involving 3q26, but also with other unfavorable karyotypes (e.g., -7/7q- and 11q23 aberrations) and a poor prognosis ([460]).

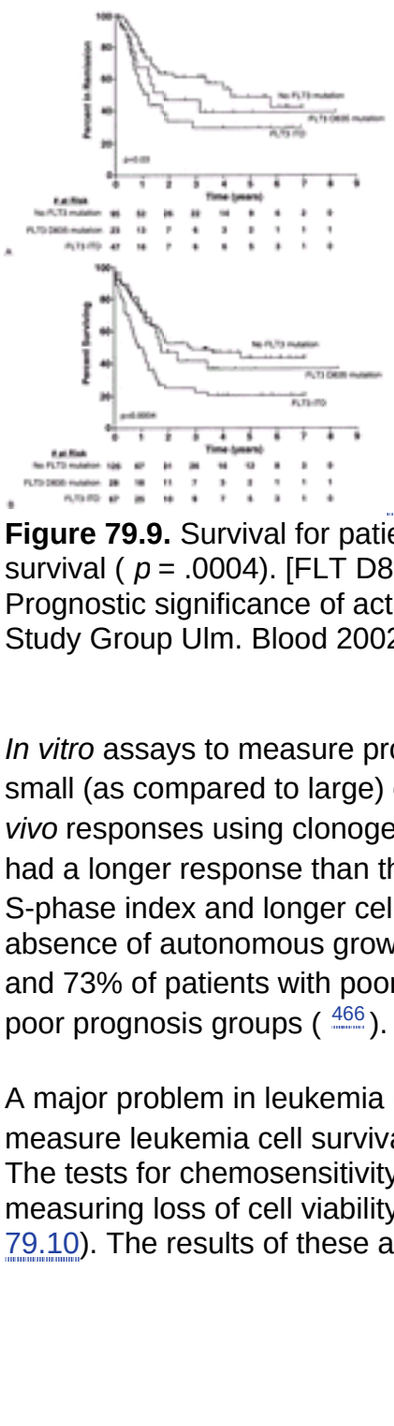

Figure 79.9. Survival for patients with normal cytogenetics according to Fms-like tyrosine kinase (FLT3) mutation status. **A:** Remission duration ($p = .03$). **B:** Overall survival ($p = .0004$). [FLT D835, Asp835 (three-letter amino acid code); FLT3 ITD, internal tandem duplication.] [From Frohling S, Schenk RF, Beitruck J, et al. Prognostic significance of activating FLT3 mutations in younger adults (16 to 60 years) with acute myeloid leukemia and normal cytogenetics: a study of the AML Study Group Ulm. Blood 2002;100:4372–4380.]

In vitro assays to measure proliferation or chemosensitivity have been of uncertain value but continue to be investigated. Clonogenic assays indicate that growth in small (as compared to large) clusters is associated with a better response to therapy ([461]). *In vitro* sensitivity to ara-C and daunorubicin has been correlated with *in vivo* responses using clonogenic assays ([462] , [463]). Patients whose leukemia cells readily phosphorylate ara-C *in vitro* and retain it in its active form (ara-CTP) have had a longer response than those with low ara-CTP retention ([464]). Bromodeoxyuridine has been used for *in vitro* assessment of cell cycling, and patients with a high S-phase index and longer cell cycling times have had longer remission durations ([238]). Correlations between cytogenetics and bone marrow cultures indicate an absence of autonomous growth *in vitro* in patients with favorable cytogenetics compared to partial or full autonomous growth in 50% of patients with intermediate-risk and 73% of patients with poor-risk cytogenetics ($p = .0004$) ([465]). Cytokine-induced proliferation *in vitro* may also subdivide intermediate-risk patients into good and poor prognosis groups ([466]).

A major problem in leukemia is the inability to consistently predict chemosensitivity to a specific drug in an individual patient. Several types of *in vitro* assays that measure leukemia cell survival after exposure to chemotherapeutic agents have been evaluated for their ability to predict clinical responses ([463] , [467] , [468] , [469] and [470]). The tests for chemosensitivity have included long-term assays based on clonal growth of leukemia colony-forming cells, short-term assays of the total cell population measuring loss of cell viability, and a rapid microculture kinetic assay that determines the extent of apoptosis in leukemia cells after exposure to cytotoxic agents (Fig. 79.10). The results of these assays have been variable in their ability to predict response and survival.

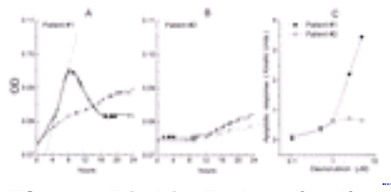

Figure 79.10. Determination of chemosensitivity to daunorubicin using the microculture kinetic (MiCK) assay of apoptosis. Myeloblasts from a patient with responsive acute myeloid leukemia (AML) **(A)** and a patient with resistant AML **(B)** are shown. The MiCK assay monitors the optical density (OD) of cell cultures exposed to antitumor drugs. Plotting OD against time provides a kinetic representation of responses to drugs. Serial OD readings are shown from untreated control cultures (thin lines) and cultures with 5 µm daunorubicin (thick lines). Autonomous cell growth causes the slow OD increase in control cultures. The steep increases in the OD in **(A)** induced by daunorubicin are caused by increased side scattering of light from cells undergoing apoptosis. The slope [dotted line in **(A)**] of this steep increase, expressed as kinetic units, correlates directly with the percentage of apoptotic cells. The absence of any steep increase above controls in **(B)** indicates negligible apoptosis in response to 5 µm daunorubicin. **C:** The dose-response relationship for the two leukemias is shown over a range of daunorubicin concentrations that can be achieved *in vivo*. (Courtesy of Drs. Vladimir Kravtsov and Mark Koury, Vanderbilt University, Division of Hematology/Oncology, Nashville, TN.)

Decreased apoptosis and increased angiogenesis can contribute to leukemogenesis and poor prognosis in AML. Increased bcl-2 protein expression exerts an antiapoptotic effect on leukemia cells, but studies correlating bcl-2 expression with known prognostic factors have yielded mixed results ([471], [472]). Overexpression of VEGF correlates with increased angiogenesis and has been associated with a worse response and survival in AML ([473], [474]). Ongoing studies correlating markers for apoptosis and angiogenesis with known prognostic factors in AML may further delineate prognosis in AML and identify targets for therapy.

THERAPY

Therapy is instituted after differentiating AML from ALL (Chapter 77). Therapy for AML consists of cytotoxic chemotherapy alone or marrow/stem cell transplantation (SCT) after chemotherapy. Immunotherapy, which formerly included bacillus Calmette-Guérin scarification, is reemerging as a therapeutic modality in AML with the development of monoclonal antibodies directed toward antigens on blast cells (Chapter 74) ([475], [476], [477] and [478]).

Administration of ara-C, usually in conjunction with an anthracycline, has been the cornerstone of chemotherapy in AML for more than 30 years. Choices of dosage, schedule, and methods of administration of ara-C differ among studies and play a role in determining outcome ([479], [480], [481], [482] and [483]). SCT for selected patients in first remission appears to be superior to chemotherapy alone; however, intensification therapy with high doses of ara-C with or without anthracyclines has improved results of chemotherapy, so that the question of what is the best therapy for AML in first remission remains unanswered ([483], [484], [485] and [486]). Because of the heterogeneity of AML, therapy should probably be stratified according to clinical and cytogenetic features and possibly to other biologic data.

Therapy can be divided into two phases: induction and post-remission (Fig. 79.11). The initial goal of therapy is induction of a CR, which usually requires a period of aplasia (except in APL). CR is attained in 60 to 85% of patients. Better response rates (70 to 85%) are common in patients younger than 60 years of age without a prior myelodysplastic syndrome. Rarely, brief spontaneous remissions have occurred without therapy ([487]). As defined in a workshop sponsored by the National Cancer Institute, *CR* is the normalization of neutrophil counts (at least 1.5×10^9/L) and platelet counts (>100×10^9/L), and a marrow aspirate and biopsy that demonstrate at least 20% cellularity, less than 5% blasts, and no Auer rods, as well as absence of extramedullary leukemia ([1]). Moreover, these criteria should be sustained for at least 4 weeks or until initiation of intensification therapy, if earlier than 4 weeks. Partial remissions defined by 5 to 25% blasts are of value only in phase I and II trials. Submicroscopic residual leukemia has been demonstrated after CR is achieved with induction therapy ([488]). Randomized trials that involve no postremission therapy have cure rates approaching 0%, so postremission therapy is essential to eliminate residual disease and to achieve cure ([489]).

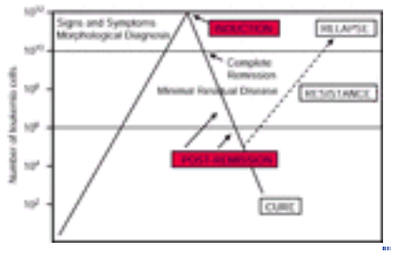

Figure 79.11. Phases of therapy. The diagnosis of acute myeloid leukemia can be made when the leukemia cell number is greater than 10^{10}. Induction therapy achieves a clinical complete remission and is followed by postremission therapy with a goal of cure. If cells develop mechanisms of resistance, relapse occurs.

Postremission therapy may consist of maintenance, consolidation, or intensification therapy. Maintenance therapy is less intensive and less myelosuppressive than induction; consolidation involves regimens similar to those used in induction; and intensification involves the use of drugs at higher dosages than in induction ([483], [490]). Maintenance therapy is not as important in AML as it is in ALL. Randomized trials show that maintenance therapy may prolong initial remissions ([491], [492]), but they also show no benefit of maintenance in improving the cure rate of AML ([493], [494]). Maintenance therapy is probably not warranted in AML if the postremission therapy is of adequate intensity ([493], [494] and [495]). There does appear to be a role for maintenance in APL (Chapter 82), and maintenance therapy could be considered in the elderly due to difficulty in delivering intensive consolidation chemotherapy. Additionally, randomized trials evaluating the role of intensive consolidation therapy have not shown an improvement in survival of the elderly.

The cure rate of adult AML by chemotherapy is usually reported as 10 to 50% and depends on a number of factors, including age, prior MDS, rapidity of obtaining a CR, and cytogenetics. Recent studies with the use of high-dose cytarabine (HiDAC) in intensification or ATRA and anthracyclines in APL indicate that selected groups of patients have a cure rate of above 50%, which approaches the cure rates achieved with alloSCT. Both postremission high-dose chemotherapy consolidation and alloSCT have better results in younger patients, but alloSCT remains superior as antileukemic therapy because relapse occurs less often after transplantation (<25% relapse). However, because of morbidity and mortality from infections and graft-versus-host disease, the cure rate with alloSCT in first CR has ranged from 45 to 75%. With the improvements in chemotherapy results, some authorities are advocating alloSCT in early relapse, with salvage rates of 15 to 30% in these patients, so that the cure rate of chemotherapy along with alloSCT at early relapse may be equivalent to that of alloSCT in first remission ([496], [497], [498] and [499]).

The evaluation of both chemotherapy and transplantation should include not only the CR and cure rates, but also the reasons for failure. The two basic reasons for failure in chemotherapy-treated patients are resistant leukemia and death from infection or hemorrhage. With improvements in transfusion support, empiric antibacterial and antifungal therapy, and availability of growth factors, the latter reason has become less significant. Preisler emphasized the importance of recognizing different types of failures in the therapy of AML (Table 79.6) ([500]). Complete, or classic, drug resistance is complex and is characterized by the failure to significantly reduce the leukemia cell burden ([501]). Different mechanisms of drug resistance may be involved. Overexpression of the MDR-1 gene is the most commonly reported abnormality in chemotherapy-resistant AML, but overexpression of other proteins, such as LRP, which alters intracellular drug distribution, have also been described ([447]). Many of the failures previously attributed to relative drug resistance more accurately represent regrowth failures, in that there is substantial leukemia cell kill, but the leukemia cells regrow before additional therapy is given ([501]). Regeneration failures are rare in the era of growth factors. Hypoplastic deaths and inadequate chemotherapy trials include patients who die before the response can be assessed. Hematologic remission can be achieved, but other markers of disease may persist, including MDS in patients with AML evolving from MDS, extramedullary disease, or persistence of abnormal cytogenetic or molecular markers. Persistence of abnormal karyotypes, as well as some molecular markers such as PML/RAR-a, tends to predict disease recurrence, but other molecular markers, such as AML/ETO1, may not correlate with clinical disease.

TABLE 79.6. Types of Failure in Therapy of Acute Myeloid Leukemia

Drug resistance: no response based on absence of hypocellularity in posttreatment marrow biopsy, usually day 14

Relative drug resistance: partial response with subsequent regrowth of leukemia within 4 wk
Regeneration failure: marrow remains hypocellular for >4 wk
Hypoplastic death (within 4 wk)
Inadequate trial (death within 2 wk of initiating therapy)
Hematologic remission but persistent disease (myelodysplasia, extramedullary disease, cytogenetic or molecular abnormalities)

Because chemotherapy is the initial therapy for all patients and alloSCT is not readily available to most patients, the primary focus of the remainder of this chapter is on chemotherapy in AML: single agent data, remission-induction combinations, and postremission therapy. Special issues in AML therapy addressed at the end of the chapter are relapsed/refractory AML, AML in the elderly, AML during pregnancy, hypocellular AML, and the role of growth factors and biologic response modifiers.

Single Agent Chemotherapy

Table 79.7 outlines active agents in AML and includes their cell cycle specificity, major toxicities, response rates, and clinical uses. Cytarabine and anthracyclines have been the subject of most intense study. Cytarabine is effective in cells in the S-phase of the cell cycle and is not active in cells that are out of cycle or in other phases of the cell cycle. Anthracyclines do not depend on the cell cycle and appear to be the most active single agents. Synergy exists between agents with different mechanisms of action, and combination chemotherapy is warranted for optimal results in AML. Still, single agent data constitute the basis for therapy and the development of new agents in phase I and II trials. Data from new single agent studies are difficult to assess because new drugs are often administered with known active agents, and the trials are in heavily pretreated patients. Results depend on how extensive prior therapy has been; for example, in initial studies involving amsacrine, the response rate was 47% in patients who had received one prior regimen, 25% in patients who had received two prior regimens, and 0% in patients treated with three or more prior regimens ([502] , [503]).

TABLE 79.7. Standard Single Agents in Acute Myeloid Leukemia

Agent	Class of Agent	Route of Delivery	Cell Cycle Specificity	Mechanism of Action	Plasma Half-Life (hr)	Main Route of Excretion	Response Rates (%)	Major Toxicities Other Than Myelosuppression	Comments
Cytarabine	Pyrimidine analog	IV, SC	S	Active form ara-CTP inhibits DNA polymerase and is incorporated in DNA (S-phase)	1–2	Renal	15–35	Cerebellar, gastrointestinal, hepatic, skin	Antileukemic effect is dose and schedule dependent. Cerebellar toxicity occurs in patients >50 yr receiving high doses (3 g/m ^{2}).
Daunorubicin, doxorubicin, idarubicin, epirubicin	Anthracycline antibiotics	IV	NS	Inhibit DNA replication by intercalation of base pairs; inhibition of topoisomerase II	15–30	Hepatic	40–50	Cardiac, alopecia, gastrointestinal	Cumulative, dose-dependent cardiomyopathy in patients receiving >500 mg/m ^{2} for daunorubicin. Increased gastrointestinal toxicity with doxorubicin. Idarubicin has longer half-life and probably better efficacy; cardiomyopathy is uncommon <290 mg/m ^{2}.
6-Thioguanine	Purine analog	PO, IV	S	Ribonucleotide form is incorporated in DNA, leading to strand breaks	6–12	Renal, hepatic	10	Hepatic, gastrointestinal	Synergistic with cytarabine; unlikely to add to combination of cytarabine and anthracycline.
Mitoxantrone	Anthraquinone	IV	NS	Intercalates into DNA; induces topoisomerase II–mediated damage	25–50	Hepatic > renal	25–50	Cardiac, gastrointestinal	Probably less cardiotoxic than anthracycline antibiotics.
VP-16 (etoposide)	Epipodophyllotoxin	IV, PO	S	Forms complex with DNA and topoisomerase II, leading to strand breaks (G $_2$-phase)	6–12	Renal > hepatic	10–30	Alopecia, gastrointestinal, hepatic, stomatitis	Effects are dose and schedule dependent. Oral dose usually is twice IV dose. Efficacious in acute monocytic leukemia of infancy. Etoposide phosphate is a water-soluble prodrug of etoposide.
Amsacrine (m-AMSA)	Acridine derivative	IV	NS	Intercalates into DNA, produces strand breaks (G $_2$-phase)	7–8	Hepatic > renal	30–50	Cardiac, including QT prolongation; gastrointestinal	Most effective when combined with high-dose cytarabine.
5-Azacytidine	Pyrimidine analog	IV, SC	S	Phosphorylated form incorporates into RNA and DNA	3–6	Renal	10–20	Gastrointestinal, hepatic, skin, neurologic	No cross-resistance with cytarabine; limited by neurologic toxicities.
Carboplatinum	Platinum analog	IV	NS	Covalent binding to DNA	2–6	Renal	20–28	Gastrointestinal	Less nephrotoxicity, ototoxicity, and emesis than cisplatinum, but more myelosuppression.
Fludarabine, cladribine, pentostatin	Purine analogs	IV	NS	Inhibit DNA polymerase, incorporation into DNA and RNA, nicotinamide adenine dinucleotide depletion	Biphasic: a <30 min; ß 6–20 hr	Hepatic, renal	5–25	Neurotoxicity, pulmonary (fludarabine); immunosuppression (T-cell depletion)	Synergism with cytarabine; can potentiate the accumulation of ara-CTP if given before cytosine arabinoside. SC and PO under development.

ara-CTP, active form of cytosine arabinoside; NS, nonspecific; S, specific.

The antileukemic effect of cytarabine depends on dosage and schedule. Cytarabine is effective at both high and standard dosages. HiDAC (3 g/m ^{2} every 12 hours for 4 to 12 doses), usually in conjunction with an anthracycline, etoposide, mito-xantrone, or L-asparaginase, is particularly effective as intensification therapy or as

therapy for relapsed disease ([504] , [505] , [506] , [507] , [508] , [509] and [510]). HiDAC can cross the blood–brain barrier and help prevent CNS leukemia; however, cerebellar toxicity may develop, particularly in patients 50 years of age or older. Lengthening the time of administration from 1 hour to 3 hours or decreasing the dose from 3.0 g/m ^{2} to 1.5 g/m ^{2} may lessen the risk of cerebellar toxicity and is common practice in patients older than 50 years of age. Conjunctivitis and a painful, blistering erythematous rash involving the palms and soles are common side effects after HiDAC. Low-dose cytarabine (10 to 20 mg/m ^{2} every 12 to 24 hours) occasionally is effective in AML and myelodysplastic syndromes ([511] , [512] , [513] and [514]). The mechanism of low-dose cytarabine was thought to involve promotion of myeloid differentiation ([515]); however, it usually results in a period of aplasia similar to that produced by conventional and high-dose regimens and is now rarely used.

The anthracyclines used to treat AML are idarubicin, daunorubicin, and doxorubicin ([516]). Idarubicin may be the preferred anthracycline in AML, based on randomized studies that generally indicate a better response and survival than with daunorubicin ([517] , [518] , [519] , [520] and [521]). New anthracyclines, including rubidizone and epidoxorubicin, are probably equivalent to the older compounds, although aclarubicin has been effective in patients whose leukemia was resistant to conventional anthracyclines. Amsacrine and mitoxantrone are efficacious agents that are nearly equivalent to the anthracyclines; mitoxantrone causes less alopecia, less gastrointestinal toxicity, and, possibly, less cardiac toxicity than the anthracyclines ([522] , [523] , [524] , [525] and [526]).

After early reports indicated efficacy in AMoL of infancy, the role of epipodophyllotoxins in the therapy of AML has expanded. In 1984, Odom and Gordon reported sustained clinical remission in four of five infants treated with epipodophyllotoxins ([527]). Subsequently, etoposide more than teniposide has been used in combination chemotherapy for patients of all ages ([528] , [529] , [530] , [531] , [532] and [533]). As with other agents, response depends on dosage and schedule of administration and the interaction with other agents, all of which continue to be investigated. Although the addition of etoposide to an anthracycline and cytarabine has not consistently improved CR rates, data from the Australian Leukemia Study Group indicate improved survival ([529]).

The mainstays of chemotherapy in AML are cytarabine, anthracyclines, mitoxantrone, and etoposide, but new agents are under development and investigation in clinical trials ([534]). In addition to cytarabine, nucleoside analogs with antileukemic activity used in clinical practice include fludarabine, gemcitabine, 2-chlorodeoxyadenosine, and 2-deoxycoformycin ([535] , [536] , [537] , [538] and [539]). Fludarabine has been given with HiDAC and G-CSF [FLAG (fludarabine, ara-C, and G-CSF)] as a salvage regimen with good efficacy and without cardiotoxicity ([540]). Troxacitabine is a novel agent in an L configuration, unlike the D configuration of the other nucleoside analogs. Troxacitabine undergoes phosphorylation and is a complete DNA chain terminator. Unlike cytarabine and fludarabine, troxacitabine is not dependent on nucleotide-specific membrane transporters, which can contribute to resistance. Additionally, troxacitabine does not inhibit ribonucleotide reductase, so it could be combined with new agents that do inhibit the enzyme ([534] , [541]). Response rates to troxacitabine in relapsed AML in phase I-II trials have been in the 13 to 18% range ([541]).

Topotecan is a topoisomerase I–acting drug with activity in refractory anemia with excess blasts, chronic myelomonocytic leukemia, and AML ([542] , [543]). Its greatest efficacy has been in conjunction with cytarabine in patients with MDS and poor prognosis cytogenetics (i.e., -5, -7) ([544] , [545]). Carboplatinum causes DNA intrastrand cross-links, has relatively low response rates in AML as a single agent, and has mainly been used with cytarabine-based regimens ([546]). Other antineoplastic agents that have been used as single agents in AML with response rates of 15% or less include corticosteroids, L-asparaginase, cyclophosphamide, vinca alkaloids, methotrexate, and tubulin-interactive agents paclitaxel and docetaxel; however, the efficacy of any of these agents may improve by synergistic interactions with other drugs ([547] and [548]). Homoharringtonine is a plant alkaloid that has minimal activity as a single agent in AML and MDS ([549]). Other anthraquinones, diaziquone and bisantrene, are less active than mitoxantrone ([550]).

New agents under study are directed at molecular pathogenetic mechanisms of leukemogenesis and include inhibition of DNA methylation, modulation of angiogenesis, inhibition of the ubiquitin–proteasome pathway, and inhibition of farnesyl transferase ([534]). DNA methylation may contribute to leukemogenesis by silencing tumor-suppressor genes ([534]). Cytosine analogs, such as 5-azacytidine and decitabine, and other agents, such as phenylbutyrate and depsipeptide, inhibit DNA methylation and have activity in phase I-II trials of patients with MDS and AML ([534] , [551] , [552] , [553] and [554]). SU5416 (semaxanib; SUGEN) is an example of a small molecule receptor tyrosine kinase inhibitor directed at the VEGF pathway; early trials with SU5416 indicate activity in AML ([555]). PS341 [bortezomib (Velcade), Millenium Pharmaceuticals] is a small molecule proteasome inhibitor whose antileukemia activity may involve inhibition of cell growth signaling, induction of apoptosis, and inhibition of adhesion molecule expression ([534] , [556]). R115777 [tipifarnib (Zarnestra), Johnson and Johnson] is a nonpeptidomimetic enzyme-specific inhibitor of farnesyl protein transferase, an enzyme that promotes RAS processing and transduction of proliferative signals ([557]). In a phase I trial of R115777, 34 patients with refractory and relapsed acute leukemias had a response rate of 29% ([557]).

Induction Therapy

At the time of diagnosis, numerous steps should be reviewed in the evaluation and preparation of the patient (Table 79.8). If transplantation is being considered as an option, HLA typing of patient and siblings and screening for cytomegalovirus antibodies should be performed. As with other potentially curable malignancies, patients with AML are treated with combinations of effective agents ([558] , [559] and [560]). The most common regimens in AML involve the use of cytarabine and an anthracycline. Other agents, including 6-thioguanine and etoposide, have been added to the combination ([529] , [561]). Ara-C usually is administered as a continuous infusion of 100 mg/m ^{2} /day for 7 days, with an anthracycline given by intravenous push on the first 3 days of therapy. This combination is called *7 and 3*, and the anthracycline and the daily dose vary among studies: daunorubicin, 45 to 60 mg/m ^{2} ; doxorubicin, 25 mg/m ^{2} ; or idarubicin, 12 mg/m ^{2} .

TABLE 79.8. Management of Acute Myeloid Leukemia at Diagnosis

Patient history
Review preceding myelodysplasia, prior diagnosis of cancer, previous chemotherapy, occupational exposure, family history
Physical examination
Assess performance status
Screen for infection: dental, nasopharyngeal, lung, perirectal
Search for extramedullary disease: skin examination, neurologic, adenopathy, organomegaly, testicular examination
Baseline laboratory
Complete blood count with differential; type and screen for crossmatch
Bone marrow examination: include cytogenetics and save sample for molecular diagnostics if applicable
Screen electrolyte, liver and renal function, tumor lysis parameters
Screen for DIC
Viral serologies, particularly HSV, cytomegalovirus, hepatitis, and human immunodeficiency virus
Determine HLA-A, -B, -DR type
Chest radiograph: rule out pneumonia, leukostasis, mediastinal mass
Cardiac status: ejection fraction by echocardiogram or MUGA
Supportive care
Transfusions: platelets, packed red blood cells (unless hyperleukocytosis); fresh frozen plasma with or without cryoprecipitate in DIC
Central line placement (unless severe DIC)
Hydration
Allopurinol or other agent to prevent lysis
Treat ongoing infections
Infection prophylaxis: acyclovir (if HSV positive), antifungal agents (fluconazole or voriconazole), antibacterial agents
If hyperleukocytosis, hydroxyurea, leukapheresis, or both
Therapy

Induction chemotherapy: cytarabine and anthracycline; use etoposide or mitoxantrone instead of anthracycline if cardiac status compromised; possible role for high-dose cytarabine

All- *trans*-retinoic acid if acute promyelocytic leukemia with anthracycline

Monitor for DIC and tumor lysis, infection, drug toxicities

DIC, disseminated intravascular coagulation; HSV, herpes simplex virus; MUGA, multigated acquisition scan.

When daunorubicin was the primary anthracycline used, the CR rate after one cycle was usually 40 to 50%, and a second cycle could be given to the remaining patients for an overall CR rate of 60 to 75%. In randomized trials, however, idarubicin plus ara-C had a higher CR rate than daunorubicin with ara-C, more often required only one cycle to achieve remission, and was associated with a better survival in two of the trials (Table 79.9) ([518], [519] and [520], [562]). *In vitro* studies have also demonstrated that idarubicin is less of a substrate for Pgp than is daunorubicin ([563]). Although some investigators have questioned whether biologically equivalent doses were used in the trials, “7 and 3” ara-C with idarubicin has become the preferred induction regimen in many centers. Randomized trials show little benefit of the addition of 6-thioguanine to induction therapy ([503]). Similarly, the addition of etoposide to “7 and 3” at 75 mg/m ^{2}/day for 7 days (“7 + 3 + 7”) did not improve CR rates and was associated with more mucositis; however, it did improve overall survival when compared to “7 and 3” ([529]). The anthraquinone derivative mitoxantrone has been extensively used with ara-C and occasionally with etoposide as part of an effective induction regimen. Mitoxantrone has been used more often at relapse and in the elderly and reportedly has less cardiotoxicity than the anthracyclines ([532], [564], [565]).

TABLE 79.9. Clinical Trials Comparing Idarubicin with Daunorubicin during Induction

Source	Regimen	No. of Patients	Median Age (yr)	Complete Remission Rate (%)		Percent of Patients Requiring More Than One Cycle to Achieve Complete Remission	Comments
				All Patients	Patients Age <60		
Berman et al. (520)	IA	60	36	80 *p* = .005	80 *p* = .005	25 *p* = .01	Variable consolidation; overall survival for IA arm was 19.5 mo compared to 13.5 mo in the DA arm (*p* = .025).
	DA	60	41	58	58	51	
Wiernik et al. (518)	IA	97	56	70 *p* = .08	83 NS	22 *p* = .015	Consolidation was 5 and 2 of same drugs; some went to transplant. Survival was 12.9 mo for IA versus 8.7 mo for DA (*p* = .038).
	DA	111	55	59	68	35	
Vogler et al. (519)	IA	105	60	71 *p* = .03	79 NS	23 NS	Median survival was not different between the two arms, but it was improved if patient received late intensification.
	DA	113	61	58	63	22	

DA, daunorubicin and cytosine arabinoside; IA, idarubicin and cytosine arabinoside.

Many studies of AML have evaluated the optimal dosage and schedules of administration of ara-C during induction ([503], [566]). “7 and 3” has been shown to be superior to the same drugs given over 5 days and 2 days, respectively ([567]), and appears equivalent to “10 and 3” ([568]). The continuous infusion of ara-C at a dosage of 100 mg/m ^{2} has been shown to be superior to pulse doses of 100 mg/m ^{2} every 12 hours ([503], [567]). Increasing the ara-C dose in “7 and 3” from 100 mg/m ^{2}/day to 200 mg/m ^{2}/day and prolonging the infusion to 10 days, in combination with daunorubicin, produced fatal gastrointestinal toxicity ([568], [569]). The optimal dosage and schedule for cytarabine may depend on individual metabolism and measurement of drug levels and continues to be the subject of investigation ([569], [570] and [571]).

Although HiDAC (1 to 3 g/m ^{2} every 12 to 24 hours, up to 12 doses) has most often been given as therapy for relapsed disease or as intensification, pilot data indicated some of the highest initial CR rates (up to 90%) when HiDAC was given during induction ([572]); however, randomized studies have not confirmed a definite advantage of HiDAC as induction therapy when compared to “7 and 3” or “7 + 3 + 7” (Table 79.10) ([573], [574]). The German AML Cooperative Group reported in a randomized trial an advantage to HiDAC with mitoxantrone over standard therapy on day 21 in patients with a poor prognosis defined as 40% or more blasts on day 16, unfavorable cytogenetics, and an elevated lactate dehydrogenase ([575]). Because there has been longer DFS with HiDAC than with conventional ara-C in persons younger than 50 years of age, the National Comprehensive Cancer Network advocates considering HiDAC during induction therapy for young patients if they are not participating in a clinical trial ([576]). Another strategy is to use HiDAC after “7 and 3” on days 8 through 10 (3 + 7 + 3), again achieving a high CR rate (89%) ([577]). The impact of HiDAC on improving survival in AML has been considerable, but the optimal dose, schedule, and timing during therapy (i.e., induction vs. post-remission) remain unresolved issues ([578], [579] and [580]).

TABLE 79.10. Clinical Trials Evaluating Role of High-Dose Cytosine Arabinoside (HiDAC) for Induction

Source	Regimen	No. of Patients	Median Age	CR Rate (%)	5-Yr Disease-Free Survival (%)	Comments
Australia Leukemia Study Group (573)	HiDAC-3-7	149	43	71 NS	41 ± 5 *p* = .007	5-yr survival was 31% for HiDAC-3-7 versus 25% for 7-3-7 (*p* = .44). Patients received two consolidations with standard doses (5 and 2-5) or bone marrow transplantation (N = 61).

CR, complete remission; DNM, daunomycin; HAM, HiDAC plus mitoxantrone; TAD, thioguanine, cytosine arabinoside, daunomycin.

Postremission (Consolidation/ Intensification) Therapy

Although additional therapy clearly is required beyond induction therapy, minor modifications of consolidation therapy with drugs at similar doses to those used in induction therapy, with or without maintenance therapy, have not had a major impact on survival in AML ([503]). With a CR rate of 60 to 75%, 15 to 25% of adults and 20 to 30% of children could be expected to have prolonged survivals after consolidation or maintenance therapy administered through 1980. Pilot studies involving the use of HiDAC at different dosages and schedules as part of postremission therapy suggested that survival in AML could be improved by dosage escalation (Table 79.11) ([504], [581], [582], [583], [584], [585] and [586]). One of the earliest reports was by Vaughan et al., who used ara-C and daunorubicin based on cytokinetic models. Initially, one cycle of therapy as induction without additional therapy resulted in a projected cure rate of 12%; however, with a second cycle as consolidation therapy, the projected cure rate was 44% of patients in first remission ([507], [583]). In a randomized trial, Preisler et al. compared a form of HiDAC as consolidation to postremission therapy with modifications of “7 and 3” that also included amsacrine ([568]). Although no statistically significant differences were found between the arms, the projected survival was 45% for all patients and was 65% for patients 45 years of age and younger. Additionally, unfavorable cytogenetics, low percentage of cells in S-phase, and high initial white blood cell count were associated with a prognosis that was less favorable than that for patients without these features. Wolff et al. reported the use of HiDAC/daunomycin intensification in AML with a projected 49% survival that was age dependent (83%, 50%, and 23% for age groups 25 years or younger, 26 to 45 years, and older than 45 years, respectively) ([585]).

[a] CR duration data for controlled studies presented for patients younger than 60 years of age.

Randomized trials were performed to confirm the value of HiDAC consolidation ([587], [588] and [589]). In an Eastern Cooperative Oncology Group trial of 143 patients in first CR after daunorubicin, cytarabine, 6-thioguanine (DAT), patients were randomized to 24 months of low-dose maintenance therapy or one course of HiDAC (3 g/m ^{2} every 12 hours for 6 days) plus amsacrine ([587]). Although HiDAC caused more toxic deaths, the 4-year DFS in patients younger than 60 years of age was 28%, compared to 15% for those receiving maintenance therapy (p = .047). The Leukemia Group for the Swiss Society for Cancer randomized 137 patients in first CR after ara-C, daunomycin, VP-16, and AMSA to standard-dose ara-C at 100 mg/m ^{2}/day 7 or to HiDAC at 3 g/m ^{2}/day every 12 hours for 6 days and found no differences in DFS ([588]). The Cancer and Leukemia Group B (CALGB) randomized 596 patients in first CR after “7 and 3” to one of three different dose schedules: HiDAC at 3 g/m ^{2} over 3 hours every 12 hours on days 1, 3, and 5 (six doses); intermediate-dose ara C at 400 mg/m ^{2}/day for 5 days by continuous infusion; or lower-dose ara-C at 100 mg/m ^{2} for 5 days by continuous infusion ([589]). The estimated probabilities of remaining in CR at 4 years for the 47 patients younger than 61 years of age were 44%, 29%, and 24% for the three treatments, respectively (Fig. 79.12; p = .002). There were no differences among the arms in patients older than 60 years of age, with a probability of 16% or less of remaining in CR.

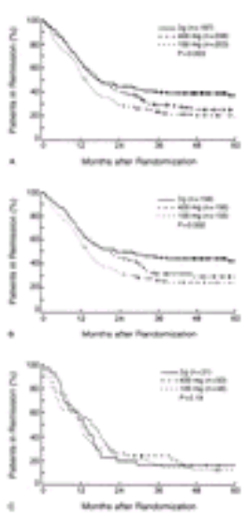

Figure 79.12. The effect of different doses of cytarabine on disease-free survival for all patients **(A)**, patients 60 years of age or younger **(B)**, and patients older than 60 years of age **(C)**. Only patients who underwent randomization are included. The p values are for the differences among the three treatment groups. Tic marks

indicate surviving patients in continuous complete remission. Median follow-up was 52 months. (From Mayer RJ, Davis RB, Schiffer CA, et al. Intensive postremission chemotherapy in adults with acute myeloid leukemia. N Engl J Med 1994;331:896–903.)

Thus, consolidation with HiDAC improves the DFS in first CR in young patients. Multiple cycles may be required to obtain the maximum benefit of HiDAC consolidation ([574], [589]). The National Comprehensive Cancer Network recommends anthracyclines as consolidation only for APL and stratifies consolidation according to age and cytogenetic risk group ([576]). For patients younger than 60 years of age, the choices are HiDAC consolidation alone (four cycles using CALGB doses and schedule) or one to two cycles followed by autologous transplantation or allogeneic transplantation. For patients older than 60 years of age not participating in a clinical trial, two cycles of standard-dose ara-C plus an anthracycline are recommended ([576]). For elderly patients with good performance status, normal renal function, and normal or favorable cytogenetics, a modified HiDAC regimen can be considered ([576]).

The roles of growth factors have been evaluated throughout the therapy of AML. They are used commonly in both induction and consolidation without evidence of adverse effects in most studies, albeit also without evidence of improved treatment outcome (*vide infra*).

Monoclonal Antibody Therapy

Monoclonal antibody therapy for hematologic malignancies has been under clinical trials for the past two decades. The antibodies can be unconjugated, or "naked," or conjugated to cytotoxic agents or radioisotopes (Chapter 74). In early studies in AML, unconjugated antibodies targeting CD14, CD15, and CD33 achieved low response rates (<10%) ([477], [590]). Consequently, investigators turned to conjugated antibody therapy, with CD33 being the best-studied target. CD33 is present on most AML cells and is not on hematopoietic stem cells; however, its presence on normal mature hematopoietic cells contributes to significant myelosuppression.

The best-studied anti-CD33 antibody conjugate is gemtuzumab ozogamicin (CMA-676, Mylotarg), which uses a recombinant humanized anti-CD33 monoclonal antibody to deliver calicheamicin, an antibiotic that binds to the minor grooves of DNA, causing double-strand breaks and apoptosis ([591]). In a phase I dose escalation trial, complete disappearance of blasts was observed in 8 of 40 patients, and gemtuzumab ozogamicin was reasonably well tolerated at the highest doses of 9 mg/m ^{2} ([371]). In three subsequent phase II trials, two doses of 9 mg/m ^{2} were given over 4 hours 14 days apart to 142 patients with CD33 $^+$ AML in untreated first relapse ([592], [593]). The overall response rate was 30% and included patients with CR and CR without full platelet recovery. There was no difference in response rates based on age (<60 years of age vs. =60 years of age) or length of first remission (<1 year vs. =1 year). Overall survival was 31% at one year with a median survival of 5.9 months ([592]). An infusion-related syndrome (chills, fever, rigors, nausea, pain, hypotension) and severe myelosuppression were common. Elevated liver functions [hyperbilirubinemia (23%) and transaminases (18%)] were usually transient ([592]).

Gemtuzumab ozogamicin was approved on May 17, 2000, by the United States Food and Drug Administration under the accelerated approval regulations. Postmarketing reports of fatal anaphylaxis, tumor lysis, adult respiratory distress syndromes, and hepatic venoocclusive disease have required labeling revisions and the initiation of a surveillance program ([593]). Tumor lysis and adult respiratory distress syndrome were primarily observed in patients with leukocytes above 30,000/ml, so the present recommendation is to reduce the counts to below 30,000 before starting gemtuzumab ozogamicin. Venoocclusive disease has been observed after SCT as well as without SCT ([593], [594]).

Radioimmunotherapy has been investigated in AML, usually in the setting of SCT. CD33, CD45, and CD66 have been the main target antigens investigated, and the radioisotopes conjugated to antibodies directed at these antigens have included ^{213}Bi, ^{131}I, ^{90}Y, and ^{88}Re ([595], [596], [597], [598] and [599]). Radioimmunotherapy offers the advantages of delivering larger doses of radiation to the marrow and less to normal tissues, in relation to standard total body irradiation (TBI) preparative regimens. Increasing the dose of TBI from 12.0 to 15.75 Gy reduced the risk of posttransplant relapse but was associated with increased organ toxicity and regimen-related mortality ([600]). A phase I trial using ^{131}I anti-CD45 (BC8) antibody with cyclophosphamide plus 12 Gy TBI in relapsed acute leukemia patients resulted in delivering approximately 20 Gy to the marrow and a projected 30% long-term survival ([597]). A phase II trial of ^{131}I-BC8 combined with busulfan and cyclophosphamide as the preparative regimen in patients with AML in first CR has a projected 70% DFS and a relapse rate of only 15% ([598]).

STEM CELL TRANSPLANTATION

Although results of studies using chemotherapy alone demonstrate a gradual improvement in survival, alloSCT continues to be the best antileukemia therapy based on the lowest relapse rates (Fig. 79.13) ([496], [601], [602]). Primary problems with alloSCT are lack of suitable donors and a high early mortality caused by organ toxicity, infections, and graft-versus-host disease (Chapter 25). The donor pool is expanding with the increased availability of unrelated donors and umbilical cord transplants ([603], [604] and [605]). Trends indicate a decrease in early mortality and an associated increase in leukemia-free survival in allogeneic transplantation, probably because of patient selection, timing of transplant, use of peripheral blood stem cells, and improved supportive care ([606]). Along with improvements and increased use of allogeneic transplants, there has been an increase in the use of autologous transplants ([607], [608], [609], [610] and [611]). In a randomized trial comparing autologous bone marrow transplantation to no further therapy after four cycles of chemotherapy, the autologous bone marrow transplantation had better DFS at 7 years (53% vs. 40%; p = .04) ([612]). Autologous transplantation is associated with a lower mortality than allogeneic transplantation, but it is associated with higher relapse rates. The role of purging remains controversial. Other controversies in transplantation for AML include the optimal preparative regimen, the best prophylaxis for graft-versus-host disease, and the role of T-cell depletion in allografts.

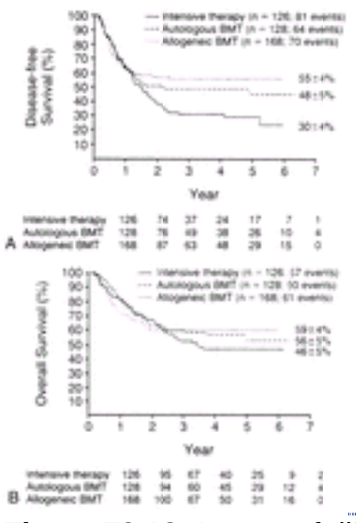

Figure 79.13. Impact of different postremission therapies on survival. **A:** Disease-free survival (DFS): Allogeneic bone marrow transplantation (BMT) has the best DFS, whereas randomization between autologous BMT and chemotherapy favored autologous BMT (p = .05). **B:** Overall survival (OS): There were no differences in OS among the three treatment groups. The number of patients at risk is shown below each time point. (From Zittoun RA, Mandelli F, Willemze R, et al. Autologous or allogeneic bone marrow transplantation compared with intensive chemotherapy in acute myelogenous leukemia. N Engl J Med 1995;332:217–223, with permission.)

Patient selection and timing of transplantation determine the expected results. In most trials, DFS is 45 to 65% in patients in first CR undergoing alloSCT from an HLA-matched family donor ([601], [613], [614]). For patients in early relapse or second CR, the DFS rate is 20 to 35%, and for patients with refractory or advanced AML the rate is 5 to 15% ([601], [615], [616]). Patients who are unsuccessful with induction and proceed to allogeneic transplantation can have prolonged DFS of 21 to 43% ([617], [618]). For autografts in first CR, the DFS is 34 to 57% with unpurged transplants and 40 to 76% with purged transplants ([610], [611] and [612]). For patients in second or third CR, the results of autografts are usually in the 20 to 40% range ([610], [611], [619], [620]). The optimal timing and type of transplant remain unresolved issues. Choices should be determined by prognostic factors and by the availability of clinical trials comparing efficacy. Unfavorable cytogenetics, preceding MDS, FAB M5-7 disease, and high white count at diagnosis have been suggested as adverse factors favoring early allogeneic transplantation; however, these factors confer a worse prognosis

with transplantation as well as with chemotherapy ([621]).

Prospective trials have attempted to answer the question of the optimal therapy in AML (Table 79.12) ([496] , [601] , [622] , [623] , [624] , [625] , [626] , [627] , [628] , [629] , [630] , [631] and [632]). Although the studies tend to favor transplantation over chemotherapy and allografting slightly over autografting, they do not account for inherent selection biases for transplantation and usually do not reflect the use of the more intensive chemotherapy regimens now available (Fig. 79.14). There has been a concern that time delay favored transplant arms, because patients were censored if they relapsed before going to transplant. Compliance and differences among protocol designs have further confounded interpretation of results ([625]). In four major prospective trials (2687 patients in first CR), only 71% of eligible patients received allogeneic transplants, and only 47% of the remainder were randomized; 66% received their assigned autograft, and 93% received chemotherapy ([625]). To overcome some of the problems, an intent to treat analysis comparing survival between donor versus no donor has been performed in many of the trials. Although the results vary, the risk of relapse is less and the DFS is better with transplantation, but the overall survival has not consistently been better for any one modality due to improved responses with chemotherapy, the procedural mortality associated with transplantation, and the ability to salvage patients relapsing after chemotherapy.

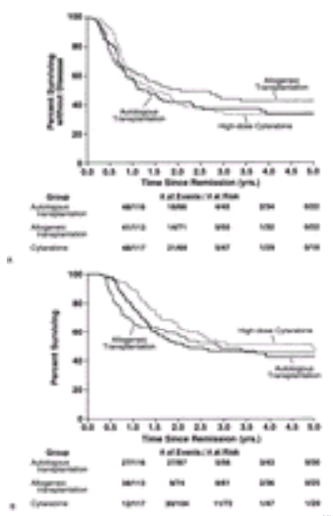

Figure 79.14. A: Disease-free survival according to postre-mission therapy was not statistically significant at 4 years: autologous bone marrow transplantation (autoBMT), 35 ± 9%; allogeneic bone marrow transplantation (alloBMT), 43 ± 10%, high-dose cytarabine, 35 ± 9%. **B:** Overall survival at 4 years was better for high-dose cytarabine, 52 ± 9%, than for either alloBMT, 46 ± 10% (*p* = .04), or autoBMT, 43 ± 9% (*p* = .05). (From Cassileth PA, Harrington DP, Appelbaum FR, et al. Chemotherapy compared with autologous or allogeneic bone marrow transplantation in the management of acute myeloid leukemia in first remission. N Engl J Med 1998;339: 1649–1656.)

Deciding if a patient in first CR should be transplanted outside a clinical trial remains a controversial issue. Patients with APL are not allografted due to the success of chemotherapy with ATRA in first CR and of autologous transplantation in a second molecular CR. Because of improved DFS after HiDAC intensification in patients with the other good-risk karyotypes [t(8;21) and inv16], allogeneic transplantation is usually recommended only if the patient relapses ([625]). The latter recommendation remains controversial in children because a randomized trial favored allogeneic transplant over chemotherapy in all risk groups; chemotherapy had equivalent survival to autografting in first CR ([630]). A more difficult decision is the use of alternative donors for patients in first CR, whose prognosis is considered so poor that the high mortality associated with an unrelated donor transplant is an acceptable risk. Poor-risk cytogenetics or FLT-3 mutations in patients with normal cytogenetics are factors that could influence the decision to proceed with an early high-risk transplant.

Despite the above reservations regarding transplantation and the trend to risk-stratify therapy according to cytogenetic risk groups, alloSCT remains the best antileukemia therapy. Additionally, overall survival after allografts is gradually improving because of a slight decrease in early mortality, the use of peripheral blood stem cells in preference to marrow, and the availability of donor lymphocyte infusions or second transplants for relapsed patients ([633]). The development of nonablative SCT is expanding the upper age limits of allogeneic transplants and lessens the early mortality ([634] , [635]). Strategies to decrease the incidence of relapse after autologous transplants include immunotherapy, positive stem cell selection, and methods to develop autologous graft versus leukemia ([636]).

SPECIAL ISSUES

Relapsed and Refractory Acute Myeloid Leukemia

Between 40 and 80% of patients with AML relapse, and 10 to 20% of patients have refractory AML (i.e., never obtain a CR) ([637], [638] and [639]). Patients with therapy-related AML may have transient responses to chemotherapy, but because almost all relapse, they should be considered for transplantation early in the course of their disease ([640], [641], [642], [643], [644] and [645]). Highly resistant AML includes not only refractory AML but also leukemia that relapses within 6 months after attainment of CR and leukemia that fails to go into a second remission ([646]). Allogeneic SCT is superior to chemotherapy for the patient with relapsed or refractory disease, but many patients either do not have a donor or are too old for transplantation ([647]). Autologous SCT is also an alternative for patients in second remission, but it is probably inferior to allografting.

Second remissions can be obtained in 30 to 50% of patients who had an initial first remission, are achieved more readily in patients with initial remissions longer than 1 year, and are generally shorter in duration than first remissions ([648], [649] and [650]). Dose escalation and use of non–cross-resistant regimens have been helpful in inducing second remissions ([651]). Single agents have been used in phase I and II studies in patients after relapse but probably are inferior to combination regimens. HiDAC alone resulted in a CR rate of 40% compared to 56% in patients receiving the combination of an anthracycline and HiDAC ([652]). Other agents including L-asparaginase, amsacrine, mitoxantrone, etoposide, and fludarabine have been used in combination with HiDAC, with CR rates between 40 to 70% ([653], [654], [655] and [656]).

Despite the ability to induce a second remission with chemotherapy, most patients cannot be cured with chemotherapy because of drug resistance ([657], [658]). Mechanisms of drug resistance include altered metabolism of drugs because of changes in enzymes ([659], [660]) and enhanced expression of MDR genes ([447], [448], [449], [450], [451], [452] and [453]). Levels of topoisomerase II may correlate with drug efficacy, as suggested by the presence of lower levels in doxorubicin-resistant P-833 leukemia cells compared to the sensitive parental lines ([660]). The best described MDR gene is MDR-1; its gene product, p-glycoprotein, is a 170-kd membrane glycoprotein that functions as a drug efflux pump ([447], [448], [449] and [450]). Elevated levels of mRNA encoded by the MDR-1 gene are found in 13 to 71% of untreated patients with AML and in 50 to 85% of patients with secondary AML and after relapse, and they appear to correlate with prognosis ([447], [449], [661]).

Reversal of drug resistance may be accomplished through the use of calcium channel antagonists such as verapamil or the immunosuppressive agent cyclosporine. The mechanism does not depend on intracellular calcium content or immunosuppression; rather, the drugs appear to compete with chemotherapy agents for binding sites on p-glycoprotein. Additionally, cyclosporine and PSC-833, a more potent and selective analog, can increase levels of chemotherapy metabolites by altering the hepatobiliary elimination of bilirubin and the chemotherapy drugs. A randomized trial comparing cyclosporine with chemotherapy versus chemotherapy alone in poor-risk AML favored the cyclosporine arm ([662]); however, trials evaluating PSC-833 have been disappointing ([663], [664]). Other proteins are also associated with drug resistance, including the 110-kd major vault protein called the LRP, which may alter intracellular drug distribution; its expression has also been associated with a poor prognosis ([451], [665]).

Acute Myeloid Leukemia in the Elderly

Older patients with AML, usually defined as those 60 years of age or older, have a worse outcome than younger patients ([666], [667]). Reasons for the poorer prognosis in older patients include differences in biology, cytogenetics, comorbid illnesses, and drug resistance ([666], [667]). The biology of AML may differ in older patients, with the malignant cell originating at an earlier stage of development than in younger patients ([187]). Prior MDS and treatment-related leukemia are more common ([666]). Unfavorable cytogenetic abnormalities are more common in the elderly, whereas the favorable core-binding factor abnormalities are less common ([666]). Drug resistance, as defined by an increased expression of the MDR-1 gene or lower CR rate, is more commonly found in elderly patients ([447], [448] and [449]). In addition, older patients are more likely to have defects in the MSH2 protein, which is involved in DNA repair and is associated with microsatellite instability and p53 mutations ([668]).

Although the overall prognosis in AML patients older than 60 years of age is poor, CR rates approaching those of younger patients can be observed, so chemotherapy should not be withheld on the basis of age alone ([666], [667], [669]). Still, because of a high treatment-related mortality in the elderly (15 to 30%) and poor long-term DFS (5 to 15%), it is important to emphasize the poor prognosis and to give consideration to supportive care alone ([667]). CR rates in the elderly are usually in the 35 to 60% range, but median remission duration is less than 1 year regardless of the type of consolidation ([666], [667]). With aging, vital organs may be compromised, requiring modifications in the agents used to treat AML. For example, a decrease in anthracycline dose has been advocated to reduce gastrointestinal and cardiac toxicity, but excessive dose reductions may compromise remission rates ([669]).

Early studies comparing low-dose chemotherapy or a watchful waiting approach to standard induction therapy in the elderly indicated a marginal benefit to standard therapy but with a high treatment-related mortality ([670], [671]). Mitoxantrone plus etoposide has been advocated for use in the elderly; however, a randomized trial comparing this combination to cytarabine plus daunorubicin showed no improvement ([672]). Intermediate to HiDAC has also not improved the survival of elderly patients with AML ([589], [673]). The use of growth factors may lessen the toxicity of therapy in the elderly, but their impact on survival has not been proven ([666]). Gemtuzumab ozogamicin (Mylotarg) has been used primarily in the setting of relapse ([592], [593] and [594]). Autologous transplantation is of uncertain benefit in the elderly, and allogeneic transplantation is usually considered too toxic, although studies are evaluating nonablative transplantation in the elderly ([634]). The main strategies to improve survival of older AML patients are to improve tolerability without losing efficacy and to overcome drug resistance ([667]).

Acute Myeloid Leukemia in Pregnancy

Development of AML during pregnancy is rare, occurring in less than 1 in 75,000 pregnancies. Nonetheless, it is a major issue ([674], [675], [676], [677] and [678]). Transmission of leukemia from mother to fetus is extremely unusual ([679], [680]). Diagnosis of AML is less common in the first trimester than in the second or third trimesters, occurring in 14% in a series of 59 patients ([677]). Teratogenic effects of chemotherapy are more common in the first trimester and appear to be minimal in the second or third trimester ([678], [681]). Some authorities advocate therapeutic abortion in the first trimester, and others suggest supportive therapy until the second trimester. Chemotherapy with intensive supportive care can result in a successful outcome for the fetus and mother with leukemia, particularly in the second or third trimester ([676], [678]). Fetuses exposed to antileukemia therapy *in utero* may have slight fetal growth restriction and transient myelosuppression if treatment is given near delivery but generally have normal growth and development in childhood ([682], [683]).

Hypocellular Acute Myeloid Leukemia

Hypocellular AML occurs in 5 to 10% of patients with AML and is defined by a decreased percentage of hematopoietic elements in the marrow biopsy; the definition of hypocellularity varies between 5 and 40% cellularity ([684]). Hypocellular AML typically is seen in patients 50 years of age or older and should be distinguished from myelodysplastic syndromes and aplastic anemia. Although results of some studies suggest that supportive care alone can result in prolonged survival, Howe et al. demonstrated a CR rate of 73% in a series of 29 patients with hypocellular AML ([685]). Although hypocellularity alone should not exclude a patient from receiving chemotherapy, caution should be exercised in treating these patients, and transplantation strategies should be considered.

Growth Factors and Biologic Response Modifiers

A variety of purified monokines and lymphokines, including colony-stimulating factors (CSFs), ILs, interferons, and TNFs, have been investigated as modifiers of cytopenias and of leukemia growth *in vitro* and *in vivo* ([686], [687]). The best studied are the myeloid growth factors GM-CSF and G-CSF. There have been differences in manufacturing the myeloid growth factors; there are glycosylated yeast-derived GM-CSF (sargramostim), nonglycosylated *Escherichia coli*–derived GM-CSF (molgrastim), glycosylated Chinese hamster ovary–derived G-CSF (lenograstim), and nonglycosylated *E. coli*–derived G-CSF (filgastrim). Use of the myeloid growth factors in AML was questioned due to *in vitro* data demonstrating increased growth of leukemia blasts in their presence. This effect on leukemia cells was used to attempt to recruit cells into S-phase, in which they would be more chemosensitive to S-phase–specific agents such as cytarabine. Other possible beneficial effects of cytokines on leukemia cells include enhancement of chemotherapy-induced apoptosis, increase in topoisomerase II levels, and down-regulation of MDR-1 ([687]).

Despite the concerns about the effect of the CSFs on leukemia cell growth, studies were initiated in the 1990s to determine their efficacy. Two of the early reports

were by Ohno et al. and Büchner et al., evaluating *E. coli*–derived G-CSF in patients with relapsed or refractory leukemia and yeast-derived GM-CSF in elderly patients with *de novo* AML, respectively. Both reports indicated the CSFs could be administered safely, with a statistically significant reduction in the duration of neutropenia and in early deaths, and trends toward an improvement in the CR rate, but not in survival ([688], [689]). Subsequently, there have been numerous phase III trials (Table 79.13) ([690], [691], [692], [693], [694], [695], [696], [697] and [698]). These studies are difficult to compare because of variable patient populations, different induction and consolidation therapies, different growth factors and timing of their use, and variable documentation of marrow hypoplasia ([687]). For the most part, the studies consistently show improved neutrophil recovery, which usually results in fewer infections and shorter hospitalizations, but they rarely show improved CR rates, relapse rates, or survival.

TABLE 79.13. Phase III Trials of Colony-Stimulating Factors in Patients with *De Novo* Acute Myeloid Leukemia

Author (Reference)	Product	No. of Patients	Age (yr)	Recruitment into Cell Cycle	Leukemia Stimulation	Neutrophil Recovery	Complete Remission	Survival
Stone (690)	*E. coli* GM-CSF	388	=60	Day 8	-	+	-	-
Witz (691)	*E. coli* GM-CSF	226	55–75	Yes	-	+	-	-
Zittoun (692)	*E. coli* GM-CSF	102	15–60	Variable	+	-	?	-
Lowenberg (693)	*E. coli* GM-CSF	316	>60	Yes	-	+	-	-
Rowe (694)	Yeast GM-CSF	117	55–70	No	-	+	-	?
Büchner (695)	Yeast GM-CSF	96	16–75	Yes	-	+	-	-
Dombret (696)	G-CSF	173	=65	Day 8	-	+	?	-
Heil (697)	G-CSF	521	Adults	Day 8	-	+	-	-
Godwin (698)	G-CSF	193	>55	No	-	+	-	-

-, no significant difference; +, ?, ?, significance noted; *E. coli*, *Escherichia coli*; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.

Adapted from Geller RB. Use of cytokines in the treatment of acute myelocytic leukemia: a critical review. J Clin Oncol 1996;14:1371–1382.

For now, the CSFs are generally regarded as safe and useful primarily as supportive care to decrease infections ([687]). Their use after chemotherapy during induction may make marrow examinations more difficult to interpret because of difficulty in distinguishing early recovery of myeloid cells from leukemia blasts. Some advocate using growth factors in induction only after aplasia has been documented or as part of a clinical trial. Their role in consolidation has not been studied as extensively as in induction.

Growth factors to stimulate platelet production have not been as successful as those for myelopoiesis and erythropoiesis. IL-2 was cloned in 1990; despite its nonspecific and modest effect on megakaryocytes, it can reduce platelet transfusion requirements in approximately one-third of patients undergoing standard chemotherapy ([699], [700]). IL-2 is associated with mild peripheral edema, dyspnea, injected conjunctiva, and a low incidence of syncope and atrial arrhythmias, and it is not routinely used in therapy for acute leukemia.

TPO, the c-mpl ligand, is the specific regulator of megakaryocyte development and platelet production and was purified in 1994 ([699], [700]). Two forms of TPO, recombinant human TPO and pegylated recombinant human megakaryocyte growth and development factor, have undergone clinical investigation. Although both stimulate megakaryocytes and platelet production and have improved platelet recovery after moderate intensity chemotherapy, they have demonstrated little benefit in improving the severe thrombocytopenia associated with induction and consolidation chemotherapy of AML ([700]).

Whereas the above cytokines appear to have a supportive role in lessening the duration of cytopenias, other cytokines are being evaluated for their antileukemia effects. Phase I-II clinical trials of IL-2 in patients with relapsed AML identified responses, particularly in those with low percentages of blasts ([701], [702]), and ongoing trials are evaluating its use in eradicating minimal residual disease after chemotherapy or transplantation ([703], [704] and [705]). Cytokines are being used to modify leukemia cells into efficient antigen-presenting cells to stimulate an antileukemic immune response ([706], [707]). Although different cocktails of cytokines have been used, GM-CSF and IL-4 in combination with an immunomodulator (soluble CD40L) or TNF-a converted AML cells into dendritic cells that could stimulate a T-cell immune response ([707]).

Leukemia cells release proangiogenic cytokines as well as proinflammatory cytokines, including IL-1, TNF, and basic fibroblast growth factor ([708]). Angiogenic factors include direct and indirect angiogens and integrins ([709]). Indirect angiogens promote vascular formation by paracrine stimulation of direct angiogens, whereas integrins interact between new blood vessels and the extracellular matrix ([709]).

VEGF is a direct angiogen that can be released by leukemia cells and promote vasculogenesis by binding to one of three receptors (VEGFR-1, -2, or -3) ([709]). Endothelial cells produce VEGF-C in response to proinflammatory cytokines and can promote leukemogenesis by interacting with its receptor VEGFR-3 (FLT-4), which is present in one-third of AML cases ([708], [710]). VEGF-C blocks chemotherapy-induced apoptosis of FLT-4+ leukemia by induction of bcl-2 with increased bcl-2 to bax ratios ([709]). Potential antileukemia therapy will be directed at blocking VEGF pathways by antibodies that neutralize VEGF or by small molecules that inhibit the receptor tyrosine kinase activity of VEGF receptors ([709]).

Gene and Antisense Therapy

Gene-marking studies have been used in the autologous transplant setting to document that harvested autologous marrow cells contribute to stem cell recovery ([711]). The clinical applicability of gene therapy in leukemia is uncertain, but it offers novel therapeutic strategies (Chapter 26). Therapeutic applications under investigation include augmentation of the immune response against leukemia cells through transfection of cytokine genes, genetic modification of marrow stem cells for resistance to chemotherapy through transfection of MDR genes, and direct modifications of the leukemia cells to enhance chemosensitivity ([712], [713] and [714]). Current phase I trials of antisense oligonucleotides in hematologic malignancies, including AML, are aimed at abrogating the expression of tumor-suppressor genes and promoting leukemia cell death ([712], [713] and [714]). More than likely, gene therapy will be additive to other therapies currently in use and have its greatest impact when the tumor burden is low.

SUMMARY AND FUTURE DIRECTIONS

Descriptions of clinicopathologic syndromes and correlations with immunophenotype, cytogenetics, and molecular genetics will continue to define subsets of AML as advocated in the WHO classification. Leukemogenesis will be best understood through the recognition of genes and their molecular interactions that promote cancer cell survival. In addition, gene expression analysis using microarrays will identify gene profiles that correlate with prognosis and promote more precise classification ([715]).

Therapeutically, patients will be stratified according to prognostic factors and genetic markers, and clinical trials will continue to define the roles of both chemotherapy and transplantation. Monoclonal antibody therapy is an effective new treatment currently under investigation. A better understanding of the mechanisms of tumor resistance and apoptosis is also needed to improve therapy. New agents in clinical trials are directed at molecular biologic targets involved in leukemia, including DNA methylation, angiogenesis, farnesyl transferase, and FLT-3. The detection of minimal residual disease is an ongoing area of study and can be a target for novel

agents, monoclonal antibodies, and gene therapy.

Acute Lymphoblastic Leukemia in Children

Acute lymphoblastic leukemia (ALL) is the most common malignant disease affecting children, accounting for approximately 30% of childhood cancers ([1]). Recent data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program place the incidence of childhood ALL at 26 per million person years in the United States ([2]). Within this cohort, approximately 75% are children younger than 10 years of age, and 50% are younger than 5 years of age. Before the advent of effective chemotherapy in the 1960s, ALL was invariably fatal. Within 20 years, however, more than 50% of children with the disease were in complete remission 5 years from diagnosis ([3]), with most of these patients considered cured (Fig. 80.1). Further progress followed the use of effective post-induction intensification based on L-asparaginase, intermediate dose methotrexate, and/or multi-agent reinduction and re-consolidation. Over 80% of children with ALL are expected to be cured in the 2000s.

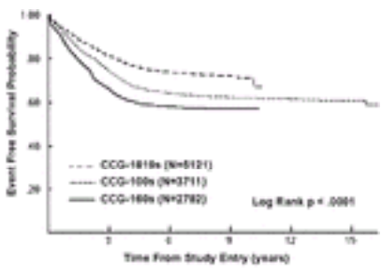

Figure 80.1. Event-free survival in Children's Cancer Group (CCG) acute lymphoblastic leukemia trials over 17 years, 1978–1995 (CCG-160s: 1978–1983; CCG-100s: 1983–1988; CCG-1819s: 1989–1995). (Courtesy of Dr. Harland N. Sather and the Children's Cancer Group, Arcadia, CA.)

Currently, new patients are stratified into prognostic groups on the basis of presenting clinical and laboratory features and initial response to therapy. Patients with favorable features can be expected to respond satisfactorily to standard therapy, whereas those with adverse features achieve better outcome with more aggressive therapeutic strategies. Increasing evidence implies that novel chemotherapy approaches and better supportive care mitigate many disease characteristics previously associated with a poor prognosis.

The diagnosis and characterization of ALL are discussed in Chapter 77. The molecular genetics of ALL are discussed in Chapter 76. This chapter is concerned with the clinical characteristics, treatment, and late sequelae.

CLINICAL FEATURES

Although it affects all age groups, ALL has its highest incidence in children between the ages of 1 and 5 years, with a peak at 3 to 4 years ([4], [5]). Curiously, this early peak is not seen in blacks, and as a result, ALL is more common in whites ([3], [6]). A slight male predominance (57%) has been noted in all demographic analyses of the disease.

Symptoms may be insidious and slowly progressive over weeks to months, or they may be acute and explosive. In general, the more indolent the onset, the better the outcome. Symptoms and signs result from either bone marrow failure or the involvement of extramedullary sites by leukemia (Table 80.1) ([7], [8]). Easy fatigue, lethargy, fever, and bone and joint pain are the most common presenting complaints. Fatigue and lethargy correlate with the presence and severity of anemia ([7]). No infectious basis for fever is found in most patients, especially if the neutrophil count exceeds 0.2 × 10^9/L ([9]). The leukemic process itself may be responsible for fever because fever resolves in most patients after the institution of chemotherapy ([10]). However, the risk of infection is still substantial at presentation, and prompt intravenous antibiotic therapy is the standard of care. Bone pain results from bone erosion or leukemic involvement of the periosteum. Young children, in particular, often present with gait disturbances or a refusal to walk. Vertebral compression fractures may complicate generalized osteoporosis. Prominent skeletal symptoms occur primarily in children with no lymphadenopathy, organomegaly, or leukocytosis, and as a result, the diagnosis of leukemia often is delayed ([11], [12] and [13]). Less commonly, bone pain is caused by recurring episodes of bone marrow necrosis ([14], [15] and [16]). Marrow necrosis also is associated with a small leukemic burden and an aleukemic blood picture. Approximately 2% of children present with marrow findings consistent with aplastic anemia; overt leukemia follows within weeks to months ([17], [18]); the majority of these children are females younger than 10 years old ([19]). Weight loss rarely is severe and is seen only in patients with longstanding symptoms. Central nervous system (CNS) involvement by leukemia occurs in approximately 2% of patients at diagnosis and may be manifested by headaches and vomiting or cranial nerve palsy ([20]). Cerebrospinal fluid (CSF) involvement is usually asymptomatic. Physical findings include various combinations of pallor, petechiae or purpura, mucous membrane bleeding, fever, lymphadenopathy, splenomegaly, hepatomegaly, tenderness over the sternum and other bones, and fundic hemorrhages. Abdominal organomegaly rarely is symptomatic. Skin involvement is rare; when it occurs, it is associated with the pre–B-cell phenotype ([21]). Infants 24 months of age or younger present with a constellation of features that portend an unfavorable outcome. They are more likely to have massively enlarged livers and spleens, hyperleukocytosis, chromosomal changes involving 11q23, involvement of spinal fluid by leukemic cells, and a slow response to therapy ([22]).

TABLE 80.1. Frequency of Clinical and Laboratory Findings at Diagnosis in 178 Children and Adults with Acute Lymphoblastic Leukemia

Clinical Features	Percentage	Laboratory Features	Percentage
Symptoms	—	White blood cells (×10^9/L)*	—
Fatigue	92	<10	40

Bone or joint pain	79	10–49	34
Fever without infection	71	50–99	15
Weight loss	66	=100	11
Abnormal masses	62	Neutrophils (×10 ^{9}/L)	—
Purpura	51	>1	73
Other hemorrhage	27	1–2	9
Infection	17	>2	18
Physical findings	—	Packed cell volume (L/L)	—
Splenomegaly	86	<30	65
Lymphadenopathy	76	>30	35
Hepatomegaly	74	Platelets (×10 ^{9}/L)	—
Sternal tenderness	69	>50	62
Purpura	50	50–150	30
Fundic hemorrhage	14	>150	8

LABORATORY FEATURES

The white blood cell (WBC) count is elevated in 60% of patients (Table 80.1). Because the number of normal leukocytes is reduced, the WBC count generally mirrors the number of circulating blast cells. Although obvious in smears of patients with high counts, leukemic blasts may be found only after careful review of blood smears from patients with decreased leukocyte counts. Occasionally, no lymphoblasts can be identified with certainty, despite extensive bone marrow involvement (aleukemic leukemia). A WBC count in excess of 50 × 10 ^{9}/L is frequently associated with prominent lymphadenopathy, hepatosplenomegaly, and the T-cell immunophenotype. Unlike the situation in acute nonlymphoblastic leukemia (ANLL), hyperleukocytosis in ALL rarely is complicated by intracerebral hemorrhages or pulmonary insufficiency ([23]).

Although occurring less frequently than in ANLL, coagulopathies may lead to both hemorrhagic and thrombotic complications ([24]). The coagulopathy usually is mediated by thrombin activation rather than by primary fibrinolysis ([25]).

Bone marrow aspiration is the standard method of establishing the diagnosis and provides cells for immunophenotypic, histochemical, and cytogenetic analysis. Bone marrow lymphoblasts are more homogenous with respect to both morphologic and biologic characteristics than those in the blood. When cell density or marrow reticulum prevents marrow aspiration, a biopsy should be performed. The marrow is hypercellular with replacement of fat spaces and normal marrow elements by leukemic cells. In contrast to ANLL, residual myeloid and erythroid precursors appear morphologically normal. Megakaryocytes are decreased or absent.

A large leukemic cell burden having a high rate of cell turnover may produce several metabolic disturbances. Chief among these is elevation of the serum uric acid level. Although gout is a rare complication of hyperuricemia ([26]), urate nephropathy is not. Acute renal failure resulting from urate nephropathy may be a presenting feature, even in the absence of a large leukemic cell burden ([27]). Increased cell destruction also is responsible for hyperphosphatemia and hypocalcemia ([28]). As with hyperuricemia, these abnormalities are most likely to pose problems after the institution of chemotherapy. The management of these metabolic complications is discussed in Chapter 72. Serum levels of lactic dehydrogenase (LDH) are increased because of an increased turnover of leukemic cells.

Radiographic examination of the chest demonstrates an anterior mediastinal mass in 5 to 10% of newly diagnosed patients. The thymic mass may be associated with pleural effusions, which on thoracentesis are found to be malignant. Skeletal lesions can be demonstrated radiographically in more than 50% of patients ([29]). The most common abnormalities include transverse metaphyseal radiolucent lines adjacent to the zone of provisional calcification at the end of long bones, generalized rarefaction of bones, cortical and trabecular osteolytic lesions, and periosteal new bone formation.

Lumbar puncture provides evidence of CNS involvement by leukemia in approximately 3% of children at diagnosis ([30]). Cytocentrifugation of CSF enhances diagnostic sensitivity by concentrating leukemic cells. Histochemical staining and determination of the immunophenotype of cells from suspicious or equivocal CSF may help to establish the presence or absence of leukemic involvement ([31]). Patients with symptomatic CNS involvement may have increased CSF pressure, elevated levels of CSF protein, and decreased glucose values.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of ALL is based on the demonstration of lymphoblasts in the bone marrow. By convention, the minimum number of bone marrow lymphoblasts required for diagnosis is set at 25%. In practice, patients with acute leukemia are found to have far more than 25% blasts. Characterization of the leukemia as lymphoblastic rather than nonlymphoblastic is based on morphologic, cytochemical, immunophenotypic, cytogenetic, and molecular biologic observations that are reviewed in detail in Chapter 77.

Occasionally, solid tumors that involve the bone marrow may be confused with lymphoblasts. In the pediatric age group, this confusion occurs most frequently with neuroblastoma ([32]). Although tumor cells tend to occur in clumps, they may replace marrow elements diffusely. Differentiation from leukemia is readily accomplished with immunohistochemistry, cytogenetic analysis, and electron microscopy. Involvement of the bone marrow by non-Hodgkin lymphoma cannot be differentiated by morphologic features or immunophenotype alone; differentiation rests on knowledge of the distribution of disease at initial presentation.

Diagnosis is not difficult once the possibility of acute leukemia is considered. Because of the variety of nonspecific symptoms caused by ALL, however, more common disorders often assume priority in the differential diagnosis. Fever, joint symptoms, and mild anemia are readily mistaken for juvenile rheumatoid arthritis or systemic lupus erythematosus ([33]). Further diagnostic confusion is assured if a test for antinuclear antibody is positive ([34]). An abnormal leukocyte differential, leukopenia, thrombocytopenia, or failure to respond to salicylate should prompt consideration of leukemia ([35]). Some infections, notably infectious mononucleosis, toxoplasmosis, and cytomegalovirus infection, also are characterized by fever, lymphadenopathy, hepatosplenomegaly, and abnormal blood lymphocytes. These infectious disorders are distinguished from acute leukemia by the distinctive morphology of reactive lymphocytes and lymphoblasts. In addition, the lymph nodes and abnormal organs associated with viral disease are usually (but not always) soft and ill defined, in contrast to the firm and discrete nature of the nodes, liver, and spleen in acute leukemia. Aplastic anemia may be impossible to distinguish from aleukemic leukemia on both clinical and hematologic grounds without a bone marrow biopsy. The serum uric acid and LDH levels characteristically are low in the former and elevated in the latter. Like ALL, idiopathic thrombocytopenic purpura occurs with greatest frequency in children between 3 and 5 years of age. The presence of symptoms other than those that can be attributed to purpura, or the detection of splenomegaly, an abnormal WBC count, or an abnormal leukocyte differential are clues that thrombocytopenia is not on an immune basis. Thrombocytopenia in the absence of other physical or hematologic manifestations occurs rarely, if at all in ALL ([36]). Acute disseminated Langerhans cell histiocytosis, like ALL, is associated with fever, purpura, hepatosplenomegaly, and pancytopenia (see Chapter 66). Unlike ALL, the skin also is frequently involved. The disorders are differentiated readily by histopathology.

CLASSIFICATION AND ASSESSMENT OF RISK

ALL is a heterogeneous group of disorders comprising subtypes that differ with respect to their pathogenesis, biology, and clinical features. Some subtypes are characterized by a small leukemic burden and indolent clinical course, whereas others have extramedullary involvement and a rapid progression. The ability to identify biologic and clinical features that influence prognosis has led to the use of different treatment regimens for different risk groups, which in turn has resulted in both improved overall outcomes and decreased toxicities for selected subsets of patients. Currently utilized schemes for classification of risk rely primarily on clinical, immunophenotypic, and cytogenetic and response features (Table 80.2). However, these features do not account for much of the variability in prognosis in childhood

ALL ([37]). Advances in the understanding of the molecular genetic features of ALL promise to lead to an improved laboratory-based classification that will ultimately result in more precise risk assignment and will direct targeted therapies.

TABLE 80.2. Prognostic Factors in Acute Lymphoblastic Leukemia

Determinants	Favorable	Unfavorable
White blood cell count	$<10 \times 10^9$/L	$>200 \times 10^9$/L
Age	3–7 yr	<1, >10 yr
Gender	Female	Male
Ethnicity	White	Black
Node, liver, spleen enlargement	Absent	Massive
Testicular enlargement	Absent	Present
Central nervous system leukemia	Absent	Overt (blasts + pleocytosis)
FAB morphologic features	L1	L2
Ploidy	Hyperdiploidy	Hypodiploidy < 45
Cytogenetic markers	Trisomies 4, 10, and/or 17 t(12;21) (tel aml1)	t(9;22) [bcr abl] t(4;11) [mll af4]
Time to remission	<14 d	>28 d
Minimal residual disease	$<10^{-4}$	$>10^{-3}$

Immunophenotype

The immunophenotypic classification of ALL is based primarily on the surface marking characteristics of leukemic blasts and recognizes two lineages of lymphocytes (T and B cells), each of which can be subclassified into several maturational stages ([38], [39]). Leukemic T cells differ from those of B-cell lineage in that they less frequently express CD10 (the “common ALL antigen” or CALLA) ([40]) and HLA-DR, they more often are PAS negative, and they may have an increased amount of acid phosphatase ([41]). Mature B-cell ALL is distinguished by surface immunoglobulin (Ig) expression, whereas so-called pre-B cells express cytoplasmic, but not surface, Ig ([42]). Precursor B-cells, although lacking both membrane and cytoplasmic immunoglobulin (cIg), express surface antigens that are shared by more mature B-lymphocytes. Commitment to B-cell differentiation may be identified by rearrangement of one or more immunoglobulin genes.

Early pre-B cell ALL comprises approximately two-thirds of cases of childhood ALL ([43], [44]) and is associated with a favorable prognosis ([44]). Although most early pre-B lymphoblasts are CALLA positive, CALLA expression does not appear to have independent prognostic significance ([45], [46]).

Pre-B cell ALL accounts for approximately 20% of childhood ALL ([44], [47]) and has been associated with a poorer outcome compared to early pre-B cell ALL ([48]). Expression of cIg in ALL is associated with a nonrandom cytogenetic abnormality, t(1;19)(q23;q13) ([49]). The presence of this translocation, which is identified at the cytogenetic level in 20 to 30% of pre-B ALL patients ([49]) is the primary determinant of adverse prognosis in pre-B ALL ([50], [51]). Patients without this lesion have a survival rate similar to that of patients with early pre-B ALL.

Mature B-cell ALL is uncommon, accounting for only 1 to 2% of ALL cases in children ([44], [45], [52]). Both B-cell ALL and Burkitt lymphoma are characterized by FAB L3 morphology ([53]), an (8;14) or related translocations ([54]), and overexpression of the *c-myc* oncogene ([55]). Children with B-cell ALL are older than those with other B-lineage subtypes and have a higher incidence of CNS involvement. Children with B-cell ALL have a poor response to, and abbreviated survival after, standard ALL therapeutic regimens ([56]); however, dose-intensive regimens of brief duration used for Burkitt lymphoma have led to cure rates of 75% or higher ([57], [58] and [59]).

Transitional pre-B ALL, characterized by expression of cytoplasmic and surface μ heavy chains without Ig light chain expression, occurs in a small (approximately 1%) subset of childhood ALL ([60]). These cases lack FAB L3 morphology or the chromosomal translocations associated with mature B-cell ALL and have a favorable outcome.

T-cell ALL accounts for approximately 15% of ALL in children ([43], [44]). It is rare in infants younger than 1 year of age ([61], [62]). T-cell ALL occurs more frequently in males and is frequently associated with a high WBC count at diagnosis ([45], [52], [63], [64]). A mediastinal mass is present in 50 to 60% of patients, and the incidence of CNS involvement is higher than in other types of ALL. Although T-cell ALL was previously associated with a poor prognosis ([65]), the recent use of more intensive therapeutic regimens has resulted in a survival approaching that of non-T cell ALL ([66], [67] and [68]). The prognostic significance of T-cell ALL is related to clinical features associated with a poor prognosis, such as high initial WBC count, age older than 15 years, massive splenomegaly, FAB L2 blast morphology, and abnormal karyotype ([63], [64]); however, some investigators have found that clinical and laboratory prognostic factors are not as predictive for outcome in T-cell ALL as in B-precursor ALL ([69]). By multivariate analysis, the T-cell immunophenotype per se does not appear to be an independent prognostic variable ([45], [70]). Among T-cell ALL patients, those with the least mature immunophenotype have a significantly worse outcome than those with more mature immunophenotypes ([71]). A subset of ALL characterized by expression of the T-cell–associated CD7 surface antigen in the absence of either CD4 or CD8 is associated with resistance to conventional chemotherapy and poor survival ([72], [73] and [74]). Absence of CD2 expression identifies a group of T-cell patients with a worse outcome ([75]).

Approximately 10 to 20% of children with ALL express myeloid-associated antigens such as CD13 and CD33 ([76], [77], [78] and [79]). Although initial reports suggested that ALL with myeloid marker expression was associated with a poorer outcome ([76], [79]), expression of myeloid antigens had no adverse prognostic significance in subsequent clinical trials of childhood ALL ([78], [80], [81]).

Other immunophenotypic markers may have prognostic significance as well. Expression of the stem-cell–associated surface antigen CD34 exerts an independent favorable effect on the outcome of B-lineage, but not T-lineage, childhood ALL ([82], [83]). Lack of expression of CD45 antigen, which is uniformly expressed in T-lineage childhood ALL but only a proportion of B-lineage ALL, was associated with lower WBC count, lower serum LDH, and hyperdiploidy in one study ([84]).

Cytogenetic Markers

Both chromosome number (ploidy) and chromosomal structural alterations have prognostic significance that is independent of other disease characteristics ([85], [86] and [87]). Patients with “normal” cytogenetics may have clonal abnormalities by molecular fluorescent *in situ* hybridization or reverse transcriptase-polymerase chain reaction assay, or both.

CHROMOSOME NUMBER Children whose blasts demonstrate a hyperdiploid karyotype (modal number of chromosomes greater than 50) experience longer remissions and better survival rates than other cytogenetic groups ([87], [88], [89], [90] and [91]). Children whose blasts by flow cytometry are judged to have 53 or more chromosomes have a relapse rate only one-third that of children with blasts with lower DNA content ([46]). Hyperdiploidy in association with trisomies of chromosomes 4, 10, and/or 17 is associated with a particularly favorable prognosis ([92], [93] and [94]). The adverse prognostic significance of a DNA index less than 1.16 persists after cessation of treatment ([95]). The adverse prognostic significance of near hyperdiploid (47 to 50 chromosomes) seen in earlier studies has improved with the use of more effective therapy ([96], [97]). Near-tetraploidy (82 to 94 chromosomes) constitutes an exception to the generally favorable impact of hyperdiploidy. This rare anomaly is associated with a high frequency of treatment failure ([98]). The prognosis for children whose blasts contain 47 to 50 chromosomes is comparable to that of children with a normal chromosome number ([54], [91]). Children with pseudodiploidy (i.e., structural rearrangement without change in total chromosome number) have

short remissions and poor survival ([87] , [89] , [90] and [91] , [99]). Hypodiploidy confers adverse risk ([97] , [100] , [101]), which persists despite intensification of therapy ([102]); near-haploidy is associated with a particularly dismal outcome ([101] , [103] , [104]). Chromosome classification adds significant prognostic information to the WBC count at diagnosis, age, FAB classification, and cell immunotype ([89] , [90] and [91] , [99] , [105]). Ploidy was the strongest predictor of outcome in one analysis of B-precursor ALL ([106]) and the only variable that added significant prognostic information to the leukocyte count in another ([91]).

STRUCTURAL CHROMOSOMAL AND GENETIC CHANGES Clonal chromosomal translocations are strong predictors of adverse treatment outcome in ALL ([88] , [107]). The t(9;22)(q32;q11), or Philadelphia (Ph) chromosome, is present in approximately 20% of adults and 5% of children with ALL at the cytogenetic level ([99] , [108] , [109] , [110] and [111]); molecular analysis to detect the *bcr-abl* fusion messenger RNA (mRNA) product identifies additional cases that are missed by standard cytogenetics ([112] , [113]). Unlike many other nonrandom translocations, the t(9;22) is not associated with a specific immunophenotype. Features associated with the Ph chromosome include high WBC count, older age, male predominance, and FAB L2 blast morphology ([110]). Although the strong adverse prognostic significance of the Ph chromosome persists after adjustment for other prognostic features ([88] , [99] , [105] , [114] , [115]), an international review concluded that some children with Ph-positive ALL and favorable prognostic features can be cured with intensive chemotherapy alone ([111]). The t(4;11)(q21;q23) is also associated with high-risk features, most notably a high WBC count and age younger than 1 year ([116] , [117]). The association of t(4;11) with leukemia in infants is particularly striking ([117] , [118]) and is associated with a poor outcome in multivariate analyses, in contrast to involvement of other 11q23 rearrangements ([119]). Leukemic blasts with t(4;11) may express early myeloid as well as B-lymphoid markers, suggesting that they may be pluripotent stem cells ([117] , [120]). Molecular analysis of the *MLL* gene at 11q23 ([121] , [122] and [123]) has demonstrated that *MLL* alterations constitute a significant independent adverse prognostic risk factor in infants with ALL and that infants who lack this alteration have a good outcome with current therapies ([124] , [125] , [126] , [127] and [128]). Even when infants are excluded, *MLL* alterations are associated with poor outcome in childhood ALL ([129]). The t(1;19)(q23;p13) is found in one-fourth of patients with the pre-B (cIg+) immunophenotype ([49] , [130]). The t(1;19) is associated with a high WBC count and DNA index <1.16, and accounts for the poor prognosis previously associated with the pre-B immunophenotype ([50] , [130] , [131]). This translocation represents fusion of the *E2A* and *PBX1* genes on chromosomes 1 and 19, respectively ([132]). Expression of the *E2A-PBX1* fusion gene is associated with the t(1;19) in cIg+, but not cIg–, cases of childhood ALL ([131]); its detection allows more precise identification of those cases at high risk for treatment failure ([133]). Patients whose leukemias bear the unbalanced, or derivative, form of the t(1;19)(q23;p13) have an outcome similar to those with the balanced translocation ([131] , [134]). Translocations involving the *c-myc* locus at 8q24, together with one of the Ig loci at 14q32, 2p12, or 22q11, are characteristic of B-cell ALL, or Burkitt leukemia, and are indistinguishable from the t(8;14) and related translocations that occur in Burkitt lymphoma ([105] , [135]). Treatment with dose-intensive chemotherapy regimens appropriate for Burkitt lymphoma has abrogated the adverse prognosis previously associated with this translocation in patients with B-cell ALL ([57] , [58] and [59]). Although abnormalities of 12p occur in approximately 10% of cases of childhood ALL ([87] , [104] , [136]), their prognostic significance is unclear ([136] , [137]). The cryptic t(12;21) is the most common cytogenetic abnormality yet recognized in childhood ALL, occurring in approximately 25% of B-precursor cases ([138] , [139] and [140]), with involvement in up to one-half of the cases involving 12p abnormalities ([141] , [142]). This translocation joins the *TEL* (or *ETV6*) gene on chromosome 12p with the *AML1* (or *CBFA2*) gene on chromosome 21 and is associated with an early pre-B immunophenotype, a younger childhood population, and nonhyperdiploidy ([138] , [143] , [144] and [145]). Although initial reports indicated that the presence of *TEL-AML1* transcripts were associated with a favorable prognosis in childhood ALL ([128] , [138] , [143] , [144] , [145] , [146] and [147]), other groups subsequently reported that the prognostic significance of *TEL-AML1* was related to intensity of therapy ([148] , [149]), confirming yet again the interaction of treatment with other prognostic variables and suggesting that this group of patients may not be ideal candidates for reduction of therapy ([150]). Deletions or translocations involving chromosome 9p occur in approximately 10% of childhood ALL and are associated with high WBC count at diagnosis, mediastinal mass, T-cell immunophenotype, and an increased risk of relapse ([151] , [152]). The cyclin-dependent kinase 4 inhibitor (*CDKN2* or p16 ^{ink4}) gene, which maps to 9p21, is deleted in 20% or more of ALL and other lymphoid malignancies ([153] , [154] and [155]). Although deletion of the p16 ^{ink4a} gene and the tandemly linked p15 ^{ink4b} gene are associated with T-cell immunophenotype, nonhyperdiploid karyotype, poor event-free survival (EFS), and disease progression ([156] , [157] , [158] , [159] and [160]), prognostic significance of loss of these genes has not been established in prospective studies ([128]).

Gene Expression Profiling

Gene expression profiling through microarray analysis has emerged as a powerful tool in advancing the understanding of the biology of acute leukemias ([161] , [162] , [163] and [164]). Gene expression profiling has independently confirmed traditional classifications of acute leukemias ([161] , [164]), identified biologically distinct categories of ALL not defined by conventional biologic analyses ([162] , [163] and [164]), and identified novel genes whose expressions are altered in ALL ([162] , [164]). Importantly, gene expression profiling also identifies patients at high risk of treatment failure independently of other prognostic factors ([162] , [164]) and is likely to supplement or even replace currently used forms of risk classification and assignment in the future ([165]).

However, differences in gene expression predict outcome within subsets. At the present time, there is no pan-ALL “good” or “bad” prognosis gene.

Drug Sensitivity

A primary cause of treatment failure in ALL is inherent or acquired resistance of leukemic blasts to chemotherapeutic agents. Drug sensitivity as determined by the *in vitro* methyl-thiazole-tetrazolium assay ([166] , [167]) correlates with induction failure, early relapse, and disease-free survival (DFS) ([168] , [169]). The level of glutathione in ALL blasts has been demonstrated to be of independent prognostic value in a multivariate analysis controlling for WBC, age, gender, and immunophenotype, presumably due to an association with resistance to chemotherapeutic agents ([170]).

Minimal Residual Disease

Patients who meet the criteria for clinical remission may nevertheless bear up to 10^{10} leukemic cells ([171]). The ability to detect small numbers of leukemic cells in bone marrow samples from patients in clinical remission using highly sensitive methods, such as polymerase chain reaction (PCR) ([172] , [173] , [174] , [175] and [176]) or multiparametric flow cytometry ([171]), has enabled the monitoring of minimal residual disease, with the possibility of intensifying therapy for patients at higher risk of relapse. A number of studies have demonstrated the ability to identify impending relapse in subsets of patients based on correlation of detection of minimal residual disease during or after completion of therapy ([172] , [173] , [174] and [175] , [177] , [178]). Variations in the sensitivity and specificity of the methods used to detect and to quantify minimal residual disease, as well as questions raised by the unexpected finding of persistent genetic abnormalities related to the leukemic clone in patients in apparent sustained remissions ([175] , [179] , [180]), have complicated the use of minimal residual disease for treatment allocation; nevertheless, recent studies using improved methodologies have shown that detection by either multiparametric flow cytometry analysis of leukemia-associated antigens ([181] , [182] , [183] , [184] and [185]) or PCR detection of leukemia-specific Ig and T-cell receptor rearrangements ([186] , [187] , [188] and [189]) have prognostic power and the likely potential to improve identification of good and poor responders (Table 80.3).

TABLE 80.3. Response and Outcome

Study/Risk Measure [a]	Percent of Patients in Poor Response Subset	Percent of Total Events in Poor Response Subset	Relative Hazard
CCG-105/AR	117/1320 (9%)	12	1.6
Day 14 marrow	M2/M3

[a] Gaynon PS, Desai AA, Bostrom BC, et al. Early response to therapy and outcome in childhood acute lymphoblastic leukemia: a review. Cancer 1997;80:1717–1726.

[b] Some patients with a poor response on CCG-1882 received an effective rescue regimen (augmented intensive therapy).

The presence of a resistant subclone concealed in the midst of a generally sensitive blast population is one potential confounder of assays of chemosensitivity and response ([190]). A marrow sample might not reflect the true leukemic burden if the marrow sample is dilute or if blasts are distributed in an anatomically heterogeneous manner throughout the marrow compartment ([191]). Malignant cells may be difficult to identify in a day 7 or day 14 marrow by light microscopy. Multiparameter flow cytometry has been proposed as a superior strategy for blast identification ([192]). However, cells may share a clonotypic features or fingerprint and not themselves be fully leukemogenic. Clonotypic features may be subject to oligoclonality or clonal evolution ([193] , [194] and [195]). In one study, immunophenotype changed between diagnosis and relapse in 29 of 40 cases studied ([196]). In another study, changes in Ig heavy chain or T-receptor gene were found in 25 of 40 cases studied ([197]). Following multiple markers per patient may minimize the impact of oligoclonality or clonal evolution. In PCR-based assays, focusing on downstream D-N-J junctional sequences instead of the more variable upstream VH-D sequences limits oligoclonality ([198]).

Other Biologic Markers

Inoculation of human leukemic cells into mice with severe combined immunodeficiency provides a model system for the study of human leukemias ([199]). Growth of leukemic blasts in severe combined immunodeficiency mice inoculated with cells from patients with both B- and T-lineage ALL has been shown to correlate with patient outcome ([200] , [201]).

Clinical Features Having Prognostic Significance

WHITE BLOOD CELL COUNT The total WBC count at the time of diagnosis is the single most powerful clinical determinant of remission induction, remission duration, and long-term survival for all age groups ([8] , [45] , [202] , [203] , [204] and [205]). The inverse relationship between remission duration and WBC or blast count is linear. A WBC count in excess of 100×10^9/L at diagnosis is particularly devastating ([206]). Patients with high WBC counts often have bulky extramedullary disease at diagnosis and are at high risk for relapse in the CNS or testes after attainment of bone marrow remission. As with other prognostic factors (except for gender), the significance of the WBC count diminishes with time, so that by 24 months from diagnosis, it is no longer predictive of outcome ([207]).

AGE The second most significant clinical prognostic factor is age at diagnosis ([5] , [8] , [205] , [208] , [209]). In the age group 2 to 6 years, long-term survival is more than one-and-a-half times that of children younger than 2 years or older than 10 years treated in an identical manner ([210]). Infants younger than 1 year of age have an especially poor prognosis, in part because of the concurrence of multiple high-risk factors, such as high WBC counts and extramedullary disease at diagnosis, which in turn are a consequence of an increased frequency of chromosomal alterations involving the *MLL* locus on chromosome 11q23 ([22] , [62] , [118] , [124] , [125] , [211]). Adolescents in the age group 10 to 20 years are also at higher risk than younger children ([212] , [213]), and they may be at higher risk than adults 20 to 50 years of age ([214]). Leukemia in adolescents, as in infants, is frequently associated with adverse prognostic factors, including high WBC counts at diagnosis, T-cell immunophenotype, FAB L2 blast morphology, a low DNA index, and ploidy other than hyperdiploidy. Despite these associations, age 10 to 20 years at diagnosis of ALL has independent adverse prognostic significance ([212] , [213]).

GENDER A difference in prognosis between boys and girls did not become apparent until the introduction of CNS-directed therapy and the emergence of a population of long-term survivors ([8] , [205] , [215]). Gender has little, if any, impact on the success of remission induction (at least in children) and relapse frequency during the first months of treatment. By 6 to 12 months, however, a higher relapse rate in boys is evident—a pattern that persists thereafter. The difference in DFS and survival is seen in all prognostic groups and cannot be attributed to the male prevalence of T-cell ALL ([209] , [216] , [217]). Notable is the observation that gender, unlike WBC count and age, fails to lose its prognostic significance with time ([207] , [218]). After discontinuation of therapy, boys continue to experience a higher incidence of relapse, which can be explained only in part by relapse in the testis, as the rate of bone marrow relapse also is higher ([207] , [217] , [218]). Intensified therapy with contemporary treatment regimens, together with stratification for other prognostic factors such as immunophenotype and DNA index, has mitigated the effect of gender on survival in some studies ([219]).

ETHNICITY In many studies in which investigators examined the effect of race on prognosis, a poorer outcome for blacks was noted ([6] , [204] , [220] , [221] , [222] and [223]). Multivariate analysis indicates that this finding in part relates to different biologic characteristics of the disease in whites and blacks. Blacks more frequently present with a high WBC count, significant adenopathy, mediastinal mass, and FAB L2 blast morphology ([222]). These adverse features are not explained by an increased proportion of the pre-B cell and T-cell phenotypes ([204]). A recent analysis of SEER data found that black males younger than 4 years of age had a poorer survival than other childhood ALL populations, supporting the hypothesis that pharmacogenetic or other as-yet unidentified biologic differences exist among populations that contribute to outcome ([2]). Like blacks, Native Americans have high WBC counts at diagnosis ([224]). The use of intensified therapy for ALL has abrogated the prognostic significance of race in some ([95] , [225]) but not other ([226] , [227]) studies. Asians receiving contemporary therapies have outcomes comparable to Europeans receiving similar treatment ([228]).

TIME TO REMISSION The percentage of marrow blasts on days 7 and 14 of induction therapy identifies groups with disparate treatment outcomes (Table 80.3). In one Children's Cancer Group (CCG) study, 39% of children had >5% blasts on day 7 of therapy. Almost all achieved remission by day 28, but retained 2.7-fold increased risk of relapse ([229]). CCG has used early marrow response for treatment allocation. Higher risk patients with greater than 25% marrow blasts on day 7 of therapy and standard risk patients with greater than 25% marrow blasts on day 14 of therapy may be “rescued” with the “augmented regimen” ([230] , [231] and [232]). The Berlin Frankfurt Munster (BFM) Group has used peripheral blood response to intrathecal methotrexate and oral prednisone to identify patients at very high risk of treatment failure ([233]). Examination of peripheral blood response has identified heterogeneity within cytogenetic subgroups like t(9;22) or t(4;11) ([234] , [235] and [236]).

LYMPHADENOPATHY AND HEPATOSPLENOMEGALY The size of peripheral lymph nodes, liver, and spleen provide an indirect measurement of leukemic cell burden. Not surprisingly, therefore, several studies demonstrated that massive lymphadenopathy ([58] , [237]), hepatomegaly, and/or splenomegaly ([210] , [238]) impact adversely on remission duration and survival. However, in multivariate analysis, the prognostic significance of these features is diminished by the level of WBC at diagnosis, early response to therapy, and other factors ([239]).

MEDIASTINAL MASS By univariate analysis, the presence of a mediastinal mass at diagnosis is a prominent poor prognostic feature. When considered with other variables, however, its prognostic significance varies among studies ([66] , [209] , [210] , [237]). Mediastinal masses are strongly associated with increased WBC count, older age, male gender, massive splenomegaly, hemoglobin concentration greater than 10 g/dl, decreased IgM levels, and slow response to therapy.

CENTRAL NERVOUS SYSTEM LEUKEMIA Involvement of the CNS by leukemia is typically defined as 5 or more WBC/µl with the presence of blast cells on cytospin preparations or the presence of cranial nerve palsy ([240]). CNS leukemia, present in approximately 5% of children at diagnosis, is associated with a significantly lower rate of remission induction, a higher risk of relapse, and a shorter survival ([205] , [210]). Although CNS disease is more common in T-cell ALL, its prognostic significance persists when adjustments are made for associated high risk factors. Recently, the use of different therapeutic strategies for childhood ALL have led to varying findings regarding the prognostic significance of less than 5 WBC/µl with blasts in the CSF at diagnosis. Both St. Jude's ([241]) and Pediatric Oncology Group (POG) ([242]) investigators observed a higher risk of CNS relapse in this group, in contrast to results obtained by the CCG ([243] , [244]). To establish uniform criteria for identifying CNS disease, the following revised definitions regarding CNS involvement at diagnosis were proposed at a consensus workshop: CNS-1 (no blast cells), CNS-2 (<5 WBC/µl with blast cells), and CNS-3 (=5 WBC/µl with blasts or cranial nerve involvement) ([245]). Adoption of these criteria will allow comparison of outcomes across varying therapeutic strategies used by different cooperative groups conducting clinical trials for childhood ALL.

BLAST MORPHOLOGY FAB morphologic classification has demonstrated strong prognostic significance in many analyses of childhood ALL ([204], [246], [247], [248], [249], [250] and [251]) but not in others ([252], [253] and [254]). FAB L1 morphologic features are associated with a more favorable prognosis than L2 in childhood ALL, whereas the L3 subtype was historically predictive of remission induction failure and short survival ([210]) when patients with this morphology were treated with standard ALL regimens. Because L1 and L2 morphology bear no relationship to immunologic subtype or other prognostic factors ([45], [249]), these morphologic subtypes were predicted to have independent prognostic significance. This theory has been borne out by multivariate analysis ([205]). In a more recent study conducted by the Nordic ALL group ([255]), L2 morphology was again found to be an adverse risk factor, independent of other prognostic factors, in the setting of contemporary intensified therapy.
HEMOGLOBIN CONCENTRATION AND PLATELET COUNT Patients who presented with a hemoglobin concentration less than 10 or 11 g/dl had a higher remission induction rate, a lower relapse rate, and a longer survival rate than those with no anemia in early analyses ([205], [210], [256]). The hemoglobin level appears to be an indirect gauge of the biologic aggressiveness of leukemia. With explosive disease, symptoms evolve before anemia has time to develop, whereas with indolent leukemia, disordered bone marrow function becomes clinically apparent before anemia. Normal hemoglobin levels are associated with bulky extramedullary involvement and a high percentage of blasts in the proliferative (S) phase of the cell cycle ([257]). An association between low platelet count (less than 30×10^9/L) and shorter remission duration has been noted in some studies ([258]). Leukemic seeding associated with petechial hemorrhages may predispose patients to testicular and CNS relapse ([259]). Both the hemoglobin level and the platelet count lose much of their independent predictive power in multivariate analyses due to other risk factors with which they are associated ([239]).
SERUM IMMUNOGLOBULINS Approximately 30% of children have reduced levels of one or more Igs at diagnosis ([260]). Low levels of IgG and IgA were historic predictors of induction failure ([205], [260]). Although by multivariate analysis the concentrations of IgG, IgA, and IgM all had prognostic significance for survival duration ([205], [260]), the identification of powerful new prognostic factors, such as early response to therapy, has rendered determination of serum Igs largely irrelevant in regard to prognostic stratification.
DOWN SYNDROME Children in whom ALL is associated with Down syndrome have a significantly lower rate of remission, a higher mortality rate during the induction phase, and a poorer long-term survival rate in many studies ([261], [262], [263], [264] and [265]) in contrast to children with acute myelogenous leukemia and Down syndrome ([266]). The adverse influence of Down syndrome is not explained by a higher incidence of associated poor prognostic features ([267]). Rather, it may be explained in part by a greater incidence of toxicity related to intensive treatment ([262], [264], [267]) and in part by failure to distinguish acute megakaryocytic leukemia (AMegL) and ALL. AMegL is the most common type of acute leukemia occurring in Down syndrome children younger than 4 years of age ([268]). Platelet-specific monoclonal antibodies and examination for platelet peroxidase may be required to differentiate AMegL and ALL. Intensification of therapy abrogates the adverse affect of Down syndrome in some studies but is attended by greater serious toxicity ([267], [269]).

Prognostic Stratification

Because treatment is the single most important prognostic factor, the relative prognostic power of disease characteristics varies from study to study. Consequently, different sets of prognostic variables have been found to be useful by those conducting clinical trials for childhood ALL. These include the WBC count, age, race, and karyotype ploidy ([204]); WBC count and size of liver and spleen ([270]); and WBC count and age alone ([30]). The CCG used the latter two variables to identify three prognostic groups within a large population of patients younger than 21 years of age treated in a uniform fashion ([205]). Children with an initial WBC count less than 10×10^9/L and between 3 and 7 years of age had a 4-year continuous remission rate of nearly 90%. This good prognosis group accounted for 27% of the study population. Average risk patients were defined as those of all ages with an initial WBC count between 10 and 50×10^9/L and those younger than 3 years or older than 7 years with a WBC count less than 10×10^9/L. This group constituted 54% of the total and had a 4-year continuous remission rate of approximately 60%. High-risk patients, identified by a WBC count in excess of 50×10^9/L, made up 19% of the population and had a median survival of only 2 years. This stratification was used prospectively to evaluate different therapeutic strategies for different prognostic groups ([30]). The CCG subsequently used the WBC count at diagnosis, age, gender, extent of extramedullary disease, FAB morphologic classification, and platelet count to stratify patients into five groups that differ with respect to prognosis, relapse patterns, and therapeutic priorities ([239], [271]). Other groups adopted similar, but slightly different, approaches ([22], [272], [273]).

Differences among the risk classification criteria used in clinical trials of childhood ALL by various groups conducting clinical trials in this population made accurate comparisons of outcomes across groups difficult, if not impossible. To overcome this obstacle, an international workshop held in Rome in 1985 developed a proposal for uniform criteria for risk-based treatment assignment ([240]); however, these recommendations were not widely adopted. A subsequent consensus workshop, sponsored by the U.S. National Cancer Institute (NCI) in collaboration with representatives from major U.S. organizations involved in the design and conduct of therapeutic trials for childhood ALL, led to the development of risk-based criteria similar to those recommended by the Rome workshop ([245]). The so-called Rome/NCI criteria define two risk groups: standard risk and high risk. The standard-risk group includes those patients with B-precursor ALL ages 1 to 9 years with a WBC count less than 50,000/µl, estimated to comprise approximately 75% of B-lineage ALL patients; these patients were estimated to have EFS of approximately 80%; the remaining high-risk patients were estimated to have EFS of approximately 65%. As different treatment strategies have yielded varying conclusions regarding the prognostic significance of the T-cell phenotype, some groups classify T-cell patients according to WBC count and age, whereas others classify all T-cell ALL patients as high-risk; uniform data collection will facilitate analysis of T-cell phenotype using different treatment strategies. Other prognostic factors obtained in all patients include DNA index, cytogenetics, early response to treatment, immunophenotype, and CNS status.

Although the Rome/NCI criteria represented a major advance in risk classification of childhood ALL, the criteria did not adequately take into account more current biologic features such as molecular genetic alterations, early response to therapy, minimal residual disease, and leukemic blast sensitivity to chemotherapeutic agents. Identification of these and other prognostic factors have led to continued discussion and refinement of risk classification strategies among those conducting clinical trials for childhood ALL ([274], [275]).

The successful intensification of therapy for high-risk ALL has weakened the power of many previously useful adverse predictive factors. Many examples illustrate the potential of newer treatment strategies to offset the negative impact of clinical and biologic variables, including high WBC counts and splenomegaly ([270], [276]), myeloid-associated antigen expression by ALL blasts ([78], [80]), t(1;19) in pre–B-cell ALL ([130]), pseudodiploidy and hypodiploidy ([277]), and the T-cell immunophenotype ([278], [279] and [280]).

TREATMENT

Perhaps four in five children with ALL may be cured with current therapies ([281], [282], [283] and [284]). Challenging popular wisdom and linear assumptions, modest, rational changes in complex therapy have had significant clinical benefit. Outcome remains poor for infants, especially those with leukemic cells bearing the translocation t(4;11) or expressing MLL-AF4 fusion mRNA by reverse transcriptase-PCR ([285], [286]) and for children and adolescents with leukemia cells bearing the translocation t(9;22) (Ph chromosome) or expressing BCR-ABL fusion mRNA ([287]). Of note, adolescents or young adults age 16 to 21 years have had better outcomes when treated by pediatric oncologists on pediatric protocols than by adult hematologists on adult protocols ([288]).

The road to cure passes through complete remission. New techniques allow supplementation of traditional microscopic marrow assessment with more sensitive laboratory measures. Remission induction in ALL is facilitated by the availability of three very active drugs in ALL with minimal myelotoxicity; namely, vincristine, a glucocorticoid (usually prednisone), and L-asparaginase. Although clinically detectable CNS leukemia is rare at diagnosis, the high frequency of subsequent “isolated” CNS relapse despite continuing marrow remission in patients who had received no CNS-directed therapy suggests that submicroscopic CNS disease is common. Thus, CNS-directed therapy is also required for cure.

Conventionally, remission has been defined by microscopic criteria (i.e., fewer than 5% blasts in a cellular marrow, recovery of peripheral neutrophils and platelets, and absence of detectable extramedullary leukemia). Should therapy halt with remission, leukemia invariably returns. Recent studies using PCR-based ([289], [290]) or other ([291]) methodologies have uniformly demonstrated residual leukemic cells or cells sharing clonotypic features with the leukemic clone in patients in first remission.

Treatment is generally divided into phases: induction, intensification, and maintenance. The goal of induction is remission, or the eradication of all microscopically detectable leukemia. The goal of intensification is improvement in the quality of remission. Postinduction intensification has been a productive strategy for enhancing cure rates since the 1980s. The goal of maintenance is the preservation of remission. ALL, and childhood ALL in particular, is unique in its requirement for prolonged, 2- to 3-year moderate therapy. Other chemosensitive cancers, such as testicular cancer and Hodgkin disease, have no need for prolonged therapy after remission.

Outcome is usually described in terms of survival, EFS, DFS, and leukemia- or relapse-free survival. Survival is simply the cumulative percentage of living patients, with or without leukemic relapse or second malignant neoplasm. EFS is the cumulative fraction or percentage of patients surviving from time of diagnosis with no intervening adverse event such as failure to achieve remission, death, relapse, or second malignant neoplasm. DFS includes only patients who achieve remission and describes the cumulative fraction or percentage of patients surviving with no intervening adverse event such as death, relapse, or second malignant neoplasm. Leukemia- or relapse-free survival describes the cumulative fraction or percentage of patients in remission who survive with no intervening relapse. Patients with adverse events, such as death or second malignant neoplasm, are excluded. Currently, attention has broadened to include potential late effects of therapy that may have a lasting impact on quality of life such as neurocognitive damage, anthracycline cardiotoxicity, secondary malignant neoplasms, or avascular necrosis of bone.

Primary Treatment

REMISSION INDUCTION In childhood ALL, a three-drug induction, using vincristine, prednisone, and doxorubicin, proved superior to vincristine and prednisone alone more in terms of long-term EFS (63% vs. 37%) than in terms of remission induction (93% vs. 100%) ([292]). The UKALL VIII trial examined the addition of daunomycin (D) to vincristine, prednisone, and L-asparaginase (VPL) in 630 children. Patients who received daunomycin (VPLD) had an increased treatment mortality and a somewhat lower relapse rate with no statistically significant overall improvement in EFS or survival ([293]). The CCG 105 study similarly found no clear benefit for intermediate-risk patients in an intensive VPLD induction with daunorubicin, 25 mg/m ^{2} weekly × 4, prednisone at 60 mg/m ^{2}/day, and cyclophosphamide, cytosine arabinoside, and 6-mercaptopurine (6-MP) consolidation compared to a VPL induction with prednisone at 40 mg/m ^{2}/day in induction and daily oral 6-MP in consolidation. The relative event rate was 0.85 (N = 804, p =.19) ([294]). Current practice uses three or four drugs in induction for lower-risk children and four to seven drugs for higher-risk children ([295]). Dexamethasone may be substituted for prednisone. Dexamethasone is known to provide better CNS penetration ([296]) and has been reported to be 16 times more active against ALL blasts *in vitro* ([297]). Compared to historical controls who received prednisone, the Dutch ALL VI trial showed 80% versus 66% 3-year EFS advantage for dexamethasone for standard-risk patients ([298]). The CCG 1922 study examined the same question in a randomized trial. Accrual was completed in 1995, and results favor dexamethasone over prednisone in terms of both CNS relapse rate and EFS ([299]). The UKALL '97 trial also compared dexamethasone and prednisone with similar findings ([300]). Concerns have been raised about unacceptable toxicity when dexamethasone is used as part of a four-drug induction ([301]). Recent trials call attention to L-asparaginase and asparagine depletion. Asselin et al. ([302]) describe the differing pharmacokinetics of different asparaginase preparations, such as native *Escherichia coli* asparaginase, *Erwinia* asparaginase, and polyethylene glycol–modified *E. coli* (PEG) asparaginase. Native *Erwinia* asparaginase is known to have a shorter half-life than native *E. coli* asparaginase (0.65 days vs. 1.28 days in naïve patients) ([302], [303]). The European Organization for Research on the Treatment of Cancer (EORTC) compared *E. coli* and *Erwinia* asparaginase at 10,000 IU/m ^{2} twice weekly in induction and intensification in EORTC 58881, a schedule that may have exaggerated pharmacologic differences more than the thrice-weekly schedule. A total of 652 patients were randomized. At 4 years, the EFS was 75% for *E. coli* and 62% for *Erwinia* asparaginase (p <.001) ([304]). Unit/unit substitution of *Erwinia* asparaginase for native *E. coli* asparaginase also adversely impacted EFS on the Dana Farber Cancer Institute (DFCI) 95-01 trial ([305]). Asparagine depletion may fail because of pharmacology or because of the presence of neutralizing antibodies without clinical allergy (i.e., silent hypersensitization). Several groups have reported that conventional doses and schedules of *Erwinia* asparaginase fail to provide the expected continuous asparagine depletion for an increasing fraction of patients with repeated exposures ([306], [307]). Cheung et al. report that patients may develop high-titer antibodies to native *E. coli* asparaginase after a single course without anaphylaxis ([308]). Patients with antibodies were more likely to relapse ([308]) and appeared less likely to respond to asparaginase-containing regimens in subsequent therapy ([309], [310]). Intensive therapy, including alkylating agents, may prevent emergence of antibodies ([308]).

PRESYMPTOMATIC CENTRAL NERVOUS SYSTEM THERAPY Although overt CNS leukemia is rare at diagnosis, prevention of later CNS relapse was a major barrier to cure. Conventional criteria for CNS leukemia require pleocytosis (5 or more cells/μl) and the unambiguous identification of blasts in the CSF ([311]). The incidence of CNS leukemia at diagnosis is less than 5%. However, in the absence of CNS-directed therapy, 50 to 70% of children have their first leukemic relapse in the CNS while in marrow remission ([312]). Isolated CNS relapse is most commonly followed by marrow relapse despite apparently successful eradication of CSF blasts. Between 1967 and 1968, Simone et al. at St. Jude's Children's Research Hospital treated 31 children with no evidence of CNS leukemia at diagnosis with 24 Gy presymptomatic cranial irradiation and intrathecal methotrexate in Study V. Only three had a subsequent CNS relapse, and more than one-half were long-term, disease-free survivors. Between 1968 and 1971, Simone et al. demonstrated the effectiveness of 24 Gy presymptomatic craniospinal irradiation in preventing CNS relapse and subsequent marrow relapse compared to no presymptomatic CNS directed treatment in Study VI and a similar benefit for 24 Gy craniospinal irradiation and 24 Gy cranial irradiation with intrathecal methotrexate in Study VII. In striking contrast to prior experience, more than one-half of patients were and remain long-term, disease-free survivors ([313], [314]). In 1980, Green et al. compared three regimens using different strategies for presymptomatic CNS therapy: 2400 Gy cranial irradiation and six doses of intrathecal methotrexate, intermediate-dose intravenous methotrexate with six doses of intrathecal methotrexate, and six doses of intrathecal methotrexate alone ([315]). Intrathecal therapy was limited to the first 2 to 3 months of treatment rather than extended throughout therapy. Cranial irradiation and intrathecal methotrexate provided the lowest rate of CNS relapse overall. However, the regimen with intravenous and intrathecal methotrexate provided the best overall DFS for lower-risk patients. The regimen with cranial irradiation and intrathecal methotrexate provided the best DFS in higher-risk patients. Subsequently, the dose of cranial irradiation was reduced to 18 Gy with no loss of efficacy in CCG trials ([316]). Dosage of intrathecal therapy is usually based on age rather than body surface area ([317]). Concerns about neurocognitive side effects ([318], [319]) and secondary brain tumors ([320]) after cranial irradiation have led to its inexorable replacement for patients without overt CNS disease at diagnosis by improved systemic therapy and intrathecal therapy extended through at least the first 7 months of treatment ([321], [322], [323], [324], [325] and [326]) or by very-high-dose parenteral methotrexate ([327], [328]). Craniospinal irradiation remains an important therapeutic modality for children with overt CNS disease at diagnosis. In CCG trials, children with overt CNS disease at diagnosis received craniospinal irradiation and had outcomes similar to other children without overt CNS disease matched by WBC and age ([329]). The CCG 161 trial showed that intrathecal therapy extended through the 2- to 3-year duration of systemic therapy could replace cranial irradiation and limited intrathecal therapy for lower-risk patients ages 2 to 10 years with WBC less than 10,000/μl ([322]). The CCG 105 trial extended this observation to intermediate-risk children between the ages of 1 and 9 years with WBC below 50,000/μl but only when patients received intensified systemic therapy ([324]). When patients received only "standard" systemic therapy, cranial irradiation and limited intrathecal therapy were superior to extended intrathecal methotrexate with no irradiation. In CCG 1882, higher-risk patients, either older than 10 years of age or with WBC =50,000/μl or higher and a rapid initial response to induction therapy received either 18 Gy cranial irradiation and extended intrathecal methotrexate or additional intrathecal methotrexate with no whole-brain irradiation. All received intensive systemic therapy. The cumulative incidence of isolated CNS relapse was 3.6% for patients not receiving cranial irradiation and 2.3% for patients receiving cranial irradiation. However, patients receiving additional intrathecal methotrexate had somewhat fewer bone marrow relapses, and the ultimate DFS was similar. Thus, cranial irradiation could be replaced with aggressive intrathecal methotrexate for this population also in the presence of effective systemic therapy ([330]). Others have used intrathecal triple therapy—that is, methotrexate, cytosine arabinoside, and hydrocortisone—in place of single-agent methotrexate and successfully omitted cranial irradiation ([323], [325]). In the absence of cranial irradiation, Pullen and POG co-workers showed that extended intrathecal triple therapy better prevented CNS relapse than extended intermediate-dose intravenous methotrexate and more limited intrathecal methotrexate. The cumulative CNS relapse rates were 4.7% and 10.9% overall ([323]). Conter et al. from the *Associazone Italiana di Ematologia ed Oncologia Pediatrica* (AIEOP) found that extended intrathecal triple therapy every 8 weeks with no cranial irradiation limited the incidence of CNS relapse to 5% ([325]). Stork et al. recently reported a randomized comparison of intrathecal triple and single agent methotrexate therapy with more than 2000 randomized patients ([331]). Although intrathecal triple therapy halved the CNS relapse rate, EFS was similar at 5 years, and survival was actually statistically inferior due to inferior salvage from the excess of bone marrow relapses ([331]).

POSTINDUCTION INTENSIFICATION The observation of Freeman et al. ([332], [333]) that postinduction intensification with parenteral intermediate-dose methotrexate and leucovorin rescue yielded lower marrow and testicular relapse rates than cranial irradiation and limited intrathecal methotrexate has led to continuing examination of postinduction intensification with prolonged 24- to 36-hour intravenous methotrexate infusions with leucovorin rescue in a number of trials ([327], [328], [334], [335], [336], [337] and [338]). More recently, oral methotrexate, 25 to 30 mg/m ^{2} every 6 hours × four doses, and intravenous methotrexate by 4-hour infusion have been proposed as outpatient alternatives to inpatient, prolonged, intermediate-dose intravenous methotrexate infusions ([339], [340]). Value has been shown for additional methotrexate in the form of intermediate-dose intravenous methotrexate with leucovorin rescue and for substitution of intravenous methotrexate with no leucovorin rescue for oral methotrexate in randomized trials. The POG 9404 study showed an advantage of additional intermediate-dose methotrexate with leucovorin rescue over no methotrexate for T-cell patients ([341]). Two trials show an advantage for parenteral methotrexate with no leucovorin rescue over conventional weekly oral methotrexate ([342], [343]). Demonstration of an advantage in overall DFS for postinduction intensification limited to parenteral methotrexate with leucovorin rescue over oral methotrexate has been more elusive. In St. Jude's Study X, Abromowitch et al. ([335], [336]) compared one regimen that added parenteral methotrexate, 1 g/m ^{2}, to daily oral 6-MP to a second regimen, including cranial irradiation and rotating drug pairs: 6-MP–methotrexate, cyclophosphamide–doxorubicin, and teniposide–cytosine arabinoside. The 4-year DFS was 67% for the first regimen and 56% for the second (p = .049). Differences were more striking for lower-risk patients ([335], [336]). BFM investigators claim advantage for intermediate-dose methotrexate, 5 g/m ^{2}, for T-cell patients in BFM 86 ([344], [345]). On the other hand, CCG-144 compared very-high-dose parenteral methotrexate (33.6 g/m ^{2}) with no intrathecal therapy to cranial irradiation and limited intrathecal methotrexate and found no advantage in overall DFS, although parenteral methotrexate provided adequate CNS prophylaxis ([328]). The German COALL 82 trial replaced cyclophosphamide with three 3-g/m ^{2}

methotrexate infusions with folinic acid rescue, 15 mg/m ^{2} every 6 hours × 10. Patient entry was halted when outcome was found inferior to the previous trial, which did not include parenteral methotrexate ([334]). CCG-139 found no benefit for the addition of parenteral methotrexate, 500 mg/m ^{2}, three times during consolidation and every 6 weeks during maintenance compared to a regimen that included no intravenous methotrexate for intermediate-risk patients. All patients received extended intrathecal methotrexate ([338]). No benefit was found for intravenous methotrexate and rescue in a British study ([346]). Benefit is claimed in one subset but not overall in the French FRALLE93 study (346a, 346b). German COALL investigators comment on the inimical effects on outcome of “too early” or excess folinic acid rescue ([347]). Given the abiding interest in parenteral methotrexate, intensive scheduled oral methotrexate, 25 to 30 mg/m ^{2} every 6 hours × 4, has been proposed as an outpatient alternative to parenteral methotrexate, which might provide similar drug exposure ([339]). When intensive scheduled oral methotrexate was administered with no leucovorin, 16 out of 111 patients had one or more seizures, and six additional patients had transient episodes of weakness with unilateral paresthesias, generally 2 weeks after the last of a series of biweekly courses. After leucovorin, 5 mg/m ^{2}, was added 24 and 36 hours after the last dose of each course of oral methotrexate, no further neurologic toxicity was seen in the next 24 patients ([348]). More recently, oral methotrexate, 30 mg/m ^{2} every 6 hours × 4, was compared to intravenous methotrexate, 1 g/m ^{2} over 24 hours, for lower-risk patients in a randomized POG trial. All patients received intravenous leucovorin, 5 mg/m ^{2} every 6 hours × 5. At 3 years, the EFS was 78% for oral methotrexate versus 89% for parenteral methotrexate ([340]). Moderate to severe neurotoxicity, most commonly generalized or focal seizures, occurred in 7.2% of patients receiving parenteral methotrexate and 3.7% of patients receiving scheduled oral methotrexate ([349]). Other postinduction intensification strategies have shown benefit. Researchers from DFCI introduced an effective program, including extended use of weekly L-asparaginase ([350] , [351]). Extended asparaginase strategies have been tested in a number of other current trials. No advantage was found for additional asparaginase in Italian or German studies ([337] , [352]). POG also found no advantage for additional intramuscular L-asparaginase, 25,000 U/m ^{2}/week × 24 for standard-risk B-precursor patients ([353]). However, advantage was shown in another POG trial for T-cell disease ([354]). In 1970, investigators from the BFM Group introduced a 3-month intensive induction/consolidation phase called *protocol I*, which added pulses of cyclophosphamide, cytosine arabinoside, and 6-MP to a VPLD induction. No striking benefit followed ([355]). In 1976, they added a second intensive phase after consolidation, variously called *protocol II* in Europe and *delayed intensification* in North America. Protocol II included a reinduction segment of vincristine, dexamethasone, L-asparaginase, and doxorubicin followed by a reconsolidation segment of cyclophosphamide, cytosine arabinoside, and 6-thioguanine (6-TG). Outcomes improved compared to historical controls, and advantages were most striking for higher-risk patients ([356]). Between 1983 and 1989, the CCG 106 and CCG 123 studies compared therapy based on the BFM ‘76 trial for higher-risk patients with then-current CCG therapy and demonstrated an unambiguous improvement in EFS for BFM-based therapy. The 7-year EFSs were 63% and 42% in CCG 106 ([357] , [358]) and 67% and 50% in CCG 123 ([359]). Advantages were apparent in survival as well as EFS. CCG 105 extended this finding to intermediate-risk patients, 73% versus 61% (Fig. 80.2) (global p = .006). Of great interest, outcome with protocol II alone with no intensive induction/consolidation (protocol I) was superior to “standard” therapy and similar in outcome as treatment with both protocols I and II, quite contrary to a “more is better” popular wisdom. Omission of protocol I avoided the short- and long-term morbidity of daunorubicin, 100 mg/m ^{2}, and cyclophosphamide, 2 g/m ^{2}, and 8.4 days of hospitalization per patient ([294]). The BFM ‘81 trial ultimately confirmed the benefit of postinduction intensification for lower-risk patients, 84% versus 62% ([360]). This finding was confirmed in a putative lowest-risk population in CCG 1881, in which patients who received delayed intensification had a 4-year EFS of 88%, compared to 82% for patients who had not ([361]). Patients on the standard arm in the CCG trial received vincristine and prednisone pulses q4wk and intrathecal methotrexate q12wk in maintenance (not received in the BFM trial). Lower-risk patients tend to have a prolonged period of risk of relapse, and any differences between regimens may emerge only later.

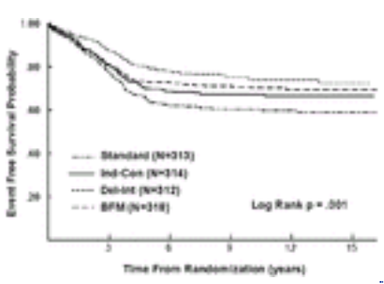

Figure 80.2. Impacts of intensive induction/consolidation (Ind-Con) and delayed intensification (Del-Int) on the event-free survival of children with average risk acute lymphoblastic leukemia. BFM, both intensive induction consolidation and delayed intensification based on the Berlin Frankfurt Munster 76/79 study; standard, neither intensive induction consolidation nor delayed intensification. (Children's Cancer Group-105 study; chair Dr. David G. Tubergen.) (Courtesy of Dr. Harland N. Sather and the Children's Cancer Group, Arcadia, CA.)

A further CCG modification of this therapy, the “augmented regimen,” posited that more resistant cells responsible for relapse might need a stronger and more prolonged postinduction intensification. The “augmented regimen” provided two applications of delayed intensification and four 2-week courses of nonmyelosuppressive vincristine and L-asparaginase during the periods of myelosuppression that invariably follow the cyclophosphamide, cytosine arabinoside, and thiopurine pulses in consolidation (protocol Ib) and reconsolidation (protocol IIb). Two courses of five Capizzi I pulses ([362] , [363]) of vincristine, parenteral methotrexate, and L-asparaginase replace the two 2-month courses of oral 6-MP and methotrexate between consolidation and delayed intensification #1 and delayed intensification #1 and delayed intensification #2. Higher-risk patients with a poor initial response to therapy (i.e., greater than 25% marrow blasts on day 7 of therapy) comprised the study population. At 5 years, DFS was 75% for the “augmented regimen” and 55% for standard intensive therapy (Fig. 80.3) ([84]). The “augmented regimen” was shown to be helpful for slower response, standard-risk patients with more than 25% marrow blasts on day 14 of induction ([365]).

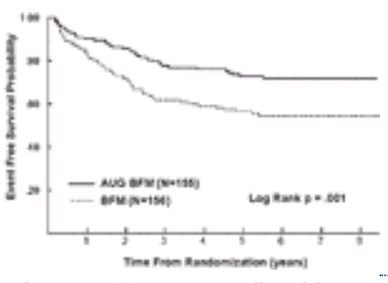

Figure 80.3. Benefit of longer and stronger postinduction intensification (AUG BFM) therapy on the event-free survival of children and adolescents with higher risk acute lymphoblastic leukemia and a poor day 7 marrow response. BFM, standard post-induction intensification based on the Berlin Frankfurt Munster 76/79 study. (Children's Cancer Group-1882 study; chair Dr. James B. Nachman.) (Courtesy of Dr. Harland N. Sather and the Children's Cancer Group, Arcadia, CA.)

Subsequently, two delayed intensification phases proved superior to one delayed intensification phase for standard-risk patients ([366]). Double delayed intensification was shown advantageous overall, but the benefit was greater for slower response patients, with more than 5% marrow blasts on day 7 of therapy, and less for faster response patients, with fewer than 5% blasts. Recently, Italian investigators found benefit for two delayed intensification phases among “prednisone poor response” patients (366a). The current CCG higher-risk trial examines the effects of the length and strength of postinduction intensification in higher-risk, rapid, day 7 response patients (CCG 1961). The current standard risk trial examines the value of one or two delayed intensification phases for patients who received dexamethasone in induction and reexamines the relation between early response and optimal length of postinduction intensification (CCG-1991). The Childhood ALL Collaborative Group compiled data from seven randomized trials that examined the role of postinduction intensification on outcome ([367]). Only trials that included an intensification block believed to be strong enough and long enough to induce remission in a patient at diagnosis or relapse were considered. More than 2600 patients were included in the metaanalysis. Intensification, however constituted, provided an overall 8.2 percentage point advantage in EFS (p <.00001) and a 4.2 percentage point advantage in survival (p = .01). Overall, marrow relapse was decreased by 36%, CNS relapse by 41%, and testicular relapse by 31%. Remission deaths were increased to 4.9% versus 3.3% (p = .08). On the other hand, 15 trials examining additional agents or higher doses of conventional agents after induction in 3133 patients found no advantage in EFS or survival.

Maintenance Therapy

Daily oral 6-MP and weekly oral methotrexate with an extended periodic intrathecal therapy comprise the most common maintenance or continuation regimens. Ratios of weekly cumulative doses of 6-MP and methotrexate range from 8 to 26. Outcome with half-dose therapy is less effective than full dose ([368]). However, no advantage has been shown for increased-intensity oral 6-MP and methotrexate ([369]) or the addition of cytosine arabinoside or cyclophosphamide to this basic platform ([368]). Intramuscular methotrexate is no more effective than oral methotrexate ([370]). However, every-2-week or every-4-week intravenous methotrexate may be more effective than conventional weekly oral methotrexate ([342] , [343]).

Vincristine and prednisone pulses may be useful in maintenance in preventing relapse, but demonstration of any impact on survival is less compelling. The Childhood ALL Collaborative Group compiled five randomized trials examining vincristine and prednisone pulses in maintenance for 1251 children ([367]). The overall difference

in lifetable EFS was 10.5 percentage points (p <.0003), and the difference is survival was 4.5 percentage points (p = .1). Pulses resulted in a 36% reduction in bone marrow relapse (p = .0003) and a 59% reduction in testicular relapse (p = .0003). The reduction in deaths was 16%, however, and not statistically significant by conventional criteria.

Of course, this type of analysis cannot determine the value of vincristine and prednisone pulses in other specific contexts. Interventions may be useful in one context and redundant in another. The role of vincristine and dexamethasone pulses is under study in a current International BFM Study Group protocol in which all patients receive effective postinduction intensification.

Variations in the common continuation therapy program are found in the DFCI studies ([284], [350], [351]), the NY I and NY II protocols ([371], [372]), and Japanese studies ([343]). The Japanese Children's Cancer and Leukemia Study Group compared 6-MP, 175 mg/m ^{2}/day days 0 to 4, and intravenous methotrexate, 225 mg/m ^{2} day 14, with daily oral 6-MP, 50 mg/m ^{2}, and weekly oral methotrexate, 20 mg/m ^{2}. All patients received vincristine and prednisone pulses every 4 weeks and intrathecal methotrexate every 12 weeks. The 5-year EFS was 73% for the intermittent alternating regimen and 50% for the conventional regimen. The conventional regimen had more infections and late marrow, CNS, and testicular relapses ([343]).

Interpatient variations in 6-MP absorption are well known ([373]). Several laboratories have found an association between levels of erythrocyte TG nucleotides and freedom from relapse ([374], [375]). This observation encouraged attempts to improve outcome by enhancing intracellular TG nucleotide accumulation. Strategies include replacement of oral 6-MP by parenteral 6-MP ([376]) or by oral or parenteral 6-TG ([377], [378] and [379]).

Intravenous 6-MP provides less interpatient variability and more predictable plasma levels ([380], [381]). A number of randomized outcome comparisons were undertaken. Thus far, intravenous 6-MP has provided no clinical advantage over oral 6-MP in any study ([299], [382]).

Oral 6-TG is known to provide levels of erythrocyte thioguanine nucleotides four to six times higher than equitoxic doses of oral 6-MP ([377], [378]). *In vitro*, 6-TG is approximately tenfold more potent and provides potentially therapeutic levels in the CSF ([379]). Stork et al. have reported an advantage for 6-TG for standard-risk patients in terms of CNS relapse and EFS, but at a cost of sinusoidal obstruction syndrome ([331]). The 5-year EFS was 84% for 6-TG and 77% for 6-MP. A smaller German COALL trial has shown no advantage for 6-TG ([383]).

Continuation therapy for 2 to 3 years is most usual in childhood ALL. Despite effective postinduction intensification, the BFM Group found that 18 months of treatment was inferior to 24 months (83% vs. 77%) ([384]). The Childhood ALL Collaborative Group compiled 16 randomized trials that compared shorter and longer therapy in a metaanalysis that included 3861 patients ([367]). Longer therapy provided a small but statistically significant 3.3 percentage point improvement in EFS and a statistically not significant 0.8 percentage point improvement in survival. An advantage for longer therapy was found in the 24- versus 18-month and 36- versus 24-month comparisons but not in the 60- versus 36-month comparisons. Longer therapy provided statistically significant reductions in bone marrow relapse (26%) and testicular relapse (36%), but patients on longer therapy were more likely to die in remission (2.7% vs. 1.2%). Contrary to popular memory, boys and girls derived similar, small benefit from longer therapy. Of course, this type of analysis cannot determine the value of duration of continuation therapy in regimens not studied, but cross-study consistency lends weight to its conclusions. The debate continues whether more effective postinduction intensification will allow briefer maintenance therapy or, conversely, will add value to longer therapy as more patients are brought to 24 months in remission. Optimal duration of therapy may differ among subsets, being more important in standard-risk patients and less important in older or T-cell patients.

Relapse

Population-based SEER data found a 69% 5-year survival for children ages 0 to 14 years diagnosed with ALL in the United States between 1978 and 1986 ([385]). More recent data have raised this number to 79% for children diagnosed between 1986 and 1992, an increase of 10 percentage points relative to 1983 to 1985 ([386]). EFS may be a better measure of ultimate outcome than survival because relapsed patients carry a high risk of subsequent relapse and death after an initial relapse.

Despite improvements in the treatment of childhood ALL, relapsed ALL makes a major contribution to the morbidity and mortality of childhood cancer. SEER data estimate a 5-year survival of 69% for children diagnosed between 1983 and 1987 ([385]). The corresponding death rate is 31%. If the incidence of childhood ALL is 31/10 ^{6} per year ([387]), then the incidence of death from childhood ALL is approximately 10/10 ^{6} per year. More children die from ALL than are diagnosed with non-Hodgkin lymphoma, Wilms' tumor, Hodgkin disease, CNS primitive neuroectodermal tumor, acute myeloid leukemia, and rhabdomyosarcoma ([387]). Only newly diagnosed astrocytomas/gliomas and perhaps neuroblastoma are more common.

Relapse remains the principal barrier to cure. Between 1983 and 1989, 3712 eligible patients were enrolled in the CCG 100 series trials (Table 80.4); 1363 patients had an adverse event ([388]). Of these, 191 did not achieve remission or died from toxicity (14% of adverse events; 5% overall). Twenty-eight had a second malignant neoplasm (2% of adverse events). A total of 1144 had a relapse (84%) at one or more sites. Marrow, CNS, and testicular relapses were most common. Rare sites included isolated leukemic infiltration of the lymph nodes, eyes, and bone in CCG and other studies ([388], [389] and [390]).

TABLE 80.4. Survival after Relapse: Children's Cancer Group 100 Series

	N	6-Year Second Event-Free Survival (%)	6-Year Survival (%)
Isolated marrow relapse	642	16	20
<18 mo	233	5	6
18–35 mo	194	10	11
=36 mo	215	33	43
Isolated central nervous system relapse	220	37	48
<18 mo	102	24	33
18–35 mo	84	44	59
=36 mo	34	59	72
Isolated testicular relapse	112	64	70
<18 mo	22	48	52
18–35 mo	24	44	57
=36 mo	66	76	81
Combined marrow relapse	120	29	29
<18 mo	34	9	9
18–35 mo	26	11	11
=36 mo	60	48	49

NOTE: Other sites of relapse include lymph node (seven), eye (five), bone (four), and liver, skin, kidney, uterus, nasal mucosa, and ear (one each).
From Walters R, Kantarjian HM, Keating MJ, et al. The importance of cytogenetic studies in adult acute lymphocytic leukemia. Am J Med 1990;89:579–587, with permission.

Overall, fewer than one in four patients with relapse achieve long-term survival. Among patients with marrow relapse before 3 years from diagnosis, long-term survival is rare (below 10%). Table 80.4 depicts data from the CCG 100 series by site and time to relapse. Combined marrow and CNS relapse may have a better outcome than isolated marrow relapse ([391]). Survival is better for later marrow relapse and for extramedullary relapse, but Wheeler et al. noted that patients who relapse and

survive also bear additional risk of long-term morbidity ([392]). Inability to provide effective therapy after relapse maintains the imperative to prevent relapse at almost any cost and motivates the exposure of all children to the increased morbidity of ever more intensive therapy, when less intensive therapy would suffice for a growing majority of children.

TREATMENT OF MARROW RELAPSE Treatment of relapse begins with an attempt to obtain a second remission. This is usually successful with agents similar to those used at initial presentation, both in children and adults. In pediatric series, remission induction rates range from 71 to 97% ([393] , [394] , [395] , [396] and [397]). One study used the same treatment for adults and children; 71% of children achieved remission compared to 55% of adults ([398]). Retreatment of the CNS appears critical even in isolated bone marrow relapse ([399]). Some sort of postinduction therapy is generally pursued, ranging from conventional chemotherapy intensification and maintenance to marrow ablative therapy and stem cell rescue (see Bone Marrow Transplantation). Outcomes improve with an increasing duration of first remission ([388] , [389]), with protocol as opposed to ad hoc therapy ([400]), and less certainly with increasing intensity of otherwise somewhat effective therapy ([392] , [396]). A substantial number of patients with an initial relapse after 3 years achieve long-term DFS with chemotherapy without bone marrow transplant (BMT). In some series, this fraction exceeds 50% ([396] , [401]). Sensitivity to chemotherapy often decreases between presentation and relapse and between first and subsequent relapse, as seen in decreasing remission induction rates. The *in vitro* 3-[4,5-dimethyl-thiazole-2,5-] tetrazolium diphenyl bromide (methyl-thiazole-tetrazolium) assay shows a more than 100-fold increase in prednisolone LC_{50} between presentation and initial early relapse, and more than 800-fold between presentation and multiple relapse ([402]). Patients with loss of p53 function (i.e., abnormal p53 or amplified mdm-2) tend to have earlier relapses and less satisfactory responses to subsequent therapy. Although usually intact at diagnosis, diminished p53 function is associated with a very high risk of early treatment failure ([403]). Function may be present at diagnosis but lost at relapse ([404] , [405] and [406]). Loss of p53 function may protect leukemia cells from apoptosis and produce resistance to radiation and a variety of anticancer drugs ([407]). However, sensitivity to some interventions, such as asparagine depletion, may be preserved, as shown by Abshire et al.'s demonstration that weekly PEG asparaginase was superior to biweekly PEG asparaginase in patients with ALL in first remission ([310]).

TREATMENT OF ISOLATED EXTRAMEDULLARY RELAPSE Isolated extramedullary relapses are rarely truly isolated to the apparent site of involvement. Three of six patients with apparently isolated testicular relapse had more widespread nodal disease on laparotomy ([408]). PCR-based assays usually show the presence of marrow cells sharing the clonotypic Ig or T-receptor rearrangement found in the leukemic blasts at presentation ([409] , [410] and [411]). The principal clinical challenge of isolated extramedullary relapse is prevention of subsequent marrow relapse. Local control of CNS or testicular sites can usually be obtained and maintained with chemotherapy and radiation therapy. Thus, isolated extramedullary relapse often or even usually represents a failure of systemic therapy, not only local therapy.

ISOLATED CENTRAL NERVOUS SYSTEM RELAPSE CNS disease may present with signs of increased intracranial pressure, such as headache or vomiting (especially morning vomiting). Because all patients receive maintenance intrathecal therapy, most CNS relapses are discovered incidentally. CNS relapses tend to occur between 1 and 3 years after diagnosis. CNS blasts may be cleared with weekly or twice weekly intrathecal therapy. Three-agent methotrexate, hydrocortisone, and cytosine arabinoside therapy was no more effective than two-agent methotrexate and hydrocortisone therapy in one trial ([412]). Cranial irradiation and intrathecal maintenance therapy were less effective in maintaining CNS remission than craniospinal irradiation ([413]). Patients undergo systemic reinduction therapy, and cranial or craniospinal irradiation is administered 1 month ([414]) to 6 months ([396] , [415] , [416]) from relapse. Radiation may be delayed to preserve marrow reserve for aggressive systemic therapy. The dose of cranial irradiation is generally 18 to 24 Gy. The spinal dose is 6 to 15 Gy ([396] , [415] , [416]). Steinherz et al. obtained excellent results with neuraxis dose between 6 and 9 Gy with subsequent intraventricular and intrathecal chemotherapy ([417]). Overall, at least 50% of patients may achieve long-term DFS after CNS relapse. The marrow is the principal site of treatment failure. In the past, most children received cranial irradiation as part of their initial presymptomatic CNS therapy and treatment after CNS relapse represented a second radiation exposure and higher cumulative dose. Mulhern et al. ([418]) found an average of more than 10 points decline in full-scale intelligence quotient (IQ) compared to population norms in 40 children 6 years after CNS relapse. Eight children were labeled mentally retarded and were receiving special education assistance. Younger children and those with seizures or structural brain abnormalities had the poorest cognitive outcomes ([418]). Winick et al. ([414]) studied 120 patients with isolated CNS relapse of whom 14 had received prior cranial irradiation. Of these, 17% had signs or symptoms of leukoencephalopathy, presenting with seizure in 85%, and ataxia, memory loss, and motor and cranial nerve deficits in others. Of children with prior cranial irradiation, 27% had significant neurotoxicity compared to 15% of children who did not ($p = .33$). Twelve patients had progressive neurologic deterioration despite the cessation of intrathecal therapy. Eight had mild, stable symptoms and, of these, four had learning disabilities ([414]). Prevention of subsequent relapse and preservation of neurocognitive function remain dual challenges for patients with CNS relapse.

ISOLATED TESTICULAR RELAPSE Testicular leukemia presents with unilateral or bilateral painless testicular enlargement. At least one-half of cases occur longer than 3 years from diagnosis. Outcomes appear better for patients with overt disease after completion of therapy than for patients with overt disease while still on therapy ([419]). In two trials, approximately 10% of boys had occult testicular relapse on elective biopsy at 3 years from diagnosis. However, no advantage could be shown for early diagnosis, and 25 of 839 boys with negative initial biopsies had subsequent testicular relapse ([420] , [421]). CCG has reported a series of patients with overt isolated testicular relapse on or shortly after initial therapy. Patients received salvage chemotherapy as per the NY I ([422]) or CCG BFM-based ([423] , [424]) regimens and bilateral testicular irradiation. Intrathecal methotrexate was used for presymptomatic CNS therapy. Among 57 boys, the 5-year EFS was 43% ([424]). This result is similar to that obtained in a POG series with somewhat different chemotherapy ([425]). For patients with an earlier or later overt testicular relapse, POG investigators obtained 4-year EFS of 53% or 84% ([426]). In adults, testicular irradiation doses greater than 4 to 6 Gy may result in persistent azoospermia. Even scatter from spinal irradiation may cause elevation of follicle-stimulating hormone or decreased testicular volume in some patients. Leydig cell function is generally spared. However, testicular irradiation doses greater than 20 Gy may compromise Leydig cell function in children, resulting in elevated luteinizing hormone, decreased testosterone, and delayed puberty ([427]). Doses greater than 20 Gy are generally used in the treatment of testicular relapse.

Bone Marrow Transplantation

The potential benefit of allogeneic BMT derives from the opportunity for marrow ablative therapy—that is, high-dose chemotherapy with or without total body irradiation (TBI)—and from the possible graft-versus-leukemia effect. The success of match-related donor (MRD) BMT for some patients and a frequent lack of compatible family donors has led to consideration of other stem cell sources, such as purged or unpurged autologous marrow or peripheral blood stem cells ([428] , [429] and [430]), matched but unrelated donor (MUD) ([431] , [432] and [433]), or peripheral blood or cord blood ([434] , [435]) stem cells, and related but partially mismatched marrow ([436]), peripheral blood, or cord blood stem cells.

Definition of the role of BMT in childhood ALL has been an ongoing challenge. Interpretation of reported BMT outcomes is complicated by the preponderance of small series, selection bias, waiting-time bias, and lack of adequate controls. Even in aggregate, small series may not be representative of the total experience. Small numbers quickly erode statistical power and obscure possibly important differences. Selection biases may also complicate comparisons. In “treatment-received” reports, patients who relapse before a BMT may be performed are excluded from the “treatment-received” experience. Such patients are included in a chemotherapy control. Patients deemed clinically unfit for BMT because of organ dysfunction or deep-seated infection are excluded from the BMT arm but may be included in the chemotherapy control. Their outcome is likely worse than average. Various statistical techniques can adjust for waiting-time bias, but selection bias proves more intractable. Intent-to-treat analysis is the best response.

Comparisons also are statistically challenging. The value of BMT may not be uniform among the various patient subsets that are conglomerated to form a very-high-risk group. The literature is replete with small trials for which large differences are required for any chance for statistical significance. Real differences may be modest, though important, and less than hoped. BMT and chemotherapy have differing patterns of failure. Transplant outcomes suffer from early mortality, whereas chemotherapy patients tend to survive early and relapse later. Graphic representations of EFS curves often cross. This violation of proportional hazards undermines the often-used log rank statistic and argues for a cure model ([437] , [438]).

Interpretation of BMT results is also complicated by differences in therapy before BMT, in marrow ablative therapy, in graft-versus-host disease prophylaxis, and in supportive care. Comparisons depend on the detailed treatments studied. The superiority of a particular transplant regimen over a particular chemotherapy regimen does not imply that the same or a second transplant regimen will necessarily be superior to a second chemotherapy regimen.

To minimize possible biases, several studies have attempted to compare outcomes after MRD BMT and continued chemotherapy based on donor availability and intent to treat with less than definitive conclusions. Physician and patient compliance with highly controversial treatment allocation schemes may be inconsistent and an additional source of bias. Multicenter BMT registries have made a major contribution to what knowledge is available. Proctor commented that more has been learned in this arena from such trials with constructed controls than from methodologically superior but clinically unfeasible classic randomized trials ([439]).

In a rare prospective trial, Wheeler et al. ([440]) in the British Medical Research Council designated as “very high risk” on the basis of presenting clinical and cytogenetic features 473 of 3676 children diagnosed between 1985 and 1997. Two hundred eighty-eight patients were tissue typed. Ninety-nine patients had a MRD, and 76 underwent BMT in first remission. One hundred eighty-nine patients had no MRD, and 25 underwent BMT from a MUD, contrary to protocol. At 10 years, the

adjusted EFS was 45% for 101 children receiving first-remission BMT versus 39% for 351 children receiving chemotherapy. In contrast, in an intent-to-treat analysis, the 10-year EFS was 50% for children without an MRD, compared to 40% for children with an MRD ([440]). A near population-based retrospective review of 326 children and adolescents with t(9;22) showed a significant advantage for MRD BMT but not MUD BMT ([287]). No similar advantage was seen in a similar study of infants and children with 11q23 abnormalities ([286]). An ongoing European cooperative trial is expected to contribute greatly to this question ([441]).

Bone marrow relapse is the principal failing for chemotherapy. Treatment-related mortality (TRM) poses a major challenge for BMT. In first remission, Uderzo et al. reported 13% TRM for MRD BMT and 30% for MUD BMT ([442]).

Second-remission BMT remains an option for some patients treated with chemotherapy initially. However, when first-remission BMT is deferred, patients may not achieve second remission or may experience toxicity or deep-seated infection, precluding subsequent BMT. Second remissions may be too transient to allow BMT in second remission.

For children in second marrow remission, matched family donor allogeneic transplant has been recommended ([443]). International Bone Marrow Transplant Registry data suggest that MRD BMT is superior to chemotherapy for both early and late marrow relapse (using an historical POG control). Using matched controls, the 5-year DFS was estimated at 40% for 255 BMT patients and 17% for 255 matched chemotherapy patients, excluding patients who failed to achieve or maintained remission long enough to have received a transplant had they had a donor. Comparisons of BMT and chemotherapy outcomes for initial remissions before 18 months, at 18 to 36 months, and at 36 months or later were 29% versus 14%, 41% versus 7%, and 53% versus 32%, respectively. For 51 patients in second remission, Dopfer et al. ([444]) reported an overall 7-year DFS of 52%. Comparisons of BMT and chemotherapy outcomes for early and late relapse were 56% versus 22% and 47% versus 41% ([444]). Uderzo et al. ([445]) compared 57 patients after matched family donor BMT and 230 patients after chemotherapy. At 5 years, the DFS rates were 41% and 22%. Differences were significant after correction for time to transplant or waiting time bias and most striking for children with early relapse before 30 months ([445]). Hoogerbrugge et al. ([446]) compared 25 MRD BMT patients with 97 chemotherapy patients in second remission in a case-control study. The 4-year DFS was 44% for the BMT patients and 24% for chemotherapy patients (not significant) ([446]).

The British Medical Research Council has undertaken two prospective trials in patients after relapse. Wheeler et al. studied 489 children who relapsed from the UKALL X trial ([447]). Harrison et al. studied 256 relapsed children enrolled in the UKALL R1 trial ([448]). In adjusted comparisons, BMT improved 5-year EFS from 26% to 41% in UKALL X ($p = .05$). The 5-year EFS was only 3% for patients with marrow relapse before 2 years, whatever therapy was pursued. The 5-year EFS was 66% for late extramedullary relapse. On the UKALL R1 study, 67 children had MRD BMT, and 139 had no MRD. Sixty-three of 67 patients with MRDs underwent BMT. However, contrary to protocol, 41 of 139 patients with no MRD underwent MUD BMT! Six of 41 MUD patients died from TRM (15%). Within the power of the comparison, no statistically significant difference was apparent in intent-to-treat comparisons of patients with MRD versus patients with no MRD or in adjusted treatment-received comparisons of patients undergoing BMT versus patients receiving chemotherapy.

CCG undertook a prospective trial for children with ALL and early marrow relapse, CCG-1941. Two hundred fifteen patients enrolled. One hundred sixty-five achieved remission (77%). Forty-two refused postinduction allocation. Fifty-one patients had MRDs. Forty of 51 underwent BMT in second remission. Subsequently, eight died from TRM (20%) and 19 relapsed. Seventy-two patients had no MRD and were allocated to alternative-donor BMT or chemotherapy. Of 37 patients allocated to alternative-donor BMT, 20 underwent BMT (19 MUD BMTs and one autologous BMT) in second remission. Subsequently, eight died from TRM (40%) and six relapsed. Of 35 patients allocated to chemotherapy, ten patients underwent alternative-donor BMT anyway! Of these ten, four died from TRM and three relapsed. Twenty-five patients received only chemotherapy; two died from TRM and 16 relapsed. The 2-year EFS for MRD BMT and alternative BMT was 40% and 23%. By intent-to-treat from the end of induction, the 3-year DFS was 29%, 18%, and 28% for MRD BMT, alternative BMT, and chemotherapy, respectively. Censoring the chemotherapy patients who underwent BMT, the DFS is 36%. Differences were not significant ([449]).

The lesson is drawn that clinical outcomes are disappointing after marrow relapse despite reasonable transplant outcomes. Likely differences between BMT outcomes and chemotherapy outcomes are minor compared to the number of patients who fail to achieve a durable remission, die from TRM, or relapse despite BMT or chemotherapy. Improving BMT or chemotherapy outcomes, or both, is a greater imperative than continued “apples and oranges” comparisons that seek to define more precisely relatively minor differences between continually changing BMT and chemotherapy regimens.

BMT outcomes might be improved by bringing patients to transplant with less disease, better conditioning, less TRM, and/or enhancement of the graft-versus-leukemia effect. Increasing data link post-BMT outcomes to submicroscopic pre-BMT minimal residual disease ([450] , [451]). Proof that one ablation regimen is better than another has been elusive. Cyclophosphamide/TBI regimens may be superior to busulfan/cyclophosphamide regimens ([452]). Outcomes with TBI/cytosine arabinoside, cyclophosphamide/TBI, or hyperfractionated TBI/cyclophosphamide ablations were similar ([453]). Dopfer et al. advocated an etoposide/TBI regimen ([444]). Limitation of post-BMT graft-versus-host disease prophylaxis may enhance graft-versus-leukemia effect ([454]).

Future progress may come from better understanding of the agents that already contribute to cure and development of strategies that add to this therapeutic platform. Despite the complexity of current multidrug chemotherapy, thoughtful modifications have resulted in continuing improvements in outcome for newly diagnosed patients with ALL. The augmented BFM regimen rescues many standard and higher risk slow-response patients ([364] , [365]). As predicted by laboratory observations, dexamethasone is superior to prednisone ([299]), and 6-TG is superior to 6-MP despite important concerns about the sinusoidal obstruction syndrome ([331]). More is not always better ([294]). Monoclonal antibodies, such as rituximab ([455] , [456]), and immunotoxins, such as BL22 ([457]), have already shown promise in adult malignancies and may prove suitable additions to current therapy in ALL.

Outcomes

QUALITY OF LIFE The strikingly improved DFS of children with ALL and the availability of a variety of useful therapeutic strategies compel a careful consideration of the long-term sequelae of treatment. One therapy may be superior to another on the basis of the long-term health-related quality of life of survivors and not simply on the basis of transient morbidity or EFS. Barr et al. proposed to measure the global health status of leukemia survivors in terms of sensation (i.e., sight, hearing, and speech), mobility, emotion, cognition, self-care, pain, and fertility ([458] , [459] and [460]). The Canadian General Social Survey examined the areas of vision, hearing, speech, ambulation, dexterity, emotion, cognition, and pain for 15- to 19-year-olds and found that 45%, 31%, and 24% had difficulties in zero, one, and two or more domains, respectively. Corresponding data for three populations of children with ALL ranged from 30 to 60%, 32 to 47%, and 8 to 26%, respectively. Three of 25 patients (12%) with standard-risk ALL were found to have deficits in the emotional domain compared to 139 of 662 teenagers (21%) in the Canadian population. Five of 25 patients (20%) were found to have deficits in the cognitive domain compared to 159 of 662 teenagers (24%). Neither comparison reached statistical significance ([460]). Study populations are scanty, and instruments are evolving, but careful evaluation of the health status and health concerns of long-term survivors is critical. Neither bland reassurance nor alarming anecdotes suffice.

NEUROPSYCHOLOGICAL SEQUELAE The neurotoxicity of brain irradiation, parenteral methotrexate, and intrathecal therapy has evoked ongoing concern. Jankovic et al. evaluated 203 children over 6 years in a multicenter European study ([319]). They found that 18-Gy brain irradiation resulted in a gradual decline in full-scale IQ score, approaching 4 points per year, first apparent 3 to 7 years after diagnosis. A similar decline was not seen in patients who received parenteral methotrexate and no brain irradiation. The risk appeared to be largely confined to children younger than 3 years at the time of diagnosis. However, biweekly parenteral methotrexate may have short-term and long-term neurotoxicity. The POG comparison of parenteral methotrexate and intensive scheduled oral methotrexate found moderate to severe short-term neurotoxicity in 7.1% of patients receiving parenteral methotrexate and 3.7% in patients receiving intensive oral methotrexate. Generalized or focal seizures were the most common toxicity (present in 86% of patients with neurotoxicity). Recurrent events occurred in 25% of patients who received parenteral methotrexate. Leukoencephalopathy with or without microangiopathic calcifications were found in 75% of patients who had clinical neurotoxicity after parenteral methotrexate ([349]). No patient received cranial irradiation. Although the long-term neurocognitive outcomes of infants ([461]) and older children ([462]) treated with very-high-dose methotrexate are excellent, others have found that children who receive parenteral and intrathecal methotrexate show decreases in IQ similar to those found for children treated with 18-Gy cranial irradiation and intrathecal methotrexate. Mulhern et al. found that 22 to 30% of patients exhibited a “clinically significant” decrease of 15 or more points in full-scale IQ, whether they had received cranial irradiation or intensive intravenous methotrexate ([463]). Testing 6 years after completion of treatment found that 60% of patients who received intrathecal therapy and cranial irradiation or parenteral methotrexate had more than 15-point decreases on one or more neuropsychological measures ([464]). Administration of a memory battery found losses in short-term and long-term recall of correct order with visual or auditory presentation. School performance was similarly affected ([465]). Recently, the acute neurotoxicity of intermediate-dose methotrexate regimens raised questions about long-term neurocognitive damage ([349]). Waber et al. have raised concerns about the potential neurocognitive effects of dexamethasone ([466]). The clinical impact of numeric differences in test scores is hard for physicians to interpret and communicate to families. Haupt et al. compared 593 adult survivors of ALL and 409 sibling controls and looked at more tangible endpoints ([467]). Whereas patients were approximately 3.4 times more likely

than their siblings to enter a special education program, they were just as likely to enter a gifted and talented program. The risk of school difficulties increased with decreasing age at diagnosis and increasing dose of cranial irradiation. However, patients were just as likely as controls to graduate from high school, enter college, or earn a bachelor's degree. These observations provide a clinical context for the isolated results of neuropsychological tests.

SECONDARY MALIGNANT NEOPLASMS Secondary malignant neoplasms have been seen in childhood ALL, especially associated with cranial irradiation and epipodophyllotoxin therapy. In 1991, Neglia et al. reported a retrospective cohort study of 9720 children with ALL treated between 1972 and 1988 ([320]). With median follow-up of 4.7 years (2 months to 16 years), 43 secondary neoplasms were identified, seven times more than among age-matched controls. The cumulative incidence of secondary neoplasms was 2.5% at 15 years. They found 24 brain tumors, ten leukemias or lymphomas, and nine other tumors. The incidence of brain tumors was 22 times higher than among age-matched controls. All brain tumors arose in children younger than 5 years of age at diagnosis who had received cranial irradiation. Brain tumors included glioblastomas or high-grade astrocytomas (58%); primitive neuroectodermal tumors, including medulloblastoma (17%); meningioma (8%); low-grade astrocytomas (8%); brainstem glioma (4%); and ependymoma (4%). Only two patients had secondary acute nonlymphocytic leukemia. No patient received epipodophyllotoxins. The low incidence of secondary malignancies has been confirmed in more recent reports ([468]). Epipodophyllotoxins (teniposide and etoposide) have been associated with a higher rate of secondary acute nonlymphocytic leukemia ([469] , [470] and [471]). These cases often involve a chromosomal abnormality at 11q23. Pui et al. ([469]) found secondary acute nonlymphocytic leukemia as a first adverse event in 17 of 734 patients or 3.8% at 6 years. Among patients who had received weekly or semiweekly epipodophyllotoxins, the cumulative incidence was 12% ([469]). Winick et al. ([470]) reported a cumulative 4-year incidence of 5.9% for secondary acute nonlymphocytic leukemia for children who had received semiweekly etoposide, three doses during consolidation therapy followed by 2 doses every 9 weeks during continuation therapy ([470]). Katz and POG co-workers found a 20% cumulative incidence of acute nonlymphocytic leukemia for children with T-cell ALL who had received semiweekly teniposide ([471]).

AVASCULAR NECROSIS OF BONE Avascular necrosis of bone has been recognized with increasing frequency in the greater number of surviving older children and adults with ALL after chemotherapy ([472] , [473] and [474]) or after BMT (Fig. 80.4) ([410]). Prolonged administration of glucocorticoids, such as prednisone or dexamethasone, is the most likely cause. Involvement is often multifocal. Avascular necrosis of a weight-bearing joint, such as the hip, can be a source of life-long pain and disability and demonstrates the inadequacy of outcome measures such as EFS. Therapeutic options are limited.

Coronal **(A)** and sagittal **(B)** T2 images from a magnetic resonance imaging scan demonstrating corticosteroid-induced avascular necrosis of the right medial femoral condyle in a 15-year-old white girl. (Courtesy of Dr. Leonard A. Mattano, Michigan State University/Kalamazoo Center for Medical Studies.)

CARDIAC TOXICITY Anthracyclines are commonly used in the treatment of ALL in adults and children. Lipschultz et al. studied 115 children 1 to 15 years after completion of treatment on DFCI protocols between 1972 and 1987 ([475]). Cumulative anthracycline exposures ranged from 45 mg/m ^{2} to 550 mg/m ^{2}. Doxorubicin was the anthracycline used, which milligram per milligram may be more cardiotoxic than daunorubicin. Eleven patients had clinical congestive heart failure within 1 year of the completion of therapy (10%), which seems extraordinarily high compared to other less thoroughly evaluated patient populations ([281] , [282] and [283]). No other patient has subsequently developed clinical congestive heart failure. However, 17% of patients who had received only 45 mg/m ^{2} of doxorubicin had slightly elevated, age-adjusted, left-ventricular load, as measured by end-systolic wall stress. Of patients who received more than 228 mg/m ^{2}, 65% had increased afterload and 23% had decreased left-ventricular contractility as measured by stress-velocity index. Overall, fractional shortening more than 2 SD below normal occurred in 28% of patients, but values normalized in 19 of 32 patients on subsequent follow-up. Among patients who had received at least 228 mg/m ^{2}, increased afterload was related to age younger than 4 years at time of treatment, and decreased contractility was related to cumulative dose.

ENDOCRINOLOGIC DISTURBANCES Treatment, including cranial irradiation without gonadal irradiation, may lead to primary germ-cell dysfunction, as manifest by elevated levels of follicle-stimulating hormone in boys and girls. Testicular volume is decreased ([427] , [476]). Puberty may be precocious or premature for girls ([476] , [477]). The data for boys are mixed ([427] , [477]). Cranial or craniospinal irradiation may lead to short stature. Among children younger than 12 years old at the time of diagnosis, 74% were more than 1 SD below norms for height, and 37% were more than 2 SD ([478]). Rappaport and Brauner found that 56% of children with ALL who had received 24-Gy cranial irradiation had growth hormone deficiency ([479]). Growth hormone replacement may be useful ([480]). However, some concerns remain about a modest increase in the rate of secondary neoplasms ([481]). The increasingly limited role of presymptomatic cranial irradiation will probably limit the clinical impact of these problems.

MELANOCYTIC NEVI An increased number of melanocytic nevi have been found among survivors of childhood leukemia and other cancers ([482] , [483] and [484]). Neglia et al. found only one case of melanoma among 9720 survivors of ALL, but median follow-up was less than 5 years ([320]). The total number of melanocytic nevi is the most powerful predictor for the development of melanoma ([485] , [486]), and further study is warranted.

Acute Myelogenous Leukemia in Children

HISTORICAL BACKGROUND

Acute myelogenous leukemia (AML) represents a heterogeneous group of hematologic malignancies arising from the transformation and expansion of an early myeloid stem cell. The term *leukemia* originated from Virchow, who, in 1845, recognized a clinical entity characterized by too many white blood cells, leading him to name the condition *white blood*, or leukemia ([1]). Of some historical interest is that Dr. John Hughes Bennett's report of a case of leukemia preceded Virchow's description by approximately 6 weeks ([1]). However, Bennett had concluded that the condition was secondary to an infection and referred to it as *pyemia*. The term *myelogenous*, or *myeloid*, derives from the terms *myelos*, meaning marrow, and *genesis*, meaning birth.

The original cases of Virchow and Bennett probably represented what we now know to be either chronic lymphocytic or myelogenous leukemia. The first likely case of acute leukemia was reported by Friedreich and was believed to be lymphocytic ([2]). It would take the definition of the myeloblast as a precursor cell for granulocytes by Naegeli in 1900 to set the stage for the identification of the first cases of AML or what was originally termed *acute nonlymphocytic leukemia* ([3]). Even during the first half of the twentieth century, reports describing different types of myeloid leukemia made it clear that this was not one but a variety of distinct disorders, all deriving from a bone marrow precursor myeloblast. Initially, cases of monocytic leukemia were described followed by myelomonocytic leukemia ([3] , [4]). Cases of erythroleukemia, megakaryoblastic leukemia, and acute promyelocytic leukemia (APL) were subsequently described in 1917, 1931, and 1957, respectively ([5] , [6] and [7]). During the mid-1970s, the French/American/British (FAB) classification system was agreed on and defined the major categories of AML as M1 through M7 ([8]).

The description and classification of AML moved more rapidly than the development of effective treatments. During the mid-1800s, Virchow used diet therapies, ferric iodide, and application of abdominal and foot baths ([1]). In 1865, Lissauer used arsenic (Fowler solution) to treat patients with leukemia but with little success ([1]). Radiation therapy was used in the late 1800s, mostly as a form of palliation for chronic leukemias ([1]). In 1938, Forkner stated, “although leukemia is a fatal disease much can be done to add to the comfort, and promote the general health of sufferers from the chronic forms of the disease. Unfortunately acute leukemia does not respond satisfactorily to any form of treatment” ([1]). In 1948, Farber demonstrated that the use of the antimetabolite aminopterin could produce transient remissions in children with acute lymphocytic leukemia (ALL) ([9]). The pioneering work resulted in the National Cancer Institute developing screening programs for other possible antitumor therapies during the 1950s. During the 1960s, several chemotherapeutic agents, particularly cytarabine and anthracyclines, were developed and used in the treatment of AML. During the 1970s, clinical trials demonstrated that combining these two agents would result in long-term remissions for 10 to 15% of patients with AML. The subsequent introduction of more intensive remission induction regimens and postremission therapy increased attention to supportive concerns, and the development of bone marrow transplantation has led to current cure rates of approximately 50% ([10] , [11]).

This chapter focuses on AML in pediatric patients, with an emphasis on the development of clinical trials and outcomes and some of the unique types of AML observed during childhood, as well the issue of late effects and future directions. Information that is similar in both adults and children, such as the classification of *de novo* AML and cytogenetics, may be found in Chapter 79.

EPIDEMIOLOGY

Approximately 6500 children younger than 20 years of age develop acute leukemia annually in the United States, and AML represents approximately 15%, resulting in just fewer than 1000 cases/year ([12]). The remaining cases of acute leukemia in children and adolescents are lymphoblastic leukemia. Essentially the opposite ratios exist for adults, with AML accounting for approximately 80% of acute leukemia and lymphoblastic the remaining 20%. SEER (*S*urveillance, *E*pidemiology, and *E*nd *R*esults) program data indicate that there has been no significant increase in AML in childhood over the past two decades ([12]).

The incidence of AML in children remains stable during childhood, except for a slight increase during adolescence and a peak during the neonatal period ([12]). The incidence of AML in adults continues to increase throughout life and particularly beyond 55 years of age, during which time secondary AML and myelodysplastic syndromes (MDSs) with evolution to AML both increase dramatically ([12]). There does not appear to be a sex predilection.

Some variation in the incidence of AML in children has been reported among different racial and ethnic groups. For example, black children have an incidence of 5.8 cases/million compared to 4.8 cases/million in white children ([13] , [14]). Children of Hispanic background have the highest incidence ([15] , [16] , [17] and [18]). This difference is primarily due to APL having a higher incidence in Hispanic and Latin populations. A higher incidence of AML in Asia has also been reported ([15]). The increasing incidence of secondary leukemia, resulting from chemotherapy and radiation treatment for other malignancies, is a growing problem in pediatrics ([19] , [20] , [21] , [22] , [23] and [24]).

CELLULAR AND MOLECULAR ORIGINS OF ACUTE MYELOGENOUS LEUKEMIA: HEMATOPOIETIC HIERARCHIES

The determination of the AML stem cell is not solely of biologic interest but has profound significance for understanding the causes of leukemia and the development of curative therapies. This section discusses the cellular and molecular determinants of AML, and the implications for therapeutic intervention are covered in the section Future Therapeutic Challenges.

Normal hematopoiesis occurs through a series of complex changes that facilitate multipotential hematopoietic stem cells both to expand and to differentiate into various mature blood cell types. Because AML is derived from an abnormal immature hematopoietic precursor cell, these leukemias also have the capacity to expand and to show characteristics of limited differentiation. Thus, myeloid leukemias retain many of the molecular and cellular phenotypic characteristics of their normal

hematopoietic origins, providing the means to distinguish subtypes of the disease and define potential leukemic stem cell compartments. For example, although most myeloid leukemia cells often express growth, survival, and differentiation receptors for specific cytokines such as the c-kit, the FLT-3 receptor, and granulocyte-macrophage colony-stimulating factor receptor, some subtypes express more lineage-specific surface receptors and proteins, such as for granulocyte colony-stimulating factor (G-CSF) and erythropoietin. The same is true for the expression of differentiation markers, including cytoplasmic enzymes such as myeloperoxidase and esterases, as well as surface markers characteristic of various myeloid lineages such as megakaryoblastic, erythroid, or monocytic. These diverse phenotypic characteristics of different subtypes suggest significant heterogeneity of both the genetic changes and the cell of origin in AML.

Some of the earliest biologic tools used to define the cellular compartment in which leukemic stem cells arise included the use of X-linked glucose-6-phosphate dehydrogenase isoenzyme analysis in female patients with chronic myelogenous leukemia (CML) and then AML ([25], [26]). Subsequently, karyotypic abnormalities were examined in the maturing colony-forming units to evaluate which lineage (colony-forming unit stem, colony-forming unit granulocyte-macrophage, colony-forming unit megakaryocyte, colony-forming unit granulocyte, colony-forming unit eosinophil, and so forth) contained the aberrant chromosomal marker ([27]). These studies revealed that although CML arises in a very early pluripotential hematopoietic stem cell, there are cases of AML that arise in more mature pluri- and unipotential progenitor cells ([27]). For example, in adults, it has been estimated that approximately one-third of *de novo* AML may arise from erythroid and megakaryoblastic lineage-committed progenitors, and the remainder show clonality in the granulocytic or monocytic lineages ([28], [29]). Similar analyses have not been done in pediatric patients to any great extent.

Immunophenotypic analysis of aberrant cell-surface antigen expression as a marker of lineage clonogenicity has more recently been applied to this question. The results have estimated that approximately one-third of cases are derived from less mature pluripotential progenitors and up to two-thirds from more lineage-restricted progenitors, such as from the colony-forming unit granulocyte-macrophage stage ([27], [30], [31]). This type of work led to the conclusion that the AML stem cell frequently arises from different stages of maturing myeloid progenitors, resulting in the heterogeneity of various AML subtypes. Furthermore, this conclusion would predict that the genetic changes that contribute to AML would also occur at that stage of maturation.

This view has been substantially challenged in the last several years by work focused on more accurately defining and purifying the self-renewing AML stem cell. By depleting samples of different AML subtypes using antibodies directed to lineage-specific surface antigens, a very small percentage of lineage-negative (Lin $^-$) cells were isolated that had the capacity to generate AML when transferred to immunodeficient mice. These leukemogenic CD34 $^+$, CD38 $^-$, Lin $^-$ cells (termed *self-renewing leukemia-initiating cell*) were rare, having a frequency of as few as 0.2 to 200/10 ^{6} mononuclear cells from patient AML samples ([32], [33] and [34]). Of further significance was that the frequency of the self-renewing leukemia-initiating cell did not correlate with age, sex, or FAB classification, with the exception of some cases of APL ([32]). In the case of APL, a significant portion of cases appeared to be derived from a more committed progenitor cell ([32], [35]). Other studies have determined whether specific molecular abnormalities (detected by fluorescence *in situ* hybridization or polymerase chain reaction) are present or absent in sorted primitive cells; the results have in most instances confirmed these conclusions as to the more primitive nature of the AML stem cell ([36]). Subsequent investigations identified both CD34 $^+$ and CD34 $^-$ lineage-negative self-renewing leukemia-initiating cell populations that were present at extremely low frequency, demonstrating that the AML stem cell is in most cases derived from a very immature hematopoietic precursor cell ([37]).

The recognition that certain fluorescent dyes could be differentially taken up or excluded from primitive hematopoietic and leukemic stem cells has provided yet another important tool to investigate the origins of AML. Using Hoechst 33342 blue and red fluorescent dyes along with flow cytometry, a “side population” of cells was demonstrated that was characterized by being CD34 low to negative, Thy-1 $^-$, and Lin $^-$ ([38], [39]). This “side population” of very immature cells was found primarily, if not exclusively, in the bone marrow and was observed in both pediatric and adult AML; it was also capable of generating more mature myeloid precursors containing cytogenetic abnormalities characteristic of the AML clone. These results have provided further support for the conclusion that, in most cases of AML, the leukemic stem cell is represented by a very immature self-renewing phenotype with limited differentiation capability (Fig. 81.1).

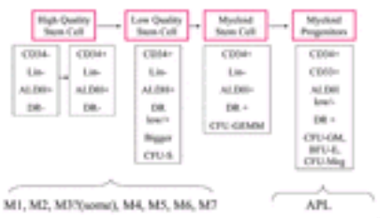

Figure 81.1. Myeloid cell differentiation and leukemogenesis. The lineage stage from which the leukemic stem cell in different subtypes of acute myelogenous leukemia originates is estimated based on several recent manuscripts ([32], [34], [35], [37], [38] and [39]) and discussions with Dr. Rick Jones, Johns Hopkins. ALDH, aldehyde dehydrogenase; APL, acute promyelocytic leukemia; BFU-E, burst-forming unit erythroid; CFU-GEMM, colony-forming unit granulocyte-erythroid-monocyte-macrophage; CFU-GM, colony-forming unit granulocyte-macrophage; CFU-Meg, colony-forming unit megakaryocyte; CFU-S, colony-forming unit stem; DR, major histocompatibility class II antigens; Lin $^-$, cells depleted of common differentiation antigens.

When these results are placed into the context of the hematopoietic differentiation schema, the conclusion can be made that there must be primary genetic changes that occur in a very primitive self-renewing stem cell and that the nature of those genetic changes in part determine the subtype of AML. For example, a t(8;21) abnormality may lead to M1 AML with minimal differentiation, whereas an inv(16) abnormality may result in an M4eo subtype. The initiating events may primarily affect the ability of the leukemic stem cell to differentiate but retain the ability to self-replicate ([40]). Subsequent genetic changes, such as mutation pathways regulating apoptosis, cell survival, and proliferation, may further change the phenotype of the leukemia as well as provide the proliferative potential of the leukemia. This latter type of genetic change involves mostly secondary mutations that affect the function of growth and survival factor receptors, such as FLT-3 or c-kit ([41]). By themselves, the different types of mutations are insufficient to cause leukemia. However, when present together in the same cell, they can cooperate and lead to the development of AML ([42]).

These results have important implications not only for understanding the etiology and pathogenesis of AML, but also for the development of more effective treatments. The causes of generating genetic mutations contributing to AML involve both inherited and environmental factors. In pediatrics, the former class of factors is particularly important.

PREDISPOSING FACTORS AND PATHOPHYSIOLOGY

Inherited Predisposition Syndromes

ABNORMAL CHROMOSOMAL NUMBER Trisomy 21, or Down syndrome (DS), represents the most common inherited condition that predisposes to the development of leukemia ([17], [43], [44] and [45]). The overall risk of developing leukemia has been estimated to be approximately 14-fold above that of the general population ([17], [43], [44] and [45]). Although older children with DS have a similar frequency of ALL and AML, within the first 3 years of life, AML, and particularly acute megakaryoblastic leukemia (AMKL), predominates ([46], [47] and [48]). Patients with DS also have an increased predisposition to develop a condition known as *preleukemia* or *transient myeloproliferative disorder* (TMD). Approximately 10% of newborns with DS develop TMD. Although clinically indistinguishable from congenital leukemia, TMD, as the name suggests, is usually self-resolving. Importantly, even children who are mosaic for trisomy 21 but phenotypically normal share the increased risk of developing TMD and subsequent leukemia ([49]). However, approximately 20 to 30% of children whose TMD resolves still develop AMKL ([50]). The close association of trisomy 21 with TMD and AMKL suggests that predisposing genetic events exist. AML-1, which is located on chromosome 21 and known to be involved in some subtypes of AML, has been etiologically implicated, but no definitive evidence has yet demonstrated a specific mutation or gene dosage effect leading to AML ([51], [52] and [53]). However, other investigations have demonstrated the interesting finding that TMD and AMKL are both characterized by mutations of the GATA-1 gene that result in the introduction of a premature stop codon, truncating GATA-1 before the amino-terminal activation domain and reducing its transcriptional activation ability ([54]). The same GATA-1 mutation has been observed in the blasts from TMD as well as in AMKL ([54], [55], [56], [57] and [58]). These results strongly argue that mutations in the GATA-1 hematopoietic transcription factor are an early event in the development of TMD and AMKL in children with DS. It remains unclear why a majority of children with DS and TMD show regression of their disease. An increased risk of developing AML in patients with Klinefelter syndrome (XXY) and Turner syndrome (XO) has also been reported, but the numbers of such cases are quite low ([59], [60]).

INHERITED MARROW FAILURE AND CHROMOSOME INSTABILITY SYNDROMES There are several important inherited syndromes characterized by progressive marrow failure and cytopenias with a high frequency of AML. Fanconi anemia (FA) is an autosomal-recessive inherited disorder with common congenital abnormalities including skeletal abnormalities, short stature, microcephaly, cardiac abnormalities, genitourinary tract abnormalities, café-au-lait spots, and mental retardation. Patients with FA have an estimated 15,000 times greater risk than the general population for developing AML and an actuarial risk of MDS or AML of approximately 52% by 40 years of age ([61], [62], [63] and [64]). There are multiple gene defects that give rise to FA and affect distinct but functionally related proteins that regulate cell cycle progression and DNA repair; the mutations result in a hypersensitivity to genotoxic agents such as mitomycin C or diepoxybutane and chromosomal instability ([65], [66]). Somatic mutations in several of the FA genes have also been observed in AML outside the setting of FA, thus further strengthening the link of these genes with predisposition for AML ([67], [68]). Dyskeratosis congenita is a primarily X-linked DNA repair syndrome characterized by skin pigmentation, nail dystrophy, and mucosal leukoplakia, as well as a predisposition to developing marrow aplasia, MDS, and AML ([69]). Mutations have been reported in the DKC1 gene that encodes dyskerin, a catalytic subunit of nucleolar RNA particles and a component of the telomerase complex ([70], [71]). Thus, dyskeratosis congenita may be considered a premature aging and an AML predisposition syndrome ([72]). Other DNA repair/chromosome instability syndromes that can lead to leukemia, although more commonly ALL, include Bloom syndrome, secondary to an inherited defect in the *blm* helicase gene, and ataxia telangiectasia, due to defects in the ATM gene ([73], [74], [75], [76], [77] and [78]).

DEFECTS IN GENES REGULATING DIFFERENTIATION AND CELL PROLIFERATION PATHWAYS The familial platelet disorder with a propensity to develop AML has been described that involves the transcription factor CFFA2 ([79], [80], [81], [82], [83], [84], [85] and [86]). Congenital amegakaryocytic thrombocytopenia is caused by inherited mutations in the thrombopoietin receptor (c-mpl) and may develop into MDS/AML ([87], [88]). There have also been acquired forms of amegakaryocytic thrombocytopenia ([89], [90] and [91]). Severe congenital neutropenia (Kostmann syndrome) represents an important inherited cytopenia of the granulocytic lineage with an increased risk of MDS/AML that increases with age ([92], [93], [94] and [95]). Introduction of G-CSF for the treatment of patients with Kostmann syndrome has been linked to the development of AML. However, it is possible that patients on G-CSF may survive for longer periods, raising the possibility that the development of AML is secondary to an intrinsically increased risk of leukemia in patients with Kostmann syndrome or a combination of this predisposition and G-CSF stimulation. Mutations in the elastase gene have been associated with both cyclic neutropenias as well as Kostmann syndrome ([96]). However, an attempt to generate a mouse model of Kostmann syndrome by homologous recombination of the elastase gene did not result in a neutropenia, raising the possibility that elastase is not responsible for Kostmann syndrome or that the murine system has alternative, compensatory pathways ([97], [98]). The detection of somatic activating mutations of the G-CSF receptor has been observed before the development of overt AML in patients with Kostmann syndrome ([99], [100]). Thus, when a rising WBC count is observed in a patient with Kostmann syndrome who was previously stable on G-CSF, one should consider that auto-activating mutations of G-CSF have occurred and that the patient has developed AML. Shwachman-Diamond syndrome, inherited in an autosomal-recessive fashion, is characterized by pancreatic insufficiency, skeletal abnormalities, neutropenia, and an increased incidence of MDS and AML ([101], [102]). Diamond-Blackfan anemia (DBA) is another inherited syndrome characterized by congenital anemia, skeletal and urogenital abnormalities, and an increased risk of developing MDS and AML ([65], [103]). An association of mutations in the RPS19 gene, encoding a ribosomal protein product and located at chromosome 19q13.2, has been reported. Mutations in the RPS19 gene have been reported to occur in approximately 25% of cases ([104], [105], [106] and [107]). Another potential locus leading to DBA, representing another 25 to 30% of cases, has been localized on chromosome 8 ([108]). There are clearly other genetic defects that must account for the remaining cases. In addition to showing an increased frequency of AML, patients with DBA also appear to have a predisposition to other cancers, making DBA a true cancer predisposition syndrome ([103], [109]). Neurofibromatosis type 1 and Noonan syndrome represent two distinct but related disorders that are caused by different molecular lesions leading to increased activation of the RAS gene pathways and a predisposition for developing myeloid leukemias, including juvenile myelomonocytic leukemia (JMML), MDS, and AML ([110], [111]). Neurofibromatosis type 1 results from mutations in the gene encoding a guanosine triphosphatase, called *neurofibromin* ([111], [112]). This guanosine triphosphatase converts activated guanosine triphosphate–RAS to inactive guanosine diphosphate–RAS but, when mutated, leads to the accumulation of activated guanosine triphosphate–RAS. Increased activated guanosine triphosphate–RAS leads to persistent stimulation and proliferation with an increased likelihood of developing leukemia ([112], [113]). In a murine model of neurofibromatosis type 1, exposure of mice with hematopoietic cells of a null phenotype for neurofibromin to alkylating agents increased the incidence of leukemia, suggesting that mutations in neurofibromin are necessary but not sufficient in causing leukemia ([114]). Recently, defects in the gene encoding the PTPN11 phosphatase have been shown to account for approximately one-third of the cases of Noonan syndrome ([115], [116]). Germline mutations of PTPN11 have been shown to lead to Noonan syndrome and JMML, whereas somatic gain-of-function mutations of PTPN11 may account for approximately one-third of acquired JMML and a smaller percentage of patients with MDS or AML, or both ([117]). Thus, alteration of the PTPN11 phosphatase increases activity of downstream RAS-activated pathways and links different genetic defects to both the development of inherited disorders and a predisposition to myeloid leukemia. The discovery of these genetic pathways led to the elucidation of somatically acquired genetic defects that contribute to leukemia, similar to what has been observed in the case of FA genes.

TWINS AND FAMILIAL CASES The increased frequency of both AML and ALL in siblings of patients with leukemia has been recognized since the early 1920s ([118], [119]). The risk for identical twins is high when leukemia first develops during infancy; in most cases, transmission has been shown to be the result of transplacental transfer. Transmission rates have been reported to be approximately 20 to 30%, although other investigators have concluded transmission rates may approach 100% ([120]). There is also a high concordance of timing of the onset of leukemia. Molecular studies have demonstrated that identical molecular defects characterized the leukemia in both twins ([121], [122], [123], [124], [125] and [126]). Clinical follow-up is therefore essential in identical twins when one of them is diagnosed with acute leukemia. These normal twins should be followed approximately every 1 to 2 months until approximately 2 years of age with physical examinations and peripheral blood cell counts. Bone marrow examinations should only be done when clinically indicated. The risk of developing acute leukemia for nonidentical twins has been estimated to be a two- to fourfold increase until approximately 6 years of age, after which the risk becomes similar to that of the general population. Relatively rare occurrences of familial leukemia strongly suggest other hereditary contributions to the development of AML ([127], [128] and [129]). Familial cases have been reported to be associated with constitutional translocations involving t(7;20)(p13;p12) ([130]) and t(3;6)(p14;p11) ([131]). Familial monosomy 7 is also reported to be linked to the development of MDS or AML, or both ([132]).

Acquired Predisposition

A variety of acquired AML predisposition disorders exist. Up to 20% of patients with severe aplastic leukemia treated with immunosuppressive agents may develop MDS or AML ([133], [134] and [135]). Similarly, paroxysmal nocturnal hemoglobinuria, an acquired pancytopenic condition, may evolve to MDS/AML ([136]). The development of MDS can also be considered an acquired, predisposing condition for AML ([137]). As noted in the section Defects in Genes Regulating Differentiation and Cell Proliferation Pathways, amegakaryocytic thrombocytopenia is another condition with an increased incidence of AML. Acquired monosomy 7 may predispose individuals to developing MDS and AML ([138]). The acquisition of predisposing conditions or chromosomal abnormalities is often linked to environmental exposures.

ENVIRONMENTAL FACTORS A wide variety of genotoxic environmental exposures can predispose individuals to AML. For example, in the period after the dropping of atomic bombs on Nagasaki and Hiroshima during World War II, an approximately 20-fold increase in myeloid leukemia was documented, with a peak in incidence between 6 and 8 years ([139], [140], [141] and [142]). The absence of a documented increase in leukemia in children exposed prenatally to the radiation of the atomic bombs has been reported ([143]) and may be consistent with the absence of definitive evidence that prenatal exposure to x-rays increases leukemia risk ([144], [145]). There remains no convincing evidence that ultrasound or the effects of living near high-voltage power lines predisposes individuals to leukemia, although reports differ in their conclusions ([146], [147] and [148]). Prenatal exposure to chemical genotoxic agents has been reported to increase postnatal incidence of myeloid leukemia. For example, maternal alcohol consumption has been associated with an increased risk of AML in offspring ([149], [150] and [151]). A significant dose response of prenatal alcohol consumption and the development of AML in offspring was documented ([149]). However, not all reports have concluded such strong associations ([152]). There has been an association of maternal ingestion of topoisomerase II inhibitors and the development of AML with malignant lymphoblastic lymphoma rearrangements in offspring ([153], [154] and [155]). Parental smoking of tobacco or marijuana has also been associated with an increased incidence of AML in offspring ([156]), although there are reports with dissenting conclusions ([157], [158]). Some reports have linked cigarette smoking in adults to an increased incidence of AML, making antismoking, preventive counseling important—particularly during teenage years ([151], [159], [160], [161], [162] and [163]). Exposure of individuals to environmentally derived genotoxic agents is quite substantial, and several specific examples of such exposures have been shown to be etiologically related to the development of AML. Such exposures include petroleum products, benzene, pesticides, and herbicides ([164], [165], [166], [167] and [168]). Interestingly, in some instances, such as with organophosphate pesticides, children may be at greater risk for accumulating higher levels of the chemicals ([169]). This represents an important example of age-dependent differences that may contribute to increased susceptibility of AML. An increasingly worrisome group of patients are those who develop AML as a result of chemotherapeutic exposures for treatment of their primary cancer or even nonmalignant conditions. For example, exposure to alkylating agents, commonly used to treat brain tumors, lymphomas, and other solid tumors, results in an increased incidence of secondary AML, with a peak incidence at 4 to 5 years, but with an at-risk period extending 12 years ([170], [171], [172], [173] and [174]). Exposure to topoisomerase I inhibitors, including anthracyclines, and topoisomerase II inhibitors, including epipodophyllotoxins such as etoposide, is also etiologically linked to the development of AML ([24], [171], [175]). Whereas cumulative dose and schedule of drug delivery may play important roles in the development of AML ([22], [176]), nearly any exposures to such genotoxic agents can result in secondary AML, as demonstrated in a child initially treated for neuroblastoma ([177], [178]). The development of secondary AML in patients treated first for primary cancers may be one of the most compelling reasons to develop

alternative and less genotoxic approaches to therapy.

PRESENTATION

The clinical presentation of AML varies greatly, although in general, systemic symptoms and severity of illness are proportional to the leukemic cell burden. The systemic symptoms presenting at diagnosis stem from more than 10^{12} leukemia cells crowding out normal hematopoietic cells in the marrow and invading extramedullary sites such as soft tissues, skin (leukemia cutis), gingivae, orbit, and brain. Patients typically present with signs and symptoms of diminished numbers of normal white blood cells, red blood cells, and platelets. On occasion, other organ systems may be involved at presentation, as in the case of coagulopathy seen most commonly in APL or end-organ damage due to hyperleukocytosis.

Marrow replacement may cause neutropenia, anemia, and thrombocytopenia. Neutropenia places patients at risk for opportunistic bacterial infections, which may be either gram-positive cocci or gram-negative rods. Typical sites of infection at diagnosis include bacteremias with or without septicemia, pneumonia, sinusitis, typhlitis, and perirectal abscesses. Invasive fungal infections are rarely seen at diagnosis in the pediatric patient, although the risk for these infections increases as the patient's duration of hospital stay and immunosuppression increases. Approximately 50% of patients have hepatosplenomegaly and lymphadenopathy. Gingival hyperplasia and leukemia cutis are less frequent but particularly characteristic of myeloid leukemia with monocytic differentiation.

Patients may also present with anemia, which gives rise to fatigue, pallor, and, in extreme cases, hemodynamic instability. The anemia is typically normocytic and normochromic, although evidence of red cell fragmentation may be seen in severe cases of disseminated intravascular coagulation (DIC). The median hemoglobin is approximately 7 g/dl with a range of 2.5 to 14.0 g/dl ([179]).

Nearly 75% of patients present with a platelet count less than 100,000 platelets/ml ([180]). Thrombocytopenia may cause petechiae, purpura, mucosal bleeding, and, rarely, central nervous system (CNS) and pulmonary hemorrhage. Thrombocytopenia is exacerbated by coagulopathy, especially in the M3 and M5 AML subtypes. Although the mechanism for DIC is not known in M5 AML, there is convincing evidence that expression of annexin II, a receptor for fibrinolytic proteins, facilitates plasminogen activation by associating plasminogen and its activator, tissue plasminogen activator, at the APL (M3) leukemic blast cell surface ([181]).

Patients with peripheral blast counts greater than 200,000/mm^3 are at risk for CNS stroke due to hyperviscosity, and benefit from leukapheresis to drop the blast count rapidly ([182]). Similarly, pulmonary insufficiency may occur in patients with very high leukemia blast counts. Approximately 5% of patients with AML have CNS disease at diagnosis, and a smaller percentage presents with CNS chloromas ([183]). These patients may have headaches, cranial nerve palsies, focal neurologic deficits, or, rarely, seizures.

DIFFERENTIAL DIAGNOSIS

Whereas the diagnosis of acute myeloid leukemia is generally straightforward, the differential diagnosis is broad, including both malignant and nonmalignant conditions. Juvenile rheumatoid arthritis, infectious mononucleosis, aplastic anemia, congenital and acquired cytopenias, and the transient myeloproliferative syndrome of DS infants may all mimic AML. AML may be mistaken for MDS or chronic leukemias, including CML, chronic myelomonocytic leukemia, and JMML. Undifferentiated leukemia or FAB L2 ALL may be morphologically difficult to distinguish from megakaryoblastic AML. Metastatic rhabdomyosarcoma may appear like megakaryoblastic or monoblastic AML, as may metastatic neuroblastoma, especially in the neonate.

The diagnosis of AML is typically made on bone marrow aspirate examination, with special stains, flow cytometry, and cytogenetics providing additional data. On occasion, definitive diagnosis is difficult either because of technical difficulties in obtaining an adequate specimen or because of conflicting data. Repeat marrow aspirate and biopsy may provide a specimen adequate for diagnosis. Touch preparations of the bone marrow biopsy may be used in cases in which bone marrow aspiration is difficult.

ACUTE MYELOGENOUS LEUKEMIA SUBTYPES

In general, the FAB classification system for acute myeloid leukemia applies equally well to pediatric and adult myeloid leukemias. Some important differences, however, occur in the epidemiology of certain FAB and cytogenetic subtypes. These differences are summarized here, and a complete description of the FAB classification system can be found in Chapter 79. FAB subtypes M0, M1, M2, and M3 are more common in older rather than younger children ([184] , [185]), with frequencies in children 10 to 15 years of age very similar to reported adult frequencies ([186]). On the other hand, FAB subtypes M5 and M7 are significantly more common in younger children ([184] , [185]), although an increase in the frequency of M5 has been reported in older adult cases of AML ([187]). Several cytogenetic abnormalities parallel FAB frequencies and are summarized in Table 81.1. Younger children are less likely to have t(8;21) and t(15;17) but more frequently have chromosome abnormalities involving 11q23. Likewise, the increased frequency of M7 AML in young patients is due to the high rate of M7 in DS patients ([184] , [185] , [188]).

THERAPY FOR PATIENTS WITH NEWLY DIAGNOSED ACUTE MYELOGENOUS LEUKEMIA

Background

Pediatric AML protocols begin with a remission induction regimen, followed by a course of consolidation therapy and, subsequently, an intensification course, which may include hematopoietic stem cell transplantation (HSCT). This relatively brief but intensive approach has yielded an approximately 50% chance of cure across different cooperative group protocols ([189] , [190] and [191]). The most recent cooperative group AML trial schemas and results that have been reported in peer-reviewed publications are shown in Figure 81.2 and Figure 81.3. Although there is general agreement that pediatric AML therapy should be based on the use of anthracyclines and cytarabine, pediatric cooperative groups differ in their induction regimens and use of HSCT transplant in intensification ([192] , [193]). The major pediatric cooperative groups are also presently evaluating varied risk stratification methods as well as the use of novel agents.

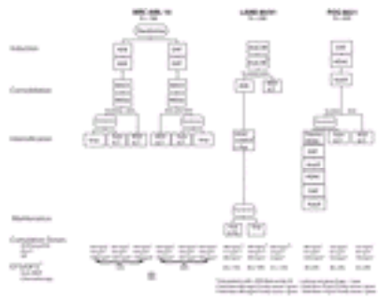

Figure 81.2. Medical Research Council (MRC) acute myelogenous leukemia (AML) 10, Leucamie Aique Myeloide Enfant (LAME) 89/91, and Pediatric Oncology Group (POG)-8821 treatment schema ([190] , [204] , [206] , [212] ,351,352). **MRC reported 5-year disease-free survival (DFS) (relapse or death). LAME reported 6-year DFS (relapse or death). POG reported 3-year event-free survival (EFS) (treatment failure or death). ADE, cytarabine, daunorubicin, etoposide; AraC, cytarabine; AraC/M, cytarabine, mitoxantrone; AutoSCT, autologous stem cell transplant; Aza/E, azacitidine, cytarabine; DAT, daunorubicin, cytarabine, thioguanine; HDAC, high-dose cytarabine; MACE, amsacrine, cytarabine, etoposide; mAMSA, amsacrine; MiDac, mitoxantrone, etoposide; MSD, matched sibling donor; Rx, therapy; SCT, stem cell transplant; L-Asp, L-asparaginase; 6-TG, 6-thioguanine.

Figure 81.3. Children's Cancer Group (CCG)-2891 and Berlin-Frankfurt-Munster (BFM) 93 treatment schema. *BFM reported 6-year event-free survival (EFS) (death, relapse, resistant disease, second malignancy). CCG reported 6-year disease-free survival (DFS) (death, relapse, induction failure). ADE, cytarabine, daunorubicin, etoposide; AIE, cytarabine, idarubicin, etoposide; AraC, cytarabine; Auto SCT, autologous stem cell transplant; 5-Aza, azacitidine; CPM, cyclophosphamide; DCTER, dexamethasone, cytarabine, thioguanine, etoposide, rubidomycin; DNM, daunomycin; Dox, doxorubicin; HAM, high-dose cytarabine, mitoxantrone; HDAC, high-dose cytarabine; L-Asp, L-asparaginase; MSD, matched sibling donor; Pred, prednisone; SCT, stem cell transplant; 6-TG, thioguanine; VCR, vincristine; VP, etoposide; XRT, radiotherapy.

Induction Therapy

Induction therapy has two goals: first, to reduce the malignant blast bone marrow percentage to less than 5% or to eliminate overt extramedullary disease, or both, and second, to restore normal hematopoiesis. Current pediatric cooperative group approaches are based on the standard “7 and 3” induction regimen of 7 days of cytarabine at 100 mg/m ^{2} and 3 days of daunorubicin at 45 to 60 mg/m ^{2}. The most recent published induction regimens and results are listed in Table 81.2.

TABLE 81.2. Pediatric Acute Myelogenous Leukemia Induction Regimens

Study	Patients	Cytosine Arabinoside (mg/m ^{2})	DNR (mg/m ^{2})	DNR Equivalent (mg/m ^{2})	Other Agents	Complete Remission Rate (%)	Reference

Despite the different approaches taken by the cooperative groups, several important conclusions can be gained from these studies. First, remission quality modifies relapse risk, and more intensive induction regimens may provide deeper (less minimal residual disease) remissions with lower relapse rates. This is best shown in Children's Cancer Group (CCG)–2891 study, in which the intensively timed DCTER (dexamethasone, cytarabine, thioguanine, etoposide, and rubidomycin) arm had a similar induction success rate compared to the standard timing regimen, but the relapse rate for the intensively timed arm was lower irrespective of postinduction therapy ([190]). However, more intensive induction regimens also carry greater treatment-related morbidity and mortality that can diminish the net benefit of such intensive therapy. In general, each trial using a very intensive induction regimen has noted an initial toxic death rate of approximately 10 to 15%, which decreases

with acquired treatment experience ([194]).

This high induction mortality rate has been reduced in several studies by mandated supportive care guidelines (see section Supportive Care). Although escalating the economic cost of AML therapy, these supportive care guidelines are critical for improved outcomes. In the CCG, these guidelines mandate early initiation of broad-spectrum antibiotics, including vancomycin at the first febrile episode, early initiation of treatment doses of amphotericin after 3 days of persistent fevers, hospitalization until granulocyte recovery, strict hand washing, and use of high-efficiency particulate air—filtered rooms whenever possible. Institution of these guidelines lowered toxic mortality to approximately 5% across cooperative group trials ([194]).

Recent cooperative group AML trials have also sought to answer three additional remission induction questions. First, what are the optimal dose and schedule of cytarabine? Second, what agents can be added to the cytarabine and anthracycline backbone? Third, is mitoxantrone a better anthracycline than daunorubicin? Although dose intensification of cytarabine has not been demonstrated to improve remission induction rates, higher doses appear to confer lower rates of leukemia relapse ([195] , [196]). This overall gain in patient survival with higher-dose cytarabine is diminished by increased toxicity, although some subgroups, such as those having core-binding factor AML [e.g., t(8;20)], experience an improved outcome ([197]).

Whereas the addition of other agents to the “7 and 3” backbone has helped increase induction rates from 70 to 85%, no randomized trial has demonstrated superiority of a particular agent, or combination of agents, over any other combination. Specifically, the Medical Research Council (MRC)-10 trial tested 6-thioguanine versus etoposide with daunomycin and cytarabine and found no statistically significant difference between the two induction regimens ([191]).

Finally, debate continues over the optimal anthracycline choice in induction. The Berlin-Frankfurt-Munster (BFM) group showed evidence that idarubicin was superior to daunomycin in induction ([198]), and a metaanalysis by MRC/Institute for Cancer Research of randomized idarubicin/daunomycin comparisons suggested that idarubicin is superior ([199]). The MRC AML-12 trial, which randomized daunorubicin versus mitoxantrone on a backbone of cytarabine and etoposide, showed no benefit of idarubicin. The mitoxantrone arm, however, experienced substantially more toxicity ([200]). The CCG-2941 trial showed that idarubicin was too toxic to be used in sequential courses of intensively timed IdaDCTER therapy ([201] , [202]).

In summary, present-day pediatric AML induction regimens successfully induce remission in approximately 85% of patients using a variety of induction strategies. The improvements in induction remission rates have come primarily from intensification of therapy, either by adding additional agents to the “7 and 3” backbone or from dose intensification. Although successful, it appears unlikely that further dose escalation or intensification will significantly improve remission rates. Thus, a central remission induction question now centers on the selection and safe integration of novel agents, such as gemtuzumab ozogamicin (Mylotarg), which may increase antileukemic activity with less toxicity than conventional chemotherapy ([203]).

Hematopoietic Stem Cell Transplantation

All pediatric cooperative groups agree that intensive cytarabine-based postremission induction therapy is required to minimize relapse risk if a matched sibling donor (MSD) is not available. However, substantial debate exists over the use of an appropriately matched MSD. The various cooperative groups agree that allogeneic HSCT reduces the risk of leukemia relapse, but they differ in their assessment of the impact of transplant-related mortality and lower salvage of relapse after HSCT on the overall outcome of patients ([192] , [193]). Randomized trials in the United States and France have demonstrated that matched related donor (MRD) HSCT significantly improves both event-free survival (EFS) and overall survival (OS) over intensive chemotherapy or autologous hematopoietic stem cell transplant (auto HSCT) ([204] , [205] and [206]).

Based on these trials, American and French cooperative groups offer MRD HSCT to all patients with appropriately MRDs in first complete remission (CR). The MRC and BFM groups, however, do not offer MRD HSCT in first CR to all patients because the AML-10 ([207]) and BFM trials ([189] , [208]) did not show a statistically significant advantage for MRD bone marrow transplant for patients with “standard risk” AML as defined by each group. The discordant results of these trials may stem from the different patient populations and treatment protocols of each cooperative group and the statistical limitations of relatively small numbers, as well as the biases of parents, guardians, and physicians regarding postinduction therapies. Difficulties performing randomized trials testing HSCT questions and the strongly held opinions on the role of HSCT make it unlikely that the role of HSCT in pediatric AML will be definitively addressed in a randomized trial.

Several studies have sought to evaluate the role of HSCT with either a metaanalysis or a decision analysis approach. The metaanalysis by Bleakley et al. demonstrated that MSD HSCT decreased relapse risk while improving both disease-free and overall survival. However, the analyzed data were inadequate to evaluate individual risk groups (i.e., favorable vs. unfavorable cytogenetics) ([209]). A decision analysis by Hertenstein et al. also reached the conclusion that MSD HSCT improved disease-free survival over chemotherapy alone. However, this decision analysis did not evaluate the role of stratification based on leukemia cytogenetics ([210]). Sung et al. recently published a decision analysis that evaluated three treatment strategies: all HSCT, no HSCT, or HSCT for patients without favorable leukemia cytogenetics [i.e., without t(8;21), t(15;17), or inv(16)] ([211]). In this analysis, the strategy of cytogenetic testing and offering MSD HSCT to patients without favorable leukemia cytogenetics was the most optimal one ([211]). Completion of a metaanalysis with individual patient data, as well further refinement in outcome measure of decision analysis, may enable these methods to provide guidance to the selection of HSCT for pediatric AML patients.

Intensification and Maintenance Therapy

If MRD HSCT is not available or selected, then chemotherapy-based consolidation and intensification regimens should follow induction therapy. Several cooperative group trials have addressed the role of auto HSCT in postremission therapy. CCG, the Pediatric Oncology Group, and Leucamie Aique Myeloide Enfant studies showed no benefit from auto HSCT when compared to varied chemotherapy courses ([204] , [205] and [206]). However, the combined pediatric and adult experience in MRC AML-10 demonstrated a significant disease-free benefit for auto HSCT compared to no further therapy after four courses of intensive chemotherapy, although OS was not improved ([212]). Current protocols from the MRC, BFM, and St. Jude Children's Research Hospital (Fig. 81.4) do not use auto HSCT; it appears unlikely that auto HSCT will play a prominent role in pediatric AML therapy in the future.

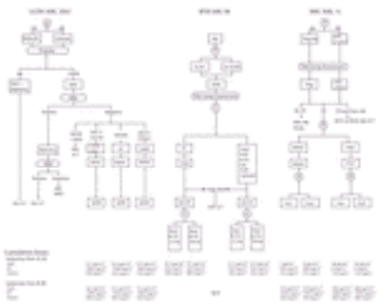

Figure 81.4. St. Jude's Children's Research Hospital (SJCRH) acute myelogenous leukemia (AML) 2002, Berlin-Frankfurt-Munster (BFM) 98, and Medical Research Council (MRC) AML 15 treatment schema. ADE, cytarabine, daunorubicin, etoposide; AI, cytarabine, mitoxantrone; AIE, cytarabine, idarubicin, etoposide; Allo SCT, allogeneic stem cell transplant; AraC, cytarabine; 2CDA, cladribine; CE, cytarabine, etoposide; CR, complete responder/response; Dauno, daunorubicin; Flag, fludarabine; Flag-Ida, fludarabine, idarubicin; GCSF, granulocyte colony-stimulating factor; Gy, Gray; HAM, high-dose cytarabine, mitoxantrone; HDAC, high-dose cytarabine; HDAcDE, high-dose cytarabine, daunorubicin, etoposide; HD/VP, high-dose cytarabine, etoposide; HR/SR, high risk/standard risk; Ida, idarubicin; idAM, intermediate-dose cytarabine, mitoxantrone; LDAcDE, low-dose cytarabine, daunorubicin, etoposide; MACE, amsacrine, cytarabine, etoposide; MFD SCT, matched family donor stem cell transplant; MidAC, mitoxantrone, etoposide; MRD, minimal residual disease; MSD, matched sibling donor; MUD SCT, matched unrelated donor stem cell transplant; NR, nonresponder; PR, partial responder; Pred, prednisone; 6-TG, thioguanine; SCT, stem cell transplant; VCR, vincristine.

Although agreement exists on the role of cytarabine-based intensification therapy, especially for core-binding factor myeloid leukemias in which additional courses of cytarabine appear to significantly decrease relapse risk, the optimal number of cycles of intensification chemotherapy is not known ([190] , [213] , [214]). The published pediatric AML trials have used either two or three courses of consolidation therapy, for a total of four or five courses of therapy ([198] , [206] , [212] , [215]). The MRC AML-10 randomized patients to either auto HSCT transplant or no further therapy and demonstrated a decreased relapse risk in patients receiving auto HSCT. However, the

addition of auto HSCT was associated with significant morbidity and mortality, thus abrogating any OS advantage ([212]). MRC AML-12 randomized patients in all risk categories to either two or three consolidation cycles ([216]). These results, however, have not yet been reported in a peer-reviewed setting.

Debate also exists about the role of ALL-like maintenance therapy. Presently, only the BFM group uses a maintenance phase of chemotherapy. The BFM group bases this choice on the results of BFM-87, in which a maintenance phase was beneficial to a low-risk group of patients not receiving HSCT ([208]). Other cooperative groups, however, have shown that maintenance therapy is associated with a decrease in both EFS and OS when compared to shorter, more intensive regimens ([204] , [217] , [218]).

Summary of *De Novo* Therapy

Despite differences in the use of anthracyclines, HSCT, and maintenance therapy, pediatric cooperative groups share a common treatment approach based on anthracyclines and cytarabine as the primary chemotherapy agents. This common backbone, as well as differences, can be seen in currently ongoing clinical trials within the MRC-15, BFM-98, and St. Jude's Children's Research Hospital AML 2002 protocols, illustrated in Figure 81.4. These trials focus on evaluating cooperative group-specific risk stratification methods as well as the use of novel agents, primarily gemtuzumab ozogamicin. Although potentially limited by small numbers of patients in subgroups, these trials will provide important information about the success of implementing risk-stratified approaches to AML therapy. With careful long-term follow-up of enrolled patients, important data on the risks and severity of late effects may also be obtained. These data may enable more precise determination of the overall risks and benefits of each therapeutic approach.

THERAPY FOR PATIENTS WITH RELAPSED/REFRACTORY DISEASE

Despite AML treatment intensification, refractory disease and relapse remain the major causes of treatment failure. Reinduction regimens typically use high-dose cytarabine, even if prior therapy has included substantial cytarabine exposure. With the addition of such agents as mitoxantrone, etoposide, fludarabine, or 2-chlorodeoxyadenosine to cytarabine, a substantial percentage of relapsed or refractory patients achieve CR ([219] , [220] and [221]). There is evidence that the combination of fludarabine, idarubicin, and cytarabine (FLAG-Ida) has a high remission induction rate, which may be of longer duration. However, the toxicity associated with this regimen is also substantial ([222] , [223]). The combination of mitoxantrone and high-dose cytarabine used in the CCG-2951 study achieved a 76% overall remission rate ([224]). One adult trial has demonstrated that gemtuzumab ozogamicin, an anti–CD-33 antibody covalently linked to calicheamicin, in combination with idarubicin and cytarabine, is effective in the relapsed or refractory setting ([203]), and pediatric trials are presently under way.

Generally, patients with refractory or relapsed AML undergo allogeneic HSCT with either a related or an unrelated donor ([225]). Conditioning regimens vary widely. Despite, or perhaps because of, this wide variation, no randomized trial has evaluated the optimal HSCT conditioning regimen in the relapse setting. Because many investigators are reluctant to give conditioning regimens that include total body irradiation to young children, the balance between risks and benefits of total body irradiation–containing regimens for relapsed AML is unknown. Unrelated donor sources may include cord blood as well as haplo-identical grafts ([204] , [206] , [226] , [227]). Although the use of cord blood units and haplo-identical grafts makes alternative donors available for almost every patient, both of these stem cell sources have disadvantages over fully matched unrelated donors. Cord blood grafts may have less of a graft-versus-leukemia effect, and the small number of stem cells can delay engraftment or increase graft failure ([228]). Haplo-identical grafts are associated with higher rates of graft-versus-host disease ([229]), as well as higher rates of viral infections and posttransplant lymphoproliferative disease due to the intensive immunosuppressive transplant regimens used ([230]).

Despite the increased risks of toxicity, infectious complications, and graft-versus-host disease associated with the allogeneic transplant typically used for relapsed or refractory AML, between 20 and 50% of patients may be salvaged ([231] , [232]). Salvage rates are significantly affected by the duration of first CR, with shorter CR-1 (e.g., <6 months or while on therapy) being associated with lower salvage rates ([233]). Leukemia karyotype may also modify the probability of achieving CR in the relapsed or refractory setting ([234]). Overall, poor prognosis patients have a 3-year survival of less than 20%, whereas patients with initial CR lasting longer than 1 year may have a 30 to 40% 3-year survival.

SUPPORTIVE CARE

Current AML protocols are among the most intensive chemotherapy protocols and cause a wide variety of severe complications. AML treatment-related morbidity and mortality significantly affect OS of patients, both through treatment delays and toxic deaths. Thus, AML patients should be cared for by physicians and nurses experienced in AML therapy in institutions with appropriate laboratory, radiology, blood-banking, and surgical services. These necessary support services are expensive and require substantial commitment and resources from the patient's family and health care systems.

Standardization of supportive care, as shown by Riley et al., may reduce treatment-related mortality by 50% ([194]). AML supportive care guidelines typically focus on infection prophylaxis and treatment, although hematologic support is also critical. Fever and neutropenia in AML patients constitute a medical emergency ([235] , [236]). After obtaining blood cultures, broad-spectrum antibiotic therapy should be instituted rapidly. Coverage for penicillin-resistant *Streptococcus viridans* and gram-negative organisms should be given, and anaerobic coverage should be added if clinically indicated. Local microbial resistance patterns dictate selection of initial antibiotics, although vancomycin and ceftazidime are typically included in the initial antibiotic selection. Patients should remain on broad-spectrum coverage until their neutropenia shows signs of resolution. Vancomycin use may be limited to 24 to 48 hours until a resistant *S. viridans* infection has been excluded. Although patients with AML are at risk for a wide range of bacterial infections, gram-negative organisms occur frequently at diagnosis, and a-hemolytic streptococcus is often seen after intensive consolidation regimens ([237]).

Empiric antifungal therapy should begin if fever persists for more than 3 to 5 days after initiation of antibiotic therapy or with recurrent fever. Amphotericin B has been the first-line choice for antifungal coverage, although recently, voriconazole has been shown to be superior against *Aspergillus* in a randomized clinical trial ([238]). Selection of the appropriate antifungal agent is guided by culture results, which may require biopsy, radiographic findings of lesions difficult to biopsy, and the side effect profiles of the various antifungal agents. Importantly, strict hand-washing guidelines, mandated hospitalization until neutrophil recovery, and use of high-efficiency particulate air–filtered rooms whenever possible all significantly decrease the incidence, morbidity, and mortality of infections in pediatric AML patients.

Multiple studies in children and adults have demonstrated that G-CSF may decrease the length of neutropenia and the length of hospital stay, but it does not alter severe toxicity or infection rates ([239] , [240] , [241] and [242]). Unlike studies in adults, G-CSF treatment in patients with hypercellular day 7 bone marrows on CCG-2891 had a statistically significantly improved remission rate and OS ([239]).

Prophylaxis against opportunistic infections is also an important supportive care issue. Although *Pneumocystis carinii* is rare in pediatric patients with AML, prophylaxis with trimethoprim-sulfamethoxazole is often given. *S. viridans* sepsis may be prevented by penicillin prophylaxis in centers where *S. viridans* remains penicillin sensitive. Penicillin resistance, however, is becoming common. High-efficiency particulate air filtration has been shown to diminish *Aspergillus* infection in marrow transplant patients and likely benefits AML patients who experience prolonged periods of neutropenia and immunosuppression ([243]).

Patients undergoing AML therapy also require substantial blood product support. In MRC-10, approximately 20% of all pediatric deaths were due to hemorrhage, with two patients dying before initiation of therapy and five patients dying during induction therapy ([194]). Whereas the typical platelet transfusion threshold is conventionally 10,000 to 20,000 ([244]), AML patients often present with DIC and infections that markedly increase the risks of severe hemorrhage, even at platelet counts that would otherwise be considered safe. Thus, patients at increased risk for hemorrhagic complications should have their platelet counts maintained at a higher level, and hemostatic factor replacement by fresh frozen plasma or clotting factors should be judiciously used ([245]). Standard hemoglobin transfusion thresholds for pediatric AML patients range from 7 to 9 mg/dl ([246]), although moderately higher hemoglobin levels may be sought in situations in which maximal oxygen-carrying capacity and intravascular volume expansion are needed. Prospective randomized trials to determine the potential advantage of maintaining higher hemoglobin levels in children have not been reported.

LATE EFFECTS OF THERAPY

Although intensive AML protocols cure a substantial fraction of children with AML, the late effects of these therapies are significant. Several investigators have reported on AML late effects, but population-based follow-up studies of recent intensive therapies are lacking and remain a critically needed area of research ([247] , [248] , [249] and [250]). Leung et al., reporting on 77 patients surviving more than 10 years from diagnosis, observed that increasing radiation dose as well as younger age at

diagnosis and initiation of radiation therapy were risk factors for growth delay, infertility, academic difficulties, cataracts, and hypothyroidism. Patients receiving total body irradiation had lower cumulative anthracycline doses (204 mg/m ^{2} vs. 335 mg/m ^{2}) but did not have a lower rate of cardiomyopathy ([250]). Patients who survive AML therapy also have a significantly increased rate of secondary malignancies ([173]). However, primary disease relapse and therapy-related morbidity decrease EFS significantly more than secondary AML.

MANAGEMENT OF PATIENTS WITH DOWN SYNDROME

The majority of leukemias in children with DS are lymphoid, although DS children comprise 10% of pediatric AML patients, with the M7 FAB subtype being most common ([251]). The elevated risk of AML in DS children is first seen in the neonatal period: Up to 10% of newborns with DS experience TMD. TMD is very similar to M7 AML, except that trisomy 21 is usually the only karyotypic abnormality and that the leukemia nearly always regresses by 2 to 3 months of age without therapy ([252]). However, some patients with TMD require low-dose cytarabine therapy due to severe hepatic infiltration or other complications ([252] , [253]). On occasion, TMD may be fatal due to hepatic fibrosis, DIC, or other organ dysfunction due to leukemic cell infiltration ([252] , [253]).

All infants with DS, including those who have had TMD, should be considered at risk for developing AML ([252]). This risk is highest between the first and third year of life. DS patients who develop AML are more at risk for fatal toxicity but have significantly more chemotherapy-responsive leukemia ([251] , [254]). DS patients older than 4 years of age have significantly inferior survival than younger patients and may require more intensive therapies. Even accounting for these high-risk patients, children with DS have better outcomes than non-DS children when less-intensive therapies are used ([46] , [48] , [254] , [255]).

MANAGEMENT OF INFANTS WITH CONGENITAL ACUTE MYELOGENOUS LEUKEMIA

Approximately 120 patients with congenital AML have been reported in case reports and reviews ([256] , [257] , [258] and [259]). Congenital leukemia is defined by (a) presentation in the first month of life, (b) presence of inappropriate numbers of immature myeloid, lymphoid, or erythroid cells, (c) infiltrations of immature cells into nonhematopoietic tissues, and (d) absence of other etiologies ([260]). Approximately two-thirds of patients present with leukemia cutis, giving a “blueberry muffin” baby appearance that may also be seen in metastatic neuroblastoma or rhabdomyosarcoma and histiocytosis ([261]). Hepatosplenomegaly is also typically present, but lymphadenopathy less so; CNS involvement is present in 50% of cases that included performance of a lumbar puncture ([261]). The WBC count is typically elevated, and the majority of reported congenital myeloid leukemias have been of the M5 subtype. A majority of congenital AML cases have abnormal cytogenetic findings, with approximately one-fourth of cases having 11q23 abnormalities ([261]). Although spontaneous remissions have been reported ([262]), OS tends to be poor, with an OS of 24% at 2 years in the most comprehensive review ([261]).

MANAGEMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

The therapy for pediatric and adult APL is essentially identical for pediatric and adult patients. Thus, pediatric patients have usually been enrolled in various adult APL cooperative group trials. APL therapy is now based on the use of all- *trans*-retinoic acid (ATRA), a differentiating agent that induces remission in a majority of patients with APL when used as a single agent (see Chapter 79 on adult AML) ([263] , [264]). Importantly, patients with FAB M3 natural killer cells and t(11;17) do not respond to ATRA ([265] , [266]). Whereas a majority of patients enter remission with ATRA, disease recurrence uniformly occurs within 3 to 4 months without additional therapy ([266]). Multiple trials have demonstrated a benefit to ATRA/chemotherapy combinations ([267] , [268] , [269] and [270]), with recent evidence suggesting that anthracyclines play a more important role in APL therapy than cytosine arabinoside ([271] , [272]). To date, two reports have described treating APL with gemtuzumab ozogamicin, both alone ([273]) and in combination with ATRA ([274]).

Children with the t(15;17) respond equally well to ATRA, as do adults with AML. Both children and adults appear to have an induction mortality rate of 10% due to hemorrhagic complications ([275]). This complication rate has not significantly been altered by ATRA therapy. The risk of retinoic acid syndrome, or acute pulmonary failure, appears to be equal in children and adults ([276]). However, pediatric patients have an increased risk for pseudotumor cerebri ([277]). Treatment of retinoic acid syndrome centers on discontinuation of ATRA and initiation of dexamethasone therapy ([276]).

Arsenic trioxide has also shown efficacy as a differentiating agent in APL ([278]). Arsenic does not appear to be cross resistant with ATRA and, thus, has an important role in relapsed APL in which remission induction rates are approximately 85% ([278] , [279] and [280]). Arsenic has been associated with sudden cardiac death in APL patients due to prolonged cardiac repolarization ([281] , [282]). Arsenic should be used with caution in patients with known prolonged QT or in those taking medications known to prolong the QT interval. A significant challenge for future clinical trials is how to incorporate arsenic into treatment regimens for newly diagnosed patients alone or in combination with ATRA or chemotherapy, or both.

MANAGEMENT OF PATIENTS WITH INHERITED SYNDROMES CHARACTERIZED BY DNA REPAIR DEFECTS OR CYTOPENIAS, OR BOTH

Patients with inherited syndromes characterized by DNA repair defects usually are not able to tolerate the effects of chemotherapy or radiation treatment as well as other children with AML. For example, patients with FA require substantial dose reductions in chemotherapeutic drugs as well as bone marrow transplantation regimens, but such patients can be sometimes cured of their AML ([283]). Reduced-intensity regimens are therefore recommended for such patients ([283] , [284] and [285]).

Patients with Kostmann syndrome who develop AML can also be cured. Because of their severely compromised ability to generate granulocytes, these patients can have significant problems with infections. However, bone marrow transplantation has been successfully used ([286] , [287]).

Aside from case reports and small case series, few data have been reported on the therapy and outcome of patients with constitutional abnormalities or conditions with a predisposition for developing AML.

PROGNOSTIC FACTORS

With the improved survival of pediatric patients with AML, prognostic factors that predict treatment outcome gain importance, and the number of patients required to develop and evaluate prognostic models increases. At this time, prognostic factors may be grouped into three general categories: host factors, disease factors, and treatment response. As illustrated in Figure 81.5, these factors interact to determine patient outcome.

Figure 81.5. Relationship of prognostic factors in pediatric acute myelogenous leukemia. See text for details. FAB, French/American/British classification; MRD, minimal residual disease; PCR, polymerase chain reaction; WBC, white blood cell.

Of the host factors, patient age, race, and select constitutional abnormalities are most strongly correlated with outcome. In general, patient age is inversely related to treatment outcome. This relationship was best demonstrated in the MRC AML-10 trial and was confirmed in MRC AML-12, in which infants, despite worse toxicity, had

higher survival rates than older children ([225], [288]). The CCG-2891 trial has also demonstrated a benefit of young age ([190]).

Although patient gender is not usually included in risk models, girls generally have marginally better outcomes than boys. In CCG studies, race has consistently been a predictor of outcome, specifically with blacks having a poorer outcome than whites ([289]). This difference was statistically significant only for patients treated with chemotherapy alone. The reasons for this difference in outcome are not known but may be related to pharmacogenetic differences in the host or characteristics of the leukemia. As AML therapy is primarily inpatient hospital based, it is unlikely that access to medical care or issues of treatment compliance are involved.

Whereas the pharmacogenetic basis of treatment response is poorly understood, homozygous deletions of the GST theta gene, a detoxifying phase II enzyme, are associated with decreased survival (52% vs. 40%, $p = .05$) ([290]). This difference in survival is due to an excess of toxicity in patients who are GST theta null (24% vs. 12%, $p = .05$) and has been replicated in separate patient populations ([222]).

Patients with constitutional abnormalities also have altered risk of treatment response. Most notably, patients with trisomy 21 experience more therapy-related toxicity but have higher survival rates than patients with a normal constitutional karyotype when less-intensive regimens are used ([251]). Interestingly, age also prognosticates outcome for patients with trisomy 21, with older patients having a worse prognosis than younger ones. Patients with other constitutional abnormalities such as FA, Shwachman syndrome, or Kostmann syndrome also have increased toxicity with standard AML therapy. The underlying cytopenias in the patients also limit their ability to recover normal hematopoiesis after AML therapy. As a result, these patients are generally excluded from standard AML protocols.

Several characteristics of leukemia are also associated with outcome. These characteristics include initial WBC count, FAB morphology, and cytogenetics. Like age, initial WBC blast count is inversely related to outcome. An initial WBC count less than 20,000 WBCs/ml ^{3} is associated with a favorable prognosis, whereas an initial WBC count greater than 100,000 WBCs/ml ^{3} has been associated with an unfavorable prognosis in both the MRC and BFM trials ([291]). In CCG-2891, patients with a WBC count greater than 330,000 WBCs/ml ^{3} had an unfavorable prognosis, with an EFS of 7%, due to early death, induction failure, and relapse.

Whereas FAB group has been associated with treatment outcome, different studies have found different associations. The BFM group reported that patients with FAB M1-M4 had improved survival over patients with either M0 or M5-7 ([292]). However, in both MRC-10 and CCG-2891, the M5 FAB subtype was associated with favorable prognosis ([184], [190]). FAB M7 in non–trisomy 21 patients has also been associated with poor survival in CCG studies ([251]).

The cytogenetics karyotype of the leukemia blasts is a robust predictor of outcome. Patients with t(15;17), t(8;21), and inv(16) fare better than patients with other cytogenetic findings ([188], [255]). Patients with monosomy 7 or 5 do poorly, as do patients with complex karyotypes ([293], [294]).

Much present work is focused on defining molecular prognostic factors for AML treatment response. To date, the most robust predictor is the presence of the FLT-3 internal tandem duplication (FLT-3/ITD), which is present in 10 to 30% of leukemic blasts ([295], [296]). The presence of the FLT-3/ITD is strongly correlated with poorer outcome, and recent work has shown that the number of internal tandem duplications is critical ([297]). Patients with a high FLT-3/ITD mutant allele ratio define an even higher risk group. Recent work has also focused on using RNA expression arrays to predict treatment outcome ([298]). Although technically and analytically more complex, these expression arrays may yield new prognostic variables and stratification schemas in the future.

Treatment response, in addition to host and disease characteristics, also predicts outcome. Currently, treatment response is measured by morphology, multiparameter flow cytometry (MFC), or molecular techniques. Although morphology is less sensitive than either molecular methods or MFC, it is readily available and is the most technically straightforward. Studies across cooperative groups have demonstrated that patients who do not achieve remission after two induction cycles have a survival rate of less than 10%, and patients whose bone marrow blast counts are between 5 to 25% at day 14 also have decreased EFS and OS ([190], [288], [291]).

Cytogenetic evaluation of bone marrow specimens is another molecular method for evaluating treatment response. Detection of residual, nonrandom, abnormal karyotypes strongly predicts later morphologic relapse. This method is limited by difficulties in growing sufficient numbers of cells from heavily treated bone marrow samples, although fluorescence *in situ* hybridization of interphase chromosomes partially overcomes this limitation ([299]). The relatively large percentage of patients with normal karyotypes significantly limits this approach.

Polymerase chain reaction–based approaches are also available for monitoring treatment response. Persistent detection of the t(15;17) fusion gene is associated with a high risk of relapse, although the most sensitive assays can detect residual t(15;17) products in patients in remission ([300], [301] and [302]). The t(8;21) translocation may remain positive on polymerase chain reaction assays in patients who are in long-term remission, indicating that this translocation may be necessary but not sufficient for leukemic cell transformation. Development of assays to detect inv(16) and t(11q23) abnormalities are limited by the heterogeneous nature of these chromosomal changes ([303]).

Whereas both *ras* mutations and the Wilms' tumor gene (*wt1*) have been evaluated as predictors of treatment outcome, both markers have significant limitations that require further evaluation. Mutations in *ras* are present in approximately 25% of AML cases, although the mutations are not uniformly stable between diagnostic and subsequent specimens ([304], [305]). The same type of instability is observed for mutations in cytokine receptor genes, such as FLT-3 ([297], [306]). When one considers the group of pediatric patients with AML that includes a combination of mutations involving *ras*, c-kit, and FLT-3, an overall decrease in survival is observed ([307]). The WT1 gene is present in a majority of AML blasts, and persistent detection of WT1 transcripts has been associated with poorer outcome ([308]). However, less than 50% of FAB M5 blasts express WT1, thus limiting its universal applicability.

Multiparameter flow cytometry (MFC) can detect patient-specific blast flow signatures on up to 85% of samples with a detection sensitivity of approximately 10^{-3} ([309]). Wormann et al. first described the use of MFC to detect residual AML blasts in 45 adult patients ([310]). Sievers et al. applied MFC in 39 pediatric patients and then validated this approach in 252 patients treated in CCG-2941 and CCG-2961 ([309], [311]). In the validation cohort, patients with residual disease by MFC had a 41% OS at 3 years, whereas patients without residual disease had a 69% OS ($p = .0058$). In Cox proportional hazard analysis, MFC was the strongest predictor of outcome.

Despite some differences in risk group definition, the pediatric cooperative groups generally agree on the factors most predictive of treatment response. The development of more sensitive and universally applicable measures of treatment response may further refine the risk stratification process. Likewise, incorporation of pharmacogenetic patient information and leukemic blast gene expression data may also improve the predictive abilities of current risk stratification schemes. Finally, treatment stratification may be possible based on specific genetic lesions that have targeted therapies available. For example, activating *ras* mutations are potential targets for roughly 25% of pediatric AML. Farnesyl transferase inhibitors are currently in phase I testing in children and adults ([312], [313]). Compounds with substantial preclinical activity with FLT-3/ITD–positive AML are also being introduced into clinical trials ([314], [315], [316] and [317]).

FUTURE THERAPEUTIC CHALLENGES

Although dose intensification with chemotherapy with or without bone marrow transplantation has significantly improved the outcome of patients with AML, the associated morbidity and mortality preclude similar approaches from being pursued in the future. Instead, future therapeutic advances need to deliver greater leukemic cell killing but without additional collateral toxicity to normal tissues. These advances have been focused on developing targeted therapies directed toward specific molecular pathways that lead to increased leukemic cell survival, proliferation, and drug resistance ([318]). In part because of the tremendous advances in understanding the genetic defects and their molecular consequences in AML, there are many potential therapeutic targets that are being explored ([318]).

Ideally, molecularly targeted therapies should be tumor specific. Such approaches would be directed at blocking a molecular abnormality expressed by the leukemic cells but not by normal cells. Examples of this approach include strategies targeting the unique fusion proteins that result from distinctive chromosomal translocations or the use of agents that would specifically exploit a mutation in a cytokine receptor such as FLT-3/ITD or activating amino acid changes of FLT-3 or c-kit ([314], [317], [319], [320]). Differentiation therapies such as ATRA for APL are specifically targeted treatment. Other differentiation therapies directed at demethylation and histone deacetylase pathways may be less specific but are still intended to reexpress critical proliferation, survival, or antiapoptotic gene products whose expression has been repressed through tumor-specific epigenetic silencing ([321], [322], [323], [324] and [325]).

A second approach would be to target pathways or molecular targets that were shared by tumor cells and some normal cells but on which leukemic cells are more

dependent in terms of their survival and proliferation. Such strategies include the antisense inhibition of antiapoptotic pathways dependent on bcl-2 expression ([326], [327]), the inhibition of farnesyl transferase activation of proteins such as RAS ([312], [313]), and immunotherapy directed toward differentiation antigens such as CD33 ([203], [328], [329], [330] and [331]). Although this latter approach may not be leukemia specific, its selective action may be less toxic than traditional chemotherapeutic drugs.

Both specific and selective targeted therapies are currently being tested in both adult and pediatric patients with AML. However, recent data have demonstrated that even molecularly targeted therapies are not often as specific as initial results would suggest and that leukemia resistance can develop. These points are especially evident for imatinib (Gleevec), initially developed as a specific inhibitor of the bcr-abl fusion kinase ([332], [333], [334] and [335]). However, subsequent reports have demonstrated that imatinib also can inhibit receptors such as c-kit and platelet-derived growth factor ([336]). Whereas imatinib may not be specific for bcr-abl, its ability to inhibit different mutations of the c-kit receptor is quite variable. For example, activating mutations of c-kit involving the juxtamembrane domain, which are commonly observed in gastrointestinal stromal cell tumors, are particularly sensitive to imatinib ([337]). However, activating mutations of c-kit that involve amino acid changes in the kinase domain are quite resistant to the action of imatinib ([338]). These observations point out that such small molecule inhibitors may be less specific in some situations while exquisitely specific in terms of their ability to detect different structural motifs. A third critical lesson that imatinib has provided is that multiple forms of tumor cell resistance mechanisms can rapidly develop to molecularly targeted therapies. In the case of imatinib, up-regulation of adenosine triphosphate–dependent multidrug resistance transporters, increased expression of bcr-abl, and point mutations of bcr-abl abrogating imatinib binding have all been described as playing an important role in leukemic cell resistance ([339], [340] and [341]). Reports are also now showing that some patients with CML who are being treated with imatinib have developed clonal evolution of their CML and MDS/AML ([342], [343]). This last point raises the important issue of whether a therapy, molecularly targeted or not, is actually having an impact on the leukemic stem cell and not only on downstream progeny.

The AML stem cell, as discussed in the section Cellular and Molecular Origins of Acute Myelogenous Leukemia: Hematopoietic Hierarchies, commonly arises from an early point in the myeloid lineage. This appears to be true for most subtypes of AML, with the notable exception of some cases of APL. A major question for molecularly targeted therapies, then, is what impact do they have on the leukemic stem cell? This is no small task to ask of any therapy because so little is known about the physiology or mechanisms of drug resistance and survival. Experimental work involving leukemic stem cells has been slow in coming because, like their normal hematopoietic counterparts, they are usually quiescent, have a relatively long lifespan, and are extremely rare in terms of the entire population of leukemic progeny.

As pointed out by Reya and Weisman, the fundamentally critical target in treating leukemia, and all forms of cancer, is the eradication of the malignant stem cell ([344]). Most therapeutic agents are cytoreductive but do not necessarily target the leukemic stem cell compartment. Such treatments usually produce rapid early responses but are too often doomed to eventual failure due to relapse—a situation commonly observed in the majority of patients with AML who achieve an initial remission but then relapse. Targeting the leukemic stem cell would be predicted to show a slow rather than rapid response rate; that is, if the self-replicating leukemic stem cell were targeted, then the progeny with limited replicative potential would gradually be eliminated through apoptosis or senescence.

A critical question, then, is what targeted therapies that are being developed truly target the leukemic stem cell or are directed toward a more cytoreductive role that targets leukemic cell progeny with limited replicative potential? Thus far, most data would support the conclusion that most of the currently targeted therapies are more likely to be primarily cytoreductive. For example, at least some of the cytokine receptor mutations appear to be acquired and possibly second or third mutations ([297], [306], [345]). Similarly, most altered signal transduction pathways often represent secondary changes leading to increased proliferation and decreased apoptosis, such as mutations in RAS or altered bcl-2 expression ([41]). Vaccine-based treatments for AML remain potentially important but currently are relatively crude in that they usually represent whole cell vaccines ([346], [347], [348] and [349]). There are few data on what specific immunogenic antigens on leukemic stem cells would be good targets for more directed vaccine therapies. Differentiation therapies may provide a more leukemic stem cell–directed therapy, especially those directed toward “first hit” molecular lesions, possibly such as some of the known translocations observed in AML ([350]). But these approaches are also still relatively nonspecific in that approaches of genomic demethylation and histone deacetylase inhibition are currently not directed in terms of their effect on specific genes.

Although targeted therapies hold significant hope for improved antileukemic activity and for potentially sparing normal tissues from damage, there are clearly significant hurdles to overcome, including learning how to optimize such agents alone and in combination with other drugs. Some of these challenges include those we have not yet conquered for even conventional therapy. A greater focus on the biology of the leukemic stem cell and whether a therapeutic target is relevant to the physiology and survival of that cell should take on an increasingly important role in future studies.

Acute Promyelocytic Leukemia

Acute myeloid leukemia (AML) is a malignant disorder of the bone marrow in which a maturational arrest in blood cell progenitors results in failure of normal hematopoiesis. *Acute promyelocytic leukemia* (APL) is a subtype of AML with a defined clinical course and a biology that is distinct from the other forms of AML. Morphologically, the most common form of APL can have a striking appearance, as the bone marrow is effaced by heavily granulated cells with folded, twisted nuclei. Biologically, the cytogenetic changes define the syndrome, and the molecular consequences of the chromosomal changes found in APL are crucial in leukemogenesis. Clinically, patients typically display symptoms associated with cytopenias. The hemorrhagic complications are, however, often out of proportion to the degree of thrombocytopenia, reflecting the underlying biologic properties of the transformed promyelocyte. Historically, recognition of this form of AML as a separate entity was important for the clinician, not because the chemotherapy used as treatment differed substantially from that used for the other subtypes of AML, but because the relatively common occurrence of life-threatening coagulopathy mandated special supportive maneuvers, including the use of low-dose heparin and aggressive blood product support. Yet, despite prompt diagnosis and attention to potential complications associated with the institution of therapy, periinduction mortality was often significant, with some older series reporting an incidence approaching 50% ([1], [2], [12]). Hence, APL came to typify the worst features associated with leukemia: a fulminant disorder that struck primarily young people, had devastating effects on an individual's life, and resulted in death for a large number of patients during the initial phases of treatment.

The last two decades have seen a fundamental shift from this paradigm, with APL now recognized as one of the most curable forms of acute leukemia. In part, this change has been accomplished because supportive care has been refined. The most dramatic event, however, has been the introduction of therapy with all-*trans*-retinoic acid (ATRA). Subsequent laboratory investigations into the mechanism of the differentiating effect of ATRA have led to an understanding of the basic biology of APL, making the disease a model for the development of new therapies with possible applications across the entire field of oncology.

EPIDEMIOLOGY

AML is, in itself, a rare disease. In 2001, there were approximately 10,000 new cases of AML in the United States ([3]). AML affects slightly more males than females, and the median age of these patients is 64 years. APL comprises approximately 8 to 13% of adult AML cases. In contrast to the other AML subtypes, APL tends to occur in younger patients ([4]). An increased incidence has been reported in Hispanic populations ([5]). One group has reported an association with obesity ([6]). Although relatively uncommon in children, clustering of cases in pediatric populations has been described, raising the issue of possible environmental exposure ([7]). APL generally is not preceded by a myelodysplastic syndrome. The disease may, however, result as a consequence of prior therapy for an unrelated malignancy ([8]). In such cases, the clinical characteristics are determined by the karyotype, and these patients do as well as individuals who present with *de novo* disease. This is in marked contrast to other secondary myeloid leukemias that result from exposure to radiation, topoisomerase therapy, or alkylating agents, in which the prognosis is significantly worse.

CLINICAL PRESENTATION

Like any acute leukemia, the symptoms associated with APL may be relatively nonspecific. Most patients complain of fatigue, with a significant decrease in their previous level of activity. The manifestations of hemorrhage are often the most dramatic findings in the physical examination. There may be prominent petechiae or extensive ecchymotic involvement of the skin. Visual changes may result from retinal hemorrhages, and subconjunctival hemorrhage may follow episodes of coughing or vomiting. Overt hemorrhage from the gums, nose, mouth, or other bodily orifices can occur.

Frank infiltration of extramedullary sites [i.e., skin, central nervous system (CNS), and gums] is rare in newly diagnosed patients, although such findings have been described in patients who relapse after therapy ([9], [10]).

LABORATORY ANALYSIS

The clinical laboratory plays an important role in the diagnosis of APL and serves to focus nonspecific complaints and signs toward a hematologic origin. A complete blood count is among the first laboratory tests obtained and is almost always abnormal. Cytopenias of all three lineages are the most common findings. The white blood cell count (WBC) may be elevated in 10 to 30% of patients and has been associated with a morphologic variant of APL (see below) ([11], [12], [13], [14], [15] and [16]). Early recognition of this entity is important, as such patients have a higher incidence of periinduction morbidity/mortality and may warrant more aggressive management.

Quantitative abnormalities mandate that the peripheral smear be reviewed by an experienced morphologist. The peripheral blood often contains heavily granulated cells that are characteristic of the disease, but these are more likely to be found in the bone marrow. Direct examination of the blood smear also serves to verify any abnormalities and avoid spurious values such as thrombocytopenia secondary to platelet clumping. In addition, many of the standard Coulter counter instruments that rely solely on changes in electric impedance to generate blood cell differentials are unable to differentiate the heavily granulated promyelocytes from granulocytes, causing a false reading on the machine-generated differential. Some of the newer blood analyzers rely on a combination of light scatter and flow cytochemistry (detecting myeloperoxidase content) to differentiate between peripheral blood cell types. The high myeloperoxidase content of the abnormal promyelocytes produces a characteristic scatterplot (Fig. 82.1), which can aid in the confirmation of the diagnosis ([17], [18]). This finding is particularly useful in identifying patients with the microgranular variant because the cytochemical properties of the cell are unchanged and detected by flow cytometry, whereas the morphology may be problematic.

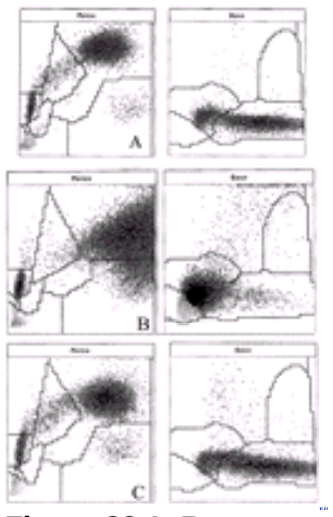

Figure 82.1. Representative cytograms from an automated blood analyzer that plots cell volume (*y-axis*) versus peroxidase (Perox) activity (*x-axis*) to generate a blood cell differential. **A:** Normal cytogram shows a cluster of cells in the upper right of the peroxidase channel (*left panel*) typical for granulocytes. **B:** Untreated acute promyelocytic leukemia. The granulocyte cluster is now shifted to the extreme right, reflecting the high myeloperoxidase content of the abnormal promyelocytes. This pattern is characteristic of acute promyelocytic leukemia and is preserved in the microgranular variant. **C:** Treated acute promyelocytic leukemia. The same patient approximately 35 days after receiving all- *trans*-retinoic acid, idarubicin, and cytarabine. The normal pattern has been restored. Baso, basophil channel; perox, peroxidase channel.

The other blood tests obtained at the time of diagnosis generally serve to screen for complications that can be associated with the leukemia. Serum electrolyte abnormalities need to be corrected, particularly before the institution of cytotoxic chemotherapy ([19]). Adequate renal function is extremely important, as aggressive blood product replacement can be anticipated in this disorder, and the management of extreme fluid overload may complicate care.

Coagulation Studies

Because the recognition and management of coagulopathy is of the utmost importance in treating patients with APL, the initial laboratory evaluation may include a platelet count, prothrombin time, activated partial thromboplastin time, D-dimer or fibrin split products, and fibrinogen ([20]). This disease-related coagulopathy represents a major source of morbidity, and, despite the effective antileukemia therapy presently available, it remains the leading cause of periinduction mortality. The mechanism underlying the coagulopathy is complex and has been the subject of intensive investigation. Historically, the coagulopathy was ascribed to disseminated intravascular coagulation, which resulted as the abnormal promyelocytes lysed and liberated the procoagulant contents of their granules ([22]). Evidence for disseminated intravascular coagulation as the underlying mechanism includes the finding that APL cells release increased levels of tissue factor ([23], [24]). Tissue factor may serve to promote interaction between factor VII and other circulating procoagulants, resulting in a widespread generation of thrombin. The coagulopathy can occur in the absence of chemotherapy as the neoplastic cells undergo autolysis, and it is found in approximately 80% of APL patients at the time of diagnosis. The coagulopathy may be exacerbated by the institution of chemotherapy that results in the massive lysis of abnormal promyelocytes, amplifying the already existing activation of the coagulation pathway. Both the prothrombin time and partial thromboplastin time are abnormally elevated, whereas the fibrinogen is low, reflecting an ongoing consumption. In addition, a number of other coagulation parameters, such as the thrombin time and the level of fibrin split products, are elevated, reflecting widespread disruption of the normal coagulation cascade. It is important to note that a fibrinogen in the low range of normal is still cause for concern, given that it is an acute phase reactant and ordinarily would be elevated in an ill patient. Serial measurements (approximately 6 to 12 hours apart) often reveal the developing hypofibrinogenemia indicative of consumption and help guide replacement therapy with blood products.

More recently, another explanation for the underlying coagulopathy has attributed the bleeding diathesis to primary fibrinol-ysis ([25]). An ongoing unchecked process results in a low fibrinogen, producing a clinical picture in which hemorrhage is the primary sequelae. Evidence for this hypothesis has been provided by the finding that low plasma levels of plasminogen, a $_2$-plasmin inhibitor, and plasminogen-activator inhibitor 1 are found in fibrinolytic states and are also found in APL. In addition, annexin II, a cell-surface receptor for plasminogen and tissue plasminogen activator, is expressed at abnormally high levels on APL cells but not on blasts from other forms of acute leukemia ([26]). The increased expression of annexin II may lead to overproduction of plasmin, which results in dysregulated fibrinolysis. The potential for hemorrhage is further amplified by the depletion of the main inhibitor of plasmin, a $_2$-plasmin inhibitor, which is consumed in an effort to counter the increased production of plasmin. The clinical manifestations of the coagulopathy are controlled, and some of the coagulation parameters progressively improve within days after the institution of therapy with either ATRA or arsenic trioxide (ATO) ([19], [21]).

Morphology, Cytochemistry, and Immunophenotype

Examination of the bone marrow aspirate and biopsy are the standard tests by which the diagnosis of acute leukemia is made. The morphologic features of the cells in the blood and the bone marrow may be different, underscoring the importance of sampling the bone marrow. The various morphologic subtypes of APL and their defining features are summarized in Table 82.1 ([13], [14] and [15], [27], [28]). Characteristic examples of the morphology are provided in Figure 82.2. In the classic hypergranular variety of APL, the bone marrow aspirate is generally hypercellular, and the abnormal promyelocytes constitute the predominant population. Blasts may be increased, but their number alone may not meet the minimal criteria by which classification systems like the French-American-British (FAB) and World Health Organization define AML. The malignant promyelocytes need to be considered in total to establish a diagnosis of AML. The malignant promyelocytes may be slightly larger than their normal counterparts. Such cells are heavily granulated; the granules often obscure the nucleus, making the nucleocytoplasmic border somewhat indistinct. In addition, the nucleus may be folded or bilobed. The cytoplasm often contains vacuoles, and distinctive Auer rods are frequently visible. *Auer rods* are coalesced primary granules and may be abundant. Multiple Auer rods clustered together within a single cell resemble a bundle of sticks or twigs, and such cells have been labeled *Faggot cells* (after the French term for *bundle of sticks*). Globular cytoplasmic inclusions (pseudo–Chédiak-Higashi inclusions) have also been described. The term *flaming promyelocyte* has been coined to describe cells that appear to be “breaking apart,” taking on a vibrant reddish purple hue with the apparent liberation of granules into the surrounding cellular matrix.

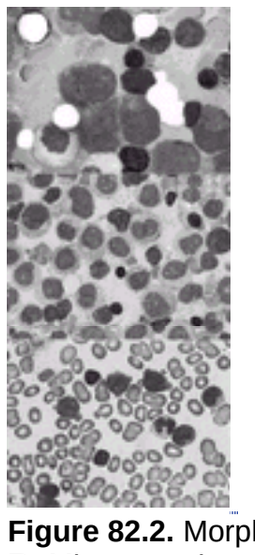

Figure 82.2. Morphologic subtypes of acute promyelocytic leukemia. **A:** “Classic” M3 is characterized by heavily granulated promyelocytes with abundant Auer rods. **B:** Microgranular variant (M $_3$v) has fine granulation with a bilobed, folded nucleus. **C:** Hyperbasophilic variant has few granules, intense basophilia, and small cytoplasmic projections or buds reminiscent of micromegakaryocytes (100×, MacNeal Tetrachrome). See Color Plate.

TABLE 82.1. Morphologic Subtypes of Acute Promyelocytic Leukemia

	Hypergranular (Classic M 3)	Microgranular (M 3v)	Hyperbasophilic	Promyelocytic Leukemia Zinc Finger/Retinoic Acid Receptor-a (M 3r)
Nucleus	Folded, lobulated granules obscure borders	Irregular, folded	High nucleocytoplasmic ratio	Regular; condensed chromatin pattern; Pelgerlike cells
Cytoplasm	Prominent azurophilic granules	Fine, small granules; dusky appearance	Granules sparse; strongly basophilic; cytoplasmic “budding” noted	Granularity: midway between classic M 3 and FAB M 2
Auer rods	Frequent; Faggot cells	Rare	Not seen	Rare; Faggot cells absent

Identification of the microgranular variant (M 3v according to the FAB classification system) may be more problematic ([13], [14]). This entity generally constitutes approximately 20 to 30% of APL cases. It was first recognized because it shares some clinical features as well as the typical t(15;17) with the hypergranular form of APL. The granules in the microgranular variant are less prominent, somewhat dispersed, and may be difficult to visualize using light microscopy. Instead, the granulation may be fine, and the cells may appear dusky. The shape of the nucleus, which has a characteristic bilobed, folded appearance, is often the key to identifying this disorder. Auer rods may be present but are generally less plentiful than in the hypergranular variety. Another clue to diagnosis is the finding of the more typical hypergranulated forms in the bone marrow. The peripheral WBC may be higher than in the classic variety, and any hypergranulated promyelocytes are less likely to be found in the peripheral blood. The characteristic cytogram found via flow cytochemistry (Fig. 82.1B) is preserved in the microgranular variant, providing useful rapid confirmation of the diagnosis before the cytogenetic or molecular results are available ([18]).

A third morphologic form of APL, the hyperbasophilic variant, has been described ([15]). This is a relatively uncommon form of APL, which some experts group within the M 3v category. However, the morphologic features are distinct enough to warrant separate consideration. The cells in this disorder have few, if any, granules. Instead, the cytoplasm is deeply basophilic and may have small blebs, buds, or projections, making the appearance reminiscent of micromegakaryocytes. The nucleus tends to occupy most of the cell and has an irregular, lobulated appearance. Both the microgranular and hyperbasophilic variants can be mistaken for an acute monocytic leukemia. A variant form of AML associated with CD56 expression and natural killer cell lineage has been confused with M 3v but lacks the defining t(15;17) cytogenetic abnormality ([29]). More recently, a European consensus group has described distinctive morphologic features of APL variants associated with the promyelocytic leukemia zinc finger gene (PLZF)/RA receptor-a (RARa) fusion products (see below) and has proposed a new morphologic category, M 3r. These leukemias have a regular nuclear outline, rarely have Auer rods, and have a cytoplasmic granularity that is intermediate between the M3 and M2 varieties of AML ([28]).

Although not diagnostic for APL, cytochemistry and immunophenotyping may help characterize APL. The cytochemical properties of the abnormal promyelocytes are consistent with a diagnosis of AML ([13], [14] and [15], [27], [30]). The hypergranular variety stains intensely with Sudan black, myeloperoxidase, or chlor-acetate esterase. The microgranular variant retains this staining pattern, although the degree of positivity may be less intense. As discussed above, the high myeloperoxidase content of abnormal promyelocytes may be detected in the peripheral blood using modern blood analyzers. Less useful is the observation that nonspecific esterase activity has been noted in some abnormal promyelocytes, further confusing the differentiation between acute monocytic leukemia and some forms of APL ([31]). These reactions are weaker than those found in monocytes, and some forms of the isoenzymes found in monocytes are absent in the abnormal promyelocytes. Metachromatic staining with toluidine blue has been reported in cases of APL with basophilic differentiation.

Immunophenotyping is also useful in confirming the diagnosis of APL ([30], [32]). *Promyelocytes* are partially differentiated cells that are reflected in the immunophenotype. The cells express the early myeloid marker CD33 but lack HLA-DR, a marker often associated with some earlier progenitor cells. It is important to emphasize that this immunophenotypic profile is characteristic, but not diagnostic, of APL. Up to 20% of other types of AML may express CD33 but not HLA-DR. The marker CD9 is expressed in APL but not in other AML subtypes ([33]). However, the utility of this finding is practically nil, as few screening panels used for diagnosis contain CD9 as part of the initial workup. The stem cell marker, C34, is generally not expressed, whereas the myeloid lineage marker CD 13 is occasionally observed and possibly associated with the development of retinoic acid syndrome (RAS) ([34]). The T-cell marker CD7 is negative as are the myelomonocytic markers CD11b and CD14. CD11b is also an indicator of myeloid maturation and, along with CD16, a surface marker found on granulocytes, can be induced with differentiation therapy. The aberrant expression of the T-cell marker CD2 has been correlated with the microgranular variant. Reports of a correlation with the short form of the promyelocytic leukemia (PML)/RARa fusion transcripts have been mixed ([35], [36], [37] and [38]). Expression of the P-glycoprotein associated with the MDR phenotype is generally not found in APL. The natural killer marker, CD56, has been reported in true APL (as opposed to natural killer-AML) and has been associated with a poor prognosis ([39], [40]).

Differential Diagnosis

As discussed above, the morphologic appearance of APL can be quite striking given the characteristic appearance of the most common variety, the hypergranular form. The differential diagnosis of APL includes reactive disorders of the bone marrow as well as other subtypes of acute leukemia. Recovery from an insult that produces relative aplasia can result in increased myeloid activity with a left shift in the myeloid series. Therapy with the myeloid growth factors, granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor, can result in a hypercellular bone marrow with prominent toxic granulations. Maturation, however, is preserved, and Auer rods are not found. Other marrow elements, such as erythroid and megakaryocytic precursors, are present, although the relative number appears somewhat diminished. Chronic myelogenous leukemia may appear with a hypercellular marrow containing a predominant myeloid component that appears heavily granulated. In this disorder, all stages of maturation are present and accompanied by increased eosinophils, basophils, or both. Acute myeloid leukemia with maturation (FAB M2) may contain blasts as well as cells that contain too many granules to be considered blasts but are not mature enough to be classified as promyelocytes. Auer rods are also found in this AML subtype, but these occur as single structures and not as clusters. Faggot cells are generally not found. Abnormal promyelocytes can be seen, but these cells do not constitute the predominant population in the bone marrow. A monocytic component may be present in less than 20% of the nonerythroid elements. The microgranular and hyperbasophilic variants may be mistaken for monocytic leukemia because of the deeply staining cytoplasm, lack of granules, and folded, convoluted nuclei. Other rare forms of leukemia, such as mast-cell leukemia or basophilic leukemia, may, at first, be confused with APL but lack characteristic features such as Auer rods and the nuclear folding pattern and present with granules, which can be readily distinguished from those of the promyelocyte using conventional histochemical stains.

Cytogenetics and Molecular Biology

Despite the minor variations in phenotype discussed above, APL as a clinical syndrome is defined by its cytogenetics. The balanced translocation between chromosomes 15 and 17 characterizes over 95% of cases of APL ([41], [42]). The breakpoints for the translocation usually occur at q22 loci on chromosome 15 and at q21 on chromosome 17. The t(15;17) is generally detected by conventional cytogenetic techniques and provides definitive evidence of the diagnosis of APL. The molecular consequences of this translocation result in a fusion of a portion of the gene for RARa on chromosome 17 to part of the PML gene on chromosome 15 ([43], [44], [45] and [46]). Although the break within the RAR gene is invariably within the second intron of the gene, the point of rearrangement within the PML gene can occur at two major breakpoints, resulting in three isoforms of the transcript. Breakpoints within PML intron 3 (bcr3) generally yield a shorter messenger RNA transcript, whereas breakpoints within intron 6 (bcr1) result in the long form of the transcript ([47]). Breakpoints within intron 6 of PML can also occur at a second site (bcr2) and result in a transcript of variable length. The site of the breakpoint has been reported to have prognostic implications, as newly diagnosed patients with the short isoform appear to have a shorter disease-free survival (DFS) and overall survival (OS) compared to patients with the long isoform in some series ([34], [48]). Other authors have correlated the isoform with various other prognostic factors but discount an independent effect on outcome ([49]). In all cases, the chimeric gene products that result from this translocation have fundamental implications for the cell and are believed to be causative in producing the malignant phenotype. Variations of this translocation exist and, in some instances, have profound clinical implications.

Although the t(15;17) is the defining cytogenetic abnormality in APL, other additional chromosomal abnormalities can be found in 30 to 40% of patients with APL ([50], [51]). The most common of these are trisomy 8 and isochromosome 17. Additional chromosomal abnormalities do not have a negative effect on the overall prognosis ([51], [52]). Complex translocations involving other chromosomes in addition to 15 and 17 can occur.

Masked translocations, in which pieces of chromosome 15 and 17 are transposed but escape detection by conventional techniques, have been reported ([53], [54]). In

most of these cases, the molecular abnormality, either the PML-RARa or the reciprocal RARa-PML transcript, can be detected. Expression of the fusion gene product ultimately results in the clinical syndrome identified with APL despite the lack of gross chromosomal changes.

Variant translocations also exist and are rare as clinical entities but are instructive in helping to define the biology of APL. The most common variants involve translocations between chromosome 17 and either chromosome 5 or 11 ([55], [56], [57], [58] and [59]). These variant translocations retain the same break within the RARa intron but differ in the molecular partner gene (X gene), which may account for some of the differences regarding their functional effects on the cell. The individual variants are summarized in Table 82.2. The structural changes within these genes may affect the normal function of the wild-type product, resulting in the phenotypic abnormality, which is expressed as the leukemia. Most notable among the variants is the t(11;17) (q23q21) because this entity is resistant to the differentiation effects of ATRA. This chromosomal translocation results in a fusion of the RAR gene with PLZF. PLZF is similar to PML in that it has profound implications for the cell with regard to regulation of transcription of target genes resulting in differentiation. However, PLZF is distinctly different from PML in that properties of this gene product interact differently with RA, rendering it ineffective ([60]). In addition, this form of APL also has a poor response to standard chemotherapy, underscoring the multiple differences in biology between these two entities.

TABLE 82.2. Acute Promyelocytic Leukemia: Chromosomal Translocations and Fusion Products

Translocation	Frequency (%)	Molecular Fusion Product (X-RARa)	Function "X" Gene	Retinoid Sensitive	Chemotherapy Sensitive
(15;17) (q22,q21)	95	PML-RARa	Transcriptional	+	+
(11;17) (q23,q21)	<5	PLZF-RARa	Developmental/differentiation control	–	–
(5;17) (q35,q21)	<1	NPM-RARa	Ribonucleoprotein maturation and transport	+	+
(11;17) (q13,q21)	<1	NuMA-RARa	Structural role in mitosis, apoptosis, and interphase nuclear matrix	±	±
(17;17) (q11,q21)	<1	STAT 5b-RARa	Signal transduction, transcriptional factor	–	?

+, sensitive; -, not sensitive; ±, may be sensitive; NPM, nucleophosmin; NuMA, nuclear mitotic apparatus; PLZF, promyelocytic leukemia zinc finger; PML, promyelocytic leukemia; RARa, retinoic acid receptor-a; STAT 5b, signal transducer and activator of transcription 5b; "X," RARa partner gene.

Based on experimental data generated in cell lines, transgenic mice, and correlations with clinical treatment data, a model for leukemogenesis in APL has been developed ([61], [62], [63], [64] and [65]). On the most basic level, this hypothesis states that APL results from transcriptional dysregulation of differentiation produced by the PML-RARa gene product. In the normal cell, RARa plays an important role in modulating myeloid differentiation by virtue of its ability to recruit various nuclear corepressors like SMRT/N-CoR and mSin3. These transcription corepressors, in turn, bind various histone deacetylases, affecting chromatin conformation resulting in repression of transcription of target genes fundamental to the differentiation process. Under physiologic conditions, binding of RA causes dissociation of the corepressor complex, recruits transcriptional activators, and "opens" the chromatin, facilitating the transcription of the various target genes and allowing normal maturation. The PML-RARa fusion protein has an increased affinity for the N-CoR corepressor complex, such that physiologic doses of RA ($<10^{-8}$ M) fail to produce a dissociation of the complex, resulting in continued transcriptional repression and a maturational block. Instead, supraphysiologic doses achieved by the administration of ATRA are required to recapitulate the behavior of the wild-type receptor. In the PLZF-RARa variant, there is a second binding site for the corepressor proteins within the PLZF portion of the fusion protein that is not sensitive to RA. Hence, even supraphysiologic doses are unable to free the corepressor complex and permit the conformational changes in the histones necessary for permitting differentiation to occur. This may be an explanation for the clinical resistance of t(11;17) to ATRA and has led investigators to explore compounds like histone deacetylase inhibitors that bypass corepressor binding as defined by the activity of RA receptors and directly effect transcriptional activation.

Although the model of transcriptional repression through chromatin remodeling may rest on the interaction of the aberrant RARa fusion protein with key regulatory genetic elements, the primary partners in the molecular fusion proteins, namely PML and PLZF, may also serve to amplify dysregulation of transcription ([60], [62]). PML does not directly bind DNA but has been found to regulate transcription through interaction with a number of transcription factors and repressors ([66], [67] and [68]). In the normal cell, PML is localized in discreet subnuclear structures called *PML oncogenic domains* or *PML nuclear bodies* (PNBs). These PNBs may functionally regulate transcription either by providing an environment where the various regulatory factors can interact or be modified or by binding various transcription activators/repressors or sequestering them from circulating in the nucleoplasm, thereby preventing any interaction with other regulatory elements. This function, in turn, may affect fundamental cellular process, such as growth, senescence, and apoptosis. PML-RAR disrupts the organization and function of the PNBs and displaces PML, forming a microspeckled pattern in the nucleus. Treatment with RA causes the PNBs to reorganize and, presumably, restores not only the structure but the functional activity.

Less is known about the function of PLZF. It also modulates transcriptional repression through multiple interactions with SMRT/N-CoR/mSin3/HDAC complexes and may localize in structures similar to the PNBs. Some of the mediators with which PLZF interacts are insensitive to modulation by RA, and these properties are retained in the PLZF-RAR fusion product, resulting in clinical ATRA resistance.

In addition to providing an understanding of the underlying biology of leukemia with possible application to cancer as a whole, the molecular genetics of APL also provide a useful tool for the clinician in confirming the diagnosis and planning therapy. As discussed above, the vast majority of APL cases are characterized by the t(15;17), resulting in a PML-RAR fusion product. These genetic changes are specific for APL, and, using the modern molecular technique of reverse transcriptase polymerase chain reaction (RT-PCR), they are easily detectable ([69], [70] and [71]). RT-PCR has become a standard tool in the management of APL. It is now readily available in commercial laboratories, and there is usually a rapid turnaround time. RT-PCR is useful in confirming the diagnosis of APL, particularly in cases in which morphology is problematic. In addition, this unique molecular "signature" can be used to monitor response and test for minimal residual disease (MRD) ([48], [69], [70], [71], [72] and [73]). This ability to use an effective method to detect MRD is in sharp contrast to the other forms of AML, in which response is assessed primarily through morphologic examination of the bone marrow and blood. Therefore, in APL, the concept of remission can be redefined to include a molecular response. Molecular relapse can be detected before it is clinically apparent, and this information can be used to guide therapy. An effective treatment regimen renders the RT-PCR assay for PML-RAR negative. Conversion from a negative result to a positive result that is reproducible on two sequential assays is predictive of clinical relapse. Some groups have reported highly successful results by treating the disease in molecular relapse before the occurrence of the full-blown clinical syndrome ([74]). This has led to the standard recommendation that patients with APL be serially monitored for PML-RAR via RT-PCR every 3 months during the first 2 years after remission is achieved, when the risk of relapse is the greatest ([48]).

THERAPY OF ACUTE PROMYELOCYTIC LEUKEMIA

General Principles of Management

The primary life-threatening complications of acute leukemia are infection and hemorrhage ([75]). The key to the successful management of the patient with APL is anticipating the complications and instituting therapy early enough to limit toxicity. The available therapies, including ATRA, ATO, and conventional chemotherapy, all have potent antileukemia effects. The main challenge lies in supporting the patient through the 3 to 5 weeks of therapy necessary to achieve remission.

Stabilizing the patient requires interpretation of the history, clinical presentation, and initial laboratory data to correctly diagnose the underlying condition as APL. Many patients present to medical attention with fever, and, because infection in the setting of neutropenia can be rapidly fatal, empiric antibiotics are promptly started after an initial attempt at identifying a source of infection ([76]). This empiric antibiotic coverage can be altered based on the sensitivities of any organism isolated from the various cultures. Continued fever despite broad-spectrum antibiotics may require empiric therapy with an antifungal, such as amphotericin or a liposomal

amphotericin preparation.

Approximately 80% of patients with APL present with coagulopathy in addition to thrombocytopenia. As discussed above, laboratory tests that are useful as indicators of coagulopathy include the platelet count, prothrombin time, partial thromboplastin time, and fibrinogen levels. Other coagulation parameters, such as thrombin time, ethanol gelation test, and protamine sulfate test, may also be obtained but add little to the clinical decision-making process besides confirming the presence of a coagulopathy. Management of this coagulopathy requires treating the underlying leukemia. However, the administration of conventional cytotoxic chemotherapy may, at first, exacerbate the coagulopathy. The use of a continuous infusion of low-dose heparin (7 to 10 U/kg/hr) gradually evolved as a strategy to support patients through the initial phases of the chemotherapy until the leukemia burden had been decreased and the coagulopathy resolved. Although the rationale for such a strategy was, at best, unclear, some early studies reported a decreased rate of morbidity/mortality when heparin was used prophylactically when compared with historical controls with no heparin. Subsequently, a randomized study examining the use of heparin in APL patients failed to show any advantage when compared with aggressive blood product support ([77]). In addition, the introduction of RA changed the clinical scenario because this therapy does not cause an immediate, massive cell lysis and does not worsen the coagulopathy. Instead, the clinical coagulopathy typically abates after approximately 5 to 8 days of therapy.

Therefore, the initial therapy for the coagulopathy before the onset of the stabilizing effect seen with the retinoid is primarily supportive and based on aggressive platelet and blood product support. Frequent monitoring is the cornerstone of this management strategy. Intervention may be based on a worsening trend in a laboratory value such as the fibrinogen level. Platelets and fresh frozen plasma may be transfused multiple times per day to maintain a platelet count above 50,000/µl and fibrinogen levels above 100 mg/dl ([20]). In rare instances when the fresh frozen plasma is ineffective at supporting fibrinogen levels, cryoprecipitate may be administered to treat a fibrinogen level below 100 mg/dl. Others have advocated the use of low-dose heparin in cases in which the fibrinogen is unable to be maintained by replacement therapy alone.

Despite aggressive blood product support and early administration of either ATRA or arsenic, patients can and do experience catastrophic hemorrhage or thrombosis. In these instances, it may be appropriate to institute life-support measures, after discussion with the patient's health care proxy, in an effort to stabilize the patient while continuing to administer the leukemia therapy. Hemorrhage in the lung may require mechanical ventilation to support the airways, whereas a limited CNS hemorrhage may require measures to reduce intracranial pressure. The use of the antifibrinolytic ϵ-aminocaproic acid has been advocated by some for use with CNS bleeding to inhibit fibrinol-ysis and help stabilize any clot formation ([78]). Underlying such heroic measures is the recognition that APL is ultimately a curable disease in the modern era. Primary resistance to either ATRA or ATO is rare, and most of the patients who do not respond to these therapies do so because they are unable to be supported through the acute phases of the illness.

Assessment of Response

The traditional therapy for AML has relied on the strategy of using cytotoxic chemotherapy to induce bone marrow aplasia and clear the bone marrow of the malignant clone, allowing subsequent regrowth of normal progenitor cells with the restoration of normal hematopoiesis. A standard method for assessing whether aplasia has been achieved is to perform a bone marrow examination on approximately day 14 of therapy. The finding of persistent blasts on this day 14 bone marrow examination may prompt retreatment with a second course of induction therapy.

This paradigm does not apply to APL. The day 14 bone marrow examination after the initial course of induction chemotherapy may reveal persistent abnormal promyelocytes, yet the patients are able to achieve remission at week 4 or 5 without further chemotherapy ([79]). Therefore, finding these abnormal promyelocytes should not automatically trigger a second course of chemotherapy. The pattern of response of APL to standard induction therapy is atypical and once again underscores that this disease is biologically distinct from other forms of AML. Some have interpreted these findings to mean that standard chemotherapy has a differentiating effect on the abnormal promyelocytes, whereas still others have cited a differential effect of cytotoxic therapy on the replicating abnormal progenitors with relative sparing of the quiescent, partially differentiated promyelocytes.

The introduction of ATRA and ATO as agents that accomplish remission by inducing differentiation/apoptosis has further modified the ways in which response is determined. The standard definitions of *complete remission* (CR) established by National Cancer Institute consensus criteria still remain useful ([80]). With the widespread availability of RT-PCR, the definition of CR has been further refined to include molecular remission. Often, the first sign that a patient is responding to therapy is the resolution of the coagulopathy with progressive improvement in the various coagulation parameters ([81]). The transfusion requirements for platelets may decrease, and fresh frozen plasma may no longer be needed to maintain the fibrinogen level. Leukocytosis, which can occur with either ATRA or ATO, may represent evidence of the abnormal clone's biologic response to therapy. Peripheral blood leukocytes undergo progressive morphologic changes, which include nuclear condensation and lobulation accompanied by cytoplasmic vacuolization ([82]). Granulocytic forms with persistent azurophilic granules may appear and have been labeled “intermediate” cells, as they retain features of promyelocytes but display some morphologic characteristics of neutrophils. These cells may also display an intermediate immunophenotype with the coexpression of CD33, a marker associated with immature myeloid cells, and CD16 or CD11b cell-surface markers, which are found on granulocytes and maturing myeloid elements ([83]). Various sources have also described the occurrence of polymorphonuclear leukocytes with Auer rods, another anomalous finding resulting from differentiation of the abnormal clone. Techniques such as fluorescence *in situ* hybridization (FISH) and premature chromosomal condensation have been used to verify that morphologically maturing cells are derived from the original malignant clone ([84]).

Although there may be a variety of clinical and morphologic changes that occur with therapy, the process of achieving CR is gradual. After approximately 4 to 6 weeks of treatment, the standard definition of CR should apply: adequate cellularity as determined by bone marrow biopsy and normal maturation of all cell lines with less than 5% blasts. No cells with Auer rods should be visualized. Restoration of normal hematopoiesis should be evidenced by a peripheral blood neutrophil count greater than or equal to 1.5×10^{9}/L, and the platelet count should be greater than 100×10^{9}/L. To meet criteria for CR, these findings should be present for at least 4 weeks ([80]).

Despite fulfilling the morphologic criteria for CR, approximately 90% of patients treated with ATRA alone and 25% of patients treated with ATO alone still have molecular evidence of disease as detected by RT-PCR. The addition of chemotherapy to ATRA increases the proportion of patients who become negative for molecular evidence of the disease. Repeated cycles of ATO may be needed to achieve this molecular remission. Given the importance of the RT-PCR assay results, it is recommended that the bone marrow be sampled and examined for both morphologic and molecular evidence of remission at least every 3 months for the first 2 years postremission ([48]). Patients whose RT-PCR result converts from a negative to a positive should have the bone marrow examination repeated within 1 month to verify this result. Patients tend to relapse within 6 months of completing therapy, so it is imperative that monitoring continue during this critical time. Despite relatively intensive molecular monitoring, some patients relapse with overt clinical disease, raising questions regarding the predictive nature of the test as well as the sensitivity and standardization of the assay ([85] , [86]).

Current Therapy

APL was first recognized as a distinct subtype of AML in the 1950s ([87]). Until the late 1980s, patients with APL were treated with the standard therapy used for all subtypes of AML, consisting of a combination of an anthracycline and cytosine arabinoside. Using this approach, investigators reported CR rates in the 50 to 60% range, but with improvement in the management of infections and APL-related coagulopathy, CR rates increased to as much as 80% ([88] , [89] , [90] and [91]). The likely reasons for failure of this treatment included mortality related to sepsis, catastrophic hemorrhage, or, less frequently, primary drug resistance ([92] , [93]). However, despite this high CR rate, long-term DFS in patients with APL was approximately 30 to 40% ([94] , [95] and [96]), clearly reflecting a need for improvement in the existing approach. See Table 82.3 for representative therapies for APL.

TABLE 82.3. Representative Therapies for Newly Diagnosed Acute Promyelocytic Leukemia

Study	Therapy	Number (N)	Complete Remission (%)	EFS or DFS (%)	Relapse Rate (%)
Marty et al. (96)	Daunorubicin	83	64	—	—
Avvisati et al. (101)	Idarubicin	131	76	—	—
Warrell et al. (108)	ATRA followed by chemotherapy	49	85	—	—
Avvisati et al. (110)	Idarubicin and ATRA (elimination of cytarabine)	480	93	—	—

Sanz et al. (121)	Idarubicin and ATRA (elimination of cytarabine)	123	89	2-yr DFS: 92 ± 3	—
Tallman et al. (111) (randomized)	ATRA followed by chemotherapy vs. chemotherapy	172 vs. 174	72 vs. 69 (NS)	3-year DFS: 67 vs. 32 ($p < .001$)	—
Burnett et al. (123) (randomized)	ATRA × 5 d followed by chemotherapy vs. ATRA daily until complete remission plus chemotherapy	119 vs. 120	70 vs. 87 ($p < .001$)	DFS: 59 vs. 72 ($p = .07$)	36 vs. 20 ($p = .04$)
Fenaux et al. (112) (randomized)	ATRA followed by chemotherapy vs. chemotherapy	54 vs. 47	91 vs. 81 (NS)	4-year EFS: 63 vs. 17 ($p = .0001$)	31 vs. 78 ($p = .03$)

ATRA, all- *trans*-retinoic acid; DFS, disease-free survival; EFS, event-free survival; NS, not significant.

CHEMOTHERAPY Anthracyclines are among the most important cytotoxic agents used in treating AML. Several studies have specifically demonstrated the sensitivity of APL to this class of agents (95, 96). However, whether there is a clinical advantage of one anthracycline compared to another remains controversial. Three prospective randomized trials conducted in the early 1990s compared daunorubicin to idarubicin in adults with newly diagnosed AML. All three studies showed an improved remission rate in patients treated with idarubicin, and two suggested improved survival (97). When the survival data were updated in 1996, however, only one of these studies suggested an advantage in the idarubicin arm (98). Several investigators argued that the dose of daunorubicin used in these trials was not equivalent in intensity to that of idarubicin, which could be the explanation for the observed differences. However, no prospective randomized trial has compared daunorubicin to idarubicin in APL. Although cytosine arabinoside is the backbone of treatment for AML in general, the importance of this drug in the treatment of APL specifically remains unclear. In APL patients, monotherapy using either daunorubicin or idarubicin achieves a CR rate in the 55 to 88% range (99, 100 and 101). A retrospective analysis of 62 patients with APL treated with either single-agent daunorubicin or daunorubicin in combination with cytosine arabinoside for induction therapy showed no difference in CR rates (100). Similarly, in a randomized prospective study in untreated APL patients comparing idarubicin to the combination of idarubicin plus cytosine arabinoside, no difference in CR rate or event-free survival was observed (101). Considering the exquisite sensitivity of APL to anthracyclines, dose-intense single-agent anthracycline may be more beneficial than and a less toxic alternative to standard combination therapy. Despite this reasoning, the “7+3” regimen (cytosine arabinoside, 100 mg/m ^{2}/day continuous intravenous infusion on days 1 through 7, and daunorubicin, 50 mg/m ^{2}/day intravenously on days 1 through 3) continues to be widely used in clinical practice.

ALL- *TRANS*-RETINOIC ACID–BASED STRATEGIES The introduction of ATRA into the treatment strategy of APL fundamentally changed the management and outcome of this disease. The first series of patients treated with ATRA was reported by Huang et al. in 1987 (102). Less than 10 years later, more than 3000 APL patients worldwide had been treated with ATRA. Data published from Chinese, French, American, Italian, and Japanese investigators point toward a median CR response greater than 85% (81, 83, 102, 103 and 104). Doses up to 100 mg/m ^{2} have been used, but no particular dose-effect correlation has emerged. Most clinical experience has been obtained with a dose of 45 mg/m ^{2}/day administered as a single daily dose or as two equally divided doses given approximately 12 hours apart. In a multicenter study conducted in APL patients by Castaigne et al. (105), a dose of 25 mg/m ^{2}/day of ATRA produced similar results in terms of CR rates and pharmacokinetic parameters to ATRA at 45 mg/m ^{2}/day. The incidence of hyperleukocytosis and RAS was also the same. Therefore, the only clinical advantage of a lower dose of ATRA is a possible lower incidence of RA side effects such as headache and cheilitis. The long-term therapeutic effects of a lower dose have not been established, and, therefore, lower doses should not be used routinely as standard of care. The clinical response to ATRA is correlated with the presence of the 15;17 chromosomal translocation assessed by conventional cytogenetics or by RT-PCR (69, 70, 73). This translocation involves the molecular rearrangement of RARa, which appears to be the link to the clinical responsiveness to ATRA. Some patients with equivocal cellular morphology and normal karyotypes have shown typical rearrangements of RARa by molecular testing, and these patients are clinically responsive to ATRA (70 and 71). However, patients who are negative for PML-RARa by RT-PCR or who do not exhibit the karyotypic t(15;17) do not respond to ATRA (69, 70). Therefore, it is critical to note that patients with acute leukemia with cytogenetic or molecular findings other than the common t(15;17) or PML-RARa that is distinctly found in APL do not respond to ATRA and should be immediately treated with standard antileukemic therapy. In the initial phase II studies with ATRA in APL, two important clinical observations became evident. The first was that up to one-half of the patients developed what is now known as RAS, which often proved to be fatal in the preliminary experience (see discussion below). Gradually, a number of treatment strategies emerged that resulted in decreasing the associated morbidity/mortality of this syndrome. Currently, as the result of vigilant monitoring and initiation of high-dose dexamethasone with the first presenting sign or symptom, few patients die as a result of RAS. The other observation was that remissions induced and maintained solely by ATRA are brief in duration. In the initial New York series, the median remission duration was 3.5 months (107, 108). In fact, few patients in this and other series maintained a remission greater than 1 year (17, 21, 51, 52). Subsequently, both randomized (108, 109) and nonrandomized (110) studies revealed that, by combining standard induction therapy with ATRA, followed by consolidation treatments using several cycles of anthracycline-based regimens, remissions were not only durable but superior to those achieved by chemotherapy alone. In the initial trials incorporating ATRA into the treatment for APL, the drug was given as a single agent until CR was achieved; then, patients were consolidated with chemotherapy. However, the optimal schedule and duration of ATRA therapy needed to be determined to obtain the best clinical outcome. In the U.S. Intergroup Study (111), 346 newly diagnosed APL patients were randomized to receive either ATRA or daunorubicin plus cytosine arabinoside for remission induction. Patients who obtained CR received two cycles of consolidation therapy; the first cycle of treatment was identical to the induction chemotherapy, and the second cycle of consolidation consisted of high-dose cytosine arabinoside plus daunorubicin. Patients who remained in remission after completing consolidation therapy were randomized to either observation only or maintenance treatment with ATRA. Therefore, the majority of patients in this trial received ATRA either as induction therapy, maintenance, or both. Although there was no significant difference in the CR rate between the ATRA (72%) and chemotherapy (69%) induction groups, the 3-year DFS was statistically improved in the patients treated with ATRA compared to those treated with standard antileukemic therapy (72% vs. 32%; $p < .001$). This trial clearly showed the benefit of ATRA in the management of APL, particularly when ATRA was incorporated into the induction therapy. The group of patients who received no ATRA had a 3-year DFS of only 18%, which was consistent with the historical survival rate of APL patients. A large European study (112) addressed the issue of scheduling the ATRA and chemotherapy by prospectively randomizing 413 untreated APL patients between concurrent ATRA plus chemotherapy (daunorubicin and cytosine arabinoside) and sequential ATRA followed by the same chemotherapy. Induction therapy was stratified based on both age (> or =65 years) and on presenting WBC (> or =5000/μl). Patients with WBC greater than 5000 per μl and younger than 65 years old (163 patients) were not randomized but were treated with concurrent ATRA and chemotherapy starting on day 1, and patients who were older than 65 years old (66 patients) were not randomized but were treated with ATRA followed sequentially by chemotherapy. Patients who achieved CR, irrespective of their induction regimen, received one to two additional courses of consolidation chemotherapy (one course if older than 65) and were then randomized to receive either 2 years of maintenance chemotherapy consisting of (a) ATRA alone, (b) methotrexate plus 6-mercaptopurine (6-MP), or (c) ATRA plus methotrexate and 6-MP, or no maintenance chemotherapy (observation only). The proportion of patients achieving CR in these two induction groups was no different, with an overall CR rate of 92%. However, the event-free survival at 2 years was estimated at 84% in the concurrent ATRA plus chemotherapy group versus 77% in the ATRA followed by chemotherapy group ($p = .1$). This benefit appears to occur from a reduction in the risk of relapse, which at 2 years was 6% in the concurrent arm and 16% in the sequential arm ($p = .04$). Another possible advantage from the concurrent ATRA plus chemotherapy treatment approach appears to be a greater than 50% reduction in the incidence of the potentially fatal RAS (113). The Italian cooperative group [Gruppo Italiano Malattie Ematologiche Maligne dell'Adulto (GIMEMA)] took a slightly different approach by eliminating cytosine arabinoside from induction therapy and using the combination of ATRA and idarubicin (referred to as “AIDA” for *A*TRA plus *ida*rubicin) for remission induction in newly diagnosed APL (114). In this multicenter trial, 253 patients with positive cytogenetics for t(15;17), a molecularly positive result by RT-PCR for the PML-RARa fusion gene, or both were treated with ATRA until CR. Intravenous idarubicin (12 mg/m ^{2}/day) was given concurrently with ATRA on days 2, 4, 6, and 8. Patients who achieved CR were consolidated with three cycles of combination cytotoxic chemotherapy. Using this induction regimen, 229 of 240 (95%) patients who were able to be evaluated achieved CR. There were 11 deaths related to early complications. The molecular conversion rate from PCR-positive to PCR-negative for PML-RARa after induction therapy was 60.5%, which increased to 95% after completion of the third cycle of consolidation therapy. The estimated actuarial event-free survival for all 253 patients was 83% and 79% at 1 and 2 years, respectively. These are among the best results reported for treating adults with acute leukemia.

Duration of All- trans-Retinoic Acid Therapy Currently, ATRA is recommended as part of the induction regimen and as maintenance therapy, which is initiated after the completion of consolidation chemotherapy. There is no benefit to continuous treatment with ATRA once patients have achieved CR. Generally, patients who relapse while taking ATRA or shortly after discontinuing ATRA do not respond to further treatment with standard- or high-dose ATRA therapy (102, 108). It would be particularly unusual for patients with a molecular diagnosis of APL who are retinoid naïve to be resistant to ATRA. Given the limited duration of remission with ATRA as a single agent, acquired resistance to ATRA could theoretically result from genetic or epigenetic events (115). Although acquired resistance in HL-60, a retinoid-sensitive leukemic cell line, has been associated with point mutations in the RARa fusion gene (116, 117), clinical specimens collected from patients before treatment with ATRA and at the time of relapse have not shown additional mutations in PML-RARa (118). It appears that multiple mechanisms are likely involved in the development of resistance. Continuous daily treatment with ATRA is associated with a marked decrease in plasma drug concentrations occurring as early as 1 to 2 weeks after initiation of therapy (119). The mechanisms by which this occurs include induction of cytochrome P-450 catabolic enzymes, increased expression of oxidative cofactors, up-regulation of cellular RA binding proteins, or all three (119, 120). These biologic mechanisms function cooperatively to modulate intracellular retinoid concentrations. Therefore, it is conceivable that prolonged administration of ATRA could result in the development of clinical resistance due to an inability to sustain effective concentrations *in vivo* that would be required to achieve cytodifferentiation.

POSTREMISSION CONSOLIDATION THERAPY As discussed above, treatment of APL with ATRA alone or in combination with chemotherapy yields a complete clinical remission rate as high as 85 to 95%. However, MRD detected by a positive RT-PCR for the PML-RARa transcript is present in 80 to 90% and in 50% of patients after induction therapy with ATRA alone ([48]) and ATRA plus chemotherapy ([121]), respectively. Invariably, patients with positive cytogenetics for t(15;17) or MRD determined by RT-PCR will clinically relapse ([69] , [70] , [71] , [72] and [73] , [122]). The proportion of patients with MRD is significantly reduced by the administration of postremission chemotherapy, which translates into a higher percentage of patients cured ([70] , [72] , [121]). The Memorial Sloan-Kettering group performed serial PCR analysis on the bone marrow of 47 patients with untreated APL who received ATRA induction therapy followed by consolidation treatment with chemotherapy, RA, and biologic agents ([48]). Forty of 47 patients (85%) had MRD detectable by RT-PCR after ATRA induction, and only four patients (10%) had detectable MRD after completing three cycles of consolidation therapy. Although several groups have incorporated high-dose cytosine arabinoside as part of the consolidation strategy ([111] , [123] , [124]), there have been no substantial data to support the benefit of dose-intense cytosine arabinoside in either induction or consolidation. Instead, dose intensification of the anthracycline appears to be of primary importance. In a 1999 nonrandomized prospective study conducted by the Spanish Programa para el Tratamiento de Hemopatías Malignas group, 123 newly diagnosed molecularly confirmed APL patients were treated with a modified AIDA regimen for induction and consolidation (cytosine arabinoside and etoposide were eliminated from consolidation) ([121]). After the completion of consolidation therapy, patients who remained in remission received maintenance therapy with mercaptopurine, methotrexate, and, intermittently, ATRA. CR was obtained in 89% ([109]) and resulted in a molecular remission in 51% of patients after induction therapy and in 93% after the completion of consolidation treatment. The 2-year DFS and OS estimates were 92% and 82%, respectively. These results are similar to those obtained in the German AML Cooperative Group study (CR, 92%; DFS, 96%; OS, 88%) ([72]), in which intensified double-induction therapy with high-dose cytosine arabinoside with ATRA was administered. Similar results were observed in other trials that used dose-intense cytosine arabinoside ([124]). Therefore, for previously untreated patients, most groups use a combination of ATRA and chemotherapy (anthracycline-based) for remission induction. Once remission is achieved, ATRA is discontinued, and two cycles of an anthracycline-based regimen are generally administered as consolidation therapy with the goal of eliminating MRD. As previously noted, this approach has been extremely effective, with 80 to 85% of patients achieving long-term DFS and, in all likelihood, cured ([108] , [122]). However, patients in remission should be monitored for evidence of MRD by RT-PCR. The experience to date shows that patients who remain positive during remission or those who convert from negative to positive inevitably relapse ([69] , [70]). Such patients should be considered candidates for additional therapy during remission, in particular allogeneic bone marrow or stem cell transplantation.

MAINTENANCE THERAPY Traditionally, maintenance therapy has not been a critical component of the “state of the art” management of AML. However, in APL, there are several small studies that have suggested a possible benefit of maintenance chemotherapy ([106] , [125]). In an early trial conducted at the MD Anderson Cancer Center, 39 of 70 patients with APL who received 6-MP and methotrexate as maintenance therapy had a sustained 3-year remission rate that was almost twice as high as that of patients who did not receive maintenance therapy (56% vs. 30%; $p < .01$) ([106]). Subsequently, results of two randomized trials ([111] , [112]) and one nonrandomized trial ([121]) have shown a reduction in the risk of relapse in patients treated with ATRA, chemotherapy, or both as maintenance. In the European APL 93 trial ([112]), the largest of these three studies, 289 patients who had completed consolidation therapy were randomized to no maintenance or to maintenance with (a) ATRA (45 mg/m ^{2}/day for 15 days every 3 months), (b) continuous low-dose chemotherapy with 6-MP (90 mg/m ^{2}/day) plus methotrexate (50 mg/m ^{2} given weekly), or (c) to both ATRA and continuous low-dose chemotherapy. The 2-year relapse incidence was 13% in patients who received ATRA compared to 25% in those who did not receive ATRA ($p = .2$) and 11% in patients who received chemotherapy as maintenance compared to 27% in those who did not receive chemotherapy as maintenance ($p = .0003$). However, the relapse rate (6 of 74 patients, 8%) was lowest in those patients who were randomized to receive both ATRA and low-dose chemotherapy. In addition, there was an improvement in OS ($p = .01$) in those patients who received chemotherapy maintenance, and a similar trend appeared in those patients who received ATRA maintenance ($p = .22$). Interestingly, high-risk patients (presenting WBC >5000 and >60 years of age) who received both ATRA and low-dose chemotherapy seemed to benefit the most from such therapy. Currently, two large ongoing randomized trials will help define the dose, schedule, and role of ATRA and chemotherapy maintenance in APL. The GIMEMA Cooperative Group is randomizing newly diagnosed APL patients to either no maintenance or to maintenance therapy using the same dose and schedules of maintenance therapy used in the APL 93 study: ATRA or continuous low-dose chemotherapy with 6-MP plus methotrexate or both ATRA and continuous low-dose chemotherapy. The North American Intergroup is evaluating ATRA given alone every other week versus ATRA given every other week with continuous low-dose 6-MP plus weekly methotrexate.

ADVERSE EFFECTS OF RETINOIC ACID The toxicity profile of ATRA is comparable to that of other retinoids. APL patients, however, are uniquely prone to the development of hyperleukocytosis and RAS ([126]). RAS is characterized by fever, respiratory distress, radiographic pulmonary infiltrates, pleural or pericardial effusions, weight gain due to fluid overload, episodic hypotension, and acute renal failure. RAS has a reported incidence as high as 50% ([126]). The clinical diagnosis can be challenging because this patient population is at risk to develop pneumonia, sepsis, and congestive heart failure because of the disease and complications of cytotoxic chemotherapy. The first sign or symptom of RAS has been reported to occur anytime within the first few days to weeks after initiating ATRA therapy ([118]). It is interesting that there have been reports of RAS occurring in patients who were maintained on ATRA and whose marrow was recovering after myelosuppressive doses of chemotherapy ([125]). Although hyperleukocytosis is frequently observed preceding RAS, the reaction may occur with a normal leukocyte count in up to one-third of cases ([34] , [107] , [126]). Clinically, RAS gives the impression of a “capillary leak syndrome.” Postmortem examinations performed on patients who had progressive hypoxemia and multiorgan failure revealed extensive infiltration of maturing myeloid cells into lung, skin, kidney, liver, and lymph nodes ([126]). The cause of RAS is unknown, although several mechanisms have been proposed, including release of vasoactive cytokines, increased expression of adhesion molecules on myeloid cell surfaces, and attainment of migratory capabilities by the malignant promyelocytes as they undergo differentiation ([34] , [126]). ATRA increases the expression of the surface integrin intracellular adhesion molecule-1 in certain cell lines. Of clinical importance, this effect can be blocked by treatment with dexamethasone ([127] , [128]). Development of this reaction is also correlated with expression of CD13 (aminopeptidase N) ([34]), which has been associated with a poor outcome in patients with acute myeloid leukemia. These observations suggest a link to the clinical experience of extravascular adhesion and migration of differentiating cells in this reaction. The progression of RAS can be terminated by early intervention with a short course of high-dose dexamethasone (10 mg twice per day for 3 days), and, as a result, the mortality from this adverse event has decreased significantly ([129]). However, the importance of immediate recognition and appropriate intervention cannot be overemphasized. The development of any unexplained sign or symptom, particularly fluid retention, hectic fevers, and pulmonary infiltrates, should prompt immediate dexamethasone treatment. Fully established RAS has proved especially difficult to manage and often results in significant morbidity and, frequently, death. Therefore, the benefits of empiric steroid therapy far outweigh the risk of complications associated with inappropriate use in leukemic patients with infections. In a nonrandomized prospective study, the Australian Study Group treated patients with prophylactic corticoste-roids (prednisone, 75 mg/day) and reported a lower incidence of pulmonary toxicity and RAS ([130]). Most groups have not adopted this as a standard approach given the risks/benefits of corticosteroids but instead administer dexamethasone at the earliest appearance of any of the signs or symptoms suggestive of RAS. Although APL is generally associated with leukopenia at the time of presentation, leukocytosis (=10,000 cells/mm ^{3}) frequently occurs in APL patients treated with ATRA alone. In general, it was recognized that patients who developed leukocytosis while receiving ATRA fared as well as patients who developed the RAS. In addition, it has been suggested that the development of leukocytosis and RAS is associated with a higher risk of extramedullary relapse ([131]). The prevention and management of leukocytosis involve using full-dose chemotherapy along with ATRA. The concurrent administration of these agents also appears to result in a lower incidence of RAS. With ATRA alone, the incidence of RAS is approximately 25%, and, when ATRA is given concurrently with chemotherapy, the GIMEMA Trial, the Japanese Adult Leukemia Study Group, and the European APL study reported an incidence of RAS of 10%, 6%, and 15%, respectively ([111] , [112] , [121]).

MANAGEMENT OF RELAPSED ACUTE PROMYELOCYTIC LEUKEMIA The incorporation of ATRA into the treatment regimen for newly diagnosed APL has significantly improved the remission rate and has more than doubled the survival of newly diagnosed patients over that achieved with chemotherapy alone ([83] , [111] , [132]). Nonetheless, despite these improvements, 15 to 20% of these patients relapse and are often resistant to further treatment with ATRA ([83] , [103] , [122]). However, some patients who have relapsed more than 6 months after completing their last ATRA therapy have achieved a second CR when retreated with ATRA ([92]). This relative “reversal of resistance” may be related, in part, to the metabolism of ATRA. The plasma levels of ATRA have been shown to decline over time in pharmacokinetics studies in which ATRA was given continuously, in part, as a result of autoinduction as discussed earlier. Clinically, this could result in a subtherapeutic plasma level and, thereby, give the appearance of drug resistance. The up-regulation of the respective metabolic enzymes reverses after a defined period from discontinuation of therapy ([133] , [134]). Therefore, when reinstituting therapy with standard doses of ATRA, the therapeutic levels needed clinically to induce myeloid differentiation are once again obtained. Patients who achieve a second CR, irrespective of agent(s) used, need additional curative therapy. Salvage therapy often entails high doses of cytotoxic chemotherapy followed by either autologous or allogeneic transplantation. Such an approach carries a risk of significant morbidity and mortality and may not be appropriate for some patients, an important consideration in treating very young or elderly patients. Also, an allograft is contingent on finding an HLA-identical donor, which only occurs for a subset of patients. Since the incorporation of ATRA as part of standard first-line therapy, there have been limited clinical data available reviewing the role of dose-intense chemotherapy followed by transplantation in relapsed patients. In the European APL 91 trial ([112]) and the Italian GIMEMA Group study ([114]), 4 of 5 patients and 6 of 15 patients, respectively, in second CR who underwent allografts obtained a prolonged CR. Thomas et al. ([135]) reported treating 50 patients with APL in first relapse with single agent ATRA until CR, followed by sequential EMA chemotherapy (*e*toposide, 200 mg/m ^{2}/day for 3 days; *m*itoxantrone, 12 mg/m ^{2}/day for 3 days; and cytosine *a*rabinoside, 500 mg/m ^{2}/day for two sequences of 3 days). Forty-five patients (90%) achieved a second CR; 37 of these 45 patients had ATRA as part of their first remission regimen when newly diagnosed. While in second CR, 11 patients underwent HLA-identical allogeneic transplant and had a median DFS of 8.2 months; 22 patients underwent autologous transplants and had a 3-year DFS rate of 77%. These results suggest that transplantation effectively cures a large proportion of these patients in first relapse at the risk of significant but acceptable toxicity. For patients undergoing an autologous transplantation, an important consideration is the RT-PCR status for PML-RARa, which is indicative of MRD. Meloni et al. ([136]) reported the results of 15 relapsed APL patients who underwent autologous transplantation in second CR. Seven of these patients' cells used in the graft were positive for PML-RARa, and all

relapsed less than 9 months after the transplant. In comparison, only one of eight patients whose cells were RT-PCR–negative for PML-RARa relapsed.

Arsenic Trioxide Abandoned 30 years ago as an anticancer medicine, arsenic has recently attracted renewed attention as a treatment for relapsed APL. Based on impressive results from China ([137], [138] and [139]), a pilot trial in 12 patients with relapsed APL was conducted at Memorial Sloan-Kettering Cancer Center that demonstrated the effectiveness of ATO. Eleven patients (92%) achieved CR ([140]). Subsequently, a U.S. multicenter study ([141]) was performed to evaluate the efficacy of ATO for remission induction and consolidation in a population of patients with APL who had relapsed from prior retinoid- and anthracycline-based chemotherapy. In this study, 40 patients were treated with a daily 1-hour infusion of 0.15 mg/kg of ATO until obvious leukemic cells in the bone marrow were eliminated. Patients who achieved CR were eligible for one additional consolidation course of ATO, consisting of 25 doses. Thirty-four patients (85%) achieved CR. The median time to bone marrow remission (i.e., elimination of all visible leukemic cells on bone marrow aspirate review) was 35 days (range, 20 to 61 days), which was the determining factor to discontinue the ATO. The median time to clinical CR was 59 days (range, 28 to 85 days). An indicator of the efficacy of this agent was the observation that 78% of these patients converted from RT-PCR–positive to –negative for the PML-RARa transcript by the completion of their consolidation therapy. Subsequently, 18 patients received one to four additional cycles of ATO as maintenance on a different protocol, and 12 patients underwent allogeneic (N = 9) or autologous (N = 3) transplant post–ATO treatment while in CR. When the data from the 12 patients treated in the original single-institution study of ATO are combined with results from the 40 patients treated in this multicenter study, the Kaplan-Meier 18-month estimates of OS and relapse-free survival are 66% and 50%, respectively ([141]). Of note, over one-half of these 52 patients were alive at the 18-month follow-up, irrespective of age or number of prior relapses. No difference in survival as a function of time from last ATRA therapy was noted. The most common adverse events observed with ATO in the U.S. multicenter study included leukocytosis (>10,000 WBC/mm ^{3}) during induction therapy, mild hyperglycemia, and fatigue. Also, ten patients developed signs or symptoms suggestive of RAS and were effectively treated with dexamethasone. A potentially life-threatening side effect was Q-T prolongation on electrocardiogram, which was observed in 63% of patients. Although all of these patients were asymptomatic, including one patient that developed a brief episode of torsades de pointes, there have been more recent reports of sudden cardiac death ([142], [143]) associated with ATO therapy in APL patients. Therefore, close monitoring, including aggressive management of electrolytes, particularly potassium and magnesium, is undertaken in conjunction with ATO therapy. Both intravenous and oral supplements are liberally provided to maintain the serum potassium at greater than 4.0 mEq/L and the magnesium level at greater than 1.8 mg/dl. In addition, every effort is made to limit the concomitant use of other agents known to prolong Q-T intervals or induce ventricular arrhythmias. Based on these results, ATO (Trisenox) is used as standard therapy in patients who have had a second relapse and is now more frequently used in patients in first relapse, particularly in those patients whose first CR lasted less than 12 months. However, the best treatment strategy for patients who achieve CR with arsenic remains to be determined. Although 10 of 21 patients treated in the U.S. multicenter study who received only ATO were without evidence of either clinical or molecular recurrence at a median of 18 months of follow-up, there are little data on the long-term outcome. Therefore, patients who relapse and are candidates for either allogeneic or autologous transplants should be managed accordingly. The use of ATO is currently being explored in newly diagnosed patients as part of induction or consolidation therapy in the United States and in Europe.

Gemtuzumab Ozogamicin Other agents that may be of benefit in patients with relapsed APL include liposomal ATRA and gemtuzumab ozogamicin (Mylotarg). Douer at al. ([144]) conducted a trial using a liposomal formulation of ATRA and administering it intravenously in 69 patients: 32 with newly diagnosed APL, 35 with relapsed APL, and two patients who had not responded to oral ATRA. CR was achieved in 62% of newly diagnosed patients and in 70% of patients with first relapse who were ATRA-naïve or off oral ATRA for 1 year or more. In those patients who were in first relapse and off oral ATRA for less than 1 year or in at least their second relapse, 20% achieved CR. However, the proportion of patients responding may be no different than expected in the same population treated with oral ATRA. This agent may be more important in a patient population in which oral ATRA is not ideal, such as patients who are not able to tolerate or absorb the oral formulation. *Gemtuzumab ozogamicin* is an engineered human anti-CD33 antibody linked with the potent antitumor antibiotic calicheamicin. This agent binds to the CD33 antigen that is found on the surface of more than 80% of patients with AML, including APL. Clinical remissions have been observed with gemtuzumab ozogamicin, including a clinical and molecular remission in a patient with multiple relapsed APL ([145]). This drug is currently approved to treat patients who are at least 60 years old in first relapse with CD33 $^+$ AML.

EXTRAMEDULLARY RELAPSE Extramedullary disease (EMD) occurs in approximately 5 to 10% of adult patients with AML, most commonly in the myelomonocytic and monocytic subtypes ([146]). In general, the incidence of EMD in patients with APL has been considered rare ([147], [148]). However, since the early 1990s, there have been numerous reported cases in patients with APL at the time of relapse, mostly involving the skin and CNS ([148], [149], [150] and [151]). In the Italian GIMEMA Group study, 13 of 97 patients with relapsed APL had EMD, and, in the European APL 93 trial, 3 of 75 relapsed patients had documented EMD. Specchia et al. ([152]) analyzed the incidence of EMD involvement in their series of APL patients who were treated with either chemotherapy alone or with ATRA and idarubicin (AIDA regimen) and subsequently relapsed. Accounting for all relapses, there were no conclusive data to support a higher incidence of EMD in patients treated with ATRA. However, the proportion of patients with EMD that had CNS involvement was significantly higher in the group that received ATRA as part of their induction therapy compared to those who received only chemotherapy. One explanation for this observation is that ATRA therapy induces the expression of adhesion molecules such as CD11c, CD13, and CD56 in the malignant promyelocytes and, thereby, may facilitate CNS infiltration ([153], [154] and [155]). Of note, there was no comparative difference in the incidence of other sites of EMD. It is clinically important that 14 of the 16 patients on the AIDA trial with EMD found at relapse also had hematologic or molecular evidence of disease. Treatment for CNS relapse requires systemic reinduction along with four to six cycles of intrathecal methotrexate or cytosine arabinoside. Some patients may benefit from additional cranial-spinal radiation. To date, there is no specific risk factor identified to predict CNS relapse. In addition, CNS prophylaxis with either intrathecal chemotherapy alone or combined with cranial irradiation has not been shown to improve DFS in adults with AML in general. This is probably because the majority of patients have systemic relapse in addition to CNS relapse or EMD.

SUMMARY

APL represents a model for modern cancer therapy. It is unique in that the identification of the specific genotype that is used for diagnosis, monitoring MRD, and detection of early relapse has also resulted in a greater understanding of the fundamental biology of this disease, which serves as template for the development of targeted therapies. Transgenic mice models ([146]) that stably carry the t(15;17) genotype and express a malignant phenotype have been developed and are currently used to test potential novel therapies and identify new targets in the preclinical setting. APL is the first known disease that is clinically sensitive to differentiation therapy, and, as a result, the paradigm for the treatment of leukemia has been irrevocably altered. As medicine moves through the era of genomics, proteomics, and rationale drug design, the models of pathogenesis based on interactions between the PML-RARa fusion products, corepressor binding proteins, and histone deacetylase may be instrumental in the understanding and treatment of other forms of malignancy.

Myelodysplastic Syndromes

The diagnosis and management of patients with myelodysplastic syndrome (MDS) remain challenges that are distinct from those for most other hematologic malignancies. Therapeutic goals vary among individuals and are influenced by hematologic presentation, prognosis, and age. No single treatment is uniformly effective or addresses the clinical needs of all patients. The standard of care ranges from amelioration of hematologic deficits with blood product transfusions and administration of recombinant growth factors to aggressive chemotherapy and stem cell transplantation for younger individuals with more aggressive disease. Given that the median age of patients with MDS exceeds 65 years, broad application of more aggressive therapeutic approaches is limited.

The MDSs represent a spectrum of stem cell malignancies that manifest dysplastic and ineffective hematopoiesis, which is associated with a variable risk of transformation to acute leukemia ([1], [2], [3] and [4]). Although generally arising *de novo*, with the risk increasing proportionate to age, MDS may also occur years after exposure to mutagenic chemotherapy ([5]). Although uniform morphologic classifications for MDS have emerged only recently, descriptions of the disease have existed for more than 70 years. In 1938, Rhoades and Barker ([6]) described 60 patients with refractory anemia (RA), which was unrelated to any associated systemic melee. Hamilton-Paterson ([7]) later proposed the term *preleukemic anemia* to describe cases of RA that antedated the development of acute myelogenous leukemia. The term *preleukemia* was applied by Block et al. ([8]) in 1953 to describe patients with one or more refractory cytopenias whose natural history of disease included the potential for leukemia transformation.

Although these nosologic references persist to date, case studies raised awareness that the hematologic presentation and natural history of the preleukemic states vary. Bjorkman ([9]) chronicled cases of RA that were associated with ringed sideroblasts in the bone marrow (BM), in which leukemic conversion represents a rare event. In 1963, Rheingold et al. ([10]) described a leukemia variant that was characterized by a subacute clinical course and a variable percentage of marrow blasts; the authors called this variant *smoldering acute leukemia*.

In the 1970s, chronic myelomonocytic leukemia (CMML) was recognized as a distinct preleukemic syndrome ([11], [12] and [13]). Dreyfus' ([14]) seminal observation that patients who presented with a RA and higher than normal BM blast percentage experienced more rapid hematologic deterioration proved to be a reproducible measure to gauge differences in clinical behavior and continues to be applied even today in prognostic staging systems. In 1976, the French/American/British (FAB) Cooperative Group first adopted diagnostic criteria for the preleukemic syndromes of refractory anemia with excess blasts (RAEB) and CMML ([15]). Three additional subtypes were added 6 years later to complete the current FAB classification scheme within the unifying diagnostic category of *MDS* ([16]). The terms that were previously applied to describe the preleukemic states in the hematology literature are summarized in Table 83.1. The World Health Organization recently proposed modifications to the FAB criteria to strengthen the prognostic usefulness of the classification system.

TABLE 83.1. Chronology and Terminology of the Myelodysplastic Syndromes

Term	Year	Author
Refractory anemia	1938	Rhoades and Barker (6)
Preleukemic anemia	1949	Hamilton-Paterson (7)
Preleukemia	1953	Block et al. (8)
Refractory anemia with ringed sideroblasts	1956	Bjorkman (9)
Refractory normoblastic anemia	1959	Dacie et al. (417)
Smoldering acute leukemia	1963	Rheingold et al. (10)
Chronic erythremic myelosis	1969	Dameshek (418)
Preleukemic syndrome	1973	Saarni and Linman (419)
Subacute myelomonocytic leukemia	1974	Sexauer et al. (420)
Chronic myelomonocytic leukemia	1974	Miescher and Farguet (11)
Hypoplastic acute myelogenous leukemia	1975	Beard et al. (421)
Refractory anemia with excess myeloblasts	1976	Dreyfus (14)
Hematopoietic dysplasia	1978	Linman and Bagby (422)
Subacute myeloid leukemia	1979	Cohen et al. (423)
Dysmyelopoietic syndrome	1980	Streuli et al. (424)
Myelodysplastic syndromes	1982	Bennett et al. (16)

CLASSIFICATION AND DIAGNOSIS

Based on peripheral blood and BM findings of unexplained hematopoietic dysplasia in two or more lineages, the FAB Cooperative Group ([16]) distinguishes five morphologic subtypes of MDS (Table 83.2), which include RA, refractory anemia with ringed sideroblasts (RARS), RAEB, refractory anemia with excess blasts in transformation (RAEB-t), and CMML. The presence of more than 15% of ringed sideroblasts in the BM accompanied by an increase in myeloblasts (>5%) or monocytosis is regarded as RAEB or CMML, respectively ([17]). These patients have a more unfavorable clinical course and a shorter survival than patients with RARS ([18]). Although the validity of the FAB classification has been questioned, it remains the most widely applied classification because of its reproducibility and usefulness as a reference for case comparison. Among 1640 cases that have been classified according to this scheme ([19] , [20] , [21] , [22] , [23] , [24] , [25] , [26] , [27] , [28] , [29] and [30]), 346 (21%) fulfilled the criteria for RA, 303 (17%) fulfilled the criteria for RARS, 219 (13%) fulfilled the criteria for CMML, 614 (37%) fulfilled the criteria for RAEB, and 159 (12%) fulfilled the criteria for RAEB-t. Despite its usefulness, some cases of MDS are not readily categorized by the FAB criteria. This is particularly true for patients with therapy-related MDS (t-MDS) ([31]). In such cases, the terms *unclassifiable MDS* ([32]) or *RA with multilineage dysplasia* have been applied ([33]).

TABLE 83.2. French/American/British Classification of the Myelodysplastic Syndromes

Classification	Blast Cells (%)		Ringed Sideroblasts (%)	Monocytes > 1 × 10^9/L
	Bone Marrow	Peripheral Blood		
RA	<5	<1	<15	–
RA with ringed sideroblasts	<5	<1	>15	–
RA with excess blasts	5 to 20	<5	Variable	–
Chronic myelo-monocytic leukemia	<20	<5	Variable	+
RA with excess blasts in transformation	21 to 30	± 1	Variable	±

RA, refractory anemia.

CMML is distinguished by an absolute monocytosis that exceeds 1000/µl, increased marrow myelomonocytic precursors, and single- or multilineage cytologic dysplasia. Circulating blasts should not exceed 5%, accompanied by fewer than 20% BM blasts ([16]). Controversy remains concerning the inclusion of CMML among the MDSs because of its characteristic proliferative features that are akin to chronic myelogenous leukemia (CML). Indeed, retrospective studies of Philadelphia (Ph) chromosome–negative CML indicate that many cases fulfill the criteria for CMML or other MDS subtypes ([34] , [35]). Molecular screening for the bcr/abl fusion gene, which is characteristic of CML, by polymerase chain reaction of fluorescence *in situ* hybridization (FISH) is necessary to assure discrimination among these entities ([36]). Nonetheless, rare patients display features of CMML and CML and lack the Ph chromosome or its gene rearrangement. The FAB group recently proposed the term *atypical CML* with specific diagnostic criteria to distinguish this particular subset of patients ([37] , [38]).

A recognized limitation of the FAB classification is that anemia, per se, cannot be characterized morphologically, and the term *RA* may not apply when other deficits predominate. Recently, the World Health Organization (WHO) proposed a new classification system for MDS, which is summarized in Table 83.3 ([39]). The new schema lowers the diagnostic threshold for MDS to include one or more dysplastic lineages, while creating new subtypes that are distinguished by the number of dysplastic lineages and by smaller increments in marrow blast percentage. The subtype of RAEB-t is eliminated to lower the boundary for acute myeloid leukemia (AML) to 20% myeloblasts. The WHO system incorporates one cytogenetic abnormality, that is, an isolated interstitial deletion of chromosome 5q31-33, as a diagnostic requisite for the new category of *5q– syndrome*. MDS cases with nonerythroid, single-lineage dysplasia are regarded as *MDS unclassifiable*. Retrospective application of the WHO system suggests that it offers improved prognostic discrimination but lacks power when the FAB system is applied with the recently adopted International Prognostic Scoring System (IPSS) ([40] , [41] and [42]). Finally, the WHO proposal creates a new diagnostic category, which is termed *myelodysplastic/myeloproliferative diseases*, that recognizes disorders with overlapping dysplastic and proliferative features, including CMML, atypical CML, and juvenile myelomonocytic leukemia (JMML). The diagnostic criteria for CMML require leukocytosis of greater than 13,000/µl, and three prognostically distinct subgroups are proposed, distinguished by blast percentage and associated eosinophilia (Table 83.4). The latter subgroup characteristically displays a rearrangement of the platelet-derived growth factor (PDGF)–ß receptor gene (*PDGF ß R*) on chromosome 5q33, resulting in constitutive receptor activation ([43]).

TABLE 83.3. World Health Organization Classification of the Myelodysplastic Syndromes

Classification	Peripheral Blood	Bone Marrow
Refractory anemia	Anemia No or rare blasts	Erythroid dysplasia only <5% blasts <15% ringed sideroblasts
Refractory anemia with ringed sideroblasts	Anemia No blasts	>15% ringed sideroblasts Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia	Cytopenias (bicytopenia or pancytopenia) No or rare blasts No Auer rods <1 × 10^9/L monocytes	Dysplasia in >10% of the cells of two or more myeloid lines <5% blasts in the marrow No Auer rods <15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts	Cytopenias (bicytopenia or pancytopenia) No or rare blasts No Auer rods <1 × 10^9/L monocytes	Dysplasia in >10% of the cells of two or more myeloid lines <5% blasts in the marrow >15% ringed sideroblasts No Auer rods
Refractory anemia with excess blasts 1	Cytopenias <5% blasts No Auer rods <1 × 10^9/L monocytes	Unilineage or multilineage dysplasia 5 to 9% blasts No Auer rods
Refractory anemia with excess blasts 2	Cytopenias 5 to 19% blasts Auer rods present <1 × 10^9/L monocytes	Unilineage or multilineage dysplasia 10 to 19% blasts Auer rods present
Myelodysplastic syndrome, unclassified	Cytopenias	Unilineage dysplasia: one myeloid cell line

	No or rare blasts	<5% blasts
	No Auer rods	No Auer rods
5q– syndrome	Anemia	Normal to increased megakaryocytes with hypolobated nuclei
	Usually normal or increased platelet count	<5% blasts
	<5% blasts	Isolated del(5q) cytogenetic abnormality
		No Auer rods

TABLE 83.4. Diagnostic Criteria for Chronic Myelomonocytic Leukemia According to the World Health Organization

Persistent peripheral blood monocytosis is >1 × 10^9/L.
Absence of Philadelphia chromosome or BCR/ABL rearrangement.
Blasts [a] are <20% in peripheral blood or bone marrow.
Dysplasia in one or more myeloid lineages, or, in the absence of dysplasia, CMML can be diagnosed, if all other criteria are met, together with either of the following:
- Presence of a clonal cytogenetic abnormality.
- Monocytosis has been persistent for at least 3 months and all other causes of monocytosis have been excluded.

Subgroups
- CMML-1: Blasts <5% in peripheral blood and <10% in bone marrow.
- CMML-2: Blasts 5 to 19% in peripheral blood, 10 to 19% in bone marrow, or Auer rods are present and blasts are <20% in peripheral blood or bone marrow.
- CMML-1 or CMML-2 with eosinophilia: Criteria for CMML-1 and CMML-2 are present, and the eosinophil count in peripheral blood is >1.5 × 10^9/L.

CMML, chronic myelomonocytic leukemia.

[a] Blasts include myeloblasts, monoblasts, and promonocytes.

A diagnosis of MDS should be considered in any individual with unexplained, persistent cytopenias or monocytosis. Careful inspection of the peripheral blood smear and BM is necessary to document the requisite dysplastic cytologic features in one or more hematopoietic lineages ([4], [16]). The presence of nuclear hyposegmentation of granulocytes, that is, pseudo–Pelger-Huët anomaly, mononuclear or micromegakaryocytes ([26]), hypogranular neutrophils or megakaryocytes ([44], [45]), macroovalocytes, and acanthocytes ([46]), may be evident. Because these findings alone are not diagnostic of MDS, possible contributing conditions must be excluded. The preponderance of macrocytic anemia in MDS necessitates exclusion of vitamin B_{12} and folate deficiency. Nutritional status, alcohol and drug use, occupational exposure to petrochemicals and other toxins, prior treatment with antineoplastics or radiotherapy, and risk factors for human immunodeficiency virus (HIV) should be elicited. Dysplastic hematopoiesis is a common finding that accompanies HIV infection ([47], [48], [49], [50] and [51]). Hematopoietic dysplasia in such patients may result from medications, opportunistic infection, or a direct effect of HIV on hematopoietic progenitors ([52], [53]). Serologic screening for HIV should be considered in patients who are at risk for virus exposure with unexplained cytopenia or myelo-dysplasia. Cytogenetic analysis ([54]), BM progenitor colony-forming capacity ([55]), trephine biopsies ([56], [57], [58] and [59]), flow cytometry ([60], [61] and [62]), and immunohistochemical studies ([59], [63], [64]) may be helpful, particularly in cases in which morphologic findings are equivocal. The identification of clonal cytogenetics may, in some cases, prove diagnostic ([54]).

In addition to its importance in the assessment of BM cellularity, the trephine biopsy may provide confirmatory or diagnostic information. Immature myeloid elements, for example, may be displaced from their normal paratrabecular location to aggregates in central marrow spaces ([56], [57]). This displacement of granulocyte precursors is termed *abnormal localization of immature precursors (ALIP)* ([56], [57]) and may be detected in any, but often a more advanced, FAB subtype, thus providing morphologic evidence for the imminent risk of leukemia transformation ([32]). Evidence of dysplastic thrombopoiesis, reticulin fibrosis, presence of lymphoid aggregates or lymphocytic infiltration, and immunohistochemical studies can be discerned from biopsy and clot sections ([32], [43], [44], [48]).

The diagnosis of MDS may be enhanced by the application of cytochemical stains and immunophenotyping studies ([17], [32], [59], [63], [64]). The former include iron stains for identification of ringed sideroblasts and periodic acid-Schiff–reactive erythroblasts to assess dyserythropoiesis, peroxidase or Sudan black B to confirm the myeloid lineage of blasts, and nonspecific or double esterase stains to discern abnormal granulocyte and monocyte forms ([17], [64]). Immunocytochemistry ([65]) may be necessary to exclude a lymphoid origin of primitive blasts, whereas erythroid precursors may be distinguished by a glycophorin-A expression; myeloid precursors may be quantified by using antibodies to CD13, CD14, and CD33 ([66]). Dysplastic or immature megakaryocytes may be detected by antibodies with specificity for factor VIII ([67]) or CD41 ([68]) or the HPI-ID monoclonal antibody ([64]).

Although most patients with MDS have normal or increased BM cellularity, in 8 to 28% of patients, the cellularity is less than 25% and is lower than expected for the patient's age ([56], [59], [69], [70], [71] and [72]). The distinction between aplastic anemia and hypocellular MDS is important, because the clinical course differs and may impact patient management. The presence of a clonal chromosomal abnormality confirms a diagnosis of MDS ([73]).

Myelofibrosis, an abnormal increase in the number and caliber of reticulin fibers in the BM biopsy, may be detected by a silver impregnation stain ([74]). Mild to moderate myelofibrosis is reported in as much as 50% of MDS cases, and marked fibrosis is demonstrable in 10 to 15% ([75], [76], [77] and [78]). Myelofibrosis may accompany any morphology but is most common in t-MDS ([31]). Patients with hyperfibrotic variants are often pancytopenic, with trilineage dysplasia, absent organomegaly, and atypical megakaryocytic hyperplasia ([75], [76], [77] and [78]). The intense fibroblastic proliferation is believed to arise from the liberation of soluble effectors, such as transforming growth factor-ß and PDGF from dysplastic megakaryocytes ([76]). The absence of splenomegaly and the often rapidly progressive clinical course offer discrimination of this MDS variant from idiopathic myelofibrosis. Despite these differences, distinguishing this variant from other disorders, such as primary myelofibrosis, the accelerated phase of chronic myeloid leukemia, and acute megakaryocytic leukemia, may, in some cases, be problematic ([32]).

CLINICAL MANIFESTATIONS

The precise incidence of *de novo* MDS is not known; however, estimates indicate that it probably exceeds the incidence for AML in the elderly. It remains clear, nonetheless, that the risk increases with age. In one study, the annual incidence per 100,000 was estimated at 0.5 for people younger than 50 years of age, compared to 5.3 for ages 50 to 59 years, 15 for ages 60 to 69 years, 49 for ages 70 to 79 years, and 89 for ages older than 80 years ([79]). Aul et al. ([80]) report a crude annual incidence of 4.1 per 100,000 for MDS and 2.1 per 100,000 for AML. The median age in most series approximates 65 years, and, in the majority of cases, there is a male predominance ([1], [2], [3] and [4], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29] and [30]). Onset of the disease before 50 years of age is unusual ([81]), with the specific exception of mutagen-induced MDS ([30], [31]).

Although rare in childhood, MDS occurs with a median age at onset of 6 years of age ([82], [83], [84], [85] and [86]). Two ill-defined syndromes predominate: JMML and the monosomy 7 syndrome ([84], [85], [86], [87] and [88]). These disorders share considerable clinical and hematologic overlap, making their distinction somewhat arbitrary. The characteristic features, which include splenomegaly, leukocytosis with monocytosis, frequent skin involvement, anemia, thrombocytopenia, and polyclonal gammopathy, correspond to those of adult CMML. Elevation in hemoglobulin F and a natural history that is punctuated by progressive marrow failure serve to distinguish JMML from the monosomy 7 syndrome, in which susceptibility to bacterial infection, a familial tendency, and transformation to acute leukemia predominate ([85], [86], [88], [89], [90], [91] and [92]). Although the FAB classification does not recognize these childhood syndromes, it can, nonetheless, be applied successfully in the pediatric population with the majority of cases classified as CMML, RAEB, and RAEB-t, whereas RARS, a common category in adults, is rare ([84], [85] and [86], [89], [93]). A

recent consensus panel recommended a revised classification scheme that incorporates elements of the adult WHO and FAB criteria. These include the category of *myelodysplastic and myeloproliferative disease*, which includes CMML, secondary CMML, and Ph-negative CML, and the category of *MDS*, which includes a consolidation of FAB subtypes of RA and RARS as *refractory cytopenias*, as well as RAEB and RAEB-t ([93]).

Clinical signs and symptoms at presentation generally relate to peripheral cytopenias and are not necessarily disease specific. Many patients are asymptomatic, with a diagnosis that is established fortuitously on routine laboratory screening. Others present with fatigue, weakness, exercise intolerance, angina, dizziness, or an altered sense of well-being as a result of unrecognized anemia ([1], [2] and [3]). Less commonly, infection ([13], [19], [94]), easy bruising, or bleeding precipitates laboratory investigation ([1], [2] and [3], [19], [20]). Although neutropenia is largely responsible for the high incidence of infection in MDS, granulocyte dysfunction, which is manifested by impaired chemotaxis and microbial killing, also contributes to this high incidence ([94], [95]). Bacterial infections predominate, with the skin representing the most common recurring site of infection ([94]). Infections may be occult, respond poorly to antibiotics, and resolve slowly ([96]). Indeed, infection remains the principal cause of mortality in patients with MDS ([14], [19], [94]). Although fungal, viral, and mycobacterial infections may occur, they are rare in the absence of concurrent treatment with systemic immunosuppressants ([94], [97]).

Autoimmune abnormalities, although uncommon, may complicate the disease course in some patients ([98], [99], [100], [101] and [102]). Among 221 cases in one series, 14% of patients experienced autoimmune disorders ([98]). The most common manifestations included cutaneus vasculitis and monoarticular arthritis ([98]). An acute clinical syndrome that is characterized by cutaneous vasculitis, fever, arthritis, peripheral edema, and pulmonary infiltrates was reported in seven patients. Other autoimmune abnormalities included pericarditis, pleural effusions, skin ulcerations, iritis, myositis, and peripheral neuropathy ([98]). Although connective tissue disorders, such as relapsing polychondritis, polymyalgia rheumatica, Raynaud disease, Sjögren syndrome, inflammatory bowel disease, pyoderma gangrenosum, and glomerulonephritis, have been reported in association with MDS ([98], [99], [100], [101], [102] and [103]), a causal relationship has not been established. These so-called paraneoplastic autoimmune complications generally respond to immunosuppressive agents ([98]). However, in less responsive cases ([98], [103]), such autoimmune syndromes may contribute to early mortality.

Although cutaneous manifestations of MDS are uncommon, two syndromes occur with sufficient frequency to merit description. Sweet syndrome, or acute febrile neutrophilic dermatosis, when complicating the course of MDS ([104], [105] and [106]), often heralds transformation to acute leukemia ([104]). Paracrine and autocrine elaboration of cytokines, such as interleukin (IL)-6 and granulocyte colony-stimulating factor (G-CSF), have been implicated in the pathogenesis of this condition ([106]). Granulocytic sarcoma ([104], [105], [106] and [107]), like Sweet syndrome, may herald disease acceleration ([107], [108], [109] and [110]).

Physical findings in patients with MDS reflect the underlying hematologic disturbance. Sixty percent of patients have pallor, and 26% have petechiae or purpura ([20]). Unlike the myeloproliferative syndromes or lymphoid leukemias, hepatomegaly, splenomegaly, and lymphadenopathy are uncommon ([2]). The singular exception is CMML. Splenomegaly may be massive in as much as 25% of patients with this disease type and, not uncommonly, is accompanied by hepatomegaly or nodular cutaneous leukemic infiltrates ([12], [111], [112], [113] and [114]). Pleural and pericardial effusions and ascites may occur in CMML patients with exceedingly high or uncontrolled monocytosis ([115]) but often resolve with antileukemic therapy. Systemic symptoms of fever and weight loss are uncommon but generally represent late manifestations of the disease or its attendant complications ([20]).

LABORATORY FINDINGS

The hematologic manifestations in MDS are protean (Table 83.5). Nevertheless, hematologic deficits that involve one or more lineages with cytologic dysplasia represent the hallmark of the disease ([1], [2], [3] and [4], [16], [17], [20], [21], [22] and [23]). Anemia is almost uniformly present and is associated with an inappropriately low reticulocyte response. Pancytopenia may be present in as much as 50% of patients at the time of diagnosis; however, anemia may represent the only cytopenia or is accompanied by thrombocytopenia or neutropenia. Fewer than 5% of patients present with an isolated cytopenia or monocytosis in the absence of anemia ([2]).

TABLE 83.5. Morphologic Abnormalities in Myelodysplastic Syndromes

Lineage	Peripheral Blood	Bone Marrow
Erythroid	Ovalomacrocytes	Megaloblastoid erythropoiesis
	Elliptocytes	Nuclear budding
	Acanthocytes	Ringed sideroblasts
	Stomatocytes	Internuclear bridging
	Teardrops	Karyorrhexis
	Nucleated erythrocytes	Nuclear fragments
	Basophilic stippling	Cytoplasmic vacuolization
	Howell-Jolly bodies	Multinucleation
Myeloid	Pseudo–Pelger-HuHuët anomaly	Defective granulation
	Auer rods	Maturation arrest at myelocyte stage
	Hypogranulation	Increase in monocytoid forms
	Nuclear sticks	Abnormal localization of immature precursors
	Hypersegmentation	
	Ring-shaped nuclei	
Megakaryocyte	Giant platelets	Micromegakaryocytes
	Hypogranular or agranular platelets	Hypogranulation
		Multiple small nuclei

Erythrocyte morphology is usually normocytic or macrocytic ([14], [116], [117]), although patients with RARS may present with microcytic or hypochromic erythrocytes as an isolated or dimorphic population ([118]). Reticulocytosis may be indicative of a superimposed autoimmune hemolytic anemia ([119], [120]) or may be a marker of delayed reticulocyte maturation, so-called pseudoreticulocytosis ([121], [122]). Ovalomacrocytosis is the best recognized erythrocyte abnormality. In extreme cases, elliptocytes ([123], [124]), teardrops, schistocytes, stomatocytes, or acanthocytes ([46]) may predominate (Fig. 83.1), reflecting intrinsic alterations in cytoskeletal proteins ([124], [125]). Basophilic stippling, Howell-Jolly bodies, and megaloblastoid nucleated red cells may also be found in the peripheral smear. The peripheral blood findings in MDS represent a peripheral extension of the dyserythropoietic features in marrow precursors that characteristically display delayed and distorted nuclear and cytoplasmic maturation. These findings include erythroid hyperplasia with megaloblastoid features, nuclear budding, multinucleation, karyorrhexis, and cytoplasmic vacuole formation (Fig. 83.2) ([14], [116]). Pathologic sideroblasts that contain more than five iron granules per cell may be evident (Fig. 83.3). Sideroblasts in which iron granules occupy more than one-third of the nuclear rim are referred to as *ringed sideroblasts* ([126]). Ringed sideroblasts and increased storage iron may be found in any of the FAB subtypes, but the former is characteristic of RARS. In RARS, a population of ragged, poorly hemoglobinized normoblasts may be identified, often accompanied by course stippling ([127]). Although erythroid hyperplasia generally accompanies ineffective erythropoiesis, red cell aplasia or hypoplasia may manifest in other cases, representing a defining feature of the *5q– syndrome* ([128]). Internuclear bridging, which is characterized by chromatin threads that tether dissociated nuclei, reflects impaired mitosis and may compound the addition or deletion of genetic material ([129]). Finally, abnormalities of erythrocyte glycolytic enzymes ([130], [131]), elevation in hemoglobin F content ([132]), alterations in blood group antigens ([133]), increased susceptibility to complement cytolysis ([116]), and paroxysmal nocturnal hemoglobinuria (PNH)–like antigenic effects ([134], [135] and [136]) have been described. Acquired hemoglobin H disease has been documented in rare cases of MDS ([137]) and results in a spectrum of red cell morphology that is analogous to thalassemia, including ghosted erythrocytes with profound hypochromia.

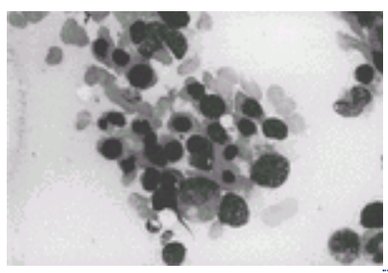

Figure 83.2. Dyserythropoiesis with nuclear budding and megaloblastoid erythropoiesis in refractory anemia (Wright-Giemsa stain ×1250). See Color Plate.

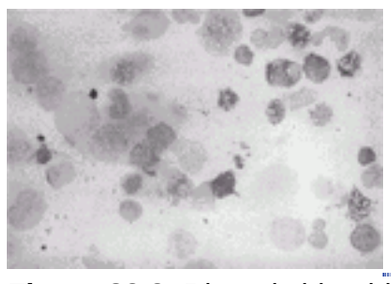

Figure 83.3. Ringed sideroblasts in refractory anemia with ringed sideroblasts (Prussian blue stain ×1250). See Color Plate.

Leukopenia, which results from absolute neutropenia, is detected in as much as 50% of patients at the time of diagnosis ([30]). Circulating myelocytes and myeloblasts may be identified but generally constitute fewer than 5% of the leukocyte differential. Auer rods are rare, but their presence serves to identify the FAB category of RAEB-t ([16] , [138]). Granulocytes commonly display reduced segmentation (Fig. 83.4), the so-called pseudo–Pelger-Huët anomaly ([26]), which is often accompanied by reduced or absent granulation ([44] , [139]). Whether neutrophil hyposegmentation represents perturbed differentiation or excess chromatin condensation from accelerated apoptosis is unknown ([140]). Occasionally, granulocytes manifest a clumped chromatin pattern in which blocks of chromatin are separated by a void in nuclear material, creating an appearance of nuclear fragmentation that is associated with a loss of segmentation ([141] , [142]). This granulocytic feature is linked to a specific karyotypic abnormality, (del 14) ([141] , [142]). Ring-shaped nuclei and nuclear sticks may be identified ([143]), particularly in t-MDS. Ring-shaped granulocyte nuclei are believed to represent a transitional stage to the band form (acquired Pelger-Huët formation) and are considered a cytologic feature of abnormal myeloid maturation ([17]). Pseudo–Chédiak-Higashi anomaly and myelokathexis-like features are rarely evident. Myeloperoxidase ([95]) and alkaline phosphatase ([116]) activities may be diminished in myeloid elements, whereas monocyte-specific esterase may be increased ([144]). As a consequence, granulocytes may be dysfunctional and display defective phagocytosis, bactericidal activity, adhesion, and chemotaxis ([95]), leading to impaired resistance to bacterial infections. These features may have a common cytogenetic basis that is linked to complete or partial deletion of chromosome 7 ([88] , [145]). Abnormal patterns of myeloid maturation antigen expression are common, providing further diagnostic and prognostic discrimination ([146] , [147]). Impaired myeloid maturation is often apparent on inspection of the BM aspirate. The percentage of myeloblasts may be increased, and a maturation arrest may be apparent at the myelocyte stage ([4]). As with erythroid precursors, maturation of the cytoplasm may progress more rapidly than the nucleus ([81]). In addition, clusters of immature cells may coalesce centrally in the marrow space rather than along the endosteal surface ([57]).

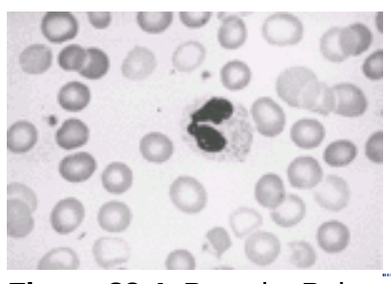

Figure 83.4. Pseudo–Pelger-HuHuët anomaly in a patient with refractory anemia (hematoxylin and eosin stain ×1250). See Color Plate.

Varying severity of thrombocytopenia is present in 25% of patients with MDS ([30]) and rarely represents an isolated early manifestation of the disease ([148]). Thrombocytosis is less common but occurs in association with a specific cytogenetic abnormality, that is, an interstitial deletion of the long arm of chromosome 5 or the *5q– syndrome* ([54]). Giant platelets or circulating megakaryocyte fragments, hypogranular forms, and dwarf or micromegakaryocytes may be present ([149]). These morphologic abnormalities can be accompanied by an increased bleeding tendency, despite the presence of apparent adequate platelet number ([150]). Prolongation of the bleeding time has been ascribed to intrinsic platelet dysfunction, as evidenced by decreased collagen- or epinephrine-induced platelet aggregation ([151]). Megakaryocytes are usually normal or increased and sometimes occur in clusters. Rarely, amegakaryocytosis is noted. Abnormal megakaryocytes, including micromegakaryocytes, large mononuclear forms, megakaryocytes with multiple dispersed nuclei, and hypogranular megakaryocytes, are common BM findings ([16] , [26] , [45]) (Fig. 83.5). Nonlobulated or mononuclear megakaryocytes may be identified, particularly in association with the 5q– syndrome ([54]). Kuriyama et al. ([26]) proposed that the finding of micromegakaryocytes that are detected in the BM when coupled with pseudo–Pelger-Huët anomaly in the peripheral smear is the most specific morphologic feature that supports the diagnosis of MDS.

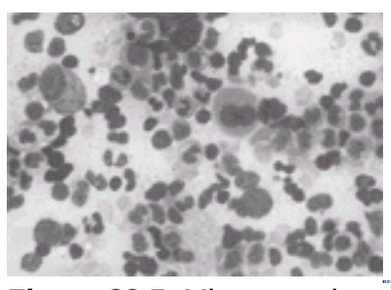

Figure 83.5. Micromegakaryocytes in a patient with refractory anemia with excess blasts (Wright-Giemsa stain ×1250). See Color Plate.

In FAB categories other than CMML, relative elevations in monocyte count are common. In CMML, however, absolute monocytosis (i.e.,>1000/µl) is a prerequisite and

is often accompanied by atypical cytologic features and granulocytosis (Fig. 83.6) ([12]). The BM is uniformly hypercellular with pronounced granulocytic hyperplasia and mononuclear cells that exhibit cytologic features that are intermediate between myelocytes and monocytes; these cells are aptly termed *paramyeloid cells* ([12]). Discrete nodules of immature monocytic elements may be present on the trephine biopsy and can be distinguished from myeloid precursors by using a combined esterase stain. Muramidase (lysozyme) activity may be increased in the blood or urine ([152]), reflecting heightened monocyte generation.

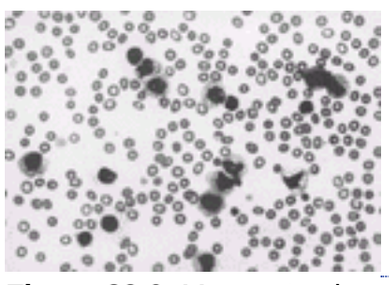

Figure 83.6. Monocytes in a patient with chronic myelomonocytic leukemia (hematoxylin and eosin stain ×1250). See Color Plate.

Abnormalities of the immune system may be demonstrable, but, in the majority of cases, lymphocytes are not derived from the malignant clone ([153]). Lymphopenia, accounted for largely by a reduced number of $CD4^+$ cells, inversely relates to the number of transfusions received ([146], [154]). Quantitative decreases in natural killer (NK) cells are routine, but $CD8^+$ cells are normal or slightly increased ([155]). Immunoglobulin production is variably affected, with hypogammaglobulinemia, polyclonal hypergammaglobulinemia, and monoclonal gammopathy reported in 13%, 30%, and 12%, of patients, respectively ([156]). Serologic abnormalities are found in greatest frequency in CMML, with polyclonal gammopathy reported in 47% of patients in one series ([111]). Indeed, autoantibodies, antiplatelet antibodies, erythrocyte autoantibodies, and positive antiglobulin tests may be detected in this and other morphologic subtypes ([156]). Rarely, coexistent clonal lymphocyte or plasma cell populations may be identified ([157], [158] and [159]).

The BM in MDS is usually hypercellular and is accompanied by single-lineage or multilineage dysplasia ([56], [57] and [58]) (Fig. 83.7). The classic paradox of pancytopenia, despite the presence of a hypercellular marrow, reflects accelerated intramedullary cell death ([160], [161], [162], [163], [164] and [165]). Although hypocellularity is uncommon, it is found with greatest frequency in t-MDS ([31]). Marrow cells in these patients are, as a rule, morphologically and karyotypically abnormal, thereby facilitating distinction from aplastic anemia. Eosinophilia ([166]), an increase in mast cells ([167]), plasmacytosis, and sea blue histiocytosis (Fig. 83.8) ([168]) may also be apparent in the BM aspirate.

PATHOGENESIS

The cytopenias that characterize MDS represent a late manifestation of the malignant transformation of primitive hematopoietic progenitors. Evidence from interphase cytogenetics, X chromosome inactivation, and analysis of polymorphic alleles indicates that these disorders derive from the clonal expansion of a multipotent hematopoietic progenitor that is capable of granulocyte, monocyte, erythrocyte, and megakaryocyte differentiation ([169], [170], [171], [172], [173] and [174]). Although initial studies suggested occasional involvement of B lymphocytes ([169]), more recent investigations indicate that this is rarely the case ([172], [173], [174] and [175]). The persistence of polyclonal hematopoiesis in a variable fraction of BM cells suggests that chromosome aberrations are a secondary event in the neoplastic process.

Like the disease itself, the factors that contribute to its development are heterogeneous. The high incidence of MDS in the elderly and the strong age dependence for development of t-MDS imply that factors inherent to *hematopoietic senescence* are important in the disease pathogenesis. There is accumulating evidence that environmental and heritable factors modify a person's cumulative risk. Exposure to genotoxic agents that are used in cancer therapy is by far the best characterized risk. Case control studies of patients who are treated with alkylating agents for Hodgkin disease, non-Hodgkin lymphoma, or other malignancies show an excess risk of t-MDS and AML that becomes apparent immediately after completion of therapy and reaches its peak at 5 years ([176], [177], [178], [179], [180], [181], [182] and [183]). Indeed, a myelodysplastic phase is observed in at least 70% of patients who develop secondary leukemia. The cumulative risk is greatest for patients who are treated with alkylator-based chemotherapy, but it is directly related to the cumulative dose and the duration of exposure, alkylator type, and treatment intensity ([176], [177], [180], [182]). Treatment with radiotherapy is associated with a low, but measurable, risk of myeloid malignancy that may compound the risk that is attributed to chemotherapy alone ([176], [184], [185]). The risk is greatest in patients older than 40 years of age with relapsed disease and in patients who were treated with extended courses of chemotherapy ([177], [182], [184], [186], [187]). The actuarial risk for t-MDS ranges from 3 to 4% at 10 years after alkylator therapy, after which the risk sharply diminishes. After salvage therapy for Hodgkin disease, however, the cumulative risk may approach 10%. A male predominance is evident in *de novo* and t-MDS, reflecting possible sexual disparity in patterns of environmental exposure or the hematopoietic stimulatory effects of androgens. Splenectomy has also been implicated as a contributing risk factor in some, but not all, studies ([176], [188]).

The risk of developing t-MDS or AML is amplified in long-term survivors of autologous stem cell transplantation for lymphoid malignancies. In registry and published single institution experiences, the cumulative risk reaches 8 to 20% at 10 years' follow-up ([189], [190], [191] and [192]). Cumulative risk increases with a lower autograft $CD34^+$ cell yield, the type and duration of pretransplant salvage therapy, the use of dose-intensive chemotherapy for progenitor mobilization, the inclusion of high-intensity total body irradiation pretransplant conditioning (>12 Gy), and the use of a peripheral blood, versus BM, progenitor cell source. In the majority of cases, karyotypic abnormalities in t-MDS and AML are demonstrable in pretransplant marrow or autograft specimens, implicating the mutagenic effects of conventional dose therapy in the initiation of the myelodysplastic clone, which often antedates administration of the transplant conditioning regimen ([193]).

The cytotoxic agents that are implicated in the pathogenesis of t-MDS extend beyond the classic alkylators. Treatment with the ß-emitter phosphorus-32 for polycythemia vera heightens the incidence of t-MDS to 10 to 15%, far exceeding the low intrinsic propensity that is attributed to the disease itself (less than 5%) ([182],

[194], [195]). The latent interval from treatment to emergence of MDS is much longer (11 years) than that observed after treatment with alkylating agents. Less commonly, topo-isomerase II (Topo II)–interactive agents, such as the anthracyclines and the epipodophyllotoxin, etoposide, may be associated with the development of secondary myeloid malignancy ([196], [197] and [198]). In the vast majority of cases, the MDS phase is brief or absent with rapid conversion to AML, which generally occurs within 1 to 3 years after completion of therapy. Unlike radiation- or alkylator-induced myeloid malignancies, those malignancies that are related to anthracycline or epipodophyllotoxin treatment often harbor a balanced chromosome translocation or abnormality that affects chromosome 11q23.

With the exception of Topo II–associated malignancies, 60 to 80% of t-MDSs harbor numerical or structural deletions of chromosomes 5 or 7 ([31], [199], [200], [201] and [202]). Although deletions of these particular chromosomes are common in *de novo* MDS, their frequency is far greater in treatment-related cases. These similarities in cytogenetic pattern have heightened concern that *de novo* and secondary MDS (s-MDS) share pathogenetic features. Although fewer than 15% of patients with MDS have a history of treatment with cytotoxic agents, occupational or environmental exposure to potentially genotoxic chemicals has been implicated in the disease pathogenesis. People who are exposed to benzene for prolonged periods have a 5- to 20-fold excess risk of myeloid malignancy, which includes MDS ([203], [204]). Like therapeutic alkylators, the leukemia risk in exposed workers rises in direct proportion to the duration and intensity of cumulative exposure ([203], [204], [205] and [206]). Epidemiologic studies indicate that other agents, including solvents, petrochemicals, and insecticides, may contribute to an excess risk of MDS or AML ([207], [208]). Indeed, in case-controlled studies, a greater frequency and intensity of exposure to petrochemicals and other solvents is demonstrable in patients with *de novo* MDS ([209]). This association is not evident in all studies ([210], [211] and [212]). Tobacco smoke, which contains a number of leukemogens, including nitrosamines, benzene, and polonium-210, has not been addressed in the pathogenesis of MDS. Case-controlled studies support an association between cigarette smoking and adult AML and therefore imply a similar relationship for MDS ([213], [214], [215], [216] and [217]).

Genetic polymorphisms that predispose to differences in capacity to detoxify chemical mutagens may contribute to individual differences in MDS susceptibility ([218]). The genes that encode glutathione- *S*-transferases, for example, which conjugate glutathione to DNA-reactive electrophiles, show considerable genetic and corresponding functional polymorphisms in humans ([219]). Case-controlled studies suggest that the *GST*-theta1 null genotype, alone or when associated with the *GST*-mu-1 null phenotype, is associated with a fourfold or greater excess risk of MDS in some populations ([218], [220], [221]). However, this association has not been confirmed in all studies ([222], [223]). Recent investigations suggest that null polymorphisms of two or more glutathione- *S*-transferases increase susceptibility to the mutagenic effects of breast cancer chemotherapy or environmental toxins ([224], [225]). Similarly, high- and low-activity polymorphisms of the microsomal epoxide hydrolase (*HYL1*) and nicotinamide adenine dinucleotide phosphate–quinine oxidoreductase (*NQO1*) genes, respectively, have been linked to greater risk of and specific chromosome abnormalities in AML ([226], [227]). Observations such as these suggest that heritable deficiencies of enzymes that are involved in mutagen detoxification may heighten the risk of MDS, raising hope that chemoprevention may modify disease risk in the future.

Reports of t-MDS or AML harboring chromosome 5 and 7 abnormalities that emerge after treatment with dose-intensive anthracyclines and all- *trans*-retinoic acid for acute promyelocytic leukemia suggest that the mutagenic effects of Topo II inhibitors may be modified by interaction with non-DNA-targeted antineoplastics ([228], [229] and [230]). Indeed, emergence of Ph chromosome–negative myelodysplastic clones in CML patients who achieve complete Ph suppression with imatinib (Gleevec) has raised consideration that such clones reflect the reemergence of genetically unstable clones that preceded acquisition of the *BCR/ABL* translocation ([231], [232]).

For the majority of adults, there is no family history or identifiable genetic predisposition. Although MDS is uncommon in people younger than 50 years of age, the prevalence of familial disease is greatest in this age group. In one series of 550 adults with *de novo* MDS, fewer than 7% of patients were younger than 50 years of age ([233]). Familial MDS clusters accounted for 14% of patients in the younger cohort, a frequency that is 35 times greater than that estimated for older patients. Although MDS is rare in childhood, approximately one-third of cases result from a genetic predisposition (Table 83.6) ([85], [86]). The most important heritable condition is trisomy 21 ([86]). Children with Down syndrome are 10 to 30 times more likely to develop acute megakaryoblastic leukemia, which is estimated to occur in 1% of affected children overall ([234]). As much as 50% of cases are preceded by MDS that is associated with the acquired chromosome abnormalities trisomy 8 or monosomy 7 ([235]). Other, less common, constitutional karyotypic abnormalities include trisomy 8 mosaicism and familial monosomy 7 ([85], [88], [236], [237] and [238]). The precise molecular disturbance that is responsible for the excess myeloid malignancy risk in the latter constitutional abnormalities remains unknown. In an investigation of children with monosomy 7–associated malignancy, loss of paternal alleles was evident in the majority of cases, suggesting that a simple gene dosage effect may contribute to the risk ([239]). Other heritable conditions include the DNA repair deficiency syndromes Fanconi anemia, ataxia-telangiectasia, and Bloom syndrome. Congenital disorders, such as neurofibromatosis 1 (NF1) and the congenital neutropenia syndromes, Kostmann agranulocytosis and Shwachman-Diamond syndrome, may antedate development of MDS ([240], [241] and [242]). The identification of activating point mutations of the G-CSF receptor gene in myeloid progenitors of patients who experienced the malignant transformation of Kostmann syndrome raised concern that treatment with this cytokine may increase the risk of malignant transformation.

TABLE 83.6. Predisposing Factors and Epidemiologic Associations

Heritable predisposition
Constitutional genetic disorders
Down syndrome (trisomy 21)
Trisomy 8 mosaicism
Familial monosomy 7
Neurofibromatosis 1
Germ cell tumors (embryonal dysgenesis)
Congenital neutropenia (Kostmann syndrome or Shwachman-Diamond syndrome)
DNA repair deficiencies
Fanconi anemia
Ataxia telangiectasia
Bloom syndrome
Xeroderma pigmentosum
Mutagen detoxification (GSTq1-null)
Acquired
Senescence
Mutagen exposure
Genotoxic therapy
Alkylators
Topoisomerase II interactive agents
ß-emitters (phosphorus-32)
Autologous bone marrow transplantation
Environmental or occupational exposure (e.g., benzene)
Tobacco
Aplastic anemia
Paroxysmal nocturnal hemoglobinuria
Polycythemia vera

Other BM disorders that are known to affect stem cell development may predispose to MDS and AML. The best characterized of these disorders include PNH and aplastic anemia ([243], [244] and [245]). In either disorder, hematopoietic clones are deficient in glycosyl phosphatidyl inositol–anchored membrane proteins in approximately 20% of affected patients and associate with a specific major histocompatibility complex (MHC) phenotype, HLA-DR15 ([135], [246], [247]). The high

predisposition for MDS development and MHC association suggests that a disturbance that is intrinsic to the PNH clone per se or a common immune pathogenesis may be responsible. Indeed, the incomplete hematologic recovery that is observed in patients with aplastic anemia who are treated with immunosuppressive therapy implies persistence of an intrinsic stem cell defect. The incidence of secondary myeloid malignancy, MDS in particular, ranges from 13 to 25% at 10-year observation; frequencies that exceed the prevalence of the PNH defect in aplastic anemia ([248], [249]). Multipotential differentiation of malignant germ cells may explain the association between extragonadal germ cell tumors and hematologic malignancies, which include MDS. The latter may occur concurrently or may succeed clinical recognition of yolk sac malignancies, but they typically harbor the same karyotypic abnormality isochromosome (12p) ([250], [251], [252] and [253]).

BIOLOGIC FEATURES

The hematologic features in patients with MDS reflect an uncoupling of proliferation and differentiation programs within hematopoietic progenitors. As a result, ineffective hematopoiesis prevails, evidenced by BM hypercellularity, excess intramedullary cell death, and peripheral blood cytopenias ([254], [255], [256], [257] and [258]). Appropriate activation of growth arrest signals is a requisite for terminal differentiation of hematopoietic precursors. Evidence to date indicates that unimpaired cell cycle transition represents an inherent disturbance in MDS that contributes in part to the disease pathobiology. Cellular homeostasis in MDS is profoundly disturbed and is characterized by a high proportion of cells proliferating and undergoing programmed cell death ([160], [161]). This kinetic imbalance represents a dynamic continuum, such that the apoptotic index exceeds the proliferative rate in lower-risk MDS, whereas, in more advanced disease, apoptotic escape emerges despite a sustained elevation in proliferative fraction ([259]). Up-regulation of antiapo-ptotic proteins, such as Bcl-2 and Bcl-X_L, occurs with apoptotic suppression, creating a milieu that is favorable for leukemia transformation ([259], [260]). Compared to *de novo* AML, the apoptotic index is higher in RAEB and RAEB-t, providing a biologic distinction between these related disease entities ([261], [262]).

In patients with pure sideroblastic anemia (RARS), dyserythropoiesis predominates, and impairment of progenitor growth is often restricted to the erythroid lineage ([23], [263], [264]). Ferrokinetic studies indicate that ineffective erythropoiesis is greatest in this FAB category, which may account for the erythroid hyperplasia characteristic on BM examination ([254], [255]). The profound disturbance in erythropoiesis may be compounded by abnormalities in mitochondrial iron metabolism. Multiple, but generally inconsistent, mitochondrial cytochrome defects are demonstrable in RARS that may contribute to or result from deposition of insoluble ferritin iron, the biochemical hallmark of this specific MDS subtype ([23], [265], [266] and [267]). This finding is associated with impaired cell cycle transition, which limits entry of erythroid progenitors into S phase, impaired protein synthesis, and accelerated cell death. Aberrant internuclear junctions that are evident on cytologic examination may add to intramedullary red cell loss ([129], [268]).

Clonogenic growth of multipotent and primitive erythroid progenitors, as well as long-term culture-initiating cells, is nearly uniformly deficient ([269], [270], [271] and [272]). With the exception of CMML, MDS progenitors exhibit impaired response to growth factor stimulation, despite normal cytokine receptor display, intact ligand binding capacity, and appropriate receptor signal activation ([271], [273], [274], [275] and [276]). *In vitro* proliferative response of erythroid precursors to erythropoietin (EPO) appears normal; however, excessive apoptosis supersedes with terminal differentiation, corresponding to maturation-dependent overexpression of fas ligand ([276]). As a consequence, the proportion of apoptotic cells is greater in differentiating erythroid precursors compared to the progenitor population ([161]). Susceptibility to fas ligand–induced programmed cell death varies with cytogenetic abnormality and disease stage. Fas (CD95) expression and susceptibility to ligand-induced apoptosis are increased in $CD34^+$ cells that are derived from patients with trisomy 8, whereas the opposite is true for monosomy 7 or isolated 5q interstitial deletions ([277]). CD95 receptor density on $CD34^+$ cells inversely correlates with blast percentage, whereas fas ligand density remains preserved, indicating that fas-resistant myeloblast populations emerge with disease progression ([278], [279]). Investigations that demonstrate improved cloning efficiency and reduced apoptosis with fas blockade support an effector role for death receptor-mediated apoptosis in lower-risk patients ([280], [281]). Membrane expression of the tumor necrosis factor (TNF)-related apoptosis-inducing ligand receptors and corresponding susceptibility to cell death that is induced by TNF-related apoptosis-inducing ligand are similarly increased in MDS compared to normal $CD34^+$ progenitors ([282]).

Accumulating evidence indicates that regulation of apoptosis and death receptor/ligand display arises from a complex interaction between the myelodysplastic clone and the microenvironment. Medullary apoptosis often occurs in cellular clusters that encompass hematopoietic and stromal elements, implicating local generation of aptogenic molecules ([160], [283]). TNF-a and interferon-? cooperate to up-regulate CD95 in normal marrow $CD34^+$ cells and to restore fas ligand susceptibility ([284], [285] and [286]). As described previously, fas receptor and ligand display are up-regulated in myelodysplastic $CD34^+$ cells, permitting autocrine and paracrine triggering of the cell death program ([278], [287], [288]). Overproduction of aptogenic cytokines, including TNF-a, macrophage inhibitory protein-1a, transforming growth factor-ß, IL-1ß, and interferon-?, is demonstrable in the BM microenvironment and the plasma of patients with MDS ([160], [284], [285], [289], [290] and [291]). *In vitro* neutralization of TNF-a enhances the outgrowth of hematopoietic progenitors in MDS ([287]). Similarly, elevations in plasma TNF-a correlate with oxidative DNA injury and depletion of cellular glutathione in the $CD34^+$ compartment, as well as caspase-3 activity, thus supporting an effector or potentiating role for these cytokines in the ineffective hematopoiesis of MDS ([291], [292]). Monocytes, macrophages, and stromal elements have been identified as the cellular origin of medullary aptogenic cytokine production ([283], [290], [293]). Accelerated loss of hematopoietic precursors may also occur through cellular immune-mediated cytotoxicity in selected patients, illustrating overlap with aplastic anemia. Oligoclonal hematopoietic inhibitory T lymphocytes with class I MHC antigen restriction act as cellular effectors of ineffective hematopoiesis ([294]). In approximately 11% of patients, clonal expansion of an NK-like cell population with a phenotype ($CD8^+$, $CD57^+$, $CD56^+$) that is analogous to large granular lymphocytes is demonstrable, suggesting pathogenetic overlap with large granular lymphocytic leukemia ([295]).

Recent investigations indicate that autocrine production of angiogenic molecules promotes expansion of the leukemic clone while fostering the generation of aptogenic cytokines. Vascular endothelial growth factor (VEGF), in particular, the principal regulator of neovascularity in solid tumors, is overexpressed concordantly with its high affinity receptors (VEGFR-1 or VEGFR-2, or both) by myeloblasts and malignant monocytes ([296]). BM neovascularity increases in proportion to marrow blast percentage, implicating myeloblasts per se as the principal source of angiogenic molecules ([297], [298], [299] and [300]). VEGF neutralization suppresses *in vitro* leukemia colony formation in advanced MDS, whereas recombinant human VEGF stimulates leukemia colony formation, supporting an autocrine role in expansion of the leukemic clone ([296], [301]). Central medullary clusters of myeloblasts (i.e., ALIP) display VEGF competence, overexpressing VEGF and VEGFR-1, providing the first biologic insight into the pathogenesis of this morphologic and prognostic feature. Paracrine induction of inflammatory cytokines from receptor-competent endothelial cells and macrophages may augment ineffective hematopoiesis. *In vitro* neutralization of VEGF suppresses the generation of TNF-a from MDS BM stroma while promoting recovery of multipotent and erythroid progenitors ([296]). Such findings implicating autocrine production of VEGF as a potentially important feature of the malignant phenotype in MDS have facilitated development of novel therapeutic strategies for these disorders.

Although impaired progenitor growth is the hallmark of MDS, two distinct syndromes, CMML and JMML, represent distinct exceptions. Both disorders are characterized by exuberant and spontaneous proliferation of granulocyte-macrophage (colony-forming unit–granulocyte-macrophage) progenitors in clonogenic assays ([23], [302], [303]). Autocrine and paracrine production of a number of cytokines, including IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-1, and TNFa, have been implicated in the propagation of myeloid colonies ([304], [305], [306], [307] and [308]). GM-CSF neutralization extinguishes spontaneous colony formation in CMML and JMML, implicating selective hypersensitivity to this growth factor in this unique biologic feature ([304], [306], [307], [309]). Although our understanding of the biology of these disorders derives largely from investigations of JMML, both disorders share overlapping biologic features. Mitogenic response to GM-CSF requires RAS activation ([310]), and constitutive activation that results in expanded RAS–guanosine triphosphate (GTP) pools is demonstrable in the majority of patients. Constitutive Ras signaling is demonstrable in 40 to 70% of cases of adult CMML, resulting from activating point mutations of *RAS* alleles or from reciprocal chromosome translocations that deregulate receptor tyrosine kinases (RTKs) ([43], [311], [312]). Although *RAS* mutations are detected in fewer than 20% of cases of JMML ([313]), 30% of patients harbor inactivating mutations of the neurofibromin 1 gene (*NF1*), which encodes a GTP hydrolase (GTPase) activating protein (GAP) that negatively regulates RAS by accelerating GTP hydrolysis ([314]). Reciprocal translocations that involve chromosomes 5q33 or 8p11 create novel fusion genes that involve the PDGF-ß and Fibroblast growth factor receptor V (FGFR1) RTKs, respectively, and corresponding constitutive RTK signaling ([43], [315], [314], [315], [316], [317], [318] and [319]). Although a number of chromosomes and genes may partner in the gene rearrangements (Table 83.7), the clinical phenotype is distinct and is recognized by the WHO classification as CMML with eosinophilia. Transgenic mouse models have confirmed that these novel RTK fusion genes, which activate PDGFRß, are singularly responsible for these myeloproliferative disorders and are selectively responsive to RTK inhibitors ([315], [320], [321]).

TABLE 83.7. Tyrosine Kinase Fusion Genes in Chronic Myelomonocytic Leukemia with Eosinophilia

Fusion Gene	Translocation
ZNF198-FGFR1	t(8;13)(p11;q12)
FOP-FGFR1	t(6;8)(q27;p11)
CEP110-FGFR1	t(8;9)(p11;q33)
BCR-FGFR1	t(8;22)(p11;q22)
ETV6-PDGFRB	t(5;12)(q33;p13)
HIP1-PDGFRB	t(5;7)(q33;q11)
H4-PDGFRB	t(5;10)(q33;q21)
RAB5-PDGFRB	t(5;17)(q33;p13)

MOLECULAR AND CYTOGENETIC ABNORMALITIES

Epigenetic events, such as methylation silencing of the cyclin-dependent kinase inhibitor, p15, may override or compound genetic aberrations to heighten the risk for leukemia transformation. Aberrant methylation of promoter CpG islands contributes to repression of gene transcription in human malignancies and, in MDS in particular, has been implicated in the epigenetic silencing of the p15 protooncogene ([322], [323]). Methylation silencing of p15 is rare in patients with MDS and low leukemia burden but is detected in more than 75% of cases with excess blasts and occurs uniformly with progression to AML.

In keeping with the approach in the present chapter, the classification of MDS according to the FAB group ([16]) (Table 83.2) is followed, because cytogenetic results in MDS that are based on the WHO classification ([39]) (Table 83.3) are too sparse for consideration.

Even though MDS progresses not infrequently to AML, specific changes that are seen in this leukemia, such as t(8;21) in M2, t(15;17) in M3, and inv(16) in M4, although encountered, are rare in MDS. However, the overall karyotypic similarity between MDS and AML strongly emphasizes the pathogenetic relationship between these two disorders. The cytogenetic data support the view that at least some MDSs represent a continuum of early preleukemia phases. Thus, a patient may progress from RA through RAEB and RAEB-t to reach the end stage of overt AML. It is uncertain whether the transition from MDS to AML always requires additional genomic changes. At the cytogenetic level, it is common not to see secondary aberrations during the transition of MDS to AML, although examples to the contrary also exist.

More than 3500 karyotypes, appearing in more than 800 publications, have been described in MDS ([425]). Although there exists considerable heterogeneity among these karyotypes, which may be complex in a significant number of cases, some of the MDS subtypes are characterized by recurrent cytogenetic (karyotypic, chromosomal) abnormalities, and some of the chromosomal changes occur nonrandomly among the various MDS subtypes. These areas and some other facets of the cytogenetics of MDS are addressed in the following paragraphs. Space limitations and other considerations preclude an exhaustive review of the large literature on the cytogenetics and molecular genetics in MDS, and, hence, only the salient aspects of these areas, with appropriate references, are presented in this chapter.

Clonal chromosome abnormalities occur in 30 to 50% of successfully karyotyped cases of *de novo* MDS and in approximately 80% of s-MDS and t-MDS ([425], [426]). The cytogenetic abnormalities that are seen in MDS strongly support the view that MDSs are of truly neoplastic nature, and the nonrandom distribution of these abnormalities has helped classify the cytogenetic changes that are probably primary and others that represent karyotypic evolution as the disease progresses toward an increasingly aggressive phenotype. The characteristic chromosomal changes that are encountered in MDS include a large number of rearrangements (translocations, deletions, inversions, and insertions) and a lesser number of numerical changes (monosomies and trisomies).

Cytogenetic Changes That Are Associated with Clinical Subtypes of Myelodysplastic Syndrome: 5q– Syndrome

Although deletions of 5q may be observed in a whole spectrum of *de novo* and therapy-related AML and MDS, the *5q– syndrome* has a rather narrow definition. A deletion of 5q in patients with RA was first reported by Van den Berghe et al. ([427]) in 1974, and the clinical state associated with it is now known as the *5q– syndrome*. This syndrome occurs primarily in elderly women and is associated with therapy-resistant macrocytic anemia, a normal or elevated platelet count, and an increased number of megakaryocytes with characteristic morphologic abnormalities (e.g., hypolobulated nuclei) ([428]). The clinical course is usually mild, and transformation to AML is rare, especially in patients with 5q– as the only cytogenetic change. There is general consensus that the deletion of 5q in this syndrome is interstitial, with the breakpoints that are most frequently cited being 5q31-q33, although some heterogeneity of the breakpoints may exist, ranging from bands 5q12 to 5q35.

The molecular basis of the 5q– syndrome has been the subject of much investigation, although the putative tumor-suppressor gene for the syndrome remains undetermined. The common deleted region of the 5q– syndrome has been narrowed to an approximately 1.5-megabase interval at 5q32 flanked by D5S413 and the *GLRA1* gene ([429]). This region contains 40 genes, 33 of which are expressed in $CD34^+$ cells and therefore represent candidate genes, because they are expressed within the hematopoietic stem and progenitor cell compartment. Good candidates for the 5q– syndrome include *MEGF1* and *G3BP*, among others. The common deleted region in the 5q– syndrome is distinct from that of the del(5)(q31) in AML and some other more aggressive forms of MDS ([430], [431]).

Refractory Anemia

More than 500 cases of RA with karyotypic changes have been reported; generally, the changes are less extensive than they are in other subtypes of MDS (1.7 aberrations per RA case vs. 1.9 aberrations for unselected MDS) ([432]). The most common chromosomal changes in RA are del(5q), -7, and +8. The del(5q) is found in at least 50% of RA cases, is clearly the most common change in MDS, and is often a sole abnormality ([433]).

Refractory Anemia with Ringed Sideroblasts

Approximately 20% of RARS cases have clonal cytogenetic changes that are similar to the percentages that are seen in RA ([27], [338], [339]), in contrast to almost 40% in MDS as a whole. The types of karyotypic changes that are seen in RARS are not markedly different from those in other MDS subgroups ([432], [433]). The nonrandom changes include trisomy 8 (+8), the most common change, which occurs in one-third to one-fourth of all abnormal RARS cases, followed by del(5q), which is seen in 50% of RA but only in approximately 25% of RARS, a frequency that is similar for MDS overall. Next in frequency are -7, del(11q23), and del(20q), each of which is seen in approximately 10% of RARS cases. Increased iron stores in the marrow have been reported in RARS with del(11q23) ([434]); the latter may be associated with therapeutic exposure to epipodophyllotoxins ([198], [435]). Translocations with 11q23 may involve a number of different partners, such as 2p22, 19p13.3, 19p13.1, 4q21, 6q27, 1p32, 16p13.1, 10p13, and 17q25 (in decreasing order of frequency). In a significant number of the cases with 11q23 involvement, the *MLL* gene is affected.

Although deletion of 20q may occur in a number of myeloid disorders, it is not uncommonly seen in RARS. These deletions appear to be interstitial in nature (apparently always encompassing 20q11.2-q12). The nature of the genes that are affected by these deletions has not been established with certainty.

Refractory Anemia with Excess Blasts and Refractory Anemia with Excess Blasts in Transformation

RAEB and RAEB-t are more frequently associated with chromosomal changes than RA and RARS, with the frequency of these associations ranging from 45 to 60% versus 20 to 30%, respectively. Thus, the incidence and the extent of cytogenetic changes in MDS seem to be roughly proportional to the number of myeloblasts in the marrow ([426]). The same karyotypic aberrations that are seen in other MDS subgroups are also seen in RAEB and RAEB-t. Thus, a deletion of 5q is the most frequent structural anomaly (25% of cases). Monosomy 5 (-5) is relatively common (10% of cases) but is rare in this subgroup, as in other *de novo* MDSs, as a solitary aberration. Monosomy 7 (-7) is more common (25% or more of cases) in RAEB-t than in any other subtype of MDS. Among other abnormalities, such as del(11q), it is more common in s-MDS than in the *de novo* variety of disease. Del(7q), like monosomy 7, is more commonly found with other karyotypic aberrations than as the only change. The extent of del(7q) varies among cases. Trisomy 8 (+8) is another common change in RAEB-t, as it is in other subtypes of MDS, occurring in approximately 15 to 20% of cases.

Chronic Myelomonocytic Leukemia

Although CMML is not included among the MDS in the WHO classification, it has been included in most of the studies on chromosome changes in MDS and hence is discussed in this section. Cytogenetic changes occur in approximately one-third of the cases, with monosomy 7 (-7) and +8 being the most common and, often, the sole abnormality. Loss of the Y chromosome in males is seen more frequently in CMML than in other MDS subgroups, and may possibly be related to the age of the patient, and may not be involved in the neoplastic process. A specific translocation t(5;12)(q13;p13) has been reported in CMML ([436]) that leads to a fusion gene *TEL-PDGFB* ([43]). Some of the molecular consequences of this translocation are mentioned in the section on Molecular Changes in Myelodysplastic Syndrome. Other translocations that result in tyrosine kinase fusion genes in CMML are shown in Table 83.7. The infrequent occurrence of 5q– in CMML sets this leukemia somewhat apart from other MDS forms and has been used as an indicator that CMML may not belong to the MDS group of disorders ([39]).

Some Aspects of Common Cytogenetic Abnormalities in Myelodysplastic Syndrome: Partial Trisomy of 1q

Involvement of 1q is not uncommon in MDS (and AML) and can take the form of partial trisomy of this arm through a number of different translocations, such as der(Y;1)(q12;q12), der(1;7)(q10;p10)(p10), der(1;15)(q10;q10), der(16)t(1;16)(q11;q11), der(1;18)(q10;q10), der(1;19)(q21~q23;p13.3), and dic(1;10)(p11;p11) ([437], [438], [439], [440] and [441]).

Rearrangements of 3q26

Generally, patients with rearrangements at 3q26 have received prior therapy with an alkylating agent for an unrelated disease. Dysmegakaryopoiesis is present in 90% of cases that carry an inv(3)(q21q26) or t(3;3)(q21;q36). An activated or inappropriate expression of the *EVI1* oncogene that is located at 3q26 is observed. However, *ETV1* is also activated in 30% of MDS without 3q rearrangements ([442]). Patients with a t(3;21)(q26;q22) (Fig. 83.9) usually exhibit thrombocytopenia. This translocation has also been observed in CML and leads to a fusion between *ETV1* at 3q26 and *AML1* at 21q22 ([443]). The involved genes in the t(3;5)(q25;q34) are *MLF1* and *NPA*, respectively ([444]).

Figure 83.9. Karyotype of a bone marrow cell from a patient with myelodysplastic syndrome (MDS) that contains some of the common changes that are seen in this disease: 45,XY,t(3;21) (q26.3;q22), del(5)(q13q33), and -7. These changes are compatible with those seen in secondary MDS or therapy-related MDS.

Other 5q Deletions

The 5q– anomaly is found in all myeloid-derived cells, including megakaryocytes, monocytic cells, erythroblastic-derivative cells, and, in rare cases, even in B cells ([445], [446]) in MDS, including the 5q– syndrome. Deletions of the long (q) arm of chromosome 5 are generally interstitial (Fig. 83.9), often with a proximal breakpoint between bands 5q13 and 5q22 and a distal breakpoint between bands 5q32 and 5q35, although deletions may be seen outside these regions ([447], [448] and [449]). The type of deletion is often correlated with clinical features. For example, the most common type of deletion, del(5)(q13q33), is predominant in women, shares clinical features with the 5q– syndrome, and carries a relatively good prognosis. Efforts are still in progress to determine the molecular events in 5q deletions because of the highly complex and heterogeneous genetic features that result from deletion of the 5q region, which suggest that more than one gene is responsible. Many growth factors and growth factor receptors have been localized to 5q31-q33, such as GM-CSF, IL-3, IL-4, IL-5, and IL-9. Other genes within the same region have also been investigated, such as *ERG1* tumor-suppressor genes; *CDC25C*, a G2 checkpoint gene; *IRF1*, which encodes an interferon regulatory factor ([450]); *FMS*, the gene that encodes the receptor for *CSF1*; and the *ETF1* gene at 5q31 ([451]). At present, one is led to the conclusion that the role of oncogene and tumor-suppressor gene changes at the causative level and subsequent progression in MDS with 5q– (including the 5q– syndrome), remains uncertain.

Deletion of 7q (7q-) and -7

Changes of chromosome 7 are common in MDS, especially in RAEB, RAEB-t, and CMML; these changes are particularly evident in s-MDS or t-MDS and are associated with a shorter survival than in MDS cases with other cytogenetic changes ([426]). In 80% of cases with chromosome 7 involvement, deletions of the long arm occur mainly in two important regions: proximal breakpoints in 7q11-q22 and distal breakpoints in 7q31-q36. In the remaining cases, deletions are observed in the 7q32-q33 region ([452]). The smallest overlapping region that is deleted is 7q22, which contains genes that are involved in DNA repair mechanisms (i.e., *EPO*, *PLANH1*, and *ASNS*). Their role in the pathogenesis of MDS is still unclear.

Monosomy 7 is frequently observed as an isolated chromosome aberration in adults with MDS who are younger than 50 years of age ([233]), whereas, in older patients, it is associated with other chromosome abnormalities ([453]). It can be readily detected by FISH analysis. It is the most frequent chromosome change that is seen as the sole abnormality in MDS in children who are younger than 4 years of age. Monosomy 7 syndrome occurs predominantly in boys with splenomegaly, thrombocytopenia, and a poor prognosis and may not be readily separated from JMML, which also shows monosomy 7 in 25% of cases ([88]). Monosomy 7 is also found in childhood preleukemic disorders that may evolve to MDS and AML, such as Fanconi anemia, Kostmann syndrome, Shwachman-Diamond syndrome, NF1, and a rare type of the so-called familial MDS ([454]). Because cells with -7 (as well as those with +8) have a proliferative advantage *in vitro*, it has been recommended that, to more accurately quantify the exact incidence of -7 in the marrow, FISH or other similar approaches on interphase nuclei should be used to determine the true incidence of -7 rather than that obtained by conventional cytogenetic techniques ([453], [455]). Deletion of 7q in MDS may progress to complete loss (monosomy) of this chromosome, an event that is usually associated with clinical progression of the disease. Paradoxically, progression of 5q– to -5 is seldom seen.

The familial occurrence of complete (-7) or partial monosomy 7 (7q–) in association with MDS (or AML) has been reported. Although a hypothesis of a germ-line mutation of a tumor-suppressor gene on chromosome 7 as a first step in the pathogenesis of these cases had been advanced ([456]), the fact that -7 may be of different parental origin (456a) argues against such a hypothesis and points to an inherited mutation in any of a group of mutator genes as a more likely cause of familial -7 in the absence of a recognized mendelian disease.

A significant association of -7 with expression of the multidrug resistance P-170 glycoprotein has been observed ([457]). *RAS* gene mutations or loss of the *NF1* gene are thought to be critical events in the pathogenesis of MDS with 7q–.

11q23 in Myelodysplastic Syndrome

Translocations that involve 11q23 are well established changes in acute leukemia, as well as in t-MDS and s-MDS, usually affecting the *MLL* gene at 11q23. Recurring translocation partners are 9p22, 19p13.3, 19p13.1, 4q21, 6q27, 1p32, 16p13.1, 10p13, and 17q25, in order of frequency. These translocations are relatively rare in primary MDS ([426]). Breakpoints at 11q outside the *MLL* gene have been reported in *de novo* MDS, that is, t(11;21)(q24;q11), which is frequently associated with 5q– ([458]) and inv(11)(p15q22), resulting in fusion between the neucleoporin gene (*NU98*) and an RNA helicase gene (*DDX10*) whose transcript is thought to interfere with hematopoietic differentiation ([459]). For clinical involvement and a variety of other aspects of involvement of 11q23, see the report of a special workshop ([460]). Band 11q23 translocation breakpoints are DNA Topo II cleavage sites and involve the *MLL* gene in translocation processes ([461], [462]).

12p Deletions (12p–)

Deletions of 12p may occur as sole cytogenetic events in MDS or may be part of a more complicated karyotype ([463], [464]). These deletions are usually interstitial between 12p11 and 12p13, with the latter being most commonly affected and quite unstable ([465], [466]); both TEL (*ETV6*) and *CDKN1B* genes are generally deleted ([467], [468]). However, FISH studies have revealed that some of these deletions have hidden rearrangements of *TEL* (*ETV6*) that are located at 12p13.1. Although the t(5;12)(q33;p13) was first described in patients with CMML ([469]), it has been observed in other MDS types and is frequently associated with eosinophilia and monocytosis ([436], [470]). The translocation results in a fusion transcript between the genes *TEL* (*ETV6*) at 12p13 and *PDGFRß* at 5q33 ([43]). Variant translocations that involve chromosomal regions, such as 1p36, 3q26, 5q31, 6p21, 9q22, and 10q24, have been described as fusion partners of *TEL* (*ETV6*) in MDS ([470], [471], [472] and [473]).

It has been suggested that the fusion *ETV6/PDGFRß* gene leads to high tyrosine kinase activity of *PDGFRß*, with malignant transformation due to an altered *RAS* signal transduction pathway ([43]). In the *TEL/PDGFRß* fusion, *TEL* contributes to the amino-terminal oligomerization domain, which is critical for the activation of *PDGFRß* ([468]). Inversions of chromosome 12, paracentric and pericentric—for example, inv(12)(p13p15) and inv(12)(p15q24)—have been described in some cases of MDS, with the abnormality occurring as the sole karyotypic change in some of the cases ([474], [475] and [476]).

17p Deletions (17p–)

Unbalanced rearrangements of chromosome 17 may result in 17p deletions, such as t(5;17)(p11;p11), t(7;17)(p11;p11), or i(17)(q10). Generally, del(17p) is associated with other chromosome abnormalities. A particular type of dysgranulopoiesis, which combines pseudo–Pelger-Huët hypolobulation of the nucleus and small vacuoles in neutrophils, is seen in some cases of MDS with 17p–. Of interest, the same type of dysgranulopoiesis is seen in CML in blast crisis that exhibits an i(17)(q10) ([477]). These patients usually have point mutations in *TP53* with a poor response to chemotherapy and short survival ([341]). The 17p anomaly is found in *de novo* MDS but more frequently in patients who received chemotherapy or radiation therapy, or both ([478]). The *TP53* gene acts as a tumor-suppressor gene that is involved in the control of the cell cycle, DNA repair, and apoptosis. The incidence of *TP53* mutations in MDS is 2 to 5% of the cases ([479]).

Deletions of (20q)

Deletions of interstitial nature in the long arm of chromosome 20 (20q) are seen in approximately 5% of MDS, primarily affecting the erythrocytic and megakaryocytic lineages ([480]). The crucial region that is lost in MDS has been delineated (between D20S174 and D20S17) at which a number of tumor-suppressor genes may be located ([175]).

X Chromosome Changes

Loss of an X chromosome in some female patients with MDS has been shown with FISH to affect blast cells, as well as myeloid elements of the marrow ([481]). A typical structural rearrangement (isodicentric chromosome X) with a breakpoint at Xq13 has been proposed for some cases of RARS ([482]). Xq13 may be involved in translocations in MDS without sideroblasts ([483]).

Trisomy 8 (+8)

Trisomy 8 is a frequent aberration in MDS, and is the most common among trisomies ([484]), and appears to be confined to the myeloid elements of the marrow, as is shown by FISH studies ([485]). In rare and unusual cases, lymphocytes may show +8 ([486]). Trisomy 8 may be present as the sole cytogenetic change in MDS or with other chromosome abnormalities. The molecular basis for the effects of +8 in MDS and AML remains undetermined ([487]). The incidence of +8 as a sole cytogenetic change in MDS and related conditions varies in relation to gender, age, prior genotoxic exposure, and cell morphology ([488]). Clonal evolution from +8 to tetrasomy 8 (+8,+8) may be associated with development of AML from MDS ([489]). An interesting observation is the presence of a constitutional mosaicism for +8 in 15 to 20% of cases of MDS and AML ([490]). Functional impairment of the $CD34^{+}/CD38^{-}Thy\text{-}1^{+}$ hematopoietic stem cell pool in patients with trisomy 8 (+8) has been reported ([491]). It is associated with an intermediate prognosis.

Other Trisomies in Myelodysplastic Syndrome

Trisomy of whole chromosomes, besides the +8, may be seen in various subtypes of MDS, as well as in AML. Trisomy 14 may occur as a sole abnormality ([492]) or as part of a more complicated karyotype. This trisomy may be seen in several subtypes of MDS ([493]) and carries with it a rather poor prognosis ([492]).

Trisomy 15, with or without sex chromosome loss, may be present as a sole change in MDS or as part of a more complicated karyotype ([494], [495]). The anomaly tends to occur in elderly patients. Rare trisomies in MDS involve chromosomes 11 (+11) ([496]), 13 (+13) ([497], [498]), 19 (+19) ([499]), and 21 (+21) ([500]). Although these trisomic changes are seen more often in acute leukemia, and their significance in MDS is relatively uncertain, they may play a part in the leukemic transformation of MDS.

Trisomy 6 appears to be a nonrandom karyotypic change that may be helpful to differentiate between true aplastic anemia and rare MDS with aplastic BM ([501]).

Gene Amplification in Myelodysplastic Syndrome

Gene amplification, which is usually associated with resistance to chemotherapy, may be identified cytogenetically as double-minute chromosomes (dmins) and as homogeneously staining regions ([426]). Although rare in MDS, such changes have been found in all subgroups of MDS ([502], [503]). They may represent the only karyotypic change but are more often associated with 5q–, +4 (associated with *C-MYC* amplification), or trisomy 6 (+6) ([502], [503], [504] and [505]). Overexpression of the multidrug resistance gene (*MDR-1*) leads to the accumulation of a glycoprotein that is named P-170, which acts as a transmembrane drug efflux pump. High expression of P-170 may be seen at diagnosis of MDS, mainly in cells with an immature phenotype, $CD34^{+}$ or, in early committed myeloid cells, $CD13^{+}$ and $CD33^{+}$ ([388], [457]). A high risk of leukemic evolution exists in these cases. Monosomy 7 (-7) is a karyotypic change that has been related to P-170 expression ([457]). Amplification of the *MLL* gene in cases of MDS with dmin or homogeneously staining regions has been reported ([506]).

Secondary and Therapy-Related Myelodysplastic Syndrome

s-MDS is an entity in which a toxic cause for the disease can be established with some certainty. It is possible that a still unknown and possibly significant portion of *de novo* MDS is in fact of so-called secondary nature, particularly those MDSs with changes of chromosomes 5 and 7 (i.e., 5q–, -5, 7q–, and -7) ([426]). s-MDS (and AML) may also develop after exposure to genotoxins, besides those related to therapy of specific diseases. Such genotoxins include occupational exposure to chemical solvents, insecticides, and petroleum products. These exposures are frequently associated with loss of material from chromosomes 5 and 7 ([432]).

Generally, t-MDSs are much more aggressive clinically than *de novo* MDS and demonstrate recurrent cytogenetic changes, depending on the therapy that is administered. Therapy-related hematologic disease follows treatment of malignancies in 0 to 20% of patients, depending on the patient population, the treatment strategies used, and the follow-up time. Balanced translocations after topoisomerase inhibitors, affecting especially bands 11q23 and 21q22, have been described ([197]).

s-MDS or t-MDS is more often associated not only with cytogenetic changes (80 to 85% vs. 45% of cases) but also with more aberrations than *de novo* MDS ([507]). Complex and hypodiploid karyotypes are more common in t-MDS than in *de novo* MDS. Furthermore, s-MDS and t-MDS more frequently evolve into AML than *de novo* MDS with or without additional cytogenetic abnormalities that accompany or cause the transformation. Thus, the cytogenetic information on secondary AML is

relevant to s-MDS and t-MDS, and, in fact, such information shows considerable overlap ([426]).

The most frequent cytogenetic abnormalities in s-MDS and t-MDS are -7 (41%), 5q– (28%), and -5 (13%), followed by der(21q), +8, 7q–, der(12p), t(1;7), -12, -17, der(17p), der(3p), der(6p), and -18. Clones with single aberrations were seen in nearly 50% of the cases. Monosomy 7 (-7) was found to be more common in t-MDS after chemotherapy with alkylating agents, whereas 5q– was associated with exposure to ionizing radiation ([507]).

An international workshop dealt with balanced rearrangements that were seen in 20 to 30% of MDS ([508]) after therapy for other disorders ([509]). The crucial role of DNA Topo II inhibitors in the development of these t-MDS was stressed, that is, balanced translocations that involved 11q23 (and the *MLL* gene), inv(16)(p13q22) (and rearrangements of the *CBFB* and *MYH11* genes), t(15;17)(q22;q12) (and the *PML* and *RARA* genes), and t(8;21)(q22;q22) (and the *ETO* and *AML1* genes), as well as a number of rare balanced aberrations, some of which were rather unique in nature. The occurrence of these changes, which was generally thought to be specific for some *de novo* AML subtypes, in t-MDS was addressed at the workshop. The reader is referred to the full report of this workshop for correlations of the previously mentioned cytogenetic changes in t-MDS with clinical and prognostic parameters, as well as more complete cytogenetic data. For example, the data suggested that involvement of the *MLL* gene may be more closely associated with epipodophyllotoxins, whereas the anthracyclines were associated more often with 21q22 aberrations ([509]).

Some MLL breakpoints that are induced by Topo II inhibitors *in vitro* map to preferred sites ([462]). The 3' portion of the MLL bcr is one of these sites, and, in one series of t-AML patients, MLL breakpoints mapped close to this site. A new target gene in t-MDS and AML, *NUP98*, in chromosome band 11p15 has been implicated because of its recurrent involvement in several different chromosome rearrangements, such as inv(11)(p13q22), t(11;17)(p15;q21), t(11;12)(p15;p13), t(7;11)(p15;p15), t(11;20)(p15;q11), t(2;11)(q31;p15), and t(4;11)(q21;p15). The mechanisms that underlie these translocations are unclear. A role of DNA Topo II in the generation of the 11p15 translocations has been suggested because of the finding of 4–base pair (bp) microduplications at the breakpoints of derivative chromosomes, which implies that these translocations were initiated by a 4-bp staggered DNA break.

Molecular Changes in Myelodysplastic Syndrome

Not all molecular genetic changes in MDS are reflected in the cytogenetic abnormalities that are encountered in these disease states, nor have all the cytogenetic abnormalities been translated into defined molecular genetic events. A number of genes has been reported to be affected or involved in MDS, with the possibility that some of these changes may play a primary role in the pathogenesis of these diseases, whereas others may be secondarily affected.

RAS mutations may be an early or late change in MDS, but the relation to transformation to AML remains uncertain ([510] , [511] , [512] , [513] , [514] and [515]), although some studies point to *RAS* mutations in MDS as being associated with disease progression and poor survival ([511] , [516] , [517]).

Acquired *RAS* gene mutations (mainly *N-RAS*) are found in 20 to 40% of MDS and AML cases ([512]). Although some correlation of *N-RAS* mutations with the cytogenetic changes in MDS (5q-, -7, and +8) may exist, such mutations may be seen in the cells of MDS cases with normal karyotypes ([512] , [518]). As a consequence of mutation, the active RAS-GTP is not inactivated to its guanosine diphosphate counterpart with consequent up-regulation of a signal transduction pathway. *N-RAS* mutations have been preferentially associated with the monocytic component of MDS and an increased risk of progression to AML ([511]). An overexpression of the p21 product of *RAS* has been found in nearly 30% of MDS ([519]). Involvement of *N-RAS* (located on chromosome 2), *H-RAS* (located on chromosome 11), and *K-RAS* (located at 12p12) does not correlate with the karyotypic rearrangements of these chromosomes in MDS. However, a case of MDS with a typical t(5;12) and *K-RAS* overexpression has been reported ([469]).

In addition to oncogenic point mutations, two other mechanisms in which *RAS* may be deregulated have been implicated in myeloid disorders. As mentioned previously, a specific translocation t(5;12)(q33;p13) has been described in CMML, leading to a fusion gene *TEL-PDGFB* ([43]), which is assumed to be oncogenic owing to constitutive receptor activation and, therefore, increased *RAS* activation ([520]). This event appears equivalent to constitutive activation of the c-*FMS* receptor, which is also known to occur in MDS and AML.

The neurofibromatosis gene *NF1* encodes a GAP that is responsible for inactivating *RAS* ([521]), and, thus, children with defects of *NF1* have deregulated *RAS* activation that may possibly be related to their predisposition to MDS and AML ([319]). However, in adult cases, inactivating *NF1* mutations are uncommon ([522] , [523] , [524] and [525]). It appears that the most common method of *RAS* activation in adult MDS (and AML) is by point mutations of the *N-RAS* and, to a lesser extent, the *K-RAS* genes ([512]).

The protein product of the gene *NF1*, neurofibromin, has extensive homology with the catalytic domain of GAPs, such as p120 ^{GAP}, which are known to accelerate the intrinsic GTPase activity of p21 ^{ras} proteins. Hence, the loss of *NF1* may mimic the effect of oncogenic *RAS* point mutations that cause high constitutive RAS-GTP levels ([526] , [527]). Decreased levels of NF1 protein have been found in the BM of patients with MDS ([528]).

Involvement or loss of the *FMS* gene (located at 5q33) in the 5q– anomaly ([529]) remains uncertain in view of mutations that are seen in MDS that have also been found in normal individuals ([530]). The core-binding factor (CBF) complex is a heterodimeric transcription factor that is composed of two subunits, CBFa (located at 21q22) and CBFß (located at 16q22), that play a major role in hematopoiesis. Both members are frequently altered by translocations or inversions. In contrast to *AML1* gene mutations in t-MDS and t-AML, none of CBFß was seen in these states ([531] , [532]).

The role played by cell cycle regulators, such as the cyclin-dependent kinase inhibitor genes (located at 9p21), which produce p15 and p16, has not been elucidated in MDS ([322] , [533]). The *DCC* gene (located at 18q21) appears not to be affected in MDS ([534]). The hypermethylation of the calcitonin gene (located at 11p15) has been a controversial finding in MDS ([535] , [536]).

Apoptosis (programmed cell death) is an active cellular process that regulates cell population size by decreasing cell survival ([162]). Increased apoptosis may play an important role in the early pathogenesis of MDS, a mechanism that may be responsible for the paradox of marrow hypercellularity and peripheral blood pancytopenia in MDS ([537]). Involvement of mitochondria and mutations of their DNA in MDS remains to be more clearly elucidated ([538] , [539]).

Comment

In all probability, gene expression profiling of MDS, as has been done in some leukemias, will reveal hitherto unrecognized genetic changes ([540] , [541] and [542]) that will be of aid in the classification, prognosis, and understanding of MDS. FISH and spectral karyotyping ([447] , [543] , [544]), as well as comparitive genomic hybridization, have revealed chromosomal changes in some MDSs, including RA, that are not seen with G-banding ([545]), including the demonstration that a substantial number of MDS cases with del(5q) are, in fact, der(5) as a result of unbalanced translocations. In more advanced stages of MDS, del(5q) has been shown to be associated with dmin (representing gene amplification) that originate from the deleted long arm of chromosome 5.

Although much has been learned about some of the genetic pathways leading to *de novo* and t-MDS ([546]) and the impact of cytogenetic changes on the prognosis of these syndromes (Table 83.8 and Table 83.9) ([162] , [497] , [547]), the basic events underlying MDS remain essentially unknown ([262]).

TABLE 83.8. Survival and Leukemic Transformation According to French/American/British (FAB) Subtype

FAB Subtype (%)	Median Survival in Months (Range)	Percent of Leukemic Transformation (Range)
RA (25)	37 (19 to 64)	11 (0 to 20)
RA with ringed sideroblasts (18)	49 (21 to 76)	5 (0 to 15)
RA with excess blasts (28)	9 (7 to 15)	23 (11 to 50)

RA with excess blasts in transformation (12)	6 (5 to 12)	48 (11 to 75)
Chronic myelomonocytic leukemia (17)	22 (8 to 60 +)	20 (3 to 55)
All patients		19

RA, refractory anemia.
NOTE: Based on data relating to 1914 patients compiled from nine reports (references 20, 24, 287, 288, 289, 290 and 291, 293, 361).

TABLE 83.9. Prognosis in Myelodysplastic Syndrome According to Cytogenetic Findings

Prognostic Category	Karyotypic Change	Median Survival (Mo)
Good	Normal	>24
	del(5q) alone	
	del(20q) alone	
Intermediate	+8	18
	Single karyotypic anomaly	
	Double abnormalities	
	Other changes	
Poor	Complex karyotypes	<12
	Chromosome 3 changes	
	Chromosome 7 changes	

PROGNOSTIC FEATURES

The MDSs display remarkable clinical, pathologic, and cytogenetic heterogeneity, thereby necessitating careful scrutiny of prognostic features to optimize treatment decisions. The FAB classification enjoyed widespread acceptance because of its prognostic usefulness, owing almost entirely to the impact of graded differences in blast percentage on leukemia transformation and cytopenic complications (20, 324, 325, 326, 327, 328, 329, 330 and 331). Despite this, prognostic distinctions are readily discernible within each of the three ranges of blast percentage: less than 5% (RA and RARS), 5 to 20% (RAEB), and 21 to 30% (RAEB-t) (Table 83.10). For example, although the FAB classification includes Auer rods as a diagnostic criterion for RAEB-t, inclusion of cases harboring fewer than 20% blasts does not carry the same prognostic connotation. In one large series of patients, RAEB-t cases classified solely by the presence of Auer rods had a median survival that was approximately 41 weeks longer than that of patients whose marrow blast percentage exceeded 20% (138). There remains considerable heterogeneity within other FAB types, indicating that factors other than leukemia load impact survival within morphologically defined subgroups. These features can be segregated into four categories that reflect leukemia burden, lineage penetrance and severity of the maturation defect, genetic and molecular abnormalities, and clinical and pathologic features (Table 83.10). Independent of blast percentage, an increased fraction of CD34 + cells in the BM or peripheral blood, a leukemic pattern of growth progenitor, and ALIP are recognized surrogate markers of survival and leukemic potential (24, 59, 332, 333). The number of cytopenias and lineages displaying cytologic dysplasia, as well as the severity of cytopenias, provides an index of the penetrance and severity of the maturation disturbance. In RARS, for example, patients with hematologic abnormalities that are restricted to the erythroid lineage have a median survival of approximately 76 months, compared to 24 months for patients with a multilineage disturbance (264). For this reason, the term *pure sideroblastic anemia* has been adopted by the WHO to distinguish such patients from those with a multilineage hematopoietic disturbance.

TABLE 83.10. Prognostic Factors in Myelodysplastic Syndrome

Leukemia burden
French/American/British type
Abnormal localization of immature precursors
In vitro culture pattern
Lineage penetrance and severity of maturation impairment
Number of cytopenias
Number of dysplastic lineages
Cytopenia severity
Fraction CD34 + cells
Genetic abnormalities
Cytogenetic pattern
DNA ploidy
Protooncogene mutations
Clinical and pathologic features
De novo versus therapy-related myelodysplastic syndrome
Myelofibrosis
Abnormal localization of immature precursors
Granulocytic sarcoma

Cytogenetic abnormalities offer additional prognostic discrimination (29, 334, 335, 336, 337, 338, 339 and 340). Although the presence of one or more chromosome abnormalities is generally associated with an inferior survival compared to a normal karyotype, three specific abnormalities, when present as a simple chromosome abnormality, are associated with a more favorable clinical course. These include del(5q), del(20q), and monosomy Y. Other karyotypic abnormalities that are associated with rapid progression of disease and an otherwise unfavorable clinical course include monosomy 7 and del(7q), trisomy 8, abnormalities of 3q26, del(12p), iso(17q), and complex cytogenetic abnormalities. DNA aneuploidy and the presence of point mutations affecting *ras* and the p53 protooncogenes adversely affect the risk of leukemic conversion and overall survival in most series (61, 341, 342).Clinical and pathologic features are also informative. s-MDS or t-MDS exhibits trilineage hematopoietic dysplasia that is associated with rapid conversion to acute leukemia and short overall survival (5). Granulocytic sarcomas occur in 5% of patients, a frequency that approaches the incidence in myeloproliferative disorders (107, 110). The most common sites of extramedullary involvement include the skin, lymph nodes, and nasal sinuses. Emergence of a granulocytic sarcoma is a harbinger of leukemic transformation that may precede medullary progression by months. Finally, the presence of excessive medullary fibrosis, or so-called hyperfibrotic MDS, is associated with an inferior survival that approximates that for RAEB (75, 77, 78, 343, 344). To what extent any of these prognostic factors are independent predictors of disease outcome is not clear, and, for this reason, scoring systems that incorporate hematologic, cytogenetic, and clinical features have been constructed that serve as reproducible and validated prognostic models (42, 326, 327, 328 and 329). The IPSS was developed and has been accepted as a consensus risk-adapted model for MDS since its inception in 1997 (42). The IPSS represents the culmination of data analysis from more than 800 patients with *de novo* MDS and nonproliferative CMML (i.e., white blood cell =12,000/µl). This prognostic model applies a score

that is weighted according to statistical power for each of three features: BM blast percentage, cytogenetic pattern, and the number of cytopenias (Table 83.11). The cumulative score enables discrimination of patients into four subgroups with varying expectations for survival and risk of and interval to AML progression (Table 83.12). Although age offers further survival discrimination in lower-risk patients (i.e., low and intermediate-1 risk), it has no correlation with risk for leukemia evolution and therefore is not included in the prognostic model. Proliferative CMML was excluded from the IPSS model; however, a number of disease specific prognostic variables have been identified from retrospective analyses, including blast percentage as recognized by the WHO classification, white blood cell or monocyte count, anemia, thrombocytopenia, lactate dehydrogenase, and spleen size ([112], [345], [346]). The M. D. Anderson Prognostic Score was developed as a prognostic model specific for CMML based on data that were collated from more than 200 consecutive patients ([347]). Variables with independent prognostic significance include hemoglobin, absolute lymphocyte count, circulating immature myelomonocytic cells, and BM blast percentage. Grading of these variables permits stratification of patients with CMML into four prognostic categories, with an expected median survival ranging from 5 to 24 months (Table 83.13).

TABLE 83.11. International Prognostic Scoring System

Prognostic Variable	0	0.5	1	1.5	2
Bone marrow blast percentage	<5	5 to 10	—	11 to 20	21 to 30
Karyotype [a]	Good	Intermediate	—	Poor	—
Cytopenias	0/1	2/3	—	—	—

[a] Good, normal, -Y, del(5q), del (20q); poor, complex (= three abnormalities) or chromosome 7 anomalies; intermediate, other abnormalities.

MANAGEMENT

To date, no treatment other than hematopoietic stem cell transplantation offers significant curative potential in MDS; however, an improved understanding of disease biology has led to development of novel therapeutics that may alter the natural history of the disease. Management recommendations should be guided by the risks imposed by the disease itself, the patient's age, morphologic type, and performance status. Selection of treatment reflects the intended therapeutic goal as judged by prognostic category and patient preference. To ensure that new therapeutics are judged by uniformly accepted measures of benefit, an international working group proposed criteria for hematologic, BM, and cytogenetic response to be applied to all MDS clinical trials ([348]). Implicit in these recommendations is the notion that patients with low- or intermediate-1–risk IPSS categories experience longer survival, and therefore, amelioration of hematologic deficits should represent the principal therapeutic goal, whereas, in higher risk patients, extending survival is of immediate priority, allowing incorporation of complete pathologic and cytogenetic remission as an early surrogate milestone for survival extension.

Low- and Intermediate-1–Risk Myelodysplastic Syndrome

In lower-risk MDS, treatment with recombinant human EPO (rhu-EPO) may improve anemia and reduce transfusion requirements in 15% of unselected patients ([349], [350]). The potential for benefit with rhu-EPO that is administered alone or in combination with a myeloid growth factor, such as G-CSF, inversely correlates with EPO level and red blood cell (RBC) transfusion burden. Those patients with suboptimal endogenous EPO response to anemia (i.e., pretransfusion serum EPO < 100 mU/ml) and moderate to low transfusion requirement (=2 U packed RBCs per month) have a response probability that exceeds 70%, whereas greater transfusion burden or EPO level, or both, substantially diminish response expectation (=23%) (50a,50b). A recent report suggests that response rate to rhu-EPO may be improved by the addition of intermittent oral all *-trans*-retinoic acid ([351]), which merits further investigation. A younger individual (younger than 55 years of age) with lower-risk disease that fails traditional hematopoietic promoting therapy may be considered for allogeneic stem cell transplantation. Recognizing that the latter has an inherently high procedure-related mortality (15 to 35%), novel disease-targeted therapies with the potential for durable erythropoietic remitting activity should be considered before proceeding to hematopoietic stem cell allografting.

Innovative approaches to restore effective blood cell production in lower-risk disease have targeted biologic effectors of ineffective hematopoiesis. In nearly all circumstances, ineffective erythropoiesis represents the most pervasive and responsive hematopoietic deficit. Such targeted therapeutics include immunosuppressive therapy with antithymocyte globulin (ATG) or cyclosporin A, or both; the phosphoaminothiol amifostine; angiogenesis inhibitors, such as thalidomide or one of its structural analogs; and TNF-a inhibitors. Recognition that immunologic suppression of progenitor growth may contribute to impairment of hematopoiesis in hypocellular variants led to recent trials using immunosuppressive therapy. Earlier studies using corticosteroids were complicated by an unacceptable risk of infection ([352]). Nevertheless, clinical response correlated with the capacity of corticosteroids to enhance *in vitro* growth of myeloid colonies. Treatment with cyclosporin A or ATG offers high response rates in appropriately selected candidates with lower-risk disease ([353], [354], [355], [356] and [357]). Approximately one-third of patients with RBC transfusion-dependent MDS and low leukemia burden (<15% blasts) were successfully managed with a single course of ATG (40 mg/kg for 4 days) in a National Institutes of Health trial, restoring transfusion-independence that was sustained in 87% of responders beyond 2.5 years ([357]). Although results of randomized comparative trials are not as yet mature, single institution series suggest that erythropoietic response is associated with longer survival and time to disease progression compared to nonresponders. Many patients who are responsive to immunosuppressive therapy harbor hematopoietic-inhibitory T lymphocytes, and can

be identified prospectively through clinical and biologic features ([283], [294]). Indeed, four or more of the following features, including hypocellularity, age younger than 60 years, RA morphologic category, normal karyotype, PNH antigenic phenotype, or HLA class II DR2/15 MHC expression, yielded a 90% major erythropoietic response probability in the National Institutes of Health trial ([247], [357]). In unselected patients, the response rate is low, with significant treatment-associated morbidity ([358]).

Organic thiols neutralize oxygen free radicals generated in response to apoptotic signals and improve apoptotic defense in hematopoietic progenitors ([359]). Amifostine is a phosphorylated aminothiol developed as a radioprotectant that augments MDS progenitor colony-forming capacity while preserving maturation capacity ([360]). In a phase I and II clinical trial ([361]), amifostine administered intravenously three times per week yielded a more than 50% increase in neutrophil count in 78% of subjects and improved erythropoiesis or thrombocytopenia in 33% and 43% of patients, respectively. Subsequent phase II trials, using more stringent response criteria, suggest that response rates are lower when amifostine is used as a single agent ([362], [363] and [364]). Administration of this cytoprotectant in combination with other antiapoptotic agents may be a potentially more effective means to ameliorate ineffective erythropoiesis and represents a fertile avenue for further investigation ([365]).

Strategies intended to suppress the generation of apopto-genic cytokines or to inhibit the action of angiogenic molecules have shown considerable promise. Thalidomide displays antiangiogenic and anti-TNF-a properties and represents the most extensively investigated antiangiogenic agent ([366]). In a phase II trial of thalidomide in MDS, 15 of 51 evaluable patients (29%) who completed 12 weeks of treatment experienced RBC transfusion independence or a more than 50% decrease in transfusion burden after a median interval of 16 weeks, whereas responses in other lineages were uncommon ([367]). The erythropoietic potential of thalidomide in MDS is currently under investigation in a national, randomized, placebo-controlled trial. Nevertheless, other institutional studies have confirmed its erythropoietic activity ([368]). Although an active agent, cumulative neurotoxicity limits the necessary prolonged drug administration or significant dose escalation. Novel, more potent thalidomide analogs that are devoid of neurological toxicity are currently completing phase II investigation ([369], [370]). Preliminary results of a clinical trial investigating the immunomodulatory analog, CC5013 (Celgene Inc, Warren, NJ) indicate a greater than 50% erythropoietic remitting activity (i.e., transfusion-independence) in lower-risk MDS with fewer side effects than the parent compound ([371]). Treatment with TNF-a selective agents, such as soluble cytokine receptors [etanercept (Enbrel)] or neutralizing humanized monoclonal antibody (infliximab), have demonstrated only modest erythropoietic benefit ([372], [373] and [374]).

Primary management for many patients remains largely supportive, including administration of RBC transfusions for symptomatic anemia, platelet transfusions for bleeding, and the judicious use of hematopoietic cytokines. Particular attention must be given to the potential for iron overload, which may ensue when the cumulative transfusion burden exceeds 30 U, but it can be delayed by the administration of an iron chelator, such as desferrioxamine ([375]). Empiric treatment with hematinic supplements, such as folate, is generally not beneficial unless vitamin deficiency is present. Rare patients with RARS may experience hematologic improvement with pyridoxine supplementation. In view of its low cost and tolerance, an empiric trial is warranted in symptomatic patients. Androgens and corticosteroids seldom yield sustained hematologic benefit ([376], [377]).

The recombinant myeloid growth factors G-CSF and GM-CSF restore granulocyte production in 75 to 90% of neutropenic patients ([378]). Initial concerns that such cytokines might accelerate leukemia transformation restricted their application to patients with low leukemic burden. In one of the few randomized trials performed in MDS, treatment with GM-CSF significantly reduced the frequency of infection, without adversely affecting disease progression, in neutropenic patients who were treated for 90 days ([379]). Nevertheless, given the excessive cost of these cytokines and the necessity for continuous administration, their use has been relegated to the management of neutropenic patients with intercurrent infection.

Intermediate-2– and High-Risk Myelodysplastic Syndrome

Given the limited life expectancy of patients with higher-risk MDS, management takes on greater urgency, with the immediate goal of extending survival by suppression of the malignant clone. Although allogeneic stem cell transplantation is potentially curative in 25 to 50% of younger (younger than 55 years of age) individuals, alternate strategies for the more infirm, elderly population range from low- and high-intensity chemotherapy to DNA methyltransferase inhibitors (DMTIs), reduced-intensity stem cell allografting, and investigational studies. Chemotherapy regimens applied in AML, which include cytarabine and an anthracycline, appear less active in advanced MDS and generally are not curative ([380], [381]). Randomized trials comparing induction chemotherapy to supportive care are lacking; however, intensive chemotherapy offers the potential to suppress leukemia burden, to provide interim improvement in cytopenias, and to yield sustained complete remissions in some patients. Topotecan and cytarabine combinations, popularized in recent years, offer no significant advantage over standard anthracycline-containing regimens and may have inferior remission durability ([381], [382]). Younger patients with RAEB-t are more likely to benefit from intensive chemotherapy, prompting recommendations that such patients may be more accurately regarded as oligoblastic presentations of *de novo* AML, as recognized by the WHO classification. Despite a comparatively high remission rate in this disease category, fewer than 10 to 20% of patients can be expected to remain in remission beyond 2 years. For this reason, selection of patients for intensive treatment should be based on features that are predictive of response to intensive chemotherapy. These include a normal karyotype, the presence of Auer rods, and younger age. Using these criteria, complete remission rates ranging from 70 to 85% can be expected in patients who are younger than 55 years of age, compared to remission rates of 25 to 45% in older patients ([383], [384] and [385]).

Strategies targeting an important mechanism of chemotherapy resistance in advanced MDS and secondary AML have emerged as a promising strategy for intensive induction therapy. P-glycoprotein (P-gp) is a highly conserved plasma membrane glycoprotein encoded by the *MDR1* gene that functions as an adenosine triphosphate–dependent multidrug exporter with broad specificity for natural product-derived antineoplastics ([386], [387]). P-gp is natively overexpressed by myeloblasts in RAEB-t, and secondary AML and is associated with a lower probability of complete remission and inferior disease-free survival ([388], [389] and [390]). A randomized phase III trial performed by the Southwest Oncology Group showed that concurrent treatment with the P-gp inhibitor cyclosporin A and infusional daunorubicin after cytarabine significantly reduces induction resistance in high-risk patients and significantly prolongs not only the duration of remission, but also overall survival ([391]). Similar results were reported in a French Cooperative Group study that used quinine as a P-gp modulator ([392]), indicating that this targeted induction strategy may significantly extend survival for selected individuals who are candidates for more intensive therapy. Low-dose cytarabine or melphalan monotherapy offers an outpatient alternative to intensive remission induction therapy with reduced treatment-related morbidity but may result in prolonged myelosuppression while inducing remissions in fewer than 30% of patients ([393], [394], [395] and [396]). Low-dose cytarabine has received the most scrutiny, yielding response rates ranging from 10 to 25% in phase II trials but offering no benefit compared to supportive care in a National Cancer Institute–sponsored intergroup study that involved all FAB types ([393]). Nevertheless, selected higher-risk patients may benefit from low-intensity chemotherapy, necessitating scrutiny of predictive variables ([394]).

Stem cell allografting after high-dose chemotherapy and radiotherapy conditioning remains the standard of care for younger individuals. Patients with lower-risk features (e.g., IPSS intermediate-1), normal or more favorable cytogenetics, and a histocompatible related or volunteer donor have a probability for sustained remission and possible cure that ranges between 40 and 60% ([397], [398] and [399]). Despite its obvious benefits, allogeneic hematopoietic stem cell transplantation remains a high-risk procedure with a mortality of 25 to 40% that rises directly with age. A number of factors influence the outcome of stem cell allografting by impacting the probability of relapse or the risk of procedure-related complications. Variables, such as the percentage of blasts, cytogenetic pattern, IPSS risk category, and treatment-related MDS versus *de novo* MDS, affect the probability of relapse after transplantation, whereas age, duration of disease, platelet count, and donor MHC compatibility impact treatment-related mortality. Knowing this, early allogeneic BM transplantation is justified within the first year of diagnosis to optimize procedure outcome in younger patients with limiting cytopenias or other risk factors. Autologous SCT after high-intensity conditioning offers greater safety; however, the risk of relapse is much higher and appears to be of limited value in older individuals ([400]). Reduced-intensity conditioning regimens that rely on donor immune response to eradicate the malignant clone carry lower procedure-related mortality, but conclusions as to long-term benefit and expectations for sustained donor engraftment are premature ([401]).

Less aggressive approaches targeting biologic features implicated in evolution of disease in MDS have shown considerable promise. DMTIs, 5-azacytidine (5-aza), and 5-aza-2'-deoxycytidine (decitabine), have undergone the most extensive clinical investigation ([402], [403], [404], [405] and [406]). Aberrant methylation of promoter CpG islands promotes recruitment of transcriptional corepressors and histone deacetylases, with consequent chromatin condensation and repression of gene expression in human malignancies. In MDS in particular, DNA hypermethylation has been implicated in the epigenetic silencing of the p15 protooncogene that is linked to leukemia transformation ([322], [323]). Global genomic hypomethylation induced by DMTIs results in derepression of previously silenced genes and, *in vitro*, differentiation of leukemia cell lines ([407]). A phase III trial performed by the Cancer and Leukemia Group B comparing subcutaneous treatment with 5-aza to best supportive care revealed a significant advantage in hematologic response rate (60% vs. 5%), time to leukemia transformation or death (21 months vs. 13 months), and frequency of AML transformation (11% vs. 31%), favoring 5-aza, with accompanying improvement in quality of life parameters ([405], [408]). A randomized trial of similar design

evaluating decitabine is nearing completion. Nonetheless, results of phase II investigations have provided proof of principle that this agent effectively restores p15 expression with a corresponding high rate of remitting activity ([406]).

Arsenic trioxide (ATO) (Trisenox, Cell Therapeutics Incorporated, Seattle, WA), recently received orphan drug designation from the Food and Drug Administration for the treatment of MDS. Arsenicals have a long history of application in human leukemia but only recently gained renewed recognition by virtue of activity in acute promyelocytic leukemia. ATO has multiple biologic effects that include apoptosis induction via disruption of survival signals, suppression of angiogenesis, and promotion of cellular differentiation ([409]). Phase II multicenter trials are ongoing in the United States and Europe to delineate its potential in advanced MDS. Preliminary results of the U.S. trial indicate that approximately one-third of patients treated with ATO may benefit by multilineage hematopoietic improvement or reduction in BM blast percentage, or both ([410]).

Activating point mutations of the *RAS* protooncogene are detected in fewer than 20% of unselected patients with MDS but are common in CMML. The *RAS* gene superfamily encodes GTPases that serve as critical regulatory elements in signal transduction, cellular proliferation, and maintenance of the malignant phenotype. Farnesylation represents the first posttranslational modification of Ras-GTPases that is necessary for plasma membrane association and transforming activity ([411]). The farnesyl protein transferase inhibitors are potent, orally bioavailable inhibitors of Ras activation and other prenylation-dependent molecules. These agents, as a class, are able to modulate multiple signaling pathways that have been implicated in the pathobiology or progression of CMML and MDS. Preliminary results of phase I and II studies in MDS and CMML indicate promising hematopoietic promoting activity that extends to nonerythroid lineages ([412] , [413]).

Perhaps the most important therapeutic discovery in the management of CMML in recent years is the activity of imatinib (Gleevec) in those patients harboring a reciprocal chromosome translocation involving chromosome 5q33 ([321]). These translocations are associated with the clinical phenotype of CMML with eosinophilia, as described by the WHO classification, and arise from the generation of novel fusion genes involving the PDGF-ß receptor with constitutive RTK signaling ([43] , [315] , [319]). Imatinib binds to the adenosine triphosphate binding pocket of the PDGF-ß receptor, analogous to its interaction with BCR/ABL, to act as a potent inhibitor of receptor kinase activity ([315]). Among the five patients reported to date, each achieved rapid hematologic control and sustained complete cytogenetic remission with imatinib monotherapy ([321] , [414]).

The retinoids have not yielded the hematologic potential hoped for in MDS but may have a role in selected patients, such as in those patients with the pediatric syndrome of JMML. Isotretinoin attenuates the spontaneous *in vitro* proliferation of myeloid progenitors that are characteristic of this disease ([415]). In one report, six of ten JMML patients treated with isotretinoin experienced a complete or partial remission characterized by normalization of the white blood cell count and resolution of organomegaly ([415]). Although treatment was well-tolerated, and responses were sustained, all patients had a normal karyotype and otherwise favorable prognostic features. It remains to be seen whether isotretinoin has remitting activity in high-risk patients. A variety of other agents have been tested in small numbers of patients without consistent benefit. In one series, the attenuated, synthetic androgen danazol ameliorated thrombocytopenia in as much as one-third of patients. However, responses were observed only in patients with antiplatelet antibodies and moderate thrombocytopenia (greater than 20,000/µl), indicating that patients with severe thrombocytopenia are least likely to benefit ([416]).

Since the 1980s, the number of patients diagnosed with MDS has steadily risen owing to the extended survival of the aging population. With current advances in the understanding of the pathobiology of MDS and with prognostic models to appropriately guide therapy, patients have access to an array of promising novel therapeutics with greater expectation for benefit. The identification of relevant biologic targets in MDS has raised expectations for the development of effective disease-specific therapies. Enrollment in clinical trials should be encouraged for patients in whom standard therapy offers the prospect for low probability of success.

Chronic Myeloid Leukemia

HISTORY

Chronic myeloid leukemia (CML) is a clonal stem cell disorder characterized by increased proliferation of myeloid elements at all stages of differentiation ([1]). Its incidence increases steadily with age. In the United States, the disease most commonly occurs in middle-aged adults. CML is characterized by two distinct clinical phases. The first (chronic) phase is marked by a proliferation of myeloid cells showing a full range of maturation. Eventually, a decrease in myeloid differentiation generally occurs, and the disease enters an advanced state (accelerated phase or blast crisis/phase) with a very poor prognosis.

CML was first described in the nineteenth century ([2], [3], [4], [5] and [6]), and research over the next 100 years focused on its clinical and morphologic features. In 1960, Nowell and Hungerford ([7]) documented an abnormal G-group chromosome in cells from patients with CML. This was the first time that a consistent chromosome abnormality had been documented in a human malignancy. The new marker was named the *Philadelphia chromosome* (Ph) in honor of the city in which it was discovered. In 1960, it was not possible to determine which of the small G-group chromosomes were involved in the formation of the Ph chromosome. However, with the advent of chromosomal banding in the 1970s, it was demonstrated that the Ph chromosome was actually a translocation between chromosomes 9 and 22, t(9;22)(p34.1;q11.21) ([8], [9]). In a small proportion of patients with CML, complex translocations have also been shown to occur, of which chromosome 22 is universally and chromosome 9 is usually involved ([1], [10], [11] and [12]).

During the 1980s, a series of investigators showed that the *ABL* protooncogene on chromosome 9 was reciprocally translocated near the *BCR* gene on chromosome 22 (Fig. 84.1) ([11], [13], [14], [15] and [16]). This genetic alteration resulted in the formation of a chimeric protein, BCR-ABL. The fusion product is generally expressed as a chimeric protein of 210,000 d molecular weight (called *p210*). p210 has tyrosine kinase activity and is overexpressed in freshly isolated cells and cell lines derived from patients with CML ([17], [18] and [19]). Subsequent investigators have demonstrated that p210 acts by releasing controls on stem cell proliferation or by blocking programmed cell death in ways that lead to CML. More recently, investigators have shown additional BCR-ABL breakpoints and novel fusion proteins of different sizes.

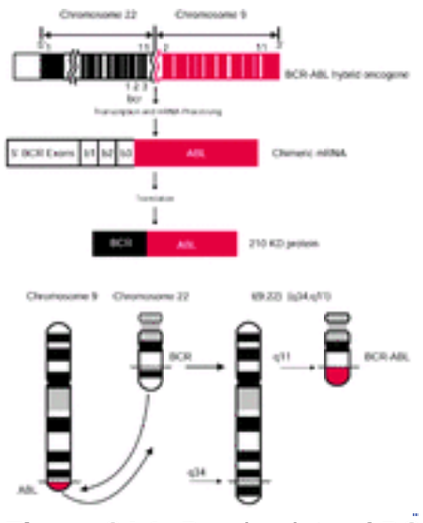

Figure 84.1. Breakpoints of BCR and ABL genes on chromosomes 9 and 22. mRNA, messenger RNA.

The continued growth in our understanding of the role of BCR-ABL chimeric protein in oncogenesis during the 1980s and 1990s has made CML a potentially curable disease. In addition, a wide variety of diagnostic tests, novel therapeutic interventions, and sensitive measures of therapeutic efficacy have evolved, all of which are discussed in this chapter.

INCIDENCE AND RELATIONSHIP TO OTHER MYELOPROLIFERATIVE DISORDERS

CML is principally a disease of adults, with a yearly incidence of 1 in 100,000 in Western countries ([20]). There is an increasing frequency with age, and the peak age of incidence is 53 years. Men are affected more often than women (3:2) ([21], [22]). It is uncommon in children and accounts for less than 5% of all childhood leukemias ([23]). The etiology of CML is unknown in most cases, although CML may develop after radiation exposure. Other environmental factors have not been well documented.

CML is one of several chronic myeloproliferative diseases (CMPDs; Table 84.1) ([24], [25]). *CMPDs* are distinct, but closely related, clonal disorders of pluripotential hematopoietic stem cells in the marrow. In all CMPDs, the proliferative capacity of the neoplastic stem cell is not properly controlled, and excessive hematopoiesis occurs initially. The neoplastic stem cell retains its ability to undergo complete differentiation, and, as a result, a marked increase in the number of mature and immature cells in the blood and bone marrow occurs. These differentiated neoplastic cells generally have few, if any, morphologic or functional abnormalities.

TABLE 84.1. Classification of Myeloproliferative Disorders

Typical chronic myeloid leukemia
  Morphologic variants
    Chronic eosinophilic leukemia
    Chronic basophilic leukemia
    Chronic neutrophilic leukemia
Essential thrombocythemia
Polycythemia vera
Idiopathic myelofibrosis
Chronic myelomonocytic leukemia, proliferative type
Atypical chronic myeloid leukemia

CMPDs are distinguished from each other by the predominant type of differentiation that the neoplastic stem cell undergoes [such as the myeloid line in CML or megakaryocytes in essential thrombocythemia (ET)]. Furthermore, CMPDs are progressive and may change from a disease with excessive production of well-formed and functioning cells to a disorder associated with bone marrow failure or transformation to acute leukemia. Despite the similar cell and tissue of origin, it is not possible to group and treat all CMPDs as one disease because there are differences in the prognosis and optimal treatment of CMPDs. Thus, proper diagnosis and distinction of these entities are imperative.

The most common CMPDs include CML, ET, idiopathic myelofibrosis, and polycythemia vera (Table 84.1) ([24], [25]). CML, ET, and polycythemia vera represent excessive proliferation and differentiation, predominantly along myeloid, megakaryocytic, and erythroid lineages, respectively. Idiopathic myelofibrosis has also been called *myelosclerosis with myeloid metaplasia* or *agnogenic myeloid metaplasia* and is characterized by excessive marrow fibrosis. Chronic neutrophilic leukemia (CNL) is uncommon and identified by excessive neutrophil production without the myeloid precursors seen in CML ([26], [27]). Recent findings indicate that most cases of CNL may actually be a subset of CML because a novel Ph chromosome may be detected in CNL resulting from a novel breakpoint of the *BCR* gene. Chronic myelomonocytic leukemia is generally viewed as a myelodysplastic syndrome; however, there is at least a subset of this disease that has clinical, histologic, and pathogenetic characteristics more consistent with a myeloproliferative disease ([28]). A small minority of cases of the hypereosinophilic syndrome have clinical and pathologic findings that allow classification as a CMPD and are sometimes called *chronic eosinophilic leukemia* ([29], [30], [31], [32], [33] and [34]).

CML may occur in children and is called *adult form CML*. On the other hand, juvenile CML, now referred to as *juvenile myelomonocytic leukemia* (JMML), and a related or identical process, *monosomy 7 syndrome*, have traditionally been classified as CMPDs, but more recent studies show that they are probably best thought of as myelodysplastic or preacute leukemic states ([35], [36]). JMML is morphologically, cytogenetically, and clinically distinct from adult CML ([37]). It is clinically aggressive and more similar in its course to acute myeloid leukemia (AML). Furthermore, in contrast to adult CML that occurs more often in adolescents, juvenile CML occurs more often in very young children. However, JMML is discussed in this chapter to distinguish it from CML.

Because CMPDs arise from a pluripotential stem cell that differentiates along all cell lines with only varying predominance along one or another cell line, it is not surprising that the clinical and morphologic features occasionally overlap, and classification and diagnosis are difficult. Fortunately, our understanding and ability to test for these disorders have grown, and most cases can be precisely defined. In particular, the advent of cytogenetics and molecular techniques has allowed for documentation of a simple or complex translocation between chromosomes 9 and 22, a finding required for diagnosis of CML. Despite the availability of these new techniques, there are some cases that clinically and histologically appear to be CML, but a t(9:22) cannot be demonstrated. Although these tumors are not related to CML pathogenetically or biologically, the World Health Organization has retained the term *atypical CML* or *Ph*(–) *CML* ([37]). These cases are quite heterogeneous and probably represent other myeloproliferative/myelodysplastic disorders or chronic myelomonocytic leukemia ([38], [39] and [40]).

CLINICAL PRESENTATION

The onset of symptoms in CML is usually insidious, with most patients presenting in chronic phase. In the past, symptoms of vigorous hematopoiesis (fever, sweats, bone pain, weight loss, and fatigue) or signs of extramedullary hematopoiesis (splenomegaly and left upper quadrant discomfort) caused patients to seek medical attention (Table 84.2) ([41], [42], [43], [44] and [45]). Occasionally, more unusual symptoms, such as bleeding, thrombosis, arthralgia, leukemic infiltration in sites such as the skin, peptic ulceration, spinal cord compression, and priapism, may be the primary presentation ([46]). However, with current medical practice, it is becoming more common for patients to be diagnosed before the development of any symptoms because of periodic routine medical evaluation with physical examination and laboratory testing. Estimates now indicate that 10 to 30% of patients are diagnosed before the development of symptoms ([21]). Approximately 10% of patients present in accelerated phase, and another 10% of patients present in blast phase.

TABLE 84.2. Symptoms and Signs of Chronic Phase Chronic Myeloid Leukemia at Presentation

Presentation of Chronic Myeloid Leukemia	Patients Experiencing Sign or Symptom (%)
Symptoms	
Fatigue	83
Weight loss	61
Abdominal fullness and anorexia	38
Easy bruising or bleeding	35
Abdominal pain	33
Fever	11
Signs	
Splenomegaly	95
Sternal tenderness	78
Lymphadenopathy	64
Hepatomegaly	48
Purpura	27
Retinal hemorrhage	21

By following multiple clinical parameters in untreated patients, previous investigators have constructed regression curves describing the chronology of clinical events in CML ([47]). These observations indicate that approximately 6 years elapse from the time of the initial chromosomal translocation until patients become symptomatic. Once a leukocytosis is present, it takes approximately 19 months (range, 7 to 24 months) for the white blood cell (WBC) count to reach 100,000/µl (Fig. 84.2). The median survival of patients with CML after diagnosis is approximately 4 to 5 years ([1], [48], [49] and [50]). Thus, the total duration of CML from its initiation appears to be approximately 10 years in the typical case. Increased absolute numbers of basophils are present in most patients early in the disease, even before the WBC count is elevated (Fig. 84.3). Anemia is not an early finding, but thrombocytosis is often noted. The leukocyte alkaline phosphatase (LAP) level generally is low, even when the WBC count is less than 20,000/µl, and falls further as the disease develops. The spleen rarely is palpable until the number of WBCs exceeds 40,000/µl, and symptoms usually appear when the WBC count reaches levels between 30,000 and 90,000/µl.

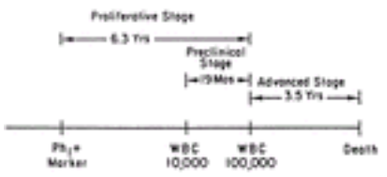

Figure 84.2. Putative phases and timing of chronic myeloid leukemia progression. Ph, Philadelphia chromosome; WBC, white blood cell count.

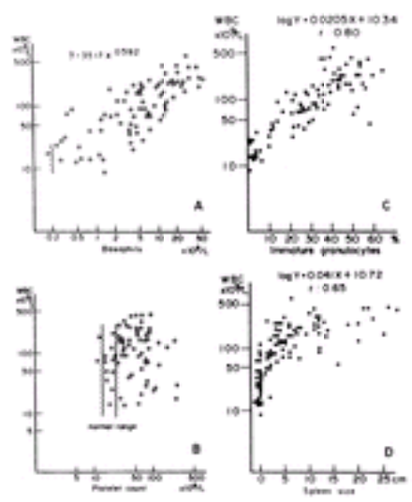

Figure 84.3. Relationship of leukocytosis to various clinical and laboratory parameters. WBC, white blood cell count.

At the time of presentation, the spleen varies in size, ranging from just a palpable tip to a mass filling the abdomen. Approximately 50% of patients have splenomegaly extending more than 10 cm below the costal margin at the time of diagnosis. Spleen size correlates reasonably well with the magnitude of the leukocyte count. The spleen is quite firm and usually nontender (unless splenic infarction is present), and the notch may be palpable. Hepatomegaly is less common. Splenic infarct is common and can herald the presentation of the illness. Sternal tenderness is a reliable sign of disease and usually is limited to a small area, most commonly the midbody (fifth intercostal space) of the sternum. If true sternal tenderness is present, the patient withdraws or complains spontaneously when firm pressure is applied to the tender area. Lymph nodes are palpable in most patients but rarely are greater than 1 cm in largest diameter.

In chronic phase, the distinction must be made with reactive leukocytosis ([51]). The distinction between CML presenting in lymphoid blast crises and Ph(+) acute lymphocytic leukemia (ALL) may be clinically difficult, and additional diagnostic procedures are necessary. CML may also present in myeloid blast crisis, which may be distinguished from *de novo* AML using ancillary testing. Diagnostic procedures to distinguish between these possibilities are discussed later in this chapter.

CLINICAL COURSE

The chronic phase is characterized by robust marrow proliferation and maturation, with the increased WBC usually not leading to clinical complications. Thus, emergent treatment for leukocytosis is not generally required. Sequelae of leukostasis are uncommon, although cases of papilledema, blindness, and stroke have been reported with extreme WBC elevations (above 250,000/µl) even when an excess of blasts is not present ([52]). On the other hand, blast crisis often causes leukostatic syndromes, as do other variants of AML, in which efforts to rapidly control the WBC count are mandatory.

In most untreated patients, a steady, progressive increase in the leukocyte count is observed. In some untreated patients and, occasionally, in patients receiving therapy, cyclic WBC variations occurring at 2- to 4-month peak-to-peak intervals may be noted (Fig. 84.4) ([53] , [54] , [55] , [56] and [57]). These cycles may be extreme, ranging from a normal count at the nadir to more than 200,000/µl. These WBC cycles represent an actual change in total body leukocytes rather than some form of leukocyte redistribution because cyclic changes in the size of the spleen and levels of serum B_{12} and lysozyme coincide with changes in leukocyte count ([56]). Reticulocytes and platelets may also cycle, although out of phase with neutrophils and myeloid precursors. Some evidence exists of in-phase cycling of basophils, eosinophils, monocytes, and nucleated red blood cells. Neutrophil LAP levels cycle in inverse relation to the leukocyte count ([53]). Because cytotoxic therapy usually is initiated as soon as the diagnosis has been established, the true frequency of cyclic leukocytosis in patients with CML is difficult to estimate. In defining clinical situations or in making therapeutic decisions, the possibility of a periodic fluctuating WBC, as opposed to poorly controlled blood counts, must be considered.

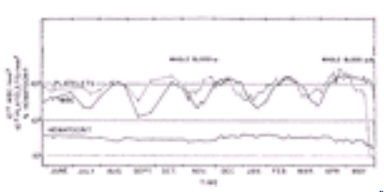

Figure 84.4. Cyclic variations in blood counts in chronic myeloid leukemia. WBC, white blood cell count.

Adverse clinical consequences of abnormal myeloproliferation are usually not seen during chronic phase ([58] , [59] and [60]). Patients with CML do not suffer from an increase in bacterial or fungal infections (which are normally prevented by adequate levels of neutrophils) until an advanced state of blast crisis. Platelet dysfunction is common in CML, and many patients present with some mild bleeding tendencies ([61] , [62] and [63]). Marked elevation of the platelet count to over 1,000,000/µl occasionally can be associated with an increased likelihood of thrombosis and warrants therapy to lower the platelet count ([64]). To avoid thrombosis, care should be taken to control the platelet count or to administer antiplatelet agents before splenectomy ([65]).

Patient performance status and quality of life are not altered in the chronic phase, especially if excellent blood count control is achieved. Unfortunately, chronic phase inexorably progresses to the more advanced states of disease. This progression to blast phase occurs at an approximate rate of 5% in the first year and 20 to 25% in each year thereafter ([48] , [49]). Once the blast phase is entered, long-term survival is uncommon, with most patients expiring within 3 to 6 months. Thus, in describing the natural history of CML, it is appropriate to denote either the development of blast crisis or overall survival as the important terminal outcome.

Subgroups of patients with different survival curves have been defined using multivariate analysis and Cox proportionate hazards models of presenting clinical features. Various parameters that have been included are the magnitude of initial elevation of the WBC count, extreme basophilia, massive hepatosplenomegaly, thrombocytopenia, thrombocytosis, multiple chromosomal abnormalities, male sex, poor performance status, black ethnicity, marrow fibrosis, and increasing patient age. Unfortunately, not all of these features have consistently affected survival, and recent attempts to use molecular sites of the BCR-ABL translocation have not led to improved prediction of survival ([66] , [67]).

Sokal et al. evaluated 813 patients with CML and found a median survival of 47 months, representing a good-risk group of patients ([68]). Features significant in this analysis include spleen size and the percentage of circulating blasts. These, along with age, behaved as a continuous variable. Other meaningful features included a platelet count above 700,000/µl, more than 15% basophils plus eosinophils, marrow blasts above 5%, and additional karyotypic abnormalities aside from the Ph chromosome. In a Cox proportionate hazards model, blast percentage, spleen size, platelet count, and age were developed into a model. Figure 84.5 demonstrates distinct survival curves, with median survival from 28 to 67 months.

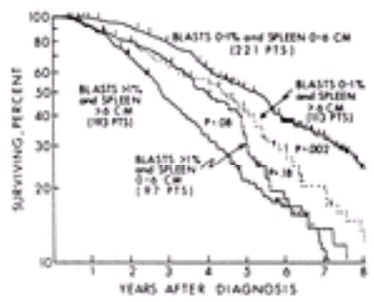

Figure 84.5. Survival curves of prognostic subgroups. PTS, patients.

Mosaicism, both Ph(+) and Ph(–) cells in direct marrow preparations, has been considered indicative of a good prognosis in most, but not all, series ([69], [70], [71], [72], [73] and [74]). Sokal described 22 patients with CML who had a mixture of Ph(+) and Ph(–) cells at the time of diagnosis ([69]). The survival of this group did not differ significantly from that in the total population of 195 patients with Ph(+) CML from which they were drawn ([75]).

Progression from chronic phase to the more advanced states is made by both clinical and laboratory features ([76], [77]). Clinical features indicating a more difficult-to-control marrow proliferative state suggest progression to accelerated phase. These include a rapidly rising WBC count that is more difficult to lower with antiproliferative agents, increasing organomegaly, fever, bone pain, and weight loss. Laboratory features include more immature cells in the bloodstream or marrow, increasing eosinophils or basophils, and the appearance of more chromosome anomalies, including additional Ph chromosomes. Not all forms of chromosome clonal evolution are associated with rapid disease progression ([78]). The clinical features of transformation from chronic phase are found in Table 84.3.

TABLE 84.3. Definitions of Accelerated Phase (AP) or Blastic Phase (BP) Chronic Myeloid Leukemia

Symptoms of AP	Signs and Laboratory Features of AP
Fever	Increasing peripheral basophilia to >20%
Night sweats	Peripheral blood blasts >10%
Weight loss	—
Refractory splenomegaly	Marrow blasts >10%
Bone pain	Cytogenetic clonal evolution
	Difficult to control white blood cells with antiproliferative treatment
	Marrow reticulin or collagen fibrosis
	Thrombocytopenia (<100,000/µl) unrelated to treatment
Symptoms of BP	**Signs and Laboratory Features of BP**
Similar to AP lymphadenopathy	Peripheral blood blasts >20%
Extramedullary blastic chloromas	Marrow blasts >20%
	Clumps of blasts on marrow examination
	Extramedullary blastic chloroma

Not all patients transform from chronic phase to accelerated phase to blast phase in a systematic fashion. The blast phase can occur rather abruptly and without substantial warning. Compared to accelerated phase, blast phase is more easily defined as meeting the strict definition of acute leukemia. In this case, either the marrow is composed of large clumps of blasts or the percentage of blasts and promyelocytes is so high as to confer the diagnosis of acute leukemia. Blast phase CML has particular features, including a high prevalence of central nervous system involvement and lymph node chloromas. If suspected, biopsy of the involved tissue is required along with genetic and phenotypic analysis to identify the blast population. Blast crisis, as the obvious cause of death in CML, has been reported to occur in 60 to 90% of patients in studies ([79], [80] and [81]). Patients not succumbing to blast transformation have had marrow failure states similar to advanced myelofibrosis as their cause of death ([79], [82], [83] and [84]).

For all practical purposes, any change from the expected clinical course of CML should raise the suspicion that blast crisis is beginning ([85]). The appearance of fibrosis in the bone marrow is considered an ominous sign. Fever without explanation when CML appears to be under moderately good control may herald blast crisis; however, fever may be associated with typical CML when the disease is untreated ([79], [86]). The development of anemia or splenomegaly of a degree disproportionate to the WBC count may precede the onset of obvious blast crisis. Development of thrombocytopenia may herald blast crisis, as may the unexpected development of thrombocytosis ([64]). Clinically evident invasion of organs other than the marrow, spleen, and liver is somewhat unusual in typical chronic phase CML. Evidence of such invasion, particularly the sudden enlargement of lymph nodes, often signals blast crisis.

A substantial proportion of patients have evidence of blast crisis at one localized site while the marrow and blood still appear typical of chronic stage. Such cases are noted frequently (12 of 73 in one series) ([87]). Lymph nodes probably are the most common site for localized blast crisis, although it may develop in bone and be associated with destruction of bone or other tissues ([88]). In some patients, new chromosome abnormalities are present in the local site but not in the marrow ([89], [90] and [91]). A case of recurrent blast crisis after allogeneic marrow transplantation was distinguished from posttransplant lymphoproliferative syndrome by genetic studies ([92]). This case and others indicate that evaluation of localized tumors in patients with chronic phase CML requires morphologic, immunologic, and genetic studies. As blast crisis supervenes, other chromosomal abnormalities, in addition to the Ph chromosome, often appear (60 to 90%) ([74], [77], [79], [80], [93], [94] and [95]). As with most of the other changes that have been discussed, the development of additional chromosomal abnormalities is not specific for blast crisis; some patients, including those with duplication of the Ph chromosome, have remained in the chronic phase for prolonged periods ([79], [95]).

A number of patients have been described in whom chromosome abnormalities in addition to the Ph chromosome were detected in the spleen or lymph nodes before they were present in marrow, in a higher proportion in the spleen, or in different anatomic sites. These observations led to the belief that blast crisis clones may originate in the spleen before frank blast crisis and formed part of the rationale for the extensive and unsuccessful trials of splenectomy in patients with CML. Systemic treatment of localized blast crisis is justified because localized crisis rapidly becomes widespread.

Blast phase is characterized by all of the morbid manifestations of acute leukemia. Patients suffer from severe bacterial or fungal infections and hemorrhage caused by neutropenia and thrombocytopenia, respectively. These complications inexorably lead to death within 3 to 6 months.

DIAGNOSIS

Chronic Phase

The diagnosis of CML rests on the examination of a peripheral blood smear and marrow biopsy. The documentation of either a Ph chromosome by karyotypic analysis or the presence of the BCR-ABL translocation by Southern blot or polymerase chain reaction (PCR) assays confirms the diagnosis.

PERIPHERAL BLOOD FINDINGS The most important histologic finding in the peripheral blood is a neutrophilic leukocytosis and basophilia (Table 84.4). The leukocytosis ranges from 20,000/µl to more than 500,000/µl, with a mean range of 134,000 to 225,000/µl in most studies ([45], [96], [97]). A decreased LAP is present as an early manifestation in almost all cases ([98]).

TABLE 84.4. Morphologic Abnormalities in Blood Smears of 50 Untreated Patients with Chronic Myeloid Leukemia

Abnormality	Patients Exhibiting Abnormality (%)
Nucleated erythrocytes	98
Dyserythropoietic (binucleate)	12
Target cells	2
Giant platelets	2
Megakaryocytic nucleoli	24
Binucleate of lobular leukocyte nuclei	
Blasts	2
Promyelocytes	2
Myelocytes	6
Hypogranular leukocytes	
Myelocytes	8
Segmented neutrophils	2
Basophils	12
Eosinophils	4
Cells in mitosis	14
Giant metamyelocytes	24
Pelger-Hüet cells	4
Hypersegmented neutrophils	12
Leukocytes with mixed basophil-eosinophil granules	8

The leukocytosis is predominantly neutrophilic, with all stages of neutrophilic maturation represented, from myeloblast to segmented neutrophil. The myelocyte and segmented neutrophil usually predominate, and all the neutrophilic precursors appear morphologically normal by light and electron microscopy ([99], [100]). Pelger-Hüet abnormalities may exist late in the disease. Myeloblasts do not usually exceed 3% of the total WBC count. An absolute basophilia is invariably present and of critical importance; the diagnosis should be questioned without a documented Ph chromosome or BCR-ABL fusion product ([46], [98], [100]). Basophilia may also precede clinical manifestations by many years ([47], [98]). There may be an eosinophilia as well, but its presence does not carry the diagnostic significance of the basophilia and neutrophilic leukocytosis ([17], [46], [98]). Occasional hybrid cells with mixed basophil-eosinophil granulation or mixed basophilic–mast cell granulation are found ([101], [102] and [103]). The marked leukocytosis in cases of CML typically is associated with an absolute monocytosis but relative monocytopenia ([38], [45]). The mean percentage of monocytes is approximately 2% or less of the WBC count, although the relative number of monocytes may increase with evolution to blast crisis. The absence of a marked monocytosis in the early phases of CML is helpful in distinguishing some cases from chronic myelomonocytic leukemia. Absolute lymphocyte counts are variable, although a lymphocytosis is common. Thrombocytosis is present in approximately one-half of cases, occasionally above 1,000,000/µl. Platelet counts of under 100,000/µl are very uncommon (45,63,96,104). The platelets may vary in appearance, occasionally being of large size or diminished or absent granulation. Megakaryocytes are seen in the peripheral blood in approximately one-fourth of cases ([45], [63], [96], [104]). Most patients have a normochromic/normocytic anemia at the time of diagnosis, although normal or elevated hemoglobin levels are reported ([45], [97]). As may be expected in proliferative, marrow-based processes, the severity of the anemia is directly proportional to the degree of leukocytosis. Minimal anisocytosis and poikilocytosis with occasional nucleated red blood cells are seen in most cases. A coincidental hemolytic anemia is rarely present. Significant abnormalities in red blood cell morphology should suggest an underlying red blood cell disorder or a part of the evolution to blast crisis.

BONE MARROW FINDINGS Marrow examination can be useful in distinguishing CML from other CMPDs and reactive processes. The bone marrow is markedly hypercellular, predominantly because of a proliferation of neutrophilic precursors from myeloblasts to segmented neutrophils ([99], [104], [105]). The maturation sequence and morphology at each stage are normal, although the relative increase in myelocytes seen in the peripheral blood is also seen in the bone marrow. Myeloblasts do not usually exceed 5% of the marrow elements. The myeloid precursors usually are located in a periosteal location as seen in normal marrow. Increased numbers of basophils, eosinophils, hybrid cells, and their precursors as seen in the peripheral blood are also present. Megakaryocytes are typically increased in number and occasionally clustered in groups of three or more in central intertrabecular regions ([104], [105]). The megakaryocyte clustering is not as pronounced as it is in ET. The megakaryocytes of CML are slightly smaller than normal megakaryocytes, and occasional micromegakaryocytes are present. Some cases of CML present with a decreased number of megakaryocytes ([104], [106], [107]), and some authors propose a subdivision of CML based on the number of megakaryocytes ([104], [108], [109]). *Common* or *granulocytic CML* has a decreased, normal, or slightly increased number of megakaryocytes, whereas a marked increase in megakaryocytes may be called *megakaryocytic CML*. The clinical significance of this division has not been demonstrated. Macrophages with coarse, granular, periodic acid-Schiff (PAS)–positive, cytoplasmic material (pseudo–Gaucher cells) are present in approximately one-third of patients ([110], [111]). These inclusions are the result of increased lipid turnover from granulocytic membranes and are of three types: blue birefringent inclusions, the most common (Gaucher-like); blue nonbirefringent, sea-blue histiocytes; and gray-green with birefringent. Iron stores in macrophages as detected by Prussian blue staining are decreased in virtually all cases to amounts lower than in normal subjects. Erythroid precursors may be present in increased, normal, or decreased numbers, although the myeloid to erythroid ratio is invariably increased ([35], [97]). Erythroid precursors may be distributed unevenly as well, with virtually no erythroid cells in some microscopic fields and numerous cells in others. Deposition of connective tissue as detected by reticulin or PAS stains is not noted in most cases ([83], [84], [112], [113]). Nevertheless, in some cases, deposition of connective tissue ranging from an increased number and thickness of fibers to multifocal areas of acellular connective tissue deposition reminiscent of idiopathic myelosclerosis. The deposition is typically around vessels and near megakaryocytes. Connective tissue deposition is associated with larger spleen sizes, increased blast percentages in the peripheral blood, decreased hemoglobin levels, and additional karyotypic abnormalities. As a result, it is not surprising that most studies have indicated that reticulin fiber deposition is associated with a worse prognosis, although a small set of patients with marked fibrosis and early stage CML has been reported to have a prolonged course.

CYTOGENETIC FINDINGS Karyotypic analysis is usually best performed from the bone marrow material, although peripheral blood may be used. The finding of a simple or complex translocation between chromosomes 9 and 22, generally the t(9;22)(q34;q11), confirms the diagnosis, and 5 to 10% of the cases have a variant translocation leading to rearrangement of the BCR gene ([114]). Patients with variant and classic Ph-producing translocations are clinically and hematologically identical and distinct from Ph(–) cases. Typically, the Ph chromosome remains the sole chromosomal abnormality throughout most of the chronic phase. In a small number of cases with clinical and morphologic features of CML, a t(9:22) or some variant thereof is not identified by karyotypic analysis but may be demonstrated by molecular techniques such as Southern blot or PCR. The variant Ph chromosomes fall into two subgroups: simple and complex. In simple variant translocations, the segment from 22q is translocated onto a chromosome other than 9. Three or more chromosomes are involved in complex variant translocations. Although the disease appears identical among patients with classic and variant Ph chromosomes, there is controversy as to whether the chromosomal breakpoints and other molecular features are identical ([114], [115], [116] and [117]). Although t(9;22) is the hallmark of CML, it is not exclusive to CML. ALL may be accompanied by a t(9;22) in 10 to 20% of adult and in 2 to 5% of childhood cases. In addition, a t(9;22) appears to be found in some bona fide cases of *de novo* AML as well as in very rare cases of lymphoma and myeloma. Recently, Ph(+) CNL has also been added to this group.

MOLECULAR DIAGNOSIS AND CLINICAL CORRELATE All patients with CML and a demonstrable classic Ph chromosome by cytogenetics have molecular fusion of the BCR and ABL genes. This chromosomal translocation may also be demonstrated by Southern blot analysis ([11]), or the transcripted messenger RNA (mRNA) fusion product may be detected by reverse transcriptase PCR (RT-PCR) ([118]). Although Southern blot analysis and RT-PCR may not detect complex translocations, Southern blot can detect a translocation in a small minority of cases of CML reported as falsely negative using cytogenetic analysis ([119], [120]). The clinical and hematologic features of this small cohort of cases that are falsely karyotypically normal but have BCR rearrangement detected by Southern blot are comparable with cases having karyotypically obvious Ph chromosomes ([121], [122]). Using both cytogenetic and molecular techniques, a Ph chromosome can be demonstrated in all but approximately 1% of cases. These cases have been called *Ph*(–) *CML* or *atypical CML* by some. However, they probably represent another type of CMPD, so it is not surprising that these behave more aggressively than CML ([38], [39]). RT-PCR detects different length products corresponding to chimeric BCR-ABL proteins of 190 kd, 210 kd, and 230 kd. The breakpoint as detected by RT-PCR may be helpful in distinguishing ALL, CML, AML, and CNL. In the vast majority of cases of CML in adults and in virtually all cases in children, a p210 fusion protein is present. Cases of Ph(+) ALL are associated with the p190 protein, although rare cases of CML and AML with the smaller fusion protein have been reported. A large p230 fusion protein is present in cases of CNL. The p230 transcript has also been reported in cases of CML, but review of these reports suggests that these cases may actually represent CNL. There are also two types of p210 transcripts: b2a2 and b3a2. Although definitive prognostic differences between these groups are controversial, patients with b3a2 transcripts are likely to have higher platelet counts. In addition, the relative frequency of b2a2 and b3a2 is different in childhood and adult CML, with two-thirds of adults having b3a2 transcripts and the overwhelming majority of children with CML having b2a2 transcripts.

ULTRASTRUCTURAL ANALYSIS AND IMMUNOPHENOTYPIC FINDINGS Flow cytometric analysis does not have a significant role in the diagnosis of the chronic phase of CML because the phenotype of the cells in CML is the same as that of normal cells. The ultrastructural appearance of the majority of mature granulocytes of CML is the same as that of normal granulocytes ([100], [103]). The neutrophil precursors show some differences from their normal counterparts, although none of the findings is diagnostic. Bundles of microfilaments, deep nuclear folds, and mitochondria in the perinuclear hof are seen in myeloblasts and promyelocytes. Mixed-granule populations appreciated histologically are present by electron microscopy as well ([123]).
EXTRAMEDULLARY DISEASE During the chronic phase, the cells of CML infiltrate the spleen and liver. In the spleen, the pulp cords are predominantly infiltrated, and the malpighian corpuscles diminish in prominence as the disease progresses. Foci of myelopoiesis may be seen in the sinusoids ([123]). This latter finding probably represents secondary extramedullary hematopoiesis and is not part of the primary disease process. Collections of infiltrating leukemic cells may also be seen in hepatic sinuses. Lymphadenopathy should be worrisome as an indication of transformation to the terminal phase.

Transformation to Terminal Phase (Blast Crisis or Accelerated Phase)

CML usually transforms to a more aggressive disease after 2 to 4 years and occurs in at least two clinical manifestations: accelerated phase and blast crisis. Histologic, cytogenetic, and molecular findings accompany this transformation ([71], [72], [73], [74], [75] and [76]).

HISTOPATHOLOGY The transformation process may be abrupt, with a rapidly increasing percentage of blasts with a clinical course similar to *de novo* acute leukemia (blast crisis), or slower and more progressive, with marrow failure resulting in anemia and thrombocytopenia (accelerated phase). Blast crisis, an obvious cause of death, represents the transformation of CML to the equivalent of acute leukemia and is generally defined as more than 20% blasts in the peripheral blood or bone marrow aspirate smear ([1], [123]) or by microscopic identification of a large cluster of blasts in a marrow biopsy or extramedullary site biopsy ([1], [87], [123], [124], [125], [126], [127], [128], [129], [130], [131], [132] and [133]). In approximately two-thirds of cases of CML in blast transformation, the blasts are myeloid by traditional cytologic and immunophenotypic analysis. These myeloid cases can represent the spectrum of nonlymphocytic leukemias, resembling myeloid (M1–2), myelomonocytic (M4–5), erythroblastic (M6), or megakaryoblastic (M7) leukemias. Auer rods are very rarely, if ever, observed. Cytochemical reactions with Sudan black and myeloperoxidase are markedly decreased and often absent, so negativity does not exclude the diagnosis of acute myeloblastic leukemia. Flow cytometric analysis demonstrates the presence of nonlymphocytic markers, whereas electron microscopy demonstrates ultrastructural features (i.e., granules) consistent with nonlymphocytic differentiation. These cases are usually negative for terminal deoxynucleotidyl transferase, although a significant number of terminal deoxynucleotidyl transferase–positive myeloblastic cases have been reported. In one-third of the cases of transformation, the blasts have morphologic, immunophenotypic, and ultrastructural features of lymphoblasts ([87], [125], [128], [129], [130], [131], [132] and [133]). These blasts may exhibit the cytologic features of all types of ALL, most commonly L1 or L2. Similar to the blasts in *de novo* ALL, Sudan black, myeloperoxidase, and chloroacetate esterase are negative. However, the blasts may have block PAS positivity. Lymphoid antigens, usually B-cell antigens, are expressed on the cell surface. T lymphoblasts arising in CML have been described, although they are very rare. The lymphoblasts are terminal deoxynucleotidyl transferase–positive in the majority of cases and have characteristics of B-cell precursor lymphoblasts. The majority are CD10 (CALLA) and CD19 without surface immunoglobulins. Cytoplasmic μ heavy chains may be seen in some cases. Although the majority of cases of blast transformation are characterized by an increase of blasts in marrow and blood, a number of patients present with extramedullary manifestations. The cytologic, immunologic, and cytogenetic features of these cases are similar to those of other cases of blast transformation of CML occurring in the marrow. Because the detection of transformation at an earlier stage might lead to more effective treatment, criteria that might indicate an earlier phase or different clinical behavior of transformation (accelerated phase) have also been proposed ([123], [132], [134]). These include myelofibrosis, basophilia in excess of 20%, hemoglobin of less than 7 g/dl, platelets less than 100,000/μl, karyotypic evolution, and a number of blasts that is increased but less than 20%. Although it is well documented that cases of CML proceed through a chronic phase to a phase with a low blast count to a phase with higher blast counts, the difficulty with the additional criteria for accelerated phase is that it is unclear whether all these cases represent an earlier phase of blast crisis or simply variants of CML with a slightly worse prognosis. In addition, the use of one or the other of these terms to distinguish patients with high or low blast counts does not alter prognosis or treatment.
LEUKOCYTE ALKALINE PHOSPHATE LAP values are often increased when CML transforms to blast crisis or accelerated phase. However, LAP values are quite variable and are influenced by frequent coincident processes such as infection. Several other serum or urinary proteins have been reported to increase with the onset of terminal phase, including cationic leukocyte antigen, erythrocyte membrane proteins, and fucosyl transferase. The clinical relevance of these latter tests is not established.
CYTOGENETIC FINDINGS The evolution of chronic phase CML to accelerated or blast phase is accompanied by cytogenetic changes in 70 to 80% of cases ([114], [135], [136]). The most common abnormalities in addition to the Ph chromosome are (in order of frequency): an additional Ph chromosome, trisomy, isochromosome 17, and +19. The second Ph seems to result from duplication of the first because additional abnormal chromosome 9 is not observed. The prognostic significance of additional chromosomal abnormalities without histologic changes may indicate a poor prognosis because these chromosome changes usually precede the hematologic manifestations by several months. Nevertheless, the development of additional chromosomal abnormalities alone is not specific for evolution to the terminal phase, as some patients have remained in chronic phase for prolonged periods.
MOLECULAR FINDINGS Two molecular tests that detect the size or amount of the BCR-ABL mRNA transcript may be useful in evaluating transformation of CML: quantitative PCR and the size of the BCR-ABL gene product. Two sizes of BCR-ABL fusion mRNA message have been detected that correspond to proteins with molecular weights of 190 kd and 210 kd. Generally, cases of blast transformation in CML express the 210-kd form, whereas cases of *de novo* ALL with a Ph chromosome express the 190-kd form ([137]). Because some cases of blast transformation of CML present without a previously diagnosed chronic phase, the underlying CML is suggested by the presence of a 210-kd product. In addition, the presence of a 190-kd form in conjunction with a 210-kd product suggests evolution to terminal phase. The emergence of a p190 transcript in the background of p210 CML has been used as a suggestion of transformation to terminal phase. Although this may be the case, low levels of p190 products may also be generated through alternative splicing of the p210 fusion transcript and do not indicate transformation universally. Quantitation of the amount of BCR-ABL message may be documented by quantitative PCR. Although not widely used, this test can semiquantitate the level of BCR-ABL mRNA transcript in patients with CML. Although the absolute level is not predictive of transformation, an increase from a previously documented baseline for that patient is predictive of impending transformation, usually 6 months later ([138]).

Juvenile Chronic Myelogenous Leukemia

Myeloproliferative disorders occurring in children may have similar or identical features to adult Ph(+) CML ([1]). However, it has become clear that at least two entities are represented by these processes: an adult form of CML occurring in juveniles and a juvenile type of CML (JMML) ([35], [139], [140], [141] and [142]). The adult form of CML has the same clinical, morphologic, and cytogenetic findings as adult Ph(+) CML and represents the same disease in a younger age group. The juvenile form represents a distinct disease that is hematologically similar and accounts for 2% of childhood leukemias ([35], [142]). However, JMML is Ph(–) and clinically aggressive, with a course similar to that of AML. Juvenile CML is also much more common in young children, whereas the adult form is more common in adolescents. Although JMML and monosomy 7 have distinct cytogenetic findings, some investigators suggest that JMML and monosomy 7 syndrome represent the same spectrum of disease ([36]). In addition, the aggressive nature of JMML and monosomy 7 syndrome, their occasional overt progression to acute leukemia, and the demonstration of excessive myelomonocytic proliferation in the marrow have led some investigators to suggest the encompassing term *JMML* ([35], [36], [143]).

In JMML, LAP levels are generally reduced as they are in the adult form. However, in contrast to the adult form, fetal hemoglobin is increased in approximately one-half of cases. The elevated fetal hemoglobin may be useful in distinguishing JMML from other entities. In addition, levels of several red blood cell enzymes and proteins are reduced, including hemoglobin A_2 and erythrocyte carbonic anhydrase, whereas glucose-6-phosphate is increased. JMML has a prominent monocytic component with excessive monocyte proliferation in the absence of growth factors and suppression of normal hematopoietic colony formation ([139], [140] and [141]), findings that have been shown consistently. Polyclonal elevation of immunoglobulins is common. If cases of monosomy 7 syndrome are excluded, consistent chromosomal abnormalities are not found ([36], [144], [145]).

The leukocyte count is usually elevated in JMML but less than in the adult form ([139], [140], [141], [142] and [143]). Thrombocytopenia is usually present. The leukocyte differential shows a higher proportion of immature myeloid precursors than in the adult form. Basophilia may be present but is not a consistent feature as in the adult form. Nucleated red blood cells, occasional plasma cells, and immunoblasts may also be noted. The marrow is hypercellular and contains increased blasts, immature monocytes, and monocytes. Megakaryocytes are usually decreased.

The differential diagnosis may be difficult because of differing concepts of the disease and overlap with monosomy 7 syndrome ([36]). Monosomy 7 syndrome usually occurs before the age of 2 years and typically presents with rash, hepatomegaly, and lymphadenopathy. Although monosomy 7 syndrome usually presents with anemia, thrombocytopenia, monocytosis, and erythroid precursors in the blood similar to JMML, monosomy 7 syndrome has normal or only slightly increased fetal hemoglobin levels. Furthermore, the demonstration of monosomy 7 in the myeloid cells confirms the diagnosis.

Children with Epstein-Barr virus infection may have hematologic findings similar to those of JMML, including leukocytosis, thrombocytopenia, hepatomegaly, and

elevated levels of fetal hemoglobin. Serologic testing may assist in the diagnosis of these cases.

CELLULAR AND MOLECULAR PATHOGENESIS

Hematopoiesis in CML is clonal, derives from a pluripotent stem cell, and is fairly normal with respect to cellular maturation and function ([146]). However, there is a relentless rise in the WBC count. The Ph chromosome is the hallmark of CML, and its acquisition, presumably during a division of a pluripotent stem cell, is part of the molecular and cellular defects that ultimately produce CML. The unequivocal demonstration of Ph chromosomes in all blood cell types, including B and T cells, is widely accepted as evidence that the neoplastic clone originates in a very primitive pluripotent stem cell. However, these findings do not exclude the possibility that expression of BCR-ABL fusion protein may affect lineage commitment. To understand how expression of BCR-ABL protein causes CML, it is necessary to define in what ways hematopoiesis in CML is abnormal and in what manner these hematopoietic abnormalities change over time with progression of the disease from a chronic to an acute form.

Disease Initiation

The cardinal feature of chronic phase CML is myeloproliferation, predominantly leading to an excess of myeloid precursors and mature forms. To understand the relationship among the t(9:22), the clinical course of CML, and therapies, such as a-interferon, and how this relationship affects the disease progression, it is necessary to define the cellular and molecular defects in CML.

The clinical phases of CML are manifestations of three distinct pathogenetic phases:

Phase 1: *preclinical stage*. Clonal proliferation of pluripotent Ph(–) bone marrow cells. These cells are genetically unstable and have a growth advantage over normal stem cells. Very little is known about the pathogenetic mechanisms of this stage.
Phase 2: *acquisition of the Ph chromosome or some variant leading to the production of a BCR-ABL gene product*. It is not known whether the acquisition of the Ph chromosome leads inexorably to CML. However, in the right genetic background, the acquisition of t(9;22) is clinically manifested as the chronic phase of the disease. It is characterized by an abnormal proliferation of marrow elements, predominantly myeloid precursors. This seems to occur because of two interrelated abnormalities. One is a subtle imbalance in cell maturation, the consequence of which is that CML progenitor cells undergo a few more divisions than their normal counterparts. The second abnormality is that immature CML precursor cells seem less responsive to molecules or stromal cell–precursor cell interactions that inhibit growth of their normal counterparts. Consequently, CML cells continue dividing even when normal cells cease doing so. Because hematopoiesis and granulocyte production are hierarchical and amplicative, the net effect is to produce billions of excess granulocytes.
Phase 3: *accelerated phase or blast crisis in which the increased genetic instability leads to additional chromosomal abnormalities, leading to increasing malignant subclones*. The accelerated or blast phase is characterized by the loss of differentiation and additional cytogenetic abnormalities. This biologic event corresponds to a histologic appearance and clinical behavior identical to those of acute leukemia.

Information concerning the preclinical stage of CML comes from small cohorts of patients who were medically followed before the development of symptoms or diagnosis. The largest series of this type is that of Kamada and Uchino, who reported 20 cases (16 survivors of the Hiroshima atomic bombing) ([47]). Assessment occurred at least twice yearly from a normal state to the development of early CML and through the symptomatic phase of the disease. Data were added from four other patients in whom a diagnosis was made when the WBC count was less than 42,000/µl. Once these 20 patients became symptomatic, the disease pattern did not differ from that seen in other bomb survivors with CML or from those patients not exposed to excessive radiation who developed CML. In all 20 patients, the Ph chromosome was present at diagnosis. In 17 cases, all marrow metaphases examined were Ph(+). In three cases, a minor population of metaphases (3 to 12%) were Ph(–) but abnormal, suggesting that the Ph(+) clone replaces normal myeloid cells before the WBC count becomes abnormal. The leukemic clone may actually develop before the translocation of the c-abl oncogene from chromosome 9 to chromosome 22, thus explaining the presence of Ph(–) B lymphocytes derived from the same clonal stem cell as the leukemic clone of myeloid cells (i.e., glucose-6-phosphate dehydrogenase type A or B only) in glucose-6-phosphate dehydrogenase heterozygous patients with CML ([147]). In ten patients, the diagnosis was made when the WBC count was less than 14,000/µl by detecting the presence of the Ph chromosome.

ROLE OF BCR-ABL The translocation of genetic material between chromosomes 9 and 22 ultimately results in the production of a chimeric molecule composed partly of the ABL gene and partly of the BCR gene ([137]). Understanding how the chimeric BCR-ABL fusion product causes the proliferation abnormalities that result in excess granulocyte production requires knowledge of the normal ABL and BCR genes. In normal individuals, BCR and ABL proteins are expressed in virtually all cells. In CML, a t(9;22) results in a hybrid BCR-ABL gene in which exon 1 of ABL is replaced by 5' exons of BCR (Fig. 84.1) ([137]). The breakpoint in the BCR gene occurs in an approximately 5.8-kb intronic region called the *major breakpoint cluster region* (M-bcr), spanning five exons named *b1* to *b5*, now known to be exons 12 to 16 of the BCR gene. The breakpoint in the ABL gene can occur anywhere within a 300-kb or larger segment at the 5' end of the gene. The fusion mRNA product is translated into a chimeric protein whose molecular weight is usually 210 kd. Because this BCR-ABL protein occurs in all cases of CML, it is reasonable to assume that it is critical to the pathogenesis of the disease. Indeed, studies using transgenic mice expressing BCR-ABL protein develop a disease similar to chronic phase CML in humans ([148]). In addition, antisense oligomers to the BCR-ABL mRNA junction may suppress leukemia colony formation but not normal colony formation ([13]). There is variation in the BCR-ABL fusion transcripts and proteins formed in CML and among other diseases with a t(9;22) ([148] , [149] , [150] , [151] and [152]). Three different breakpoint areas in the BCR gene have been described: major (M-bcr), minor (m-bcr), and µ-bcr. A translocation occurs between one of the exons in one of these three areas in the *BCR* gene and the second exon of *ABL*. A nomenclature has been developed to describe these different breakpoints. For instance, fusion junctions are called b3a2, e1a2, e19a2, and so on. The first alphanumeric pair refers to the exon used in the *BCR* gene that fuses with the second exon of *ABL* (a2). The M-bcr exons are called b1 to b5; e1, e2, e1', and e2' are exons used in the m-bcr; and the µ-bcr has exons e19 and e20. Generally, the BCR-ABL hybrid results from a b3a2 or b2a2 junction encoding a p210 BCR-ABL fusion protein. Taken together, the data so far suggest that one can distinguish at least three clinicopathologic entities among the chronic (p210 CML, p190 CML, and p230 CNL) and two acute Ph(+) myeloid leukemias (p210 AML and p190 ALL) ([137] , [148] , [149] , [150] , [151] , [152] , [153] and [154]). The overwhelming majority of CML cases result from a b2a2 or b3a2 fusion leading to the formation of a p210 BCR-ABL protein. In two-thirds of ALL cases and in rare cases of CML and AML, exons among the m-bcr form an e1a2 junction and lead to a smaller mRNA transcript and a p190 BCR-ABL fusion protein. In rare cases of CML and in cases of CNL, exons e19 and e20 are used, forming an e19a2 mRNA transcript and a larger p230 BCR-ABL chimeric protein. It is also worth noting that BCR breakpoints outside the three characterized breakpoint regions have also been identified in rare cases of CML and ALL. In addition, t(9;22) using the minor and major breakpoint cluster regions have been rarely found in other hematopoietic neoplasms, including myeloma, ET, and B-cell lymphomas ([148] , [155] , [156] , [157] , [158] , [159] and [160]). The clinical significance of different breakpoints in CML is not well defined. However, some intriguing correlations have been observed. Both childhood and adult CML are almost always of the p210 type. However, in contrast to adults, in whom two-thirds of cases have the b3a2 transcript, children with CML have a predominance of b2a2 fusion junctions ([161]). Furthermore, two different groups report that the b3a2 transcript is associated with higher platelet counts than the b2a2 in p210 CML ([162] , [163]). However, a third group and a CML trial in the United Kingdom have not been able to show a correlation. Investigations into how the normal *ABL* and *BCR* genes regulate growth suggest several ways in which this chimeric molecule may promote uncontrolled growth ([134] , [137]). The protooncogene *ABL* has been more widely studied of the two and acts primarily as a protein that phosphorylates tyrosine residues on itself and other proteins. The protein structure of ABL is complex. ABL has at least three functional domains: the domain responsible for phosphorylation and two other domains, SH2 and SH3, that regulate the activity of the former domain. The ability of ABL to transform cells is proportional to its ability to phosphorylate tyrosine residues. Currently, it is believed that ABL binds to a protein target. The SH2 domain up-regulates ABL activity and increases kinase activity, which promotes cellular transformation. Alternatively, the SH3 domain down-regulates kinase and transformation activity. In addition, it has been suggested that the SH3 region may also be responsible for regulating guanosine triphosphatase activity, a signal pathway known to be involved in the signal transduction pathway of another protooncogene, *ras*, whose abnormal expression is associated with cancer development. There are two other important functional domains in the ABL protein. First, there is a domain that binds specific nucleotide sequences of DNA. These structural data and other data suggest that ABL may also be a transcription factor. Second, there is a region that facilitates binding to f-actin in the cytoplasm. Compared to the *ABL* gene, considerably less is known about the structure and functional activities of the *BCR* gene ([125] , [137]). BCR protein may be a serine/threonine kinase rather than a tyrosine kinase like ABL. Some researchers suggest that BCR is a serine/threonine kinase, whereas others indicate that BCR is homologous to the cyclins, which regulate the cell cycle. A BCR-ABL fusion protein is produced that contains the N-terminus of the BCR protein and the C-terminus of the ABL protein. Mutation studies indicate that loss of the normal *N*-terminal region of ABL leads to increased tyrosine phosphorylation activity relative to its normal counterparts, increased f-actin binding, and decreased nuclear translocation. Presumably, these changes result in the proliferation defects seen in myeloid precursors in CML. Finally, some evidence indicates that ABL kinase activity is not the sole abnormality in CML. Other researchers suggest that BCR-ABL fusion protein may interact or interfere with other protooncogene pathways, such as the signaling pathways involving *ras*, *myc*, or *myb*, indicating the possibility that a cascade of protooncogene abnormalities may ultimately be found to be involved in BCR-ABL–mediated transformation.
ROLE OF CELL CONTACTS AND SOLUBLE MEDIATORS In addition to the signaling defects caused by BCR-ABL fusion protein, CML precursor cells are not inhibited by stromal cell contacts and soluble molecule mediators in the bone marrow microenvironment. CML precursor cells do not appear to adhere as well to stromal cell and extracellular matrix components of the marrow compartment as their normal counterparts ([164] , [165] and [166]). So-called juxtacrine signaling, the

interplay between adhesion and soluble factors, inhibits cellular growth; decreased adherence leads to an increased proliferation rate of CML precursors compared to their normal counterparts. a-Interferon enhances the interaction of CML precursor cells with the stroma and decreases the proliferative activity of CML precursor cells, leading to a return to normal hematopoiesis. This antiproliferative effect of a-interferon appears to be the result of modulation of *BCR-ABL* gene expression of CML precursor cells as well as enhanced cell–cell contacts in the marrow microenvironment ([164], [165] and [166]). In addition, stem cell colony formation assays show that the leukemic stem cell population in the marrow can be rather small, but it may be markedly elevated in the blood.

Disease Progression

Progression of CML to the accelerated or blast phase is associated with the acquisition of additional chromosomal and genetic abnormalities. Chromosomal instability of the malignant clone is a fundamental characteristic of disease progression in CML. The t(9;22) remains the sole chromosome abnormality throughout the chronic phase, and its expression continues during blast crisis. However, 70 to 80% of patients develop additional chromosomal abnormalities with disease progression. These chromosomal changes may be detected in extramedullary tissue before the hematologic and clinical manifestations of blast crisis. Secondary chromosomal changes have been reported in more than 1500 patients with CML. Although there is no single pathway of progression, chromosomes 8, 17, 19, and 22 are most commonly involved in disease progression.

A number of oncogenes have been implicated in disease progression. Several groups suggest that the site of the intronic breakpoint affects prognosis, but the results have not been confirmed by others. Alterations in p53 correlate with progression to blast crisis or accelerated phase in one-fourth to one-third of patients with CML. In addition, structural abnormalities of the *Rb*, *myc*, and *ras* genes have been associated with progression in small cohorts of patients (114,135,136,167). Evidence of aberrant growth factor production or secretion in disease progression has also been reported. These factors include interleukin-1b, interleukin-6, and granulocyte-macrophage colony-stimulating factor, all of which may be involved in adherence to stromal cells.

In summary, there is now a wealth of information that supports an essential role for chimeric BCR-ABL protein in the initiation of CML. An assortment of forces seems to drive disease progression and transformation to an aggressive acute leukemic phenotype (blast crisis). These factors include chromosomal abnormalities, oncogene alteration, cytokine secretion, and alteration in cellular adherence. The precise nature of all of these events remains unclear.

THERAPY

The initial therapy for patients presenting in chronic phase requires controlling the elevated WBC count, reducing the symptoms of concomitant splenomegaly, and treating any metabolic complications caused by the profound marrow proliferation. Hyperuricemia and gout can occur before therapy and can worsen with cytotoxic treatment. All patients should be placed on agents, such as allopurinol, to lower uric acid and prevent gout and renal damage. These agents should be continued at least until control of the excessive hematopoiesis is obtained. Fictitious elevations of serum potassium with a markedly elevated WBC count can be noted because of cell lysis after collection of blood samples. On the other hand, fictitious decrease in blood glucose can result from glucose metabolism in the blood-collecting tube by the elevated WBC. Careful blood collection, rapid performance of analyses, and collection in blood tubes with antimetabolizing agents, such as fluoride salts, may be required to distinguish spurious laboratory values. Criteria for a complete hematologic response (CHR) include a WBC count of less than 10,000/µl, a platelet count of less than 450,000/µl, no immature cells in the peripheral blood, and no palpable splenomegaly. A cytogenetic response is determined by assessing the percentage of Ph(+) cells in metaphase in the bone marrow. Complete, partial, and minor cytogenetic responses are defined as 0%, 1 to 34%, and 35 to 65% Ph(+) cells, respectively. A major response is defined as either a complete or partial cytogenetic response.

Rapid lowering of the WBC count is not generally required because symptoms of leukostasis are an uncommon manifestation of chronic phase CML. Rapid lowering can also lead to tumor lysis syndrome. Patients should undergo emergent leukapheresis and initiation of cytotoxic chemotherapy only if symptoms of leukostasis are believed to be present as manifested by central nervous system, pulmonary, or hemorrhagic events. Cranial radiation, although used for central nervous system leukostasis associated with AML and blast phase CML, is not generally performed for CML in chronic phase ([168]).

Hydroxyurea

Hydroxyurea has a modest side-effect profile and rapid onset of action. This drug, acting as an inhibitor of ribonucleotide reductase, can lower blood counts within 1 to 2 days, especially if higher than standard doses are used. The advantages of hydroxyurea are the rapid onset, the lack of serious side effects, and the rapid recovery of counts if excessive lowering of the WBC count occurs ([169], [170] and [171]). The side effects of hydroxyurea are mild nausea and skin rash. Unlike busulfan (BU), hydroxyurea requires fastidious management. Blood counts should be measured weekly until a stable dose is determined. The usual dosage of hydroxyurea is between 500 and 3000 mg/day; greater dosages may be required initially. Hydroxyurea must be given daily and continually because the WBC rises rapidly after the drug is discontinued. With the use of hydroxyurea, most patients have excellent control of their blood counts, although most show persistent presence of the Ph chromosome. Compared to BU, hydroxyurea has been associated with a lower incidence of posttransplant complications, such as interstitial pneumonia, and can be used in pregnant patients because it is not mutagenic ([172]).

Busulfan

Despite having a lower efficacy than hydroxyurea or a-interferon, BU has certain advantages that continue to sustain its use ([173]). BU has a predictable dose, gradually lowers the blood counts, and does not require as frequent WBC measurements as hydroxyurea. However, BU can cause severe side effects, consisting of pulmonary fibrosis, rash, hypoadrenalism, and severe and prolonged lowering of blood counts, especially if a-interferon is subsequently used ([174]). Severe and prolonged marrow aplasia has been described after BU therapy. Once therapy is stopped, BU-associated leukopenia can require many weeks to resolve. Patients with profound BU myelosuppression can achieve substantial cytogenetic remissions, although the consequences of severe cytopenias do not warrant the deliberate use of dose-intensive BU without some form of stem cell rescue ([175]).

BU can be started at a dosage of 6 to 10 mg, which can be reduced to 2 to 4 mg/day once the WBC reaches 20,000/µl ([176], [177]). If blood counts are stable and less than 20,000/µl, BU can be discontinued. Evaluation of the WBC should be maintained every month. BU can be intermittently restarted with rising WBC or can be continued at low dosage. However, prolonged use can be associated with side effects. BU should be limited to patients who are intolerant of other therapies or who cannot maintain close and frequent medical supervision. BU should not be used in patients expected to undergo bone marrow transplantation (BMT) because adverse affects on transplantation outcome are reported ([178]).

a-Interferon

a-Interferon was the treatment of choice in patients with CML who were not candidates for allogeneic BMT before the introduction of imatinib. The mechanism of action of a-interferon is not known. Its pleiotropic effects include antiproliferative effects, immune modulation, antiangiogenesis, and modulation of the cytoadhesion between stromal cells and hematopoietic progenitors. a-Interferon is considerably more effective during early chronic phase ([179]). CHRs of more than 70% occur when a-interferon is used in early chronic phase ([180], [181], [182] and [183]). The standard dose used is 5 million units (MU)/m^2 daily by subcutaneous administration. In addition to the clinical response, more than 50% of patients have some cytogenetic response characterized by partial reemergence of Ph(–) hematopoiesis, as determined by karyotype or by fluorescence *in situ* hybridization analysis ([184], [185]).

A number of biologic variables may predict a-interferon–induced cytogenetic responses in patients with CML. A major cytogenetic response with a-interferon was associated with high interferon regulatory factor 4 expression ([186]), a high interferon consensus sequence binding protein ([187]), a high interferon-aR2c/glucose-6-phosphate dehydrogenase H ratio ([188]), and a high ratio of interferon regulatory factor 1/interferon regulatory factor 2 expression ([189]). Clinical variables can be used to predict patient risk categories and the expected benefit of a-interferon at diagnosis ([68], [190]) (Table 84.5). The Hasford score was developed to predict the survival of patients being treated with a-interferon. Patients at low risk treated with a-interferon had a median survival of 100 months, whereas patients at high risk had a median survival of 45 months ([190]). Low-risk cases, which account for 50% of CML patients, would thus be good candidates for a-interferon treatment. The *in vivo* response to a-interferon is an important treatment prognostic factor. Patients experiencing reduction of Ph(+) cells and, especially, those having a major cytogenetic response [below 35% Ph(+) cells in marrow examination] have been shown to have superior survival, estimated to be above 80% at 5 years ([180], [183], [191], [192] and [193]). Thus, there are clinical variables determined before and after initiating therapy that can help predict which patients may derive meaningful clinical benefit from a-interferon therapy.

TABLE 84.5. Hasford Risk Score for Patients with Chronic Myeloid Leukemia

Calculation of total score	
Age (yr)	0.6666 when age =50; 0 when <50
Spleen size [a] (cm)	0.042 × spleen size below left costal margin
Platelets (×10 ^{3}/μl)	1.0956 when =1500/μl; 0 when <1500/μl
Myeloblasts [b] (%)	0.0584 × % myeloblasts
Eosinophils [b] (%)	0.0413 × % eosinophils
Basophils [b] (%)	0.2039 when basophils >3%
Assessment of relative risk	
Relative risk = total × 1000	
Low, <780; intermediate, 781–1479; high, =1480	

[a] Spleen measured below left costal margin.

[b] Peripheral blood %.

Many patients require large doses of a-interferon for maximal benefit. However, because of its predictable early side effects, the drug should be started at lower doses and gradually increased once side-effect tachyphylaxis occurs. A standard initial dose is 1 to 3 MU subcutaneously given 3 to 7 days per week. Doses can be gradually increased to a final daily dose of 5 MU/m ^{2}. It is recommended to start hydroxyurea to decrease the WBC to 10,000 to 20,000/μl before initiating a-interferon. Patients having flulike side effects can be treated with acetaminophen or nonsteroidal antiinflammatories, and those with insomnia can be treated with amitriptyline (12.5 to 50.0 mg) or with a temporary dosage reduction. Many patients administer their a-interferon before bedtime to lessen their awareness of constitutional symptoms. Patients using a-interferon should be warned about side effects, as in randomized trials more than 25% of patients are intolerant of high-dose a-interferon and must decrease their dosage or choose alternative agents. The dose of a-interferon should be reduced for a patient with a WBC count less than 2,000/μl or a platelet count less than 50,000/μl. The a-interferon dose should also be reduced for grade 3 to 4 toxicity. Older patients often have decreased tolerance to a-interferon ([194]).

The optimal dosage of a-interferon remains unclear. Various dosages have been used, and many patients require down-adjustment from higher dosages. In general, higher dosages have been shown to improve efficacy, but with more side effects ([195]). A recent trial suggests that a lower dosage (2 MU/m ^{2}) administered three times per week (approximately one-sixth of standard weekly dosing) was as effective as the standard dosage (5 MU/m ^{2}) given daily ([196]). However, these results have not been confirmed.

Four major trials have compared a-interferon to either hydroxyurea or BU ([173] , [182] , [197] , [198] , [199] and [200]). A fifth trial compared hydroxyurea to hydroxyurea and a-interferon ([201]). These trials support the observation that CHRs and cytogenetic responses are more common with a-interferon. Although not universally noted, survival appears to be improved with a-interferon, which is especially correlated with achievement of a cytogenetic response. A summary of these trials is included in Table 84.6. A metaanalysis of all the randomized trials provided conclusive evidence of a-interferon's superiority in overall survival (57% at 5 years) compared with conventional single-agent therapy (42% at 5 years) ([200]).

TABLE 84.6. Results of Randomized Trials of a-Interferon (IFN)

Study	Therapy Used	Patients (No.)	Daily Median a-IFN Dose Administered (MU/m ^{2})	Complete Hematologic Response Noted (%)	Major Cytogenetic Response Noted (%)	Complete Cytogenetic Response Noted (%)	Median Survival (mo)	*p*-Value for Survival [a]

[a] Comparing other therapy to a-IFN.

Preclinical ([202]) and phase II studies ([203]) suggested the benefit of combining cytosine arabinoside (ara-C) with a-interferon. Two randomized trials have tested whether adding ara-C to a-interferon improves clinical outcomes. A national French study of 721 patients demonstrated that ara-C (20 mg/m ^{2}/day for 10 days per month), when added to a-interferon (5 MU/m ^{2}/day), improved cytogenetic response and survival ([204]). The major cytogenetic response at 12 months was 35% and 21% and the 5-year survival was 70% and 62% for the combination and a-interferon arms, respectively. However, an Italian study of 538 patients using a similar protocol confirmed that the combination produced an improved major cytogenetic response (28% vs. 18% at 24 months) but failed to demonstrate a significant survival advantage between the two treatment arms (5-year survival, 68% vs. 65%) ([205]). The toxicity of the combination arm was greater in both studies than with a-interferon alone (Table 84.7).

TABLE 84.7. Complete Hematologic Response, Major Cytogenetic Response, and 5-Year Survival of Interferon (IFN)- and IFN/Cytosine Arabinoside (ara-C)–Treated Patients

	French Trial			Italian Trial		
	IFN (%)	IFN/ara-C (%)	*p*-Value	IFN (%)	IFN/ara-C (%)	*p*-Value
Complete hematologic response at 6 mo	55	66	.003	55	62	.11
Major cytogenetic response at 12 mo	21	35	.001	13	21	.012
5-Yr survival	62	70	.02	65	68	.77

Two retrospective analyses have been performed comparing a-interferon therapy and HLA-identical sibling allogeneic bone marrow transplant. In the first analysis, 548 transplant patients from the International Bone Marrow Transplant Registry were compared to 121 patients who received hydroxyurea and 75 patients who received a-interferon on a randomized German CML Study Group trial ([206]). In this study, patients treated with a-interferon and hydroxyurea were evaluated as one group. Thus, the results of this trial need to be interpreted with caution. For the first 18 months, mortality was higher in the transplant group. From 18 to 56 months, the survival of both groups was similar, and, after 56 months, there was a survival advantage for the transplant group. For patients in the low-risk Sokal group, a statistically significant survival for the transplant cohort was only seen after almost 8 years. In a second study by the Italian Cooperative Study Group on CML, 840 patients younger than 56 years and entered on prospective trials were analyzed ([207]). Although there was a trend for improved survival for allogeneic BMT compared with a-interferon in all groups, this was only statistically significantly superior in patients younger than 32 years and with a high-risk Sokal score (Table 84.8). A multicenter prospective trial in Japan compared a-interferon in 175 patients with allogeneic BMT in 79 patients, of whom 50 received a transplant from an HLA-identical related donor and 29 from HLA-matched unrelated donors ([208]). At a median follow-up of 38 months, the 5-year survival rate was 79% for the a-interferon group and 72% and 67% for the related and unrelated donor transplant groups, respectively. In subset analysis, transplantation resulted in improved survival only in the younger patient with a higher Sokal risk. Taken together, these studies suggest that allogeneic BMT results in a significantly improved survival, most notably in younger patients with higher risk Sokal scores.

TABLE 84.8. Ten-Year Survival of Standard Allogeneic Bone Marrow Transplant Patients and a-Interferon Therapy Patients

Sokal Score	Low Risk (<0.8)		High Risk (=0.8)	
Age (yr)	=32	>32	=32	>32
Standard allogeneic bone marrow transplant (%)	62	50	65	47
a-Interferon therapy (%)	57	44	14	17
p-Value	.74	.15	.008	.50

Imatinib (Gleevec)

The 2-phenylaminopyrimidine derivative imatinib is an abl-specific tyrosine kinase inhibitor that inhibits the proliferation of CML cell lines by inhibiting BCR-ABL kinase activity ([209]). The drug is administered orally and is generally well tolerated. In a phase I study of patients resistant to or intolerant of a-interferon, a dose-response relationship was demonstrated ([210]). A maximum tolerated dose was not established, but a dose of 400 mg/day was recommended for phase II study.

In a multicenter phase II trial, a total of 454 patients with confirmed chronic phase CML in whom previous therapy with a-interferon had failed were treated with 400 mg of imatinib daily ([211]). Imatinib induced a CHR in 95% and a major cytogenetic response in 60% of patients. After a median follow-up of 18 months, CML had progressed to the accelerated or blast phase in 11% of patients, and 95% of the patients were alive. Only 2% of patients discontinued treatment because of drug-related adverse events, and no treatment-related deaths occurred. Supporting data have been reported in an Italian study in which 194 patients with CML resistant to a-interferon were evaluated ([212]). A CHR was obtained in 93%, and the major cytogenetic response rate was 44% at 6 months.

In a study of CML patients in accelerated phase, 181 evaluable patients were treated with 400 mg or 600 mg of imatinib daily. The hematologic response rate was 82%. The rate of major cytogenetic response was 24%. The estimated 12-month progression-free and overall survival rates were 59% and 74%, respectively. Nonhematologic toxicity was usually mild or moderate, and hematologic toxicity was manageable. Imatinib at doses of 600 mg/day resulted in a higher cytogenetic response (28% compared with 16%), a longer time to disease progression (67% compared with 44% at 12 months), and increased overall survival (78% compared with 65% at 12 months) with no clinically relevant increase in toxicity ([213]). In a second trial, 75 patients in accelerated phase were treated with imatinib at a dose of 600 mg daily that could be escalated to 800 mg in the case of no response. The hematologic response was 86% at 3 months. The major cytogenetic response was 10% at 3 and 6 months ([214]).

Two studies have been reported using imatinib in patients with CML in blast crisis. In the first, a total of 260 patients with CML were enrolled of whom 229 had a confirmed diagnosis of CML in blast crisis ([215]). Patients were treated with imatinib in daily oral doses of 400 mg or 600 mg. Imatinib induced hematologic responses in 52% and cytogenetic responses in 16% of patients. Median survival time was 6.9 months. In the second trial, 75 patients, 65 with myeloid and 10 with lymphoid blast phase CML, were treated with imatinib at doses of 300 to 1000 mg/day ([216]). The objective response rate was 52%. Response rates were not different between myeloid and lymphoid groups. The cytogenetic response rate was 16%. The estimated median overall survival was 6.5 months. In 56 patients with relapsed or refractory Ph(+) acute lymphoblastic leukemia, imatinib was given once daily at 400 mg or 600 mg. Imatinib induced CHRs in 29% of patients. Median estimated time to progression and overall survival were 2.2 and 4.9 months, respectively ([217]). Given the data outlined above, the U.S. Food and Drug Administration has approved imatinib for CML in blast crisis, accelerated phase, or in chronic phase after failure of a-interferon therapy.

An interim analysis of a phase III trial in newly diagnosed chronic phase CML has been presented ([218]). This multicenter, randomized study, with 1106 patients, compares imatinib at 400 mg/day with a-interferon (5 MU/m^2/day) in combination with cytarabine (20 mg/m^2/day for 10 days/month). At 6 months, the rates of major and complete cytogenetic response were 63% and 40%, respectively, in the imatinib arm versus 10% and 2% in the a-interferon arm. The imatinib arm had a significantly better outcome for time to progression (1.4% vs. 10.3% events) and time to accelerated phase/blast crisis (1.1% vs. 4.7% events). Crossovers due to intolerance occurred in less than 1% of imatinib-treated patients and in 19% of a-interferon–treated patients. The mature results of this study are eagerly awaited.

Approximately 30% of patients on imatinib with chronic phase CML experience grade 3 to 4 myelosuppression, most commonly neutropenia, followed by thrombocytopenia. Myelosuppression occurs more commonly in CML patients in accelerated phase and blast crisis, with rates of 50 to 60% in these patients. The WBC count begins to fall within the first 2 weeks and recovers within 4 to 6 weeks. The drop in the platelet count occurs in the first 3 to 4 weeks. Blood should be monitored weekly for the first month after initiating imatinib. In the chronic phase, it is recommended to withhold imatinib if the absolute neutrophil count falls below 1000/µl or if the platelets drop below 50,000/µl. Treatment may be restarted once the absolute neutrophil count has recovered to 1500/µl and the platelet count to 100,000/µl. Patients should be restarted on 400 mg/day unless they had profound myelosuppression or significantly delayed recovery. In these patients, restarting imatinib at 300 mg/day and then escalating to 400 mg/day in a few months is recommended. For patients with CML in accelerated phase or blast crisis, the decision to withhold imatinib should be weighed against the severity of their illness. A bone marrow biopsy may differentiate between bone marrow aplasia and persistent leukemia in these cases. Other common side effects include edema (50%), most commonly periorbital but also pleural or pericardial effusions, ascites, or anasarca; nausea (68%) and vomiting (50%); diarrhea (49%); muscle cramps (46%); skin rash (39%); and bone pain or arthralgias (20 to 40%). Edema should be managed with diuretics. In severe cases, imatinib treatment should be discontinued and restarted at reduced doses once edema is controlled. Nausea can be reduced by taking imatinib with food, dividing the dose, or using antinausea medications. Muscle cramps may be alleviated with calcium and magnesium supplementation. The skin rash is usually a maculopapular rash that is manageable with antihistamines or topical steroids. A few patients may develop a desquamative rash that requires discontinuation of imatinib and steroid therapy. Hepatotoxicity occurs in less than 5% of patients at a median of 3 months from the onset of therapy. It is recommended that liver function tests be monitored every other week in the first month and monthly thereafter. Imatinib should be discontinued for significant elevations of aspartate aminotransferase or alanine aminotransferase and restarted at a reduced dose once the liver function tests have normalized. The dose may be increased if there is no further rise in the liver function tests. An evaluation for other causes of liver dysfunction should be undertaken, including viral studies, a serum ferritin, and an a_1-antitrypsin level, and concurrent use of hepatotoxic drugs such as acetaminophen. Imatinib is metabolized by the CYP3A4/5 P-450 enzyme system. Thus, caution needs to be exercised when concurrent administration of drugs that affect or are affected by this system is used.

Drug resistance is associated with the reactivation of BCR-ABL signal transduction in all cases examined ([219] , [220] , [221] , [222] and [223]). Resistance is associated with either a single amino acid substitution in the adenosine triphosphate–binding region of BCR-ABL or with progressive BCR-ABL gene amplification. *In vitro* studies

have shown additive or synergistic activity of imatinib in combination with various cytotoxic agents, laying the groundwork for clinical studies using imatinib in combination with these agents ([224], [225] and [226]).

Other Drugs

Homoharringtonine (HHT) is a semisynthetic plant alkaloid. Phase II studies have shown activity in both chronic and more advanced phase CML. HHT has been used in combination with a-interferon and ara-C with promising results. In one study of 47 patients, HHT in combination with a-interferon produced a CHR rate of 85%, with major cytogenetic responses in 49% of patients and complete cytogenetic responses in 21% of patients. Myelosuppression was frequent but manageable ([227]). In a series of 100 a-interferon–resistant patients with chronic phase CML who received HHT and ara-C, the CHR rate in chronic phase was 72% and the cytogenetic response rate was 32% (major response, 15%; complete response, 5%). Toxicities were acceptable ([228]).

Decitabine, a hypomethylating agent, has been used to treat 31 patients with nonlymphoid blast crisis. The response rate was 26%, and the major toxicity was myelosuppression ([229]).

Polyethylene glycol interferon, a modified a-interferon molecule that is covalently linked to polyethylene glycol, has a longer half-life than a-interferon and can be administered once weekly. Based on the safety and tolerability profile in phase I studies, the dose of 6 µg/kg/week was selected for further study in phase II and III trials. This dose has a safety profile that appears comparable with that associated with 3 to 5 MU/m^2/day of a-interferon. Of 27 patients, 13 (48%) who did not respond to a-interferon therapy had either a CHR or improved cytogenetic response ([230], [231]).

Other tyrosine kinase inhibitors are under development. For example, a group of pyrido[2,3-d]pyrimidine src tyrosine kinase inhibitors has demonstrated profound inhibition of cell lines strictly dependent on BCR-ABL for growth as well as primary progenitor cells derived from patients with CML ([232]).

Marrow Transplantation

First developed in the 1970s, allogeneic hematopoietic stem cell transplantation (HSCT) was initially characterized by poor overall survival because of several serious and fatal complications. These included organ toxicity from the cytoreductive regimen, acute and chronic graft-versus-host disease (GVHD), bacterial and fungal infections, cytomegalovirus infection, and disease relapse ([233], [234] and [235]). Currently, all of these issues are well studied and more effectively prevented or treated, resulting in better survival results. It is now estimated that patients younger than 50 years of age can expect more than a 50% likelihood of long-term disease-free survival after allogeneic HSCT performed in first chronic phase (Fig. 84.6). Individual centers present data demonstrating even better survival than in large-scale conglomerated series of patients ([236], [237], [238] and [239]).

Figure 84.6. Survival curves for chronic myeloid leukemia patients receiving HLA-compatible family transplants.

HSCT performed in blast phase is unsatisfactory, with survival of less than 10%. Intermediate long-term results with survival of 25 to 35% are reported for patients transplanted in accelerated phase or for those who enter a second chronic phase and then undergo transplantation. Variability in the results of transplantation for patients in accelerated phase may be caused by the difficulty of defining this phase and by patients with minimal evidence of transformation to accelerated phase such as those with minor additional chromosome abnormalities compared to those with overt manifestations ([76]).

Various clinical parameters influence the likelihood of long-term survival after allogeneic HSCT. Increasing patient age, increasing interval from diagnosis, prior BU therapy, and more advanced stage of disease negatively affect outcome ([179], [240], [241]). Cytomegalovirus serologic status of the patient has also been found to affect outcome in unrelated donors but not in sibling donors ([242], [243]). Neither hydroxyurea nor a-interferon before allogeneic HSCT affects outcome ([244], [245]). In a retrospective analysis of 3142 patients treated with allogeneic HSCT for CML between 1989 and 1997 reported to the European Group for Blood and Marrow Transplantation, a risk score based on previously reported major pretransplant risk factors was developed ([242]). Histocompatibility, stage of disease at time of transplantation, age, sex of donor and recipient, and time from diagnosis to transplantation were found to be predictive variables (Table 84.9). Transplantation survival rates can exceed 70% and can be as low as 20% in patients with the best and worst prognostic features, respectively.

TABLE 84.9. Five-Year Probability of Leukemia-Free Survival, Transplant-Related Mortality, and Survival for Allogeneic Transplant Patients

Risk Score [a]	Leukemia-Free Survival (%)	Transplant-Related Mortality (%)	Survival (%)
0	60	20	72
1	60	23	70
2	47	31	62
3	37	46	48
4	35	51	40
5	19	71	18
6	16	73	22

[a] The risk score was calculated as follows: (a) donor type: HLA-matched sibling = 0, matched unrelated donor = 1; (b) stage of disease: chronic phase = 0, accelerated phase = 1, blast crisis = 2; (c) age (yr): <20 = 0, 20–40 = 1, >40 = 2; (d) donor/recipient gender: other = 0, female donor/male recipient = 1; (e) interval from diagnosis to transplant: <12 mo = 0, >12 mo = 1.

Modified from Gratwohl A, Hermans J, Goldman JM, et al. Risk assessment for patients with chronic myeloid leukaemia before allogeneic blood or marrow transplantation. Chronic Leukemia Working Party of the European Group for Blood and Marrow Transplantation. Lancet 1998;352:1087–1092.

BU (16 mg/kg) with cyclophosphamide (120 mg/kg) is the most commonly used pretransplant cytoreductive regimen ([246]). Overall survival is similar and toxicity lower than for regimens that include total body irradiation ([247], [248]). This is not true for acute leukemia, for which regimens containing total body irradiation appear superior ([249]). With the BU-cyclophosphamide regimen, virtually all patients enter a full molecular remission. Attempts to improve the cytotoxic regimen have yielded increased toxicity without better efficacy ([250]).

After HSCT, patients can be followed up by molecular evaluation of their marrow or peripheral blood for a rearranged BCR-ABL gene ([251], [252] and [253]). Transient reemergence of rearranged BCR-ABL can be observed using sensitive fluorescence *in situ* hybridization or RT-PCR techniques. If the abnormality remains present or

if quantitative evaluation indicates increasing amounts, relapse should be suspected ([254], [255], [256], [257], [258] and [259]).

Approximately 15 to 20% of allogeneically transplanted patients relapse with regrowth of host (recipient) cells. Patients experiencing GVHD have a lower rate of relapse than similar patients without GVHD. This phenomenon, known as the *graft-versus-leukemia reaction*, is best described in syngeneic HSCT, in which relapse is considerably higher than in allogeneic HSCT ([260], [261]). Syngeneic HSCT eliminates the contribution of autologous reinfusion of malignant cells, eliminating all other parameters except GVHD. A few intriguing cases of relapse in donor cells have been noted, with implications for the pathogenesis and acquisition of the disease ([262], [263]).

CML relapse after allogeneic HSCT can be reversed with discontinuation of GVHD therapy, treatment with a-interferon, performance of a second marrow transplant, or infusion of donor-derived leukocytes ([264], [265], [266], [267], [268] and [269]). These approaches augment the immune mechanism of graft-versus-leukemia and may cause flaring of GVHD and marrow aplasia ([270], [271]). Recent observations suggest that reinfusion of donor lymphocytes without additional cytotoxic treatment is the best method to combat relapse, with more than 75% of patients with chronic phase relapse reentering molecular remission ([272], [273], [274], [275], [276], [277], [278], [279], [280], [281] and [282]). The estimated dosage of reinfused T cells needed to control relapse is approximately 5×10^7 cells/kg. This dosage may reduce the risk of severe GVHD and still maintain the graft-versus-leukemia effect ([283], [284]). Lower dosages may be less effective, and higher dosages cause more GVHD. Adverse effects of donor lymphocyte infusion are marrow aplasia and GVHD ([285]). Marrow aplasia is more common when recipient cells (as opposed to donor cells) are the predominant source of hematopoiesis. The addition of a-interferon or interleukin-2 after donor leukocyte infusion has not been shown to conclusively affect remission ([261], [286]). Results from infusion of donor lymphocytes are better during molecular or cytogenetic relapse than in overt relapse and are substantially inferior for advanced disease ([287]). Current strategies to improve results of donor lymphocyte infusion have concentrated on decreasing the risk of GVHD after infusion. These strategies include selective depletion of lymphocyte subsets ([288], [289]), incremental doses of donor lymphocyte infusions ([290]), and gene modification of donor lymphocytes ([291], [292]). The advanced disease group is the only subset in which second marrow transplantation (as opposed to infusion of donor leukocytes) should be initially considered, yielding a survival rate of approximately 25% ([293]). Imatinib has been used in patients with CML who have relapsed after both autologous ([294]) and allogeneic HSCT ([295]). Response rates, both hematologic and cytogenetic, are high, especially in patients with chronic phase relapse.

GVHD remains the most problematic complication after allogeneic HSCT ([233]). The usual practice to prevent GVHD is posttransplant immunosuppression with two agents such as cyclosporine and methotrexate ([296]). Other agents, such as tacrolimus, methylprednisolone, antithymocyte globulin, monoclonal T-cell antibodies, and photoactive therapy, can also be used ([297]). Despite prophylaxis, 40 to 50% of patients receiving matched-sibling HSCT still develop GVHD, with 10% of cases being severe, leading to patient death. Efforts to reduce GVHD have been attempted but, unfortunately, have generally caused concomitant deleterious effects on relapse by reducing the graft-versus-leukemia reaction ([298], [299]). This sequence of events is best demonstrated with *ex vivo* T-cell depletion of the donor marrow, which leads to an increase in lymphocyte chimerism and residual leukemia ([300], [301]). Although reducing overall morbidity and virtually eliminating severe GVHD, potent T-cell depletion causes a marked increase in CML relapse (50% or more), resulting in inferior overall survival. Modification of T-cell depletion with partial depletion, increased pre- and posttransplant immunosuppression, and periodic donor leukocyte or T-cell reinfusion is currently under investigation ([302]).

Unfortunately, only approximately 25% of patients have siblings who are genotypic matched donors, defined by identical inheritance on chromosome 6 of the major histocompatible complex. Typing between donor and recipient, now performed by serologic and DNA-based methods, routinely reports on alleles at both the A and B loci (class I) and the DR locus (class II). Thus, a *full sibling match* is defined as a six-antigen match. Siblings and extended family members having fewer than six matched antigens can serve as donors. Survival using minimally disparate (phenotypic six-antigen and five-antigen) matches may not be significantly different from that of genotypic matched donors, although the rate of allogeneic complications increases ([303], [304] and [305]). These complications include graft rejection, failure of sustained marrow regeneration, and severe GVHD ([306]). Thus, in the absence of a sibling match, evaluation of the extended family should be pursued, especially if patient antigens are duplicated or one haplotype is uncommon and the other very common. Donors who are more disparate (less than a five-antigen match) are not routinely used. Haploidentical (three antigens matched) transplants are presently under investigation using a combination of more intense cytoreductive therapy and limited *ex vivo* T-cell depletion followed by long-term immunosuppression ([307], [308]).

Transplantation using matched unrelated donors, fostered by the National Marrow Donor Program and other large national donor centers, is an alternative for patients without suitable matched related donors. Initial reports described results that were inferior to fully matched sibling donor HSCT ([309], [310], [311], [312] and [313]). Increasing age of the patient and donor and increasing duration of chronic phase all reduced survival ([314], [315] and [316]). Because of substantial GVHD, *ex vivo* T-cell depletion for unrelated HSCT may result in satisfactory outcome ([302]). In the initial reports, donors were selected by serologic determination of HLA antigens ([316], [317]). It is now known that DNA methods are more precise in determining DR, other class II antigens, and, more recently, class I antigens. Using donors selected by DNA methodology for class II HLA yielded results not dissimilar to those of similarly matched related donor HSCT ([318]). Further improved survival is likely with DNA-based methods to select class I as well as class II HLA combined with matching for other loci such as C, DP, and DQ ([319], [320]). Despite these results, matched unrelated donor transplants are still associated with substantial allogeneic complications, especially GVHD and prolonged and pronounced immunodeficiency, limiting applicability to patients younger than 40 years old ([321], [322]). Improved results and wider applicability will require more effective methods of prophylaxis and treatment of GVHD and of augmenting immune reconstitution.

With the current size of the pool of volunteer donors, approximately 75% of white patients can locate a suitable matched volunteer donor ([323]). Patients belonging to minority ethnic groups have lower rates of success in locating a fully matched donor. Blacks, because of their greater prevalence of uncommon HLA, have a success rate of finding matched donors one-half that of American whites. The success of finding donors for minority groups will be improved only by a substantial increase in their donor pool.

Peripheral blood stem cell transplantation (PBSCT) has emerged as an alternative to BMT. Nearly all studies have indicated faster engraftment and earlier hematopoietic recovery with PBSCT than with BMT ([324], [325] and [326]). In some studies, the incidence of clinical extensive chronic GVHD in allogeneic recipients was higher with PBSCT than with BMT ([327], [328]), but others have not confirmed these findings ([324], [329]). Some studies have found improved overall survival using PBSCT ([330], [331]), although this is not universal ([329]). Cord blood is a rich source of hematopoietic stem cells and has been used in allogeneic marrow transplantation ([332]). Most experience with cord blood cell transplantation has been limited to children ([333]), but recent reports have extended its promise to adults ([334], [335] and [336]). Preliminary results suggest that GVHD may be much less common and less severe, thus permitting the use of more disparate donors ([336]). If true, this form of transplantation could extend allogeneic applicability to even more patients, especially those belonging to minority ethnic groups.

Much experience has been gained with nonmyeloablative HSCT, and the biology, indications, and limitations are becoming clearer ([337], [338], [339], [340] and [341]). Nonmyeloablative conditioning allows consistent engraftment of allografts from matched related, matched unrelated, and even partially matched donors. Nonmyeloablative HSCT has been able to reduce the toxicity of allogeneic HSCT. A number of studies have reported remissions, including molecular remissions, in a significant number of patients. The major toxicity continues to be GVHD. This therapy is usually reserved for patients over the age of 60 years or younger patients with severe comorbidities.

It is well established that normal cells reside in CML marrow but are displaced by the proliferative abnormal cells ([342], [343] and [344]). After intense cytotoxic therapy, the kinetics of recovery of hematopoiesis indicate that normal cells may proliferate faster than leukemic cells. Normal hematopoietic progenitor and stem cells are noted in the circulation during the early phase of count recovery after intense chemotherapy ([345], [346]). Collection of these *in vivo* purged marrow cells by either marrow aspiration or leukapheresis can, depending on the timing of collection, result in a large quantity of presumed normal stem cells ([347]). Mobilization of Ph(–) stem cells can be obtained in a significant percentage of patients in early chronic phase CML ([348]), and a number of patients can become Ph(–) after subsequent autologous HSCT ([349], [350]). However, genetic marking of the autologous hemopoietic stem cells has revealed that Ph(+) cells present in the autograft can contribute to relapse of CML ([351]). There are little long-term data on the results with autologous HSCT, and its role in the treatment of CML is not defined. Although potentially applicable to an older group of patients, the use of autologous HSCT remains an unproven therapeutic intervention that should be limited to well-designed studies for patients who are too old for allogeneic HCST or those who do not have suitable HLA-compatible family or unrelated marrow donors.

Allogeneic HSCT in advanced stages of CML is far less successful than in the first chronic phase. Although patients can be cured in the blast phase, the 10% long-term survival suggests that transplantation should be performed before transformation. The results in accelerated phase are intermediate between chronic phase and blast phase but are significantly inferior to the former. Patients (predominantly with lymphoid phenotype) evolving into blast phase but reverting into a second chronic phase with chemotherapy can undergo allogeneic HSCT with results similar to those in the accelerated phase. Other forms of transplantation using

autologous collected stem cells have not been proven to be beneficial when performed during advanced stages of CML.

In summary, allogeneic HSCT results in a 50 to 70% leukemia-free survival in a selected group of patients with chronic phase CML. This modality of therapy continues to improve with respect to diminishing toxicity. At the present time, allogeneic HSCT is the only treatment modality that produces a long-term leukemia-free survival in a significant number of patients. The role of allogeneic HSCT in CML is discussed below.

APPROACH TO A NEWLY DIAGNOSED PATIENT WITH CHRONIC MYELOID LEUKEMIA

The treatment of CML has become more complex, with many options for individual patients ([352], [353]). Furthermore, as new therapies emerge and established therapies improve, it may become increasingly difficult to counsel newly diagnosed patients in a rapidly changing field. The treatment paradigm at the present time is whether or not to recommend transplantation to a patient. It is also conceivable that transplantation and conventional therapies may become complementary treatments in the future, rather than the “either/or” decision that patients are often faced with today. The analyses comparing transplant to nontransplant therapies are hampered not only by the limitations of the studies comparing a-interferon to transplantation but also because of the (presumed) dramatically improved nontransplant therapies available with the advent of imatinib. Currently, there are no long-term data with imatinib. Based on preliminary results, at the very least, the hematologic and cytogenetic responses compare favorably with a-interferon–based therapy ([218]). Although the relationship between a cytogenetic response and prognosis is well established with a-interferon, one cannot automatically assume that this relationship will be true with imatinib. However, if hematologic and cytogenetic responses to imatinib are found to be durable, it may be reasonable to first treat every new patient with imatinib-based therapy. Patients in the appropriate age group in whom this therapy fails and who have an HLA-matched sibling or unrelated donor could subsequently be offered allogeneic HSCT. This approach has the advantage of avoiding the early mortality associated with allogeneic HSCT. There are no data to suggest that imatinib could adversely affect the outcome of allogeneic HSCT. However, it is conceivable that patients who do not respond adequately or who relapse after treatment with imatinib will inherently be a cohort of patients with a worse prognosis and, thus, have poorer transplantation outcomes. Given that one of the variables associated with improved outcome for allogeneic HSCT is transplantation within the first year, the above approach may reduce the chance of cure in patients who might otherwise have been offered transplantation early. Thus, another approach is to identify a subset of patients for whom upfront transplantation could be recommended. This would be based on the presumptions that this cohort of patients has a low mortality with transplantation and that this risk is outweighed by the risk of delaying this potentially curative treatment. Given the data comparing a-interferon with allogeneic HSCT, it seems reasonable to consider allogeneic HSCT for younger patients (<35–40 years) with an HLA-identical sibling donor and a high-risk Sokal or Hasford score. Despite the approximately 20% transplant-related mortality, transplantation seems to afford a significant survival benefit for this group compared to a-interferon. For patients with a matched unrelated donor, the age group cut-off may be decreased by approximately 10 years (<25–30 years). Similarly, for patients with a low-risk Sokal or Hasford score, a similar adjustment may be considered. Clearly, this decision will ultimately need to be made by patients after careful and deliberate counseling by their physicians. Patients who present with accelerated phase or blast crisis should be treated initially with imatinib at the higher dose of 600 mg/day, and suitable patients should be referred for an allogeneic HSCT.

Polycythemia Vera

DEFINITION AND HISTORY

Polycythemia vera (PV), also commonly called *polycythemia rubra vera*, is a chronic, clonal, myeloproliferative disorder characterized by a striking, absolute increase in the number of red blood corpuscles and in the total blood volume, and usually by leukocytosis, thrombocytosis, and splenomegaly. The bone marrow is typically hypercellular and exhibits hyperplasia of myeloid, erythroid, and megakaryocyte lineages.

In 1892, Vaquez described persistent polycythemia, as distinguished from relative and transient forms, in a man whom he believed to have a congenital cardiac lesion even though no auscultatory signs were noted. At autopsy, 1 year after the patient was first examined, his heart was found to be normal ([1]). In 1903 and 1908, Osler further clarified the clinical picture of the disease ([2]) and Türk, in 1904, called attention to the occurrence of leukocytosis as well as to immature forms of cells of the red and white series, suggesting a hyperplastic disorder of blood formation involving the marrow as a tissue and not merely erythrocytes ([3]). Thus, the general clinical picture of the disease was established in the earliest publications.

Synonyms less commonly used for PV include erythremia, splenomegalic polycythemia, Vaquez disease, Osler disease, polycythemia with chronic cyanosis, myelopathic polycythemia, erythrocytosis megalosplenica, and cryptogenic polycythemia.

EPIDEMIOLOGY

The age- and sex-adjusted incidence rate of PV was 1.9 per 100,000 person years in Olmstead County, Minnesota during the years 1935 to 1989 ([4]), and 2.6 per 100,000 person years in Malmo, Sweden during 1980 to 1984. PV appears to be somewhat more common in men than in women, with reported male to female ratios ranging from 1.2 to 2.2 in various studies ([4], [6], [7] and [8]). PV in younger patients reportedly shows less of a male predominance ([8]). Some ([5]) but not all ([4]) studies have suggested that the incidence of PV is increasing with time. The frequency of PV according to age and sex is shown in Figure 85.1.

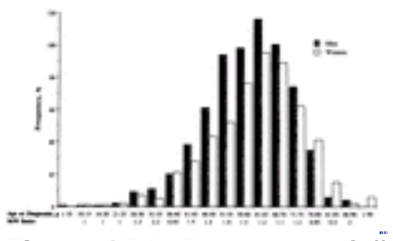

Figure 85.1. Frequency of diagnosis of polycythemia vera according to age and sex. Age at diagnosis of polycythemia vera for 671 men (55%) and 542 women (45%). M/W, ratio of men to women for diagnosis of polycythemia vera in each 5-year group. (From Gruppo Italiano Studio Policitemia. Polycythemia vera: the natural history of 1213 patients followed for 20 years. Ann Intern Med 1995;123:656–664, with permission.)

PV tends to be a disease of older individuals, with peak incidence observed at 60 to 80 years of age ([6], [8]), with maximum incidence exceeding 20 per 100,000 person years ([4]). The mean age at diagnosis has increased steadily since the 1920s ([6], [9], [10], [11] and [12]). Cases of PV have also been reported in patients younger than the age of 40 years ([13], [14]).

Racial and ethnic factors influence the incidence of PV. PV is significantly less common in blacks than in whites ([7], [10], [15]). In contrast, PV is more common in individuals of Jewish origin (an observation originally made by Türk) than in individuals not of Jewish origin ([7], [10], [16], [17] and [18]). Ashkenazi Jews in Northern Israel exhibit a higher incidence of PV than do their neighbors of Arab or Sephardic Jewish origins ([18]).

Familial occurrence of PV has been reported by 6% of patients enrolled in the protocols of the Polycythemia Vera Study Group and in intermittent sporadic cases ([19], [20] and [21]). It was previously claimed that PV affected primarily those of slender body habitus, but there is little evidence to support this statement ([10]).

CLINICAL FEATURES

The symptoms and signs of PV can be attributed in large part to the expanded total blood volume and to the slowing of the blood flow as a result of increased blood viscosity, as discussed in Chapter 50. It is evident from the history in most cases that the disorder probably has been present for a long time. Patients may complain of headache, dizziness, tinnitus, visual disturbances, dyspnea, lassitude, or weakness. Although the color of the skin often is acknowledged to have been abnormal for a long time, this complaint alone rarely brings the patient to the physician. Skin and mucous membrane hemorrhages are not uncommon; these, or a sense of

weight or swelling in the abdomen owing to enlargement of the spleen, may be the initial symptoms. The lack of specificity of symptoms may in fact contribute to the delay in diagnosis. On the other hand, some patients have no complaints whatever, the polycythemia being discovered incidentally. Table 85.1 lists the frequency of common symptoms and physical findings in patients with PV.

TABLE 85.1. Physical Findings and Symptoms in Polycythemia Vera

Physical Findings	Frequency (%)
Splenomegaly	70
Skin plethora	67
Conjunctival plethora	59
Engorged vessels in the optic fluid	46
Hepatomegaly	40
Systolic blood pressure>140 mm Hg	72
Diastolic blood pressure>90 mm Hg	32
Symptoms	
Headache	48
Weakness	47
Pruritus	43
Dizziness	43
Diaphoresis	33
Visual disturbances	31
Weight loss	29
Paresthesias	29
Dyspnea	26
Joint symptoms	26
Epigastric discomfort	24

Data from Berlin NI. Diagnosis and classification of the polycythemias. Semin Haematol 1975;12:339–351.

Skin and Mucous Membranes

The color of the face is not cyanotic but is rather “ruddy,” as might be produced by severe sunburn or a profound blush. The face also often appears swollen. This “rubor” may be so intense that it produces a startling appearance. The face, particularly the lips, cheeks, tip of the nose, ears, and neck, show this color (Fig. 85.2), but the skin of the trunk usually is not particularly affected. The distal portions of the extremities exhibit these changes more than the proximal portions and may be more truly cyanotic. The skin capillaries are distended, and the capillary loops are enlarged. The degree of red or blue coloration depends on the state of dilation of the peripheral vascular network and on the speed of circulation through these areas, because these factors determine the quantity of reduced hemoglobin present ([22]). These findings are not unique to PV, but are also observed in patients with an elevated hematocrit from secondary erythrocytosis.

Figure 85.2. Photograph of a drawing (original in color) of one of Osler's original patients.

Ecchymoses of various sizes are common as the disease progresses. Red or dark-violet spots or brownish pigmentation of the skin may be found, and a great variety of skin lesions ([23], [24]) have been observed, including dry skin, eczema, acneiform or urticarial changes, acne rosacea, acne urticata ([25]), urticaria pigmentosa ([26]), and even a nodular eruption resembling leukemia cutis ([27]). Purpura were observed in 13 of 163 PV patients in one series ([28]). The eyes may appear bloodshot. The mucous membranes may be a deep raspberry-red, and epistaxis and/or gingival bleeding may occur.

A common complaint is intense itching after exposure to water (most typically in a bath or shower)—the so-called “aquagenic pruritus.” This may be the initial presentation of PV and is reported in up to 60% of PV patients younger than the age of 40 years ([14], [29]). The itching may be so troublesome that bathing with hot or even warm water is avoided. The reaction is less frequent after the use of cold water. This complaint tends to disappear as the polycythemia is treated, but may require specific intervention. Reddening, swelling, and pain in the digits (erythromelalgia) may occur and are typically associated with extreme platelet elevations ([30], [31]).

Cardiovascular System

Cardiac symptoms are not particularly prominent, and cardiac hypertrophy is typically absent. The circulatory minute volume is reduced, and the velocity of blood flow is greatly lowered ([32]), but the cardiac output and work are normal ([33], [34]). When echocardiographic abnormalities are observed, they are typically associated with previous thromboembolic events and consequent pulmonary hypertension ([35]). Whether PV increases the risk for myocardial infarction is unclear, because PV occurs in the population generally considered to be at highest risk for this disorder. Increased blood viscosity related to polycythemia, however, may contribute to symptoms in patients with atherosclerotic cardiovascular disease ([36], [37]). Thrombotic events, in both the arterial and venous circulations, are common in patients with PV. Nineteen percent of the 1213 patients followed by the Gruppo Italiano Studio Policitemia experienced a thrombotic event. Of these, 50.5% of nonfatal thrombotic events occurred in the arterial circulation and 38.5% in the venous circulation; insufficient data were available to allow a determination to be made in the remaining 11%. More than 80% of fatal thromboses were arterial ([8]). Other abnormalities of the venous system include varicosities and phlebitis ([38]). Moderate or significant thickening of the peripheral arteries is found in patients with PV, and coronary thrombosis, claudication without occlusion, arterial occlusion with gangrene, acroparesthesia, Raynaud phenomenon, and thromboangiitis obliterans have been described ([30]).

As noted in Table 85.1 and in other studies ([39], [40]), hypertension is relatively common in patients with PV. It is unclear whether this reflects the increased incidence

of hypertension in the middle aged and elderly or is a consequence of increased blood viscosity. Certainly, improvement of blood viscosity by reduction of the red cell volume aids in the control of blood pressure ([40]).

Gastrointestinal System

In addition to nonspecific gastrointestinal symptoms experienced by everyone at some time, such as feelings of fullness, thirst, gas pains, and constipation, patients with PV have an increased frequency of peptic ulcer, gastrointestinal bleeding, or thrombosis of mesenteric vessels. Duodenal ulcer has been found in as many as 8% of patients with PV, almost four times more than in a control series ([41]). In another series of 125 patients, duodenal ulcer was found in 16% of patients, and gastric ulcer was found in 7% ([42]). It has been suggested that these ulcers follow thrombosis in the vessels of the first part of the duodenum and are produced by digestion of the area of local necrosis ([43]). The relationship of blood basophil concentration, histamine content, gastric acid secretion, and dyspepsia on peptic ulceration has also been examined in a small group of patients with PV ([44], [45]). No convincing correlations were demonstrated. The relationship between PV and *Helicobacter pylori* infection has not been explored.

Massive hemorrhage from varices in the esophagus, stomach, or bowel may be observed ([46]). Thrombosis in the mesenteric veins and arteries may be mistaken for peritonitis or the perforation of an ulcer. Hepatomegaly is common (Table 85.1), and cirrhosis has also been reported ([47]). *Mosse syndrome* is a term applied by some to the coexistence of cirrhosis and PV ([48]). Budd-Chiari syndrome has also been reported ([49], [50] and [51]).

Splenomegaly

Clinically appreciable splenomegaly occurs in more than two-thirds of PV patients (Table 85.1) ([9], [12]). The size of the spleen varies greatly in individual patients and occasionally may extend to the pelvic brim ([39]). It is usually hard and smooth. Patients may experience pain in the splenic region, and after infarction a friction rub can be heard in this area. The general assumption is that polycythemia antedates the enlargement of the spleen and that engorgement of this organ with blood and extramedullary hematopoiesis are the major contributors to splenomegaly.

Respiratory System

Dyspnea on severe exertion is common, and hoarseness is not unusual. Chest radiographs often reveal prominent vascular markings. Before the establishment of the Polycythemia Vera Study Group diagnostic criteria, which require a reasonably normal arterial oxygen saturation for the diagnosis of PV, it was noted that the vast majority of patients with PV had normal arterial oxygen saturation, even when the hemoglobin levels were high, indicating that the high viscosity of the blood does not prevent normal blood oxygenation; oxygen dissociation studies were also normal ([52], [53] and [54]). High diffusing capacities, which were reduced after phlebotomy, were also noted in a number of patients with PV ([55]). In another study, hypoxia, as evidenced by a low arterial oxygen tension and saturation, was observed in the absence of demonstrable coexistent cardiorespiratory disease ([56]). In these individuals, ventilation-perfusion ratios were altered, and the diffusing capacity was low. The authors postulated that these findings might be the result of an alteration of the pulmonary vasculature caused by unrecognized thromboembolism. They were probably correct in this assumption. Pulmonary hypertension is reported in patients with PV and other myeloproliferative disorders ([35], [57]).

Genitourinary System

Vesical, vaginal, and uterine bleeding have been reported, as has nontraumatic perirenal hematoma ([58]). When hypertension is noted, albuminuria and signs of renal disease may be found.

Neuromuscular System

Headache is the most common neurologic symptom ([59]), but lassitude, vertigo and giddiness, transitory syncope, insomnia, weakness, and a sensation of fullness in the head and numbness and tingling in the fingers (less often in the feet) are common.

Visual disturbances are common and include transitory dimness of vision, or even temporary blindness, scotomas, specks and bright points in front of the field of vision, diplopia, and temporary paralysis of one of the eye muscles. On examination of the eye grounds, the vessels may be engorged, tortuous, and irregular in diameter; the veins may be dark purple, and the retina deeply colored. Papilledema and embolism of the central retinal artery have been reported ([60]).

The cerebrospinal fluid pressure may be increased ([24]). Ringing and roaring in the ears are exceedingly common when the hematocrit is significantly elevated. Ménière syndrome has also been reported.

Vascular lesions of the brain constitute the most serious complication of PV. A variety of neurologic syndromes, ranging from hemiparesis to seizures to alteration of cerebral function, have been reported in patients with PV. All such symptoms and signs presumably are secondary to increased blood volume and/or decreased blood flow. Investigators have shown clearly that cerebral blood flow is greatly diminished at hematocrit levels between 0.53 and 0.62 ([61]), and that elevated hematocrit is a risk factor for cerebrovascular accidents ([62], [63]). Central nervous system vascular events represented 30% of the nonfatal thrombotic events observed in the Gruppo Italiano Study, and 10.3% of deaths ([8]).

Pain in the limbs may be troublesome and severe. It has been attributed to pressure on the bone by swollen, hyperplastic bone marrow. Unusual paresthesias may be encountered, but anatomic evidence of spinal cord changes has not typically been found at autopsy.

BLOOD AND LABORATORY FINDINGS

Hematologic Findings

ERYTHROCYTES Hemoglobin concentration typically is in the range of 18 to 24 g/dl. Red cell counts of 7 to 10 × 10^{12}/L are common when patients with this disease are first evaluated, and values as high as 12 and even 15 × 10^{12}/L have been recorded ([64]). The highest hematocrit recorded is 0.92 in a patient with PV in whom the red cell count was 10.37 × 10^{12}/L ([65]). The individual erythrocytes usually appear normal. Slight anisocytosis may be evident, but poikilocytosis is unusual. Polychromatophilia and, occasionally, basophilic stippling may be found. An occasional normoblast may be observed in the blood smear and such a finding, in the presence of a relatively normal or definitely increased red cell count, should arouse suspicion of PV. The reticulocyte count, in percent, is not significantly increased. After hemorrhage, however, the reticulocytes may be increased, and a number of other immature forms of the red cell series may be encountered. If bleeding occurs repeatedly, iron-deficient erythropoiesis may develop. This raises an interesting semantic point: these patients are iron deficient in that iron stores are absent, but the total body iron content, including the iron present as hemoglobin in red cells, may be normal. Increased resistance to osmotic lysis has been reported for PV erythrocytes ([66], [67]).

LEUKOCYTES Leukocyte counts of 25.0 × 10^{9}/L are not uncommon ([68]), and values above 50.0 × 10^{9}/L have been reported ([69], [70]). The myeloid leukocytes are both relatively and absolutely increased, metamyelocytes are increased in number, and 1 or 2% of myelocytes, sometimes more, are found. Myeloblasts usually are not observed. Basophil, eosinophil, or monocyte concentrations may be increased and provide a marker of an underlying myeloproliferative disorder. Leukocytes from patients with PV exhibit increased metabolic activity ([71]). Neither Vaquez nor Osler appreciated the significance of the moderate or even marked leukocytosis, together with a “shift to the left” in the myeloid series of leukocytes, that often is present in this disease initially named after them. Türk, in 1904, called attention to this significant finding, which suggested that the whole bone marrow, rather than the erythropoietic tissue alone, was hyperactive. The leukocyte counts were greater than 10.0 × 10^{9}/L in 50% of Osler's patients and greater than 12.0 × 10^{9}/L in 43% of the 325 Polycythemia Vera Study Group patients ([32]). In another series of 127 patients, the white cell count was elevated in 84% of patients ([45]).

PLATELETS The platelet count frequently is increased, usually in the 500 to 1000 × 10^{9}/L range, but counts as high as 3000 and even 6000 × 10^{9}/L have been reported ([72]). Bleeding time and conventional coagulation parameters usually are normal, but the clot may retract poorly. An artefactual elevation of protime and activated partial thromboplastin time may be observed in patients with erythrocytosis. The standard citrated tube used for coagulation studies contains a fixed quantity of anticoagulant for a fixed volume of blood. In polycythemia, there is a relative reduction of plasma, meaning that there will be excess anticoagulant for the volume of

plasma. Functional assays of coagulation factors will thus be prolonged. This prolongation has no clinical significance, other than provoking panic on the part of the individual reviewing the laboratory results. The leukocyte and platelet counts are not always increased above normal in patients with otherwise typical disease. Such normal values were found in 20% of the patients in one series ([12]). Morphologic and qualitative functional platelet abnormalities often are detectable. Platelets may appear to be abnormally large, and even bizarre shaped, and megakaryocyte fragments sometimes are seen in the blood smear. The hemorrhagic complications of this disease suggest that a hemostatic defect may be present, although physical distention of the vascular bed undoubtedly contributes to bleeding when it occurs. Platelet function defects reported in PV include shortened platelet survival in patients with erythromelalgia ([73]), altered von Willebrand factor multimers ([74]), deficient platelet-aggregating factor–induced aggregation ([75]), increased platelet thromboxane production ([76]), and platelet factor 3 deficiency ([77]). Plasminogen activator inhibitor-1 levels have been reported to be both elevated ([78]) or decreased ([79]) in patients with PV. Platelet glycoprotein IIIa expression has also been reported to be decreased in PV patients ([80]).

TOTAL BLOOD VOLUME The total blood volume characteristically is increased. The enormous increase in blood volume, which distends even the smaller vessels of the whole body, no doubt accounts for many of the symptoms of this disease. In a group of 30 patients in whom the hematocrit was 0.55 or greater, the total red cell volume, measured by the radioactive phosphorus (^{32}P)-labeled red cell method, was 38.8 to 91.9 ml/kg body weight as compared with the normal average of 29.9 ml/kg ([81]). In two-thirds of this patient group, the plasma volumes were below the lower limits of normal, and in none was the plasma volume above normal. Similar observations have been made using the chromium isotope method ([6] , [12]). Because of variations in plasma volume, the packed cell volume (or hematocrit) gives only a rough indication of the size of the red cell mass.

ERYTHROCYTE KINETICS Erythrokinetic studies have shown active hemoglobin production, but otherwise, findings have been diverse. Erythrocyte survival may be normal ([72]) or shortened ([82]), and splenic sequestration may or may not be present. As measured by the 15 N-glycine method, the rate of hemoglobin production was approximately two times the normal rate. The plasma iron turnover rate was also increased ([83]). This value was not reduced to normal by oxygen administration, as occurs when polycythemia is caused by anoxia. Increased serum bilirubin ([65] , [67]) and increased urine and stool urobilinogen ([84]) levels have been demonstrated in some patients with PV, but when allowance is made for the increase in the total amount of hemoglobin that must be degraded, fecal urobilinogen values rarely are increased above expected values and may, in fact, be somewhat reduced.

NEUTROPHIL KINETICS Studies of neutrophil kinetics in patients with PV in whom neutrophil counts ranged from normal to 23.9 × 10^{9}/L showed a blood neutrophil pool that ranged from normal to 12 times normal, with increased margination and a normal or slightly prolonged half disappearance time. The blood neutrophil turnover rate (effective neutrophil production) usually was increased and varied from normal to five times normal mean values ([85]). Increased polymorphonuclear leukocyte activation is also observed in PV patients, and is associated with evidence of endothelial damage ([86]).

PLATELET KINETICS Studies of platelet kinetics in five patients with PV in whom the platelet concentration was increased revealed effective production rates that ranged from 2 to 13 times normal. The marrow megakaryocyte mass was increased in all five patients studied ([87]).

FIBRINOGEN TURNOVER Results of studies involving three patients with erythremia indicated that fibrinogen was consumed in the course of chronic disseminated intravascular coagulation ([88]); similar findings were observed in several patients with erythrocytosis secondary to pulmonary insufficiency. No correlations between fibrinolytic parameters and thrombotic complications of PV has been reported ([89]).

Other Laboratory Findings

The viscosity of the blood may be five to eight times greater than normal ([65] , [90]). The specific gravity is 1.075 to 1.080, compared with the normal range of 1.055 to 1.065. The degree of abnormality varies with the relative quantity of red corpuscles. The viscosity and specific gravity of the serum were actually less than normal ([91]). The erythrocyte sedimentation rate of polycythemic blood is significantly increased. The urine may be normal, but albuminuria is found occasionally, and, less often, casts are present ([68]). The increased urobilinogenuria noted in some of the patients has been mentioned. Studies of renal hemodynamics suggested that glomerular filtration, despite the decreased fraction of plasma in the blood, is kept at almost normal values by an increase in renal blood flow and in the proportion of plasma filtered ([92]). The amount of uric acid in the serum may be normal or increased. Hyperuricemia was present in 70% of 127 patients in one series ([45]) and in 55% of 325 patients ([6]) in another series. Values ranged from 2.8 to 11.7 mg/dl (average, 6.6 mg) ([68]). Secondary gout occurs in 5% ([10] , [12]) or more of these patients ([12] , [42] , [45] , [93]), and symptoms often are atypical ([64]). The occurrence of hyperuricemia in association with PV is attributable to overproduction of uric acid ([94] , [95]). A vitamin B_{12}–binding protein, which may be an altered form ([96]) of transcobalamin I (Chapter 32), has been found in the plasma of patients with PV ([97]) and in a variety of conditions involving leukocytosis ([96]). The presence of this protein may explain the observation that, whereas serum B_{12} content may be within the normal range or only moderately elevated, the capacity of the serum to bind additional vitamin B_{12} added *in vitro* (unsaturated B_{12}-binding capacity, $UB_{12}BC$) is increased. Plasma homocysteine levels in polycythemic patients appear to be normal ([98]).

Spurious hyperkalemia has been noted when platelets are greatly increased in number ([99]). Hyperhistaminemia and hyperhistaminuria were reported in two-thirds of a series of patients with PV ([100]), which may explain, in part, the pruritus often present. The basal metabolic rate may be increased moderately ([101]). Gastric acidity ranges from absent to increased.

Patients with PV and thrombosis exhibit a greater frequency of procoagulant abnormalities in antithrombin III, protein C, protein S, and resistance to activated protein C, than do PV patients without thrombosis ([102]). Studies of prothrombin and factor V gene polymorphisms with a thrombotic diathesis showed no increased incidence of these abnormalities in PV patients ([103]). However, polymorphisms of the PI^{A2} allele of platelet glycoprotein IIIa were associated with increased arterial thrombosis in PV and essential thrombocythemia patients ([103]).

Bone Marrow

The value of bone marrow examination is debatable in the differentiation of PV from other myeloproliferative disorders, from secondary polycythemia, from spurious polycythemia, or from the normal state. Some investigators believe it to be an invaluable aid for making this differentiation ([104] , [105]); others regard it as an important diagnostic tool but not one that is capable of definitively establishing the diagnosis ([9]). The Polycythemia Vera Study Group does not include the bone marrow among its diagnostic criteria for PV.

The marrow typically is hypercellular ([106] , [107]) (Fig. 85.3), but normal cellularity is noted at the time of diagnosis in approximately 13% of cases ([108]). The hyperplasia involves all of the marrow elements and displaces marrow fat. Cellularity can be estimated with considerable accuracy by low-power examination of clot sections and needle or trephine biopsies. Planimetry or more detailed and time-consuming examination is not necessary ([104]), because comparative studies have shown good correlation between estimates and actual measurements of cellularity ([103] , [109]). In several series, the mean cellularity of the marrow was 80 to 90% compared to approximately 30% in normal subjects and 40% in patients with secondary erythrocytosis ([104] , [105] , [109]). As mentioned, a few patients with untreated PV may have normal marrow cellularity ([108] , [109]). Thus, the lack of hypercellularity does not exclude the diagnosis but should make it suspect.

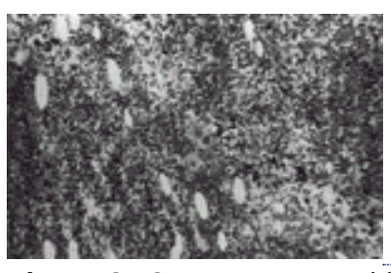

Figure 85.3. Bone marrow biopsy from a patient with polycythemia vera, showing hypercellularity and hyperplasia of myeloid, erythroid, and megakaryocyte series (1000×).

An increase in megakaryocyte number and size is well documented in association with PV and was reported in 95% of 175 cases. When the number of megakaryocytes was expressed in terms of fat-free marrow, however, the megakaryocyte hyperplasia was shown to be proportional to overall marrow cellularity ([109]). The ratio of the different cell types in the marrow is not strikingly different from normal. Clumps of pronormoblasts and basophilic erythroblasts are seen ([106]), and the

percentage of nucleated red cells may be moderately elevated ([110]) Myelocyte and myeloblast numbers may be greater than normal, and an increase in eosinophils ([104]) and basophils may be found ([110]).

Iron pigment is absent from the marrow in more than 90% of patients, even when phlebotomy has not been performed ([104], [109]). Increased marrow iron stores has been suggested as a morphologic hallmark favoring a secondary form of erythrocytosis over PV ([111]). An increase in marrow reticulin levels and/or fibrosis has often been reported, but an increase was observed in only 11 to 15% of patients studied early in the course of their disease ([108], [109]). The increase in reticulin correlates with the degree of marrow cellularity ([109]). It is slowly progressive but no increase occurs in association with a particular form of treatment or with the duration of the disease ([108]). Marrow vascularity may be increased in PV and other myeloproliferative disorders ([112]).

Cytogenetics

In early studies of cytogenetic abnormalities associated with PV, aneuploidy was noted in some patients; however, many subjects had been treated previously and modern banding techniques were not used ([113]). In more modern studies, cytogenetic abnormalities were observed in 20 to 43% of patients ([112], [113] and [114]). The frequency of chromosomal abnormalities varied with the clinical picture. Results from two series are presented in Table 85.2 ([115], [116]). Fewer than 20% of patients studied at diagnosis had a cytogenetic abnormality. Patients evaluated during a clinical course not associated with progression had cytogenetic abnormalities in 25 to 35% of cases. However, patients who progressed to either myeloid metaplasia, myelofibrosis, or acute leukemia/myelodysplastic syndrome had abnormal cytogenetics in 75 to 100% of evaluations. The greater frequency of cytogenetic abnormalities in patients progressing to myelofibrosis in one of these series may reflect the greater utilization of ^{32}P therapy and alkylating agents among those patients ([116]). The cytogenetic abnormalities most commonly observed were trisomy 8, trisomy 9, and deletions of Y, 5q, 6q, 7q, 11q, 13q, and 20q ([115]). Although cytogenetics do not predict outcome, they appear to be correlated with disease stage and duration. Specific evaluation for trisomy 8, trisomy 9, and 20q- by fluorescent *in situ* hybridization may be a useful adjunct to conventional cytogenetics ([117]).

TABLE 85.2. Frequency of Abnormal Cytogenetics by Polycythemia Vera Disease Stage in Two Series

		Frequency (Expressed as Percentage of Patients)				
Reference	Patient Number	At Diagnosis	Polycythemia Vera	Myelofibrosis	Myeloid Metaplasia	Acute Leukemia/Myelodysplasia
116	64	17	32	85	75	75
115	37	14	25	40	78	100

PATHOGENESIS

The cause of PV is unknown. The early suggestion that this disease was the compensatory result of anoxemia of the bone marrow was based on the presence of capillary thickening and subintimal and adventitial fibrosis of small vessels in the bone marrow ([17]). Direct measurements of bone marrow oxygen saturation, however, gave normal values ([118], [119]), and the lack of elevated serum or urinary erythropoietin levels ([120], [121]) is also contrary to this hypothesis.

Clonality

In view of the increased production and turnover of erythrocytes, neutrophils, and platelets as well as the hypercellular marrow, a more likely possibility is that cell production in PV is abnormal at the stem cell level. Evidence supporting this hypothesis was provided by a study of two black female patients with PV who were heterozygous for X-linked glucose-6-phosphate dehydrogenase deficiency ([122]). In these patients, tissues not affected by this disease (skin fibroblasts and lymphocytes) possessed both A and B type glucose-6-phosphate dehydrogenase isozymes, as expected. Red blood cells, granulocytes, and platelets contained only one isozyme (type A), however, thus demonstrating a probable clonal origin of this disorder at a pluripotent hematopoietic progenitor level. In one other patient, most B lymphocytes were also from the disease clone ([123]), indicating involvement of an earlier hematopoietic progenitor that had differentiation potential for the lymphoid as well as the myeloid, erythroid, and megakaryocytic series.

Hematopoietic Progenitor Studies

The number of erythroid progenitors [burst-forming units erythroid (BFUs-E)] and erythroid colony-forming units erythroid (CFUs-E) detected in PV patients has been variously reported as either similar to that observed in normal persons or increased ([124], [125]). It has also been suggested that there is an increase in cycling of primitive BFUs-E, and that CFUs-E (typically observed only in marrow) are to be found in the peripheral blood of patients with PV ([126], [127]).

A hallmark of PV (and other myeloproliferative disorders as well) is erythroid progenitor colony formation *in vitro* without the addition of exogenous erythropoietin—the phenomenon called *endogenous erythroid colonies* or sometimes *erythropoietin-independent colony formation* (Fig. 85.4) ([128], [129]). This phenomenon has been observed with progenitors cultured from the marrow ([124], [126], [130], [131], [132] and [133]) or the blood ([124], [126], [127], [133]) of PV patients. This can be a consequence of true erythropoietin independence or of exquisite sensitivity to erythropoietin, which would permit a response to the extremely small quantities of erythropoietin present in the serum used in culture media. A variety of investigators, using either serum-free medium or neutralizing antibodies to erythropoietin in serum-containing medium, have provided data suggesting that endogenous erythroid colonies are a consequence of enhanced sensitivity to erythropoietin ([132], [134], [135] and [136]). Another group subsequently reported studies suggesting that endogenous erythroid colonies are a consequence of an altered response pattern induced by hypersensitivity to interleukin-3 ([137]). A more recent report, using antibodies capable of blocking the erythropoietin receptor, suggests that BFUs-E fall into two categories: those that exhibit a normal response to erythropoietin and those that are truly erythropoietin-independent ([138]).

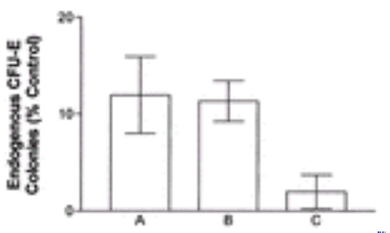

Figure 85.4. Endogenous erythroid colony formation in polycythemia vera. Colony-forming unit erythroid (*CFU-E*) colony formation *in vitro* in the absence of exogenous erythropoietin by patients with polycythemia vera (*A*, *B*) and secondary polycythemia (*C*). Results are expressed as a percentage of colony formation in the presence of erythropoietin 1 U/ml.

In addition to interleukin-3 and erythropoietin, erythroid progenitors from PV patients have been reported to exhibit hypersensitivity to granulocyte-macrophage colony-stimulating factor, interleukin-1, stem cell factor, and insulin-like growth factor-1 ([137], [139], [140], [141], [142] and [143]).

Hematopoietic Growth Factor Signal Transduction

The reported hypersensitivity of erythroid progenitors to erythropoietin in PV prompted evaluation of the erythropoietin receptor in this disease. The normal human erythropoietin receptor, although the product of a single gene, is expressed on CFU-E as a high- and low-affinity receptor ([144], [145]). In CFU-E generated from PV patients, only the low-affinity receptor is present ([146]). This differs from the finding in normal individuals, patients with hemolysis, or patients with secondary

erythrocytosis. Studies of the erythropoietin receptor gene in PV have typically shown no mutations ([147], [148]), suggesting that the presence of only the low-affinity receptor class is the result of an alteration in posttranslational processing. Normal erythroid progenitors have been reported to express both a full-length erythropoietin receptor and a nonfunctional truncated version, which is believed to act as a dominant negative regulator of erythropoietin signal transduction. Expression of the truncated variant is reportedly decreased in PV patients, suggesting a mechanism for erythropoietin hypersensitivity ([149]).

The thrombopoietin receptor (Mpl) has been reported to be markedly decreased or absent on the platelets of PV patients and also of some individuals with myelofibrosis ([150]). These individuals exhibit decreased thrombopoietin-induced tyrosine phosphorylation ([150]). This decrease in phosphorylation appears to result from aberrant signaling through an abnormal Mpl characterized by decreased glycosylation ([151], [152]). It has been suggested that this abnormality in Mpl expression and function is both a marker for PV and, through suppression of apoptosis, a potential pathophysiologic contributor ([152]). Other investigators have questioned the usefulness of Mpl as a diagnostic marker of PV, as marked heterogeneity in its expression was observed in their laboratory, resulting in overlap with normal individuals ([153]).

The characteristic behavior of hematopoietic progenitors in PV may also reflect constitutive or deregulated activation of antiapoptotic mechanisms. Various investigators studying PV have reported constitutive activation of Stat 3 ([154]); deregulation of the anti-apoptotic protein Bcl-x ([155]); decreased expression of SHP-1 phosphatase, a negative regulator of hematopoietic growth factor–induced mitogenesis ([156]); increased protein tyrosine phosphatase activity ([157]); and decreased sensitivity of protein kinase C to the effects of inhibitors ([158]). The tumor-suppressor gene H19 has also been reported to be decreased in PV patients ([159]).

PRV-1 is a gene of the urokinase plasminogen activator receptor superfamily, which is highly expressed in granulocytes from PV patients but not from patients with other chronic myeloproliferative disorders or from normal individuals ([160]). Polymerase chain reaction–based techniques for detecting PRV-1 have been developed, and appear to be highly sensitive and specific for PV ([161], [162]). Genomic analysis suggests that PRV-1 is an allele of the gene encoding the neutrophil glycoprotein CD177 ([163]). It appears at present that PRV-1 is a marker of PV rather than a contributor to its pathogenesis.

DIAGNOSIS

The approach to patients with elevated hemoglobin concentrations and hematocrit is outlined in Chapter 50. The Polycythemia Vera Study Group developed a set of criteria that are useful clinically and conceptually (Table 85.3) (6). The diagnosis of PV requires the presence of all three major criteria (M) or the first two major criteria and two minor criteria (m). The first major criterion provides confirmation that the patient has actual polycythemia, as indicated by an elevated red cell mass. The second major criterion rules out the most common etiology of secondary polycythemia, severe arterial hypoxemia, by demonstrating a normal or only moderately reduced arterial oxygen saturation. The third criterion, evidence of a myeloproliferative syndrome, is provided either by the third major criterion, splenomegaly appreciable on physical examination, or by two of the four minor criteria.

TABLE 85.3. Polycythemia Vera Study Group Diagnostic Criteria: Significance and Proposed Alternatives/Additions

Significance	Original Criteria	Alternative/Additional Criteria
M1. Identifies actual polycythemia vs. spurious polycythemia	M1. Increased RCM Male >36 ml/mg Female >32 ml/kg	M1. RCM >125% of predicted
M2. Rules out most common etiology of secondary polycythemia	M2. Arterial O_2 saturation>92%	M2. Serum erythropoietin concentration not elevated
M3. Evidence of a myeloproliferative state	M3. Clinical splenomegaly or two of the following: m1. Thrombocytosis >400,000/ µl m2. Leukocytosis >12,000/ µl m3. Leukocyte alkaline phosphatase activity >100 (no fever or infection) m4. Serum B_{12} (>900 pg/ml) or unsaturated B_{12} binding capacity (>2200 pg/ml)	M3. (additional minor criteria) Splenomegaly apparent only on scans Hypercellular marrow with trilineage hyperplasia Characteristic hematopoietic colony response to growth factors Evidence of clonal marrow cell population PRV-1 gene expression in granulocytes Decreased Mpl expression on platelets

RCM, red cell mass.

It should, however, be remembered that the Polycythemia Vera Study Group's goal was to establish exclusive criteria, which would mean that all patients included in their protocols had clear-cut and inarguable PV. Although most PV patients meet the diagnostic criteria, some do not.

In the early phases of PV, the red cell mass may not be sufficiently elevated to meet the established criterion (Table 85.3). It has been proposed that a red cell mass >125% of predicted is a more appropriate diagnostic criterion for polycythemia ([164]). In other circumstances, blood loss may result in “auto-phlebotomy”—that is, the patient becomes iron deficient, and the hemoglobin and hematocrit fall into the normal range. A patient with an otherwise typical picture of PV would then appear to have either chronic myelogenous leukemia (CML), essential thrombocytosis, or the early cellular phase of myelofibrosis. The diagnosis of essential thrombocytosis requires demonstration of reticuloendothelial iron stores (Chapter 56), and myelofibrosis requires demonstration of marrow fibrosis (Chapter 86), so that bone marrow examination would distinguish PV from both of these disorders. The major differential would be with CML. This question arises in 10 to 40% of PV patients ([28], [45]). Testing for the Philadelphia chromosome or *bcr-abl* gene rearrangement would permit CML to be diagnosed with considerable certainty. In addition, the leukocyte alkaline phosphatase score is normal or elevated in 80 to 100% of PV patients ([45], [93], [165]) and typically low in CML patients.

As noted earlier, the majority of PV patients have normal arterial oxygen saturation. There is no intrinsic reason, however, why a patient with an underlying lung disease might not coincidentally have PV. In patients with a picture otherwise characteristic of PV but with arterial oxygen saturation below 92%, another marker for secondary polycythemia should be sought. The serum erythropoietin concentration is widely used by hematologists ([166]). Although it is of arguable utility in the differential diagnosis of polycythemia (discussed in Chapter 50), failure to detect an elevated erythropoietin level in a polycythemic patient with reduced arterial oxygen saturation would be evidence against a secondary polycythemia. A decreased serum erythropoietin concentration has been proposed as an additional minor criterion ([164]). Birgegard and Wide have reported that PV can be distinguished from secondary polycythemia by the erythropoietin response to phlebotomy: the erythropoietin concentration rises after phlebotomy in secondary erythrocytosis but remains unchanged in PV ([167]).

It has been suggested that splenomegaly appreciated only by radiographic techniques should be considered a minor criterion ([164]); experience suggests that most practitioners regard it as the equivalent of splenomegaly observed on physical examination. Absence of splenomegaly or of two minor criteria necessitates a search for other features of myeloproliferative syndromes. Likely possibilities would include a hypercellular bone marrow exhibiting hyperplasia of all cell lines, peripheral blood basophilia, or an assay for endogenous erythroid colonies. The drawback to the latter is that it is a specialized procedure that typically must be done in a research laboratory, and thus is of limited availability. It is, however, a useful method for identifying cases of PV “masked” by other concurrent conditions ([168]). Other possibilities would include decreased platelet Mpl expression, detection of PRV-1 by polymerase chain reaction, or demonstration of a clonal population of marrow cells ([164]).

NATURAL HISTORY

The clinical picture of PV is characterized by the complications of polycythemia-induced hyperviscosity, expanded blood volume, and thrombosis. The occurrence of these complications is significantly affected by therapy and is discussed under specific therapeutic modalities.

Two other significant complications that may be observed late in the course of PV are the development of myeloid metaplasia with myelofibrosis and acute leukemia. In perhaps 25% of patients with PV, a progressive reduction in erythrocyte survival, decreased erythropoiesis, and myelofibrosis develop ([169], [170]). Extramedullary hematopoiesis takes place in the spleen and liver. A rising leukocyte count with increased immature myeloid forms accompanies these changes. In addition, the teardrop and nucleated red cells characteristic of myelofibrosis and myeloid metaplasia appear in the blood ([170]). The spleen may enlarge dramatically. A picture simulating that of acute myeloblastic leukemia develops in approximately one-third of these patients ([170]). Others develop progressive anemia and thrombocytopenia and die of a variety of intercurrent complications in the “spent” or “burnt-out” phase of myeloid metaplasia ([171]). It has been suggested that postpolycythemia myeloid metaplasia syndrome is related to the use of ^{32}P therapy ([171]), although it clearly occurs in patients who have never received this therapy. In still other patients (14 to 20% in most series) ([8], [172]), an acute leukemia-like picture develops without preceding evidence of myeloid metaplasia or myelofibrosis ([170]). It has been suggested that the small number of patients who have cytogenetic abnormalities at diagnosis are those who will eventually develop leukemia, but this is not observed in all series ([115], [116], [170]). The effect of therapy on the development of leukemia is discussed in the Chemotherapy section that follows.

A number of other diseases have been reported in association with PV. It is unclear whether these represent coincidence or an actual pathophysiologic relationship. These include hyperthyroidism ([65]), neurofibromatosis (von Recklinghausen disease) ([173]), paroxysmal nocturnal hemoglobinuria ([174]), agranulocytosis ([175]), chronic lymphocytic leukemia ([176]), lymphoma, multiple myeloma ([177]), osteosclerosis ([70]), as well as development of a marrow picture resembling aplastic anemia ([178]) or pernicious anemia ([179]).

The median survival of untreated PV patients is reported to be 18 months ([180]). Overall survival of PV patients appears decreased compared to age- and sex-matched controls ([4]). Table 85.4 gives the causes of death from two large series of PV patients ([8], [181]). Thrombotic events remained the leading cause of death (approximately 30% in both series), followed by acute leukemia and other malignancies, hemorrhage, and myelofibrosis/myeloid metaplasia, which represented 2 to 4% of patients.

TABLE 85.4. Causes of Death in Polycythemia Vera Patients

Cause of Death	PVSG (%)	GISP (%)
Thrombosis/thromboembolism	31	29.7
Acute myeloid leukemia	19	14.6
Other malignancy	15	15.5
Hemorrhage	6	2.6
Myelofibrosis/myeloid metaplasia	4	2.6
Other	25	35.0

TREATMENT

The object of therapy in PV is to produce a reduction in the red cell mass by methods that (a) permit the longest survival; (b) are associated with fewest significant complications, allowing the patient maximum quality of life; and (c) are least expensive and inconvenient for the patient.

Phlebotomy

Phlebotomy offers prompt and effective reduction of the red cell mass and blood volume to normal values. Many patients can be maintained in an essentially normal state by phlebotomy together with a few simple adjuvants, when necessary, to control hyperuricemia or pruritus. The advantages of phlebotomy are that it is inexpensive, requires extremely limited technical support, and allows rapid control of symptoms. Criticisms of phlebotomy are the potential problem of venous access in elderly patients, that it does not address leukocytosis or thrombocytosis, and that erythropoiesis is stimulated by the blood loss ([120]). This last point is only a transient concern; the goal of phlebotomy is to induce a state of iron deficiency that will itself suppress erythropoiesis.

The Polycythemia Vera Study Group took patients who had been phlebotomized to maintain a normal hematocrit (less than 0.45) and then randomized patients to phlebotomy to maintain the hematocrit in this range, to therapy with ^{32}P, or to therapy with chlorambucil ([182]). Median survival from study entry until death was 9.1 years for patients in the chlorambucil arm, 10.9 years for ^{32}P-treated patients, and 12.6 years for phlebotomized patients ($p = .008$). The survival differences did not become apparent until after 7 years into the study, indicating that the development of late events (principally leukemia) was responsible for these differences ([182]). Acute leukemia developed in 1.5% of phlebotomy patients, 14.2% of chlorambucil patients, and 9.6% of ^{32}P patients. This complication was more frequent in patients with the “spent phase” of PV. Myelofibrosis was observed in 8.6%, 7.1%, and 7.7% of the phlebotomy, chlorambucil, and ^{32}P patients, respectively ([182]).

The apparent advantage of phlebotomy was undercut by an increased risk of thrombosis. Thrombosis-free cumulative survival was significantly worse in the phlebotomy arm ($p = .015$). This increased risk was predominantly limited to the first 3 years of therapy ([182]). Advanced age and history of previous thrombosis contributed to the relative risk of thrombosis in this and other studies ([8], [181]).

Phlebotomy and Antiplatelet Agents

In an effort to reduce the thrombotic risk that impairs the otherwise excellent response to phlebotomy, the Polycythemia Vera Study Group randomized patients to phlebotomy with aspirin, 300 mg three times daily, and dipyridamole (Persantine), 75 mg three times daily, versus ^{32}P. The study was stopped early because of excessive thrombosis, hemorrhage, and death in the phlebotomy/aspirin/dipyridamole arm ([182]). A subsequent study, however, found that total aspirin doses of 325 mg/day or less and phlebotomy resulted in no hemorrhagic or thrombotic complications in 69 patient years of follow-up ([183]). However, this latter study contained a preponderance of patients with known disease duration longer than 3 years; as discussed above, the thrombotic risk occurs predominantly in the first 3 years after diagnosis. A small placebo-controlled study performed by the Gruppo Italiano Studio Policitemia using an aspirin dose of 40 mg/day (112 patients followed for 1 year) reported similar results ([184]).

The goal of phlebotomy should be to maintain the hematocrit in the normal range (0.42 to 0.46). In elderly patients, patients with known cardiovascular disease, or hospitalized patients with severe symptoms, phlebotomy should be initiated cautiously, either using frequent small-volume phlebotomy (100 to 150 ml every day or on alternate days) or in larger (500 ml) volumes using fluid replacement so that the patient remains isovolemic ([185], [186]). The hazards of excessively aggressive initial phlebotomy have been well described ([187]). After the hematocrit falls to less than 0.55, or more than 750 to 1000 ml of blood have been removed, phlebotomy of 250 to 500 ml can generally be carried out safely at weekly or less frequent intervals, as clinically indicated. Some advocate the administration of iron during phlebotomy to prevent the “symptoms” of iron deficiency. In many ways, this defeats the long-term purpose of phlebotomy: to establish a state of iron deficiency that will restrict red cell production. It has also been demonstrated that iron-deficient PV patients have no significant symptoms compared to other PV patients ([188]).

Chemotherapy

ALKYLATING AGENTS A number of chemotherapeutic agents have been used for the treatment of PV. These include benzene ([189]), phenylhydrazine ([190]), Fowler's solution (potassium arsenite) ([191]), nitrogen mustard ([192]), melphalan ([193]), triethylene melamine ([194]), thiotepa ([195]), pyrimethamine ([196]), Vercyte (a neutral piperazine compound) ([197]), and a variety of other agents ([198], [199] and [200]). For the most part, these agents have fallen into disuse in PV, typically through a poor toxicity to efficacy ratio. Busulphan, pipobroman, and chlorambucil are alkylating agents that were widely used in PV in the modern era, but the increased frequency of leukemia observed with alkylating agents led to a discontinuation of their first-line use ([201], [202]). They may have some utility in selected cases.
HYDROXYUREA The nonalkylating myelosuppressive agent hydroxyurea is the chemotherapeutic agent most widely used in PV at present. Its efficacy in controlling erythrocyte, leukocyte, and platelet counts in PV has been clearly demonstrated ([203], [204]). Thrombotic complications are less common than are observed in patients treated with phlebotomy only ([182]). Hydroxyurea permits rapid reduction of leukocyte and platelet counts; supplemental phlebotomy may occasionally be necessary to reduce the red cell mass ([182]). As a rule, neutropenia or thrombocytopenia corrects rapidly after cessation or reduction of hydroxyurea dose; for the same reason, however, missing a few days of therapy may be associated with recurrence of leukocytosis or thrombocytosis. The incidence of leukemia in patients treated long term with hydroxyurea appears to be low and similar to that observed in patients treated with phlebotomy alone ([182], [205], [206]), but requires further investigation. A study in which older PV patients initially treated with ^{32}P were randomized to maintenance with hydroxyurea or observation with phlebotomy showed a higher incidence of leukemia in the hydroxyurea arm. This suggests that there is at least some leukemogenic potential with this agent ([207]). The usual starting dose of hydroxyurea is 500 mg either once or twice daily and is adjusted according to clinical requirements.
INTERFERON Recombinant human interferon-a is an agent that has also demonstrated efficacy in PV ([208], [209] and [210]). In at least one study, interferon was more efficacious than phlebotomy ([210]). Another group found that only a subset of patients were responsive to interferon ([209]). In general, interferon appears to control leukocytosis and thrombocytosis and to reduce or eliminate the need for phlebotomy in a significant proportion of patients ([211], [212] and [213]). It also appears to improve pruritus ([211], [212], [214]). Reversal of marrow fibrosis has been reported in some, although not all, studies ([211], [215]). The precise role of interferon in PV, whether as therapy of first or later choice, remains to be firmly established, as does its optimum dose schedule. Many hematologists use interferon as first-line therapy in younger patients, particularly women of childbearing years.
ANAGRELIDE Anagrelide is a platelet-aggregating agent that is useful in the control of thrombocytosis refractory to hydroxyurea or interferon in myeloproliferative disorders such as PV ([216]).
RADIOACTIVE PHOSPHORUS Whole-body or regional external beam irradiation is not especially useful ([217], [218]). However, administration of ^{32}P remains a technique of definite utility although limited applicability. ^{32}P is typically provided as a dibasic sodium salt and administered intravenously ([219], [220]). It passes to tissues that have a high phosphorus content and metabolize phosphorus rapidly. Its uptake by rapidly dividing cells is greater than that by normal cells. Because the physical half-life of this isotope is 14.3 days, steady irradiation of tissue takes place for several weeks ([219]). Its concentration in bone makes ^{32}P valuable in the management of hematopoietic disorders, particularly PV. In patients with PV, ^{32}P induces satisfactory clinical and hematologic remissions that may last years ([40], [220]). The fall in the red cell count usually does not begin until 30 to 60 days from the time ^{32}P is given. Therefore, initial phlebotomy may be indicated for symptomatic control. As with any myelosuppressive agent, care must be taken to avoid producing anemia, leukopenia, or thrombocytopenia. A usual dose is 3 to 5 mCi of ^{32}P intravenously, or 2.3 mCi/m^2 ([221]). No additional ^{32}P is given for 3 months to avoid cumulative effects. If the hematocrit rises above 0.46 in the interval, phlebotomy should be performed. If, after 3 months, the need for phlebotomy persists and leukopenia and thrombocytopenia are not present, a second injection of 1 to 4 mCi may be given. Examinations are repeated at 3-month intervals. Some patients do not require a second injection or further phlebotomies for 6 to 18 months or longer. A small minority, perhaps 10% of patients, need a third injection. After this third injection, no further injections are given for at least 12 to 18 months ([222]). An analysis of 300 courses administered to 139 patients showed that an average of 6.7 mCi had been given during the first 6 months of treatment ([68]). Most of these patients were re-treated within intervals of 6 to 10 months. In another series of 241 patients ([223]), the average dose required to produce remissions was 5.7 mCi in patients without leukocytosis or myeloid immaturity and as much as 8.3 mCi in others. The range of dose required was 3 to 21 mCi. As outlined above, ^{32}P is effective and easily tolerated therapy. Survival after treatment is reported to be 10 to 14.5 years ([68], [172], [220], [224]). The principal drawback to ^{32}P therapy is the increased incidence of acute leukemia ([170], [182], [224]). As previously noted, the risk of leukemia (10 to 15%) develops after 7 or more years on treatment ([182]). In elderly patients (older than 75 years), the benefits of ^{32}P may exceed the potential risks. ^{32}P may be useful, therefore, in carefully selected patients, and obviously with a full explanation of the associated risks and benefits.

Other Modalities

Splenectomy is useful only as a palliative measure in the late stages of the disease, when the spleen becomes massive and causes early satiety and weight loss, severe anemia, or thrombocytopenia ([171]). Hematopoietic stem cell transplantation has been reported in ten PV patients who had progressed to myelofibrosis or myelodysplastic syndrome/acute leukemia ([225]). Five of these patients had a complete response. There is also one report of a successful bone marrow transplant in an adolescent with PV ([226]).

Special Topics

PRURITUS It has been reported that pruritus, upper gastrointestinal distress, and the urticarial manifestations of PV correlate with increased levels of whole blood histamine, which in turn is roughly related to the basophil leukocyte count ([99]) [although other studies have questioned this model ([227])]. These clinical manifestations were controlled by the administration of a potent antihistaminic agent, cyproheptadine (4 mg three or four times per day), in 12 of 18 patients so treated ([99]). More recent experience suggests a satisfactory response in less than one-third of patients with significant pruritus ([20]). Cimetidine ([228]) and hydroxyurea ([229]) have been useful in approximately 40% of patients with pruritus. Interferon has been used in intractable cases ([214]). Anecdotal experience suggests that aspirin (80 to 325 mg/day) also relieves pruritus in certain patients. As noted earlier, the most effective management of pruritus is establishing good hematologic control of PV.
HYPERURICEMIA Because of the excessive urinary load of uric acid excreted by patients with myeloproliferative disorders ([230]), urate may be precipitated in the kidneys, leading to stone formation or nephropathy. In one series, urolithiasis occurred in 40% of 44 patients with gout secondary to another disorder as compared to 20% of 937 patients with primary gout ([231]). An effective means of reducing uric acid production in patients with PV, other than by myelosuppression, is by the use of allopurinol, 300 mg/day ([214]). This agent is most useful during the short periods at the initiation of cytoreductive therapy when cell turnover is likely to be high and the avoidance of uric acid deposition is a major concern.
SURGERY Patients with poorly controlled PV are at increased risk for complications of elective surgery. In a series of 54 PV patients, a complication rate of 83% (46% morbidity, 37% mortality) was observed in poorly controlled patients, compared to a complication rate of 21% (16% morbidity, 5% mortality) in well-controlled patients ([232]). Fewer and less serious complications were observed in patients who had had stable, well-controlled counts for more than 4 months ([232]). It is recommended that PV patients undergoing elective surgery be in good hematologic control for at least 4 months. In more urgent surgery, control should be obtained as quickly as possible using phlebotomy with volume replacement, hydroxyurea, and cytapheresis if necessary, and should be maintained as long as possible pre- and postoperatively.

Summary and Recommendations for Treatment

Although treatment with phlebotomy, ^{32}P, or a variety of chemotherapeutic agents is effective and prolongs survival, no modality is clearly the best for everyone. The following recommendations represent a reasonable approach. More detailed recommendations have been published by the Polycythemia Vera Study Group ([172], [233]).

1. Most newly diagnosed patients should undergo phlebotomy to obtain symptomatic control of polycythemia. The rate and volume of phlebotomy is dictated by the patient's clinical status, as outlined in the section on phlebotomy above. The hematocrit should be reduced to the upper normal range (approximately 0.45).
2. The long-term therapy chosen to control PV varies according to the patient's clinical status. Young patients (younger than 50 years) with no history of thrombosis and without severe thrombocytosis (greater than 1,000,000/µl) can probably be managed best with phlebotomy alone, with a target hematocrit of 0.45. The addition of aspirin, 325 mg per day or less, may be beneficial. Patients with a history of thrombosis who are older than 70 years or with severe thrombocytosis should be treated with myelosuppressive agents. Patients between the ages of 50 and 70 years with no history of thrombosis or severe thrombocytosis can be managed with myelosuppressive agents or phlebotomy, although the latter modality may increase their risk for thrombotic events.
3. The current myelosuppressive agent of first choice is hydroxyurea. Although the additional risk of leukemia with long-term hydroxyurea therapy appears to be small, it is probably not zero ([234]). ^{32}P may be useful in a small number of carefully selected elderly patients, in whom the potential leukemic risks are outweighed by ease of administration and limitations imposed by other clinical conditions. Interferon is clearly an effective agent in PV and should be considered a possible alternative to hydroxyurea. It may be particularly useful in younger patients and women of childbearing years.

Myelofibrosis

Myelofibrosis is a term referring to deposition of excess collagen in the bone marrow. It is a defining characteristic of a distinct clonal hematopoietic stem cell disorder, which is related to the other chronic myeloproliferative disorders (CMPDs). This uncommon disorder was first described in 1879 ([1]) and has been given more than 30 names, including primary myelofibrosis, osteomyelofibrosis, agnogenic myeloid metaplasia, idiopathic myelofibrosis, and most commonly, myelofibrosis with myeloid metaplasia (MMM) ([2]). MMM must be distinguished from other diseases in which myelofibrosis is a secondary phenomenon (Table 86.1) ([3]). In a rare familial disorder, primary hypertrophic osteoarthropathy, myelofibrosis may be a primary disorder of marrow fibroblast growth ([4]).

TABLE 86.1. Conditions in Which Myelofibrosis May Occur

Neoplastic conditions
Chronic myeloproliferative disorders
Agnogenic myeloid metaplasia
Polycythemia rubra vera
Chronic myeloid leukemia
Other neoplastic conditions
Acute megakaryoblastic leukemia (M7)
Myelodysplasia with fibrosis
“Transitional” agnogenic myeloid metaplasia–myelodysplastic myeloproliferative syndrome
Other acute myeloid leukemias
Acute lymphoid leukemia
Hairy cell leukemia
Myeloma
Carcinoma
Systemic mastocytosis
Nonneoplastic conditions
Granulomatous disease
Paget disease
Hypoparathyroidism
Hyperparathyroidism
Osteoporosis
Renal osteodystrophy
Vitamin D deficiency
Gray platelet syndrome
Systemic lupus erythematosus
Systemic sclerosis

ETIOLOGY AND PATHOGENESIS

Epidemiology

The cause of MMM is unknown. In most cases, no inciting factors are found, but epidemiologic studies have identified some associations. MMM may occur after exposure to toluene and benzene ([5], [6] and [7]). It may also occur after exposure to ionizing radiation ([8], [9]). A very high incidence of MMM was observed in patients given the thorium-based radiographic contrast material, Thorotrast ([8]), and victims of the atomic bombing of Hiroshima had a risk of MMM 18 times that of the remainder of the Japanese population, with symptoms appearing an average of 6 years after exposure ([9]). Tefferi measured a baseline annual incidence of 1.5 cases per 100,000 in a North American population ([3]).

Clonal Hematopoiesis

In 1951, Dameshak grouped MMM with chronic myeloid leukemia (CML), polycythemia vera (PV), and essential thrombocythemia (ET) as a CMPD because of the clinical and morphologic similarity of these conditions ([10]). All display a hyperplastic bone marrow, hematopoiesis independent of physiologic stimuli, a phase of increased circulating blood cell concentrations, a tendency toward the development of marrow fibrosis, and a tendency to terminate in acute leukemia. All CMPDs

arise as somatic mutations of a pluripotent hematopoietic stem cell. Several observations confirm that there is neoplastic clonal hematopoiesis in MMM. Various clonal cytogenetic abnormalities are present in half of patients at diagnosis ([11], [12], [13], [14], [15] and [16]). Other markers of clonality are observed in circulating neutrophils, red cells, platelets, lymphocytes, and their marrow precursors. These include the distribution of glucose-6-phosphate dehydrogenase isoenzymes, the pattern of X chromosome inactivation in women, cell membrane defects, and mutations of the N-ras gene ([17], [18], [19], [20], [21], [22], [23], [24], [25] and [26]). The circulating progenitor cell concentration in MMM is 10 to 20 times normal, and $CD34^+$ progenitor cells in circulation are increased 400 times above normal levels ([27], [28], [29], [30], [31] and [32]). Progenitor cells from MMM patients are hypersensitive to cytokines and can proliferate *in vitro* without cytokine stimulation ([33], [34]). This property is a consistent feature of all the CMPDs. Megakaryocyte progenitors from MMM patients may also differentiate independent of thrombopoietin (TPO), the physiologic stimulus ([35], [36]).

Molecular Events

Mutagens presumably initiate events that produce the clonal hemopathy in MMM. There is no consistent cytogenetic abnormality in this disease similar to the *bcr/abl* gene rearrangement in CML that calls attention to candidate genes important in pathogenesis. The molecular events leading to development of MMM have not been elucidated but are under investigation in several laboratories. Differential expression of a panel of candidate genes has been studied in cytokine-independent progenitor cells from MMM patients versus cytokine-dependent (and presumably normal) progenitors. The FKBP51 immunophilin is overexpressed in most patients studied, and its functioning appears to confer cytokine independence ([37]). The GATA-1 transcription factor is active in normal megakaryocyte differentiation ([38]). A genetically altered mouse has been created that has impaired expression of GATA-1 and develops a syndrome similar to MMM ([39]). This observation suggests that events directed by GATA-1 may be important in the development of MMM. Other growth-related genes that have been examined include the retinoblastoma gene, which may be deleted or altered in expression ([22], [23] and [24]), and the calcitonin gene, which may be methylated ([24]). Disease progression in MMM may be associated with abnormalities of p53 or ras genes ([26]).

Bone Marrow Fibrosis and Extramedullary Hematopoiesis

Myelofibrosis in MMM is a secondary reaction to the clonal hemopathy ([40]). Fibroblasts secrete the collagen, which accumulates; these cells are normal and polyclonal ([41], [42], [43], [44], [45] and [46]). They are stimulated by cytokines released from neoplastic megakaryocytes and other clonally expanded hematopoietic cells ([40], [47]). Both breakdown and synthesis of collagen are affected, but increased synthesis of collagen appears to be most important, as the concentration of procollagen cleavage products is a marker for new collagen synthesis and correlates with disease activity ([48], [49], [50], [51], [52] and [53]). Collagen is deposited in the extracellular space and the vascular elements of the bone marrow. Four of the five types of collagen are normally present. The major components of the fibrosis in MMM are type 1 and 3 collagen, and collagen deposition increases with the duration of disease ([48], [49] and [50]). In early stages of MMM, there is a high percentage of newly synthesized collagen (type 3); in later stages, a high percentage of a more stable, polymeric collagen (type 1) is found ([48]). In addition, a smaller proportion of hexosamine-containing matrix molecules is found in MMM as compared with normal marrow, and the proportion decreases further with the duration of MMM. Bone marrow vascularity is consistently increased in MMM. The degree of neovascularity correlates with the extent of disease and may be important to the development of the fibrosis ([52]).

Transforming growth factor (TGF)-ß is the principal mediator of collagen accumulation in MMM ([46], [53], [54], [55], [56], [57], [58] and [59]). This cytokine is synthesized by megakaryocytes and endothelial cells as well as by the monocyte-macrophage system ([57], [58]). It is more potent in stimulating collagen secretion than either platelet-derived growth factor or epidermal growth factor ([57]) and may regulate the expression of these two cytokines ([57], [58]). TGF-ß is also a potent stimulus of angiogenesis, acting in part through vascular endothelial growth factor ([60]). Elevated levels of TGF-ß are detected in the circulating platelets and megakaryocyte fragments of MMM patients, and circulating concentrations of TGF-ß are increased ([61], [62]). Monocytes and macrophages arise from the neoplastic clone and may be another source of cytokines. TGF-ß is secreted in increased amounts by monocytes from patients with MMM as compared with normal controls, and its messenger RNA is expressed at elevated levels in blood mononuclear cells in MMM patients ([55], [56], [57], [58] and [59]). Other growth factors are also believed to be stimulatory to fibroblasts in MMM. These include platelet-derived growth factor, which is present in elevated concentration in MMM megakaryocytes, epidermal growth factor, endothelial cell growth factor, interleukin-1, basic fibroblast growth factor, and calmodulin ([55], [56], [61], [62], [63], [64], [65] and [66]). Several mechanisms for release of increased levels of cytokines into the marrow environment have been proposed: simple secretion of a-granules from the megakaryocytes, intramedullary death of dysplastic megakaryocytes with dissolution of their cytoplasm ([67]), and damage to megakaryocyte cytoplasm by engulfment of polymorphonuclear leukocytes ([68]).

Mice exposed to very high concentrations of TPO develop a syndrome similar to MMM. Mice injected repeatedly with polyethylene glycol–conjugated TPO or transfected to express the TPO gene exhibit megakaryocyte hyperplasia, thrombocytosis, bone marrow fibrosis, and extramedullary hematopoiesis ([69], [70]). The syndrome remits in mice that are no longer injected and in genetically altered mice that are treated by bone marrow transplantation. However, the role of TPO in MMM is unclear. Circulating levels of TPO in MMM patients are elevated but do not correlate with the megakaryocyte mass ([71], [72]). The apparent elevation of TPO levels in MMM may result from altered clearance mechanisms ([73], [74]). Moreover, TPO inhibits proliferation of hematopoietic stem cells from MMM patients ([35], [75]).

The distribution of extramedullary hematopoiesis in MMM approximates that in the fetus, and the liver and spleen are invariably involved ([76]). In a vascular injury model of myelofibrosis, ultrastructural studies reveal crowding of hematopoiesis out of the scarred marrow and early release of hematopoietic precursors. Extramedullary sites are colonized by the displaced hematopoietic cells ([2], [77]). A similar abnormal release of marrow precursors from distorted sinusoids produces extramedullary hematopoiesis in metastatic cancer and may be a general mechanism ([78]).

FEATURES OF DISEASE AT DIAGNOSIS

MMM affects mostly middle-aged and elderly patients. The median age at diagnosis is 60 years, and men and women are affected with equal frequency ([2], [76], [79], [80], [81], [82], [83], [84], [85], [86], [87] and [88]). MMM is less common in younger adults and rare in children, with boys affected twice as often as girls ([89], [90]). A familial form has been reported in several kindreds ([91], [92]).

Symptoms

MMM is asymptomatic in 25% of patients at presentation, and the diagnosis is suggested by abnormal blood findings or incidentally discovered splenomegaly ([2]) (Table 86.2). Most patients report fatigue, and weight loss is common (7 to 39%) ([2], [76], [85]). Hypermetabolic symptoms, such as fever and night sweats, occur in 5 to 20% of patients, and bleeding and bruising occur in a similar proportion ([2], [76], [85]). Patients may note a mass in the abdomen. Gout and renal colic affect 4 to 6% of patients, but tophi are unusual ([2]). Another symptom noted by a few patients is diarrhea, the cause of which usually is obscure. Sternal tenderness is sometimes noted.

Signs

Splenomegaly is the only physical finding in the majority of patients at presentation, and the spleen may be quite large (2, 76, 79, 80, 81, 82, 83, 84, 85, 86, 87 and 88) (Table 86.2). Absence of splenomegaly is rare (93). Hepatomegaly is found in half of patients at diagnosis, and 2 to 6% also have portal hypertension, which may be complicated by ascites, esophageal varices, gastrointestinal bleeding, and hepatic encephalopathy (2, 76, 83, 85). Petechiae, ecchymoses, and lymphadenopathy are detected in a few patients (81, 84). Some exhibit neutrophilic dermatosis similar to Sweet syndrome, and a few have dermal extramedullary hematopoiesis (94, 95). Many have osteosclerosis. In a few patients, osteosclerosis is associated with periostitis leading to bony pain (2, 76, 79, 80, 81, 82, 83, 84, 85, 86, 87 and 88) or deafness (76). When serosal surfaces are involved by extramedullary hematopoiesis, there may be symptomatic pleural or pericardial effusions or ascites (96, 97 and 98). The central nervous system is a common site of symptomatic deposits. Associated neurologic complications include increased intracranial pressure, delirium, coma, subdural hemorrhage, motor and sensory impairment, and paralysis (99, 100, 101, 102, 103, 104 and 105).

Laboratory Findings

BLOOD The characteristic peripheral blood finding in MMM is the presence of teardrop-shaped red cells associated with circulating nucleated red cells (Fig. 86.1), immature neutrophilic leukocytes, and abnormally large platelets (2, 76). Fragmented, target, and polychromatophilic red cells and increased numbers of reticulocytes are usually present. These morphologic abnormalities are the result of altered hematopoiesis, early release of cells from the marrow, and extramedullary hematopoiesis. Because the number of teardrop cells in circulation declines after splenectomy, these cells are believed to arise from extramedullary hematopoiesis. However, the mechanism by which this shape is induced is obscure (106).

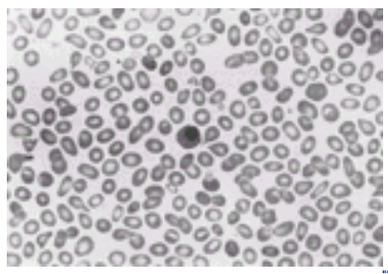

Figure 86.1. Teardrop poikilocytes and nucleated red cell from the blood of a patient with myelofibrosis (Wright stain ×400 original magnification).

The concentration of circulating blood cells varies widely among MMM patients and with the course of the illness in any one patient. Anemia with a hemoglobin less than 10 g per dl develops in 60% of patients with MMM, and some degree is usually present at diagnosis (2, 76). There are dilutional effects from expanded plasma volume (107), and both marrow underproduction (76, 82, 107, 108, 109, 110 and 111) and hemolysis occur. Causes of hemolysis include hypersplenism (76, 107, 112), red cell autoantibodies (76, 82, 113, 114), acquired hemoglobin H (115), and membrane complement sensitivity similar to that in *de novo* paroxysmal nocturnal hemoglobinuria (17, 18, 116) (see Chapter 37). In one series, 10% of patients exhibited hemolysis due to a paroxysmal nocturnal hemoglobinuria–like defect, and the paroxysmal nocturnal hemoglobinuria phenotype may occasionally be the predominate clinical manifestation (17). Red cells are generally normochromic and normocytic, but classic nutritional deficiencies also occur. Depletion of folate may produce a macrocytic anemia (117, 118), and iron-deficient microcytic anemia due to gastrointestinal bleeding is sometimes observed. Leukocyte counts are increased in approximately 50% but are decreased in approximately 25% of MMM patients at the time of diagnosis (76). Eosinophilia and basophilia are often present, and the number of lymphocytes is usually normal. Some myeloblasts circulate in the peripheral blood and may not necessarily indicate conversion to acute leukemia. However, a concentration of myeloblasts above 1% may indicate a poor prognosis. Hypersegmented neutrophils may be seen, and levels of neutrophil enzymes may be altered (80, 82, 119, 120, 121, 122, 123, 124 and 125). The platelet concentration is increased at the time of diagnosis in 50% of patients. However, with disease progression, thrombocytopenia becomes common. Extreme thrombocytosis in a few patients may make a distinction from ET difficult. Platelets are usually large, and intact or fragmented megakaryocytes circulate (79). Platelet function is often abnormal. Abnormal bleeding times and clot retraction, a reduced level of platelet factor 3, reduced platelet adhesiveness, and reduced lipoxygenase activity may be present (126, 127, 128 and 129). Alterations of soluble clotting factors also occur. Subclinical disseminated intravascular coagulation is found in 15% of patients with advanced MMM, and acquired factor V deficiency may be present (2, 130). Levels of uric acid and lactic dehydrogenase are increased in most patients, reflecting an expanded mass of hematopoietic cells, ineffective hematopoiesis, or both (76, 80). The level of serum alkaline phosphatase is increased in half the patients and is believed to be related to bone rather than liver disease (76). Levels of albumin, cholesterol, and lipoproteins are generally decreased (131). Increased serum levels of vitamin B_{12} found in patients with leukocytosis reflect the increased neutrophil mass (132, 133).

BONE MARROW Aspiration of bone marrow may be unsuccessful (dry tap), and biopsy is required to diagnose MMM. A consensus conference was convened by the Italian Society of Hematology to develop diagnostic criteria. Morphologic and clinical data were combined to differentiate MMM from other CMPDs and from myelodysplastic syndromes with marrow fibrosis (134, 135). These criteria define marrow fibrosis and morphologic evidence for marrow hyperplasia and extramedullary hematopoiesis. All three elements must be present to sustain a diagnosis of MMM (Table 86.3). Fibrosis is present at some point in all cases of MMM, but its extent varies. Early in the disease, fibrosis may be minimal, and evidence of marrow hyperplasia may be more striking. This has been termed the *cellular phase* of MMM. If marrow fibrosis is not evident in a patient suspected of having MMM, a second specimen should be obtained from a different site, because it may not be uniformly distributed throughout the marrow. Fibrosis may be graded according to published systems, and histologic evidence of osteosclerosis may be noted (48, 136, 137) (Fig. 86.2). When there is massive fibrosis, overall cellularity may be decreased, but evidence of megakaryocytic hyperplasia remains (136). Bone marrow sinusoids are expanded, and there is intravascular hematopoiesis (Fig. 86.3B) (136). Increased numbers of mast cells may be observed in biopsies adjacent to fibrosis (138). Smears from successful aspirates may show no abnormality, but usually there is neutrophilic and megakaryocytic hyperplasia. Micromegakaryocytes and macromegakaryocytes are observed, and there is nuclear-cytoplasmic asynchrony. Increased polyploidy (64N cells) is often demonstrable (139, 140). Granulocytes may be hyper- or hypolobulated and may exhibit an acquired Pelger-Huët anomaly or nuclear-cytoplasmic asynchrony (141). Erythroid precursors may be normal or increased. Isotopic scanning of marrow with sulfur colloid (for reticuloendothelial cells) and with iron (for erythroid cells) reveals expansion of marrow into the normally inactive long bones (142, 143). Magnetic resonance scanning can also document expansion of marrow in MMM by a change in signal characteristics in long bones (144).

TABLE 86.3. Italian Consensus Conference for Diagnosis of Myelofibrosis with Myeloid Metaplasia

Major criteria	
	Diffuse bone marrow fibrosis
	Absence of t9:22 chromosome or *bcr/abl* rearrangement in peripheral blood cells

Splenomegaly

Minor criteria

Anisopoikilocytosis with teardrop red cells

Circulating immature myeloid cells

Circulating nucleated red cells

Clustered marrow megakaryoblasts and anomalous megakaryocytes

Myeloid metaplasia

NOTE: All three major criteria plus any two minor criteria OR the first two major criteria plus any four minor criteria must be present to sustain a diagnosis of myelofibrosis with myeloid metaplasia.

Bone marrow biopsy sections from two patients with agnogenic myeloid metaplasia demonstrating a proliferative-phase bone marrow with hyperplasia involving all cell lines and relatively little fibrosis (hematoxylin and eosin, ×200 original magnification) **(A)** and intense fibrosis with new bone formation, dilated sinusoids, and residual megakaryocytes (hematoxylin and eosin, ×100 original magnification) **(B)**.

CHROMOSOME ABNORMALITIES Half of MMM patients have clonal karyotypic abnormalities at diagnosis ([11], [12], [13], [14], [15] and [16], [145], [146], [147] and [148]). Only a minority demonstrate the abnormality in all metaphases examined, indicating that many MMM patients have residual normal hematopoietic cells ([145]). The most common findings are deletion of a segment of the chromosome bearing the retinoblastoma gene, del 13(q13q21) and del 20q ([146], [147]). Other chromosomal defects are not random. Chromosomes 1, 5, 7, 8, 9, 13, 20, and 21 are most commonly affected. Monosomy and trisomy are common, and partial deletions and translocations also occur. Fibroblasts do not share the chromosomal abnormalities found in hematopoietic cells in MMM ([36]).

IMMUNE DISORDERS Clinically significant immunologic abnormalities are common in MMM, in contrast with the other CMPDs. B and T lymphocytes are directly affected by the stem cell defect in MMM in at least some patients, and functional defects of T or B cells may be demonstrated ([22], [149]). A variety of abnormalities of humoral immunity have been described. Depressed levels of C3 occur and may cause increased susceptibility to bacterial infection ([150], [151]). Circulating immune complexes have been found, and their concentration correlates with the state of disease activity ([152]). Pathologic autoantibodies that may occur include antierythrocyte autoantibodies ([2], [150], [152], [153] and [154]), antiplatelet antibodies ([155]), antinuclear antibodies ([150], [156]), antiimmunoglobulins ([150], [156]), and antiphospholipid antibodies ([150], [157]). Bone marrows in MMM often have lymphoid infiltrates ([157], [158]). Monoclonal gammopathy may occur in as many as 10% of MMM patients, and several cases of simultaneous MMM and plasma cell dyscrasia have been reported ([154], [158], [159]).

PATHOLOGY The characteristic features of MMM are fibrosis of the bone marrow, as described above, and extramedullary hematopoiesis. Bone marrow fibrosis is associated with osteosclerosis in 30 to 70% of patients ([76]). It is most common for the axial skeleton and proximal long bones to be affected. The bony cortex appears thickened, and the normal trabecular pattern is lost ([160]). Extramedullary hematopoiesis is present in the spleen and is responsible for the splenic enlargement. The liver is likewise involved in most patients. Any organ may be engaged in extramedullary hematopoiesis; it occurs, in approximate decreasing frequency, in lymph nodes, kidneys, adrenals, peritoneum, gut, pleura, lungs, fatty tissue, skin, breast, dura, ovaries, and thymus ([76]). The hematopoietic islands may contain any combination of myeloid precursor lineages and may be microscopic infiltrates or macroscopic tumors ([161]). The proportion of erythroid cells is higher in extramedullary sites than in the marrow, and extramedullary erythropoiesis tends to be associated with a lower mitotic index and a higher percentage of immature and megaloblastic cells than medullary erythropoiesis ([162]). Damage to target organs occurs by physical compression of adjacent normal tissue, but their normal architecture usually is preserved.

NATURAL HISTORY AND SURVIVAL

MMM has a median survival of 3 to 7 years, and less than 20% of patients survive more than 10 years ([2], [76], [79], [80], [81], [82], [83], [84] and [85], [163]). This prognosis approximates the median time to development of blast crisis in CML and is considerably worse than survival in ET and PV ([163]). Patients with evidence of a greater disease burden at diagnosis experience shorter survival ([76]). Favorable prognostic factors include lack of constitutional symptoms, hemoglobin levels of 10 g per dl or more, platelet counts of 100×10^9 per L or more, and absence of hepatomegaly ([85]). Younger patients have a better survival ([15], [164], [165]), as do those with a low concentration of circulating myeloblasts ([164]).

Some cytogenetic abnormalities, such as a single clone with translocation of chromosome 1, 5q-, trisomy 8, 13q-, or 20q-, may be associated with a better prognosis ([166]), but the overall subset of patients with any chromosome abnormality has been reported to have a poorer prognosis than patients with normal karyotypes ([146]). Additionally, patients with increased plasma volume or increased plasma levels of soluble interleukin-2 receptor appear to have a poorer survival ([107], [167]). Several prognostic scores have been devised that use age, hemoglobin level, constitutional symptoms, and karyotype ([15], [164], [165]). Patients may be stratified with these systems into risk groups with life expectancies as short as 16 months and as long as 180 months ([15]).

Over time, the severity of symptoms and cytopenias in MMM progresses despite occasional spontaneous improvements ([2]). Weight loss becomes more troublesome, and edema of the lower extremities often develops. Infections, especially pneumonia, are frequent ([76], [150]). Most patients experience progressive splenic enlargement leading to pain, and bone pain is frequent with time ([76], [168]). Portal hypertension with esophageal varices eventually complicates the course of 17% of patients with MMM. It results from increased splenoportal blood flow, hepatic vein thrombosis, thrombosis of the portal vein, transfusion-induced hemochromatosis,

and intrasinusoidal hematopoiesis ([76], [161], [169], [170]). Bleeding due to thrombocytopenia, platelet defects, disseminated intravascular coagulation, or factor deficiencies tends to develop ([2]). Over time, tumors composed of hematopoietic tissue become more common and may damage vital structures, especially in the central nervous system ([99], [100], [101], [102], [103], [104] and [105], [171]).

The causes of death in MMM are variable. Infection, hemorrhage, cardiac failure, and cerebrovascular accidents are common, and renal failure, hepatic failure, or thrombosis is also reported in most series ([2], [76], [80], [81], [82], [83], [84] and [85], [163], [172], [173] and [174]). Leukemic conversion has been reported in 5 to 20% of patients with MMM ([80], [82], [172], [173]). The onset of leukemia is usually abrupt, and most patients have had a rapidly fatal course ([147]). Many cases occur without exposure to cytotoxic therapy, and cases of acute lymphocytic leukemia as well as all classes of acute myeloid leukemia have occurred ([22], [84], [174]).

THERAPY

MMM may be cured by hematopoietic stem cell transplantation (HSCT), but HSCT is generally reserved for younger individuals and carries a significant risk of mortality (Table 86.4). No other form of therapy has been shown to prolong survival or prevent progression of myelofibrosis; thus, there must be clear indications for intervention. Supportive therapy is directed toward specific complications. Many patients are asymptomatic and require only observation. Allopurinol is used to keep serum levels of uric acid within normal limits to avoid urate nephropathy and renal calculi and to prevent gout ([2], [76]). Anemia and thrombocytopenia may be present at diagnosis and usually progress to a point at which symptoms result. When therapeutic maneuvers fail to improve hematopoiesis, treatment consists of transfusions as needed to maintain adequate blood counts. Because of the frequency of hemolysis, folate supplementation is also given.

TABLE 86.4. Therapy for Patients with Myelofibrosis with Myeloid Metaplasia

Indication	Therapeutic Option
Young (=45 yr) patient with =2 adverse risk factors [a]	Consider allogeneic hematopoietic stem cell transplantation
Hyperuricemia or gout	Allopurinol
Anemia	Trial of androgens and corticoste-roids; transfusion; splenectomy for refractory hemolysis or excessive transfusion requirement
Severe thrombocytopenia	Splenectomy
Splenic pain	Splenectomy or irradiation
Portal hypertension	Splenectomy
Symptomatic extramedullary focus	Irradiation
Severe hypermetabolic symptoms	Chemotherapy
Hepatomegaly after splenectomy	Chemotherapy
Symptomatic thrombocytosis	Chemotherapy

[a] Hemoglobin <10 g/dl, abnormal karyotype, constitutional symptoms, >1% circulating blasts ([164]).

Allogeneic Hematopoietic Stem Cell Transplantation

All of the CMPDs may cured by allogeneic HSCT. The utility of this approach has been limited by the age and condition of many of the patients, by the availability of suitable donors, and by the morbidity and mortality associated with the procedure. However, donor procurement programs, conditioning regimens, and supportive care have continued to improve. The presence of marrow fibrosis and splenomegaly in MMM patients does not seem to be an obstacle to HSCT ([175], [176]).

There are now several published series describing results in patients with MMM, including an international cooperative trial with 55 patients ([177], [178] and [179]). Most of these patients were young (median age, 42 years in the largest series) and had HLA-identical related donors. However, in the Seattle series, 8 of 19 donors were HLA-matched but unrelated, and 2 of 19 donors were one-antigen mismatches ([178]). Overall survival in the largest series was approximately 50% at 5 years. Abnormal karyotype, anemia, and older age were associated with poorer outcome in that series, and there was a 14% 5-year survival for MMM patients over the age of 45 ([179]). However, a recent communication from the Seattle group predicts a more favorable outcome of 50% in patients over age 45 ([180]). Lower intensity conditioning regimens that may be more tolerable for older MMM patients are being examined and show initially positive results in terms of engraftment and resolution of disease features ([181], [182]). It seems clear that younger patients with two or more adverse risk factors who have a poor predicted survival without curative treatment should be considered for HSCT shortly after diagnosis ([179], [183]). Older patients, who may have a poor outcome with HSCT, and those without adverse risk factors at diagnosis may be better served by delaying consideration of HSCT until adverse factors develop. However, data are still too limited to suggest a more definitive approach to this issue.

Androgens and Corticosteroids

Androgens may be given to treat anemia associated with MMM. Response rates of 29 to 57% have been reported in various series ([184], [185] and [186]). Spontaneous improvement may occur in MMM, so apparent responses to therapy must be reviewed critically ([184], [185] and [186]). Young women with minimal splenomegaly and patients with normal karyotypes appear to benefit most ([109], [119], [184], [185] and [186]). Men must be screened for prostate cancer with digital rectal examination and prostate-specific antigen determination, and women must be cautioned about virilizing effects before androgen therapy. Liver function tests should be monitored during therapy.

Several dosing schedules have been used successfully ([2], [109], [119], [184], [185] and [186]). A reasonable regimen is to give the oral synthetic androgen fluoxymesterone in doses of 10 mg two to three times daily. If no improvement is noted after 3 to 6 months, androgen therapy should be discontinued ([2]). Some patients who do not respond to one androgen preparation may respond to another ([2]). Because red cell survival is often shortened in MMM, adrenal corticosteroids may improve red cell survival and anemia. Oral prednisone at doses of 1 mg/kg daily produces responses in 25 to 50% of patients ([2], [81]). Again, the best responses have been observed in women ([2]). However, this dose of prednisone cannot be given indefinitely because of steroid toxicity. Patients with hemolysis should also receive folic acid supplementation. Androgens and corticosteroids are probably best given in combination. Therapy may be initiated with prednisone at 30 mg daily given in combination with fluoxy-mesterone at 10 mg twice daily. If a patient responds after a month, the prednisone may be withdrawn while fluoxymesterone is continued.

Chemotherapy

Chemotherapy rarely induces a hematologic remission and does not alter the overall course of MMM, but it may be very useful for relief of symptoms ([2], [3], [76], [79], [80], [81], [82], [83], [84], [85], [86], [87] and [88], [166], [187]). Chemotherapy reduces the liver and spleen size and alleviates weight loss, fever, and night sweats in up to 70% of patients ([2]). It also reduces elevated leukocyte and platelet counts and occasionally may correct anemia ([79], [81], [119], [187]). Busulfan, melphalan, 6-thioguanine, and hydroxyurea have all been used successfully for these indications ([166], [187], [188]). Patients with MMM are especially prone to develop myelotoxicity, so chemotherapy must be used more cautiously than in the treatment of other CMPDs. For example, 2 to 4 mg/day of busulfan probably is the maximal dose that can be given with any degree of safety to patients with MMM. Patients must be monitored at frequent intervals, and late or prolonged cytopenias may occur. Hydroxyurea should probably be initiated at a reduced dose of 500 to 1000 mg every other day. Cautious dose adjustments should be based on clinical response and current blood counts.

Irradiation

MMM patients with hypersplenism may respond to splenic irradiation when there is a contraindication to splenectomy. Most patients experience relief of pain and a

50% or more reduction in spleen size ([189], [190] and [191]). Splenic irradiation may produce life-threatening cytopenias, so the treatment must be administered in small fractions with close clinical monitoring ([191]). Fractions of 15 to 100 cGy are usually given 2 to 3 days per week. Total doses of 700 to 2400 cGy can give satisfactory results with tolerable toxicity ([189], [190] and [191]). However, the benefits often are temporary, lasting only a few months. Symptomatic extramedullary hematopoietic tumors also respond to radiation therapy. It is especially useful for bone pain from tumors or periostitis and for central nervous system deposits ([103], [192], [193]). Irradiation may also be administered as radiophosphate ([2]).

Splenectomy

Splenectomy may be considered for treatment of refractory cytopenias, portal hypertension, or symptoms of hypersplenism ([2], [107], [194], [195], [196], [197], [198], [199], [200], [201] and [202]). Most patients benefit with resolution of hypersplenic symptoms and signs of portal hypertension (97% and 83%, respectively). The majority have improvement in anemia and thrombocytopenia (70% and 56%, respectively) ([195]). However, many of these benefits may not persist at 1 year postprocedure ([200]). Splenectomy is hazardous in MMM because of the size of the organ, its frequent adhesion to adjacent structures, its increased blood flow, and the compromised state of the patients. Low-grade disseminated intravascular coagulation, evidenced by elevated D-dimer levels, is also common in MMM and leads to increased bleeding risk if it is not sought and corrected preoperatively. Acute operative mortality up to 38% was reported in early series ([195]). Current mortality rates at experienced centers are better, usually less than 10% in hospital and 25% at 3 months ([200]).

Splenectomy has been criticized due to the fear of producing an aplastic crisis on the supposition that the spleen may be the sole site of hematopoiesis if the marrow is severely fibrotic ([76]). Even in advanced MMM, the marrow is usually the principal site of hematopoiesis ([107]), and in practice, aplastic crises are not usually observed. Concern has also been raised that splenectomy may precipitate leukemic transformation ([202]). However, analysis of histologic risk factors for leukemia in resected MMM spleens suggests that the progression of hypersplenism necessitating the procedure may often be the result of disease progression already in progress ([203]). Complications of splenectomy are significant and include intraabdominal infection, extreme thrombocytosis with thrombosis, and a rapidly enlarging liver ([195], [200], [201]). The latter two complications may require a postoperative course of chemotherapy ([204]).

Other Measures

Small clinical trials and case reports have suggested the possible utility of a number of other therapies for MMM. Interferons have been studied because of their activity against TGF-ß and their efficacy in CML ([61], [205]). Interferon-a may diminish bone pain, thrombocytopenia, and splenic enlargement, but its efficacy is limited by severe flulike symptoms and, on occasion, worsened anemia ([206], [207], [208], [209], [210] and [211]). Vitamin D analogs suppress megakaryocyte proliferation and reverse myelofibrosis associated with rickets ([48], [49], [212], [213]). Vitamin D derivatives have thus been given to patients with MMM and have shown benefit in several cases ([214], [215] and [216]). Anagrelide reduces platelet counts in MMM but does not provide other clinical benefits ([217]). Small series of MMM patients with anemia have been treated with erythropoietin. Both positive ([218]) and negative ([219]) results have been reported. The effect of erythropoietin may be greater if it is administered in combination with interferon ([220]). The antiangiogenic agent thalidomide has been given to several series of patients with advanced MMM. Approximately 20% have had some benefit, with decrease in constitutional symptoms and spleen size and improvement in blood counts ([221], [222] and [223]). Serious side effects, including extreme leukocytosis and thrombocytosis and pericardial extramedullary hematopoiesis, have occurred, and a very low starting dose (50 mg daily) and cautious dose escalation are suggested ([221]). The soluble tumor necrosis factor receptor, etanercept, has been used to reverse constitutional symptoms and is active in approximately half the patients treated ([224]). Suramin and imatinib have been given to a number of patients with MMM without apparent benefit ([225], [226]).

Mechanical curettage of small amounts (150 g) of fibrotic marrow from the iliac bone in MMM may be associated with an increased hematopoiesis and improvement in anemia ([227], [228]), but it is a complex procedure and is not successful in all patients ([227], [228]). Autologous HSCT after high-dose busulfan conditioning has been offered to a small series of patients with advanced MMM refractory to other maneuvers. Although there was a significant mortality (6 of 21 patients), most patients had improvement in hypersplenic symptoms, and approximately half had improvement in anemia and thrombocytopenia ([229], [230]).

DIFFERENTIAL DIAGNOSIS

The diagnosis of MMM rests on the demonstration of the triad of bone marrow fibrosis, extramedullary hematopoiesis, and evidence of clonal hematopoiesis in the absence of some underlying disease. There are no pathognomonic findings, and evidence of clonal hematopoiesis is indirect if karyotypic abnormalities are not present. A bone marrow biopsy is essential to demonstrate fibrosis. It may also provide evidence for clonal hematopoiesis in the form of panhyperplasia and exclude an infiltrative process. The criteria developed by the Italian consensus conference provide considerable guidance but may not recognize all patients with early-phase MMM (Table 86.3). Consideration of the patient's clinical course and careful judgment may be required.

Acute Myelofibrosis

MMM may be confused with acute myelofibrosis. In 1963, Lewis and Szur described five patients with bone marrow fibrosis, pancytopenia, fever, and a rapidly fatal course ([231]). They termed this syndrome “malignant myelosclerosis,” and it has come to be called *acute myelosclerosis* or *acute myelofibrosis* ([232], [233], [234], [235], [236], [237], [238], [239], [240] and [241]). Published series have included patients with fibrosis complicating acute leukemia ([233], [234], [235], [236], [237], [238], [239] and [240]), with MMM in transition to acute leukemia ([81], [82], [172], [173]), and with fibrosis complicating myelodysplastic syndromes ([242], [243], [244] and [245]). However, it has become clear that most patients with this syndrome have experienced a rapidly developing aleukemic form of acute megakaryoblastic leukemia (French-American-British M7), and many consider the two diagnoses to be equivalent (see Chapter 79) ([246], [247] and [248]). Acute myelofibrosis must be distinguished from MMM, because the former is treated as an acute leukemia. Splenomegaly is absent in acute myelofibrosis, and there is usually a diagnostic increase in megakaryoblasts in the marrow.

Other Chronic Myeloproliferative Disorders

MMM must sometimes be distinguished from CML, ET, and PV. When marrow fibrosis becomes a prominent feature of one of the other CMPDs, diagnosis may be difficult. PV terminates in an MMM-like syndrome in 15 to 20% of patients (see Chapter 85) ([249]). Myelofibrosis in PV most commonly occurs after years of disease. Because patients with postpolycythemic PV become symptomatic from the expanded red cell mass and come to medical attention early in their course, their diagnosis is usually made before marrow fibrosis develops. A patient with PV first encountered with myelofibrosis in the postpolycythemic phase usually pursues a more rapidly progressive course than an MMM patient ([249]). Fibrosis may be present in CML at diagnosis or develop as the disease progresses ([250], [251]). In most cases, differentiation of MMM and CML is straightforward on the basis of genetic analysis. A karyotype or a fluorescence *in situ* hybridization probe for the *bcr*/abl gene rearrangement can usually be accomplished on bone marrow or peripheral blood. Approximately 95% of patients with typical CML have the t9:22 Philadelphia (Ph1) chromosome abnormality, and most of the remainder exhibit molecular evidence of the *bcr/abl* gene rearrangement (see Chapter 84). In the rare instance in which neither the 9:22 translocation nor the *bcr/abl* can be detected in a patient suspected of having one of the two disorders, other factors may be considered. In CML, the size of the spleen is proportional to the white cell count. Thus, if the spleen is large, but the leukocyte count is less than 100×10^9 per L, MMM rather than CML may be present. When bone marrow fibrosis is present in ET, this condition may resemble an early phase of MMM. In fact, making a clear distinction may not be possible ([245]), and the patient may require observation over time.

Secondary Forms of Myelofibrosis

Myelofibrosis may occur as a reaction to malignancy, infections, and other diseases (Table 86.1). It may be associated with peripheral blood changes and extramedullary hematopoiesis that mimic MMM ([160]). In 50,277 consecutive blood smears in patients studied at the Mayo Clinic, there was a leukoerythroblastic picture in 215, or 0.4% ([252]). Two-thirds of these patients proved to have some form of neoplastic disease, and the remainder suffered from a wide range of illnesses.

The diagnosis of secondary myelofibrosis is based on identification of the underlying disease. Secondary myelofibrosis is a regular feature of some conditions, such as postpolycythemic PV ([245]), and an uncommon complication of others, such as systemic lupus erythematosus and rickets ([212], [213], [253], [254]). When myelofibrosis is due to infection, the infection usually is chronic, widespread, and easily diagnosed. Tuberculosis and fungal infections are now generally treated before secondary myelofibrosis develops ([255]). Most cases of secondary myelofibrosis are now due to metastatic malignancy ([253]). Tumor is not always demonstrable in the bone marrow when myelofibrosis develops, but in most cases, the malignancy is widely metastatic and easily recognized. Rarely, a malignancy is occult at presentation,

and a mistaken diagnosis of MMM may be made ([78], [256]). Measurement of urinary hydroxyproline, a metabolite of collagen, can help to distinguish secondary myelofibrosis from MMM ([257]). Its excretion is normal in patients with MMM but increased in patients with cancer and secondary myelofibrosis ([257]). Therapy for secondary myelofibrosis consists of treating the underlying disease. Reversal of fibrosis has been well documented after successful treatment of PV, Hodgkin disease, and metastatic prostate and breast carcinoma ([258], [259], [260] and [261]).

Systemic Mastocytosis

HISTORICAL BACKGROUND

Mastocytosis—a heterogeneous disease characterized by abnormal growth and accumulation of mast cells in one or more organs—has sparked the interest of the biomedical community for decades, though deeper understanding of the pathophysiology of this collective group of unusual disorders has only become manifest within the past several years. In 1878, Paul Ehrlich first identified the mast cell as a distinct cell type packed with meta-chromatic granules ([1]). Its role in the immune response was at that time unknown, as no disease or animal model could be identified from which a biologic role of mast cells could be inferred. The first case of mastocytosis was reported in 1869 by Nettleship and Tay under the heading of “rare forms of urticaria” and was described as “brown cutaneous lesions that whealed after scratching” ([2]). These lesions were termed *urticaria pigmentosa* (UP) 1 year after this initial description ([3]). The association between mast cells and mastocytosis was finally made in 1887, when Unna found that UP lesions were characterized by an increased number of mast cells in the dermis ([4]).

Subsequent appreciation of the full clinical spectrum of these disorders has identified forms of mastocytosis that also involve mast cell infiltration of visceral organs, and these forms of disease have collectively been termed *systemic mastocytosis* (SM) ([5]). The one unifying feature of this diverse group of disorders is a pathologic increase in mast cells in specific tissues. It is now known that SM can present with or without skin lesions and may show an indolent or aggressive clinical course; in some cases complicated by concomitant emergence of a clonal nonmast cell lineage disorder, such as one of the myeloproliferative disorders or myelodysplastic syndromes. This has led to further classification of mastocytosis based on hematologic findings, molecular markers, and serum levels of biomarkers such as tryptase, and the cluster designation (CD) markers CD2 and CD25; thereby prognosticating patients into better defined clinical categories than had been previously tenable. This updated reclassification of mastocytosis has been adopted by the World Health Organization (WHO) as the new classification scheme for mastocytosis ([6]).

PATHOPHYSIOLOGY

The current understanding of the etiology of mastocytosis has evolved from concentrated research efforts in the 1990s that have linked two key factors that control mast cell growth and activity—stem cell factor (SCF) and the SCF receptor, Kit. The two resultant hypotheses on the pathophysiology of mastocytosis that have thus emerged focus on disruption of the normal function of Kit or dysregulation of production of SCF, or both.

Mastocytosis is recognized in the majority of cases to represent a clonal disorder of the pluripotential hematopoietic progenitor cell that gives rise to B cells and monocytes, as well as mast cells ([7] , [8] , [9] and [10]). This precursor is believed to be more primitive than precursors committed to either the neutrophil/macrophage or erythroid cell lineages, with the affected clone showing variable expansion in these lineages in the peripheral blood of patients with SM ([11]). Thus, mastocytosis in such cases represents a somatic cell disorder that is confined to hematopoietic lineages. Although T and B cells of such mastocytosis patients carry a codon 816 mutation (such as Asp816Val), unlike mast cells, these cells do not express surface Kit when mature, and thus may be less susceptible to the biologic effects of constitutively activated Kit.

Early research efforts in the area of mast cell physiology concentrated on identifying the key biochemical pathways and mediators in these disorders that accounted for the various clinical sequelae seen in physiologic processes due to mast cell activation, including anaphylaxis and other allergic disease. Subsequent work by Kitamura and others ([12] , [13] and [14]) focused on murine models of mast cell deficiency via studies on mice that exhibited either abnormal Kit (W/W ^{v} mice) ([12]) or decreased production of SCF (Sl/Sl ^{d} mice) ([13]) and laid the foundation for suggesting the pathophysiologic basis of human mastocytosis as comprising dysfunction at the c-kit-SCF locus. Two predominant hypotheses thus emerged regarding the etiology of mastocytosis: (a) mastocytosis as a result of local overproduction of soluble SCF and (b) mastocytosis as a result of mutations in Kit that lead to ligand-independent activation and proliferation. Irrespective of etiology, the pathologic sequelae of mastocytosis seen clinically largely reflects increased mast cell numbers at normal and abnormal sites.

Mast cells normally reside in tissue, generally located near epithelial surfaces, blood vessels, nerves, and glands. They are derived from CD34 $^{+}$ pluripotential progenitors (stem cells) ([15] , [16] , [17] and [18]), which give rise to mast cells, monocytes, and B cells ([7] , [11]). Precommitted mast cell progenitors are CD34 $^{+}$, CD13 $^{+}$, and CD117 $^{+}$ ([17] , [18] , [19] , [20] and [21]). Except for a population of mast cells that reside in the bone marrow, mast cells complete their maturation in peripheral tissues. During maturation, mast cells down-regulate CD34 and several other receptors, but continue to express cell surface CD117 and CD13 ([16] , [17] and [18] , [21]). During terminal maturation, CD13 expression also decreases ([20]). Under normal physiologic conditions, mast cells and their progenitors do not or only minimally express CD2, CD25, or CD35 on their cell surface. This expression pattern, however, is altered in most patients with mastocytosis ([22] , [23]).

Mast cells are heterogeneous in terms of their morphologic, biochemical, and functional characteristics. These differences appear to correlate with differences in their anatomic locations and, when perturbed in function, correlate with the specific signs and symptoms reported clinically. Clinical sequelae of mastocytosis are thus not only the result of organ infiltration but also the direct result of mast cell mediator release from spontaneous or triggered mechanisms.

Mast cells are deemed to be long-lived cells, though it appears that at least some mast cells may proliferate locally in tissues in response to inflammatory or repair processes. In tissue sections, mast cells typically appear as either round or elongated cells, usually with a nonsegmented nucleus with moderate condensation of nuclear chromatin, and contain prominent cytoplasmic granules and lipid bodies. The cytoplasmic granules of mast cells contain heparin and chondroitin sulfate proteoglycans, consisting of sulfated glycosaminoglycans covalently linked to a protein core. Under appropriate conditions, the proteoglycans stain metachromatically with basic dyes. In humans, mast cells may be characterized as either mucosal or connective tissue mast cells; the former being located at mucosal locations, such as the lamina propria of the gastrointestinal (GI) tract, and containing a specific tryptase (thus a “T type” mast cell), the latter—more commonly found near the epithelial surface of the skin, and respiratory, GI, and genitourinary tracts and containing both tryptase and a chymotryptase (CT mast cells) ([24]). Human mast cell granules also contain tumor necrosis factor-a, histamine, acid hydrolases, cathepsin G, and carboxypeptidase ([25]). They may be activated by a number of stimuli that are both Fc $_{e}$RI dependent and Fc $_{e}$RI independent. After activation, mast cells may immediately release granule-associated mediators and generate lipid-derived substances that induce immediate allergic responses. Together, these mediators are deemed responsible for many of the clinical sequelae of the immediate hypersensitivity reaction, including pruritus, flushing, palpitations, and lightheadedness; also commonly reported in many patients with mastocytosis.

Major lipid mediators produced on appropriate activation via immunoglobulin E (IgE) or non-IgE stimuli include prostaglandin D $_{2}$ and leukotriene C $_{4}$ ([24]). Mast cell activation may be followed hours later by synthesis and release of additional chemokines and cytokines, and which may contribute to chronic inflammation. Cytokines reported to be synthesized and released from mast cells include macrophage inhibitory protein 1-a, basic fibroblast growth factor, vascular endothelial growth factor,

interleukin-4 (IL-4), IL-5, IL-6, IL-8, IL-13, and IL-16 ([24], [26]).

Studies performed in rodents, nonhuman primates, and humans have shown that many aspects of mast cell development are critically regulated by SCF. SCF is produced by B-lymphoid cells, endothelial cells, fibroblasts, and mast cells. SCF promotes the *in vitro* growth, differentiation, and survival of mast cells derived from human $CD34^{+}$ cells from human bone marrow or peripheral blood via Kit dimerization ([15], [26], [27]) and has been shown to work in concert with other growth factors, such as IL-3, to induce optimal mast cell precursor proliferation ([16]). It has also been reported to be present in the lesional skin of patients with UP ([28]) but was not identified in blister fluids ([29]) and has been reported on the surface membrane of circulating neoplastic mast cells ([30]). SCF can also directly promote mast cell mediator release and, at low concentrations, appears to augment mast cell mediator release in response to stimulation by IgE and antigen. Cells bearing mutated Kit on their surface have been shown to have an increased chemotactic response toward SCF. SCF may influence the response of mast cells and lymphoid progenitor cells, which also bear Kit and thus contribute to the development of mast cell lesions ([31]). An immunohistochemical study of bone marrow lesions of patients with systemic indolent mastocytosis confirmed that SCF was present in lesional mast cells, with a granular staining pattern surrounded by lymphoid aggregates that were comprised of B and T cells—suggesting a potential feedback loop for growth and differentiation of mast cells and lymphoid progenitors ([32]). These findings support the autocrine or paracrine secretion of SCF hypothesis for the etiology of mastocytosis in which SCF may promote chemotaxis and proliferation of mast cells, in particular those mast cells and lymphoid progenitors bearing mutated Kit.

The companion hypothesis for excessive mast cell numbers at various organ sites in mastocytosis is based on disordered signaling through Kit due to one of several somatic point mutations, most studied of which is the Asp816Val mutation (though other mutations at codon 816 with substitution of tyrosine and phenylalanine for aspartic acid have also been described in human subjects) and that favor ligand-independent activation and proliferation of mast cells.

Kit is present on mast cells and lymphoid progenitor cells and is critical for development of both lineages. Signaling through Kit is essential for the proliferation of $CD34^{+}CD117^{+}$ mast cell precursors and their subsequent migration into tissues where they differentiate into mast cells. The binding of SCF to Kit induces dimerization, with activation of intrinsic tyrosine kinase activity and phosphorylation of the receptor. This in turn leads to exposure of specific recognition motifs for intracellular binding proteins containing Src homology (SH2) domains such as phospholipase C?-1, phosphatidylinositol-3' kinase, mitogen-activated kinase, and Ras protein ([33], [34]). Activating or gain-of-function mutations in Kit are associated with constitutive tyrosine kinase activation and ligand-independent autophosphorylation of the Kit; thereby giving affected mast cells a survival advantage over wild-type cells ([34], [35] and [36]).

The Asp816Val mutation was first reported in the peripheral blood mononuclear cells (PBMCs) of adult patients with mastocytosis with an associated hematologic disorder and in patients with persistent mastocytosis and extensive disease ([37], [38]) but codon 816 mutations (Asp816Phe, Asp816Tyr) have been shown to be present in UP lesions of all adults examined and in a subset of pediatric patients with more severe mastocytosis ([38], [39] and [40]). A Gly839Lys mutation has been reported in skin lesions of some pediatric patients with mastocytosis ([10], [41]) and, thus far, somewhat different mutation patterns appear to be emerging for adult versus pediatric-onset mastocytosis, which may explain the differences in presentation and clinical course for these two different patient populations ([38], [41], [42]).

All evidence to date indicates that the c-kit mutation occurs in a mast cell progenitor and then, as the clone expands, it initially becomes detectable in skin lesions ([43]). With greater clonal expansion and disease progression, the mutated clone may become detectable in peripheral blood cells as noted in earlier studies performed on $CD34^{+}$ cells isolated from mastocytosis patients, which showed that in the presence of the same amount of SCF, greater numbers of mast cells arose from hematopoietic progenitor cells of mastocytosis patients than from healthy volunteers ([44]).

Additional c-kit mutations have since been identified that may play a role in the etiology of mastocytosis in some patients ([42]). These mutations consist of substitutions of glycine for valine in codon 560 within the juxtamembrane domain of Kit and detected in the human mast cell leukemia (MCL) cell line HMC-1 ([35]). The downstream signal transduction pathways responsible for oncogenesis by these point mutations have yet to be fully elucidated, although impaired association of mutated Kit with the p85 subunit of phosphatidylinositol 3'-kinase appears to play a role in ligand-independent growth and suppression of apoptosis ([31], [45]).

Irrespective of effects on Kit, inhibition of mast cell apoptosis through other biologic pathways may also contribute to the pathogenesis of mastocytosis. IL-4 is known to promote apoptosis of mast cells ([46], [47]). A polymorphism in the gene for the IL-4 receptor a chain has been shown to be associated with less extensive mast cell involvement, with disease usually localized to the skin ([48]). In addition, the bone marrow cells of patients with mastocytosis have been found to constitutively express the antiapoptotic proteins Bcl-XL and Bcl-2 ([49], [50]) and may explain the long survival of these cells and perhaps their resistance to chemotherapy-induced apoptosis.

In the genesis of mastocytosis, more aggressive forms of this disease may be characterized by other unique features that enhance the clonal expansion of mast cell populations bearing these changes. Thus, at least in some patients, one or more independent additional mutations in $CD34^{+}$ progenitor cells, mast cells, or an altogether different group of cells that have yet to be identified may comprise the underlying molecular basis for the mastocytosis phenotype.

It appears that consistent with the progressive genetic instability that is often described in other human tumors, increased chromosomal abnormalities that are unrelated to the c-kit locus have likewise been detected in patients with more malignant forms of mastocytosis, and new abnormalities may appear in a subset of such patients on disease progression ([51], [52]). No recurrent patterns of chromosomal changes have been consistently reported in patients with SM. The implications of these findings are that, at least in some patients with mastocytosis, the etiology of their disease may extend beyond a specific mutation event in a DNA “hotspot” and may encompass a broader chromosomal problem of genetic instability, in which subsequent clonal abnormalities that are detected do not represent the primary genetic event.

Dysregulation of other cellular processes that control cell growth have likewise been described in malignant mast cells. Tumor mast cell lines appear to express persistently high telom-erase activity throughout the cell cycle and do not appear to be subject to the normal regulatory feedbacks seen in nontumor-igenic mast cells ([53]). Maintenance of the high telomerase activity in tumor mast cell lines does not appear to be dependent on intracellular signals or cell replication, in contrast to normal human progenitor mast cells that experience transient induction of telomerase activity that is dependent on growth factor–mediated signals such as SCF-, IL-3-, and IL-6–mediated p38 mitogen-activated kinase and phosphatidylinositol-3' kinase ([53]).

CLINICAL FEATURES

The clinical manifestations of mastocytosis are diverse and may be divided into those that are systemic or localized ([54], [55], [56], [57], [58], [59] and [60]). Systemic effects of this disorder result from the release of significant amounts of mast cell mediators into the circulation. Clinical signs and symptoms that comprise systemic mediator release are those reported with anaphylaxis and include flushing, pruritus, hypotension, syncope, palpitations, and tachycardia ([61]). GI symptoms are commonly associated with mastocytosis and include nausea, vomiting, abdominal cramping, or bloating, and/or diarrhea. Peptic ulcer disease, which appears to reflect at least partially increased gastric acid secretion due to hyperhistaminemia, may occur in up to 50% of patients with systemic disease ([60]). Malabsorption, though less common, tends to be mild and may occur in those with progressive disease. Local sequelae of mastocytosis are largely due to the effects of mast cell collections at specific organ sites and may result in severe end-organ dysfunction due to infiltration of normal tissue with mast cells and subsequent fibrosis (e.g., cardiomyopathy, end-stage liver disease due to fibrosis, and bone marrow failure).

For some patients, in particular those with advanced disease or with an associated hematologic disorder, the most bothersome complaints include severe and nonspecific constitutional symptoms of fatigue, weakness, anorexia, weight loss, low-grade fevers, night sweats, musculoskeletal pain, headaches, depression, and even subtle cognitive deficits such as mild memory loss. Clearly, some of these symptoms are attributable to ongoing chronic disease, whereas others (e.g., memory loss), may in part be a result of the central nervous system effects of histamine and other mast cell mediators.

Attacks may be precipitated by physical stimuli such as heat, cold, pressure, alcohol, and medications (e.g., opiates, nonste-roidal antiinflammatory agents, and estrogens), radiocontrast agents, and venoms. Patients with aggressive disease also often present with unexplained lymphadenopathy, splenomegaly, or hepatomegaly that may or may not be symptomatic. One of the most difficult clinical scenarios of mastocytosis from a management perspective is the treatment of severe musculoskeletal pain and/or pathologic fractures due to the osteoporosis that results from release of mast cell mediators and/or an expanding marrow compartment with active proliferation of mast cells. Besides local disruption of normal bone architecture, mast cell infiltration of bone may cause bone loss due to the secretion of heparin, IL-6, and other ill-defined mediators and from their paracrine effects on osteoclast function.

The most frequently involved organs in SM are the skin, bone marrow, lymph nodes, spleen, liver, and GI tract. The lungs are usually spared in mastocytosis. Atopy and airway hyperreactivity are not generally a feature of this disease.

The prognosis of patients with mastocytosis is dependent on the extent of disease and presence of an associated hematologic disorder. Patients with cutaneous disease or limited extracutaneous involvement tend to have an indolent course. Few, if any of these patients have been documented to progress to more aggressive forms of mastocytosis. Conversely, patients with peripheral blood c-kit mutation positivity by reverse transcriptase-polymerase chain reaction analysis, an associated hematologic disorder, or presence of a significant hematologic abnormality, late age of disease onset, and/or an elevated serum lactic dehydrogenase are more likely to have an aggressive disease course with shortened survival ([62], [63]).

Classification schemes for mastocytosis, as originally proposed by Travis et al. ([63]) and then modified by Metcalfe ([59]) (to include lymphadenopathic mastocytosis with eosinophilia), have been updated to reflect new information on the molecular, genetic, and clinical features of these disorders ([64], [65] and [66]). This current classification of mastocytosis was adopted by the WHO ([6], [65]) and is provided in Table 87.1. This classification differs from previous versions by including a smouldering mastocytosis category and other rare variants of mastocytosis, such as mast cell sarcoma (MCS) and extracutaneous mastocytoma, and by providing criteria for diagnosis of each disease category. Major and minor criteria for diagnosis of cutaneous and SM are provided in Table 87.2 and a listing of “B” and “C” findings, which are used to prognosticate patients are listed in Table 87.3.

TABLE 87.1. Classification of Mastocytosis: Adapted from the World Health Organization

Variant Term	Subvariants
Cutaneous mastocytosis (CM)	Urticaria pigmentosa (UP)
	Maculopapular CM (MPCM)
	Diffuse CM (DCM)
	Cutaneous mastocytoma
Indolent systemic mastocytosis (ISM)	Smouldering SM
	Isolated bone marrow mastocytosis
Systemic mastocytosis with an associated clonal hematologic nonmast cell lineage disease (SM-AHNMD)	Acute myeloid leukemia (SM-AML)
	Myelodysplastic syndrome (SM-MDS)
	Myeloproliferative disorders (SM-MPD)
	Chronic myelomonocytic leukemia (SM-CMML)
	Non-Hodgkin lymphoma (SM-NHL)
Aggressive systemic mastocytosis (ASM)	Lymphadenopathic SM with eosinophilia
Mast cell leukemia (MCL)	Aleukemic MCL
Mast cell sarcoma (MCS)	—
Extracutaneous mastocytoma	—

NOTE: For details of the World Health Organization classification of mastocytosis, see Valent P, Horny HP, Li CY, et al. Mastocytosis. In: Jaffe ES, Harris NL, Stein H, Vardiman JW, eds. World Health Organization classification of tumours. Pathology and genetics of tumours of the haematopoietic and lymphoid tissues. Lyon: IARC Press, 2001:291–302.

TABLE 87.2. Criteria Defining Systemic Mastocytosis

Major

Multifocal dense infiltrates of MCs in bone marrow or other extracutaneous organ(s) (>15 MCs in aggregate) and confirmed by tryptase immunohistochemistry or other special stains

Minor

MCs in bone marrow or other extracutaneous organ(s) demonstrate abnormal morphologic features (>25%)

Detection of Kit mutation at codon 816 in peripheral blood, bone marrow, or other extracutaneous organs

MCs in blood, bone marrow, or other extracutaneous organs coexpress CD117 with CD2 or CD25

Serum total tryptase >20 ng/ml (not applicable in patients with systemic mastocytosis with an associated clonal hematologic nonmast cell lineage disease)

MCs, mast cells.

NOTE: The diagnosis of systemic mastocytosis is established if at least one major and one minor or at least three minor criteria are fulfilled (6).

TABLE 87.3. World Health Organization Definition of “B” and “C” Findings

B findings (indicative of a high burden of mast cells and expansion of the genetic defect into various myeloid lineages)

A >30% infiltration of the bone marrow by mast cells (focal, dense aggregates) or serum total tryptase >200 ng/ml

Histologic evidence of dysmyelopoiesis or myeloproliferative changes on bone marrow biopsy or in the peripheral blood, but not meeting criteria for a myelodysplastic syndrome or myeloproliferative disorder

Demonstration of organomegaly: hepatomegaly, splenomegaly, or lymphadenopathy (on computed tomography or ultrasound: >2 cm) without impairment of organ function

C findings (indicative of impaired organ function due to mast cell infiltration)

Bone marrow dysfunction as shown by =1 cytopenias: absolute neutrophil count <1000/µl or hemoglobin <10 g/dl or platelets <100,000/µL

Palpable hepatomegaly with impaired liver function, ascites, and/or portal hypertension

Skeletal involvement with large-sized osteolysis or/and severe osteoporosis causing pathologic fractures

Palpable splenomegaly with hypersplenism

Malabsorption with weight loss

Adapted from Valent P, Horny HP, Li CY, et al. Mastocytosis. In: Jaffe ES, Harris NL, Stein H, Vardiman JW, eds. World Health Organization classification of tumours. Pathology and genetics of tumours of the haematopoietic and lymphoid tissues. Lyon: IARC Press, 2001:291–302.

Cutaneous Mastocytosis

Cutaneous mastocytosis comprises three distinct clinical variants: UP/maculopapular cutaneous mastocytosis (MPCM), solitary mastocytoma, and diffuse-erythrodermic disease also known as *diffuse cutaneous mastocytosis* (DCM). UP is further subcategorized into four subvariants: typical UP, a plaque form, a

nodular form, and telangiectasia macularis eruptiva perstans (TMEP) ([6]).

The classic lesions of cutaneous mast cell disease are UP—reddish-brown macules, papules or plaques that urticate [i.e., form a wheal and erythema with a distinct border when stroked (a positive Darier sign)]. However, in a number of patients, cutaneous lesions are lacking, and other organs, particularly the bone marrow, must be biopsied to make the diagnosis.

UP lesions tend to occur in a generalized distribution, most commonly occurring over the trunk and generally sparing the face, scalp, palms, and soles. When abundant, they may form a cobblestone appearance. There appears to be no sex predilection or familial pattern of cutaneous disease, though mastocytosis of one form or another has been described in families, including several sets of twins ([24]).

Histologically, UP lesions are composed of a collection of mast cells within the papillary dermis with variable extension throughout the reticular dermis and into the subcutaneous fat. An increase in dermal mast cells =10 times that of normal skin, in the absence of other pathology is generally diagnostic of UP ([26] , [67]). In or adjacent to UP lesions, petechiae, ecchymoses, or telangiectasias may be present. Blister formation and hemorrhage may also occur, particularly in infants and young children. This complication is presumed to occur due to high local levels of mediators released from mast cells, but why this younger age group is more adversely affected is unknown. After age 10 years, vesicles do not generally occur, and UP lesions tend to be smaller and more numerous. UP lesions tend to follow a biphasic curve, with one peak at 2.5 months of age and another at 26.5 years ([67] , [68]). Of pediatric patients in whom UP occurs, approximately half lose these lesions by adolescence. The remaining patients generally have lighter macular lesions at previous involved sites. Pruritus is the most common symptom that accompanies UP. Approximately 15 to 30% of pediatric patients whose skin lesions persist into adulthood progress to develop SM ([69]).

Although UP in adults may persist indefinitely, a subset of patients, estimated from 7 to 19% in published series, experience a fading or resolution of lesions over time ([70]). Regression of UP in patients with indolent SM (ISM) appears to parallel a decrease in disease severity (e.g., constitutional symptoms), although bone marrow findings of ISM remain. In contrast, disappearance of lesions in patients with an associated hematologic disorder may herald progression of disease, with more severe bone marrow pathology noted on follow-up biopsies. Hence, changes in the intensity of UP may have different clinical significance in patients with indolent versus more aggressive categories of mastocytosis such as SM with an associated hematologic nonmast cell disorder (SM-AHNMD). Conclusions from an analysis of 106 adult patients with SM followed for a minimum of 10 years indicated that remission of UP could not be predicted on the basis of the extent and distribution of UP or the extent of organ involvement; the severity and frequency of symptoms of mast cell mediator release, abdominal pain, or constitutional symptoms; or plasma tryptase levels ([70]). The absence or presence of the Asp816Val mutation in PBMCs did not predict the course of UP. Disease progression in patients with SM-AHNMD is therefore better monitored with bone marrow biopsy findings than with changes in the number, distribution, or intensity of skin lesions.

In addition to the presence of typical skin lesions on clinical examination, diagnosis of UP is based on histopathologic evidence of significant mast cell infiltrates in lesional skin, absence of signs of systemic involvement, and serum tryptase levels that are generally within normal limits (<20 ng/ml) ([6]). In adults with cutaneous mastocytosis, systemic disease is excluded by bone marrow examination ([6]).

DCM is a less frequent cutaneous manifestation of mastocytosis and generally presents before the age of 3 years ([24] , [26] , [56]). The entire skin is involved and may present as a yellow-red-brown discoloration with a peau d'orange appearance, or as a generalized erythroderma in which severe edema gives the skin a doughy appearance. Additionally, yellow-cream–colored papules have been described that resemble xanthomas and pseudoxanthoma elasticum ([24] , [71]). Only rarely does skin appear normal in DCM. Dermatographism and formation of hemorrhagic blisters may occur. GI manifestations, such as diarrhea, flushing, and hypotension, may be associated, and such patients have an increased risk for more serious clinical sequelae such as shock, significant GI bleeding, and death. DCM may resolve spontaneously by age 5 to 15 months, but when persistent, the skin may remain thickened and doughy and recalcitrant to treatment.

Solitary mastocytomas are a fairly common cutaneous variant of mastocytosis that may present at birth or more commonly within the first 3 months of age, with spontaneous involution during childhood ([72] , [73] and [74]). They are only rarely described in adults. They present as macules, plaques, or nodules and are formed by dermal collections of mast cells without cellular atypia. They are most commonly seen on the extremities and rarely involve the palms or soles. When systemic symptoms are present, they most commonly involve flushing.

TMEP is another rare form of mastocytosis (<1% of cases) that is traditionally thought to be limited to the skin and only reported in adults. Select cases with concomitant splenomegaly, increased mast cells in the bone marrow, and abnormal skeletal radiographs suggest that this form of cutaneous disease may have systemic features ([75] , [76] and [77]). The characteristic skin lesion in TMEP is a telangiectatic, red macule on a tan-brown background. Individual lesions are 2 to 6 mm in diameter and are without sharply defined borders. Pruritus, purpura, and blister formation are not generally associated with TMEP, though lesions may become edematous when rubbed. Occasionally, these lesions are found to coexist with UP ([24]).

Indolent Systemic Mastocytosis

ISM may be characterized by mast cell involvement at various organ sites, although significant organ dysfunction (C findings) is virtually always absent, and prognosis in these patients is generally good. The bone marrow is the most common site of extracutaneous mastocytosis, with as many as 90% of adult patients with indolent disease demonstrating bone marrow mast cell infiltration ([63]). The criteria for diagnosis of SM is provided in Table 87.2 ([6]).

Characteristic bone marrow lesions of SM comprise focal or diffuse aggregates of mast cells. Focal infiltrates are frequently observed in paratrabecular and perivascular areas and are often associated with adjacent lymphoid or eosinophil aggregates, or both ([77]). Histologically, mast cells in these patients show characteristic cytologic abnormalities, including cytoplasmic surface projections, eccentric oval nuclei, and a hypogranulated cytoplasm (atypical mast cell type I) ([6]). A representative bone marrow aspirate from a patient with indolent SM with characteristic morphologic features compared with a control bone marrow aspirate is shown in Figure 87.1. Clonal mast cells express CD2 or CD25, or both, on their cell surface, and the *c-kit* mutation Asp816Val ([6]). The bone marrow lesions of SM contain a mixed population of B and T cells, in addition to mast cells identified by antitryptase staining ([32]). The histopathology of these lymphoid aggregates is similar to benign lymphoid aggregates associated with reactive bone marrow ([78]) and not lymphoproliferative disease—the latter being highly uncommon in patients with adult-onset ISM. In bone marrow extensively involved by mast cell infiltration, the bony trabeculae may be moderately to markedly thickened.

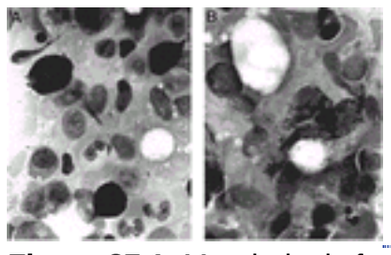

Figure 87.1. Morphologic features of mast cells from normal versus mastocytosis bone marrow aspirate. Panel **A** shows staining of a control bone marrow aspirate from an individual with aplastic anemia using toluidine blue stain (magnification, 40×). Panel **B** shows a hematoxylin and eosin stain of a bone marrow aspirate acquired from a patient with indolent systemic mastocytosis and illustrates representative spindle-shaped mast cells with an eccentric nucleus (magnification, 40×). See Color Plate. (Provided courtesy of Dr. Cem Akin, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)

A number of hematologic abnormalities have been reported in patients with SM, including cytopenias (e.g., anemia, thrombocytopenia, leukopenia, and lymphopenia) and increased white blood cell counts (e.g., leukocytosis, eosinophilia, basophilia, monocytosis, lymphocytosis, and thrombocytosis) ([79]). Hematologic abnormalities in children with mastocytosis are rare, with a normochromic normocytic anemia being the most common finding ([41]). Prolonged bleeding times have been reported in infants with mastocytosis due to abnormal thrombin clotting times. In published reports of rare pediatric mastocytosis patients who have developed an associated hematologic malignancy, these were most frequently acute myeloid leukemias and acute lymphoblastic leukemias ([41] , [80]).

Isolated bone marrow mastocytosis is a rare subvariant of ISM that is distinctive in lacking cutaneous and multiorgan involvement ([6]). The tryptase level in this group

of patients is usually >20 ng/ml. These patients generally require no specific therapy, but ISM must be differentiated from aggressive SM (ASM) or MCL, in which skin lesions are also absent.

Smouldering mastocytosis is another subvariant of ISM ([81], [82], [83] and [84]). Unlike typical ISM, these patients manifest two or more B findings (but no C findings) and have a higher mast cell burden [e.g., bone marrow infiltration grade >30% (dense infiltrates) and serum tryptase >200 ng/ml] with extension of a clonal disease process to several myeloid lineages ([81]). Although these patients have no overt myeloproliferative or myelodysplastic disease, they are at higher risk for progression to more aggressive forms of mastocytosis and carry a worse prognosis than those with indolent disease. Bone marrow lesions typically contain dense focal and diffuse mast cell infiltrates, and mast cells detected in such lesions may be immature. Markers of a poorer prognosis seen in this subvariant include a hypercellular bone marrow, hepatosplenomegaly or lymphadenopathy, and presence of the c-kit mutation in PBMCs ([81]).

In contrast to adults with SM, definitive marrow involvement in children is much less common ([85], [86]). In a study of 17 children with cutaneous or disseminated mastocytosis, only ten patients had small focal mast cell lesions on bone marrow biopsy, and only five demonstrated increased mast cells on bone marrow aspirate ([86], [87]). These aggregates were generally associated with eosinophils and early myeloid cells. Unlike the adult population, the mast cell lesions seen on bone marrow biopsy in children were found to be uniformly small and frequently located in perivascular sites ([87]).

The course of bone marrow involvement in mastocytosis is unknown. Although many patients, mostly adults and, less frequently, children, have stable or decreasing marrow involvement over time, the clinical significance of the extent of marrow involvement by mast cells remains elusive. Because studies in children have not involved large numbers of patients or followed them for extended time intervals, no conclusions can be made with regard to the significance of the progression of mast cell infiltration of the bone marrow in this population.

Lymphadenopathy is present in a subset of patients with mastocytosis and is more commonly seen in those with an associated hematologic disorder or in lymphadenopathic SM with eosinophilia. Travis and Li reported peripheral adenopathy in 26% of patients and central lymphadenopathy in 19% of patients with SM at the time of diagnosis ([88]). Hyperplasia of lymph nodes is the result of infiltration with mast cells and in approximately one-half of cases is associated with aggregates of eosinophils. Infiltrates are more commonly observed in the paracortex, follicles, medullary cords, and sinuses ([26]). Other histopathologic findings may include extramedullary hematopoiesis, small blood vessel proliferation in paracortical areas, and collagen fibrosis ([89]). On hematoxylin and eosin staining, mast cell infiltrates may resemble T-cell lymphomas in their paracortical distribution, clear cytoplasm in some cases, and associated vascular proliferation. Or conversely, mast cell infiltration may resemble follicular hyperplasia or lymphoma when they replace lymphoid follicles.

The presence of lymphadenopathy by itself does not signal aggressive disease. However, patients who present with progressive lymphadenopathy, with or without hepatosplenomegaly, and especially if accompanied by peripheral blood abnormalities, should be closely monitored for evolution into a more aggressive systemic disorder. This latter patient population may be more likely to harbor mutations in the Kit receptor, as was demonstrated in a recent survey of patients with the Asp816Val mutation and an associated hematologic disorder ([62]).

Splenomegaly due to splenic infiltration with mast cells is likewise a not infrequent finding in systemic disease, with approximately 40 to 50% of such patients presenting with splenic involvement at the time of diagnosis ([63]). Splenomegaly has also been reported to occur in the absence of demonstrable mast cell infiltration on biopsy ([90]). A review of pathologic features of 16 spleens from patients with mastocytosis showed a paratrabecular distribution of mast cell infiltrates in 15 of 16 spleens. In addition, parafollicular, follicular, and diffuse infiltrates were noted in ten (64%), two (4%), and one (7%) patients, respectively ([88]). Varying degrees of trabecular and capsular fibrosis and eosinophilic hematopoiesis and plasmacytosis were seen, and 71% of all biopsies revealed extramedullary hematopoiesis. Disorders or conditions with similar histologic features to splenic mast cell involvement include T-cell lymphoma, myeloproliferative disorders, hairy cell leukemia, follicular hyperplasia or a granulomatous process, follicular lymphoma, and Kaposi sarcoma. The prognostic significance of splenomegaly is seen with markedly increased splenic weights (>700 g) that have been reported to correlate with SM-AHNMD or ASM ([90]) and may be a contributing factor to the hematologic abnormalities seen in such patients.

Mast cell infiltration of the liver is a common finding in SM, although severe liver disease and hepatomegaly are relatively uncommon except, again, in patients with more aggressive forms of disease. In a study of 41 patients with mastocytosis, liver disease was reported in 61% ([91]). Approximately one-half of the patients with liver disease in this series exhibited elevated liver function tests—either an elevated alkaline phosphatase, 5' nucleotidase, or ?-glutamyl transpeptidase. Hepatomegaly, infiltration of the liver by mast cells on liver biopsy, and hepatic fibrosis correlated with elevated levels of serum alkaline phosphatase. These findings were more commonly seen in patients with aggressive disease, ascites, or portal hypertension. As confirmed on liver biopsy, portal fibrosis and venopathy with subsequent veno-occlusive disease appear to be a direct result of vascular obstruction by mast cell infiltrates ([91]). Fibrosis, including that which affects the liver, often accompanies mast cell proliferation and mast cell release of such proinflammatory mediators as histamine and transforming growth factor-ß.

GI symptoms reported in both retrospective and prospective studies of SM include abdominal pain, cramping, nausea, vomiting, diarrhea, and peptic ulcer disease. Less commonly seen is a malabsorption syndrome due to mucosal mast cell infiltration ([92], [93]). A prospective study published by Cherner et al. revealed that 6 of 16 patients with SM had a significantly elevated basal acid secretion, with concomitantly low gastrin levels ([92]). These data were found to be consistent with the hypothesis that histamine secreted by mast cells is the primary cause of gastric hypersecretion. However, subsequent studies have shown that biopsy of gastric tissues in mastocytosis patients with acid hypersecretion symptoms did not always demonstrate increased mast cell infiltrates, thereby suggesting that the hyperhistaminemia observed in such patients may be due to oversecretion by all mast cells and not as a result of an increased mast cell burden in the gastric tissues. GI disease is much less common in children, although GI bleeding is a potential complication with severe disease ([41]). Abdominal cramping and diarrhea have also been reported in patients with pediatric mastocytosis.

Musculoskeletal pain in patients with SM has been well documented but only recently has the pathophysiologic basis for this clinical manifestation begun to be understood. Bony infiltration with mast cells may result in osteopenia, with more aggravated cases leading to osteoporosis and pathologic fractures ([94], [95]). In some cases, osteoporosis or pathologic fractures, or both, may be the only initial manifestation of mastocytosis, with back pain secondary to osteoporosis and vertebral compression fractures a classic presentation of systemic mast cell disease ([96]).

A comprehensive review of mastocytosis patient outcomes by Travis et al. found that approximately 16% and 70% of patients, respectively, had pathologic fractures and radiologic changes at initial diagnosis ([63]). As previously described, these clinical sequelae appear to be due to the release of mast cell mediators that have either a direct or indirect effect on bone cells (e.g., histamine, heparin, and tryptase) or are involved in the promotion of the inflammatory response (e.g., histamine, heparin, leukotrienes, and IL-6) ([97], [98]). Bone scans may show focal or diffuse abnormalities, and the latter has been associated with more aggressive disease and a worse prognosis. The most commonly reported abnormalities are diffuse, poorly demarcated, sclerotic, and lucent areas involving the axial skeleton. In addition to bone loss, patients with mastocytosis may also exhibit concomitant abnormal bone formation, resulting in osteosclerosis. The finding of osteosclerosis was increasingly seen in patients harboring the Asp816Val mutation and an associated hematologic disorder ([62])—again portending a poorer long-term prognosis.

Occasionally, patients in whom bone involvement by mastocytosis is not seen on routine diagnostic evaluation and symptoms are not found to be attributable to any known cause may nonetheless report myalgias and arthralgias, often in concert with constitutional symptoms of fatigue, general weakness, and even depression. Management of this patient subset may be particularly challenging and may require behavior modification practices as well as therapeutic intervention. Patients may require both nonnarcotic and narcotic analgesics for adequate pain relief.

Systemic Mastocytosis with an Associated Hematologic Clonal Nonmast Cell Lineage Disorder

A subset of patients with SM (20 to 30%) either present with or develop over time a second hematologic disease in association with mastocytosis. These patients are categorized as SM-AHNMD ([6], [65]). The most common associated hematologic disorders that have been observed in retrospective series are the myeloproliferative disorders (e.g., chronic myelogenous leukemia), myelodysplastic syndromes (e.g., chronic myelomonocytic leukemia), acute myeloid leukemia, and the non-Hodgkin lymphomas ([79], [99], [100]). In these patients, WHO criteria to diagnose an AHNMD as well as ISM criteria should be applied ([6]). Management of these patients involves management of their underlying nonmast cell hematologic disorder either via close observation for stable disease, chemotherapy for progressive disease, or bone marrow (stem cell) transplantation in suitable candidates. The prognosis for such patients is variable and is dictated by the course of the associated nonmast cell lineage disorder.

Bone marrow findings that are more common with SM-AHNMD and have been associated with the Asp816Val c-kit mutation include a hypercellular bone marrow, dysplasia of myeloid or erythroid cell lineages, and an increased megakaryocyte number or megakaryocyte atypia ([62]). Fibrosis may be seen and is more frequent in patients with an associated hematologic disorder. Mast cells with bilobed nuclei, if seen on biopsy, portend a poor prognosis.

Aggressive Systemic Mastocytosis

ASM is a unique variant of mastocytosis characterized by abnormal myelopoiesis with mixed focal and diffuse mast cell infiltration of the bone marrow. These cells may be atypical and may be associated with other peripheral blood abnormalities (initially often presenting with eosinophilia), hepatosplenomegaly (due to mast cell infiltration), osteopenia and pathologic fractures, and life-threatening organ impairment ([59] , [101]). A subset of cases appear to be associated with a prior history of malignant germ cell tumors ([63] , [102] , [103]). In many respects, this disease has been described to resemble a “lymphomalike” illness with progressive infiltration of organs with mast cell infiltrates; the most commonly affected organs are the bone marrow, liver, spleen, and the GI tract. Cutaneous involvement is usually absent.

In some patients, bone marrow aspirates may reveal significant numbers of mast cells with bi- or multilobed nuclei (high-grade morphology). Metachromatic blasts may also be detected. The peripheral blood smear may show cytopenias, leukocytosis, eosinophilia, or monocytosis ([104]). Laboratory test abnormalities are frequently observed in such patients, with elevations in liver function, serum calcium, and alkaline phosphatase tests and prolonged prothrombin and partial thromboplastin times reported ([63]). As a result of impaired hepatic function and a propensity for spontaneous mast cell degranulation, ASM patients with more advanced disease may be at high risk for spontaneous hemorrhage during periods of mast cell activation. Serum tryptase levels may be very high and may also demonstrate wide fluctuations due to spontaneous mast cell degranulation ([102]).

Mast Cell Leukemia

MCL is an exceedingly rare variant of mastocytosis, with a grave prognosis and poorly understood pathophysiology ([105] , [106]). MCL is defined by presence of mast cells as =10% of circulating peripheral white blood cells. The bone marrow typically shows a dense and diffuse infiltration (=20%) with mast cells that display an immature, blastlike morphology with bi- or multilobed nuclei. Many of these mast cells express CD2 or CD25, or both ([107] , [108]). Other peripheral blood abnormalities may be observed and include leukocytosis, anemia, and/or thrombocytopenia ([108]). In general, such patients manifest bone marrow and peripheral blood abnormalities that are insufficient to fulfill WHO criteria for SM-AHNMD ([6]). In the aleukemic variant of MCL, mast cells account for <10% of peripheral white blood cells, and patients develop pancytopenia ([6] , [65]). Similar to aggressive mastocytosis, MCL patients are prone to bleeding diatheses, with or without signs of consumption or hyperfibrinolysis.

Mast Cell Sarcoma

MCS is a rare and ill-defined malignant mast cell neoplasm comprised of immature cells with a high nucleus to cytoplasm ratio, nucleoli, and a hypogranulated cytoplasm. It carries a highly unfavorable prognosis. The cellular atypia described in MCS is comparable to the high-grade cytologic abnormalities found in MCL. It is characterized by local, destructive, sarcomalike growth, with transformation to generalized involvement of multiple organ sites in its terminal phase. Thus far, the three cases described in the literature have included an MCS of the larynx, ascending colon, and an intracranial site ([109] , [110] and [111]). This disorder often terminates as MCL, with no known life-prolonging or curative treatments available.

Extracutaneous Mastocytoma

Extracutaneous mastocytoma is another rare variant of mast cell disease, with virtually all cases that have been reported in the literature occurring in the lungs ([112] , [113] and [114]). They are generally considered benign due to their low-grade histology (mature mast cells) and lack of progression to aggressive disease or MCL. Because they may present similarly to MCS, they must be differentiated from the latter.

LABORATORY FINDINGS

The diagnosis of mastocytosis is based on the finding of confluent clusters of mast cells in affected organ sites or diffuse infiltration with replacement of normal tissue by mast cells, coupled with clinical signs and symptoms and laboratory tests that are consistent with mast cell disease ([24] , [26] , [63] , [115] , [116]). Bone marrow biopsy in pediatric onset cutaneous disease is generally not recommended unless there is evidence of systemic disease—unexplained peripheral blood abnormalities, hepatosplenomegaly, or lymphadenopathy ([86]). Slight increases in mast cell numbers in target tissues (up to fourfold) are not diagnostic, as they may reflect normal variation or inflammatory or reactive processes ([26]). Examination of the bone marrow in patients with suspected mastocytosis should include an inspection of both the bone marrow biopsy and aspirate. Immunohistochemical staining of the bone marrow biopsy with antitryptase is the method of choice to visualize mast cells ([117] , [118] and [119]), as shown in Figure 87.2. The cellular composition of lymphoid collections is evaluated by using lineage-specific antibodies against CD3 and CD20, respectively ([32]), as seen in Figure 87.3. Other stains commonly used to detect mast cell infiltrates include Wright-Giemsa and toluidine blue, along with reticulin staining to detect fibrosis and Masson trichrome staining to evaluate the extent of collagen deposition. Mast cells also stain positively for chloroacetate esterase and aminocaproate esterase ([24]). Although some patients with mastocytosis may exhibit increased bone marrow mast cells without discrete foci of mast cells, such patients are the exception, and the diagnosis of mastocytosis must incorporate other relevant clinical and laboratory findings.

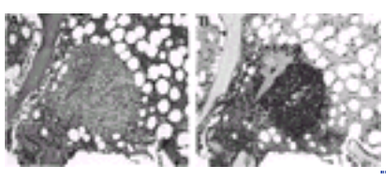

Figure 87.2. Bone marrow histopathology showing focal mast cell infiltrates in a bone marrow biopsy taken from a patient with indolent systemic mastocytosis. Panel **A** shows staining of a representative mast cell lesion with hematoxylin and eosin stain (magnification, 10×), and panel **B** shows staining of the same section with antitryptase antibody (magnification, 10×). See Color Plate. (Provided courtesy of Dr. Cem Akin, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)

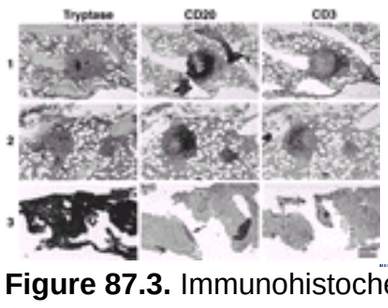

Figure 87.3. Immunohistochemical staining of lymphoid aggregates in two patients with a focal (**1** and **2**) and one patient with a diffuse (**3**) increase in mast cells. Antibodies are shown on top of each column. Nodular lesions shown in **1** and **2** contain a central core of mast cells (*arrows*) surrounded by B cells (CD20) and a peripheral rim of T cells (CD3). Diffuse mast cell infiltrates (**3**) are seen in association with a small B-cell collection (*arrow*) and scattered single T cells. The bar represents 200 µm. See Color Plate. (From Akin C, Jaffe ES, Raffeld M, et al. An immunohistochemical study of the bone marrow lesions of systemic mastocytosis. Am J Clin Pathol 2002;118:242–247, by permission of Dr. Cem Akin, National Institute of Allergy and Infectious Diseases, National Institutes of Health and the *American Journal of Clinical Pathology*.)

The finding of clusters of confluent mast cells on bone marrow aspirate is consistent with SM, however not all patients demonstrate this finding. Therefore,

underestimation of the degree of mast cell infiltration through examination of an aspirate may be more common than appreciated, with aspirates compromised because of underlying marrow fibrosis and a resultant inability to obtain adequate marrow aspirate or spicules at fibrotic marrow sites. Surrogate disease markers in mastocytosis include serum or plasma tryptase levels, serum histamine, urinary histamine metabolites, soluble CD117, soluble CD25, and CD2 ([120]).

Serum mast cell tryptase is the most commonly used surrogate marker for SM and is currently quantified using commercial enzyme-linked immunosorbent assays. It has both high sensitivity (approximately 0.2 ng/ml) and specificity ([120] , [121]). A total tryptase >20 ng/ml is suggestive of mastocytosis and has been included as a minor criterion in the diagnosis of SM as per the WHO classification scheme for mast cell disorders ([6] , [65]). Normal baseline levels in healthy individuals are generally =5 ng/ml. Tryptase levels =20 ng/ml have been detected in patients with cutaneous mastocytosis and in those with limited systemic disease ([122] , [123]). Thus, the tryptase level is an important parameter in evaluating patients with suspected mastocytosis and appears useful in assessing disease severity and monitoring disease activity.

Other mast cell mediators that are surrogate disease markers for mastocytosis are serum histamine and 24-hour urine sampling for the urinary histamine metabolites, N-methylhistamine, and methyimidazoleacetic acid. These tests are less commonly used with the availability of commercial tryptase assays. Disadvantages of using blood and urinary histamine levels for diagnosis and prognostication of patients with mastocytosis are the variability of histamine levels among healthy individuals and patients, difficulty in assay standardization, and the problem of false-positive results due to presumed synthesis of histamine by bacteria in the urinary tract. Other variables that can alter results of histamine assays (i.e., elevate histamine levels) are prior ingestion of foods rich in histamine and improper storage of the urine sample. Because basophils also contain histamine, hematologic disorders presenting with basophilia (e.g., certain myeloproliferative disorders) or allergic events that lead to basophil activation (e.g., during the collection process) result in elevated histamine levels.

Various metabolites of arachidonic acid are also elevated in patients with mastocytosis. These include urinary PGD-M or 9a,11ß-dihydroxy-15-oxo-2,2,18,19-tetranorprost-5-ene-1,20-dioxic acid, as well as plasma thromboxane B_2 and its metabolites. Because the source of prostaglandins and thromboxanes in mastocytosis is not exclusively limited to mast cells, reliance on assays that measure these metabolites are unlikely to be sufficiently specific for diagnostic purposes. However, if measured, elevations in one or more mast cell mediators raise the suspicion of mastocytosis and warrant further diagnostic evaluation.

Use of genetic markers of mastocytosis, such as evaluation for the presence of point mutations of c-kit, most commonly the Asp816Val mutation, is helpful in identifying patients with SM with more severe disease (the relative clonal expansion of cells derived from the neoplastic progenitor is expressed more readily with more aggressive mastocytosis categories) and perhaps even more helpful in following disease progression by assessing the relative intensity of the reverse transcriptase-polymerase chain reaction complementary DNA bands over the patient's course ([62]). IL-6 levels may correlate with disease severity but are not currently recommended for diagnosis or monitoring of patients ([29] , [98]). Their primary use is in the research setting.

Newer surrogate markers that may also be useful in assessing more severe forms of mastocytosis, such as SM-AHNMD, and in following disease severity are the soluble receptors CD117 (Kit) and CD25 (the a-chain of the IL-2 receptor) ([124]). These receptors are expressed in both membrane-bound and soluble form—the latter a result of proteolytic cleavage. Soluble forms of these receptors are more readily detectable in the circulation in patients with an increased mast cell burden and correlate with disease severity and bone marrow pathology. Soluble CD117 levels are also found to be elevated in some patients with acute myeloid leukemias and advanced myelodysplastic syndromes. Elevated CD25 levels may be seen in patients with hairy cell leukemia, solid tumors, and a number of infectious and autoimmune diseases. A comparison of the plasma CD117 and tryptase levels for various categories of mastocytosis revealed that tryptase levels were more sensitive indicators of early disease, whereas elevated plasma CD117 levels demonstrated a stronger correlation with advanced disease ([124]).

Additional diagnostic studies that may be helpful in evaluating extent of systemic disease include bone scans or skeletal surveys, computed tomography scan of the abdomen, upper GI series, small-bowel radiography, and, when indicated, endoscopy to rule out peptic ulcer disease or esophageal reflux.

DIFFERENTIAL DIAGNOSIS

The differential diagnostic list of disorders for mastocytosis comprises a number of other diseases that have a similar clinical presentation. These include hereditary or acquired angioedema, idiopathic flushing or anaphylaxis, carcinoid tumor, pheochromocytoma, and idiopathic capillary leak syndrome. Although hyper-IgE syndrome is listed in the differential for mastocytosis, such patients more often have distinct facial features (coarse facies), which set them apart from other similar, confounding clinical syndromes such as mastocytosis. Pheochromocytoma should be considered when episodic hypertension is a predominant clinical manifestation. Unexplained gastroduodenal disease should include evaluation for Zollinger-Ellison gastrinoma. *Helicobacter pylori* infection should be considered in all patients with gastric ulcers, even in those patients diagnosed with mastocytosis.

DCM should be included in the differential diagnosis of neonatal blister disorders such as pemphigoid ([24]). Extensive bullae with crusting may be the first presentation in an infant who later develops DCM.

A number of nonmast cell hematologic disorders, such as the myeloproliferative disorders (e.g. chronic myelogenous leukemia) or lymphoma of the bone marrow, may present with an increased number of mast cells on bone marrow biopsy, though circumscribed lesions are generally lacking in these disorders ([125] , [126]). Diseases with bone marrow lesions on biopsy that appear similar to SM on gross analysis include primary myelofibrosis, angioimmunoblastic lymphadenopathy, and eosinophilic fibrohistiocytoma ([24]). Close evaluation of histopathologic specimens differentiates these disorders from mastocytosis in part on the basis of a general absence of mast cell infiltrates. Myelofibrosis can resemble mastocytosis when fibrosis is extensive and the marrow is diffusely infiltrated with increased mast cells. The distinguishing feature between these two disorders is the overwhelming greater absolute number of mast cells on bone marrow biopsy in mastocytosis. Although differentiation of mastocytosis from angioimmunoblastic lymphadenopathy may be made on the basis of presence of plasma cells and immunoblasts in the latter and absence of neovascularity in mastocytosis, differentiation of mastocytosis from fibrohistiocytoma is more difficult. Large histiocytic cells noted in eosinophilic fibrohistiocytic lesions have a similar appearance to the large mast cells seen in many mast cell lesions ([127]). Some debate exists as to whether eosinophilic fibrohistiocytic lesions of the bone represent an indolent form of SM ([127]).

Conditions with secondary changes in mast cell numbers have been observed at sites of pathology in a number of autoimmune disorders, including systemic lupus erythematosus, rheumatoid arthritis, psoriatic arthritis, and scleroderma; with chronic liver or renal disease; and with a variety of infectious diseases, though in all cases, these increases are nominal ([26]). On resolution of the infection, mast cell numbers generally return to normal. At sites of allergic inflammation, increases of mast cells up to fourfold over normal have been described.

MANAGEMENT

Treatment of all categories of mastocytosis is primarily based on control of symptoms by blocking the action of mast cell mediators, though several new therapeutic strategies may hold promise for more severe forms of disease by targeting mast cell growth and development ([128] , [129] and [130]). Because of the heterogeneous nature of disease manifestations in this group of disorders, therapy should be individualized to each patient's clinical presentation and prognosis. A summary of treatment approaches for mastocytosis is provided in Table 87.4.

TABLE 87.4. Suggested Therapy for Mastocytosis

Hypotensive/anaphylactoid symptoms
Epinephrine [intramuscular (e.g., Epi-Pen)]
More severe, frequent episodes: consider prophylaxis with H_1, H_2 antihistamines ± corticosteroids
Cutaneous disease
Antihistamines: H_1 ± H_2
Corticosteroids
Psoralen and ultraviolet A light: consider for recalcitrant disease
Laser therapy: consider for telangiectasia macularis eruptiva perstans

Gastrointestinal disease
- Peptic ulcer disease/gastroesophageal reflux: H_2 antihistamines, omeprazole
- Abdominal cramping: cromolyn sodium
- Diarrhea: anticholinergics, cromolyn sodium, omeprazole
- Malabsorption: corticosteroids
- Ascites: corticosteroids, consider a portacaval shunt

Bone disease
- Calcium supplementation ± vitamin D
- Bisphosphonates
- Consider estrogen therapy for postmenopausal women, testosterone replacement in men with low testosterone levels
- Consider interferon-a2b in patients with severe bone disease and severe musculoskeletal pain
- Radiotherapy: palliative therapy for severe, localized bone pain

Smouldering mastocytosis
- Observe: if evidence of progressive hematologic disease, consider bone marrow transplantation, chemotherapy

Systemic mastocytosis with an associated nonmast cell lineage disorder
- If indicated, consider treatment of the associated nonmast cell hematologic disorder
- Interferon-a2b
- Consider bone marrow transplantation if an appropriate HLA match is available
- Splenectomy if patient has an enlarged spleen and/or cytopenias and if chemotherapy is to be considered

Aggressive systemic mastocytosis
- Interferon-a2b
- Cladribine
- Consider bone marrow transplantation if an appropriate HLA match is available
- Splenectomy if patient has an enlarged spleen and/or cytopenias and if chemotherapy is to be considered

Mast cell leukemia
- Chemotherapy
- Consider cladribine
- Consider phase 1 or phase 2 investigational research studies, including bone marrow transplantation

The mainstay of treatment for most categories of mastocytosis is H_1 and H_2 antihistamine blockade for prophylaxis of hypotensive episodes; for control of cutaneous manifestations, such as pruritus and flushing; and for gastric hypersecretion and corticosteroids for control of malabsorption and ascites and for prevention or amelioration of anaphylaxis ([128], [131], [132], [133] and [134]). Ketotifen, an antihistamine with mast cell stabilizing properties, is of benefit in relieving pruritus and whealing associated with mastocytosis ([135], [136] and [137]) but appears to offer no advantage over classical H_1 antihistamines such as hydroxyzine ([138]). Although no double-blind, placebo-controlled trials have been conducted assessing the relative efficacy of the newer, nonsedating antihistamines (e.g., loratadine and fexofenadine), use of these drugs have utility when patient sedation is a key concern ([139]). Alternative approaches include administration of a nonsedating antihistamine during the day, with supplementation of one of the potent sedating antihistamines at bedtime for added symptom relief.

Addition of an H_2 antihistamine, such as ranitidine, cimetidine, or famotidine, may be beneficial in cases in which insufficient symptom control is afforded by use of an H_1 antihistamine alone ([128], [140], [141], [142], [143] and [144]). Neither chemotherapy nor splenectomy appear to have any role in the treatment of cutaneous or indolent forms of mastocytosis.

For cutaneous manifestations of mastocytosis, which may be quite diverse, other therapies may be beneficial in addition to antihistamines ([128]). UP and DCM have been shown to be responsive to topical (UP) or intravenous corticosteroids (DCM) ([145], [146], [147], [148] and [149]) and oral methoxypsoralen therapy with long-wave ultraviolet radiation—psoralen and ultraviolet A light has been used for both UP and DCM ([150], [151], [152], [153], [154], [155], [156], [157] and [158]). Photochemotherapy, however, should only be used in instances of extensive cutaneous disease unresponsive to other therapy. TMEP—a rare variant of cutaneous disease, is somewhat more complicated in that lesions are chronic and tend to be unresponsive to currently available therapies ([128]). Neither corticosteroids nor psoralen and ultraviolet A light have been shown to afford significant improvement in TMEP and in UP and DCM improvement is transient. A limited body of literature indicates that laser therapy may have some utility in the treatment of TMEP ([76], [128]). In children with mastocytomas with associated severe systemic symptoms due to massive mast cell mediator release, surgical excision of the mastocytoma may be considered ([57], [58]). An alternative approach used involves injection of the mastocytoma with corticosteroids to induce involution ([159]).

Management of GI symptoms should address the type and severity of symptoms. H_2 antihistamines are specifically used to treat gastric hypersecretion and peptic ulcer disease associated with mastocytosis. Omeprazole may be effective in decreasing diarrhea in addition to controlling gastric acid hypersecretion ([160]). Anticholinergics and orally administered cromolyn sodium may also be useful for control of diarrhea ([161]). Intestinal absorption of cromolyn is limited (=1%), and a number of weeks of therapy may be needed before clinical benefits are seen ([139]). The recommended adult dosage is 200 mg four times daily, and doses ranging from 60 mg daily to 100 mg four times daily have been used in children in published studies, even though none of these were double-blind, placebo-controlled trials ([57], [58], [128]).

In addition to its efficacy in treating GI symptoms, cromolyn has been reported to decrease musculoskeletal pain and headaches and improve cognitive abilities ([128]). Its purported mechanism of action is in decreasing mast cell degranulation. As such, its use would not be expected to alter the natural course of the disease.

Malabsorption is generally managed with corticosteroids ([55], [162]). In adults, oral prednisone (40 to 60 mg/day) usually results in a decrease in malabsorption over 10 to 20 days, after which steroids can usually be tapered to as low as 15 to 20 mg every other day ([128], [129]). A more difficult treatment dilemma, ascites, has been shown to improve with systemic corticoste-roids ([128], [129]). Again, in adults, treatment with prednisone, 40 to 60 mg/day, with tapering to an every-other-day dose usually results in a decrease in ascites ([128], [129]). A subgroup of patients with mastocytosis who develop ascites may also develop portal hypertension, which may be exceedingly difficult to manage and indicates a poor prognosis ([163]). At least one patient with portal hypertension was shown to be successfully managed with a portacaval shunt ([164]).

Epinephrine is used to treat acute episodes of hypotension ([128], [165]). Treatment of refractory hypotension and shock requires fluid resuscitative measures along with additional pharmacologic intervention ([61], [128], [165]).

Osteoporosis in those with mastocytosis may be under detected and, hence, under treated. Recommended approaches to treatment include calcium supplementation and use of bisphosphonates ([128]). Narcotic analgesics should be used with care, as these, particularly at high doses or in susceptible patients, may potentiate mast cell degranulation. Radiotherapy may have a palliative role in decreasing bone pain in isolated areas ([166]). The literature indicates that interferon-a2b may have some efficacy in decreasing musculoskeletal pain and improving bone mineralization in patients with extensive bony involvement ([128]). The decision to initiate treatment with interferon-a2b therapy should take into consideration potentially debilitating side effects such as fever, malaise, nausea, and hypothyroidism, along with the small but well-described risk for anaphylaxis. Patients with mastocytosis who ultimately require joint replacement due to extensive bone loss generally tolerate these procedures well; however, such procedures do not obviate further decline in bone mass ([102], [167]).

Neither chemotherapy nor splenectomy have any role in the treatment of indolent mastocytosis. Interferon-a2b, administered subcutaneously by injection has been used in the treatment of indolent disease with mixed success ([128], [168], [169], [170], [171], [172], [173], [174] and [175]). Although interferon-a2b showed some efficacy in controlling

mast cell–mediated symptoms, such as flushing and pruritus, and symptoms such as diarrhea and abdominal pain in some patients, it failed to influence the number or extent of UP lesions and in some cases where checked, the extent of mast cell infiltration of the bone marrow ([170], [172] and [173]).

Despite therapy with multiple drugs, many patients fail to obtain adequate symptom relief, especially of musculoskeletal pain, headaches, and flushing. It is possible that newer therapies that target mediators shown to be elevated in mastocytosis may improve patient quality of life, but data are lacking in this regard. All newer therapies, especially biotechnology products or those with significant toxicities, require an appropriate risk/benefit analysis with respect to the patient's disease category and morbidity.

Therapeutic options for patients with mastocytosis with an associated clonal hematologic nonmast cell lineage disease (SM-AHNMD), ASM, and MCL are at the present time based on treating associated medical conditions and, when associated, the underlying hematologic disorder ([128], [176], [177], [178], [179], [180], [181], [182], [183], [184], [185], [186], [187], [188], [189], [190], [191], [192], [193], [194], [195] and [196]). Various chemotherapeutic regimens have been tried with mixed success and are summarized in a recent review ([128]). Regardless of the regimens used, relatively short partial remissions were noted in the majority of patients treated.

Interferon-a2b has been used to treat a number of patients with SM-AHNMD, but overall findings in these small case series are inconclusive ([102], [128], [182], [188], [189] and [190]). Although some patients noted marked clinical improvement in terms of symptomatology, little or no evidence of a decrease in mast cell infiltration was seen on bone marrow biopsy in the majority of patients. In the majority of these patients, interferon generally failed to have any effect in decreasing either the intensity or number of skin lesions ([128], [183]), as also seen in many patients with indolent disease ([170]).

Two recent case reports of the successful use of cladribine (2-chlorodeoxyadenosine), a purine nucleoside analog, in inducing clinical remissions in patients with more aggressive forms of mastocytosis suggests continued evolution in attempts to treat this disease ([195], [196]). Cladribine may be a reasonable therapeutic approach in treating those with aggressive forms of mastocytosis who have interferon-a–resistant advanced disease ([196]). In this same vein, similar treatments that target CD25 expressed on progenitor cells of patients with mastocytosis may ultimately prove to be more selective therapeutic interventions in patients whose cells express this biomarker. In other patients, bone marrow transplantation has the potential of allowing long-term engraftment of healthy bone marrow progenitors along with provision for a graft-versus-leukemia effect. Here, too, limited published data are available ([128], [197], [198] and [199]).

In SM-AHNMD patients with significant cytopenias and splenomegaly, splenectomy may result in some amelioration of the cytopenia and thereby reduce a patient's transfusion requirement or risk of bleeding or infection ([200]). Such patients might also be better able to tolerate chemotherapy, as suggested by a study in which patients with more aggressive forms of mastocytosis who underwent splenectomy had a mean survival time of 34 months compared to 26 months in those who did not undergo splenectomy ([200]).

Therapies used in the management of ASM include initial treatment with corticosteroids and H_1 and H_2 blockers, with addition of cytoreductive therapy for progressive disease. One case report describes a successful trial of cyclosporin-A (50 to 100 mg/day) given to a patient with aggressive mastocytosis ([201]). This patient demonstrated significant improvement within several weeks of cyclosporin-A treatment, which further improved when methylprednisolone (4 mg/day) was added. Other approaches, including administration of interferon-a2b, cytoreductive therapy with daunorubicin and cytosine arabinoside, or with cyclophosphamide, vincristine, and prednisone, have demonstrated mixed success and no sustained complete responses ([128], [176], [177], [178], [179], [180], [181], [182], [183], [184], [185], [186], [187], [188], [189], [190], [191], [192], [193] and [194]). Interferon-a2b appears to be useful in decreasing symptoms in patients with ASM who are no longer adequately responsive to other therapies. However, similar to outcomes seen in patients with SM-AHNMD, there is no evidence to date that it alters the course of disease ([128], [186], [202]). Because most of these studies were designed to follow patients for a relatively short period, conclusions about long-term efficacy and response rate are lacking.

Control of bone pain due to extensive skeletal involvement is a management challenge. Such patients should empirically be placed on calcium supplementation, when indicated, and possibly bisphosphonates, though extensive experience with the latter is lacking ([128], [203]). Radiotherapy or strontium-99 may have a palliative role in decreasing bone pain in isolated areas ([166], [204]). A small number of case series also indicate that a trial of interferon-a2b may have some efficacy in decreasing bone pain and improving bone mineralization in mastocytosis patients with extensive bony involvement ([181], [192], [194]). The decision to initiate treatment with interferon-a2b therapy should take into consideration potentially debilitating side effects, such as fever, malaise, nausea, and hypothyroidism, along with the small but well-described risk for anaphylaxis, versus the patient's severity of disease ([168], [205], [206] and [207]).

Prognosis for MCL is poor, and such patients should be treated with corticosteroids for mild and early stage disease ([104], [208], [209]). Review of 16 published cases of MCL revealed that the clinical manifestations, complications, and survival do not vary significantly with the percentage of peripheral blood mast cells ([105]). Chemotherapy, including cladribine, may be considered for advanced disease, but, thus far, most data are not compelling for most chemotherapeutic regimens with regard to long-term outcome ([128]). One published report showed that even aggressive, high-dose chemotherapy, which is routinely used in conditioning protocols before allogeneic bone marrow transplantation, might not be able to eradicate the dysplastic mast cells in these patients ([208], [209] and [210]). A novel approach that used antibody against the high-affinity IgE receptor that was coupled to chlorambucil and adsorbed onto sheep IgG was likewise ineffective in slowing down progression of disease, though the number of circulating mast cells decreased ([211]).

Tyrosine kinase inhibitors have been under investigation as a potential therapeutic class that could be used to interfere with mast cell proliferation and survival ([212], [213], [214], [215] and [216]). A report by Ma et al. ([215]) indicates that activation of the juxtamembrane domain Kit mutant was effectively suppressed by Imatinib (STI571), but additional studies on effects of these tyrosine kinase inhibitors, including STI571 and SU9529, on activation of the catalytic domain of Kit indicated that wild-type Kit was more effectively inhibited than Kit with a codon 816 mutation ([215], [216]). These data indicate that the catalytic domain of Kit with a codon 816 mutation is characterized by a unique activation mechanism that is resistant to tyrosine kinase inhibitors and that appears to be localized to the activation loop portion of the catalytic domain. It is not unreasonable to postulate that the patient population with mastocytosis that is most likely to respond to tyrosine kinase inhibitors will comprise those that lack a codon 816 mutation.

Despite the intricacies of treating this diverse group of disorders, an important component of management of all categories of mastocytosis is patient avoidance of triggering factors such as alcohol; nonsteroidal antiinflammatory agents in sensitive patients; pressure, friction, or extremes of temperature; and agents to which the patient is specifically allergic ([24], [26], [128], [217], [218], [219], [220], [221], [222], [223] and [224]). As with other syndromes in which patients may be at risk for severe type I hypersensitivity reactions, patients with mastocytosis should use great caution to avoid known potentiators, consider prophylactic H_1 and H_2 antihistamine treatment, and, when indicated, carry epinephrine-filled syringes and be skilled in self-administration ([128]).

Diagnosis and Classification of Non-Hodgkin Lymphomas

SPECIMEN EVALUATION

Tissue Sampling and Processing

Precise assessment of hematopathologic specimens depends, in large part, on adequate sampling and proper handling of tissues, both of which may be influenced significantly by clinicians. Therefore, effective communication between the clinician and the pathologist is imperative for obtaining pertinent patient history and the proper specimen. The largest lymph node or mass lesion generally provides the most useful material for accurate diagnosis and should undergo surgical biopsy. Fresh tissue, moistened in a balanced solution, such as normal saline, should be sent intact to the surgical pathology laboratory without delay to maximize the immunophenotypic, genotypic, and karyotypic studies that are available and to minimize irreversible tissue artifacts. Frozen sections should be discouraged on small specimens, as lymphoid hyperplasias may appear indistinguishable from lymphomas, and freezing permanently distorts the tissue. Touch imprints are generally satisfactory for initial evaluation and for directing specimen workup.

Needle biopsy and aspiration cytology is playing an expanded role in the primary diagnosis and monitoring of patients with malignant lymphomas. The major advantages of these techniques include: (a) their relatively noninvasive nature and (b) the rapidity with which morphology can be reviewed (minutes) and immunophenotyped (2 to 3 hours by flow cytometry). With computed tomography guidance, lesions in the mediastinum and retroperitoneum or in any highly vascular organ or tissue can be sampled with minimal morbidity. Further advances in flow cytometry and molecular biology have markedly reduced the amount of tissue required to provide immunophenotypic and genetic data.

Just as with lymph node and bone marrow biopsies, however, optimal information can be obtained only by close coordination between the clinician, the person performing the aspirate (radiologist or pathologist), and the hematopathologist providing ancillary diagnostic services. If the material is put into fixative, it cannot be used for flow cytometric phenotypic analysis or standard karyotypic studies.

The limitations of fine-needle aspiration include: (a) the possibility of missing focal lesions, (b) difficulty in making a primary diagnosis of malignant lymphoma in which the tumor cell is a minor population (e.g., Hodgkin lymphoma and T-cell–rich B-cell lymphoma), and (c) difficulty in precisely classifying many reactive processes in which architectural features are of prominent diagnostic importance. For example, in patients with mediastinal masses, it may be impossible to distinguish between normal thymus, thymoma, and precursor T-cell lymphoblastic lymphoma by the cytology of the lymphoid population. Furthermore, immunophenotypic studies may identify a common thymocyte phenotype that can be dominant in all three. Despite these limitations, fine-needle aspiration will play a major role in the diagnosis of many non-Hodgkin lymphomas (NHLs) in the future.

Morphologic Examination

Morphologic examination starts at low magnification to evaluate tissue architecture and patterns of infiltration. Lymphomas may cause partial or complete destruction of the normal architectural features of the lymph node. Growth patterns are generally described as nodular or diffuse. Lymphomas are often distributed within specific anatomic compartments of the lymph node, such as follicle (germinal) centers, follicle mantles, or the paracortical and medullary areas. The low magnification pattern of neoplastic cell distribution within the lymph node suggests the type of lymphoma present (Fig. 88.1). High magnification is then used to examine cytologic features, such as the neoplastic cell types [e.g., small cleaved cells (centrocytes), large transformed cells (centroblasts or immunoblasts), and plasmacytoid lymphocytes or plasma cells], because this information helps establish classification and grade of the tumor. In some lymphomas, the reactive cell constituents also may be of prognostic significance.

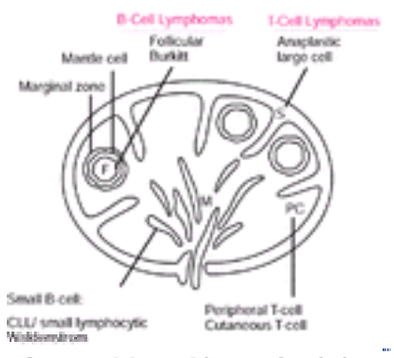

Figure 88.1. Sites of origin of malignant lymphomas in a lymph node according to anatomic and functional compartments of the immune system. CLL, chronic lymphocytic leukemia; F, follicles with germinal centers; MC, medullary cords; PC, paracortex, or interfollicular areas; S, sinuses. (Adapted from Mann RB, et al. Malignant lymphomas: a conceptual understanding of morphologic diversity. Am J Pathol 1979;94:1.)

Immunophenotypic and Genotypic Analysis

Immunophenotypic analysis uses antibodies of variable specificity to detect cellular antigens (surface, cytoplasmic or nuclear) in cell suspensions (flow cytometry) or in frozen or paraffin-embedded tissue sections (Table 88.1). These studies are often invaluable, because they help in distinguishing subtle lymphomatous infiltrates from reactive hyperplasias, can demonstrate the lineage of the neoplastic cell [e.g., B-cell, T-cell, and natural killer (NK) cell], can provide data necessary for precise classification of some lymphomas [e.g., mantle cell lymphoma vs. small lymphocytic lymphoma (SLL)] (Table 88.2), can identify important nonlineage-related markers (e.g., CD15, CD30, and CD56), and can determine the proliferative rate of lymphomas. Immunoglobulin (Ig) light chain restriction is evidence of B-cell clonality, whereas aberrant B-cell or T-cell phenotypes infer clonality ([1], [2]). As small monotypic (light chain–restricted) B-cell or genotypically clonal B-cell or T-cell populations may be seen in reactive processes, correlation of these studies with the morphologic features is essential to prevent misdiagnosis and clinical confusion ([3], [4] and [5]).

TABLE 88.1. Selected Antibodies That Are Useful in Immunophenotypic Analysis of Non-Hodgkin Lymphomas

Clusters of Differentiation (CD) Number	Antibodies	Reactivity
CD1	Leu-6, T6, and OKT6	Thymocytes, dendritic cells, and epidermal Langerhans cells
CD2	Leu-5, T11, and OKT11	T cells and natural killer cells
CD3	Leu-4, T3, OKT3, UCHT-1, and poly-CD3	T cells
CD4	Leu-3, T4, and OKT4	Helper and inducer T cells, monocytes, and macrophages
CD5	Leu-1, T1, OKT1, and UCHT-2	T cells and B-cell subset
CD7	Leu-9 and 3A1	T cells and natural killer cells
CD8	Leu-2, T8, OKT8, and UCHT-4	T-cytotoxic and -suppressor cells and natural killer cells
CD10	CALLA, J5, and BA-3	Progenitor B lymphocytes and B-cell subset (follicular center cells)
CD11b	Leu-15 and Mo-1	Granulocytes, monocytes, natural killer cells, T-cell subset
CD11c	Leu-M5 and Ki-M1	Monocytes and macrophages, granulocytes, natural killer cells, and B-cell subset (hairy cell leukemia and monocytoid B cells)
CD14	Leu-M3, Mo2, MY4, and UCHM-1	Monocytes, granulocytes, and epidermal Langerhans cells
CD15	Leu-M1 and MY1	Granulocytes, monocytes, Reed-Sternberg cells, activated lymphocytes, and some epithelial cells
CD16	Leu-11	Natural killer cells, granulocytes, macrophages, and T-cell subset
CD19	Leu-12 and B4	B cells
CD20	Leu-16, B1, and L26	B cells
CD21	B2	B-cell subset and follicular dendritic cells
CD22	Leu-14	B-cell subset
CD23	Leu-20 and B6	Activated B cells and follicular mantle B cells
CD24	BA-1	B cells and granulocytes
CD25	IL2R and Tac	Activated T and B cells and activated macrophages
CD30	Ki-1 and Ber-H2	Activated T and B cells and Reed-Sternberg cells
CD38	Leu-17 and T10	Plasma cells, thymocytes, and activated T cells
CD43	Leu-22, MT1, and DFT1	T cells, B-cell subset, granulocytes, and monocytes and macrophages
CD45	T29/33, HLe-1, and T200	Leukocytes
CD45RA	Leu-18 and 4KB5	B cells, T-cell subset, granulocytes, and monocytes
CD45RB	LCA and PD7/26/16	B cells, T-cell subset, granulocytes, and monocytes and macrophages
CD45RO	UCHL1 and A6	T cells, B-cell subset, granulocytes, and monocytes and macrophages
CD56	Leu-19 and NKH1	Natural killer cells and T-cell subset
CD57	Leu-7 and HNK1	Natural killer cells and T-cell subset
CD68	KP1, Ki-M6, and KiM7	Monocytes and macrophages
CD71	T9 and OKT9	Activated T and B cells, macrophages, and proliferating cells
CD74	LN2	B cells, monocytes and macrophages, and Reed-Sternberg cells
CDw75	LN1	B cells and some epithelial cells
CD79a	mb-1	B cells
CD103	HML-1	Intestinal intraepithelial T cells
CD138	Syndecan	Plasma cells and plasmablasts
	IgG, A, M, D, and E	Immunoglobulin heavy chains
	?, ?	Immunoglobulin light chains
	Anti-TCR aß, ßF1	aß T cells
	Anti-TCR ?sigma;	?sigma; T cells
	HLA-DR and LN3	Activated T and B cells, monocytes, and macrophages
	Anti-TdT	Lymphoblasts and some myeloblasts
	Anti-lysozyme	Monocytes, macrophages, and granulocytes
	MAC 387	Macrophage subset
	EMA	Epithelial cells, plasma cells, and some lymphoid neoplasms, including lymphocyte predominant Hodgkin lymphoma and anaplastic large cell lymphoma
	Ki-67, PCNA	Nuclear proliferation antigens
	Antiperforin; antigranzymes A, B, and C; and anti-TIA-1	Cytolytic granule-associated proteins in natural killer cells and cytotoxic T cells

TABLE 88.2. Pathologic Features in the Differential Diagnosis of Small B-Cell Lymphomas

			Immunophenotype				
	Growth Pattern	Cytology	CD5	CD23	CD10	Surface Ig	Genetics
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma	Diffuse effacement with proliferation centers	Small round nuclei, scant cytoplasm	+	+	–	Weak IgM and IgD	Trisomy 1220 to 30%
Lymphoplasmacytic lymphoma	Diffuse or interfollicular	Small lymphocytes, plasma cells, and plasmacytoid lymphocytes	–	–	–	Moderate IgM	t(9;14)(p13; q32)
Mantle cell lymphoma	Diffuse or vaguely nodular	Irregular nuclei, scant cytoplasm, and few large cells	+	–	–	Moderate IgM and IgD Lambda > kappa	t(11;14)(q13; q32)

Follicular lymphoma	Follicular	Irregular cleaved nuclei (centrocytes) and admixed large cells (centroblasts)	–	–	+	Bright IgM > IgG > IgA	t(14;18)(q32; q21) >85%
Nodal marginal zone B-cell lymphoma	Interfollicular and perisinusoidal	Small, round, and folded nuclei and abundant cytoplasm ± plasma cells	–	–	–	Moderate IgM	Trisomy 3
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue	Diffuse	Small, round, and folded nuclei and abundant cytoplasm ± plasma cells	–	–	–	IgM	Trisomy 3 t(11;18)(q21; q21)

Ig, immunoglobulin; +, positive; -, negative.

Each of the major immunologic techniques has its strengths and liabilities. Flow cytometry permits rapid analysis of large numbers of cells for virtually any surface or cytoplasmic antigen. Studies for coexpression of more than one marker are easily accomplished (e.g., CD5 on $CD19^{+}$ B-cells). Flow cytometry also allows correlation of phenotypic characteristics with cell cycle kinetics and other biological features of cells. Data storage in list mode permits retrospective off-line multiparameter analysis of lymphocyte subpopulations. However, for most analyses, flow cytometry requires viable cell populations. The quality of the information produced by flow cytometry is directly related to the quality of the communication between the flow cytometrist and the pathologist. The basic question is, “Is the cell population of interest to the pathologist the same cell population analyzed by flow cytometry?”

Immunohistochemical studies on paraffin-embedded tissue permit direct visualization of antigens on the cell of interest. Leukocyte common antigen (CD45) is a reliable marker for identifying most hematopoietic or lymphoid neoplasms but can be negative in acute leukemia, plasma cell neoplasms, and anaplastic large cell lymphoma (ALCL) ([6], [7]). Several markers that work well in paraffin, such as L-26 (CD20), polyclonal CD3, and UCHL-1 (CD45RO), are adequate to categorize most NHL as to their B-cell or T-cell lineage ([8], [9], [10] and [11]). Detection of light chain restriction is most easily achieved in B-cell lymphomas that have abundant cytoplasmic Ig (most lymphomas with plasmacytic differentiation and many large B-cell lymphomas). The major liability of paraffin immunohistochemistry is the loss of many lymphocyte antigens during tissue processing. Frozen section immunohistochemistry is performed on tissue frozen fresh or after transport in saturated ammonium chloride solution (e.g., Michel's Media and Zeus). This allows preservation of almost all membrane and cytoplasmic antigens, although morphology is suboptimal. Frozen tissue is also suitable for molecular genetic studies.

Genotypic analysis using the Southern blot technique provides a sensitive, but time-consuming and expensive, means of detecting clonal lymphoproliferations and their lineage. Polymerase chain reaction (PCR) is more sensitive than Southern blot for detecting clonality and also can be performed more rapidly. PCR is particularly helpful for establishing B-cell or T-cell clonality in lymphoproliferations present in paraffin-embedded small biopsies, such as those obtained by endoscopy ([12]). These methods are most useful when immunophenotypic studies are inconclusive and are the only practical way of proving T-cell clonality. Southern blot and PCR also can demonstrate significant chromosomal abnormalities (e.g., *BCL-1*, *BCL-2*, and *C-MYC* gene rearrangements) and viral nucleic acids that may be involved in lymphomagenesis [e.g., Epstein-Barr virus (EBV), human T-cell lymphotropic virus type 1 (HTLV-1), and human herpes virus 8]. PCR also is proving valuable in the detection of minimal amounts of residual disease in treated patients.

More recently, fluorescence *in situ* hybridization applied to paraffin-embedded tissue has allowed detection of critical translocations in lymphomas, such as mantle cell lymphoma, ALCL, Burkitt lymphoma, hepatosplenic T-cell lymphoma, and extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type, with sensitivity that is much greater than classic cytogenetics on fresh tissue or PCR on fresh or fixed tissue ([13], [14], [15], [16], [17] and [18]).

Classification of Non-Hodgkin Lymphomas

For the clinician, pathologist, and basic scientist working in lymphoid neoplasia, the classification of NHL is a persistent, confusing, and controversial problem. Several competing classification schemes have evolved, all with their supporters and detractors. In the 1950s, Rappaport developed a classification system based on growth pattern (nodular or diffuse) and cytology of lymphocytes (well differentiated, poorly differentiated, undifferentiated, or histiocytic) ([19], [20]). This scheme enjoyed enormous popularity because of its simplicity and reproducibility but was superseded by classification schemes that reflected advances in cellular immunology.

In the early 1970s, Lukes and Collins ([21]), in the United States, and Lennert ([22]), at the University of Kiel, Germany, proposed lymphoma classifications that related morphology to lymphocyte lineage. Both recognized follicular structures as a histologic correlate of B-cell differentiation. Each subdivided follicular lymphomas by the cytologic appearance of the predominant follicle center cell type: small and large cleaved cells in the Lukes-Collins Classification (centrocytes in Kiel classification) and small and large noncleaved (transformed) cells in the Lukes-Collins Classification (centroblasts in Kiel classification). For NHL with diffuse growth patterns, immunophenotypic studies facilitated and, in many cases, were essential for precise classification ([23], [24] and [25]).

In 1982, the Working Formulation (WF) was introduced in an attempt to provide a morphologic classification scheme with prognostic relevance ([26]). Although the WF was an improvement over the earlier Rappaport classification, it had the same limitations as all purely morphologic classification schemes, separating biologically closely related lymphomas and grouping together biologically unrelated entities. All consideration regarding immunophenotype was excluded, so that the WF did not foster recognition of new entities.

In 1994, the Revised European American Lymphoma (REAL) Classification ([27]) was developed for consensus of terminology and was based on the immunologic principles used by Lennert and Lukes and Collins. More recently, the World Health Organization (WHO) classification (Table 88.3) ([28]) built on the REAL Classification and corrected some of its deficiencies. Like all classifications, it was the product of political horse trading and is subject to erosion as advances in science refine clinically and biologically relevant disease entities. The WHO classification has many strengths and is comprehensive, including virtually all lymphoid malignancies described at the time of its publication in 2001. It defines diseases by four features: morphology, immunophenotype, genetics, and clinical information. Accordingly, the major diagnostic criteria for each of the major groups of NHL are presented in the following discussion.

TABLE 88.3. World Health Organization Classification of Lymphoproliferative Disorders, Including Non-Hodgkin Lymphomas

B-Cell Neoplasms	T-Cell and NK-Cell Neoplasms
Precursor B-cell neoplasm	Precursor T-cell neoplasm
Precursor B-lymphoblastic leukemia/lymphoma	Precursor T-lymphoblastic leukemia/lymphoma
Mature B-cell neoplasms	Mature T-cell and NK-cell neoplasms
Chronic lymphocytic leukemia/small lymphocytic lymphoma	T-cell prolymphocytic leukemia
B-cell prolymphocytic leukemia	T-cell large granular lymphocytic leukemia
Lymphoplasmacytic lymphoma	Aggressive NK-cell leukemia
Splenic marginal zone B-cell lymphoma	Adult T-cell leukemia/lymphoma
Hairy cell leukemia	Extranodal NK/T-cell lymphoma, nasal type
Plasma cell myeloma	Enteropathy-type T-cell lymphoma
Monoclonal gammopathy of undetermined significance	Hepatosplenic T-cell lymphoma
Solitary plasmacytoma of bone	Subcutaneous panniculitis-like T-cell lymphoma
Extraosseous plasmacytoma	Mycosis fungoides
Primary amyloidosis	Sézary syndrome
Heavy chain diseases	Primary cutaneous anaplastic large cell lymphoma
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue	Anaplastic large cell lymphoma
Nodal marginal zone B-cell lymphoma	Angioimmunoblastic T-cell lymphoma

Follicular lymphoma
Mantle cell lymphoma
Diffuse large B-cell lymphoma
Mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
Primary effusion lymphoma
Burkitt lymphoma/leukemia
B-cell proliferations of uncertain malignant potential
Lymphomatoid granulomatosis
Posttransplant lymphoproliferative disorder, polymorphic
Peripheral T-cell lymphoma, unspecified
T-cell proliferation of uncertain malignant potential
Lymphomatoid papulosis
Neoplasm of uncertain lineage and stage of differentiation
Blastic NK-cell lymphoma

NK, natural killer.

B-CELL LYMPHOMAS

Precursor B-Cell Lymphoblastic Lymphoma

Lymphoblastic lymphoma is a malignant lymphoma of precursor lymphocytes. Approximately 5 to 15% of lymphoblastic lymphomas are of B-cell lineage. They are distinguished from extramedullary acute lymphoblastic leukemia (ALL) by (a) the absence of peripheral blood involvement at presentation, (b) absence or only patchy marrow involvement (<25%) by blast cells, and (c) a clinical picture dominated by extramedullary tumor. Although they may occur at any age, the majority of these rare lymphomas have been described in children and young adults. These neoplasms present frequently in cervical lymph nodes, bone, or the central nervous system or as skin tumors of the scalp and face ([29], [30] and [31]). They almost never present as mediastinal masses.

Histologically, they exhibit a diffuse growth pattern with frequent mitoses and a “starry sky” appearance. Capsular and interfollicular involvement of lymph nodes is characteristic. Cytologically, the tumor cells are small to intermediate in size with irregular nuclear borders, dispersed chromatin, and small nucleoli ([29], [32]).

Most B-cell lymphoblastic lymphomas are CD19, CD79a, CD10, and terminal deoxynucleotidyl transferase (TdT) positive with undetectable cytoplasmic Ig and variable expression of CD45 and CD20 ([29], [32], [33]). However, a few surface Ig-positive cases have been described ([34]). As lymphoblastic lymphomas may be quite difficult to distinguish from nonhematopoietic small cell undifferentiated tumors, such as Ewing sarcoma, rhabdomyosarcoma, and neuroblastoma, as well as T-cell lymphoblastic lymphomas and blastic variants of mantle cell lymphoma, immunohistochemical studies are essential in differential diagnosis. The expression of monotypic surface Ig on tumor cells that also have a $CD5^{+}$ and $CD10^{-}$ phenotype or the presence of areas in which tumor cell cytology is more characteristic of mantle cell lymphoma is helpful in identifying blastic variants of mantle cell lymphomas ([35]).

Studies of the genetics of B-cell lymphoblastic lymphoma are limited. It appears that hyperdiploidy or the presence of many of the translocations seen in pediatric ALL, such as t(9;22), t(1;19), and t(4;11), are uncommon. Chromosome 21 additions, including trisomy and tetrasomy, have been described ([36]).

Chronic Lymphocytic Leukemia and Small Lymphocytic Lymphoma

B-cell chronic lymphocytic leukemia (CLL)/SLL is a neoplasm of small round B cells that usually have scant surface Ig and a $CD5^{+}$, $CD23^{+}$ phenotype. *SLL* is the term used to describe the disease when lymph node involvement is the dominant feature. Usually, these lymphomas present in elderly patients with a leukemic phase and generalized lymphadenopathy on routine examination. Bone marrow involvement is often extensive. Occasionally, patients present with bacterial infection related to hypogammaglobulinemia or with signs and symptoms secondary to anemia or thrombocytopenia that may have an autoimmune basis ([37]).

Lymph node architecture is totally effaced with loss of lymphoid follicles and obliteration of sinuses by an infiltrate of small round lymphocytes with condensed chromatin and scant cytoplasm. Growth centers or proliferation centers (collections of intermediate-size round lymphocytes with open chromatin and small nucleoli called *paraimmunoblasts*) are dispersed throughout the lymph node and are thought to represent foci of cell proliferation (Fig. 88.2) ([38]). Morphologic features that correlate with a worse prognosis include capsular invasion and increased numbers of large lymphocytes in the node or increased numbers (>10%) of prolymphocytes (intermediate size lymphocytes with prominent central nucleoli) in the blood ([39]). A clinically aggressive paraimmunoblastic variant of SLL has been described in which cells resembling those in growth centers predominate throughout the node ([40]). The WHO classification also includes cases corresponding to the lymphoplasmacytoid subtype of immunocytoma of the Kiel classification within the B-cell SLL group. These cases show minimal plasmacytic differentiation that is most easily recognized by the presence of cytoplasmic Ig on paraffin immunoperoxidase stains. The majority of these cases are $CD23^{+}$ and $CD5^{+}$ ([41]). The intensity of surface Ig is much brighter than the usual case of B-cell CLL/SLL ([42]).

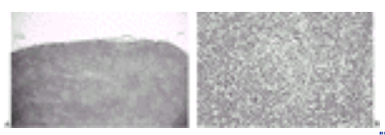

Figure 88.2. Lymph node: small lymphocytic lymphoma/chronic lymphocytic leukemia. **A:** Low magnification showing diffuse alteration of architecture, with pale areas corresponding to proliferation centers. **B:** A higher power of a growth center that is composed of intermediate-sized cells with small nucleoli that are surrounded by small round lymphocytes. See Color Plate.

Richter syndrome, which is the evolution of CLL/SLL to a large cell lymphoma, occurs in less than 5% of patients and may arise as transformation of the neoplastic small B cell or as an unrelated B-cell clone ([43], [44]). Less commonly, B-cell SLL may transform to prolymphocytic leukemia ([45]). Rarely, Hodgkin lymphoma complicates B-cell SLL ([46]). Of interest is a description of 13 cases of B-cell SLL with Reed-Sternberg-like cells that contained EBV RNA as detected by *in situ* hybridization. Three of these patients developed disseminated Hodgkin lymphoma ([47]).

On immunologic typing studies, neoplastic lymphocytes have weak or scant monotypic surface Ig, which usually is IgM associated with IgD. Neoplastic lymphocytes coexpress the nominal T-cell antigen CD5 with B-cell markers CD19, CD20 (weak); CD21, CD11c (weak); and CD23. The tumor cells are negative for FMC7, CD10, and cyclin D1. Phenotypically, B-cell SLL and CLL are identical ([48]). Admixed T cells are usually few in number. CD23 and FMC7 expression and cyclin D1 negativity are helpful in the phenotypic separation of B-cell CLL/SLL from mantle cell lymphoma, another $CD5^{+}$ small B-cell neoplasm ([49]). The coexpression of CD5 by B-cell CLL is a feature of intense interest, as $CD5^{+}$ B cells are only a small subpopulation of normal B cells but contain disproportionate numbers of cells making autoantibodies, such as rheumatoid factors ([37], [50], [51]).

Classic cytogenetic studies demonstrate specific chromosomal abnormalities in more than one-half of patients with B-cell CLL/SLL, most commonly, trisomy 12 and, less often, structural abnormalities of chromosomes 13 and 14. Trisomy 12 is correlated with mixed cell morphology, atypical immunophenotypes, and a more aggressive clinical course ([52], [53]). Recent molecular genetic studies suggest B-cell CLL/SLL can be divided into two major groups based on the presence or absence of somatic mutation. Mutation status of Ig heavy chain genes correlate with surface CD38 expression and cytoplasmic ZAP-70 expression. Deletion or inactivation of p53 and 11q deletions are poor prognostic features in multivariate analysis ([54], [55], [56], [57] and [58]).

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphomas are uncommon B-cell neoplasms composed of small lymphocytes, plasmacytoid lymphocytes, plasma cells, and variable numbers of large lymphocytes. These lymphomas, like B-cell CLL/SLL, often have marrow involvement and a leukemic phase. They are often associated with high levels of an IgM paraprotein (Waldenström macroglobulinemia) or type II cryoglobulinemia ([59], [60]). Some patients have antecedent systemic or localized abnormal immune reactions, such as Sjögren syndrome ([61]). Many patients have hepatitis C infection ([62]). These neoplasms must be differentiated from other small B-cell lymphomas that frequently exhibit plasmacytic differentiation, including nodal and extranodal marginal zone B-cell lymphomas.

Lymphoplasmacytic lymphomas are morphologically diverse and may cause diffuse or partial alteration of lymph node architecture. Many have an interfollicular distribution and abundant macrophages that may impart a mottled low-magnification appearance, resembling Hodgkin lymphoma. On high magnification, small lymphocytes are admixed with variable numbers of plasma cells, plasmacytoid lymphocytes, and admixed large lymphocytes. Other features indicating plasmacytic differentiation include Dutcher bodies (cytoplasmic Ig inclusions that appear to be intranuclear) and extracellular periodic acid-Schiff–positive material. Mast cells and hemosiderin-laden macrophages are often present. These lymphomas may transform to large cell lymphomas ([41], [63], [64] and [65]). These higher-grade lymphomas usually produce the same Ig heavy chains and light chains as the original tumor ([66]).

Plasmacytoid lymphocytes and plasma cells contain abundant intracellular Ig, which usually is monotypic IgM without IgD and can be detected using paraffin immunoperoxidase reactions. In cell suspension studies, neoplastic lymphocytes usually express more surface Ig than is usually seen in B-cell CLL/SLL ([42], [65]). Tumor cells express pan–B-cell markers CD19 and CD20 and are usually $CD5^-$ ([44]). The presence of numerous follicular dendritic cells in neoplastic infiltrates, identified by immunoperoxidase studies, is reported to have favorable prognostic implications ([67]). As the tumor cells are actively secreting Ig, many patients have high levels of monoclonal IgM producing hyperviscosity (Waldenström macroglob-ulinemia). The IgM may have rheumatoid factor activity or function as cryoglobulin, or both ([59]). Less commonly, these neoplasms may be associated with production of other Ig heavy chain classes ([68]).

The t(9;14)(p13;q32) is associated with approximately 50% of lymphomas in this group. This translocation involves the PAX-5 gene on chromosome 9, which encodes a B-cell specific transcription factor ([69]). Somatic mutations of Ig genes are commonly found in Waldenström macroglobulinemia ([70], [71]).

Mantle Cell Lymphoma

Mantle cell lymphoma is B-cell lymphoma composed of small lymphocytes with irregular nuclear outlines that have a $CD5^+$ and $CD23^-$ phenotype and overexpress cyclin D1. These lymphomas are usually widespread at diagnosis with generalized adenopathy and extensive bone marrow involvement. They may involve extranodal sites, such as Waldeyer ring, or present as lymphomatous polyposis of the lower gastrointestinal tract ([72], [73]). A few have a leukemic phase mimicking CLL, prolymphocytic leukemia, or acute leukemia (blastic variants of mantle cell lymphoma) ([74], [75]). Recognition of mantle cell lymphoma is clinically important, as these lymphomas pursue a more aggressive clinical course than other small B-cell lymphomas ([76], [77]).

Mantle cell lymphomas are composed of small lymphocytes with irregular nuclear contours. Mitotic activity is brisk, but large transformed lymphocytes are usually few in number. They usually have a diffuse growth pattern (Fig. 88.3A, Fig. 88.3B) or surround reactive germinal centers in a mantle zone pattern. Extension of the lymphoma into the capsule and perinodal fat is common ([72], [73], [78]). Transformation of mantle cell lymphoma, first recognized by Lennert as a blastic transformation of centrocytic lymphoma ([79]), is characterized morphologically by an increased cell size, frequent mitoses, and an aggressive clinical course. The differential diagnosis of blastic transformation of mantle cell lymphoma includes acute leukemia involving lymph nodes, lymphoblastic lymphoma, and transformed cutaneous T-cell lymphoma ([35], [80]).

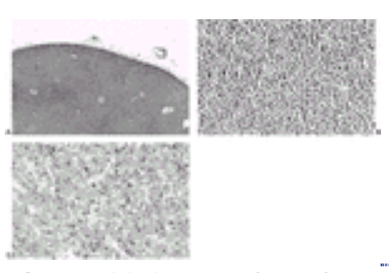

Figure 88.3. Lymph node: mantle cell lymphoma **A:** Low magnification showing diffuse architectural effacement, which, on higher magnification in **B**, is composed of sheets of small irregular lymphocytes with few large cells. **C:** Small lymphocytes exhibit nuclear staining for cyclin D1. See Color Plate.

The neoplastic cell shares immunophenotypic features with normal mantle zone lymphocytes, including moderate amounts of surface IgM, usually with IgD. Neoplastic cells are generally $CD5^+$ and $CD10^-$, but a subset of mantle cell lymphomas has $CD5^-$ tumor cells ([81]). Mantle cell lymphomas usually mark with pan–B-cell antibodies CD19, CD20, and CD22. CD23 is negative, and FMC7 is positive in contrast to the tumor cells of B-cell CLL/SLL ([49], [82]). Overexpression of cyclin D1 is almost universal in mantle cell lymphoma (Fig. 88.3C) ([83]). Overexpression of cyclin D1 is not seen in follicular hyperplasia and is uncommon in other small B-cell malignancies, with the exception of plasmacytic neoplasms and hairy cell leukemia ([84]).

On classic cytogenetics, most cases of mantle cell lymphoma show evidence of t(11;14) with *BCL-1/PRAD1* gene rearrangements involving the cyclin D1 gene ([85], [86]). Fluorescence *in situ* hybridization analysis of paraffin-embedded tissue extends the sensitivity of t(11;14) (q13;q32) detection to greater than 90% and does not require fresh or frozen tissue ([13]). A subset of patients with p53 mutations and overexpression of the p53 protein appear to have a worse prognosis ([87]).

Nodal Marginal Zone B-Cell Lymphoma

Nodal marginal zone B-cell lymphomas are uncommon lymphomas in which the tumor cells resemble the cytology of those in splenic and extranodal marginal zone B-cell lymphomas of MALT, but there is no evidence for splenic or extranodal disease. Clinically, these lymphomas appear more extensive at presentation than MALT lymphomas. They have a tendency to early relapse, and a small minority transform to large cell lymphoma ([88], [89]).

Nodal marginal zone lymphomas characteristically involve the interfollicular areas of lymph nodes and are composed predominantly of “monocytoid” small- and medium-sized lymphocytes of uniform size with distinct cell membranes that surround an abundant amount of pale cytoplasm. Nuclei are bland and oval to coffee bean in shape. In some cases, plasma cells are prominent ([90]). Admixed large lymphocytes are present, and mitotic activity is variable ([89]).

Nodal marginal zone B-cell lymphomas express pan–B-cell antigens (CD19, CD20, CD79A) and monotypic Ig (IgM without IgD) and are negative for CD5, CD10, and cyclin D1. A variable number are positive for bcl-2 protein and CD43 ([88], [91]).

Genetic studies are limited and have not identified any common cytogenetic abnormalities. Somatic mutation of the Ig genes is usually (but not always) present ([92]).

Splenic Marginal Zone B-Cell Lymphoma

Splenic marginal zone B-cell lymphoma is a small B-cell lymphoma of the white pulp of the spleen that often involves the splenic hilar lymph nodes, bone marrow, and peripheral blood. Patients with splenic marginal zone B-cell lymphoma characteristically present with splenomegaly, and many have B-symptoms (fever, weight loss, and night sweats) ([93], [94] and [95]).

The spleen has increased white pulp with nodular expansion of marginal zones and periarteriolar lymphoid sheaths. Adjacent neoplastic marginal zones merge with one another as the process extends into the red pulp. Germinal centers are often obliterated. Cytologically, neoplastic cells are small to medium sized with oval to round nuclei and moderate to abundant cytoplasm ([95]). Many cases have a lymphoplasmacytic component with monotypic cytoplasmic Ig in plasma cells and

plasmacytoid lymphocytes ([96]). The mitotic rate is usually low. Lymph node involvement demonstrates a diffuse infiltrate with patent sinuses but no residual germinal centers. Bone marrow involvement is nodular or interstitial and frequently intrasinusoidal. Tumor cells in peripheral blood often have short villous projections ([95]). Transformation to large B-cell lymphoma is seen in as much as 15% of cases ([97]).

Neoplastic cells are CD45, CD20, and bcl-2 protein positive with monotypic IgM, with or without IgD. Tumor cells are negative for CD5, CD10, CD21, CD43, and cyclin D1 ([95]). Unlike hairy cell leukemia ([93] , [94]), they are usually CD11c, CD103, and DBA.44 negative.

Allelic loss of 7q21-32 is seen in slightly less than one-half of patients. Chromosomal translocations that are seen in other small B-cell lymphomas involving *BCL-1*, *BCL-2*, and *MLT-1* are not present ([98] , [99]). On molecular genetic studies, approximately one-half of cases show somatic mutation, and one-half have unmutated Ig genes. The latter group more frequently have deletions and allelic loss of 7q31-32 and may have a worse prognosis ([100]).

Extranodal Marginal Zone B-Cell Lymphoma of Mucosa-Associated Lymphoid Tissue

Extranodal marginal zone B-cell lymphomas arise in normal sites for mucosal immunity (MALT), such as intestinal Peyer patches, or in sites of inflammation triggered by autoimmune disorders, such as Hashimoto thyroiditis or Sjögren syndrome, or by infection (*Helicobacter pylori*–associated chronic gastritis) ([101] , [102] , [103] , [104] and [105]). MALT lymphomas, many of which were diagnosed previously as pseudolymphomas, tend to remain localized, and, when dissemination occurs, it is usually to other mucosal sites. Transformation to large cell lymphoma occurs in a minority of cases ([106]).

These lymphomas are composed of small- to medium-sized lymphocytes that exhibit variable cytologic features. In some cases, lymphocytes with irregular nuclear contours resembling follicular small cleaved cells or centrocytes may predominate. Other cases may be composed primarily of cells with abundant pale cytoplasm resembling monocytoid B cells. Cases with an abundance of small lymphocytes or plasma cells also may be seen. Regardless of the neoplastic cells' appearance, they produce a diffuse infiltrate that invades epithelial structures, producing lymphoepithelial lesions (Fig. 88.4A, Fig. 88.4B) and subsequent epithelial disruption ([107]). Reactive lymphoid follicles are generally present, and the neoplastic lymphocytes may infiltrate and colonize them ([108]). Transformation to large cell lymphoma may occur ([109]).

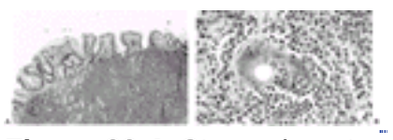

Figure 88.4. Stomach: extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue **A:** The submucosa contains a diffuse infiltrate of small lymphocytes. **B:** Centrocyte-like cells with moderate amounts of clear cytoplasm invade gastric glands, producing lymphoepithelial lesions. See Color Plate.

MALT lymphomas express B-cell antigens (CD19 and CD20) and monotypic surface Ig (usually IgM without IgD). They may be $CD43^{+}$ but usually lack other antigens expressed by small B-cell lymphomas, such as CD5, CD10, CD23, and cyclin D1. Cytoplasmic Ig is present in cases exhibiting plasmacytic differentiation ([106]).

These lymphomas demonstrate clonal Ig gene rearrangements and show extensive somatic mutations characteristic of postgerminal center B cells. The most common cytogenetic abnormality in this lymphoma is trisomy 3, seen in more than one-half of patients, but is not specific for this lymphoma ([106]). The t(11;18) chromosomal abnormality is more specific and involves fusion of the *API2* gene (an apoptosis inhibitor) on chromosome 11q21 and the *MLT1* gene (a caspaselike protease) on chromosome 18q21. It is found in 40% of patients with MALT lymphomas. Two, less common, translocations are t(1;14)(p22;q32) and t(14;18)(q32;21) ([110]). These three translocations are not found in marginal zone B-cell lymphomas of spleen and lymph node ([111]). The t(14;18)(q32q21) involves the Ig heavy chain gene locus and *MLT1* gene and is common in extragastric MALT lymphomas ([110]). T(11;18) identifies gastric MALT lymphomas that (a) present with advanced stage disease, (b) do not respond to *H. pylori* eradication, and (c) are unlikely to transform to large cell lymphoma ([112] , [113]). In contrast, the t(11;18) negative cases frequently show one or more other genetic abnormalities, suggesting two distinct pathways in the development of these lymphomas with similar morphologies ([17] , [114]).

Follicular Lymphoma

The WHO classification of follicular lymphomas requires that lymphomas in this category be at least partially follicular in its growth pattern (Fig. 88.5A). It excludes lymphomas, such as MALT lymphomas and mantle cell lymphomas, that also may have a nodular growth pattern. The incidence of follicular lymphomas is second only to DLBCL in the United States and western Europe. These usually indolent lymphomas commonly present as painless lymphadenopathy in middle-aged or elderly adults. They commonly involve the bone marrow early ([28]). Follicular lymphomas in young children and cutaneous follicular lymphomas may have a different clinical behavior than typical nodal cases ([115] , [116]).

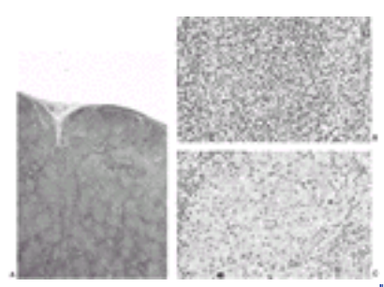

Figure 88.5. Lymph node: follicular lymphoma. **A:** Low magnification, demonstrating effacement of architecture by a nodular process. **B:** In a higher magnification, the nodules are composed almost entirely of small cleaved cells (follicular lymphoma, grade 1), whereas, in **C**, from another patient, the nodules are dominated by large noncleaved cells (follicular lymphoma, grade 3). See Color Plate.

BACKGROUND The follicle center is the major site of B-lymphocyte differentiation and proliferation ([117] , [118]). It may also serve as the site of lymphomagenesis of most B-cell lymphomas and Hodgkin lymphoma ([119]). B lymphocytes move into the follicle after they first encounter protein antigen in the paracortex to begin a series of steps that ultimately produces plasma cells with high-affinity Ig and memory B cells. Morphologically, the follicle center reflects this biologic transformation by frequent mitoses and by its range of cell types, including cleaved cells (or centrocytes) and large noncleaved cells (or centroblasts). Differentiation results in Ig heavy chain class switching from IgM to IgG, IgA, or IgE and in enhanced Ig synthesis. Proliferation produces the clonal expansion that is the basis of immunologic memory and an effective humoral immune response ([117] , [118]). Somatic mutation in the Ig genes occurring during proliferation is followed by selection of B cells with surface Ig of higher affinity for antigen. Successful interaction of B cells with antigen-bearing follicular dendritic cells triggers B-cell expression of bcl-2 protein that saves the B cell from apoptotic cell death ([120]). Tingible body macrophages mark the passing via apoptosis of B cells not selected for survival. Somatic mutation may serve to identify those neoplasms that have arisen from B cells that have been exposed to antigen in the environment of the follicle, such as follicular lymphomas and multiple myeloma, versus those that have not, such as mantle cell lymphoma. Most B-cell NHLs and Hodgkin lymphomas have extensive somatic mutations ([119] , [121] , [122]). Somatic mutation of non-Ig genes, such as *BCL-6*, may participate in lymphomagenesis ([123]). The recognition of the contribution of somatic mutation, receptor editing, and class switching in lymphomagenesis supports a major role for the follicle in neoplastic transformation ([119] , [124] , [125]).
GRADING A major problem area within those lymphomas classified as follicular lymphoma is that of grading. Virtually all follicular lymphomas are composed of a mixture of cleaved (centrocytes) and large noncleaved cells (centroblasts). Numerous studies have correlated the number of centroblasts with prognosis. Most studies agree that follicular lymphomas composed predominantly of centrocytes have a more indolent course than those composed predominantly of centroblasts ([126] , [127] , [128] and [129]). The most popular scheme for subclassification of follicular lymphoma is a modified version of that proposed by Berard, which bases categorization on numbers of large noncleaved cells per standardized high-magnification field (HMF) with fewer than six per HMF classified as grade 1 follicular lymphomas, 6 to 15 per HMF as grade 2, and greater than 15 per HMF as grade 3 follicular lymphomas ([130]). In all of these schemes of grading, there is substantial subjectivity and often disappointing interinstitutional reproducibility ([131] , [132]).

PATHOLOGY Follicular lymphomas are recognized at low magnification by the effacement of nodal architecture by follicular nodules that crowd one another and fill the cortex and the medulla (Fig. 88.5A). Tingible body macrophages are not seen in contrast to reactive follicles. Mantle zones are usually thin or absent ([133]). A small number of follicular lymphomas show differentiation to marginal zone–like cells with a “halo-like” distribution around neoplastic follicles. These marginal zone cells, although often CD10 and bcl-2 protein negative, are genetically identical to the neoplastic cells of the follicles ([134]). On high magnification, low-grade (WHO grades 1 and 2) follicular lymphomas are composed of a relatively homogeneous population of small cleaved lymphocytes (smaller than, or the same size as the macrophage nucleus) with twisted nuclei, condensed chromatin, and inapparent nucleoli (Fig. 88.5B). Cleaved cells frequently infiltrate the interfollicular areas and capsule. A variable number of large noncleaved lymphocytes with oval to round nuclei (greater in size than a macrophage nucleus), dispersed chromatin, and one to three nucleoli that often abut the nuclear membrane also are present. Grade 3 follicular lymphomas, which by definition have an increased number of large noncleaved cells (Fig. 88.5C), have been provisionally subcategorized into 3a and 3b, with the former having a mix of cleaved and large noncleaved cells, and the latter having sheets or large clusters of large noncleaved cells ([135]). Areas of diffuse growth composed predominately of cleaved cells do not appear to affect prognosis ([126]). Small cleaved follicular lymphomas with a purely diffuse growth pattern are uncommon and may be difficult to separate morphologically from mantle cell lymphoma without immunophenotypic or cytogenetic studies. Large cleaved cell lymphoma with a follicular growth pattern is not recognized as a separate entity in the WHO classification. Large cleaved cells differ from small cleaved cells not only in nuclear size (larger than macrophage nucleus), but also in chromatin pattern, which is more open with occasional small nucleoli. The nuclei are elongated and twisted like the small cleaved cell. Because of the abundant cytoplasm of tumor cells, the follicles appear pale. A minority of large cleaved follicular lymphomas exhibit a predominantly diffuse growth pattern. Several studies suggest that large cleaved cell lymphomas have a course similar to that of low-grade follicular lymphomas composed predominantly of small cleaved cells ([136], [137]). Follicular lymphomas, particularly those arising in the retroperitoneum, have a propensity for extranodal growth and interfollicular sclerosis ([138]). The sclerotic tissue is composed predominantly of type 1 collagen with variable amounts of type 3 collagen and fibronectin ([139]). Occasionally, follicular lymphomas present with massive nodal necrosis. Clonal Ig heavy chain gene rearrangements can sometimes be demonstrated in these necrotic lymph nodes without morphologically viable lymphocytes ([140], [141]). A minority of follicular lymphomas contain plasma cells that may be polyclonal or monoclonal with the same Ig heavy chain and light chain of the cleaved cells ([142]). Rarely, accumulations of intracytoplasmic Ig give cells in follicular lymphomas a signet ring cell–like appearance ([143]). A leukemic phase may be present in as much as 10% of patients with cleaved follicular lymphomas. Circulating cells show nuclear irregularity and are immunophenotypically distinct from neoplastic cells of B-cell CLL/SLL or mantle cell lymphoma ([144]). Neoplastic transformation to a large noncleaved cell lymphoma, usually with a diffuse growth pattern, occurs in approximately one-half of cases ([145], [146], [147] and [148]). Pathology reports should emphasize areas of diffuse growth of large cells, as they are sufficient for regarding the tumor as intermediate grade regardless of the grade of the tumor in follicular nodules ([149]). More recently, a rare form of transformation in which the tumor cells have a blastlike morphology has been recognized. These blastic variants of follicular lymphoma are aggressive clinically ([150]). Small cleaved follicular lymphomas express bright surface Ig fluorescence, usually IgM or IgM with IgD. Large cleaved and large noncleaved follicular lymphomas usually express IgM or IgG with approximately equal frequency. A minority of large cell follicular lymphomas are surface Ig negative but may be recognized as B-cell lymphomas by their expression of pan–B-cell markers, including CD19, CD20, and CD22 ([1], [151]). Most follicular cleaved lymphomas are CD10 $^{+}$ (WHO grades 1 and 2) as are more than one-half of large noncleaved lymphomas (WHO grade 3) ([152]). Follicular lymphomas are almost always CD5 $^{-}$, but rare CD5 $^{+}$/CD10 $^{+}$ cases have been described that often exhibit variant histopathology. This morphologic pattern may be confused with progressive transformation of germinal centers ([153], [154]). Expression of bcl-2 protein may be helpful in differentiating follicular hyperplasias from some cases of follicular lymphoma; however, overexpression of bcl-2 protein is not of help in differentiating follicular lymphomas from other NHLs ([155]). Overexpression of p53, detected by immunohistochemistry, may identify patients with increased risk for transformation ([156], [157]). Small cleaved follicular lymphomas differ from most other small B-cell lymphomas in having a significant admixture of T cells, and some authors have suggested that large numbers of T cells indicate a favorable prognostic feature ([158]). More than 85% of cleaved follicular lymphomas and 25 to 30% of DLBCLs have the t(14;18) translocation. Molecular genetic studies may identify additional cases not recognized by conventional cytogenetics ([159], [160]). Abnormalities of chromosomes 3q27, 5, 7, 12, and 13q are more common in a higher grade (WHO grade 3) or in transformation of follicular lymphoma. Abnormalities of chromosome 8q24 are associated with blastic or blastoid variants of follicular lymphoma ([161], [162]). The pattern of somatic mutation in follicular lymphomas suggests a role for antigen selection in their clonal evolution ([121], [122]).

Burkitt Lymphoma

Burkitt lymphoma is a high-grade B-cell lymphoma composed of medium-sized, rapidly dividing lymphocytes. These lymphomas usually affect children and young adults and often present at extranodal sites. Less commonly, they have a leukemic phase. Three clinical forms are recognized: (a) endemic, which classically presents as jaw or facial masses in young boys in equatorial Africa; (b) sporadic, which may present at any age with frequent abdominal involvement; and (c) immunodeficiency associated, such as in patients who are human immunodeficiency virus positive. All subtypes are characterized by chromosomal rearrangements involving the *c-myc* oncogene that lead to its inappropriate expression in B cells. All three forms are associated with EBV infection, 100% in endemic Burkitt lymphomas and 20 to 40% in sporadic and immunodeficiency-associated Burkitt lymphomas ([28], [163], [164] and [165]).

Burkitt lymphomas typically have a diffuse growth pattern that is dominated on low magnification by the “starry sky” produced by tingible body macrophages (Fig. 88.6A). Tumor cells may home into residual follicles and often have a cohesive appearance at the interface of tumor and soft tissue. Nuclear size is equivalent to that of endothelial cells or macrophages. The nuclei are round to oval with small nucleoli and a moderate amount of amphophilic cytoplasm. Mitoses are frequent (Fig. 88.6B). On Wright-stained touch imprints, the neoplastic cells show remarkable nuclear homogeneity and the presence of characteristic, vacuolated, basophilic cytoplasm. In some cases, there is more nuclear pleomorphism and numerous large cells with prominent nucleoli. A second variant shows plasmacytic differentiation with eccentric nuclei and more abundant basophilic cytoplasm. In cases with atypical histologic or immunophenotypic features, demonstration of *c-myc* gene dysregulation and translocations is essential to confirm the diagnosis ([163], [166], [167] and [168]).

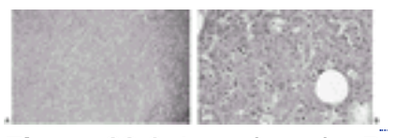

Figure 88.6. Lymph node: Burkitt lymphoma. **A:** The architecture is totally effaced by a diffuse infiltrate with a “starry sky” appearance. **B:** High power, showing a monotonous population of small transformed or noncleaved lymphocytes with round to oval nuclei and variable cytoplasm. Mitotic figures are frequent. Numerous tingible body macrophages are present. See Color Plate.

Immunophenotypically, these lymphomas have moderate amounts of monotypic surface Ig (usually IgM) and are CD10 positive but CD5 and TdT negative. The plasmacytic variants may contain intracellular Ig, and paraffin immunohistochemical staining with Ki-67 shows greater than 95% of tumor cells are positive, which is consistent with a high growth fraction ([169], [170], [171] and [172]).

These tumors have reciprocal translocations involving the *C-MYC* oncogene mapped to chromosome 8q24, which is juxtaposed to the enhancer region of the Ig heavy chain gene on chromosome 14. The translocations less commonly involve the ?–light chain (chromosome 2) and ?–light chain (chromosome 22) genes ([173]). In endemic Burkitt lymphoma, the translocation breakpoints are located in the joining region of the Ig heavy chain gene, whereas, in sporadic or immunodeficiency-associated cases, the breakpoints are within the switch region. All forms show the presence of somatic mutation, which is ongoing in some cases of epidemic Burkitt lymphoma ([174], [175] and [176]).

Diffuse Large B-Cell Lymphoma

DLBCLs are the most frequent lymphoma in North America and Europe and occur in all age groups. These lymphomas are often localized at presentation and frequently occur in extranodal sites. They may arise as a result of transformation of more indolent low-grade B-cell lymphomas. They are the most common lymphoma seen in patients with immunodeficiency ([27], [177]).

By definition, there is diffuse effacement of the architecture, usually with no residual normal nodal architecture remaining (Fig. 88.7A). Cytologically, the tumor cells most often resemble the large noncleaved cells or centroblasts of follicular lymphoma with nuclei two or more times larger than a macrophage nucleus, dispersed chromatin, and two to three small- to medium-sized nucleoli that may abut the nuclear membrane. Their cytoplasm is usually abundant. Mitotic activity is brisk (Fig. 88.7B). They often involve perinodal soft tissue and fat and may be associated with sclerosis. Several cytologic variants are described. Multilobated large B-cell

lymphomas include lymphocytes in which more than 25% of the nuclei have mulberry or cloverleaf shapes with small nucleoli and dispersed chromatin ([178], [179]). Anaplastic variants have multiple large nuclei with bizarre pleomorphic features producing a cytologic resemblance to ALCL ([180]). Rare spindle cell variants may mimic sarcoma ([181]). T-cell–rich large B-cell lymphoma is a type of DLBCL characterized by a diffuse or interfollicular growth pattern dominated by reactive, small T cells and histiocytes unlike the other variants of DLBCL. These lymphomas tend to be more widespread at presentation than the other members of this group. The neoplastic large B cells are in a minority ([182], [183]). An immunoblastic cytology is characterized by cells that have a single prominent inclusionlike nucleolus and often have features of plasmacytic differentiation (cytoplasmic basophilia and nuclear eccentricity). Immunoblastic cytology may confer a worse prognosis when compared to tumors with centroblastic morphology and may be more common in patients with immunodeficiency ([180], [184]). In addition, two subtypes of DLBCL with immunoblastic features are noteworthy. Plasmablastic lymphomas present as soft-tissue lesions of the airway in human immunodeficiency virus–positive patients. These lymphomas, which often are associated with EBV, lack CD45 and CD20 but do express plasma cell markers, such as CD138, and contain intracellular Ig ([185]). DLBCL with ALK expression have an immunoblastic cytology with prominent central nucleoli. They also have weak to absent CD20 and CD45 expression but contain monotypic IgA. These aggressive lymphomas are CD30 negative and do not harbor a t(2;5) ([186]). Finally, a controversial group in classification are the Burkitt-like lymphomas. They are B-cell lymphomas with a variable number of cytologic characteristics of Burkitt lymphoma, including a high mitotic rate, prominent cytoplasmic basophilia, and a “starry sky” pattern. The tumor cells are smaller than centroblasts but are somewhat larger and more pleomorphic than those typical of Burkitt lymphoma. In the WHO classification, cases with these features but lacking evidence of translocations causing *C-MYC* gene overexpression have been included in the DLBCL category. There is evidence to suggest that these “Burkitt-like” lymphomas have a worse prognosis than the usual DLBCL ([187]).

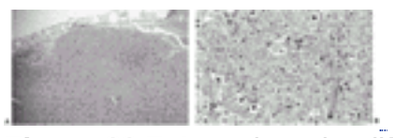

Figure 88.7. Lymph node: diffuse large B-cell lymphoma. **A:** On low magnification, the architecture is replaced by neoplastic process with a diffuse growth pattern. **B:** On high magnification, the tumor cells have large nuclei with dispersed chromatin, small nucleoli, and a variable amount of cytoplasm. Mitotic figures are easily identified. See Color Plate.

The tumor cells of DLBCL usually have monotypic surface or cytoplasmic Ig, or both, on flow cytometry or frozen section immunoperoxidase. Monotypic Ig may be detected in less than one-third of cases by paraffin immunohistochemistry ([188]). The tumor cells are usually CD45, CD19, CD20, CD22, and CD79A positive with a significant number also CD10 positive and bcl-6 positive ([189], [190]). CD30 expression is variable. A subset is CD5 positive, but this group does not appear to arise as a transformation of B-cell CLL/SLL or mantle cell lymphoma ([191]). Increased expression of Ki-67 (a marker of cell proliferation), bcl-2 protein, and CD44 (a lymphoid homing receptor) are associated with decreased survival, as is loss of the pan–B-cell markers CD20 and CD22 ([190], [192], [193] and [194]). Loss of HLA class I or class II antigens is not associated with a worse prognosis, as was originally reported ([195]).

A minority of DLBCLs have a t(14;18) ([196], [197]). Many of these lymphomas arise as transformations of cleaved follicular lymphomas, as may be suggested by antecedent biopsy or the presence of admixed cleaved follicular lymphoma in the diagnostic biopsy or at other sites (e.g., bone marrow). Overexpression of bcl-2 protein with or without an associated t(14;18) correlates with a poor prognosis ([193], [198]). Almost one-fourth of DLBCLs have rearrangements involving *BCL-6*, a gene on chromosome 3q27 that codes for a protein similar to zinc-finger transcription factors. The prognostic implications of *BCL-6* gene rearrangements are controversial, varying from study to study ([199]). Amplification of the *REL* protooncogene is seen in DLBCLs, particularly in those arising in extranodal sites, and may represent a progression-associated marker ([200]). Gene microarray analysis of tumor RNA in DLBCL has revealed two distinct patterns, germinal center B-cell–like and activated B-cell–like. The former appears to have a better prognosis than the latter ([201]).

MEDIASTINAL (THYMIC) LARGE B-CELL LYMPHOMA Mediastinal (thymic) large B-cell lymphomas often present in young adult women and are clinically aggressive. They appear to originate from thymic B cells. Mediastinal large B-cell lymphomas invade local structures (pleura, lung, and pericardium) and often produce compression of the superior vena cava and airways ([202], [203]). Mediastinal large B-cell lymphomas have a diffuse growth pattern and are frequently sclerotic. The neoplastic cells have a range of cytologic appearances from cells resembling centroblasts of the follicular center, to large cells with abundant clear cytoplasm, to cells with multilobated nuclei, and to pleomorphic variants that may appear similar to those in anaplastic carcinoma or Hodgkin lymphoma ([204], [205] and [206]). Admixed eosinophils and small lymphocytes in a sclerotic background may contribute to morphologic confusion with Hodgkin lymphomas. These lymphomas are often surface Ig negative with decreased expression of HLA class I and II antigens. They express the B-cell markers CD19, CD20, CD22, and CD79a ([205]). They are CD5 and CD10 negative. CD30 is often positive, but CD20 and CD45 positivity, along with CD15 negativity, allow distinction from syncytial variants of classical Hodgkin lymphoma and ALCL ([205], [207]). These lymphomas do not have translocations involving the *BCL-1*, *BCL-2*, or *BCL-6* gene loci ([207]). Point mutations of *C-MYC* and p53 are seen in a minority of cases ([208], [209]). Many have additions to the short arm of chromosome 9 (also seen in classic Hodgkin lymphoma), as well as abnormalities of the X chromosome and amplification of *REL1*. Somatic mutation in these lymphomas is extensive, but continuing mutation is infrequent ([210]).
INTRAVASCULAR LARGE B-CELL LYMPHOMA Rare intravascular large B-cell lymphomas are characterized by multifocal intravascular aggregates of pleomorphic cells. They have a predilection for small blood vessels in the skin and central nervous system, where they produce cutaneous plaques and focal or global neurologic signs. The tumor is often clinically unsuspected and can be easily overlooked on biopsy. The diagnosis is most commonly made at autopsy. The tumor cells have large nuclei with open chromatin, small nucleoli, and scant cytoplasm. They fill small veins and arteries, as well as capillaries. Unlike so-called angiocentric lymphomas (formerly called *lymphomatoid granulomatosis*), the neoplastic cells do not infiltrate vascular walls and are usually not associated with tissue necrosis ([211], [212], [213], [214], [215], [216] and [217]). Intravascular, or angiotropic, large B-cell lymphomas are CD20 and CD45 positive. Their peculiar intravascular location may be related to expression of CD44, a lymphocytic homing receptor. Almost all cases are bcl-2 protein positive, with a minority expressing CD5 or CD10 ([216], [217] and [218]). Genetic studies are limited but have detected extensive somatic mutation. These lymphomas do not show *BCL-2* gene rearrangements, and studies for EBV by *in situ* hybridization are negative ([216], [219]).

T-CELL AND NATURAL KILLER-CELL LYMPHOMAS

T-cell and NK-cell lymphomas may be grouped together, because their normal counterparts apparently arise from a common progenitor cell that expresses CD3e and is unable to develop into B cells ([220]). Furthermore, some lymphomas from these two lymphoid lineages have considerable morphologic, immunologic, and clinical overlap. Overall, T- and NK-cell lymphomas are less common than B-cell malignancies, as they comprise approximately 15% of the NHL in the United States and western Europe ([221]).

Classification of T- and NK-cell lymphomas has been problematic. The WF did not attempt to recognize T-cell or NK-cell lymphomas, although morphologic categories were available for lymphoblastic lymphoma and mycosis fungoides ([26]). Both of the updated early immunologically oriented schemes segregated T-cell lymphomas into particular morphologic subgroups that often were not distinct clinically ([222], [223]). The REAL Classification attempted to define “real” disease entities and considered T-cell and putative NK-cell neoplasms as a single group that was subdivided into *precursor* (phenotypically immature) and *peripheral* (phenotypically mature) categories ([27]). The peripheral T- and NK-cell neoplasms were further subdivided into definite and provisional entities, depending on the International Lymphoma Study Group's experience with each proposed entity. The current WHO classification is built on the REAL Classification and divides definite T-cell and NK-cell neoplasms into *precursor* and *mature* categories. Provisional entities are not included. The *mature* T-cell and NK-cell neoplasms are subdivided into those that are leukemic, cutaneous and extranodal, and nodal in origin. Precursor and peripheral T- and NK-cell lymphomas are discussed in the following sections. Precursor T-cell ALL (Chapter 77 and Chapter 78), T-cell prolymphocytic leukemia and T-cell large granular lymphocytic leukemia (Chapter 90 and Chapter 92), and mycosis fungoides (Chapter 94) are discussed elsewhere in this text.

Precursor T-Cell Lymphoblastic Lymphoma

T-cell lymphoblastic lymphomas are highly aggressive malignancies of immature (precursor) T cells that generally present in children and young adults who have anterior mediastinal masses, often accompanied by supradiaphragmatic lymphadenopathy. These lymphomas efface the thymic and nodal architecture in a diffuse pattern, and infiltrate the capsule and adjacent soft tissue. Numerous tingible body macrophages impart a “starry sky” appearance similar to small noncleaved cell (Burkitt and Burkitt-like) lymphomas (Fig. 88.8A). Monomorphic neoplastic lymphocytes are small to intermediate in size, contain scant cytoplasm, and have round to convoluted nuclei (Fig. 88.8B). The chromatin is dispersed and blastlike, and nucleoli are usually indistinct. Mitotic figures are abundant. These morphologic features

are indistinguishable from disseminated precursor T-cell ALL ([224]) and the infrequent B-cell lymphoblastic lymphomas that were discussed previously.

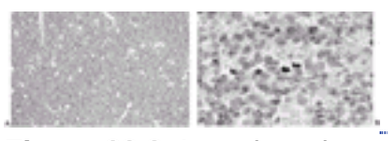

Figure 88.8. Lymph node: precursor T-cell lymphoblastic lymphoma. **A:** The nodal architecture is completely effaced by a diffuse lymphoid infiltrate. The interspersed macrophages help impart a “starry sky” appearance. **B:** The neoplastic cells are intermediate in size and have delicate chromatin that are characteristic of blasts, indistinct nucleoli, and scant cytoplasm. Frequent mitoses are present *(center)*. See Color Plate.

T-cell lymphoblastic lymphomas express diverse T-cell antigens, but most are CD3 $^{+}$ and CD7 $^{+}$. Some lesions correspond to early (CD1 $^{-}$, cytoplasmic CD3 $^{+}$, CD4 $^{-}$, and CD8 $^{-}$), common (CD1 $^{+}$, cytoplasmic CD3 $^{+}$, CD4 $^{+}$, and CD8 $^{+}$), or late (CD1 $^{-}$, surface CD3 $^{+}$, CD4 $^{+}$, or CD8 $^{+}$) thymocytes ([225]). Cytoplasmic CD3 expression is the most specific early marker of a T-cell phenotype and is also present in T-ALL ([226], [227]). TdT is present in T-cell lymphoblastic lymphomas, and 25% of these lymphomas are CD10 $^{+}$. HLA-DR expression is absent in almost all cases unlike B-ALL and most nonlymphoid leukemias. CD34 expression is also uncommon in T-cell lymphoblastic lymphomas. Occasional T-cell lymphoblastic lymphomas express NK-cell–associated antigens (e.g., CD16, CD56, or CD57) and may be of true NK-cell lineage ([228], [229] and [230]).

Because T-cell lymphoblastic lymphoma and T-ALL have considerable overlap of morphologic, immunologic, and clinical features, it may be impossible to distinguish between the two for individual precursor T-cell neoplasms. Extensive mediastinal and peripheral lymph node involvement with limited bone marrow and peripheral blood disease favors a diagnosis of T-cell lymphoblastic lymphoma, whereas the presence of greater than 25% T-cell lymphoblasts in the marrow is considered T-ALL ([27]).

Peripheral T-Cell Lymphoma, Unspecified

Several specific types of mature (peripheral) T-cell lymphomas are recognized by the WHO classification, as discussed separately in the following sections. However, approximately one-half of peripheral T-cell lymphomas (PTCLs) do not fit a distinctive type and are regarded as PTCL, unspecified. These lymphomas are postthymic T-cell malignancies that usually present in adults who have disseminated disease accompanied by B symptoms and poor performance status. There is generally a diffuse growth pattern, but rare cases may appear nodular ([231], [232]). A variety of the following morphologic features may also be seen: neoplastic lymphocytes of varying size that often have clear cytoplasm; large tumor cells that may have hyperlobate nuclei, may be multinucleate, or may resemble Reed-Sternberg cells; frequent reactive epithelioid histiocytes; delicate connective tissue bands that segregate cells into clusters; and hypervascularity ([231]). These lesions have diverse and often aberrant T-cell phenotypes ([233]). Most express a/ß T-cell receptors (TCRs) and demonstrate TCR gene rearrangements ([234], [235], [236] and [237]).

NK-cell–like T-cell lymphoma is a general term that has been applied for a heterogeneous group of PTCLs that express NK-cell–associated antigens, such as CD16, CD56, or CD57, and have azurophilic cytoplasmic granules by light or electron microscopy ([238], [239]). NK-cell–like T-cell lymphomas express surface CD3 or framework determinants of the TCR (a/ß or ?/d chains), or both, and demonstrate TCR gene rearrangements unlike true NK-cell lymphomas ([238]). Most NK-cell–like T-cell lymphomas are highly aggressive extranodal neoplasms. A leukemic phase is common that can be distinguished from large granular lymphocyte leukemias by the overall clinicopathologic features ([238]). Hepatosplenic T-cell lymphoma, subcutaneous panniculitis-like T-cell lymphoma, and enteropathy-type T-cell lymphoma (discussed in detail later) may be regarded as specific subsets of NK-cell–like T-cell lymphomas, because most thoroughly studied cases express NK-cell–associated antigens and contain cytolytic-type cytoplasmic granules ([240]). Many posttransplant PTCLs also fall within the spectrum of NK-cell–like T-cell lymphomas ([238], [241]).

T-ZONE LYMPHOMA T-zone lymphoma, considered a specific entity in the updated Kiel classification, is recognized as a morphologic variant among the PTCL, unspecified in the WHO classification. The characteristic histopathologic feature is an interfollicular growth of primarily small neoplastic T-cells with clear cytoplasm that are associated with prominent high endothelial venules and spared secondary lymphoid follicles.

LYMPHOEPITHELIOID CELL LYMPHOMA Lymphoepithelioid cell (Lennert) lymphoma ([242], [243] and [244]), another specific entity in the updated Kiel classification, is also considered a morphologic variant among PTCL, unspecified in the WHO classification. The most striking histologic feature is the numerous clusters of epithelioid histiocytes that are relatively evenly dispersed throughout tissues obliterated by a lymphomatous infiltrate composed primarily of small neoplastic T-cells. This moderately aggressive lymphoma must be distinguished from some cases of Hodgkin lymphoma, B-cell lymphomas, and other PTCLs that are also accompanied by a high content of epithelioid histiocytes ([64], [245], [246] and [247]). Misinterpretation as a reactive process may occur when attention is focused on the histiocytes rather than on the lymphoid infiltrate that destroys tissue architecture. When localized, Lennert lymphoma tends to involve the head and neck region, particularly cervical lymph nodes and sometimes Waldeyer ring.

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma, a specific subtype of PTCL, accounts for approximately 15 to 20% of all PTCLs. It also incorporates angioimmunoblastic lymphadenopathy with dysproteinemia ([248]) and immunoblastic lymphadenopathy ([249]), because the clinicopathologic features are similar for each, and most cases of angioimmunoblastic lymphadenopathy with dysproteinemia and immunoblastic lymphadenopathy show T-cell clonality and nonrandom chromosomal abnormalities ([250], [251], [252] and [253]). Patients with this moderately aggressive lymphoma are typically adults who present with generalized lymphadenopathy, B-symptoms, polyclonal hypergammaglobulinemia, skin rash, and various autoimmune phenomena.

Lymph nodes are usually effaced by a diffuse lymphoproliferation that may extend beyond the capsule into the pericapsular soft tissue. Branching high endothelial venules with hyalinized walls proliferate throughout (Fig. 88.9A). The lymphoid infiltrate often appears hypocellular because of a meshwork of follicular dendritic cells around the vessels and in residual “burned-out” follicle centers ([251]). The lymphoid infiltrate consists of a mixture of small lymphocytes and immunoblasts, the latter often having clear cytoplasm (Fig. 88.9B). Epithelioid histiocytes, eosinophils, and plasma cells are present in variable proportions, with the latter likely contributing to the hypergammaglobulinemia ([245], [254]).

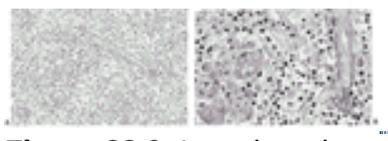

Figure 88.9. Lymph node: angioimmunoblastic T-cell lymphoma. **A:** There is a diffuse lymphoproliferation that is associated with prominent periodic acid-Schiff–staining high endothelial venules. **B:** Perivascular clusters of “clear cell” immunoblasts *(left)* are admixed with small lymphocytes and periodic acid-Schiff–staining high endothelial venules. See Color Plate.

Most angioimmunoblastic T-cell lymphomas have a CD4 $^{+}$ (helper T-cell) phenotype, and many cases have aberrant T-cell antigen expression. The neoplastic T cells frequently express CD10 ([255]). Most also demonstrate TCR gene rearrangements. EBV genomes have been detected in B cells and T cells in angioimmunoblastic T-cell lymphoma ([256], [257]). The presence of the EBV genome may be due to the decreased immunocompetence of these patients ([256]) or it may be directly involved in lymphomagenesis ([257]).

Anaplastic Large Cell Lymphoma

ALCL is typically characterized by an infiltrate of highly pleomorphic large lymphocytes that express strong reactivity with antibodies directed against CD30, a T-cell activation-associated antigen ([258]). Primary ALCL arises *de novo* and can be subdivided into nodal (systemic) and cutaneous forms ([259]). Secondary ALCL

represents a morphologic (and immunologic) transformation of another T-cell lymphoma, such as mycosis fungoides ([260]).

Primary systemic ALCL is a moderately aggressive tumor that generally presents in young patients who have peripheral lymphadenopathy and extranodal disease that often includes the skin ([259] , [261]). The lymphoma preferentially infiltrates nodal sinuses and extends into the paracortical region, often sparing secondary lymphoid follicles (Fig. 88.10A). The neoplastic large cells seem cohesive and usually have great variability in nuclear appearance, including some that are horseshoe- or doughnut-shaped ("hallmark" cells) or are multinucleate with a resemblance to Reed-Sternberg cells of Hodgkin lymphoma (Fig. 88.10B) ([262]). These features of the tumor cells are characteristic of the common variant of ALCL with pleomorphic cytology. The common variant, comprising approximately 70% of ALCL, also includes cases with monomorphic cytologic features in which the nuclei are round rather than pleomorphic ([262]). The chromatin pattern is dispersed (blastlike), and there are often prominent nucleoli. The cytoplasm is abundant, and the mitotic rate is often brisk. The common variant of ALCL may be misdiagnosed as metastatic carcinoma or malignant histiocytosis because of the pleomorphic cytologic features of the tumor cells ([258] , [263]). Small cell and lymphohistiocytic variants have been described, each comprising approximately 10% of ALCL ([264] , [265]). The latter two variants may be misdiagnosed as an inflammatory process.

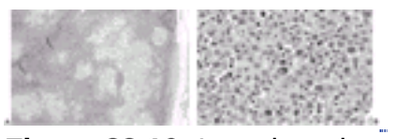

Figure 88.10. Lymph node: anaplastic large cell lymphoma. **A:** Pale-staining tumor cell infiltrates with a cohesive appearance fill the sinuses. **B:** The lymphoma is composed of pleomorphic large lymphocytes, some of which have the horseshoe- or doughnut-shaped nuclei *(center)* that are characteristic of "hallmark" cells of anaplastic large cell lymphoma. See Color Plate .

Although the tumor cells of ALCL are always CD30 $^{+}$, expression of CD30 is not synonymous with a diagnosis of ALCL as this antigen can be detected in some neoplastic cells of other T-cell and B-cell lymphomas and in Reed-Sternberg cells of Hodgkin lymphoma ([258] , [266]). Embryonal carcinoma, seminoma, and pancreatic carcinoma may also have some CD30 positivity. ([267] , [268] and [269]) Furthermore, CD30 is expressed in some florid immunoblastic reactions, such as in infectious mononucleosis ([270] , [271]). Most ALCLs have a T-cell phenotype or genotype, but 10 to 15% express B-cell antigens and are included among the DLBCL category in the WHO classification. Another 10 to 20% lack T-cell and B-cell antigens ("null" cell type) but are still grouped with T-cell ALCL. Most ALCLs demonstrate cytotoxic granule-associated proteins that are suggestive of a cytotoxic lymphocyte origin ([272] , [273]). Epithelial membrane antigen is frequently expressed by tumor cells of ALCL, particularly the primary systemic cases ([259] , [274]).

A t(2;5) (p23;q35) chromosomal abnormality is observed in approximately 60% of the primary systemic type of ALCL ([275] , [276] , [277] and [278]). This translocation fuses the anaplastic lymphoma kinase gene (*ALK*) on chromosome 2 and the nucleophosmin gene (*NPM*) on chromosome 5 ([279]). The fusion protein can be detected with a cytoplasmic and nuclear ALK staining pattern by immunohistochemistry ([280]). Approximately 70 to 80% of ALK-positive ALCL have cytoplasmic and nuclear staining, whereas the remainder have cytoplasmic staining only indicating variant translocations involving *ALK* and partner genes other than *NPM* ([281]). Variant *ALK* gene translocations include t(1;2) (q25;p23), which fuses the tropomyosin 3 (*TPM3*) gene on chromosome 1 and *ALK*; t(2;3) (p23;q21), which involves the *TRK*-fused gene (*TFG*) on chromosome 3 and *ALK*; inv ([2]) (p23 q35), which involves the *ATIC* gene (encoding for 5-aminoimidazole-4-carboxamide-ribonucleotide) on chromosome 2 and *ALK*; and t(2;17) (p23;q11-qter), which fuses the clathrin heavy chain (*CLTC*) gene on chromosome 17 and *ALK* ([282] , [283] , [284] and [285]). The ALK-positive ALCLs have been shown to have a much better 5-year survival than ALK-negative ALCLs ([286] , [287]).

Primary cutaneous ALCL typically occurs in adults who have localized disease at the time of diagnosis ([259]). This form of ALCL is often indolent and may be an extension of lymphomatoid papulosis type A. The tumor cells generally resemble those of the common variant of primary systemic ALCL and express T-cell antigens. Primary cutaneous ALCL is usually epithelial membrane antigen negative and lacks t(2;5) and ALK expression, suggesting it has a different pathogenetic mechanism than that of primary systemic ALCL ([259] , [277] , [278]).

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a peripheral T-cell neoplasm caused by HTLV-1 and has four clinical subtypes: acute, chronic, lymphomatous, and smoldering ([288] , [289] , [290] and [291]). Bone marrow infiltrates are interstitial or diffuse and may be less impressive than the degree of peripheral blood involvement. Circulating tumor cells have hyperlobate nuclei, sometimes with a cloverleaf shape. Lymph nodes are generally effaced by a diffuse infiltrate of pleomorphic lymphocytes of variable size, an appearance that may be difficult to distinguish from some PTCL, unspecified by morphology alone ([292]). Cutaneous infiltrates may be difficult to distinguish from mycosis fungoides, because ATLL can have epidermotropism with formation of Pautrier's microabscesses ([288]). The neoplastic cells express T-cell antigens but often lack CD7. Most cases are CD4 $^{+}$ and express the activation markers CD25 (interleukin-2 receptor) and HLA-DR. ATLL exhibits TCR gene rearrangements and clonal integration of HTLV-1 genomes ([291]).

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma, an extranodal lymphoma, probably arises from the cytotoxic ?/d and a/ß T cells of the splenic red pulp ([293]). Despite the few descriptions of hepatosplenic T-cell lymphomas ([294] , [295] , [296] and [297]), a fairly typical clinicopathologic picture has emerged for these neoplasms. Most cases involve young, adult men who present with B-symptoms, massive hepatosplenomegaly, no lymphadenopathy, moderate anemia, and marked thrombocytopenia. The disease is aggressive, and most patients die within 2 years, even if a remission is achieved initially with therapy.

This lymphoma preferentially infiltrates the cords and sinuses of the splenic red pulp, hepatic sinusoids, and marrow interstitium (Fig. 88.11). A leukemic phase may develop as the disease progresses ([294] , [295] , [296] and [297]). Tumor cells are generally small to intermediate in size, but some cases may have a predominance of large cells. There are condensed chromatin, indistinct nucleoli, and scant eosinophilic cytoplasm. Circulating tumor cells are generally agranular, but cytoplasmic granules have been detected by electron microscopy in some cases ([297]). There may be an associated hemophagocytosis by benign histiocytes ([297]). The characteristic phenotype is CD2 $^{+}$, CD3 $^{+}$, CD4 $^{-}$, CD5 $^{-}$, CD7 $^{+}$, and CD8 $^{-}$. Most reported cases express TCR ?/d chains, but a subset has TCR a/ß chains ([298]). The TCR ?/d cases are derived preferentially from the V $_{d}$1 subset of ?/d T cells, whereas cases of ?/d subcutaneous panniculitis-like T-cell lymphoma appear to be derived from a different ?/d T-cell subset that expresses the V $_{d}$2 gene ([299]). NK-cell–associated antigens, such as CD16 and CD56, and cytotoxic granule-associated proteins are often expressed ([295] , [296] and [297]). TCR gene rearrangements are observed. Karyotypic studies often show isochromosome 7q that may be accompanied by trisomy 8 and loss of a sex chromosome ([296] , [297] and [298] , [300]).

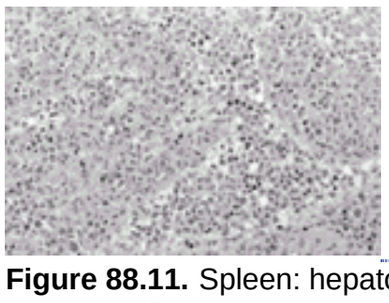

Figure 88.11. Spleen: hepatosplenic T-cell lymphoma. Intermediate-size lymphocytes are present throughout the splenic red pulp and markedly expand its sinuses. See Color Plate .

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma usually presents as multiple erythematous subcutaneous nodules of variable size (0.5 to 12.0 cm) on the extremities or trunk, or both, of adults ([301], [302] and [303]). This moderately aggressive lymphoma tends to remain localized to the subcutis throughout the clinical course that may be complicated by a severe, and often fatal, hemophagocytic syndrome.

The lymphoma primarily involves the subcutaneous adipose tissue, where there is a lobular panniculitic infiltrate of pleomorphic lymphocytes of variable size (Fig. 88.12). There may be tumor in the deep dermis, but the upper dermis and epidermis are spared. Karyorrhexis and fat necrosis are always present, as are benign histiocytes that often exhibit phagocytosis of nuclear debris or red blood cells. The lymphoma cells express a T-cell phenotype that may be aberrant. Most cases have a/ß TCR, and there is heterogeneous expression of CD4 and CD8. The few cases that lack CD4 and CD8 have ?/d TCR ([303], [304]). These lymphomas contain cytotoxic granule-associated proteins, and some also express NK-cell–associated antigens, usually CD56 ([303]). TCR gene rearrangements have been identified ([303], [305]).

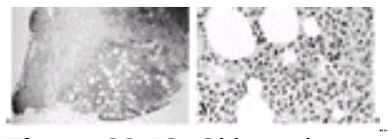

Figure 88.12. Skin: subcutaneous panniculitis-like T-cell lymphoma. **A:** There is a lobular panniculitic lymphocytic infiltrate that is confined to the subcutaneous tissue with complete sparing of the dermis. **B:** Pleomorphic tumor cells fill the interstitium and rim some of the fat spaces. See Color Plate.

Enteropathy-Type T-Cell Lymphoma

Primary intestinal T-cell lymphomas are rare ([306]), and most are considered enteropathy-type in the WHO classification. These lymphomas are regarded as *enteropathy-associated* if there is clinical evidence of malabsorption or if there is villous atrophy of the mucosa ([306], [307]). Most patients are middle-aged to elderly; it is unusual for these lymphomas to present before 40 years of age. The most common presenting symptoms are abdominal pain and weight loss. Diarrhea is present less often but is not infrequent. There may be signs of acute obstruction or spontaneous perforation. Some patients may have a history of celiac disease or other malabsorptive problem. These T-cell lymphomas are aggressive, and most patients die of their disease within 2 years of diagnosis.

The small intestine is primarily involved, with most cases being multifocal in the jejunum. The neoplastic cells always involve the mucosa (Fig. 88.13). There is often ulceration (*ulcerative jejunitis*), and there may be villous atrophy (*enteropathy-associated* T-cell lymphoma). Lymphoma cells also may infiltrate residual glandular structures producing lymphoepithelial lesions that must be distinguished from those associated with extranodal marginal zone B-cell lymphomas of MALT type. This epitheliotropism also is reminiscent of that seen in the skin in patients with mycosis fungoides ([308]). The lymphoma may extend through the bowel wall, resulting in perforation. Regional lymph nodes are often involved. Tumor cells are usually intermediate to large in size with oval to pleomorphic nuclei. There is generally abundant clear to eosinophilic cytoplasm, and azurophilic cytoplasmic granules are occasionally observed on touch imprints of the tumor ([308], [309] and [310]). Mitotic activity is usually brisk. The phenotype is variable but is often CD2 $^{+}$, CD3 $^{+}$, CD4 $^{-}$, CD5 $^{-}$, CD7 $^{+}$, CD8 $^{-/+}$, TCRa/ß positive, and TCR?/d negative. Some cases may be CD30 $^{+}$ and must be distinguished from ALCL. NK-cell–associated antigen expression, such as CD56, has been described ([309], [310]). Many cases demonstrate TCR ß-chain gene rearrangements. Comparative genomic hybridization has shown chromosomal imbalances in 87% of enteropathy-type T-cell lymphoma with gains at chromosome 9q being the most frequent, by far ([311]).

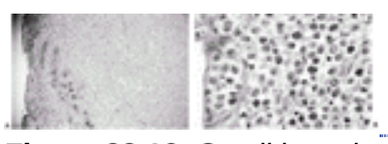

Figure 88.13. Small intestine: enteropathy-type T-cell lymphoma. **A:** The small intestinal features are markedly distorted by a lymphomatous infiltrate. There is also loss of the villous pattern at the luminal surface *(left)*. **B:** Pleomorphic tumor cells with clear cytoplasm fill the mucosa and replace the glandular epithelium. See Color Plate.

Extranodal Natural Killer/T-Cell Lymphoma, Nasal Type

Nasal NK/T-cell lymphomas occur in the nasopharyngeal or sinonasal areas and include cases with morphologic features described previously as *polymorphic reticulosis* and *lethal midline granuloma*. These lymphomas are often angiocentric, angioinvasive, and angiodestructive lesions composed of a polymorphic infiltrate of small lymphocytes and immunoblasts with significant cytologic atypia ([312], [313]). The lymphoid infiltrate often occludes vessels producing areas of ischemic necrosis. The clinical course is typically aggressive. These lymphomas are observed most frequently in east Asia and are rare in the United States and Europe. Any age group can be affected.

Recent studies have shown these lymphomas are true NK-cell lymphomas or cytotoxic PTCL. Most cases express NK-cell–associated antigens, particularly CD56, and some contain azurophilic cytoplasmic granules on Romanowsky-type–stained smears or cytotoxic granule-associated proteins recognized by immunohistochemistry ([312], [313], [314] and [315]). The true NK-cell lymphomas lack TCR gene rearrangements, whereas the few well-defined T-cell cases demonstrate TCR gene rearrangements or transcripts ([312], [313], [314] and [315]). Most of these lymphomas are EBV associated ([313], [315] and [316]).

Nonnasal NK/T-cell lymphomas may be called *extranodal NK- and T-cell lymphomas, nasal type*, because they share many of the features of the more commonly occurring NK/T-cell lymphomas in the nasal region ([317]). Skin, soft tissue, gastrointestinal tract, and testis are the most frequent nonnasal extranodal sites involved by NK/T-cell lymphomas. Some cutaneous and subcutaneous NK/T-cell lymphomas may represent secondary spread from nasal NK/T-cell lymphomas. Cutaneous cases are generally true NK-cell lymphomas ([318], [319], [320] and [321]). Most express CD56, and azurophilic cytoplasmic granules are often present. There is also a high degree of association with EBV, particularly those of apparent, true NK-cell origin ([322]).

NATURAL KILLER–CELL LYMPHOMAS

True NK-cell lymphomas are typically CD56 $^{+}$ and express some T-cell antigens, including cytoplasmic CD3, the latter due to the presence of truncated CD3e in the cytoplasm ([323]). NK-cell lymphomas lack surface CD3 and a/ß and ?/d chains of the TCR and do not rearrange their TCR genes ([323]). NK-cell lymphomas are rare outside east Asia. Many are found in the nasal region or skin, as discussed previously. A few NK-cell neoplasms present as lymphoblastic lymphomas, as mentioned previously. Rare NK-cell neoplasms present as an aggressive nonlymphoblastic leukemia/lymphoma that often involve young adult men ([324], [325]). These patients generally have fever, moderate hepatosplenomegaly, variable lymphadenopathy, and pancytopenia that may precede the overt leukemic phase. The tumor cells are atypical large lymphocytes with azurophilic cytoplasmic granules on Romanowsky-type–stained touch imprints or smears of the tumor.

Molecular Aspects of Non-Hodgkin Lymphomagenesis

The non-Hodgkin lymphomas (NHLs) are a diverse collection of lymphoid malignancies with varied pathology, cell of origin, natural history, and response to treatment. The diversity of the NHLs is reflected by the numerous subtypes and classifications ([1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12] and [13]), based primarily on morphology and immunophenotype, that have appeared over the years to describe them and that are discussed in detail in Chapter 88. The histologic diagnosis of NHL is among the most difficult tasks that surgical pathologists are asked to undertake; although the diagnosis of NHL compared to other malignancies is accurate in roughly 90% of cases, consensus among pathologists regarding the identification of specific histologic subtypes occurs only slightly more than one-half of the time ([14], [15], [16], [17] and [18]). Despite their shortcomings, the morphologic and immunophenotypic classifications of NHL have been invaluable in providing the basis for our current approach to the therapeutic management of these malignancies by providing a framework to subdivide the disease into clinically meaningful subgroups. Refinements in these classification schemes are constantly ongoing as additional parameters are identified and are shown to permit the detection of subgroups that possess unique biologic features or that have a specific response to traditional therapies or are amenable to more directed forms of treatment, or both.

One set of features that are candidates for incorporation into NHL classification systems are the molecular genetic lesions that appear to be of pathogenic importance in selected forms of NHL. Progress in this area has come about over the past 20 years with the molecular analysis of structural chromosomal abnormalities, including translocations, deletions, inversions, amplifications, and base pair mutations, which alter critical genes that normally regulate growth or differentiation (oncogenes and tumor suppressor genes, or antioncogenes), or both ([19], [20], [21], [22], [23], [24] and [25]). With the currently available molecular methods, genetic abnormalities of various types can be identified in essentially all cases of NHL. The analysis of the genetic lesions present in NHL has tended to be in the vanguard of such studies in malignant diseases; indeed, the realization that characteristic chromosomal translocations, or rearrangements, tend to occur in specific types of lymphomas, consistently altering the function of a particular gene or subset of genes, provided the initial impetus for the analysis of such abnormalities in other tumors. For example, Burkitt lymphoma was the first human tumor in which a chromosomal translocation was demonstrated by molecular analysis to be involved in its pathogenesis ([26], [27], [28] and [29]). Although the possibility of therapies aimed at malignancy-specific genetic lesions in NHL remains to be realized in the clinical setting, this issue promises to change significantly over the next decade with the current emphasis on the development of targeted therapeutic approaches for cancer ([30], [31]).

The identification of the genes involved in the pathogenesis of NHL has already had the practical benefit of allowing development of highly specific and sensitive molecular assays to detect these genetic “tags.” These assays can often resolve diagnostic ambiguities brought about by the more traditional classification methods and can be used to follow therapeutic responses, as well as for the early detection of recurrence ([32], [33]). In some instances, as described later in the chapter, the presence of specific genetic abnormalities may be of prognostic importance also. From a basic science standpoint, the isolation of lymphoma-associated and other oncogenic genes has led to the identification of proteins that not only promote the development of cancer, but that also have essential roles in normal cellular growth and development as well. The use of gene targeting methods in embryonic stem cells to create animals in which a specific gene is homozygously inactivated (e.g., knockout mice) ([34], [35]), as well as other gene inactivation techniques, such as RNA interference ([36], [37]), now allows investigators to unequivocally determine the essential functional roles that the gene plays.

A brief background regarding the mechanisms and consequences of malignancy-related chromosomal rearrangement and of normal lymphocyte development, with emphasis on the physiologic DNA rearrangements that assemble the antigen-specific immunoglobulin (Ig) and T-cell receptor (TCR) genes in B and T cells, is required before the discussion of individual genetic abnormalities in NHL. Two distinct consequences have been found to occur as a result of malignancy-related chromosomal translocations. In many cases, translocations have been shown to fuse sequences from one chromosome (often encoding a transcription factor, or a receptor or cytoplasmic tyrosine kinase) to those of a normally unrelated gene present on the other chromosome, producing a chimeric gene and a protein that possesses oncogenic capabilities. The other common mechanism by which these translocations deregulate gene function is by the relocation of the gene to the vicinity of highly active promoters or enhancers from other chromosomes (often within the Ig or TCR gene loci) that drive the expression, in an abnormal cell type or an abnormal amount, or both, of an otherwise unaltered gene product. Because the chimeric genes are unique to the cancer cells that contain them, diagnostic assays, such as fluorescence *in situ* hybridization (FISH) or RNA polymerase chain reaction (PCR), can specifically detect cases of a given translocation-containing tumor type ([38], [39], [40] and [41]). In those instances in which the expression of an otherwise unaltered gene is activated, the presence of the gene's transcripts or its encoded protein within cells that do not normally express the gene is often also helpful in making or confirming a suggested diagnosis ([33]).

Lymphocytes arise in the developing liver and bone marrow from a pluripotent hematopoietic stem cell, with early T-cell differentiation occurring in the thymus and early B cells undergoing differentiation within the bone marrow ([42], [43] and [44]). Normal lymphoid cell populations undergo diverse, clonal rearrangements of their Ig or TCR antigen receptor genes during this developmental process to generate B cells and T cells with the specificities required to support a fully competent immune system ([45], [46] and [47]). Lymphomas arise from a single progenitor lymphoid cell that has undergone genetic damage that results in deregulated growth and clonal expansion, together with arrested differentiation at a discrete stage of development. Nevertheless, malignant lymphoid cells share many features with their normal counterparts, including Ig or TCR gene rearrangement ([48], [49] and [50]); indeed, the unicellular development of lymphoma cell populations can be demonstrated by the presence of uniform rearrangements of these genes, as compared to the heterogeneous pattern of rearrangements found in populations of normal T and B cells ([51], [52], [53], [54], [55], [56], [57] and [58]).

A major advance in the characterization of the genetic abnormalities important in lymphomagenesis (and lymphoid leukemogenesis as well) was the realization that the Ig and TCR genes are common sites of illegitimate interchromosomal translocation. As mentioned, in the normal sequence of events, B and T cells rearrange their Ig or TCR gene subsegments to generate lymphoid cells with antigenic specificity ([47]). The Ig and the TCR genes are organized as discontinuous DNA segments in their embryonic or germline form that are assembled in this physiologic rearrangement process during lymphoid development. An initial sign of B-lineage commitment is the rearrangement of the Ig heavy chain locus at chromosome 14, band q32, which begins with the approximation of one of the more than 20 D_H (diversity) segments with one of the six alternative J_H (joining) segments to create a D_H/J_H region. Subsequently, the DJ segment on one allele is approximated with one of, potentially, several hundred V_H (variable) segments to create a functional VDJ segment, which joins the C_H (constant) portion of the molecule to generate the Ig heavy chain protein. Inserted extra nucleotides, called N sequences, are frequently found at the site of each junction and contribute to diversity, because they are located at the site at which the antibody molecule contacts antigen. Furthermore, a “somatic hypermutation” mechanism is activated at later stages of lymphoid development that alters selected VDJ sequences to improve antigen-binding affinity ([59], [60], [61] and [62]). Just as the physiologic process of Ig and TCR gene rearrangement can be subverted in malignancy, somatic hypermutation can also occur abnormally, resulting in the mutation of genes possessing oncogenic potential, such as BCL6 and cMYC, among others ([59], [60], [61] and [62]). The successful production of the μ-chain in the cytoplasm as a result of the rearrangement of the Ig heavy chain gene defines the so-called pre–B cell. Only if these rearrangements on the first chromosome are unsuccessful is the second allele rearranged beyond the DJ stage. Failure of this rearrangement sequence on the first allele can be of pathologic significance with regard to the development of lymphoid neoplasms. In the case of the t(14;18), as an example, instead of correctly recombining D and J segments of the Ig heavy chain locus, a broken BCL2 gene from 18q21 is introduced into these sites.

On successful rearrangement of one of the two heavy chain loci, ?–light chain gene rearrangement proceeds on chromosome 2p12. If ? gene rearrangement is unsuccessful, the ? gene on chromosome 22q11 alternatively rearranges. Illegitimate recombination of either of these gene loci with oncogenic genes can also occur

in malignancy, as noted later with the examples of the small noncleaved cell lymphomas that contain the t(2;8)(p12;q24) or the t(8;22)(q24;q11) that activate cMYC and the large-cell lymphomas containing the t(2;3)(p12;q27) or t(3;22)(q27;q11) that result in the expression of BCL6. Once functional light chains are produced, they associate by disulfide linkages to the µ heavy chain, producing a complete Ig molecule that is expressed on the cell surface. The expression of surface Ig is the hallmark of the mature B cell. The final antibody molecule is composed of two identical heavy chains that are disulfide-linked to two identical light chains. The amino-terminal variable portions of each chain possess the antigen recognition sites, whereas the carboxy-terminal constant portion is invariant in sequence and performs effector functions. The earliest recognizable B cells display only surface IgM. Subsequently, an alternative splicing mechanism places the Cµ or Cd constant heavy chain region adjacent to the same unique VDJ region, and cells express IgM and IgD simultaneously. Heavy chain class switching may then occur, in which other C_H segments (?, e, or a) are placed next to the VDJ segment, enabling the same antigen specificity to be associated with the different physiologic functions of an IgG, IgE, or IgA molecule.

Like the Ig gene loci, the genes encoding the a, ß, ?, and d TCR chains have been cloned and characterized ([47]). These genes are evolutionarily related but distinct from the Ig genes, and they likewise undergo rearrangement of their V, D, and J regions to assemble the mature TCRs expressed at the T-cell surface that demonstrate antigen-specific recognition. The ß and ? TCR genes are located on chromosomes 7q34 and 7p15, respectively, whereas the d TCR gene is located within the a TCR locus on chromosome 14q11. As with the Ig loci, illegitimate recombination of the TCR gene loci with genes normally important for the control of growth or development, or both, can lead to the transformation of lymphoid cells, as described in the following discussion in the case of the multiple translocations characteristically found in the lymphoblastic lymphomas. Thus, a pragmatic benefit of the cloning of the Ig and TCR gene loci was the resultant availability of DNA probes that permitted the relatively easy identification of these oncogenic genes.

In the sections that follow, the molecular consequences of the most frequently occurring chromosomal rearrangements in the NHLs are described, grouped under the histopathologic subtype with which each is solely, or primarily, associated (Fig. 89.1). An additional section describes genes that are aberrantly expressed owing to chromosomal rearrangements in multiple NHL subtypes, rather than being associated typically with only one specific form. Other oncogenically important, but less common, chromosomal rearrangements in the NHLs that have been characterized molecularly are described briefly in Table 89.1 and Table 89.2. Last, the usefulness of recently developed microarray technologies for determination of the global gene expression profile of NHL subtypes is detailed.

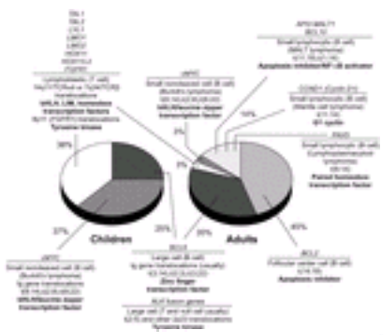

Figure 89.1. Molecular genetic aspects of non-Hodgkin lymphoma (NHL)–associated chromosomal translocations. The genes altered by the more commonly occurring chromosomal translocations in NHL are shown in italics, together with the lymphoma subtype in which they have pathogenic significance. The functional family to which each gene belongs is indicated in bold face. The percentages shown indicate the approximate representation of each histologic NHL subtype occurring in children or adults. The genes shown in this figure occur in a significant portion of (but not all) cases within each associated subtype. bHLH, basic helix-loop-helix; Ig, immunoglobulin.

TABLE 89.1. Genes Involved in B-Cell Oncogenesis via Chromosomal Translocations

Cytogenetic Abnormality [a]	Disease (Predominant Subtypes)	Involved or Presumed Target Genes (Aliases)	Presumed Function of Target Genes
t(1;14)(p22;q32)	Mucosa-associated lymphoid tissue lymphoma	*BCL10* (mE10, *CIPER, CARMEN*, *CLAP*)	Antigen receptor-induced NF-?B activation
t(1;14)(q21;q32)	B-cell precursor acute lymphoblastic leukemia, B-NHL	*BCL9*	Required for Wnt signal transduction at the level of nuclear ß-catenin
t(1;14)(q21;q32)	Myeloma, also BL with dup(1q)	*IRTA1/2*	Immunoglobulin receptor superfamily
t(1;14)(q21;q32)	DLBCL	*MUC1* (*EMA*, *CD227*, *PEM*, *PEMT*, *H23AG*, *PUM*)	Mucin (episialin); cell surface transmembrane glycoprotein
		MDC15 (ADAM15)	Metalloproteinase-like disintegrin-like and cysteine-rich protein
t(1;22)(q21;q11)	Transformed follicular B-NHL	*FCGR2B* (*CD32B*)	Low-affinity Fc ? receptor IIB; immunoreceptor tyrosine-based inhibition motif–containing receptor for the Fc domain of immunoglobulin G; binds immunoglobulin G immune complexes; member of the immunoglobulin superfamily
t(2;7) (p12;q21)	SLVL	*CDK6* (*PLSTIRE*)	Cyclin-dependent protein kinase 6; interacts with D-type cyclins and phosphorylates Rb in G_1 phase
t(2;14)(p13;q32)	B-CLL, immunocytoma, DLBL	*BCL11A* (*EV19*)	Zinc finger transcriptional repressor
t(3;14)(q27;q32)	DLBCL and others	*BCL6* (*BCL5, LAZ3*)	Zinc finger transcriptional repressor
t(4;14)(p16;q32)	Myeloma	*FGFR3* (*CEK2*, *JTK4*)	Fibroblast growth factor receptor 3; receptor tyrosine kinase that binds acidic and basic fibroblast growth factor; preferentially binds acidic fibroblast growth factor
		MMSET (*WHSC1*)	Wolf-Hirschhorn syndrome candidate 1; contains a SET domain, an HMG box and PHD fingers
t(5;14)(q31;q32)	B-cell precursor acute lymphoblastic leukemia	*IL3* (*MCGF*)	Interleukin-3 (colony-stimulating factor); hematopoietic growth factor
t(6;14)(p25;q32)	Myeloma	*IRF4* (*NF-EM5*, *MUM1*, *LSIRF*)	Interferon regulatory factor-4; transcription factor that stimulates B-cell proliferation
t(6;14)(p21;q32)	DLBCL, myeloma, SLVL, marginal zone lymphoma	*CCND3*	Cyclin D3, essential for control of the cell cycle at the G_1–S phase (start) transition; interacts with the CDC2 protein kinase
t(8;14)(q24;q32)	BL, DLBCL, B-cell prolymphocytic leukemia, myeloma	*cMYC*	basic helix-loop-helix–zip transcription factor; activates or represses expression of multiple target genes
t(9;14)(p13;q32)	Lymphoplasmacytoid lymphoma, myeloma	*PAX5* (*BSAP*)	Paired box 5; B-cell lineage-specific activator protein, transcription factor
t(10;14)(q24;q32)	DLBCL	*NFKB2* (*LYT10*, *H2TF1*)	49-kd DNA-binding subunit (p52/p100) of heterodimeric NF-?B transcription factor; complex regulates the expression of inflammatory and immune genes
t(11;14)(q13;q32)	Mantle cell lymphoma, B-cell prolymphocytic leukemia, SLVL, myeloma	*CCND1* (*BCL1*, *PRAD1*)	Cyclin D1; essential for control of the cell cycle at the G_1–S phase (start) transition; interacts with the CDK4 and CDK6 protein kinases
t(11;14)(q23;q32)	Mediastinal B-NHL	*PAFAH*a *2*	Platelet-activation factor acetylhydrolase
t(11;14)(q23;q32)	DLBCL	*RCK* (*HLR2*, *p54*, *DEAD/H BOX 6*)	DEAD/H box adenosine triphosphate–dependent RNA helicase

t(11;18)(q21;q21)	Mucosa-associated lymphoid tissue lymphoma	*API2* (*cIAP2*, *HIAP1*, *MIHC*) from 11q21; *MALT1* (*MLT*, *hParacaspase*) from 18q21	API2—apoptosis inhibitor, MALT1—unclear, but possibly regulation of NF-?B activation; possesses homology with caspases
t(12;14)(q23;q32)	DLBCL, B-CLL	*C4ST-1*	Chondroitin-4-O-sulfotransferase 1
t(12;14)(q24:q32)	BL, myeloma	*BCL7A*	Unknown; shares homology with actin-binding protein caldesmon
t(12;15)(q32;q11-13)	DLBCL	*BCL8* (*BCL8A*)	Unknown; related BCL8B protein shares extensive homology to the RG *Drosophila* protein kinase A anchoring protein
t(12;22)(p13;q11)	B-CLL	*CCND2*	Cyclin D2; essential for control of the cell cycle at the G_1–S phase (start) transition; interacts with the CDC2 protein kinase
t(14;16)(q32;q23)	Myeloma	*MAF*	Transcription factor; contains a leucine zipper motif
t(14;18)(q32;q21)	Follicular lymphoma, DLBCL	BCL2	Apoptosis inhibitor
t(14;19)(q32;q13)	B-CLL	*BCL3* (*BCL4*)	Transcriptional activating factor subunit-specific inhibitor of the transcription factor NF-?B; contains seven tandem copies of the SWI6/cdd10 motif
t(14;20)(q32;q11)	Myeloma	*MAFB* (*KRML*)	Transcription factor; contains a leucine zipper motif

B-CLL, B-cell chronic lymphocytic leukemia; BL, Burkitt lymphoma; B-NHL, B-cell non-Hodgkin lymphoma; DLBCL, diffuse large B-cell lymphoma; NF-?B, nuclear factor-?B; SLVL, splenic lymphoma with villous lymphocytes.

NOTE: The information displayed in this table focuses on genes involved in the pathogenesis of the non-Hodgkin lymphomas; however, genes that are recurrently involved in the genesis of selected other B- or T-cell lymphoid malignancies are also shown.

[a] Variant translocations affecting other immunoglobulin or T-cell receptor, or nonimmunoglobulin or non–T-cell receptor loci than the one shown do occur less commonly for many of the translocations.

Functional data were obtained from the SOURCE database (http://genome-www4.stanford.edu/cgi-bin/SMD/source/sourceSearch), as available.

TABLE 89.2. Genes Involved in T-Cell Oncogenesis via Chromosomal Translocations

Cytogenetic Abnormality [a]	Disease (Predominant Subtypes)	Involved or Presumed Target Genes (Aliases)	Presumed Function of Target Genes
t(1;7)(p34;q34)	Lymphoblastic lymphoma	*LCK* (*p56-LCK*, *LSK*)	Cytoplasmic tyrosine kinase; participates in antigen-induced T-cell activation; bound to cytoplasmic domains of either CD4 or CD8
t(1;14)(p32;q11)	Lymphoblastic lymphoma	*TAL1* (*SCL*, *TCL5*)	bHLH DNA-binding transcription factor
t(2;5)(p23;q35)	Anaplastic large cell lymphoma	*NPM-ALK*	Anaplastic lymphoma kinase; receptor tyrosine kinase that binds the ligands pleiotrophin and midkine
t(5;14)(q35;q32)	Lymphoblastic lymphoma	*HOX11L2* (*RNX*, *TLX-3*)	Homeodomain transcription factor
t(7;9)(q34;q34.3)	Lymphoblastic lymphoma	*NOTCH1* (*TAN1*)	Transmembrane protein that functions as receptor for membrane-bound ligands Jagged1, Jagged2, and Delta1; intracellular domain is proteolytically released on ligand binding, translocates to nucleus, and acts as a transcriptional activator
t(7;9)(q35;q34)	Lymphoblastic lymphoma	*TAL2*	bHLH DNA-binding transcription factor
t(7;19)(q35;p13)	Lymphoblastic lymphoma	*LYL1*	bHLH DNA-binding transcription factor
t(8;13)(p11;q12)	Lymphoblastic lymphoma	*FGFR1* (*bFGFR*, *CEK*, *FLT2*)	Fibroblast growth factor receptor 1; receptor tyrosine kinase that binds basic fibroblast growth factor
t(8;14)(q24;q11)	Lymphoblastic lymphoma	*cMYC*	bHLH-zip transcription factor; activates or represses expression of multiple target genes
t(10;14)(q24;q11)	Lymphoblastic lymphoma	*HOX11* (*TCL3*, *TLX-1*)	Homeodomain transcription factor
t(11;14)(p13;q11)	Lymphoblastic lymphoma	*LMO2* (*RBTN2*, *TTG2*)	LIM-only protein 2; cysteine-rich LIM domain transcriptional regulator
t(11;14)(p15;q11)	Lymphoblastic lymphoma	*LMO1* (*RBTN1*, *TTG1*)	LIM-only protein 1; cysteine-rich LIM domain transcriptional regulator
t(14;14)(q11;q32.1)	T-cell chronic lymphocytic leukemia, T-cell prolymphocytic leukemia/lymphoma	*TCL1*	AKT kinase coactivator
t(X;14)(q28;q11)	T-cell chronic lymphocytic leukemia, T-cell prolymphocytic leukemia/lymphoma	*MTCP-1* (*C6.1B*)	AKT kinase coactivator

bHLH, basic helix-loop-helix.

NOTE: The information displayed in this table focuses on genes involved in the pathogenesis of the non-Hodgkin lymphomas; however, genes that are recurrently involved in the genesis of selected other B- or T-cell lymphoid malignancies are also shown.

[a] Variant translocations affecting other immunoglobulin or T-cell receptor, or nonimmunoglobulin or non–T-cell receptor loci than the one shown do occur less commonly for many of the translocations.

Functional data were obtained from the SOURCE database (http://genome-www4.stanford.edu/cgi-bin/SMD/source/sourceSearch), as available.

SMALL NONCLEAVED CELL LYMPHOMA (BURKITT): cMYC

There are two types of lymphomas within the small noncleaved cell category: the Burkitt and the non-Burkitt types ([63], [64], [65], [66], [67], [68], [69], [70], [71], [72], [73] and [74]). The non-Burkitt lymphomas have a similar overall survival and response to therapy as the Burkitt type. In addition, the non-Burkitt and Burkitt lymphomas share essentially identical histologic features, with only subtle differences distinguishing the two, and both express mature B-cell surface markers. Despite their close similarities, the molecular pathogenesis of the Burkitt and non-Burkitt lymphomas is different in that the chromosomal abnormalities found in the Burkitt type that affect the *cMYC* gene are not usually considered a feature of non-Burkitt small noncleaved cell cases. In some cases, the non-Burkitt lymphomas contain the t(14;18) rearrangement that activates the expression of BCL2, whereas, in many, the molecular pathogenetic lesions remain to be defined ([70], [75], [76]).

The Burkitt-type lymphomas themselves classically comprise two subtypes: the endemic form that occurs primarily in Africa and the sporadic form that occurs throughout the world ([77], [78]). These two forms differ in terms of the frequency of their association with Epstein-Barr virus (EBV) infection and with regard to selected molecular aspects of the involvement of the cMYC gene in their pathogenesis (*vide infra*). Both of these forms affect men more often than women (with a male to female ratio of 2 to 3:1). The endemic form typically affects children between 5 and 10 years of age and usually presents with involvement of the maxilla and mandible, with abdominal and other extranodal sites also common, whereas the sporadic form occurs mainly in the adolescent and young adult age groups and usually presents as abdominal disease. These tumors, which are responsive to chemotherapy, have the highest growth rate of all lymphomas. Some 2 to 5% of patients with acute lymphoblastic leukemia have a FAB L3 morphology, with cells that contain the typical Burkitt chromosomal translocations involving cMYC and that are thought to represent Burkitt lymphoma in leukemic phase ([77]). In addition to the two originally described classical subtypes of Burkitt-type lymphomas, it has more

recently become evident that Burkitt lymphoma is also common in human immunodeficiency virus (HIV)–infected individuals ([70], [79]).

In endemic African Burkitt lymphoma, approximately 95% of tumors contain clonal EBV DNA, whereas only some 20% of tumors in the United States and Europe are EBV associated ([70], [78], [80], [81], [82] and [83]). Likewise, only a subset (approximately 40%) of HIV-associated Burkitt lymphomas are EBV associated ([70], [79]). The exact contributions of the EBV genome to the development of these lymphomas are not yet clear, but it is well known that EBV is capable of immortalizing B lymphocytes (and pre–B cells) as cell lines that proliferate indefinitely *in vitro* ([77]). The identification of clonal EBV genomes in Burkitt lymphomas indicates that EBV cell infection and immortalization is an early event that occurs before the development of frank malignant transformation, not after development of the transformed clone ([84]). Presumably, the activity of several specific EBV genome-encoded proteins expressed during acute infection is necessary for polyclonal lymphoproliferation, which is followed by the establishment of a monoclonal tumor population once the cMYC gene is activated ([70], [77]). The latent pattern of EBV-associated gene expression observed in established Burkitt lymphomas, which is more restricted than the expression pattern observed in acute infections that lead to polyclonal "lymphoblastoid" proliferation, is accompanied by the down-regulation of adhesion molecules, such as LFA-3 and intercellular adhesion molecule 1, HLA class I molecules, and immunogenic EBV proteins (e.g., Epstein-Barr nuclear antigen 2 and latent membrane protein 1), suggesting that EBV infection may facilitate escape of the lymphomas from normal immune surveillance mechanisms ([83]). Furthermore, Epstein-Barr nuclear antigen 1, which is one of the few EBV genes that continues to be expressed in established Burkitt tumors has been shown to induce B-cell lymphomas in transgenic mice ([85]), and the latently expressed Epstein-Barr–encoded RNA 1 and Epstein-Barr–encoded RNA 2, a pair of small EBV-specific RNA transcripts, exhibit oncogenic potential in cell lines experimentally ([86], [87]). Thus, an integrated model (which is yet unequivocally proven) of the role of EBV in the pathogenesis of Burkitt lymphoma supposes that the "lymphoblastoid" pattern of EBV gene expression initially drives a polyclonal B-cell expansion and that, on the stochastic acquisition of cMYC rearrangement and expression, a nascent tumor cell clone converts to the latent EBV gene expression pattern, which possibly enables escape from immune surveillance and helps sustain the fully transformed state. The EBV genome is also present in a high percentage of lymphomas associated with congenital (e.g., Wiskott-Aldrich syndrome and X-linked lymphoproliferative syndrome) or acquired [e.g., posttransplant immunosuppression and some acquired immunodeficiency syndrome (AIDS) patients] immunodeficiency states ([77], [79], [81], [88], [89], [90], [91], [92], [93], [94], [95], [96], [97], [98] and [99]), in which the impaired immune surveillance permits the expansion of an EBV-immortalized polyclonal lymphoid cell population. A more complete discussion of the role of EBV in lymphomagenesis, including in the congenital or acquired immunodeficiency diseases that predispose to NHL, and of other viruses associated with the development of NHL, is found in Chapter 67, Chapter 68 and Chapter 69.

Roughly 80% of the Burkitt lymphomas contain a t(8;14)(q24;q32) rearrangement in which translocation of one allele of the prototypic basic helix-loop-helix (bHLH)–leucine zipper transcription factor gene cMYC, normally on chromosome 8, occurs into the Ig heavy chain locus on chromosome 14, adjacent to the coding sequences of the Ig constant region ([28], [29], [70], [100], [101]). The remaining cases have a t(2;8)(p12;q24) (found in 15% of cases) or a t(8;22)(q24;q11) (5% of cases) involving cMYC and the ? or ? Ig light chain loci on chromosome 2 or 22, respectively ([102], [103], [104], [105], [106], [107] and [108]). In these two rearrangements, the cMYC gene remains on chromosome 8, and the involved light chain gene is translocated downstream of the cMYC locus. In spite of the large variation in their positions, the breakpoints on chromosome 8 in these translocations never disrupt the coding regions of the cMYC protein. Differences in the chromosome 8 breakpoint location have been noticed between endemic and sporadic Burkitt tumors ([77], [109]). The majority of endemic tumors possess breakpoints far upstream (with a smaller number far downstream) of cMYC, whereas sporadic tumors almost always have breakpoints within or close to the cMYC locus. In all instances of translocation, cMYC transcription is deregulated as a result of the juxtaposition of the locus with strong Ig gene enhancers, producing constitutive high-level expression. Because the positions of the chromosomal breakpoints in cMYC and the various Ig genes are widely dispersed, it has been difficult to design PCR-based tests to detect cMYC-Ig genes; as a result, these cMYC translocations are reliably identified only by karyotyping of metaphase chromosomes or FISH, which can be performed on metaphase chromosomes or interphase nuclei ([110]). Minimal information is available regarding the mechanisms underlying the chromosomal breaks in cMYC; for example, the breakpoints in the gene locus bear no significant homology to V(D)J or switch recombinase recognition sequences, suggesting that the breaks are not likely dependent on these activities. Interestingly, mice with genetic defects that impair the repair of double-strand DNA breaks develop pro–B-cell tumors with high frequency, all of which have chromosomal translocation involving cMyc and IgH ([111]), but the relevance of this observation to the mechanism of cMYC translocations in human Burkitt lymphomas remains to be determined.

It also appears that, in most, if not all, tumors, regardless of breakpoint location, mutations of the cMYC locus occur coincident with the translocations that can alter the transcription or other functional aspects of the gene, resulting in its deregulation ([109], [112], [113] and [114]). For example, point mutations near the 3' end of the first exon of cMYC (the gene consists of three exons, the first being noncoding, with the coding sequences present in exons 2 and 3) have been described that prevent the binding of a factor involved in suppressing the elongation of cMYC transcripts ([115]), whereas other mutations have been reported to impair the binding and suppression of the cMYC transcriptional activation domain by the Rb-related protein p107 ([116]). Another example of this mutational process occurs within exon 2 of the gene, in which amino acid substitutions that stabilize the cMYC protein occur ([117], [118]), thus increasing its cellular concentration and functional effects. One important amino acid in this regard is threonine 58, a site that normally targets the protein for proteasome-mediated degradation when phosphorylated ([119], [120]). The origin of these mutations is thought to be a consequence of the juxtaposition of the locus to Ig sequences and the exposure to the somatic mutation process that normally occurs in the variable (V) regions to contribute to diversification of the antibody response (so-called somatic hypermutation) ([59], [60], [61] and [62]).

Numerous studies have confirmed that cMYC is a transcription factor that promotes cell cycle progression and cell transformation, and inhibits differentiation ([121], [122], [123] and [124]). For example, enforced expression of cMYC in growth factor–deprived cells is sufficient to overcome cell cycle arrest and push cells into S phase ([125], [126] and [127]). Ablation of cMYC in cells using antisense oligonucleotides or expression constructs blocks entry into S phase, further indicating that cMYC function is essential for cell cycle progression ([128], [129] and [130]). *In vitro*, the pathogenesis of Burkitt lymphoma has been experimentally reproduced by demonstrating the tumorigenic conversion of EBV-infected B lymphoblasts on introduction of an activated cMYC gene into the cells ([131]). Enforced cMYC expression promotes *in vivo* transformation, as evidenced by the development of lymphomas in mice bearing the gene driven by an Ig gene enhancer ([132], [133]). In this animal model of Burkitt lymphoma, mice initially develop a polyclonal pre–B-cell hyperplasia that progresses within a short period of time to monoclonal malignancies. The time course of tumor development suggests that cMYC overexpression alone is insufficient to produce transformation, requiring cooperating genetic abnormalities for the development of a full-fledged malignancy. A number of genes that cooperate with cMYC to enhance tumorigenesis have been identified, including BCL2, PIM-1, RAS, ABL, BMI-1, and RAF-1 ([70], [121]).

The exact mechanism by which cMYC acts to promote cellular transformation is not yet clear but is thought to involve the transcriptional regulation of relevant target genes. It is known that cMYC alone or as a homodimer does not efficiently exhibit sequence-specific DNA binding. Rather, the protein exists in cells as a heterodimer with another bHLH-leucine zipper protein called *MAX*; cMYC/MAX heterodimers exhibit efficient sequence-specific DNA binding and tend to activate gene transcription ([134], [135] and [136]). However, MAX can also heterodimerize with a number of other related bHLH-leucine zipper proteins including MAD ([137]), MXI-1 (MAD2) ([138], [139] and [140]), and MNT ([141]). MAX/MAX, MAX/MAD, and MAX/MXI-1 dimers repress transcription while retaining the ability to bind to the DNA sequences also bound by cMYC/MAX heterodimers. Thus, it is generally accepted that cells contain cMYC/MAX heterodimers and MAX/MAX homodimers (as well as the aforementioned MAX/MAD and MAX/MXI-1 heterodimers) that compete for binding to similar gene target sequences and activate or inhibit transcription, respectively ([134], [135], [138], [142]). Because the cMYC messenger RNA (mRNA) and protein are short lived, and MAX is relatively stable and abundant, the level of cMYC/MAX heterodimer largely depends on the cMYC concentration in the cell. Factors that result in the increased production of cMYC (like the chromosomal translocations characteristic of Burkitt lymphoma) are thought to favor the formation of cMYC/MAX complexes and the transactivation of a set of genes essential for the progression through the G_1 phase of the cell cycle ([143]). Overexpression of cMYC also effectively decreases the heterodimerization of MAX with its other dimerization partners, such as MAD and MXI1, the expression of which is associated with cellular differentiation ([137], [139], [144], [145]). This currently accepted model of cMYC regulation (and deregulation in cancer) would predict that underproduction of inhibitory bHLH-leucine zipper proteins might also produce consequences similar to cMYC up-regulation; support for this hypothesis is provided by the phenotype of Mxi-1 knockout mice, which have an increased susceptibility to the development of lymphoma ([140]).

Transcriptional activation of genes by cMYC/MAX heterodimers, like many oncogenic transcription factors, in part involves changes in the balance of histone acetylation and deacetylation, thereby altering chromatin structure ([146], [147], [148] and [149]). For example, MAD, MXI-1 and MNT all interact with a transcriptional repressor complex that possesses histone deacetylase (HDAC) activity; increased recruitment of this complex to promoter elements correlates with HDAC-dependent silencing of transcription and cellular growth arrest plus enhanced differentiation ([138], [141], [150], [151], [152] and [153]). By contrast, cMYC interacts with the transactivation-transformation domain-associated protein (TRRAP), which recruits GCN5, a known histone acetyltransferase, providing part of the explanation for transcriptional activation by cMYC/MAX heterodimers ([154], [155], [156] and [157]). The binding of TRRAP correlates with the oncogenic ability of cMYC, pointing out the critical importance of histone acetylase activity and alterations of chromatin structure in the cellular transformation process. This importance is also borne out by the current preclinical and clinical efforts to regulate oncogenic gene expression by alteration of chromatin structure using various compounds (e.g., HDAC inhibitors) that may have therapeutic potential ([158]). Additional modulation of transcriptional control by cMYC occurs through interactions of the protein with multiple other proteins.

For example, in addition to TRRAP, the N-terminus of cMYC interacts with p107, Bin1, MM1, PAM, and AMY1, and many of these interactions appear to be mediated throughout the functionally crucial “MYC box” sequences (MB1 and MB2) within the N-terminal cMYC transcriptional activation domain ([122], [159]). Likewise, the C-terminal portion of cMYC also interacts with a host of proteins implicated in the regulation of transcription, such as YY1, AP2, BRCA1, TFII-I, and MIZ1 ([122], [159]). The significance of these cMYC-interacting proteins in the cellular transformation process is a matter of ongoing study.

cMYC expression and its deregulation influence multiple cellular processes, including cell cycle progression, differentiation, metabolism, apoptosis, immortalization, and adhesion. For example, with respect to the cell cycle, analysis of cMyc-null fibroblasts has revealed a 12-fold reduction in the expression of cell cycle–promoting cyclin D1-cyclin-dependent kinase (CDK) 4 and -CDK6 complexes ([160]). Other cell cycle-important cMYC targets include the cell cycle inhibitors p21 and p27, both of which are down-regulated by cMYC, and Cdc25A, a protein phosphatase up-regulated by cMYC that activates CDK2 and CDK4 ([161], [162]). Because terminal cellular differentiation requires exit from the cell cycle, and given that cMYC promotes constant cycling, it follows that overexpression of the protein interferes with cellular maturation. Interestingly, recent studies examining mice engineered to express a regulated cMYC gene (allowing the gene to be turned off by administration of the antibiotic doxycycline to the mice) has shown that the majority of cMYC-induced hematopoietic and other lineage tumors undergo cell cycle arrest, terminal differentiation, and regression on down-regulation of the gene ([163], [164]). Thus, continued expression of cMYC is necessary for persistence of the tumor; an obvious correlate of these findings is that inhibition of cMYC might therefore hold therapeutic benefit. A number of metabolic pathways are affected by cMYC owing to its regulation of other target genes, including nucleotide synthesis, protein synthesis, and iron metabolism ([70]). In addition, lactate dehydrogenase A transcription is activated by cMYC ([165]). Lactate dehydrogenase A expression correlates with the ability of cells to participate in aerobic glycolysis and to grow more efficiently under hypoxic conditions. cMYC may also be able to maintain the expression of telomerase, an enzyme that contributes to the immortalization of cells by permitting the indefinite maintenance of the chromosomal ends (i.e., the telomeres), which normally shorten as aging occurs. This shortening process is thought to contribute to cellular senescence. cMYC can directly induce the catalytic subunit of telomerase, known as *telomerase reverse transcriptase*, at the level of transcription ([166], [167]). Enforced expression of telomerase reverse transcriptase has been demonstrated to immortalize rodent cells experimentally and to make cells susceptible to oncogenic transformation ([167], [168]).

A brief mention at this point of the importance of the function of the p53 gene in the development and progression of NHL is warranted. Abnormalities of the p53 tumor suppressor gene appear to play a pathogenic role in some Burkitt lymphomas, as well as in a number of other NHL subtypes (*vide infra*). Mutations of this gene locus have been identified in one-third of primary biopsies and almost two-thirds of Burkitt lymphoma–derived cell lines ([169], [170]). The p53 protein, encoded on chromosome 17p13, is the most commonly mutated protein identified in human cancer and is involved in programmed cell death as well as in cell cycle regulation and DNA repair ([171], [172], [173], [174], [175], [176] and [177]). This protein, which has been referred to as the *guardian of the genome*, monitors DNA repair, helping ensure that the repair process is completed before subsequent cell division occurs ([178]). By functioning as a transcription factor to increase the expression of the p21 protein, a universal inhibitor of cyclin-CDK complexes ([179]), normal p53 can turn off DNA replication, arresting cells in G_1 phase to allow extra time for repair ([180], [181]). In addition, if the repair process fails, p53 can trigger cell death by apoptosis. Cells bearing inactivated p53 are unable to undergo these checks and balances and acquire mutations at an increased rate, allowing defective cells to replicate unrepaired DNA sequences that are passed on to their progeny and ultimately lead to the selection and outgrowth of clones with enhanced malignant potential. The tumor-suppressive effects of p53 are evident in mice lacking the protein as a result of gene targeting by homologous recombination; these animals develop normally but experience the early development of a variety of neoplasms ([182], [183]).

LYMPHOPLASMACYTOID LYMPHOMA: PAX5

Roughly 50% of the low-grade NHLs that are known as *small lymphocytic lymphomas with plasmacytoid differentiation* or *lymphoplasmacytoid lymphomas* contain a t(9;14)(p13;q32) chromosomal rearrangement. Although rare, the t(9;14) is illustrative of the involvement in malignancy of a family of transcription factors, the PAX (for *pa*ired homeobo *x*) proteins, that normally control embryonic development and organogenesis ([184], [185]). Members of this family contain two discrete DNA-binding domains—the paired box and the paired-type homeodomain—that display coordinate DNA binding specificity ([186]). The lymphomas that contain the t(9;14) comprise B cells with a plasma cell–like phenotype that possess cytoplasmic Ig, produce serum paraproteins, and typically follow an indolent clinical course followed by transformation into large-cell lymphoma ([187]). A number of other reciprocal chromosomal fusion partners with the 9p13 breakpoint have been identified cytogenetically in addition to chromosome 14q32, including 1q25, 3q27, 7q11, 12q13, 12q21, 10p13, and 9q13 ([188]). The t(9;14) results in the juxtaposition of the PAX5 (paired Homeobox-5) gene ([189]) with the Ig heavy chain locus on chromosome 14 ([190]).

PAX5 is normally expressed in fetal brain and liver during the embryonic period but is restricted to B lymphocytes and the testis after birth ([189]). PAX5 is transcribed throughout B-cell ontogeny but undergoes down-regulation during plasma cell differentiation. Knockout mice experiments have demonstrated that Pax5 is important for midbrain development and that loss of Pax5 function results in maturation arrest of lymphocytes at the pro–B-cell stage ([191]). Pax5 overexpression, by contrast, results in splenic B-cell proliferation ([192], [193]). Several genes important for B-cell development have been proposed to be PAX5 targets, including CD19, B-cell receptor component Ig alpha (mb-1), transcription factors N-MYC and LEF-1 (positively regulated by PAX5), and the cell surface protein PD-1 and the p53 tumor suppressor (which are down-regulated) ([194], [195] and [196]). In addition, the B-cell SRC family tyrosine kinase BLK, which transforms lymphoid progenitors in an activated form but is dispensable for B-cell development and activation, is up-regulated by PAX5 ([197], [198], [199] and [200]). Furthermore, PAX5 appears to be required for normal IgH VDJ recombination, given that V-to-DJ recombination is reduced approximately 50-fold in Pax5-deficient pre–B cells ([196]). In a series of elegant experiments, Busslinger and his group have shown that Pax5-null pro–B cells are incapable of B-cell–lineage differentiation and rather can actually give rise to all other hematopoietic cell types when cultured under appropriate conditions; reintroduction of the gene into pro–B cells lacking Pax5 restores their ability to differentiate into mature B cells but suppresses their differentiation into other blood lineages ([201], [202] and [203]). Pax5-null pro–B cells express genes of non–B-cell hematopoietic lineage-associated programs; restoration of Pax5 expression in these cells represses this lineage-promiscuous gene transcription while up-regulating genes critical for B-cell development. Thus, Pax5 plays an essential role in B-cell–lineage commitment by suppressing alternative hematopoietic lineage choices. The overexpression of PAX5, as a consequence of the t(9;14), down-regulates p53 ([190], [204]) and presumably also alters the expression of multiple B-cell–important target genes, thus contributing to malignant transformation.

Deregulation of PAX5 expression by a translocated IgH promoter has also been reported rarely in NHL subtypes other than lymphoplasmacytoid lymphoma and in myeloma ([205]). As noted previously, other PAX genes play a role in oncogenesis. For example, the PAX3 and PAX7 genes fuse to the forkhead domain transcription factor (FKHR) in the t(2;13)(q35;q14) and t(1;13)(p36;q14) translocations, respectively, in the skeletal muscle tumor rhabdomyosarcoma ([206]), and PAX8 forms a fusion oncoprotein, PAX8-PPAR?1, in human thyroid follicular carcinomas ([207]). PAX5 itself is aberrantly expressed in some medulloblastomas and glioblastomas through an unknown mechanism of altered regulation ([208]).

MANTLE CELL LYMPHOMA: CCND1 (CYCLIN D1)

Mantle cell lymphoma (MCL) is recognized under the Revised European American Lymphoma (REAL) and World Health Organization (WHO) classifications as a distinct clinicopathologic entity, which was referred to in the past as *centrocytic lymphoma* in the Kiel classification and *intermediately differentiated lymphoma* in the modified Rappaport classification ([12], [13], [209], [210]). The Working Formulation ([8]) failed to recognize MCL as a unique entity, and most of these lymphomas were considered to be diffuse small cleaved lymphoma (approximately 60%), follicular small cleaved lymphoma (approximately 25%), or small lymphocytic lymphoma (approximately 15%) ([211]). These B-cell lymphomas constitute roughly 6% of all NHL, predominate in men (male to female ratio, 4:1) older than 55 years of age, and are associated with an overall poor prognosis (worse than other small cell NHL subtypes), having a median survival of approximately 3 years, although some patients have an aggressive disease that leads to death in less than 1 year, whereas others manifest a rather indolent disease and may survive for more than 10 years ([210], [212], [213]). The so-called blastic variant morphology of MCL has been associated with a short survival in several reports ([214], [215]), and mutations of p53 ([216], [217] and [218]), as well as deletions of the INK4a/ARF tumor suppressor gene locus ([219], [220]), are thought to identify subsets of MCL with a particularly poor prognosis (see also the section Gene Expression Profiling in Non-Hodgkin Lymphoma at the end of this chapter for additional information regarding the diagnosis and prognosis of MCL).

MCL was not widely acknowledged as a discrete subtype of NHL until its association with a unique chromosome translocation. Almost all (>90%) cases of this lymphoma contain the translocation t(11;14)(q13;q32), which also occurs infrequently in other types of NHL, chronic lymphocytic and B-cell prolymphocytic leukemias, and multiple myeloma ([221], [222] and [223]). Although the breakpoint on chromosome 11 that is altered by the t(11;14) was cloned in 1984 ([224], [225]), CCND1, the chromosome 11 gene transcriptionally activated because of its juxtaposition near the enhancer region of the Ig heavy chain locus on 14q32, was not identified until 7 years later, because the major genomic breakpoint cluster region (designated BCL1 for B-cell lymphoma/leukemia 1) is located approximately 120 kilobases (kb) centromeric to the CCND1 coding sequences ([226], [227] and [228]). Because the breakpoints in the BCL1 genomic locus are not tightly clustered, most studies using

Southern blot analysis or PCR detect the translocation in only 50 to 70% of patients ([229], [230], [231] and [232]). Thus, conventional cytogenetics or FISH ([233], [234]) are the most sensitive means to detect the t(11;14), although detection of overexpression of the CCND1 transcript or its encoded protein, cyclin D1, by *in situ* hybridization or immunostaining have recently been shown to be sensitive diagnostic methods, because B and T lymphocytes do not normally express the gene ([33], [235], [236], [237], [238], [239], [240] and [241]).

Cyclin D1, previously also known as *PRAD1* because of its involvement in parathyroid adenoma-associated translocations in addition ([227], [242]), is overexpressed in nearly all cases of MCL but is only rarely expressed in other hematopoietic malignancies ([227], [229], [231], [232], [243], [244]). All 11;14 translocation breakpoints thus far characterized leave the CCND1 coding region intact structurally and result in increased protein expression ([228], [245], [246]). Cyclin D1 overexpression facilitates lymphomagenesis as a result of its role in the progression of cells through the G_1 to S phase transition of the cell cycle ([247], [248]). Cyclin D1, a member of the family of D-type cyclins, physically associates with and activates enzymes known as *cyclin-dependent kinases* (mainly CDK4 and CDK6). Cyclin D1–CDK complexes in turn bind to and hyperphosphorylate the retinoblastoma tumor suppressor protein (Rb) ([249], [250] and [251]), preventing Rb from interacting with and inhibiting the activity of transcription factors, such as E2F that promote S phase entry ([252], [253]). The growth inhibitory effects of Rb are thus removed, and cells undergo a shortened G_1 phase, followed by S phase entry ([177], [254]). Cyclin D1–CDK4 and -6 complexes also promote enhanced cell cycle progression by interacting with the CDK inhibitors (CDKIs) p21 and p27KIP1 ([255]), titrating these proteins away from cyclin E–CDK2 complexes. Although p21 and p27KIP1 are potent inhibitors of cyclin E–CDK2 complexes, they do not inhibit cyclin D1–CDK4 and -6 complexes. Increased cyclin E–CDK2 activity can promote S-phase entry by phosphorylating Rb and can sustain cell cycle progression by the phosphorylation of p27KIP1, which leads to the proteasome-mediated degradation of the CDKI ([177]).

Deletions of the INK4a/ARF gene locus are found in 20 to 30% of MCLs and, as mentioned previously, are associated with an inferior prognosis ([219], [220], [256], [257] and [258]). This locus encodes two structurally unrelated tumor suppressors, the p16INK4a protein, which is an inhibitor of CDK4 and CDK6 that prevents their ability to phosphorylate and inactivate the growth-suppressive Rb protein, and the human p14ARF protein, which is encoded in part from an alternative reading frame (from which it gets its name) of the INK4a locus and acts as an inhibitor of the p53 negative regulator, HDM2, to induce the tumor-suppressive functions of p53, which include the promotion of cell cycle arrest and apoptosis ([177]). Thus, loss of the INK4a and ARF proteins removes these tumor suppressor activities and cooperates with cyclin D1 overexpression to quantitatively increase MCL tumor cell proliferation and shorten patient survival ([259]).

The important role that cyclin D1 plays in oncogenesis is further highlighted by the observation that, in addition to MCL and parathyroid adenomas, the protein is overexpressed in a number of cases of breast cancer and squamous cell carcinomas of the head and neck ([260], [261]) as a result of gene amplification. Interestingly, a small percentage (approximately 9%) of otherwise typical MCLs lack cyclin D1 overexpression ([262]); some of these cases instead express high levels of cyclins D2 and D3, suggesting that the enhanced cell cycle progression mediated by cyclin D1 overexpression can be mimicked at least partly by these other D-type cyclins ([258]).

A number of cell culture–based, as well as transgenic mice, experimental studies have demonstrated the potential for cyclin D1 to contribute to oncogenesis ([263], [264], [265], [266], [267], [268] and [269]). Experiments with transgenic mice overexpressing CCND1 in their lymphoid compartment revealed subtle alterations in lymphocyte maturation and cell cycle progression ([267], [268]). Although CCND1 was not transforming by itself in these studies, the gene was shown to cooperate with MYC genes to produce B-cell lymphomas. Oncogenic cooperation of CCND1 with the Harvey RAS gene has also been reported in the transformation of primary rat embryo fibroblasts, whereas CCND1 alone or in combination with cMYC failed to transform cells in this system ([266]). These results are consistent with the oncogenic contributions of cyclin D1 overexpression to lymphoma development and progression but suggest that the protein is relatively poor at initiating the lymphomagenic process ([270]). Experience from other cyclin D1 transgenic mice studies also points to the oncogenic capabilities of the protein; for example, mice overexpressing the gene driven by the mouse mammary tumor virus promoter develop breast hyperplasia and carcinoma ([269], [271]).

It is appropriate at this point to note in greater detail that the alteration of CDKIs has been demonstrated in a variety of NHL and other cancers. Several of the CDKIs, which include p15 $^{INK4B/MTS2}$, p16 $^{INK4A/MTS1}$, p18 ^{INK4C}, p19 ^{INK4D}, p21 ^{CIP1,WAF1,SDI1,CAP20}, p27 ^{KIP1}, and p57 ^{KIP2} (the various names that have been given to these proteins are shown in this paragraph as superscripts), are altered in a variety of solid and hematopoietic malignancies, including NHL ([176], [247], [255], [272], [273]). These factors normally bind to specific CDKs, inhibiting their kinase activities and preventing cell cycle progression ([255], [272]). The inactivation of CDKI activity in cancer, usually by homozygous gene deletions but occasionally by point mutations or chromosomal rearrangements, or both, contributes to tumorigenesis because of the removal of this negative cell cycle regulation ([273]). Among the CDKIs, p16 $^{INK4A/MTS1}$ (formally also known as *CDKN2*) and the closely linked p15 $^{INK4B/MTS2}$, which are located on chromosome 9p21 and are specific inhibitors of cyclin D–associated kinases, appear by far to be the most frequently altered ([273], [274] and [275]). For example, in hematopoietic malignancies, a remarkable 75 to 80% of T-cell acute lymphocytic leukemias (ALLs) and 5 to 15% of B-cell ALLs have homozygous p16 $^{INK4A/MTS1}$ deletion, making this the most frequently altered gene locus thus far reported in ALL ([273]). Deletion of the p15 $^{INK4B/MTS2}$ gene, located only 25 kb from the p16 $^{INK4A/MTS1}$ locus, accompanies the loss of p16 $^{INK4A/MTS1}$ in most, but not all, cases. In addition, as noted previously, deletions of p16 $^{INK4A/MTS1}$ also usually involve p14 ^{ARF} as well. Interestingly, alteration of these genes is preferentially found in lymphoid cells, with only occasional myeloid malignancies possessing abnormalities (usually those cases that coexpress lymphoid lineage markers). Approximately 10% of NHL has been reported to contain cytogenetic abnormalities of 9p ([188]), and studies have revealed p15 $^{INK4B/MTS2}$ and p16 $^{INK4A/MTS1}$ alterations to result from some of these abnormalities, with cytogenetically occult alterations also common. In the NHLs other than MCL, abnormalities of these genes seem to be most common in (although not restricted to) diffuse large cell lymphomas (DLCLs), with 10 to 15% of cases reported to show alterations in most studies ([176], [276], [277], [278], [279], [280] and [281]). Interestingly, abnormalities in NHL of some CDKIs (p18 ^{INK4C}, p19 ^{INK4D}, and p21 ^{CIP1,WAF1,SDI1,CAP20}) are infrequent, whereas others (p27 ^{KIP1} and p57 ^{KIP2}) are often inactivated by various mechanisms to deregulate the cell cycle ([176], [262], [263], [264], [265], [266], [267], [268], [269], [270], [271], [272], [273], [274], [275], [276], [277], [278], [279], [280], [281], [282], [283], [284] and [285]).

FOLLICULAR LYMPHOMA: BCL2

From 80 to 90% of follicular lymphomas (FLs) (follicular small cleaved cell, follicular mixed, or follicular large cell) contain the t(14;18)(q32;q21), the most common chromosomal translocation in human lymphoid malignancy ([286], [287] and [288]). The FLs occur almost exclusively in adults and are the most common human B-cell neoplasm, constituting approximately 45% of all NHLs and 80% of all indolent lymphomas ([8]). On the derivative 14 chromosome resulting from this translocation, the gene BCL2 (for B-cell leukemia and lymphoma 2), normally located on chromosome 18, is introduced into the Ig heavy chain locus on chromosome 14 ([289], [290] and [291]). The great majority (slightly less than 70%) of breakpoints on chromosome 18 within the BCL2 locus occur in the 3' untranslated region of the gene (the major breakpoint region), and approximately 20% are found roughly 20 kb 3' to the gene locus (the minor cluster region) ([292], [293]). Both breakpoints leave the coding sequence of the gene intact. PCR-using primers that span each of these breakpoint regions can be used to identify the presence of the t(14;18) ([293], [294], [295], [296], [297], [298] and [299]). These studies have shown that cells positive for the t(14;18) persist in patients in prolonged complete clinical remission, but whether this predicts relapse remains uncertain. Insertion of BCL2 into the Ig heavy chain locus produces dysregulation of the transcription and RNA processing of the gene, resulting in the production of an inappropriately increased amount of the normal 25-kd BCL2 protein. Interestingly, lymphoid cells in the lymph nodes, tonsils, and peripheral blood of normal individuals have been demonstrated to contain BCL2-Ig rearrangement in nearly one-half of cases in some studies, suggesting that the t(14;18) could be a commonly occurring event during normal lymphocyte development and indicating that cells with the abnormality may not necessarily be committed by evolution to lymphoma ([301] and [302]).

BCL2 is a mitochondrial membrane-associated protein that is normally expressed in B cells on their activation with antigens and growth factors and that undergoes down-regulation with normal differentiation. A large number of studies performed since the mid-1980s have established the normal role of BCL2 as an inhibitor of apoptotic (programmed cell death) pathways ([303], [304]). This function of BCL2 is highly conserved in evolution, with the BCL2 homologue CED-9 of the nematode *Caenorhabditis elegans* repressing cell death during the development of the hermaphrodite worm ([305], [306]). BCL2 functions, at least partly, through protein-protein interactions with a number of BCL2 homologues, including the death-promoting 21-kd protein BAX ([307], [308]). BAX can heterodimerize with BCL2 and homodimerize with itself. When it is overexpressed in cells, BAX homodimerizes and accelerates apoptotic cell death; when BCL2 is overexpressed, it heterodimerizes with BAX and inhibits cell death. Thus, the ratio of BCL2 to BAX is critical in determining the susceptibility to apoptosis. BAK (BCL2 homologous antagonist/killer) is another BCL2 family member that can interact with BCL2 in a manner functionally similar to BAX, thus opposing the death-repressor activity of BCL2 ([309], [310] and [311]). Additional regulation of BCL2 activity is modulated by the protein BAD (BCL2/BCL-X_L–associated death promoter) ([312]), another BCL2-interacting protein that negatively regulates BCL2 by displacing BAX from BCL2/BAX heterodimers in a concentration-dependent fashion, and BAG-1 ([313]), a protein that is not significantly homologous to the BCL2 family members but that can interact with BCL2 and enhance its death-repressor activity. Yet, additional BCL2 family members have been

identified that may modulate BCL2 function or participate in the control of cell lineage–specific apoptosis ([304]).

Although BCL2 overexpression alone is insufficient to fully transform B cells, the survival advantage that overexpression provides allows time for the development of cooperating genetic mutations that produce frank lymphoma. For example, *in vitro* and *in vivo* studies have demonstrated that BCL2 can complement the cMYC protein, in part by inhibiting cMYC-induced apoptosis, to produce tumors ([314] , [315] , [316] , [317] and [318]). Transgenic mice engineered to express BCL2 within their developing B-cell compartment develop an overabundance of small resting IgM- and IgD-positive polyclonal B cells ([319] , [320]). With time, these cells, which demonstrate no proliferative advantage but exhibit prolonged survival, acquire secondary genetic abnormalities (frequently involving cMYC) that produce monoclonal, often highly aggressive malignancies ([314] , [321]). This animal model is reminiscent of the course of human FL, which can often be indolent for years before progressing to aggressive diffuse large cell lymphoma (Richter transformation) ([322]). Indeed, a substantial number of the approximately 20% diffuse B-cell lymphomas that contain the t(14;18) probably represent progression from typical FLs ([323]). Conversely, established diffuse large B-cell lymphomas (DLBCLs) can acquire BCL2 expression, due to the t(14;18) or other, unknown mechanisms, and the increased BCL2 expression in this setting has been associated with an inferior disease-free survival in several studies (reviewed in reference 324). These observations also correlate well with reports that indicate that patients whose lymphoma contains the t(14;18) as a solitary abnormality usually have an indolent course as compared to those patients whose tumors carry additional karyotypic abnormalities ([288] , [322] , [325] , [326]). For example, the ability to detect the t(14;18) by itself was found to have no impact on survival in FL patients ([327]), whereas the additional presence of structural breaks in chromosome 17 has been demonstrated to be a predictor of poor outcome ([325] , [326] , [328]). At least some of these chromosome 17 abnormalities affect the p53 gene locus at 17p13, the mutation of which has been associated with the histologic transformation of FL ([329]). The involvement of BCL2 and related proteins in NHL and many other cancers has made this family of apoptosis-regulatory proteins prime targets for therapeutic intervention using antisense and other approaches, and targeted therapies aimed at these molecules are likely to be available in the clinic in the near future ([330]).

LYMPHOBLASTIC LYMPHOMA: TAL1, TAL2, LMO1, LMO2, HOX11, HOX11L2, LYL1, CMYC, NOTCH1, LCK, AND FUSION GENES INVOLVING FGFR1

These highly aggressive lymphomas, which are almost always of a T-cell phenotype, occur most often in adolescent and young adult men and comprise approximately 40% of NHL in children and 3 to 4% of the NHLs in adults in most series ([24] , [331] , [332] , [333] , [334] and [335]). Information regarding the molecular pathogenesis of lymphoblastic lymphoma is derived primarily from the large number of studies that have been performed on the T-cell leukemias, based on the belief held by most investigators that these two clinical diagnoses represent different manifestations of a single biologic entity. In contrast to most of the other major subtypes of NHL in which one or a few chromosomal rearrangements alter the function of a single gene locus (e.g., cMYC in Burkitt lymphomas and BCL2 in the FLs), a number of translocations altering various protooncogenes [TAL1, TAL2, LMO1, LMO2, HOX11, HOX11L2, LYL1, cMYC, NOTCH1, LCK, and fibroblast growth factor receptor-1 (FGFR1)] occur in lymphoblastic lymphoma. A unifying feature of these translocations, with the exception of those involving FGFR1, is that they cause deregulated expression of the involved protooncogene by placing it near enhancer sequences present in the TCR ß-chain gene locus on chromosome 7, band q34, or the TCR a/d locus on chromosome 14, band q11. With the exception of rare chromosomal rearrangements that involve LCK, a cytoplasmic tyrosine kinase involved in interleukin (IL)-2 receptor- and TCR-mediated cell signaling in T lymphocytes ([336] , [337] , [338] , [339] , [340] , [341] , [342] and [343]); NOTCH1 (formerly known as *TAN1*), a transmembrane protein of the NOTCH gene family of membrane-spanning receptor proteins that normally play a role in the control of cell fate decisions during differentiation in a variety of tissues from flies to man ([344] , [345] , [346] , [347] , [348] , [349] and [350]); and the FGFR1 receptor tyrosine kinase, all of the genes altered by these rearrangements encode transcription factors.

Although NOTCH1 is a single-pass transmembrane receptor protein, the early observation that the T-cell acute lymphoblastic leukemia–associated t(7;9)(q34;q34.3) rearrangement results in the expression of truncated NOTCH1 polypeptides that localize primarily to the nucleus, together with subsequent data demonstrating that the cytoplasmic portions of the four mammalian NOTCH proteins interact with several transcription factors to control the activity of the factors, indicated that NOTCH1 also ultimately participates in the oncogenic process by regulating the expression of critical target genes ([344] , [345] and [346] , [348] , [349] , [351] , [352]). Normally, the NOTCH receptors and their ligands (five ligands have been identified in humans: Jagged1, Jagged2, Delta-like1, Delta-like3 and Delta-like4) are transmembrane proteins expressed on the surface of cells. The activation of NOTCH receptors by ligand binding triggers a series of proteolytic cleavages of the receptors that release the intracellular portion of the receptors from the membrane, allowing them to translocate to the cell nucleus [thus, the truncated NOTCH1 proteins expressed due to the t(7;9) represent activated versions of the protein] ([353]). In the nucleus, NOTCH proteins bind to a highly conserved transcription factor called *CSL* (for *C*BF1/RBP-Jk in mammals, suppressor of hairless in *Drosophila*, and *L*ag-1 in *C. elegans*). Binding of the intracellular portion of NOTCH proteins to CSL in the nucleus converts CSL from a transcriptional repressor into an activator of gene expression, and this activation is potentiated by the recruitment of coactivators, such as the protein known as *mastermind-like-1 (MAML1)* as well as p300 ([354]). Interestingly, CSL is a target for several EBV proteins required for B-cell transformation and is likely deregulated in a number of human tumors ([355] , [356] and [357]).

As of 2003, only a few of the target genes of NOTCH signaling have been identified; one frequent target for transcriptional up-regulation is the family of bHLH-type transcriptional repressors known as *hairy/enhancer of split (HES)* proteins that regulate embryonic patterning and cell differentiation, but it is not clear that the HES proteins are critical for oncogenic transformation by NOTCH signaling ([358]). Another possible target of NOTCH proteins that may contribute to oncogenicity includes E2A ([359]), a gene that encodes two bHLH transcription factors that are known as *E12* and *E47*, the lack of which in knockout mice produces an early block in B-cell development and a predilection to the formation of T-cell tumors ([360]). Interestingly, aberrant expression of TAL1, LMO1, or LMO2 (*vide infra*), the genes most commonly deregulated in human T-cell ALLs, also inhibits E2A activity. Activated NOTCH1 inhibits E2A-induced transcriptional activation, suggesting a common event linking various forms of T-cell malignancy. REL/nuclear factor-?B (NF-?B) transcription factors may also be involved in NOTCH-mediated oncogenesis; certain members of this family, such as v-rel, induce T-cell leukemias in animal models, and activated NOTCH1 is known to overcome CSL-mediated repression of the NF-?B2 gene promoter, suggesting that it too may activate REL factors ([353]).

The association of NOTCH1 abnormalities in T-cell malignancy parallels the importance of the protein in normal lymphoid development. For example, mouse models have demonstrated that NOTCH1 signaling is essential for normal T-cell development and that NOTCH1-mediated signals promote T-cell development at the expense of B-lymphoid development ([351] , [361] , [362]). Furthermore, mice engineered to express excess NOTCH signaling have been shown to develop T-cell malignancies ([353]). Enhanced NOTCH1 signaling also appears to promote tumor cell growth in human Hodgkin and anaplastic large cell lymphomas (ALCLs) ([363]).

The TAL1, TAL2, MYC, and LYL1 genes encode members of the bHLH class of transcription factors that are involved in translocations in the lymphoblastic malignancies ([364] , [365] , [366] , [367] , [368] , [369] , [370] , [371] and [372]). The bHLH domains of these proteins mediate protein dimerization and sequence-specific binding to DNA sequences present in the promoter and enhancer regions of key target genes, most which have yet to be identified ([373] , [374] , [375] , [376] , [377] and [378]), that normally control events in cellular differentiation or proliferation. By far, the most commonly involved of these loci is TAL1 (also known as *SCL* or *TCL5*) ([365] , [366] and [367]). Although few studies have examined lymphomas, involvement of this gene has been reported in as much as 30% of T-cell acute lymphoblastic leukemias. In 5% of T-cell ALL, the TAL1 locus on chromosome 1 is altered by the t(1;14)(p32-33;q11), whereas the remaining 25% of cases possess rearrangements of the locus that are cytogenetically unapparent and that result in an intragenic deletion of the 5' side of the gene that brings TAL1 under the control of the promoter of another chromosome 1 gene called *SIL* ([379] , [380] , [381] , [382] , [383] , [384] and [385]). TAL1 has also been reported to be overexpressed in approximately 50% of T-cell malignancies that do not contain these typical abnormalities at the gene locus ([385]), but these data are uncertain, given that a subsequent examination found the expression of TAL1 in many T-cell leukemias that lack rearrangements of the gene actually occurred in other, nonmalignant cells (e.g., erythroid cells) ([386]). The molecular genetic abnormalities that affect TAL1 result in the ectopic expression of the protein in T-lymphoid cells (normal expression of the TAL1 protein is restricted to myeloid and erythroid progenitors, megakaryocytes, mast cells, embryonic brain, and endothelial cells) ([387] , [388] , [389] , [390] , [391] , [392] , [393] , [394] and [395]). Study of TAL1-null embryonic stem cells indicates that the function of the gene is essential for the development of all hematopoietic lineages, suggesting a role in early blood cell development before lineage commitment (i.e., in the genesis of hematopoietic stem cells) has taken place ([396] , [397] , [398] , [399] , [400] , [401] , [402] , [403] , [404] and [405]). The bHLH domain of TAL1 has been shown to bind with the so-called E-protein transcription factors that include the E2A bHLH transcription factor and related proteins (E12, E47, HEB, and E2-2) ([364] , [365] , [366] , [367] , [368] , [369] , [370] , [371] , [372] , [373] , [374] , [375] , [376] , [377] , [378] , [379] , [380] , [381] , [382] , [383] , [384] , [385] , [386] , [387] , [388] , [389] , [390] , [391] , [392] , [393] , [394] , [395] , [396] , [397] , [398] , [399] , [400] , [401] , [402] , [403] , [404] , [405] , [406] , [407] , [408] , [409] and [410]) to form sequence-specific DNA-binding heterocomplexes ([411] , [412] and [413]). The exact mechanism underlying the contribution of TAL1 to the development of T-cell malignancies is not fully clear, but one suggestion is that the overexpression of the protein may act as a dominant-negative regulator of transcription, preventing the normal function of the E-proteins, which play key roles in the developmental progression of a variety of cell lineages including brain, muscle, and lymphocytes ([410] , [414]). This hypothesis is consistent with studies indicating that E-protein inactivation or inhibition can lead to T-cell leukemia/lymphoma development ([415] , [416]). Transgenic mice engineered to express TAL1 develop T-cell malignancies ([417] , [418] and [419]). TAL1-E2A heterodimers can physically interact in cells with the LMO1 and LMO2 proteins as well that are also activated in T-lymphoblastic malignancies by chromosomal translocations ([420] , [421]). “Double” transgenic mice that express TAL1 and LMO1 or LMO2 in their T cells develop abnormalities of T-cell differentiation and tumors at a significantly faster rate

than mice that express LMO1 or LMO2 only, indicating that TAL1 serves as a synergistic tumor promoter in this system ([416] , [422] , [423] and [424]).

As mentioned previously, two other transcription factor genes that are altered by translocations found in T-lymphoblastic malignancies encode the cysteine-rich LIM proteins LMO1 and LMO2 (for LIM only) ([425] , [426] , [427] and [428]). These two proteins, which were formerly known also as *rhombotin-1 (RBTN1)* and *T-cell translocation gene 1 (TTG1)*, and *rhombotin-2 (RBTN2)* and *T-cell translocation gene 2 (TTG2)*, respectively, each contain an amino-terminal transcriptional activation domain and two tandem LIM domains, the latter of which include zinc fingerlike regions ([429] , [430] , [431] and [432]). These LIM domains are structurally related to the DNA-binding zinc fingerlike domains of other transcriptional proteins, like the GATA factors ([433] , [434] , [435] , [436] and [437]), but there is no evidence that they bind to DNA. In addition, the absence of a Homeobox DNA-binding domain, which is found in other LIM family members, suggests that these proteins modulate transcription through protein–protein interactions mediated via their LIM domains. Indeed, LMO1 and LMO2 have the ability to physically associate not only with the TAL1 bHLH protein, but also with the bHLH proteins TAL2 and LYL1 that are activated in rare (2%) cases of T-cell malignancy by chromosome rearrangements ([368] , [371] , [420] , [421]). In turn, like TAL1, TAL2 and LYL1 also interact with E2A ([438]), and all three of the proteins can bind the same DNA sequences. These observations suggest that, in T cells, the different E2A-TAL1, -TAL2, or -LYL1 heterodimers may functionally inactivate normal E2A activity or control the regulation, or both, of a common set of as-yet-unidentified target genes to contribute to T-cell transformation. The LMO proteins are also involved in this process; for example, LMO2 is found in complexes in normal erythroid cells as well as T-cell lymphomas that include TAL1, E2A, GATA-1, and the ubiquitous nuclear adaptor protein Ldb1/NLI/CLIM2 ([439] , [440]), whereas LMO1 is known to bind Ldb1 ([441]). TAL1, TAL2, LYL1, and the LMO proteins may possibly contribute to T-cell oncogenesis via other mechanisms as well. TAL1 has been reported to possess antiapoptotic properties that may play a role in the process ([442] , [443]). In addition, TAL1, TAL2, and LYL1 can all physically interact with a novel guanosine triphosphate–binding protein named *DRG*, which has been shown to stimulate the cotransforming activity of MYC and RAS in an experimental model ([444]). Furthermore, LYL1, but not TAL1 or TAL2, interacts with NF-?B1 and reduces its transcriptional activity, perhaps contributing to oncogenic transformation when deregulated by aberrant expression of LYL1 ([445]). LMO2 can also bind several proteins in addition to those already mentioned, including Elf-2, an ETS family transcription factor, the retinoblastoma-binding protein 2—a protein that in turn binds Rb, p107, TATA-binding protein, and nuclear hormone receptors to modulate transcription—and AF6, a protein originally identified as a translocation partner of the MLL oncoprotein ([446] , [447] , [448] , [449] and [450]). Gene targeting experiments in mice of LMO2 and TAL1 indicate that the function of each of these proteins is critical for erythroid cell development, with mice null for the individual genes showing a similar block in red blood cell development ([396] , [397] , [451] , [452]). These observations suggest that there is a complicated interplay involving transcriptional complexes among the LMO and bHLH proteins altered in T-cell neoplasms (that also includes the GATA factors) ([435] , [437]), which controls normal hematopoietic development ([453]). T-cell malignancies from some patients have been shown to contain rearrangement of LMO2 and TAL1 gene activation as a result of promoter deletion ([421]), providing further evidence for cooperation of these genes in tumor development. Although not as common as TAL1 alterations, activation of LMO2 is found in approximately 7% of patients with T-cell lymphoblastic malignancies as a result of the t(11;14)(p13;q11), whereas LMO1 activation by the t(11;14)(p15;q11) is seen in less than 1% of patients ([429] , [430] and [431] , [454]). The oncogenic potential of LMO2 overexpression has also been demonstrated recently by the unfortunate development of a monoclonal T-cell lymphoproliferative disorder due to inadvertent insertional mutagenesis of the LMO2 gene locus after treatment of a patient with X-linked severe combined immunodeficiency using retrovirally-mediated gene therapy ([455]).

The LMO proteins are normally not expressed in T cells or their progenitors ([451] , [456]). Each of the t(11;14) rearrangements leads to the ectopic expression of a completely normal nonfusion transcript. Like TAL1, enforced expression of LMO1 or LMO2 induces T-cell tumors in transgenic mice but with relatively long latency periods that are probably required for the development of additional cooperating oncogenic “hits” ([457] , [458] , [459] , [460] and [461]).

Two final examples of the group of transcription factors that are altered in T-cell lymphoid malignancies are the HOX11 and HOX11L2 Homeobox genes, located on chromosomes 10q24 and 5q35, respectively ([462] , [463] , [464] , [465] , [466] , [467] , [468] , [469] and [470]). The Homeobox genes were first identified in *Drosophila melanogaster* as genes encoding factors (homeoproteins) that are involved in the determination of the basic body plan ([471] , [472] and [473]). Mutations of the Homeobox genes in *Drosophila* cause one body part of the organism to develop with the characteristics of another part (e.g., the Antennapedia mutant fly possesses leg structures where antennae are normally found). Homeoproteins have been identified in a wide variety of organisms and appear to play an evolutionarily conserved role as determinants of development, regulating the expression of genes in a spatial, temporal, and tissue-specific fashion. Roughly 50 mammalian Homeobox genes are present in a series of four clusters located on different chromosomes ([474] , [475] and [476]). The expression of each individual gene coincides with its linear arrangement within its cluster, thus resulting in an expression gradient along the anterior-posterior axis of the organism. As noted previously in the case of PAX5, the role of HOX11 in oncogenesis is not unique among the Homeobox genes, with many other examples of homeoprotein involvement in malignancy and other human diseases known ([190] , [474] , [477] , [478] , [479] , [480] , [481] , [482] and [483]).

Like all other homeoproteins, HOX11 localizes to the cell nucleus, binds to DNA in a sequence-specific manner, and transactivates the expression of specific target genes ([484] , [485]). HOX11 is not normally expressed in adult tissues at levels detectable by routine Northern (RNA blot) hybridization analysis, although it can be detected in a variety of tissues (including normal T cells) by more sensitive PCR-based methods ([462] , [463] and [464] , [486] , [487]). The mouse homolog, designated Tlx-1 (for T-cell leukemia Homeobox 1), is expressed in the embryo within branchial arch structures, portions of the peripheral and central nervous systems, the pancreas, the salivary glands, and the splanchnic mesoderm ([488] , [489] and [490]). Knockout mice deleted for Tlx-1 are phenotypically normal, with the remarkable exception that splenic development is completely absent ([489] , [491]). HOX11 thus appears to be a “master gene” that serves as a regulatory switch to control normal cellular growth and proliferation of splenic tissue.

HOX11 expression in T-cell lymphoblastic malignancies is found in 5 to 10% of patients, most often as a result of the t(10;14)(q24;q11) that involves the TCR a/d-chain gene complex at 14q11 but, rarely, because of the variant translocation t(7;10)(q35;q24) that contains chromosome 7 breakpoints within the TCR ß-chain gene locus ([492] , [493]). In both instances, the HOX11 coding sequence is unaltered, but the gene becomes abundantly overexpressed in T cells. Although the exact role of HOX11 in malignant transformation remains to be elucidated, the high-level expression of the gene in T lymphocytes has been demonstrated to be lymphomagenic in transgenic mice ([494]). A mean age of tumor onset of 7.5 months, together with the fact that only approximately one-third of animals develop malignancy, indicate the necessity for additional genetic changes to cooperate with HOX11 to generate a fully transformed phenotype. This observation is congruous with the results of studies in which murine hematopoietic precursors were transduced with HOX11 retroviral expression vectors to produce immortalized and immature, but IL-3 factor-dependent, nonleukemogenic cell lines ([495]).

Expression of the HOX11L2 gene, located at human chromosome band 5q34-q35, is activated in T-cell malignancy by the frequently cryptic t(5;14)(q35;q32), which has been reported in 22% of children and adolescents with T-cell ALL ([466]), and by the less frequent t(5;14)(q34;q11) that results in recombination of the HOX11L2 region with the TCR delta gene locus ([467]). Other studies have reported that HOX11L2 expression may occur aberrantly in an even higher percentage of T-cell malignancies, suggesting it to be the most frequent abnormality identified in childhood T-cell acute lymphoblastic leukemia to date, and have associated the abnormal expression of the gene with a poor clinical prognosis ([468] , [469] and [470]). HOX11L2 is similar to HOX11, and microarray analysis of T-cell malignancies aberrantly expressing either gene show marked similarities in the associated gene expression profiles ([469]); surprisingly, although HOX11L2 overexpression has been associated with a poor outcome, overexpression of HOX11 in T-cell acute lymphoblastic leukemia seems to denote a favorable prognosis, although more studies are required to confirm this observation. HOX11L2 (also called *Rnx* and *Tlx-3*) is normally expressed in the nervous system, and studies in lower vertebrates have suggested at least partial functional redundancy of the gene with HOX11 ([496] , [497]). However, the mouse knockout of Hox11L2 possesses a phenotype distinct from that of Hox11(Tlx-1)-null mouse, with absence of the gene causing a lethal central hypoventilation defect due to abnormal development of the ventral medullary respiratory center ([498]).

The so-called 8p11 myeloproliferative syndrome (EMS)/stem cell leukemia-lymphoma syndrome (SCLL), first described in 1995 ([499] , [500]), is a rare chronic myeloproliferative disorder that is characterized by marked eosinophilia in 90% of patients, generalized lymphadenopathy, and frequent development of T-cell lymphoblastic lymphomas ([501]). Of the approximately 30 cases reported in the literature as of 2003, the median age at presentation was 32 years of age (with a range from 3 to 84 years of age). The appearance of the peripheral blood in EMS/SCLL at presentation resembles, in some respects, chronic myeloid leukemia, with marked leukocytosis present in almost all patients, and the predominant cell types being neutrophils, metamyelocytes, and myelocytes. Most patients rapidly progress to acute myeloid leukemia or, less commonly, B-cell–lineage ALL, with the median time to transformation, based on the available case reports, probably between only 6 and 9 months. In spite of aggressive chemotherapy with acute myelogenous leukemia and NHL treatment protocols, most patients with EMS/SCLL die from resistant disease or early relapse within 1.5 years of diagnosis, and only aggressive chemotherapy followed by allogeneic stem cell transplantation has thus far appeared to offer the hope of cure in a few patients. Lymphoblastic lymphoma, which is uncommonly observed in other myeloproliferative disorders, is seen in more than two-thirds of EMS/SCLL cases, suggesting that the cell targeted for malignant transformation in this disorder is a lymphoid-myeloid bipotential precursor cell. The lymphoma presents at diagnosis in some cases, whereas it appears during the course of the disease in others.

Several chromosomal translocations, all involving chromosome band 8p11, have been described in karyotypes of EMS/SCLL cases, with t(8;13)(p11;q12) being the most common. Molecular cloning of the t(8;13) in 1998 showed it to produce a fusion of approximately the N-terminal two-thirds of a novel protein encoded on 13q12 and named *ZNF198* that contains zinc-fingerlike motifs with the entire kinase catalytic domain of the FGFR1, starting immediately downstream of the transmembrane domain of this receptor tyrosine kinase ([502], [503], [504] and [505]). Several of the other translocations occurring in EMS/SCLL have also recently been molecularly cloned (reviewed in reference 501); all involve the FGFR1 gene located at 8p11 and form similar fusions but with N-terminal partners other than ZNF198. All of the described N-terminal partners of the FGFR1 contain putative dimerization domains that are important for causing the constitutive, unregulated activation of the catalytic function of the kinase, producing an unrelenting growth signal to the cells that express them. Such a mechanism of NHL causation is highly reminiscent of the involvement of the anaplastic lymphoma kinase (ALK) receptor tyrosine kinase by its truncation and the generation of various ALK fusions resulting from chromosomal rearrangements in the ALCLs, as described in the following section. The dramatically positive results recently observed for the adenosine triphosphate–competitive small molecule inhibitor STI-571, imatinib (Gleevec/Glivec, Novartis Pharmaceuticals, Basel, Switzerland), in the treatment of chronic myeloid leukemias ([506]), in which an identical mechanism of oncogenesis is operative (i.e., truncation and constitutive activation of the Abelson (ABL) tyrosine kinase due to its fusion with the N-terminus of the breakpoint cluster region (BCR) protein resulting from the t(9;22) chromosomal rearrangement), holds promise that analogous small molecule inhibitors of the FGFR1 could also be effective therapies for EMS/SCLL, although this remains to be determined.

LARGE CELL LYMPHOMA: BCL6 AND FUSION GENES INVOLVING ALK

The large cell lymphomas account for 30 to 40% of newly diagnosed NHL and as much as 80% of NHL mortality ([507]). Before the 1990s, relatively little was known about the molecular pathogenesis of these lymphomas. Although studies had identified rearrangements of the *cMYC* and *BCL2* gene loci in 5 to 20% and 20%, respectively, of diffuse large cell cases ([324], [508]), these abnormalities are not specific to the large cell lymphomas, being most commonly associated with Burkitt lymphoma (cMYC) and FL (BCL2) ([324], [509], [510], [511] and [512]). In large cell cases with BCL2 involvement, the abnormality may often reflect the histologic transformation from a prior FL ([323]). As detailed in the following discussion, the cloning in the early 1990s of the chromosomal junctions of translocations in the large cell lymphomas that involve band 3q27 ([513], [514], [515], [516] and [517]), together with the characterization of the t(2;5)(p23;q35) and other translocations that involve band 2p23 that are found in the ALCL subtype ([518], [519]), has added significantly to our knowledge of the genetics of these tumors.

Karyotypic analysis of the large cell lymphomas (including diffuse large cell, diffuse mixed cell, and immunoblastic) has identified chromosomal abnormalities affecting band 3q27 in 10 to 12% of cases ([520], [521]). These abnormalities involve reciprocal translocations between the 3q27 region and a number of alternative chromosomes (more than ten), but most commonly the Ig heavy (14q32) or light (2p12; 22q11) chain loci. The gene on 3q27 altered by these translocations encodes a transcription factor of the Kruppel-like subfamily of zinc finger proteins ([522]) and has been officially named BCL6 (formerly also called *LAZ3* or *BCL5*) ([515], [517], [523], [524]). The amino-terminal portion of BCL6 contains a POZ domain ([525], [526]), a protein–protein interaction motif found in some zinc finger transcription factors, including the *Drosophila* developmental regulatory genes tramtrack ([527], [528]) and broad complex ([529]) and the human PLZF gene that is involved in occasional cases of acute promyelocytic leukemia ([530]). The POZ domain of BCL6 has been shown to mediate homodimerization of the protein, to target its subcellular localization to discrete nuclear dots, and to function as an autonomous transcriptional repression domain ([531], [532] and [533]). The fact that POZ domains can mediate protein–protein heterodimerization ([525], [526]) raised the possibility that BCL6 could act in conjunction with other POZ domain-containing transcription factors, as well as other transcription-modulating proteins—a prediction that has proved correct (*vide infra*). A specific DNA sequence to which BCL6 binds has been identified; in addition, the protein has been experimentally shown to decrease the transcription from promoters linked to this sequence, suggesting that the normal function of BCL6 is to inhibit the expression of its target genes ([531], [534], [535] and [536]).

Normal BCL6 expression is tightly regulated during B-cell development, being expressed in mature B cells but not in their precursors or their more mature progeny (i.e., immunoblasts and plasma cells) ([537], [538], [539], [540] and [541]). Within the lymph nodes, BCL6 expression is present only within the germinal centers, the structures in which antigen-primed mature B cells are programmed to undergo apoptosis, to become memory B cells, or to undergo immunoblast and plasma cell differentiation ([542], [543]). BCL6 was therefore thought to be important for germinal center–associated functions ([544]); analysis of knockout mice has supported this hypothesis, with Bcl6-null mice exhibiting an inability of follicular B cells to proliferate and to form germinal centers ([545], [546] and [547]). As a consequence of this defect, these mice have defects in their T-cell–dependent antibody responses to antigenic challenge. Bcl6 knockout mice also experience an inflammatory state characterized by myocarditis and pulmonary vasculitis with infiltrations of eosinophils and IgE-expressing B lymphocytes, due, at least in part, to an abnormal overproduction of Th2-like lymphokines, including IL-4, IL-5, IL-6, and IL-13 because of the release of transcriptional repression normally mediated by Bcl6.

The frequency of BCL6 gene rearrangement detected by molecular analysis significantly exceeds the 10 to 12% predicted by the cytogenetic study of 3q27 abnormalities in large cell lymphoma, indicating that rearrangements may also occur as a consequence of submicroscopic chromosomal abnormalities. Approximately one-third of large cell lymphomas have BCL6 gene rearrangement identified by Southern blot hybridization analysis; rearrangement of the locus occurs in as many as 45% of pure diffuse large cell cases and also, less often, in lymphomas with diffuse, mixed, small and large cell histology (10 to 20%) ([548], [549], [550], [551] and [552]). AIDS-associated DLCLs have been shown to contain BCL6 gene rearrangement in 20% of cases ([553]). BCL6 gene rearrangement is not uniquely restricted to large cell lymphoma, however, having also been identified in 5 to 14% of FLs ([515], [548], [549], [551], [552]). BCL6 rearrangements tend to occur exclusive of rearrangement of BCL2, suggesting that BCL6 is probably specifically involved in the pathogenesis of *de novo* large cell lymphoma as opposed to large cell tumors that result from the transformation of FL ([531]). Rearrangement of BCL6 has been associated with lymphomas characterized by the primary involvement of extranodal tissues and the lack of bone marrow involvement in a high percentage of cases ([531]). It has also been suggested that BCL6 alterations may be associated with lymphomas that have a favorable prognosis after chemotherapy ([550]), although this correlation has not been readily apparent in all studies ([549]).

All BCL6 breakpoints occur in or around the first exon, which is not translated, and leave the coding region of the gene intact but inserted downstream to heterologous sequences derived from the translocation partner chromosome. The BCL6 translocations that have been fully characterized thus far have been shown to result in the deregulated expression of a normal BCL6 protein because of promoter substitution ([554], [555] and [556]). The ultimate consequence of these alterations appears to be to prevent the physiologic down-regulation of BCL6 subsequent to B-cell differentiation into plasma cells ([537], [538] and [539], [544]).

In addition to chromosome translocation, involvement of BCL6 in large cell and FLs can occur as a result of somatic mutations that cluster in the same 5' noncoding region of the gene in which the 3q27 breakpoints occur ([557]). These mutations are often multiple and biallelic, are present in cases containing normal or rearranged BCL6 alleles, and therefore occur independently of mechanisms involved in chromosomal translocation. Similar high-frequency mutation (somatic hypermutation) ([59], [60], [61] and [62]) of cMYC and BCL2 has also been reported when these genes are translocated adjacent to Ig loci in lymphomas ([109], [112], [113], [558], [559]). Somatic hypermutation of the BCL6 locus presumably occurs by the same mechanisms operative in the cases of BCL2 and cMYC, but appears to be unique in that it can also occur in the absence of physical juxtaposition of Ig gene loci ([557]). Mutations of BCL6 were observed in almost three-fourths of diffuse large cell and one-half of FLs, indicating that this is a common form of genetic instability that may implicate BCL6 in the pathogenesis of a high percentage of NHL.

As noted previously, BCL6 functions as a transcriptional repressor; targets for BCL6-mediated repression have been reported to include the IL-4 and IL-5 Th2-type cytokines, the programmed cell death-2 (PDCD2) protein, and certain signal transducer and activator of transcription (STAT) protein transcriptional targets, among others ([545], [560], [561], [562], [563], [564], [565], [566] and [567]). Decreased expression of B-lymphocyte–induced maturation protein 1 (Blimp-1), a transcriptional repressor that plays a key role in the normal differentiation of B cells to mature plasma cells, and of the p27/Kip1 CDKI by BCL6 also appear important for lymphomagenesis ([562], [568]). Inhibition of gene expression by BCL6 is mediated by a protein complex containing the co-repressors SMRT and mSIN3A as well as HDACs ([569], [570] and [571]). BCL6-mediated transcriptional repression also likely involves physical interactions with other transcriptional regulators, including PLZF, BAZF, and BCL11A/Evi-9. PLZF is related to BCL6 and encodes a transcription factor also belonging to the POZ domain and Kruppel zinc finger family. BCL6 and PLZF heteroassociate and colocalize in the nuclei of cells; like BCL6, PLZF strongly represses transcription initiated from various promoters by recruiting a HDAC through SMRT-mSIN3-HDAC complexes ([572], [573]). BAZF (*B*cl6- *a*ssociated *z*inc *f*inger protein) is another POZ domain and Kruppel-like zinc finger protein that physically interacts with BCL6; BAZF binds to the same DNA-binding sequence as BCL6 and also functions as a transcriptional repressor ([574], [575]). Recent studies suggest that BAZF itself does not bind to a repressor complex and that its transrepressor activity is actually mediated by recruiting an mSin3A-HDAC complex through association with BCL6 ([576]). BCL11A is a Kruppel zinc finger protein and is the human homolog of the mouse Evi-9 gene, which is deregulated in myeloid leukemias after proviral integration ([577]). BCL11A itself is the target gene deregulated in B-cell malignancies by a rare but recurrent t(2;14)(p13;q32) chromosomal rearrangement as well as by DNA coamplification with the REL gene locus at 2p13 ([578], [579] and [580]). BCL11A physically interacts with BCL6 and, like BCL6, represses transcription. BCL11a-null mice lack B cells and also have alterations in several types of T cells, pointing out the importance of the gene in the normal development of the lymphoid system ([581], [582]).

The exact interplay among PLZF, BAZF, BCL11A, and BCL6 normally and during lymphomagenesis has not yet been clarified.

Taken together, the available data regarding normal BCL6 function permit the following explanation for the role of the protein in lymphomagenesis. Because the translocations in NHL that alter the BCL6 locus result in constitutive overexpression of the normal protein, they prevent the normal down-regulation of BCL6 that occurs on plasmacytic differentiation. Thus, lymphomas with BCL6 activation would maintain repression of BCL6 target genes, trapping the neoplastic lymphocytes at the germinal center stage of differentiation. As noted, repression of Blimp-1 by BCL6 may be especially important for malignant transformation, in part because Blimp-1 acts as a transcriptional repressor of cMYC; as such, Blimp-1 can cause growth arrest and terminal plasmacytic differentiation or apoptotic death ([568]). Repression of Blimp-1 by BCL6, which in turn allows cMYC expression, would permit continued cell growth and prevent differentiation. The repression of p27/KIP1 by BCL6 is likely also critical for malignant transformation given that this CDKI functions to arrest the cell cycle in response to extrinsic signals at the G_1 to S phase transition ([583] , [584]). Thus, repression of p27/KIP1 by BCL6 would allow inappropriately regulated proliferation. BCL6 has also recently been demonstrated to override the senescence of cells downstream of p53 and to extend the replicative lifespan of primary B cells; these effects, which appear to require the induction of cyclin D1 expression, thus render cells unresponsive to antiproliferative signals produced by the $p19^{ARF}$-p53 pathway as well ([585]).

The t(2;5)(p23;q35) is the other commonly occurring nonrandom chromosomal rearrangement associated with large cell NHL. The t(2;5) was originally identified in karyotypic analyses of NHL as a recurrent cytogenetic abnormality found in a significant but uncertain percentage of ALCLs that express the Ki-1 (CD30) antigen ([586] , [587] , [588] , [589] , [590] , [591] and [592]), a cytokine receptor for a ligand related to the tumor necrosis factor family ([593] , [594]). ALCL itself was first described by Stein et al. ([595]) in 1985 and was soon recognized as a distinct clinicopathologic entity in the revised Kiel ([11]) and REAL ([12]) classifications. More recently, as mentioned in a following discussion in detail, the so-called ALK-positive lymphomas, which comprise a distinct subset of ALCL that possesses unique biologic characteristics, have been recognized in the WHO classification of NHL ([596]). ALCL, which occurs with a bimodal age distribution that peaks in adolescents and again in older adults, constitutes approximately 2.5% of all NHL but accounts for as many as 30 to 40% of pediatric large cell lymphomas ([591] , [597] , [598] , [599] , [600] , [601] , [602] , [603] , [604] and [605]). These lymphomas are pathologically defined based on the presence of large malignant cells containing pleomorphic nuclei, clumped chromatin, prominent nucleoli, and abundant cytoplasm that preferentially involve the paracortical regions of the lymph nodes, with intrasinusoidal dissemination ([598] , [605]). Because of their anaplastic features, ALCLs can often be misdiagnosed as other conditions, including Hodgkin disease, malignant histiocytosis, mycosis fungoides, malignant melanoma, poorly differentiated metastatic carcinoma to lymph nodes, or even lymphadenopathic viral infections ([602] , [606]). In fact, the t(2;5) was actually first described in the tumor of a patient erroneously diagnosed with malignant histiocytosis ([607]). The diagnosis of ALCL can be further confounded by the existence of several variant pathologic forms, including monomorphic ([608] , [609]), small cell ([610]), microvillous ([611]), lymphohistiocytic ([612]), and the “Hodgkin-like” ([613] , [614]) variants. The characteristics of these variant pathologic forms have been nicely reviewed recently by Kinney and Kadin ([615]), Falini ([616]), and Morris et al. ([617]). Immunophenotypic analysis of ALCL reveals the majority of cases to express T-lymphoid markers (75%); less commonly, these neoplasms bear B-cell markers (approximately 15%) or have a null phenotype with neither B- nor T-antigen expression (approximately 10%).

Clinically, ALCLs typically behave as aggressive, high-grade lymphomas, with patients exhibiting peripheral lymphadenopathy and extranodal disease involving skin, bone, soft tissue, gastrointestinal tract, or lung, or a combination of these ([591] , [597] , [601] , [602] , [604] , [618] , [619] , [620] and [621]). Despite their aggressive nature, these tumors are chemosensitive at diagnosis and relapse; however, 20 to 30% of patients do eventually succumb because of refractory disease ([591] , [592] , [599] , [600] , [601] , [602] , [603] and [604] , [622] , [623]). A primary cutaneous form of ALCL that is characterized by the absence of nodal or visceral involvement at presentation and an indolent course with spontaneous remission, low recurrence rate after therapy, and infrequent visceral dissemination has also been described ([624] , [625]). Primary cutaneous ALCL is quite difficult to distinguish from lymphomatoid papulosis (LyP), a monoclonal proliferation of $CD30^+$ T cells involving the skin, that is likewise characterized by absent visceral involvement, spontaneous remission, and rare progression to frank malignant lymphoma ([626] , [627]). The t(2;5) and other translocations affecting chromosomal band 2p23 are not, however, a feature of primary cutaneous $CD30^+$ lymphoproliferative disorders nor of the lymphomas resembling ALCL that have been reported in HIV-infected patients ([606] , [628] , [629] , [630] , [631] , [632] , [633] and [634]).

Molecular analysis of the ALCLs has suggested that cMYC is mutated in a relatively high percentage of cases (approximately one-third), especially in those of B-cell lineage and in those that are HIV-associated ([635] , [636]). Activation of cMYC may also play a significant functional role in ALK-positive ALCLs, given that the NPM-ALK fusion protein (*vide infra*) appears to induce cMYC expression ([637]). The receptor for hematopoietic stem cell growth factor, c-KIT, also appears to be expressed in a high percentage of ALCL, although the functional significance of its presence remains to be defined ([638]). Other genes commonly altered in hematopoietic malignancy, including BCL2, the RAS family, p53, and Rb, are not often mutated in ALCL, however ([635]). Several studies have suggested that human T-cell leukemia virus type 1 ([639]) or EBV ([635] , [640] , [641]), or both, may also be important in the pathogenesis of some ALCL cases. For example, approximately 30% of all ALCLs involving the skin are positive for human T-cell leukemia virus type 1, and 30 to 35% of all ALCLs contain EBV genomes and EBV-specific products ([614] , [642] , [643]). As the expression of an activated cMYC gene has been experimentally demonstrated to produce the malignant conversion of EBV-infected human B lymphoblasts ([131]), it is possible but not proven that these genetic abnormalities are of pathogenic importance in a subset of ALCL.

The molecular cloning of the t(2;5) in 1994 revealed that this chromosomal rearrangement produces a fusion gene, NPM-ALK, encoding the amino-terminal portion of nucleophosmin, a nucleolar phosphoprotein encoded on chromosome 5, linked to the cytoplasmic part of ALK, a receptor tyrosine kinase of the insulin receptor subfamily that is closely related to leukocyte tyrosine kinase, on chromosome 2 (Fig. 89.2A) ([644] , [645]). NPM is a highly conserved and ubiquitously expressed 38-kd nonribosomal RNA-binding protein that shuttles ribosomal ribonucleoproteins between the nucleolus and the cytoplasm and is involved in the late stages of preribosomal particle assembly ([646] , [647] , [648] , [649] , [650] , [651] and [652]); NPM has also recently been reported to control centrosome duplication initiated by CDK2–cyclin E–mediated phosphorylation of the protein and therefore to be critical for the normal progression through mitosis ([653]). It is presently unclear whether either of these normal functions of NPM (or alterations of them) play a significant role in the development of ALCL, but the fact that a number of other proteins with different normal functions are also known to form N-terminal fusion partners with ALK (*vide infra*) suggests that these NPM functions are dispensable for oncogenesis. ALK is normally expressed mainly in the central and peripheral nervous systems ([654] , [655]), but the normal functions of this receptor tyrosine kinase remain unclear, and mice engineered to lack expression of the protein have a normal lifespan and no grossly evident abnormalities ([645]). The growth factors that bind and activate ALK normally are the small secreted proteins pleiotrophin and midkine ([656] , [657]). Interestingly, the deregulation of each of these ALK ligands has been implicated in the genesis of a variety of solid tumors via mechanisms involving autocrine tumor growth loops, as well as the promotion of tumor-associated angiogenesis (for example, see reference [658]); thus, the inappropriate activation of the full-length ALK receptor may be of pathogenic importance in these solid tumors, just as constitutively active ALK fusion proteins contribute to the genesis of ALCL.

Figure 89.2. A: Schematic of the anaplastic lymphoma kinase (ALK) receptor tyrosine kinase and the NPM-ALK fusion protein resulting from the t(2;5). Fusion of the chromosome 5 gene encoding nucleophosmin (NPM) to the chromosome 2 gene encoding ALK generates the chimeric tyrosine kinase, NPM-ALK. NPM contains an oligomerization domain (OD) (residues 1 to 117) a putative metal-binding domain (MB) (residues 104 to 115), two acidic amino acid clusters (AD) (aspartic acid/glutamic acid–rich acidic domain; residues 120 to 132 and 161 to 188) that function as acceptor regions for nucleolar targeting signals, and two nuclear localization signals (NLSs) (residues 152 to 157 and 191 to 197). ALK contains a single MAM (*M*eprin, *A*5, and protein tyrosine phosphatase *M*u) domain, a region of approximately 170 amino acids present in the extracellular portions of a number of functionally diverse proteins that may have an adhesive function (residues 480 to 635). The ligand-binding site (LBS) for pleiotrophin and midkine (ALK residues 391 to 401) is indicated. **B:** ALK fusion proteins, the chromosomal rearrangements that generate them, their occurrence in ALK-positive lymphomas and inflammatory myofibroblastic tumors (IMTs), and their subcellular localizations. The frequency of the various ALK fusions expressed in IMT has not yet been determined. ATIC, 5-aminoimidazole-4-carboxamide ribonucleotide formyltransferase/IMP cyclohydrolase; C, cytosolic; CM, cell membrane; CLTC, clathrin heavy chain; MSN, moesin; N, nuclear; NM, nuclear membrane; RanBP2, Ran-binding protein 2; TFG, TRK-fused gene; TK, tyrosine kinase catalytic domain; TM, transmembrane domain; TPM3, non-muscle tropomyosin-3; TPM4, non-muscle tropomyosin-4.

As a result of the t(2;5), the transcription of the portion of the ALK gene encoding its kinase domain is driven by the strong NPM gene promoter, leading to its inappropriate expression in lymphoid cells (in which little or no ALK is normally expressed) (519 , 644). In addition, as a result of NPM-ALK homooligomerization mediated by the NPM portion of the fusion (which contains a self-association domain), the ALK kinase catalytic function is constitutively activated and can engage and activate mitogenic signaling substrate proteins by their phosphorylation (645 , 659 , 660). The oncogenic ability of NPM-ALK can be readily demonstrated by *in vitro* transformation assays using immortalized rodent fibroblast lines, such as NIH-3T3 (659 , 660). Furthermore, lethally irradiated mice transplanted with bone marrow that expresses NPM-ALK have been demonstrated to develop lymphomas after a 3- to 4-month latency period, leading to death (661), and transgenic mice engineered to express NPM-ALK in their lymphoid cells develop both T- and B-cell lymphoproliferative malignancies that are rapidly fatal (mean survival, 18 weeks) (662).

The cloning of the t(2;5)-associated NPM-ALK fusion permitted the development of RNA-PCR, DNA-PCR, FISH, and Southern blot hybridization assays for the diagnosis of NHL containing this abnormality (606 , 629 , 663 , 664 , 665 , 666 , 667 and 668). In addition, because ALK is not normally expressed at significant levels in lymphoid cells, immunohistochemical staining of biopsy samples with anti-ALK antibodies can be used to reliably detect expression of the NPM-ALK chimeric protein in ALCL (33 , 623 , 634 , 669 , 670 and 671). Because as much as one-third of ALCLs are initially misdiagnosed based on histologic morphology alone (602 , 606), the use of these assays for NPM-ALK should be considered to clarify the diagnosis in those cases in which ALCL is considered in the differential diagnosis.

Anti-ALK immunohistochemical staining of NPM-ALK–expressing ALCL cases shows a typical staining pattern, in which the chimeric protein is present in the cytoplasm and the nucleus of the tumor cells (for example, see reference 672). The dual cytoplasmic and nuclear localization of NPM-ALK in tumor cells is due to its heterooligomerization with NPM, which includes among its normal functions the bidirectional shuttling of proteins between the cytoplasm and nucleus; thus, a portion of the NPM-ALK protein, which lacks any nuclear localization signals of its own, is transported to the nucleus (660 , 673). However, approximately 20 to 25% of ALCLs that stain positively for ALK (the so-called ALK-positive lymphomas or ALKomas) exhibit anti-ALK staining in the cytoplasm of the tumor cells only, and, when examined, these cases have been shown to possess variant chromosomal translocations involving the ALK gene locus at chromosome 2p23 but not the NPM gene from chromosome 5. In addition, immunoblotting with ALK- and NPM-specific antibodies has revealed variant ALK proteins that have different molecular masses as compared to the 80-kd NPM-ALK protein and that do not contain NPM (674). Over the past 5 years, a number of these variant ALK rearrangements have been molecularly cloned, and the ALK fusion partners have been identified. Included among these variant ALK fusion proteins are nonmuscle tropomyosin-3 (TPM3)–ALK, 5-aminoimidazole-4-carboxamide ribonucleotide formyltransferase/IMP cyclohydrolase (ATIC)–ALK, CLTC (clathrin heavy chain)–ALK, TRK-fused gene (TFG)–ALK, and moesin (MSN)–ALK, listed in the approximate order of their frequency in ALK-positive lymphomas (Fig. 89.2B) (see references 616 , 617 , and 645 for reviews). Interestingly, although ALK fusion proteins are found mainly in T- and null-cell NHLs, recent studies suggest that occasional DLBCLs can also be ALK positive, with CLTC-ALK and NPM-ALK fusions reported in such cases (675 , 676 , 676a).

The same basic cellular transforming mechanism appears to be operative for NPM-ALK and the variant ALK fusions. Specifically, the N-terminal portion of the particular ALK partner protein present in a given *X-ALK* fusion contains some form of oligomerization domain that mediates constitutive self-association of the X-ALK protein, which in turn mimics the receptor aggregation and kinase catalytic activation that normally occurs only on pleiotrophin or midkine binding to the full-length ALK receptor protein. Because these fusion proteins are constantly kinase active, they transmit unremitting mitogenic signals to cells that express them, resulting in uncontrolled proliferation. This mechanism for acquisition of oncogenic capabilities by tyrosine kinases is a commonly repeated one, not only for hematopoietic malignancies but for solid tumors as well (677). Indeed, ALK itself has recently been shown to participate in the genesis of a nonhematopoietic malignancy, the sarcoma known as *inflammatory myofibroblastic tumor (IMT)*, with some of the same ALK fusion proteins that occur in ALCL being of pathogenic importance in IMT as well (Fig. 89.2B). IMTs, which affect mainly children and young adults and are composed histopathologically of malignant myofibroblasts together with infiltrating normal reactive lymphocytes, eosinophils, and plasma cells, are typically indolent tumors and can be cured by surgical resection in most cases; however, cases of locally invasive and metastatic IMTs have been described (678 , 679). A recent study of IMTs has shown 44 of the 73 cases examined (60%) to aberrantly express ALK proteins (680); therefore, ALK deregulation appears to be of causative importance in a majority of IMTs. Thus, although the histologic appearance of IMT is not likely to be confused by an experienced pathologist, it is nonetheless important to remember that the expression of an ALK fusion protein in a malignant tumor does not invariably equate with a diagnosis of ALCL.

The molecular cloning of NPM-ALK and the variant ALK fusions and the ability to readily detect their presence in diagnostic samples using immunostaining, RNA-PCR, and other methodologies has now permitted a clear description of the clinicopathologic characteristics of the ALK-positive lymphomas. For example, it is clear that histologically defined ALCL is associated with the expression of ALK fusions in only approximately two-thirds of all cases, with NPM-ALK found in approximately 75% of ALK-positive cases and the variant ALK fusions comprising the remaining 25%. Although they are histologically indistinguishable from ALK-positive ALCLs, the molecular pathogenic mechanisms underlying the development of ALCLs that lack expression of ALK fusions (*ALK-negative ALCLs*) do not appear to involve the deregulation of tyrosine kinase activity (681) and remain unknown at this time. As it turns out, the expression of ALK fusions in ALCL defines a distinct clinicopathologic entity that is not strictly associated only with anaplastic morphology; rather, many cases are not anaplastic appearing at all, having instead a morphological spectrum that includes monomorphic diffuse large cell, small cell-predominant, and lymphohistiocytic types, among others (615 , 616 and 617). All of the described histologic variants of ALCL have been reported to express ALK fusions in a percentage of cases, including the common or classic large cell type of ALCL that can be subdivided into pleomorphic (which itself contains multiple subtypes, including the giant cell, neutrophil-rich, sarcomatoid, and signet ring variants) or monomorphic categories, the small cell variant, the lymphohistiocytic variant, and the provisional entity that is known as *ALCL, Hodgkin-like*. However, the percentage of cases that contain ALK fusions varies markedly among the histologic variants, ranging from greater than 80% of monomorphic ALCLs and 75 to 100% of the small cell variant to less than 15% of the Hodgkin-like cases (615 , 616 and 617). ALK-positive ALCLs are primarily T- or null-cell tumors, with frequent expression of epithelial membrane antigen and cytolytic granule proteins. Overall, approximately 10 to 20% of ALCLs have a B-cell phenotype, but generally less than 15% (with a range from 0 to 25%, depending on the specific study) of B-cell ALCLs have been shown to be ALK positive (617).

ALK-positive ALCLs occur predominately in children and young adults. For example, Pulford et al. (682) identified ALK expression in 88.5% of 26 children, but in only 34% of 47 adults with CD30 $^{+}$ ALCL. Similarly, Falini et al. (683) examined 96 CD30 $^{+}$ ALCLs (58 ALK-positive and 38 ALK-negative) and found the mean age of the ALK-positive cases to be 22.01 years of age (with a range from 3 to 52 years of age), whereas ALK-negative cases occurred at a mean age of 43.33 years. The tendency for ALK positivity in ALCL to be higher in children than adults reflects, at least in part, the significant number of secondary ALCLs (i.e., ALCLs that have evolved from lymphomas of other histologic subtypes) that occur uniquely in older patients. Most patients with ALK-positive lymphoma present with systemic nodal (with or without extranodal) disease, and the so-called primary systemic form of ALCL is the form specifically associated with the expression of ALK fusions (*vide infra*). Carefully randomized trials of uniformly treated and age-matched patients comparing the prognosis of ALK-positive with ALK-negative ALCL have yet to be performed; however, large retrospective clinical trials examining overall and event-free survival of NHL patients have suggested that ALCL as a whole has a significantly better outcome than non-ALCL subtypes. Furthermore, in almost all studies published, ALK-positive ALCL patients have fared dramatically better than those with ALK-negative disease after conventional combination chemotherapy, with overall 5-year survival rates of 79 to 88% compared to 28 to 40%, respectively (summarized in reference 617). It appears that the superior prognosis of ALK-positive ALCL occurs irrespective of the specific ALK fusion that is expressed, with the variant fusions being associated with an equally good outcome to that observed in the NPM-ALK–positive cases (684). The reasons for the better outcome following therapy for ALK-positive patients are unknown. The superior prognosis of ALK-positive lymphomas may occur only in T- and null-cell disease, given that B-cell NHLs that expressed ALK fusions nonetheless appeared to carry a prognosis similar to ALK-negative disease in one study (685).

In addition to the usefulness of ALK detection in establishing the diagnosis of ALK-positive primary systemic ALCL, the *absence* of ALK expression is similarly extremely useful in discriminating between this entity and its lymphoproliferative mimics, which have different natural histories. ALCL can be clinically subdivided based on sites of disease, immune status, and history of antecedent lymphoproliferative disease into primary systemic ALCL (nodal, with or without nodal involvement), primary cutaneous ALCL, HIV-related ALCL, or secondary ALCL (i.e., after LyP, Hodgkin disease or mycosis fungoides). The overall approximately 60% incidence of ALK positivity typically reported in ALCL refers specifically to the primary systemic type, with these other forms rarely, if ever, expressing ALK. Primary cutaneous ALCL typically occurs in older patients, with a median age of 60 years of age; in contrast to primary systemic ALCL, which is highly aggressive (although responsive to therapy), approximately 25% of primary cutaneous ALCLs spontaneously undergo partial or complete regression without treatment (624 , 686 , 687 and 688). Except for those patients with generalized skin involvement, who appear to be at greater risk of developing extracutaneous involvement and may benefit from multiagent systemic chemotherapy, primary cutaneous ALCL patients can be treated by excision of their lesions, with or without radiation. Thus, it is important, if possible, to discriminate between primary systemic ALCL with cutaneous involvement and primary cutaneous ALCL, which appear essentially identical histologically, for optimal treatment planning. Although the detection of ALK cannot be used to unequivocally distinguish between these two entities, ALK expression is clearly most consistent with a diagnosis of primary systemic ALCL, given that true ALK-positive–CD30 $^{+}$ primary cutaneous ALCL is rare, if existent at all. ALCL occurring in the setting of HIV infection has uniformly tested negative for ALK expression; these lymphomas represent 2 to 15% of AIDS-related lymphomas and appear to be clearly different from ALCL in patients without HIV, because most have a B-cell phenotype and are positive for EBV gene products. The prognosis of patients with ALCL in

the setting of HIV infection is usually poor and can be related in general to the immune status of the individual. Secondary ALCLs that evolve from other lymphomas or lymphoproliferative diseases usually occur in older patients and are ALK negative.

Other lymphoproliferative diseases that can mimic primary systemic ALCL, such as Hodgkin disease, LyP, and mycosis fungoides, are also ALK negative (reviewed in reference 617). Because ALCL and Hodgkin disease share a number of features in common, including CD30 expression, the presence of Reed-Sternberg–like cells in some cases of ALCL, and a similar bimodal age distribution, some investigators believed that these two lymphomas represented extremes of a continuous spectrum of malignancy ([689]). Although a few early studies performed shortly after the cloning of the t(2;5) suggested that NPM-ALK was expressed in a subset of Hodgkin disease cases, more thorough examinations of more than 800 individual cases of Hodgkin disease by multiple investigators have ruled out a role for ALK deregulation in the genesis of this malignancy. The results of these studies are consistent with the fact that the t(2;5) has not been reported in the more than 130 cases of Hodgkin disease in which karyotypes have been reported in the literature as showing chromosomal abnormalities and the observation that all nine established cell lines believed to be bona fide Hodgkin disease lines are ALK negative ([668], [671], [690], [691], [692] and [693]). Most probably, the studies in which ALK-positive Hodgkin disease cases had been reported were due to misdiagnosis (analysis of ALCL variants that are similar in histologic appearance to Hodgkin disease), sample contamination during PCR, or expression of ALK fusion transcripts in rare “normal” bystander cells [like other gene transcripts associated with malignant transformation, such as the IgH/BCL2 message associated with the t(14;18) in FLs and the t(9;22)-associated BCR-ABL fusion in chronic myeloid leukemias, the NPM-ALK fusion gene transcript can be detected by sensitive PCR-based methods in the peripheral blood of as much as 50% of healthy individuals, suggesting that the DNA recombination machinery involved in the genesis of these genetic lesions is continuously operative and that progression to malignancy likely involves the acquisition of additional, cooperating genetic mutations in affected individuals] ([694]). LyP is a clonal CD30 $^{+}$ T-cell lymphoproliferative disorder in which recurrent crops of ulcerating papules regress with scar formation in a few weeks. In 5 to 20% of cases, LyP progresses to overt lymphomas, such as Hodgkin disease, ALCL, or mycosis fungoides. This observation, together with the presence of lesions with similar histologic features shared between LyP and ALCL, indicates that LyP and primary cutaneous ALCL represent a histopathologic continuum of CD30 $^{+}$ lymphoproliferative disorders of the skin. A large number of studies have examined ALK expression in LyP and found no evidence for involvement of the gene in the genesis of the disorder (reviewed in reference 617).

Although the prognosis of patients with ALK-positive lymphoma is usually quite favorable after conventional multiagent chemotherapy, at least 20 to 30% of patients fail to respond to this treatment. Additional prognostic factors need to be identified and confirmed that permit detection of this “poor-outcome” group, so that they might be treated with alternative approaches. For instance, Nagasaka et al. ([695]) have reported a poor prognosis for ALK-positive patients whose lymphomas arise in bone, and CD56, previously shown to be a marker of high risk in acute myeloid leukemia patients, has been suggested to be a strong negative prognostic factor in a study of 143 cases of ALCL by Suzuki et al. ([696]). Although not yet available, ALK-specific targeted therapies, including adenosine triphosphate–competitive small molecule ALK tyrosine kinase inhibitors analogous to imatinib (which is used for the treatment of BCR-ABL–induced chronic myeloid leukemia) ([506]) are under development and will likely be beneficial for the treatment of patients refractory to conventional chemotherapy (and perhaps ultimately as a component of initial therapy as well).

MUCOSA-ASSOCIATED LYMPHOID TISSUE LYMPHOMA: API2-MALT1 AND BCL10

The REAL classification separates NHLs that arise from the marginal zone B cells into three distinct disorders—primary nodal marginal zone lymphomas, primary splenic marginal zone lymphomas, and extranodal lymphomas of the mucosa-associated lymphoid tissue (MALT) type ([12]). Although these disorders share a CD5 $^{-}$ and CD10 $^{-}$ B-cell phenotype, they have subtle morphologic differences and distinct clinical behaviors, suggesting that their pathogenesis differs ([697], [698], [699], [700], [701] and [702]). Marginal zone lymphomas of MALT are the most common type of lymphoma arising in extranodal locations and account for 5 to 10% of all NHLs ([703]). MALT lymphomas have frequent multicentric extranodal involvement including the gastrointestinal tract, lung, thyroid, and mammary, salivary, and lacrimal glands, and typically exhibit an indolent clinical course. These lymphomas usually originate in the setting of chronic inflammation triggered by infection or autoimmune disorders, including *Helicobacter pylori* gastritis, Sjögren syndrome, and Hashimoto thyroiditis. Abnormal B-cell proliferation in early, low-grade gastric MALT tumors is dependent in part on *H. pylori*–specific tumor-infiltrating T cells, and eradication of *H. pylori* by antibiotic treatment results in tumor regression in most, but not all, of these patients ([704]). Molecular genetic studies in the MALT lymphomas had lagged behind other subtypes of NHL until recently; in 1999, however, two recurrent chromosomal changes in these tumors—the t(11;18)(q21;q21) and the t(1;14)(p22;q32)—were characterized at the molecular level.

Three groups of investigators independently showed the t(11;18) rearrangement to produce a fusion of API2 (also known as *cIAP2*, *HIAP1*, or *MIHC*) at 11q21, which encodes an inhibitor of apoptosis protein (IAP), to a gene at 18q21 named *MLT* or *MALT1* (for *MA*LT *l*ymphoma-*a*ssociated *t*ranslocation) ([705], [706] and [707]) (Fig. 89.3A). MLT/MALT1 was also identified by an unrelated experimental approach to encode a caspase-related protein, leading to its alternative designation, *human paracaspase* (*hParacaspase*) ([708]). API2 belongs to a family of IAPs first identified in baculoviruses, in which they suppress host cell apoptotic responses to viral infection; five human IAPs have been identified—NIAP, API1 (also named *cIAP1*, *HIAP2*, and *MIHB*), API2, XIAP-hILP, and survivin ([709]). IAPs contain from one to three baculovirus inhibitor of apoptosis repeat (BIR) motifs, a caspase recruitment domain (CARD), and a C-terminal zinc-binding RING finger domain (the latter being found in all IAPs except NIAP and survivin) ([710], [711]). IAP-1 and -2 were originally identified as proteins recruited to the tumor necrosis factor receptor (TNFR) II cytoplasmic domain via association with the TNFR-associated factors (TRAFs), TRAF-1 and -2. API2 is highly expressed in lymphoid cells in the spleen and thymus and suppresses apoptosis by binding and inhibiting caspases-3 and -7, as well as the cytochrome c-mediated activation of caspase-9 ([709]). Engineered mutant IAPs that contain only BIR domains can bind and inhibit caspases, emphasizing the importance of these motifs ([712]). The MLT/MALT1/hParacaspase gene is highly expressed in peripheral blood mononuclear cells, at moderate to weak levels in bone marrow, thymus and lymph nodes, and at high levels in hematopoietic cell lines of T-cell, B-cell and myeloid lineages, suggesting a normal function in blood cell growth ([705], [706] and [707]).

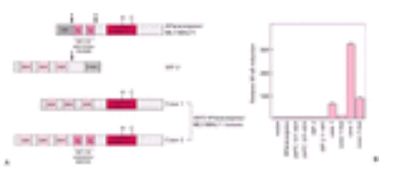

Figure 89.3. A: Schematic of the normal MALT1 and IAP-2 proteins and two examples of the fusion proteins generated by the t(11;18)(q21;q21) in MALT lymphomas. Selected motifs found in MALT1 [also known as *MLT1* or *human paracaspase* (*hParacaspase*)] and IAP-2 (also known as *AIP2*, *HIAP1* or *MIHC*) are shown. The caspase recruitment domain (not shown) of IAP-2 is located between the baculovirus inhibitor of apoptosis repeat (BIR) and zinc-binding RING finger domain (RING) motifs. The segment of MALT1 at which binding to BCL10 occurs is illustrated. *Downward-pointing arrows* indicate the locations of breakpoints typically found in MALT1 or IAP-2 in MALT lymphomas containing the t(11;18). The two fusions shown (*case 1* and *case 2*) are representative of the chimeric proteins created by the t(11;18); note that they differ primarily in the presence or absence of the BCL10 interaction motif from MALT1. **B:** t(11;18) Fusion proteins strongly activate nuclear factor-?B (NF-?B). The bar graph shows the relative induction of cellular NF-?B activity due to the experimentally engineered expression of the MLT/MALT1/hParacaspase protein, IAP-2, the t(11;18)-encoded fusion proteins (*case 1* and *case 2*), or selected experimentally-produced mutants of each. Note that the cells used for these experiments exhibit minimal NF-?B activity normally (“vector” control) and that expression of the two normal proteins induces no additional activity (*hParacaspase* and *IAP-2*). Likewise, truncated proteins (labeled ? *hPC 127-824*, ? *hPC 321-824*, and *IAP-2 1-441*) that contain the portions of MLT/MALT1/hParacaspase or IAP-2 present in the two t(11;18) fusion proteins shown in this figure do not increase cellular NF-?B activity. By contrast, the t(11;18) fusion proteins (*case 1* and *case 2*) dramatically enhance NF-?B function and those fusions capable of interacting with BCL10 (as for *case 2*) show synergistic NF-?B activation. Note also that experimentally produced mutant fusion proteins (*case 1 mut* and *case 2 mut*) in which the conserved catalytic cysteine present in the caspase homology domain of MALT1 was changed to an alanine residue lose most of their NF-?B–activating potential, indicating the functional importance of this portion of MALT1. The relevance of NF-?B activation to oncogenic transformation is discussed in the text and in reference 748. DD, death domain; Ig, immunoglobulin-like motif; H C, conserved cysteine/histidine catalytic diad required for the activity of traditional caspases. (Modified from Uren GA, O'Rourke K, Aravind L, et al. Identification of paracaspases and metacaspases: two ancient families of caspase-like proteins, one of which plays a key role in MALT lymphoma. Mol Cell 2000;6:961–967, with permission.)

The t(11;18) breakpoints are heterogeneous among MALT lymphoma cases, and additional complexity is introduced by alternative MALT1 (because *MALT1* is the official HUGO Gene Nomenclature Committee designation for MLT/MALT1/hParapcaspase, this name is used here subsequently to refer to the gene) splicing, resulting in different API2-MALT1 fusion transcripts. reverse transcriptase–PCR (RT-PCR) of the chimeric transcripts from a number of MALT tumors has revealed at least two breakpoints in API2 and three in MALT1, with at least four chimeric proteins predicted ([713], [714] and [715]). RT-PCR analysis has also revealed several differently sized fusion products in individual tumors, suggesting that alternative MALT1 splicing (in addition to different breakpoints) may also contribute to variable API2-MALT1 transcripts ([713]). In all cases described, however, the N-terminus of the fusions contains all three API2 BIR domains, and the RING finger is eliminated (as noted, suggesting the fusion may liberate the BIR motifs from negative control by the RING finger) (Fig. 89.3A). The presence of the CARD motif of API2 is

variable, but it is excluded from most fusions; inclusion of the CARD could potentially alter the caspase-binding abilities of the chimeric protein, given that a number of caspases (and many other proteins important in apoptosis regulation) also contain this homophilic interaction motif ([710]). The MALT1 sequences in the fusion vary significantly, with the only invariant portion present being the region of caspaselike homology in the C-terminus of the protein. The observation that the reciprocal MALT1-API2 fusion is expressed in only a subset of MALT lymphomas containing the t(11;18), together with cryptic deletions of 3' portions of API2 that would preclude expression of the reciprocal protein in other cases, suggests that the lymphomagenic properties of the t(11;18) reside solely in API2-MALT1. In addition to the use of RT-PCR, interphase and metaphase FISH seem to be robust diagnostic methods for detection of the t(11;18) ([705] , [706] and [707] , [716]).

The incidence of API2-MALT1 in all extranodal lymphomas of the MALT type in various anatomic locations has ranged from 19 to 36% in various studies, but the fusion appears especially frequent in gastric MALT lymphomas that lack a high-grade (large cell) component, being present in roughly 50% of such tumors ([713]). Despite the common origin of primary nodal, primary splenic, and extranodal MALT-type marginal zone lymphomas from the marginal zone B cells, only MALT lymphomas have been found to express API2-MALT1. In addition, no evidence for the t(11;18) has been found in any other type of NHL. API2-MALT1–containing MALT tumors have not been shown to possess a greater likelihood of transformation to large cell lymphoma, although the number of cases examined thus far is still relatively small. However, gastric MALT lymphomas that express API2-MALT1 appear capable of *H. pylori*–independent growth and thus do not regress on eradication of this infection after antibiotic therapy, as is the case in 75% or more of gastric MALT lymphoma patients ([717] , [718] and [719]). The API2-MALT1 fusion also has been reported in approximately 40% of pulmonary extranodal marginal zone B-cell lymphomas and may be associated especially with those tumors that occur in patients lacking autoimmune disease as a predisposing feature ([720]).

The exact contributions of the API2-MALT1 fusion to the genesis of MALT lymphomas remain to be determined, but inhibition of normal proapoptotic responses in marginal zone B-cells is almost certainly part of the lymphomagenic mechanism. Truncation of API2 due to the t(11;18) at its C-terminus, leaving the BIR domains in the lymphoma-associated fusion protein, may release their antiapoptotic effects from negative regulation normally mediated by the CARD and RING domains (as noted previously, the BIR domain alone is sufficient for caspase inhibition and suppression of apoptosis) ([712]), whereas overexpression of the RING domain alone increases cell death in a *Drosophila* experimental system ([721]). As discussed in subsequent sections in detail, the MLT/MALT1/hParacaspase protein appears to participate together with BCL10 in a novel NF-?B activation pathway; thus, deregulation of this normal function, perhaps leading to inappropriate activation of NF-?B signaling (and resultant antiapoptotic and proliferation-enhancing effects), may occur due to the API2-MALT1 fusion ([708] , [722]). Consistent with these likely lymphomagenic mechanisms, a recent study examining API2-MALT1–positive MALT tumor cells revealed fourfold higher proliferation and survival *in vitro* compared to t(11;18)-negative MALT lymphoma B cells ([723]).

The other recurrent chromosomal rearrangement observed in the MALT lymphomas is the t(1;14)(p22;q32), which is considerably less frequent than the t(11;18) ([724]). MALT lymphomas that contain the t(1;14) appear to grow more readily *in vitro* than those lacking the abnormality and to be more clinically aggressive. Like the t(11;18), the presence of the t(1;14) is believed to contribute to the development of *H. pylori*–independent growth of gastric MALT tumors.

In 1999, Willis et al. ([725]) and Zhang et al. ([726]) independently characterized the t(1;14), demonstrating a novel gene, BCL10, which encodes an NF-?B–activating protein, to be the 1p22 target of this genetic mutation. Intriguingly, like the *API2* gene altered in the t(11;18), *BCL10* encodes a CARD-containing protein. The CARD is a homotypic protein interaction motif of approximately 90 amino acids shared by proapoptotic (e.g., RAIDD/CRADD; CED4/Apaf-1; caspases-1, -2, -4, -5, -9, -11, and -12; CED3, and CARDIAK/RICK/RIP2) and antiapoptotic (e.g., cIAP1, cIAP2, and ARC) proteins ([710]). Many CARD-containing proteins are known to be essential for transducing death or survival signals. For example, CED3 and procaspase-9 associate with their regulatory proteins CED4 and Apaf-1, respectively, through CARD-mediated interactions that control activation of the caspase zymogens, thus leading to the induction of apoptotic cell death ([727] , [728]).

The t(1;14) results in significant overexpression of BCL10 due to juxtaposition of the gene locus adjacent to the *IgH* enhancer ([725] , [726]). BCL10 is ubiquitously expressed in normal tissues, although at relatively low abundance, as a single 2.8-kb transcript. The tissues exhibiting highest BCL10 expression are spleen, lymph node, and testis. *BCL10* is also expressed in B-cell lines transformed at all stages of differentiation, including pro–B-cell ALL, pre–B-cell ALL, Burkitt lymphoma, multiple myeloma, and EBV-immortalized lymphoblastoid lines. The 233-amino acid BCL10 protein contains a single CARD in its N-terminus and a serine-threonine–rich C-terminus. Human BCL10 shares 29% identity (35.5% similarity) with open reading frame E10 of the gamma herpesvirus equine herpesvirus 2, which is restricted to horses and causes pharyngitis and lymphadenopathy ([729]). Although not known to be lymphomagenic, equine herpesvirus 2 is highly related to herpesvirus saimiri, which causes fulminant T-cell lymphomas in primates and is only slightly less related to EBV and human herpesvirus 8 that are implicated in Burkitt lymphoma and lymphomas in immunocompromised patients.

Simultaneous with the cloning of the t(1;14), a number of research laboratories that study apoptosis regulation also published initial characterizations of BCL10 [referred to as *cE10* (*c*ellular *E10*), *CIPER* (*C*ED3/ *I*CH-1 *p*rodomain homologous *E*10-like *r*egulator), *CLAP* (*C*ARD- *l*ike *a*poptosis *p*rotein), *CARMEN* (*CAR*D-containing *m*olecule *e*nhancing *N*F-?B), or *mE10* (*m*ammalian *E10*)] ([730] , [731] , [732] , [733] and [734]). These studies suggested enforced expression of BCL10 in most cell types (e.g., 293T, COS, HeLa, and MCF7) to induce modest or marked (depending on the particular experiment) apoptotic death. Contrary to the apparently proapoptotic effects of BCL10 in these epithelial cell types, stable BCL10 expression could be achieved in lymphoid cell lines without inducing a propensity to apoptotic death ([725] , [726]), suggesting that the functional effects of BCL10 may depend in part on the cellular context. Cellular cues that result in BCL10 phosphorylation likely also regulate the effects of the protein on apoptosis; for example, phosphorylation of BCL10 has been reported to result in its dissociation from the apoptosis regulator, TRAF-2, and binding to cIAPs, which correlated with the promotion of apoptotic cell death ([735] , [736]).

Functional evidence of the importance of BCL10 in lymphocyte development and MALT lymphomagenesis has come from recently described mouse models. Transgenic mice in which BCL10 expression is engineered specifically in the T and B cells develop splenomegaly due to a marked and specific expansion of their marginal zone B cells in a manner reminiscent of human splenic marginal zone lymphomas ([737]). Furthermore, studies from Bcl10-deficient mice indicate that, in addition to a role in neural tube closure, Bcl10 functions as a positive regulator of lymphocyte proliferation that specifically connects antigen receptor (the B-cell receptors and TCRs) signaling in lymphoid cells to NF-?B activation ([738]). An additional study of Bcl10-deficient mice has shown the function of the gene to be essential not only for the normal development and function of marginal zone B cells, the normal cellular counterparts to MALT lymphoma tumor cells ([739] , [740]), but also for the development and function of follicular and B1 B cells as well ([741]).

In view of the data showing BCL10 to be proapoptotic in most cell types, overexpression of the protein due to the t(1;14) appeared paradoxical. To examine this issue, BCL10 transcripts from t(1;14)-positive MALT lymphomas ([725] , [726]), as well as from other NHLs and solid tumors lacking the translocation ([725]), were examined and reported to contain a variety of mutations. These data suggested that BCL10 might normally possess a tumor suppressor function, and that overexpression of loss-of-function BCL10 mutants or gain-of-function mutants (with respect to NF-?B activation, *vide infra*) might contribute to lymphomagenesis rather than overexpression of the normal protein. Prompted by these reports, a number of investigators subsequently examined various tumor types for mutations of BCL10 (see reference [742] for a review of these studies). Based on these studies, BCL10 mutations actually appear to occur rarely in nonlymphoid hematopoietic malignancies and solid tumors of all types and are thus unlikely to play a significant role in oncogenesis. The combined data suggest that, at most, 5 to 10% of B-cell NHLs may contain BCL10 mutations, whereas mutation in T-cell–lineage disease rarely, if ever, occurs. Therefore, the initially reported high frequency of BCL10 mutation in hematopoietic and solid tumors ([725]) has not been borne out by the additional data from a large number of studies. The contributions (if any) of BCL10 mutants to MALT lymphomas or other tumors are not currently clear and await further study, although a classic tumor suppressor role for the gene normally appears unlikely.

Unlike the controversy regarding the effects of BCL10 on apoptosis, essentially uniform agreement exists concerning the ability of the protein to activate NF-?B when overexpressed in cells. Dominant-negative forms of NF-?B–inducing kinase, I?B kinase (IKK) and I?B, but not dominant-negative TRAF-2, TRAF-6, or RIP, inhibit BCL10-mediated NF-?B activation, suggesting that BCL10 functions upstream of NF-?B–inducing kinase, IKK, and I?B and downstream or independent of TRAFs and RIP ([730] , [731] and [732]). Suggestive evidence for a direct role of BCL10 in TNFR-induced NF-?B activation is the demonstration that engineered expression of normal BCL10 slightly enhances tumor necrosis factor a?mediated NF-?B activation, whereas expression of the BCL10 CARD domain alone inhibits activation ([732]).

The exact mechanisms by which BCL10 normally activates NF-?B are still being clarified, but CARD-mediated interactions with a subfamily of membrane-associated guanylate kinase (MAGUK) proteins ([743]) that are called *CARD-MAGUKs* (*CARMAs*), BCL10-interacting MAGUK proteins (BIMPs), or CARD10, CARD11, and CARD14 seem to be a critical component (for example, see reference [744] and the references cited therein). MAGUKs are scaffolding proteins containing several types of protein–protein interaction motifs that bind directly to the cytoplasmic portions of membrane-spanning and other signal transduction proteins, thus organizing specific signaling pathways originating from cell membrane receptors ([743]). On engineered overexpression in cells, CARMA1 (also called *CARD11* and *BIMP3*), CARMA2 (also known as *CARD14* and *BIMP2*), and CARMA3 (also known as *CARD10* and *BIMP1*) bind to BCL10, thereby activating the NF-?B pathway. Recent studies have shown that members of this MAGUK protein subfamily organize BCL10 and other signaling proteins in NF-?B–activating pathways emerging from certain

cell surface receptors. For example, CARMA1 physically associates with the TCR and BCL10 on TCR stimulation, and a CARMA1 mutant defective for BCL10 binding has a dominant-negative effect on TCR-induced NF-?B activation ([744]).

Intriguingly, the two independent targets of the recurrent chromosomal rearrangements in MALT lymphoma, API2-MALT1 and BCL10, appear to converge functionally in the same novel NF-?B activation pathway ([708] , [722]). The normal MLT/MALT1/hParacaspase and BCL10 proteins have been shown to physically interact and cooperate in NF-?B activation ([708] , [722]). Although not yet completely elucidated, a mechanism in which BCL10 mediates oligomerization and activation of the MLT/MALT1/hParacaspase caspaselike domain, which in turn activates the IKK complex and eventually NF-?B, seems likely. MAGUK family proteins appear also to be involved in this activation pathway; for example, CARD10, BCL10, and MLT/MALT1/hParacaspase form a ternary complex in cells, with BCL10 serving as the bridge between the other two proteins ([745]). CARD10-mediated NF-?B activation requires BCL10 and IKK, indicating that the protein acts upstream of these signaling mediators. In addition, a dominant-negative CARD10 mutant protein inhibits NF-?B induction by TCR or protein kinase C activation, suggesting that the protein normally links cell surface receptor signaling downstream to BCL10 and MLT/MALT1/hParacaspase to activate NF-?B.

The BCL10 protein is normally localized to the cytoplasm of cells. For unknown reasons, MALT lymphomas that overexpress BCL10 owing to the t(1;14), as well as many MALT tumors (but not other subtypes of NHL) that do not contain this translocation, also express the protein in their nuclei ([746]). The presence of the t(11;18)-associated API2-MALT1 fusion is also associated with nuclear BCL10 expression ([747]), and MALT lymphomas bearing these two abnormal findings are more frequently aggressive and disseminated. The pathogenic significance of aberrant nuclear localization of BCL10 is not yet clear. However, the frequent association of API2-MALT1 expression with nuclear BCL10 in MALT lymphomas provides yet further suggestive evidence that the oncogenic properties of the two are interrelated.

The API2-MALT1 fusion and BCL10 can independently activate NF-?B when expressed in cells, but they markedly synergize when coexpressed ([708] , [722]) (Fig. 89.3B). Therefore, the expression of the API2-MALT1 fusion or excess BCL10 would be predicted to significantly enhance NF-?B function, leading to up-regulation of NF-?B target genes, such as TRAF-1 and -2, cIAP-1 and -2, cMYC, and IL6, all of which should promote MALT B-cell growth ([748]). Such enhancement of NF-?B activation due to the API2-MALT1 fusion or BCL10 overexpression presumably substitutes for the requirement of early, low-grade MALT lymphomas for the sustained B-cell antigen receptor stimulation that occurs with *H. pylori* gastritis or chronic autoimmune diseases.

VARIOUS NON-HODGKIN LYMPHOMA SUBTYPES: 1q21-q22 GENE LOCI (BCL9, MUC1, Fc?RIIB, IRTA1 AND -2), AND BCL8

1q21-q22 Gene Loci (BCL9, MUC1, Fc?RIIB, IRTA1 and -2)

Abnormalities of the long arm of chromosome 1, particularly the 1q21-q22 region, occur in roughly 10 to 15% of B-cell NHLs, are usually secondary, and are associated with a poor prognosis, especially in the DLCLs ([511] , [749]). Chromosomal breakpoints at 1q21-q22 show surprising heterogeneity and involve several target genes, as described in the following discussion.

In 1998, Willis et al. ([750]) reported the cloning of a t(1;14)(q21;q32) in a pre–B-cell acute lymphoblastic leukemia cell line, identifying the novel BCL9 gene. Increased transcript levels of BCL9, which encodes a 1394–amino acid protein that was noted to contain several pentapeptide repeats and a nuclear localization signal, were detectable in the cell line. BCL9 expression levels appear normally to be low in B cells, but 50-fold higher expression was found in the cell line from which the gene was cloned ([750]). However, Southern blot hybridization and FISH analyses of a panel of 39 B-cell malignancies with 1q21 abnormalities revealed the BCL9 locus to be affected in only two cases (one MCL and FL each).

The normal function of BCL9 has been partially clarified by a report in 2002 that described its *Drosophila* homolog, a segment polarity protein named *legless* (*lgs*) that is required for the development of the legs and antennae of the fly ([751]). This report showed that BCL9/lgs can form a trimolecular complex with the Wnt/wingless signaling proteins ß-catenin/arm and TCF/pan, and suggested that BCL9/lgs recruits another segment polarity gene known as *pygopus* (*pygo*) to ß-catenin in the nucleus. Wnt signal transduction is mediated by the association of ß-catenin with the nuclear TCF DNA-binding factors, and lgs and pygo were shown to be required for Wnt signaling at the level of ß-catenin. These data suggest that the recruitment of pygo to ß-catenin by lgs allows beta-catenin to transcriptionally activate Wnt target genes, which include cMYC and cyclin D1 among others ([751]).

The normal proliferation and differentiation of pro–B cells require an intact Wnt signaling pathway, suggesting that Wnt signals may provide important mitogenic stimuli at certain developmental stages ([752]). In addition, Wnt3A has been shown to have a mitogenic effect on pro–B cells ([753]), whereas some pre–B-cell ALL blasts overexpress Wnt 16 ([754]). Thus, overexpression of BCL9 owing to genetic abnormalities may drive abnormal Wnt signaling to contribute to the oncogenic transformation of lymphoid cells.

Recently, two independent reports described the characterization of a t(1;14)(q21;q32) in the same case of large cell lymphoma, identifying dysregulation of the MUC1 gene ([755] , [756]). MUC1, also called *epithelial membrane antigen*, is a glycoprotein that contains multiple copies of a tandemly repeated mucinlike domain. This glycoprotein was previously shown to be expressed in several lymphoid malignancies (75% of lymphocyte-predominant Hodgkin disease cases, 75% of plasmacytomas, and 50% of T-cell lymphomas, including essentially all ALCLs), as a result of unknown mechanisms other than 1q21-q22 rearrangements, and was shown to be involved in the progression of solid tumors ([757] , [758]). The t(1;14) results in the dramatic up-regulation of expression of an intact MUC1 protein; none of six other genes located in an 85-kb region immediately centromeric to the MUC1 locus (CLK2, propin, COTE1, GBA, metaxin, or thrombospondin-3) were found to be overexpressed because of the translocation ([756]). Southern blot analysis of 72 B-cell NHLs containing a 1q21 rearrangement revealed MUC1 rearrangement in four cases (6%). In addition, increased copy number (four to six copies) of the MUC1 locus was identified in 18 (10%) of 178 B-cell NHLs ([755]). More recently three body-cavity-based-lymphoma cell lines have been reported to contain rearrangements near MUC1 and the physically linked metalloproteinase-like, disintegrin-like, and cysteine-rich protein (MDC15) (also known as *ADAM15*, for *a d*isintegrin *a*nd *m*etalloproteinase) gene loci, and to result in MDC15 overexpression in two of the three cell lines ([759]). Thus, rearrangements at this particular 1q21 region appear to be capable of producing overexpression of MUC1 or MDC15, both of which may contribute to the extranodal presentation of certain B-cell lymphomas because of the involvement of these proteins normally in cell–cell or cell-matrix interactions ([758] , [760]).

By cloning the t(1;22)(q22;q11) in three FLs also containing t(14;18), Callanan et al. ([761]) showed FCGR2B, which encodes the immunoreceptor tyrosine-based inhibition motif–containing low-affinity IgG Fc receptor Fc?RIIB, to be the 1q22 target of this rearrangement. Fc?RIIB is an inhibitory coreceptor that effects negative regulation of immune responses mediated by activating receptors such as B-cell antigen receptors ([762]). High levels of the Fc?RIIB receptor alternative splice isoform Fc?RIIb2 were specifically overexpressed in t(1;22)-positive cases, whereas b1 isoform levels were not elevated above normal. How high-level constitutive Fc?RIIb2 expression might contribute to B-cell tumorigenesis is not clear, but Fc? receptors can clearly affect B-cell growth; for example, activation of these receptors enhances the growth and differentiation of murine B-cell–lineage progenitors *in vitro*, and Fc?RII-deficient mice have an increased B-cell compartment ([763]).

The chromosomal region 1q21-q22 is remarkably rich in FCGR genes. Three Fc?RII genes and two Fc?RIIIB genes are located in an approximately 200-kb region in 1q22. Moreover, cloning of yet another t(1;14)(q21;q32) from the FR4 myeloma cell line has revealed an additional group of highly related Fc receptor-related genes that are involved in the pathogenesis of B-cell–lineage malignancies. Hatzivassiliou et al. ([764]) reported the presence of five adjacent genes (named *Ig superfamily receptor translocation-associated* (*IRTA*) genes) from a 300-kb region spanning the breakpoint in this cell line, all of which encode surface receptor molecules that are members of the Ig gene superfamily. All IRTA genes are expressed normally in the B-cell lineage with distinct developmental stage-specific patterns; for example, IRTA1 is expressed in a marginal zone B-cell pattern, and IRTA2 is found in centrocytes, marginal zone B cells, and immunoblasts ([764] , [765]). As a result of the translocation in the FR4 cell line, IRTA1 is interrupted and fused to the Ig Calpha locus, producing a chimeric IRTA1/Calpha protein. The IRTA2 gene, normally silent in centroblasts (the presumed normal cellular counterparts of Burkitt lymphoma tumor cells), is overexpressed in Burkitt lymphoma as well as multiple myeloma cell lines carrying 1q21 abnormalities. The pathologic mechanisms by which deregulation of the IRTA genes contributes to lymphocyte proliferation are not yet clear but presumably involve, in part, a disturbance of the physiologic homeostasis between activating and inhibitory antigen receptors.

BCL8

Rearrangements affecting chromosomal bands 15q11–q13 and various partners occur in approximately 4% of DLCLs. In 1997, Dyomin et al. ([766]) identified a chromosome 15 genomic locus, which they named BCL8, at which at least some of these rearrangements occur. Transcripts from the BCL8 locus were found to be normally expressed as a major transcript of 2.6 kb and a less prominent 4.5-kb message due to differential polyadenylation, and their expression was restricted

primarily to the testis and prostate, with no transcripts being found normally in hematopoietic tissues, such as the spleen, thymus, or blood leukocytes. The cloning of the corresponding BCL8 complementary DNA species revealed a 513–base pair open reading frame predicted to encode a 19-kd protein with a high degree of homology to the N-terminus of the *D. melanogaster* protein kinase A (PKA) anchoring protein RG ([767]). RT-PCR analysis of RNAs from DLCL samples and lymphoma cell lines identified BCL8 expression in all cases having abnormalities of chromosome 15q11-q13, as well as in four of nine randomly selected DLCL cases and 6 of 15 DLCL cell lines (but none of three hyperplastic lymph nodes). The mechanism of aberrant BCL8 expression in lymphomas lacking 15q11-q13 translocations has not yet been defined.

A recently published study has identified several additional chromosomal loci sharing homology with the originally described BCL8 complementary DNA (which has subsequently been renamed *BCL8A*) ([768]). BCL8A and three related loci (designated *BCL8C*, *BCL8D*, and *BCL8E*) found on other chromosomes were found to be truncated at the genomic level, suggesting that they may actually be pseudogenes, sterile transcripts that are not translated into proteins, or that they may possibly encode truncated polypeptides of uncertain function. By contrast, a fifth related locus, *BCL8B*, which was expressed mainly in the brain, contained an uninterrupted open reading frame predicted to encode a 327-kd protein with extensive homology to the RG *Drosophila* PKA anchoring protein.

Involvement of PKA anchoring proteins in the phosphorylation and resultant inactivation of the proapopoptotic BCL2 family member BAD has been identified ([769]), suggesting a potential role for some PKA anchoring proteins in oncogenesis. However, additional studies are required to determine what, if any, protein is translated from BCL8A and what function such a protein might possess.

GENE EXPRESSION PROFILING IN NON-HODGKIN LYMPHOMA

The previous sections of this chapter have, for the most part, highlighted characteristic genetic alterations associated with specific subtypes of NHL. The current WHO classification scheme for lymphomas incorporates these recurrent aberrations along with morphologic and immunophenotypic features of the tumor cells ([770]). However, many NHL subgroups defined in this fashion remain biologically and clinically heterogeneous and vary in their response to current therapeutic regimens. This variability is due, in large measure, to molecular differences between the tumors that are not included in the current classification criteria. The information provided by the Human Genome Project has paved the way toward a comprehensive molecular characterization of lymphomas and other cancer types. One genomics-based technology that has proven useful in lymphoma classification is gene expression profiling using DNA microarrays ([25] , [771]). Using this technology, the mRNA expression levels of thousands of genes can be measured simultaneously in a tumor biopsy, thus creating a molecular portrait of the tumor. It is anticipated that, in the near future, comparison of the gene expression profiles of lymphoma samples from a large number of patients will lead to a new molecular definition of lymphoma subgroups that are more uniform in their biologic and clinical behavior. As an introduction to this technology, the following section focuses on efforts made as of 2003 concerning the expression profiling of B-cell NHL subtypes.

An initial gene expression profiling study of tumor samples from patients with DLBCL, FL, and chronic lymphocytic leukemia demonstrated that large sets of genes are characteristically and selectively expressed by each of these diagnostic subtypes ([772]). FLs, for example, display a gene expression phenotype that is characteristic of normal B cells at the germinal center stage of B-cell differentiation. By contrast, chronic lymphocytic leukemia cells share similarities in gene expression with normal peripheral blood B-cells ([772]).

Three major gene expression profiling studies have addressed the biologic and clinical heterogeneity of DLBCL ([772] , [773] and [774]). In DLBCL, current chemotherapeutic regimens (e.g., cyclophosphamide, hydroxydaunomycin, vincristine, and prednisone) achieve durable remissions in less than 50% of the patients, and multiple attempts to improve clinical outcome in this disease have failed ([775]). The clinical relevance of the histopathologic subclassification of DLBCL cases into centroblastic, immunoblastic, and other variants has not been demonstrated conclusively ([776]). Despite the fact that the marked biologic and clinical heterogeneity of DLBCL is well recognized, it is still considered a single lymphoma entity in the most recent WHO classification of lymphoid malignancies ([770]).

In the initial gene expression profiling study in DLBCL, lymph node biopsy samples from previously untreated DLBCL patients were analyzed ([772]). Genes that define the germinal center stage of B-cell differentiation were used to define two prominent DLBCL subgroups (Fig. 89.4A). The *germinal center B-cell–like* (GCB) DLBCL subgroup expressed genes characteristic of normal germinal center B cells (e.g., CD10, BCL6, and A-myb), whereas the *activated B-cell–like* (ABC) DLBCL subgroup expressed genes that are induced during mitogenic activation of peripheral blood B cells (e.g., BCL-2, IRF-4, and cyclin D2). A larger gene expression profiling study of DLBCL cases confirmed the existence of these two DLBCL subgroups but also identified another set of cases, termed *type 3 DLBCLs*, that do not resemble GCB or ABC DLBCLs and may represent additional molecular subgroups of DLBCL ([774]).

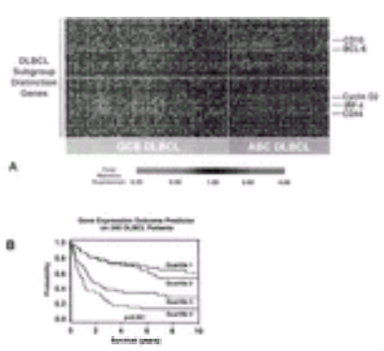

Figure 89.4. A: Subgroups of diffuse large B-cell lymphoma (DLBCL) defined by gene expression profiling. Hierarchic clustering of 188 lymph node biopsies from DLBCL patients, according to the gene expression levels of 100 selected genes. Shades of red indicate higher expression, shades of green indicate lower expression, and black indicates median expression. Each column represents one tumor sample, and each row represents a single gene. The germinal center B-cell–like DLBCLs (see text) show high expression of genes that are characteristically expressed in germinal center B cells (e.g., CD10 and BCL6), whereas activated B-cell–like DLBCLs express genes normally induced during *in vitro* activation of B cells (e.g., cyclin D2, IRF-4, and CD44). **B:** A gene expression–based outcome predictor in 240 DLBCL patients. Each case of DLBCL was assigned an outcome predictor score calculated from gene expression averages of the model components (see text for details). Patients were ranked according to their scores and divided into quartiles. The 5-year survival rates for these quartile groups are shown in the Kaplan-Meier plot. See Color Plate. (Adapted from Rosenwald A, Wright G, Chan WC, et al. The use of molecular profiling to predict survival after chemotherapy for diffuse large-B-cell lymphoma. N Engl J Med 2002;346:1937–1947, with permission.)

These observations raised the possibility that the DLBCL subgroups represent pathogenetically distinct entities that are derived from cells at different stages of B-lymphoid differentiation. Support for this hypothesis has come from analysis of Ig gene mutations and oncogenic abnormalities in the DLBCL subgroups. Although DLBCLs in the GCB and ABC subgroups were found to have mutated Ig genes, only GCB DLBCLs had ongoing somatic hypermutation of the Ig locus within the tumor clone ([777]). Because somatic hypermutation of Ig genes is a hallmark of germinal center B cells, this finding suggests that the GCB DLBCL tumors retain some of the biologic characteristics of normal B cells at this stage of differentiation.

Two recurrent chromosomal alterations in DLBCL were detected exclusively in the GCB DLBCL subgroup ([774] , [778]). The t(14;18)(q32;q21) translocation involving the BCL2 oncogene was detected in 23 to 35% of GCB DLBCL cases but never in ABC or type 3 DLBCL cases. Similarly, amplification of the cREL locus on chromosome 2p was detected in 15% of GCB DLBCLs but not in the other subgroups ([774]). By contrast, ABC DLBCLs were found to have constitutive activity of the NF-?B pathway, which is not a feature of GCB DLBCLs ([779]). These findings suggest that the DLBCL subgroups use distinct oncogenic mechanisms, which may have implications for targeted therapy in the future. Indeed, interference with the NF-?B pathway was found to kill ABC DLBCL cells *in vitro*, suggesting that pharmacologic targeting of this pathway may be beneficial for patients with this type of DLBCL ([779]).

The DLBCL gene expression subgroups were found to have distinct overall survival rates after anthracycline-based multiagent chemotherapy (e.g, the regimen of cyclophosphamide, hydroxydaunomycin, vincristine, and prednisone) ([772] , [774]). The 5-year survival rates for the GCB, ABC, and type 3 DLBCL subgroups were 60%, 35%, and 39%, respectively ([774]). However, the DLBCL subgroup distinction did not fully account for the variable response of these patients to chemotherapy, suggesting that further molecular differences among the lymphomas influence the response to chemotherapy.

To directly search for genes that influence the response of DLBCL patients to chemotherapy, clinical data were used to identify genes with expression patterns that correlated with survival ([773], [774]). This “supervised” analytic approach was used to create multivariate statistical models based on gene expression that strongly predicted survival. In one gene expression–based prognostic model, most of the genes reflected one of four biologic characteristics of the DLBCL tumors that independently influenced survival ([774]). The predictive genes in this model were classified functionally based on their membership in gene expression *signatures*. A gene expression signature is a set of genes that are selectively and coordinately expressed in a particular cell type, stage of differentiation, or cellular response ([565]).

Most of the genes that predicted poor survival when expressed belonged to the *proliferation gene expression signature* ([774]). This signature includes genes that are more highly expressed in dividing cells than in quiescent cells. This gene expression signature is a quantitative measure of proliferation rate, and its adverse prognostic influence is in accord with previous studies of tumor cell proliferation in DLBCL ([780], [781]). Many genes that predicted favorable survival when expressed belonged to the *germinal center B-cell signature*, a finding that mirrors the superior survival of the GCB DLBCL subgroup of patients that was mentioned previously. Other predictive genes in the prognostic model suggested that the host immune response to the lymphoma may be critical for a curative response to chemotherapy ([774]). Genes involved in antigen presentation to the immune system, including genes encoding major histocompatibility complex class II molecules and invariant chain, predicted favorable survival when expressed, in keeping with previous results ([782]). Other genes that predicted a favorable survival belonged to the *lymph node signature*, which corresponds to a fibrotic response to the lymphoma cells that is associated with an influx of macrophages and natural killer cells into the lymph node.

A multivariate model was created from 17 predictive genes that was shown to predict survival in an independent set of DLBCL cases, thus establishing the statistical validity of the model ([774]). Each DLBCL patient was assigned an *outcome predictor score* based on the expression of these 17 genes that was used to stratify the patients into four quartiles with 5-year survival rates of 73%, 71%, 36%, and 16% (Fig. 89.4B). This gene expression–based prognostic model functioned independently of a prognostic model based on clinical parameters, the International Prognostic Index ([783]). Because this gene expression-based prognostic model incorporates defined biologic features of DLBCL tumors, it may prove useful in identifying alternative therapies for patients who are not likely to be cured by conventional multiagent chemotherapy.

Gene expression profiling has also provided insights into the pathogenesis and clinical behavior of MCL ([258]). As noted earlier in this chapter, most cases of MCL are characterized by a common genetic alteration, the t(11;14) translocation, which juxtaposes the cyclin D1 gene to the Ig heavy chain locus ([212]). Cyclin D1 is a key regulator of the G_1 to S phase transition in the cell cycle, and its deregulation in MCL highlights the central role of abnormal proliferation in this disease. A set of *MCL signature genes* was defined by gene expression profiling that distinguished this lymphoma type from other NHLs ([258]). This gene expression signature was used to identify a novel subtype of MCLs that lack cyclin D1 expression but nevertheless express MCL signature genes and resemble cyclin D1–positive MCL morphologically and clinically ([258]). Some of these cyclin D1–negative cases express cyclin D2 or cyclin D3, suggesting that they may have developed alternative mechanisms to promote cell cycle progression.

The median length of survival of patients with cyclin D1–positive MCL is approximately 2.8 years, but some patients die within the first year of diagnosis, whereas others live for more than 10 years with this lymphoma ([213]). Much of this variable survival can be accounted for by differences in expression of the proliferation gene expression signature, with higher expression of this signature associated with shorter survival ([258]). Using this quantitative measure of tumor cell proliferation rate, MCL patients could be subdivided into quartiles with median survival times 0.8 years, 2.3 years, 3.3 years, and 6.7 years ([258]). Two oncogenic mechanisms were identified that accounted for some of this variability in proliferation and survival. Some of the more proliferative MCLs expressed higher levels of cyclin D1, and this was due to the preferential expression of a more stable isoform of cyclin D1 mRNA. In addition, deletions of the INK4a/ARF tumor suppressor locus were commonly observed among the highly proliferative MCLs. Both of these oncogenic events were independently associated with shorter survivals, but a statistical model that combined these two events did not predict length of survival as well as the proliferation gene expression signature. The proliferation signature thus acts as a quantitative integrator of multiple oncogenic events that affect the clinical course of MCL patients.

As these examples illustrate, gene expression profiling is able to identify lymphoma subtypes that are distinct pathogenetically and clinically. Furthermore, gene expression can be used to create quantitative prognostic indices that reflect biologic differences among lymphomas. In the future, it is possible that some of these prognostic differences may be used to stratify patients to more or less aggressive treatment regimens. Furthermore, the molecular diagnosis of a lymphoma subtype can provide information about the signaling pathways vital to the proliferation or survival, or both, of the lymphoma, which could prove increasingly valuable as more targeted treatments become available for NHL.

Non-Hodgkin Lymphomas in Adults

HISTORICAL PERSPECTIVE

The recognition of lymphoma evolved from Thomas Hodgkin's 1832 paper entitled “On Some Morbid Appearances of the Absorbent Glands and Spleen” ([1]). Hodgkin was the first to realize that lymphadenopathy could occur as a primary disorder rather than a secondary disorder to infection or carcinoma. Since Hodgkin's initial description, there have been four historic phases in the study of non-Hodgkin lymphoma (NHL): (a) clinical features, 1832 to 1900; (b) histopathology, 1900 to 1972; (c) immunopathology, 1972 to the present; and (d) molecular genetics, 1982 to the present. These phases naturally overlap and all contribute to the understanding of NHL.

From 1863 to 1865, Virchow ([2]) introduced the terms *aleukemia* and *lymphosarcoma* to distinguish lymphoproliferative diseases from leukemia, and, in 1871, Billroth used the term *malignant lymphoma* for a vague collection of primary lymphoid disorders ([3]). In 1893, Kundrat ([4]) proposed that the term *lymphosarcoma* was more specific than the term that was originally used by Virchow and that it should be reserved for sarcomatous tumors of lymph nodes.

At the turn of the century, Sternberg ([5]) and Reed ([6]) identified the giant cells that are characteristic of Hodgkin disease (HD) and introduced histopathology as an important method for diagnosis and classification of lymphoma. Brill et al. ([7]) and Symmers ([8]) first described follicular, or nodular, lymphoma in the 1920s and indicated that it was a malignant, albeit indolent, disorder. In 1930, Roulet ([9]) used the term *reticulum cell sarcoma* as another term for malignant lymphoma. In 1942, Gall and Mallory ([10]) developed a classification scheme on NHL that had clinical and histopathologic significance. The histopathologic phase of NHL culminated in the 1956 classic work of Rappaport ([11]), who developed a morphologic classification that was reproducible and relevant.

The complex interplay of environmental and host factors in the pathogenesis of lymphoma was recognized through Dennis Burkitt's description in 1958 of an aggressive tumor of young children that was characterized by frequent jaw and abdominal involvement (Fig. 90.1A). Using careful epidemiologic surveys, Burkitt ([12] , [13]) identified a tumor belt across equatorial Africa that was associated with temperature, rainfall, and elevation (Fig. 90.1B). Subsequently, the geographic distribution of this neoplasm was shown to correlate with that of endemic malaria.

Figure 90.1. A: Burkitt lymphoma that involves the mandible, the maxilla, and the orbit. (From O'Conor GT. Significant aspects of childhood lymphomas in Africa. Cancer Res 1963;23:1514–1527, with permission.) **B:** Lymphoma belt of Africa: Burkitt lymphoma occurred only in the areas below 3000 ft (above sea level), with mean temperature of higher than 15.6°C and with an annual rainfall of more than 50 cm. The shaded area is the area in which Burkitt lymphoma would be expected to occur; the black squares indicate the sites of the cases that were identified by Burkitt. (From Haddow AJ. An improved map for study of Burkitt's lymphoma syndrome in Africa. E Afr Med J 1963;40:429–432, with permission.)

In 1961, pathologic studies by O'Conor ([14]) suggested that the tumor was a lymphoma—an observation that was confirmed later by the demonstration of monotypic immunoglobulin (Ig) on tumor cells by Klein. In 1964, Epstein et al. ([15]) found viral particles in tumor cell lines that were derived from Burkitt's patients. A direct causative role for the virus was subsequently questioned by its infrequency in Burkitt lymphoma that occurred outside of Africa; however, the Epstein-Barr virus (EBV) was shown to be trophic for B cells, to induce B-cell proliferation and differentiation, and to be the etiologic agent for infectious mononucleosis.

The identification of a 14q+ cytogenetic abnormality in Burkitt lymphoma by Manalov and Manolova ([16]) in 1971 led to the description of the 8;14 chromosomal translocation by Zech et al. ([17]) in 1976. Subsequent molecular genetic studies showed that this translocation juxtaposed the c-myc oncogene on chromosome 8 to the Ig heavy chain gene sequences on chromosome 14 ([18]). These observations suggest that the 8;14 translocation of endemic Burkitt NHL arises in a state of EBV-induced polyclonal B-cell proliferation in the setting of immunodeficiency that is associated with chronic malaria. Support for this theory has been derived by the

role of EBV in lympho-proliferation in other immunodeficient conditions.

In 1967, Good and Finstad discussed, at an international conference on leukemia and lymphoma in Ann Arbor, Michigan, the relationship of B and T cells to lymphoid neoplasia ([3]), and Dameshek introduced the concepts that lymphoid neoplasms were aberrations of immunologically competent cells and that transformation of lymphocytes to “blast” forms (immunoblasts) could occur secondary to antigenic stimulation ([3]). In 1972, the immunologic origin of lymphoid neoplasia was confirmed by the presence of monotypic Ig on the cell surface (B cell) or by sheep erythrocyte rosette formation with neoplastic cells (T cell) ([19] , [20] and [21]). Lymphoblastic lymphoma (LL) was determined to originate from thymocytes by Smith et al. ([22]) in 1973. Barcos and Lukes ([20]) described the clinicopathologic features of “convoluted lymphocytic lymphoma” of thymic origin and used the term *LL*, which was later preferred by Nathwani et al. ([23]) because of similarities to blasts of T-cell acute lymphocytic leukemia (ALL).

The importance of distinguishing a T cell from a B cell as a separate cell of origin for lymphoma accompanied the description of adult T-cell leukemia/lymphoma (ATLL) by Takatsuki et al. ([24]) and Uchiyama et al. ([25]) in 1977. The clinical course of ATLL was variable, but the majority of patients presented with an acute form, which was characterized by lymphadenopathy; organomegaly; skin lesions; an elevated white count with multilobated lymphocytes, which were referred to as *cloverleat* or *flower* cells (Fig. 90.2A); and a rapidly fatal course. In 1980 and 1981, Gallo et al. ([26]), in the United States, and Hinuma et al. ([27]), in Japan, discovered a unique retrovirus, human T-cell leukemia virus type 1 (HTLV-1), as the etiologic agent of ATLL. HTLV-1 was shown to be endemic to certain geographic areas (Fig. 90.2B): southwestern Japan, in which 6 to 20% of the population is seropositive for HTLV-1; the Caribbean islands; New Guinea; and parts of Central Africa and South America ([28] , [29] , [30] , [31] and [32]). Some early cases were reported in Europe and parts of the United States, particularly in the Southeast ([33]).

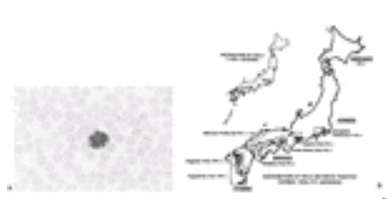

Figure 90.2. A: Peripheral blood, adult T-cell leukemia/lymphoma. A neoplastic lymphocyte shows the cloverleaf nuclear lobations that are characteristic of circulating adult T-cell leukemia/lymphoma cells. (Courtesy of William Macon, Mayo Clinic, Rochester, MN.) **B:** Comparison of the distribution of adult T-cell leukemia in Japan with the distribution of human T-cell leukemia virus (HTLV) type 1 antibody-positive healthy Japanese. See Color Plate. [From Robert-Guroff M, Gallo RC. Establishment of an etiologic relationship between the human T cell leukemia/lymphoma virus (HTLV) and adult T cell leukemia. Blut 1983;47:1–12, with permission.]

In 1974, Lennert et al. ([34]) and Lukes and Collins ([35]) classified NHL on the basis of the cell of origin within the immune system (Fig. 90.3). Subsequently, monoclonal antibodies to lymphocyte differentiation antigens have been able to detect sequential stages in the development of B and T cells and to identify subtypes of NHL. In the 1980s, the lymphoid origin of NHL was confirmed at the molecular level with the identification of specific Ig gene and T-cell receptor (TCR) gene rearrangements in B- and T-cell lymphomas, respectively ([36] , [37] , [38] and [39]).

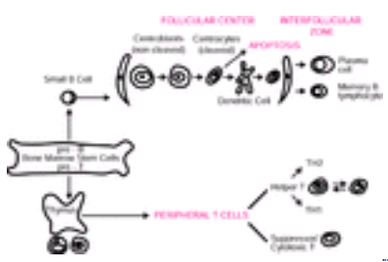

Figure 90.3. B- and T-cell differentiation pathways. B and T cells originate in the marrow, where they are antigen independent. The follicular center is a normal site of antigen-dependent B cells, which go through different stages: (a) proliferation of centroblasts (large noncleaved cells), (b) selection of centrocytes (small cleaved cells) or cell death via apoptosis, and (c) differentiation into postgerminal center memory B lymphocytes or plasma cells, often in association with increased antigen affinity and an immunoglobulin isotope switch. The T cells depend on the thymus for early differentiation before becoming peripheral T cells, which are subdivided into helper and suppressor or cytotoxic subsets. T cells predominantly populate the interfollicular zone of lymph nodes. Subsets of T helper cells (TH_2) regulate B-cell responses to antigens along with the dendritic cells, whereas others (TH_1) recruit cells (macrophages) to sites of inflammation.

Because of the diverse terminology that is used in the multiple classifications of lymphomas, there have been attempts to develop uniform pathologic descriptions with clinical usefulness. In 1982, a Working Formulation (WF) of NHL separated diseases according to histologic grade (low, intermediate, and high) and made correlations with survival ([40]); however, classification was based on morphology without using immunophenotyping or molecular genetic techniques to define histologically similar processes. In 1994, a Revised European American Lymphoma (REAL) Classification was proposed to identify specific types of lymphomas of B- and T-cell origin ([41]). The REAL Classification dropped the grading schema of lymphomas and developed a diagnosis by identifying clinical features, morphology, immunophenotype, and genetic data, when available ([42]). The World Health Organization (WHO) has adopted the diagnostic principles of the REAL Classification, and the WHO classification is used as the schema for the diagnosis of all hematopoietic neoplasms (Chapter 88) ([43] , [44]).

Progress in the last three decades has involved not only the recognition of the importance of immunopathology and molecular genetics in the definition of these diseases, but also the development of curative therapy for many patients with NHL. In this chapter, the areas that are reviewed include the epidemiology of NHL, a clinical approach, and therapeutic principles for adult NHL.

EPIDEMIOLOGY

There is an epidemic of NHL worldwide ([45]). More than 60,000 new cases per year will be diagnosed in the United States in the 2000s. Part of the increase was attributed to the development of NHL in patients with the acquired immunodeficiency syndrome (AIDS); however, there are a large number of other possible contributing factors to the epidemic (Table 90.1). Even before the AIDS crisis, there was a steady increase of 3 to 4% per year since the 1970s until 1996, when there was a plateau and even drop-off in some subgroups of patients (Fig. 90.4). Part of the drop-off is attributed to the introduction of highly active antiretroviral therapy (HAART) for AIDS patients ([46] , [47] and [48]). The rise in NHL was faster than that of all other malignancies except lung cancer in women, melanoma, and prostate cancer ([48] , [49]).

Male gender

Increasing age
Family history of non-Hodgkin lymphoma
Prior cancer history
Drug history
  Immunosuppressive agents
  Phenytoin
  Methotrexate
Occupational history
  Exposure to herbicides, pesticides, wood dust, epoxy glue, solvents
  Jobs in farming, forestry, painting, carpentry, tanning
Other possible etiologic factors
  Hair dye use
  Sunlight exposure
  Nutritional factors
  Blood transfusion

Figure 90.4. Age-adjusted incidence rates of non-Hodgkin lymphoma according to race and gender by year, 1973 to 1999. (From Ries LA, et al. SEER cancer statistics review, 1973–1999. Bethesda, MD: National Cancer Institute, 2002.)

The rise in NHL led to a symposium at the National Institutes of Health in 1991 to address whether the epidemic is real or due to changes in classification, improved diagnosis, or the AIDS crisis, or a combination of these. Although some NHL may have been previously diagnosed as HD, and new entities among NHL are being recognized, the consensus of the symposium was that the overwhelming majority of the increase in NHL was unexplained by changes in diagnosis or the development of AIDS ([50]).

Age, Race, and Gender Differences

The frequency of various lymphoid neoplasms is age dependent, has a variable worldwide distribution, and is more common in men than women. Lymphomas represent approximately 10% of all childhood cancers in developed countries and are the third most common in relative frequency, behind acute leukemias and brain tumors. They are more common in adults than in children and have a steady increase in incidence from childhood through 80 years of age (Fig. 90.5A) ([48]). They are the fifth most common cancer in the United States and represent 4% of all cancers. The mean age at diagnosis is 45 to 55 years of age, and the median age is 60 to 65 years of age. The annual incidence rate of NHL from 1995 to 1999 was 19.1 cases per 100,000 population with a 50% higher incidence for men (23.6 per 100,000) than women (15.4 per 100,000) and a 35% higher incidence among whites (19.9 per 100,000) than blacks (14.7 per 100,000) ([48]). The highest age-adjusted mortality has been in white men (10.9 per 100,000), and the lowest mortality has been in Native American (Indian/Alaska) women (3.4 per 100,000) (Fig. 90.5B) ([48]).

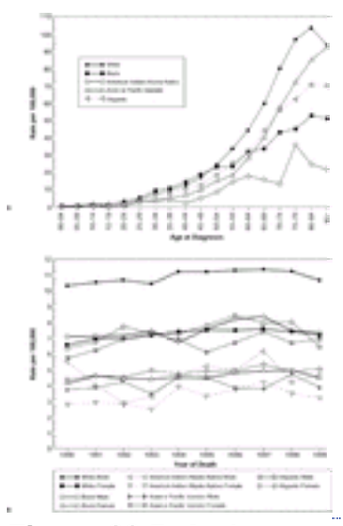

Figure 90.5. A: Age-specific incidence rates of non-Hodgkin lymphoma according to race. **B:** Age-adjusted mortality rates by expanded race and gender, 1990 to 1999. (From Ries LA, et al. SEER cancer statistics review, 1973–1999. Bethesda, MD: National Cancer Institute, 2002.)

A comparison of NHL in children and adults is outlined in Table 90.2. Lymphomas that involve peripheral lymph nodes are usually of B-cell origin in the West and are more common in adults than in children, who often present with gastrointestinal involvement [small noncleaved cell (SNC), B cell] or mediastinal widening (usually LL of T-cell origin). The histologic appearance of NHL is more variable in adults, who frequently have low-grade follicular patterns in which the majority of malignant cells are small, dormant lymphocytes; children predominantly have high-grade diffuse patterns in which the malignant cells have a “blastic” or transformed appearance and a high mitotic rate. A possible explanation of the differences between childhood and adult NHL is that most childhood lymphomas arise from early cells that are antigen independent, whereas many adult lymphomas arise from fully differentiated cells and are antigen dependent ([51]).

TABLE 90.2. Clinicopathologic Differences between Childhood and Adult Non-Hodgkin Lymphomas

	Children	Adults
Incidence	Rare	Common
Median age	10–15 yr	55–70 yr
Presentation	Extranodal > nodal	Nodal > extranodal
Most common histologic diagnoses	B cell: small noncleaved cell (Burkitt)	B cell: small lymphocytic; small cleaved (follicular center) cell; diffuse large cell
	T cell: lymphoblastic; Ki-1+ anaplastic large cell	T cell: peripheral T-cell
Immunophenotype	50–70% B cell	70–90% B cell (United States, Europe); 40–70% T cell (Asia)
Paraprotein	None	Rare (<5%)

Clinical course	Aggressive	Variable—often indolent
Curability	70–90%	<30%, except 40–70% in intermediate to high grades, particularly large cell lymphomas

Extranodal presentation of NHL occurs in 15 to 25% of adult patients in the United States ([52], [53]) and in as much as 40 to 50% of adult patients in Europe and the Far East ([54], [55]). Clinicopathologic features of the epidemic of NHL include a faster rise in extranodal than nodal disease, an increase in diffuse pattern rather than nodular pattern, and an increase in intermediate- to high-grade NHL rather than low-grade disease ([56], [57]). NHL of the brain has risen four times as rapidly as other extranodal sites and is partly due to AIDS, but the upward trend began before the AIDS crisis and continues to rise in immunocompetent hosts of all ages and in both genders ([56], [58]). The most common extranodal sites are the gastrointestinal tract and nasopharynx; other common sites include brain, skin, bone, thyroid, salivary glands, and testis.

Familial aggregation of NHL plays a small role in the epidemic and accounts for a two- to fourfold increased risk for NHL in close relatives of patients with lymphoma or another hematopoietic neoplasm ([59], [60] and [61]). Some families have various immune function abnormalities, whereas others have no discernible immune dysfunction. There is an increased risk for NHL and HD in families with an autoimmune lymphoproliferative syndrome (also known as the *Canale-Smith syndrome*), which is characterized by chronic lymphadenopathy, splenomegaly, autoimmune features, and expanded T cells, which are negative for CD4 and CD8 ([62]). The lymphomas may occur decades after recognition of the syndrome and are associated with germline Fas mutations and defective lymphocyte apoptosis ([62]). A prior history of cancer, Jewish ancestry, and small-size families have been suggested as risk factors for lymphoma ([63], [64]). Patients who have a family history of hematologic cancer and occupational exposures to certain substances (e.g., gasoline or benzene) appear to have an increased risk for NHL ([59], [60]).

Environmental Factors

Environmental associations that are implicated in the pathogenesis of NHL include infections, drug exposure, and toxic chemical exposure. Viruses, particularly EBV, play a critical role in lymphomagenesis in the immunodeficient host. Phenytoin (Dilantin) has been associated with pseudolymphoma and malignant lymphoma, with the former condition presenting with fever, rash, and adenopathy that regress after drug withdrawal ([65], [66]). Methotrexate and the tumor necrosis factor-a inhibitors (etanercept, infliximab, and adalimumab) have been associated with an increased risk of lymphoma in rheumatoid arthritis, which itself may have an increased risk (see the section Prelymphomatous Conditions) ([67]). Although epidemiologic studies are flawed by methodologic weaknesses, other implicated drugs include aspirin, antibiotics, steroids, digitalis, estrogen, and tranquilizers ([63]).

Occupational exposures have been suggested as factors in the epidemic. There appears to be a two- to threefold increased risk of NHL among people who are employed in agriculture, forestry, fishing, construction, and leather industries ([68]). Specific jobs that are at high risk include plant farmers and gardeners, painters and plasterers, carpenters, brick and stone masons, plumbers, and roofers. The chemicals that are implicated are chlorophenols and phenoxyacetic acids that are commonly found in herbicides ([68], [69], [70], [71], [72] and [73]). An excess risk has also been suggested for exposure to wood dust, epoxy glues, pesticides, fertilizers, and solvents ([63]).

Hair dyes ([74], [75]), ultraviolet light ([76], [77] and [78]), and nutritional factors ([79], [80]) have been implicated in some epidemiologic studies and have been negated in others. Hair dye is more likely to be a factor in women than in men because of a greater use in women ([56]). Several studies noted an increase in NHL among patients with melanoma or squamous cell skin cancer and suggested a role for ultraviolet light in suppression of the immune system ([76], [77]); however, there was no correlation between NHL mortality and increased ultraviolet light exposure in the southern United States, as has been observed in skin cancer ([78]). Nutritional factors, including milk, butter, liver, meat, coffee, and cola consumption, have been identified as possible risk factors ([50], [79], [81]). In one study, a high-meat diet and a high intake of fat from animal sources were associated with an increased risk of NHL in older women; there was no association with milk consumption, and there was a decreased risk with increased ingestion of fruits ([80]).

Blood transfusion has been implicated as contributing to the increased incidence of NHL ([82], [83], [84] and [85]). The use of blood products, beginning in the 1950s, has coincided with the epidemic ([84]). Transmission of infectious agents through blood transfusion could suppress the immune system and make a patient susceptible to the development of lymphoma ([83]). Blood transfusion has been associated with all types of histologies ([82], [85]). Although cohort studies have supported the connection between blood transfusion and lymphoma, case-control studies have not consistently confirmed the association ([84]).

A number of other factors have been mentioned as possibly contributing to the epidemic, including ionizing radiation, electromagnetic fields, alcohol, tobacco, and chronic fatigue syndrome, but the data are weak to support an association of any of these factors with an increased risk of NHL ([56], [86], [87], [88], [89], [90] and [91]). The epidemiology of NHL is emerging and requires carefully designed studies with large cohorts and prolonged follow-up to determine the validity of an association between a factor and NHL.

Infectious Agents

The lymphotropic viruses EBV and HTLV-1 have a pathogenetic role in predominantly B- and T-cell lymphoid neoplasias, respectively ([92]). These viruses have been well studied and continue to provide information regarding lymphomagenesis. The biology, epidemiology, and associated clinical diseases of EBV are reviewed in Chapter 67. Dysfunction in T-cell immunity can lead to polyclonal EBV lymphoproliferation, which may become an oligoclonal or monoclonal malignant B-cell lymphoma. EBV has been implicated in African Burkitt lymphoma, AIDS-related lymphomas (ARLs) [many systemic and most central nervous system (CNS)], some HD, and in some T-cell and natural killer (NK)–cell lymphomas, including nasal lymphoma ([93]), posttransplant T-cell lymphoma, and several lymphomas that developed after chronic infectious mononucleosis ([94], [95]).

HTLV-1 is an RNA-containing type C retrovirus that infects a mature T cell, usually $CD3^+$, $CD4^+$, and $HLA\text{-}DR^+$. T-cell dysregulation may initially involve an autocrine interleukin (IL)-2 loop, as well as paracrine effects from other cellular genes and cytokines, but, over time, clonal selection may result in T cells becoming IL-2 independent. Initially, the T-cell lymphoproliferation is polyclonal and is controlled by host defense mechanisms ([96], [97]); however, an oligoclonal or monoclonal T-cell proliferation may emerge, resulting in the clinical manifestations of ATLL. Mutations in tumor suppressor genes are associated with progression of ATLL ([98], [99]). Similar to EBV in lymphomagenesis, HTLV-1 may not have direct oncogenic activity but contributes to a multistep process of worsening genetic instability by interfering with mitotic checkpoints or preventing DNA repair, or both ([100], [101]).

A phylogenetic scheme of HTLV-1 has identified five major molecular subtypes, which probably spread worldwide via the slave trade: South African, Japanese, West African, Central African, and Melanesian ([102]). HTLV-1 can be transmitted by blood transfusions, needle sharing, and sexual intercourse and from mother to child through breast milk or through the placenta. The virus can have a prolonged latency period of decades before clinical syndromes appear ([96], [103], [104]) (see the section Mature T-Cell and Natural Killer–Cell Leukemias). In areas in which the virus is endemic, ATLL occurs at a rate of two to four cases per 100,000 population per year, with a lifetime risk of approximately 1 to 5% for those persons who are seropositive for HTLV-1 antibodies ([96]).

HTLV-1 infection induces the production of antibodies to various viral core proteins, which can be used as serologic markers of infection ([30], [32]). The diagnosis is usually suggested by a screening enzyme-linked immunosorbent assay and is confirmed by Western blot test. Because of slow replication, seroconversion may take as long as 2 years in HTLV-1 infection compared to the 3 to 6 months for human immunodeficiency virus (HIV) ([105]). Polymerase chain reaction (PCR) uses primers and probes of the Pol (polymerase or reverse transcripter) and Tax (transactivator) regions and is the most sensitive and specific assay for detecting HTLV-1 ([105]). HTLV-1 can lead to other diseases, including myelopathy, tropical spastic paraparesis, uveitis, bronchopneumopathy, and arthrop-athy ([105], [106]).

Other viruses have been implicated in lymphoid neoplasia and include human T-cell leukemia virus type 2, human herpesvirus (HHV) 6, HHV8 [also known as *Kaposi sarcoma–associated herpesvirus (KSHV)*], and hepatitis C. Human T-cell leukemia virus type 2 was isolated in 1982 by Kalyanaraman et al. ([107]) from a patient with an unusual T-cell variant of hairy cell leukemia. It has subsequently been isolated only rarely in lymphoid neoplasia and in HTLV-1–negative tropical spastic

paraparesis, but it is prevalent in intravenous drug abusers ([108]). Salahuddin et al. ([109]) identified HHV6 in B lymphocytes from six patients with various lymphoproliferative disorders; it was identified subsequently as the etiologic agent for exanthema subitum (roseola infantum) and as a cause for pneumonia in immunocompromised hosts ([110]). The significance of both of these viruses in lymphoproliferation remains to be determined. KSHV, also referred to as *HHV8*, has been identified in AIDS-related body cavity–based B-cell lymphomas and multicentric Castleman disease (CD) and has been associated with the EBV genome in the absence of c-myc rearrangement ([111] , [112]). Theoretically, KSHV acts synergistically with EBV to transform B cells and causes a unique clinical presentation.

Chronic hepatitis C virus (HCV) infection is often present in patients with type II cryoglobulin, and many of these patients have an underlying indolent B-cell lymphoma ([113] , [114] , [115] and [116]). A study found anti-HCV antibodies in 29 of 69 (42%) unselected patients with B-cell lymphoma who lacked an association with cryoglobulinemia ([115]). The role of HCV infection in lymphoma could be indirect or direct. Viral persistence could lend to clonal expansion of B cells, predisposing to neoplastic transformation, or, alternatively, lymphoproliferation could be the result of direct B-cell infection by HCV ([116] , [117]). Rearrangement of the *BCL2* gene occurs in three-fourths of patients with hepatitis C and mixed cryoglobulinemia and regresses with antiviral therapy ([116] , [117]).

One of the more important infections that is associated with lymphomas is *Helicobacter pylori*. This gram-negative rod was discovered by Marshall and Warren ([118]) in 1983 and was shown to be associated with peptic ulcer disease and gastric carcinoma ([119]). Gastric lymphoma was found to have a high frequency in certain parts of Europe, such as the Veneto region of Italy, and was usually a low-grade B-cell lymphoma of mucosa-associated lymphoid tissue (MALToma) ([120]). Parsonnet et al. ([121]) recognized that *H. pylori* infection preceded the development of lymphoma, and Wotherspoon et al. ([122]) reported that antibiotic treatment for *H. pylori* caused regression of the lymphoma in most patients.

PRELYMPHOMATOUS CONDITIONS

The mechanism of developing lymphomas has been best studied in those lymphomas that occur in immunodeficiency states ([123] , [124]). These disorders can be subdivided into congenital, or primary, immunodeficiencies and acquired, or secondary, immunodeficiencies (Table 90.3). Common components to all of these disorders are defects in immunoregulation, particularly in T-cell immunity, which results in decreased cytokines, and uncontrolled B-cell growth in lymphoid tissue, often in association with the EBV genome. Since 1973, cases of malignant disease in children with immunodeficiency have been recorded by immunodeficiency cancer registries, and NHL constitutes the majority of the cases ([125] , [126]). The median age of onset is 7 years of age, and there is a predominance in men rather than women due, in part, to the contribution of X-linked disorders ([125]). The importance of EBV in the pathogenesis of lympho-proliferation was suggested by Grierson and Purtilo ([127]) in 1974 when they described an X-linked disorder in which six boys in a single family died of infectious mononucleosis, agammaglobulinemia, or malignant lymphoma. The role of EBV in lymphomas that develop in patients with immunodeficiencies is addressed in Chapter 67 , Chapter 68 and Chapter 69 .

TABLE 90.3. Prelymphomatous Conditions

Congenital	Acquired
Ataxia telangiectasia	Immunodeficiency
Wiskott-Aldrich syndrome	Organ transplants
Severe combined immunodeficiency	Acquired immunodeficiency syndrome
Common variable immunodeficiency	
Hyper immunoglobulin M syndrome	Autoimmune disorders
X-linked hypogammaglobulinemia	Sjögren syndrome
X-linked lymphoproliferative syndrome	Hashimoto thyroiditis
Autoimmune lymphoproliferative syndrome	Rheumatoid arthritis
	Inflammatory bowel disease
	Castleman disease
	Hodgkin disease
	Predisposition to T-cell lymphoma
	Nontropical sprue
	Angioimmunoblastic lymphadenopathy
	Lymphomatoid papulosis

Organ Transplants

In the early 1980s, a range of lymphoproliferative lesions was described that occurred in patients who received chronic immunosuppressive therapy after solid organ transplantation. The clinical and pathologic spectrum of diseases included primary infectious mononucleosis, polymorphic B-cell hyperplasia, and intermediate- to high-grade B-cell lymphomas in which necrosis, cytologic atypia, monotypic Ig expression, and cytogenetic abnormalities were harbingers of neoplastic transformation and aggressive behavior ([128] , [129]). Serologic and molecular studies linked many of these lymphoproliferations to primary or secondary EBV infection ([130] , [131]). The risk of developing lympho-proliferation after transplantation is dependent on age, EBV status, type of transplant, and amount of immunosuppression ([128] , [129]). A lower chance occurs in older, as opposed to younger, age; sibling, as opposed to cadaver, donor; and single, as opposed to multiple, transplants. Early reports from Stanford University indicated that as many as 40% of patients who survived cardiac transplantation developed a malignant lymphoma ([132]). With less immunosuppression, the incidence is 1 to 13% after solid organ transplants, which is a 30- to 60-fold increase in lymphomas compared to the general population ([133]). The diagnosis and management of posttransplant lymphoproliferative disease is described in Chapter 67 .

Acquired Immunodeficiency Syndrome

AIDS was recognized as a disease in 1981, and the first case of lymphoma in an AIDS patient was reported in 1982 ([134]). This was followed by a series of 90 homosexual patients with NHL that was reported by Ziegler et al. ([135]) in 1984. In 1985, the diagnosis of NHL in association with positive serologic evidence for HIV became a criterion for the diagnosis of AIDS ([136]). In the series by Ziegler et al. ([135]), presenting features included generalized adenopathy and opportunistic infections in one-third of patients. Extranodal sites of disease and advanced stage occur in three-fourths of patients with ARL. The most common extranodal sites are the meninges, the gastrointestinal tract, the bone marrow, the liver, and the lungs and pleura; unusual sites include the rectum, the oral cavity, the heart and pericardium, the common bile duct, and the skin ([137]). NHL in AIDS patients is usually of B-cell origin and includes large B-cell (immunoblastic or large transformed) and small transformed B-cell histologies (Burkitt and Burkitt-like) ([137]). Unique presentations of ARL include plasmablastic lymphoma of the oral cavity ([138]) and primary effusion lymphoma ([111]). Differences in the histology of ARL have not impacted survival ([139]); however, they are likely to become more important with improved survival in AIDS.

The prevalence of NHL in AIDS is 3 to 6%, and, before the era of HAART, there were projected increased risks over time ([140] , [141]). The risk of lymphoma is 150- to 650-fold among HIV-infected patients compared to the general population and is associated with older age, severe immunodeficiency (defined by CD4 count and HIV viral load), and prolonged HIV infection ([142] , [143] and [144]). Since the introduction of HAART, epidemiologic studies are finding a decreased incidence in ARL, particularly in primary brain NHL and in immunoblastic histology ([143]). Prognostic factors and therapy of ARL are addressed in Chapter 69 .

Autoimmune and Other Immunologic Disorders

Chronic inflammation, immune hyperactivity, or immunosuppression, or a combination of these, are elements of autoimmune disorders that predispose patients to lymphoma ([145]). Many of these lymphomas arise in extranodal sites at which there is sparse lymphoid tissue; they are usually localized, low-grade B-cell MALTomas.

Isaacson ([146]) initially recognized MALTomas in the gastrointestinal tract and indicated that they were a subset of immunoproliferative small intestinal disease (IPSID), or Mediterranean lymphoma; however, they subsequently identified similar lymphomas that occurred in the lung and salivary gland. Multiple other extranodal sites have been involved with MALTomas and include thyroid gland, thymus, breast, conjunctiva, gallbladder, skin, cervix, larynx, and trachea ([146]). Although the term *MALToma* is misleading owing to the fact that not all of the lesions arise in mucosal tissue, two common features are chronic inflammation and the presence of glandular epithelium that is destroyed by progressive lymphocytic infiltration ([147]).

MALToma of the stomach serves as a model for lymphomagenesis secondary to antigenic stimulation (Fig. 90.6) ([148]). Both B and T cells are recruited to the gastric mucosa following *H. pylori* infection. Proliferation of B cells is dependent on reactive T cells ([149]). There is a continuous spectrum of pathologic lesions during the transition from gastritis to low-grade MALToma ([148]). PCR may be helpful in identifying a malignant B-cell clone that may persist after histologic regression after antibiotic therapy ([150]). Somatic hypermutation is characteristic of the B-cell clone of MALToma and, along with the observation of plasmacytic differentiation, indicates a postgerminal center origin.

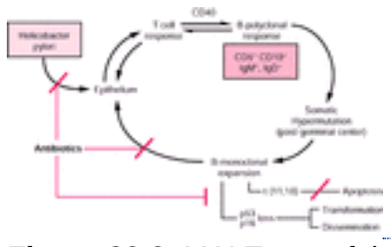

Figure 90.6. MALToma of the stomach: model for lymphomagenesis. *Helicobacter pylori* infects the epithelial cells, and there is recruitment of T and B cells. Contact-dependent T-cell help is mediated by CD40 and CD40 ligand interaction. B cells undergo a T-cell dependent polyclonal response that can develop into a postgerminal center monoclonal B-cell lymphoma. Antibiotics can eradicate *H. pylori* and cause regression of the lymphoma unless there is a clonal evolution that involves a specific translocation [i.e., t(11;18)] or a loss of tumor suppressor genes (i.e., p53, p16), which are associated with dissemination of disease.

The most common genetic abnormality in stomach MALT-oma is the t(11;18)(q21;q21), which is present in approximately one-third of cases and in as much as one-half of *H. pylori*–negative cases ([151] , [152]). The genes that are involved at t(11;18) are an apoptosis inhibitor gene *API2* and a novel 18q gene, *MALT*, and are less likely to undergo histologic transformation than other genetic abnormalities that are identified in MALTomas ([153]). Another nonrandom translocation, t(1;14)(p22;q32), which involves the *BCL10* gene, and trisomy 3 are other genetic abnormalities that are reported in MALToma and suggest the heterogeneity of lymphomagenesis in histologically similar lesions ([148] , [154] , [155]). *BCL1* and *BCL2* gene rearrangements are not present in MALTomas, and *BCL6* has only rarely been reported ([148]). There is controversy regarding whether the B-cell clones remain dependent on antigen stimulation or expand through autonomous (antigen-independent) growth ([148]). The loss of tumor suppressor genes and the amplification of 3q27 have been associated with histologic progression and dissemination of MALTomas ([153] , [156] , [157]).

Lymphomas that are associated with Sjögren syndrome and Hashimoto thyroiditis tend to occur in elderly patients and are B-cell lymphomas. Unlike other NHLs, however, they have a female predominance. The presumed pathogenesis of lymphomas in these patients is associated with chronic antigenic stimulation that causes polyclonal B-cell growth with eventual development of a monoclonal B-cell lymphoma. Bunim and Talal ([158]) reported the first association of lymphoma and Sjögren syndrome in 1963, and Kassan et al. ([159]) subsequently reported a greater than 40-fold risk for lymphomas in these patients. The histologic lesion of Sjögren syndrome is a myoepithelial sialoadenitis that is characterized by lymphoid infiltration of the salivary gland along with acinar atrophy and proliferation of ductal cells to form myoepithelial islands ([160]). Although the initial clinical course of Sjögren syndrome usually is benign, clonally rearranged Ig genes can be detected uniformly by Southern blot analysis in the biopsy of myoepithelial sialoadenitis ([161]). Furthermore, the finding of light chain restriction in minor salivary glands of the lip by *in situ* hybridization techniques correlates with development of lymphoma ([162]). These findings suggest, as in many other prelymphomatous conditions, that the so-called benign lesion actually represents a monoclonal population of unknown significance or malignant lymphoma *in situ*. Clinically overt malignant lymphoma tends to occur in those lesions with extensive, confluent areas of monotypic B-cell proliferation, and the lymphomas that are seen most commonly are monocytoid B-cell, lymphoplasmacytic, or immunoblastic sarcoma of B cells ([160]). Salivary MALTomas arise from a restricted Ig *VH* gene repertoire, which can have rheumatoid factor activity ([163]).

Lindsay and Dailey ([164]) described an association between malignant lymphoma of the thyroid and Hashimoto thyroiditis in 1957. Subsequent studies indicate that more than 75% of thyroid lymphomas are preceded by Hashimoto thyroiditis, which is made evident by thyroiditis in the nonlymphomatous portion of the pathologic specimens ([165]) and by antithyroid antibodies in most patients ([166]). There is a 60- to 80-fold increase in thyroid lymphoma after thyroiditis, but the lifetime risk is only 1 to 2% ([167] , [168]). Unlike the lesion of Sjögren syndrome, which has Ig gene rearrangement, the lesion of Hashimoto thyroiditis does not usually have a clonal population of cells that is identified by DNA analysis ([169]). Most thyroid lymphomas express surface IgG rather than the IgM that is characteristic of follicular center cell (FCC) lymphomas, thus suggesting that thyroid lymphomas involve B-cell progenitors with the ability to differentiate further from IgM to IgG production ([170] , [171]).

Lymphomas have been reported in patients with other autoimmune disorders, including rheumatoid arthritis, systemic lupus erythematosus, scleroderma, inflammatory bowel disease, and dermatomyositis; however, the increased incidence in these disorders is complicated by the use of immunosuppressive therapy and by possible methodologic flaws of epidemiologic studies ([123] , [172] , [173]). The increased risk for lymphoma in rheumatoid arthritis varies from two- to 15-fold and is higher with methotrexate use and in patients with Felty syndrome ([174] , [175] , [176] and [177]). A wide spectrum of lesions has been described with methotrexate, ranging from lesions that resemble posttransplant polymorphous lymphoproliferation to large B-cell lymphomas and HD ([176] , [178]). EBV may be present in tumor cells, and the lymphoproliferations may regress with discontinuation of methotrexate ([178] , [179]). T-cell large granular lymphocytic (LGL) leukemia is often associated with rheumatoid arthritis and neutropenia ([180]).

CD (giant lymph node hyperplasia, angiofollicular lymph node hyperplasia) was first recognized in the 1920s and was further described as a clinicopathologic entity in 1956 ([181]). It has two types of clinical presentations (localized and multicentric) and three types of histologic subtypes (hyaline vascular, plasma cell, and mixed) ([182] , [183] and [184]). The hyaline variant type is the most common subtype and presents as localized adenopathy often in the mediastinum. It can be amenable to surgical resection, and, although it was initially reported to be radioresistant, it has been successfully treated with radiation as well ([185]). The plasma cell variant is associated with systemic symptoms, anemia of chronic disease, hypergammaglobulinemia, and a variety of unusual syndromes, including myasthenia gravis, nephrotic syndrome, peripheral neuropathy, amyloidosis, and temporal arteritis ([182] , [183] and [184] , [186]). Increased expression of the gene coding for IL-6 has been identified in CD, and retroviral transduction of the gene into mice has reproduced histology and symptoms ([187]). Moreover, antibodies to IL-6 or its receptor have ameliorated the disease ([188]).

The plasma cell variant tends to be a local form, which occurs more commonly in young adults and is amenable to local therapy, or a multicentric form, which occurs in older adults or in HIV-infected patients with diffuse adenopathy and a variable, but often fatal, clinical course in which 20 to 30% of patients develop Kaposi sarcoma or B-cell lymphoma ([186] , [189]). Immunophenotyping and Ig gene rearrangements of the plasma cell variant in CD indicate that patients usually have polyclonal lesions ([190]); however, monoclonal Ig gene rearrangements have been identified in patients with the multicentric form and in patients who develop B-cell lymphoma ([191]). KSHV (HHV8) has been identified in HIV-associated multicentric CD cases ([192]). KSHV-positive plasmablasts have lambda light-chain restriction, are localized to the mantle zone of germinal centers, and can coalesce to form microscopic lymphomas ([193]). The lymphomas have had a variable histologic pattern, but they are usually of B-cell origin, with mantle cell being the most common subtype, and have a poor prognosis ([189] , [194]).

NHL may follow HD, with prior therapy and the cell-mediated immune defect characteristic of HD serving as possible contributing factors. Krikorian et al. ([195]) reported six cases from Stanford University of intermediate- to high-grade lymphoma that developed after HD. In subsequent series, authors have estimated that 1 to 5% of patients with HD develop NHL ([196]); some studies have indicated a greater risk in the nodular variant of lymphocyte predominant HD (LPHD), which, unlike other subtypes of HD, clearly has a B-cell immunophenotype ([195] , [197]). The large cell lymphomas that are associated with LPHD generally are regarded as a progression of LPHD rather than as secondary neoplasms. Single-cell analysis of the lymphocytic and histiocytic cells of LPHD have proven a clonal relation to large

B-cell lymphoma that develops in the same patient ([198]). Most NHLs that occur after all subtypes of HD are of B-cell origin ([197], [199]), but those of T-cell immunophenotype have followed HD as well ([200], [201]). The EBV genome has been found in some cases of NHL that develop after HD ([197]). The prognosis of NHL secondary to HD is poor ([195], [199]); however, responses to rituximab have occurred in large B-cell lymphoma after HD ([202]).

T-cell lymphomas commonly do not occur in the setting of immunodeficiencies, with the exception of ataxia telangiectasia; however, some disorders appear to predispose to peripheral T-cell lymphoma (PTCL), and as much as one-tenth of lymphomas in organ transplants are of T-cell origin. Posttransplant lymphoproliferative disease of T-cell origin tends to occur late and has a poor prognosis ([203]). Angioimmunoblastic lymphadenopathy and angiocentric immunoproliferative syndromes usually represent early variants of PTCL ([204]). Patients with gluten-sensitive enteropathy or celiac disease have an increased incidence of lymphoma ([205]). Although Isaacson et al. ([206]) initially reported that these lymphomas were variants of malignant histiocytosis, subsequent studies with gene rearrangement techniques indicated a T-cell origin, and they are referred to as *enteropathy-associated T-cell lymphoma (EATL)*.

Skin disorders, particularly lymphomatoid papulosis, may also evolve into a malignant cutaneous T-cell lymphoma (CTCL) (Chapter 94). Clonality, as evidenced by TCR gene rearrangements, has been detected in some patients with lymphomatoid papulosis ([207]), as well as in those with other cutaneous T-cell processes of uncertain malignant potential, such as pityriasis lichenoides et varioliformis acuta ([208]), granulomatous slack skin disease ([209]), and pagetoid reticulosis ([210]). The latter two disorders are now thought to represent variants of mycosis fungoides.

CLINICAL FEATURES AT PRESENTATION

The majority of patients with NHL present with painless adenopathy, more commonly in the cervical or supraclavicular regions ([211]). Systemic symptoms occur in less than 25% of patients in most large series ([211], [212]). When present, however, they usually are associated with advanced stages of disease and a poor prognosis. Significant cytopenias are rare, unless marrow involvement is extensive, or there are associated immune-mediated cytopenias, hypersplenism, or, rarely, hemophagocytosis.

The gastrointestinal tract and Waldeyer ring are the most common extranodal sites at presentation ([53], [213]). Gastrointestinal symptoms are often nonspecific, with vague abdominal pain being the most common presenting symptom in intestinal lymphoma. Frank bleeding occurs in less than 30% of patients with gastrointestinal lymphomas and usually is from a gastric or large bowel source ([214]). Obstruction, specifically intussusception, or perforation is more commonly associated with aggressive small bowel lymphomas, particularly Burkitt lymphoma and intestinal T-cell lymphoma ([214], [215]). Mantle cell lymphoma (MCL) presents with gastrointestinal symptoms in 20 to 30% of patients, and multiple polyposis may be found on colonoscopy. Although the mucosa often appears normal, abnormal histology is found in more than 80% of mantle cell patients ([216]). Dysphagia, airway obstruction, and eustachian tube blockage, with or without cervical adenopathy, are symptoms that suggest Waldeyer ring involvement. Epistaxis and nasal obstruction, usually with facial edema, are common signs of involvement of nasal lymphomas.

Hepatosplenomegaly is a common feature of advanced low-grade B-cell lymphoma, including small B-cell lymphocytic lymphoma, follicular lymphoma, and splenic marginal zone lymphoma (SMZL), and can be the predominant clinical feature of a rare PTCL, ?d hepatosplenic type. Primary NHL of the liver is extremely rare, usually is a large B-cell type, and can arise in immunodeficient hosts. Presenting features include right upper quadrant pain, anorexia, nausea, coagulopathy, and elevated liver enzymes without significant jaundice ([217]). Obstructive jaundice can occur in NHL secondary to periportal lymphadenopathy or primary to lymphoma of the bile duct or pancreas. Hypodense, nonenhancing masses on computed tomography (CT) imaging are characteristic of primary liver NHL. Solitary masses occur in approximately two-thirds of cases; multiple masses occur in one-third of cases, and diffuse infiltration is rare ([217]). Rarely, liver involvement with NHL may present with hepatic failure ([218]).

The skin is another common extranodal presentation of NHL, and the most common primary cutaneous type is the cerebriform T cell of mycosis fungoides or Sézary syndrome (Chapter 94). Although mycosis fungoides tends to be confined to the skin with characteristic stages, B-cell lymphomas that involve the skin only represent 20% or less of primary cutaneous lymphomas and usually present as nodules that involve the head, neck, or trunk, and more often represent evidence of systemic disease ([219]). The major types of primary cutaneous B-cell lymphoma and their distinguishing immunotypes include marginal zone (MALToma type) (CD20 $^{+}$, CD5 $^{-}$, CD10 $^{-}$), primary cutaneous follicular lymphoma (PCFL) (CD20 $^{+}$, CD10 $^{+}$), and primary cutaneous large B-cell lymphoma (PCBCL) (CD20 $^{+}$, usually CD10 $^{-}$). Other T-cell lymphomas with unique skin involvement include anaplastic large cell lymphoma (ALCL), which can be a primary cutaneous type or a systemic disease ([220]), and subcutaneous panniculitis-like PTCL.

Neurologic symptoms and signs, including headache, confusion, lethargy, dysphasia, hemiparesis, seizures, and cranial nerve palsies, and, rarely, multifocal leukoencephalopathy, may be presenting features of CNS disease and are more commonly seen in CNS lymphoma in AIDS patients or in patients with high-grade lymphomas (small noncleaved B-cell and T-cell LL) ([221], [222]). Cognitive and personality changes are more common in primary CNS lymphoma (PCNSL) owing to a predilection for involvement in the frontal lobes, the corpus callosum, and the periventricular area ([221]).

The detection of a single lesion on magnetic resonance imaging (MRI) favors PCNSL, but multifocal lesions can occur in approximately one-third of normal hosts and more frequently in AIDS patients (see the section Epidemiology) ([221]). In AIDS patients with intracranial mass lesions, the differential includes not only CNS lymphoma, but also toxoplasmosis, progressive multifocal leukoencephalopathy, and other opportunistic infections. CT scanning of CNS lymphoma usually identifies a contrast-enhancing lesion or lesions with a mass effect and edema that may have ring enhancement, a common finding in toxoplasmosis. The definitive diagnostic procedure is CT-guided stereotactic biopsy. Positron emission tomography (PET) scanning may distinguish lymphoma and toxoplasmosis and may obviate the need for biopsy in some AIDS patients ([223]).

Lymphomatous sites with a risk for CNS disease include nasopharyngeal, testicular, and extensive marrow involvement with intermediate-grade (large B-cell) to high-grade (small noncleaved B-cell and T-cell lymphoblastic) histologies. Because of the risk of leptomeningeal disease in PCNSL, ARL, the high-grade histologies, and the specific sites that were noted previously, the cerebrospinal fluid should be examined and treated early in the course of these patients. Elevated lactate dehydrogenase (LDH) and more than one extranodal site have been associated with CNS disease in patients with intermediate- to high-grade histologies ([221], [222], [224], [225]). Symptoms of spinal cord compression may include back pain, paresthesias, weakness, and incontinence and require emergent recognition and therapy.

Primary ocular lymphoma is part of the spectrum of CNS lymphoma. Approximately 5 to 15% of PCNSLs have ocular involvement at diagnosis, whereas CNS involvement may follow isolated ocular lymphoma in 50 to 80% of patients ([221]). Ocular symptoms include blurred vision, loss of visual acuity, or “floaters,” but patients can be asymptomatic ([221]). Slit lamp examination is recommended for patients with CNS or ocular lymphoma. The external eye usually is normal, and the diagnosis can be confused with uveitis, vitritis, or glaucoma ([226]).

Lymphomas of the extraocular space are more common than ocular lymphomas and can arise in the superficial conjunctiva or eyelids or deeper in the lacrimal gland or retrobulbar tissues ([227]). Blurred vision, ptosis, chemosis, epiphora, and proptosis can occur, depending on the orbital site that is involved. Most orbital lymphomas are of B-cell origin and are low grade, particularly in the conjunctiva or eyelids, but can be large B-cell lymphomas in the lacrimal gland or retrobulbar area ([227]). Bilateral involvement occurs in 10 to 15% of patients. CNS involvement rarely occurs, and the risk for distant spread is lower with conjunctival lesions ([227]).

Other symptoms and signs depend on unusual extranodal presentations. Bone pain is uncommon, unless the lymphoma has a leukemic component or the patient has extranodal bone lymphoma, which accounts for 3 to 5% of extranodal NHL ([53], [227], [228]). The long bones are most commonly affected, and there may be soft tissue swelling ([229]). The lesions may be lytic, sclerotic, or mixed with periosteal erosion and are best evaluated by MRI. Genitourinary presentations include renal mass, ureteral obstruction, testicular mass, ovarian mass, and vaginal bleeding. The most common cause of a testicular mass in an elderly man is NHL. Primary breast lymphoma is rare, accounts for 0.04 to 0.50% of all malignant breast tumors, and has a bimodal presentation ([227]). Breast lymphoma in young women is associated with pregnancy and lactation and often has diffuse involvement of both breasts ([230]). Older women tend to have discrete masses with unilateral involvement. Large B-cell lymphoma is the most common type of the previously mentioned extranodal NHL ([227]). Therapy of extranodal NHL is addressed in the section Management of Extranodal Lymphomas.

The lungs and, particularly, the heart are rarely involved in NHL, but patients commonly present with cardiopulmonary symptoms. Cough, dyspnea, and chest pain,

usually of a short duration of a few weeks, may be the presenting symptoms of mediastinal nodal involvement. The superior vena cava syndrome can occur with T-cell LL or large B-cell lymphoma of the mediastinum. Pleural effusions require immunophenotyping by flow cytometry (FC) to determine if there is lymphomatous involvement. The most common primary lung lymphoma is the low-grade small B-cell bronchus-associated lymphoid tissue lymphoma, which more commonly presents as localized opacities ([231]). Bronchoscopy may reveal bronchial narrowing, and biopsy often identifies submucosal involvement ([232]). Open lung biopsy may be required if bronchoscopy is nondiagnostic. Primary lymphoma of the pleura has been associated with chronic tuberculosis pyothorax or empyema ([233]). Primary cardiac lymphoma is extremely rare, usually occurs as a large B-cell NHL in an immunocompromised host, and may present with heart failure, pericardial effusion, or arrhythmia, including heart block ([234]).

NHL occasionally presents with metabolic and endocrine problems that tend to be more prominent after introduction of therapy, particularly in the setting of large tumor volume or aggressive histologies (Chapter 72). Hypercalcemia, hyperuricemic renal failure, and severe hypoglycemia are unusual metabolic presentations. ATLL has approximately one-fifth of patients presenting with hypercalcemia at diagnosis ([235]). A few cases of primary adrenal lymphoma have been reported, and the initial presentation is usually due to the mass effect ([236]). Rarely, adrenal insufficiency may be the initial presentation of NHL and is rapidly fatal if it is unrecognized ([237]).

STAGING

The Ann Arbor staging classification (Table 90.4), which was developed for HD in 1971, has been the standard scheme for NHL ([238]); however, it does not account for tumor burden and does not correlate well with prognosis. Other staging systems have been developed for NHL, particularly for NHL in children, specific pathologies (e.g., lymphoblastic, Burkitt, follicular), and extranodal sites of disease (e.g., cutaneous, gastrointestinal). Prognosis and therapy depend not only on stage, but also, more important, on the pathologic features of the lymphoma and a variety of clinical parameters that reflect tumor bulk and kinetics (e.g., size of mass, LDH level, number of extranodal sites) ([239], [240]).

TABLE 90.4. Staging of Non-Hodgkin Lymphoma

Staging System	Stage	Definition		
Ann Arbor	I	Involvement of a single lymph node region or a single extranodal organ or site (stage I_E).		
	II	Involvement of two or more node regions on the same side of the diaphragm or localized involvement of an extranodal site or organ (stage II_E) and one or more lymph node regions on the same side of the diaphragm.		
	III	Involvement of lymph node regions on both sides of the diaphragm that may also be accompanied by localized involvement of an extranodal organ or site (stage III_E) or spleen (stage III_S), or both (stage III_{SE}).		
	IV	Diffuse or disseminated involvement of one or more distant extranodal organs with or without associated lymph node involvement.		
	B symptoms	Fever >38°C, night sweats, or weight loss >10% of body weight in the 6 mo preceding admission, or a combination of these, is defined as a systemic symptom.		
National Cancer Institute Modified Staging System	I	One or two nodal sites or one extranodal site of disease without poor prognostic features.		
	II	More than two nodal sites of disease or one or more localized extranodal sites plus draining nodes with none of the following poor prognostic features: performance status =70, B symptoms, any mass >10 cm in diameter (particularly abdominal), serum lactate dehydrogenase >500 IU/dl, bone marrow involvement, three or more extranodal sites of disease.		
	III	Stage I or II plus any poor prognostic features.		
International Prognostic Index		Adverse factors	Risk group	Number of factors
		Performance status =2 [a]	Low	0, 1
		Lactate dehydrogenase > normal [a]	Low-intermediate	2
		Extranodal sites =2	High-intermediate	3
		Stage III and IV disease [a]	High	4, 5
		Age >60 yr		

[a] Age-adjusted factors.

The international prognostic index (IPI) (Table 90.4) was developed to correlate clinical parameters with prognosis and appears to be more useful than the Ann Arbor staging system in predicting survival (Fig. 90.7) ([241]). When the REAL Classification was under evaluation for clinical usefulness, an early report indicated that a high IPI did not predict an adverse outcome for ALCL; however, subsequent studies have indicated that the IPI correlates with prognosis for all histologies ([242], [243] and [244]). Additional biologic and genetic parameters, particularly genomic profiling, further subdivide prognostic groups in NHL (see the section Prognostic Factors).

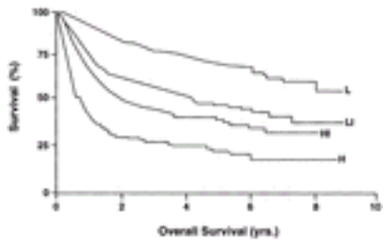

Figure 90.7. The International Prognostic Index subdivides patients with aggressive lymphoma into risk groups and correlates them with 5-year survival. L, low (73%); LI, low intermediate (51%); HI, high intermediate (43%); H, high (26%). (From Anonymous. A predictive model for aggressive non-Hodgkin's lymphoma. N Engl J Med 1993;329:987–994, with permission.)

Table 90.5 outlines the clinical evaluation and staging studies to consider when evaluating patients with NHL. Bone marrow evaluation detects disease in 20 to 40% of all patients with NHL and from 50 to 70% of patients with indolent lymphomas ([245]). FC can increase the overall percent involvement, but morphology can be positive when FC is negative, as well as vice versa ([246], [247]). Immunoperoxidase techniques may identify isolated tumor cells that are not visualized on routine hematoxylin and eosin stains. Because NHL can have focal involvement, there may be a slight advantage in performing bilateral posterior iliac crest biopsies ([248]). MRI is a sensitive technique to identify marrow involvement in patients whose biopsies have been negative ([249]). Molecular studies, such as Southern blot analysis and PCR, are more sensitive than morphology and further increase the percentage of marrow involvement; however, there is an ongoing debate about the impact of molecular markers on prognosis in NHL ([250], [251]).

TABLE 90.5. Staging Studies in Non-Hodgkin Lymphoma

Complete history and physical examination; inquiry about B symptoms, human immunodeficiency virus risk, infections, autoimmune diseases, immunosuppressive therapy

Complete blood cell count, including leukocyte count with differential; platelet count
Chemistry profile, particularly lactate dehydrogenase; also alkaline phosphatase, uric acid, creatinine, calcium, and albumin
Computed tomography of chest, abdomen, pelvis, and neck
Bone marrow aspiration and biopsy: cytogenetics and consider molecular tests (*BCL2* for follicular lymphoma, *BCL1* for mantle cell) and gene rearrangement studies in selected patients
Lumbar puncture with cytology in selected patients: all patients with small noncleaved cell and lymphoblastic lymphomas; patients with non-Hodgkin lymphoma in certain sites (i.e., nasopharynx, epidural space, testes, and large cell with marrow involvement); human immunodeficiency virus–positive patients
Gastrointestinal endoscopy for patients with Waldeyer ring involvement or abdominal symptoms
Cytologic assessment of third space fluids (pleura, peritoneum)
Immunophenotype of pathology specimen (cytogenetics and gene rearrangement data in selected patients)
Selected radiologic procedures as clinically appropriate (e.g., gallium, positron emission tomography scan, magnetic resonance imaging, ultrasound, bone scan)
Other blood evaluations: levels of ß $_2$-microglobulin and cytokines (interleukin-2 receptor, tumor necrosis factor)

Gallium and PET scans are sensitive ways to diagnose disseminated disease and may be used to assess response, particularly when residual abnormalities are noted on CT scans after therapy. Patients with a tumor that remains gallium avid during therapy are more likely to develop progressive disease than those patients with lesions that become gallium negative ([252], [253]). Similarly, persistent abnormal fluorine 18 fluorodeoxyglucose by PET after therapy is predictive of relapse and may be more sensitive than gallium scans ([254], [255]).

PROGNOSTIC FACTORS

Table 90.6 outlines clinical, laboratory, and biologic features that affect prognosis in NHL. As part of the IPI, serum LDH represents a surrogate quantitative measure for tumor burden, and other serologic markers, particularly ß $_2$-microglobulin (ß $_2$m), have been identified as prognostic factors. ß $_2$m is a low-molecular-weight polypeptide that is noncovalently linked to the heavy chain of class I histocompatibility antigens that is shed with cell turnover ([256]). Combined with serum LDH, ß $_2$m provides a reliable serologic system for predicting freedom from relapse and survival in large cell lymphoma ([257]). Patients at low risk for disease recurrence have normal levels of both markers, whereas elevations in levels of LDH and ß $_2$m (more than 3 mg/L) predict shortened remission and survival ([257]). Quantitation of a soluble, truncated IL-2 receptor that is secreted by activated lymphocytes has been applied as a serologic marker for lymphoma burden ([258], [259]). Elevations of tumor necrosis factor and its soluble receptors (p55 and p75) ([260]), IL-6 ([261]), and basic fibroblast growth factor ([262]) have correlated with a poor prognosis, whereas other cytokines, such as IL-10, have not consistently predicted prognosis ([263]).

TABLE 90.6. Clinical and Pathologic Features That Affect Treatment Outcome in Non-Hodgkin Lymphoma

Clinical features
Stage (I and II vs. III and IV)
Age (=60 vs. >60 yr)
Performance status (Eastern Cooperative Oncology Group 0, 1 vs. =2)
B symptoms
Mass size (<10 cm vs. =10 cm)
Number of extranodal sites (<2 vs. =2)
Bone marrow involvement
Treatment courses to complete remission (=3 vs. >3)
Laboratory parameters
Lactate dehydrogenase
ß $_2$-microglobulin
Interleukin-2 receptor level
Tumor necrosis factor level
Biologic characteristics
Histology
Lineage (B cell vs. T cell)
Proliferative rate
Tumor-infiltrating T-lymphocyte response
Karyotype
Genotype

Separation of NHL into three prognostic groups by histologic appearance formed the basis of the WF; however, it often combined separate entities, and it failed to recognize the impact of immunophenotyping. Although the WHO classification separates disorders into B- and T-cell neoplasms, it does not recognize the clinical grade of the disease. Clinical correlations are being recognized for the WHO classification, which combines all follicular lymphomas together, includes immunoblastic lymphoma as a subtype of diffuse large B-cell lymphoma (DLBCL), and introduces multiple types of PTCL. Although patients with a predominantly follicular lymphoma experience prolonged survival despite a continuous rate of relapse, there may be subtypes of follicular lymphoma (grade III and some types that were formerly called *nodular mixed*) without continuous relapses ([264], [265] and [266]). Some, but not all, studies suggest that immunoblastic lymphoma is a subtype of DLBCL that is associated with immunodeficiency and with inferior outcome; however, there is difficulty in reproducing the diagnosis, and the diagnosis is rare if strict criteria are applied ([267]).

Since the initial recognition of T-cell lymphomas in the 1970s, there has been disagreement about the impact of recognizing the cell of origin on prognosis. Early series of PTCL disagreed about whether PTCL has an inferior survival to the more common DLBCL ([268], [269]). Large, prospective trials have indicated a worse prognosis for PTCL than DLBCL, except for ALCL of T-cell origin, which has a survival that is equivalent or superior to DLBCL (Fig. 90.8) ([270], [271]). Within all of the categories (PTCL, DLBCL, T-cell ALCL), there are clinical, immunophenotypic, and genetic markers that further predict prognosis. Randomized pediatric trials for the most aggressive lymphomas (Burkitt and T-cell lymphoblastic) have identified the impact of pathology and different therapies on outcome ([272]). The improved response and survival of monoclonal B-cell antibody (anti-CD20) plus chemotherapy compared to chemotherapy alone in DLBCL is additional evidence that supports the importance of recognizing the cell of origin ([273]).

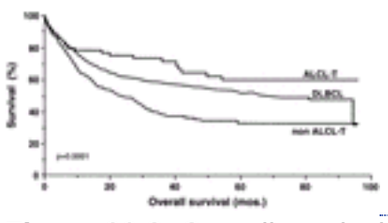

Figure 90.8. Overall survival of 228 peripheral T-cell lymphoma [non–T-cell anaplastic large cell lymphoma (ALCL-T)] and 60 ALCL-T compared to 1595 diffuse large

B-cell lymphoma (DLBCL) patients. (From Grisselbrecht C, Gaulard P, LePage E, et al. Prognostic significance of T-cell phenotype in aggressive non-Hodgkin's lymphoma. Blood 1998;92:76–82, with permission.)

Advances in lymphoma biology have contributed to the understanding of tumor-specific variables that impact on clinical behavior. Cell kinetics (low growth vs. high growth fraction), T-cell immune responses (T4 $^{+}$ and T8 $^{+}$), and cell adhesion molecules are biologic parameters that contribute to lympho-magenesis and may correlate with prognosis. Cell proliferative fraction, as determined by S-phase percentage, thymidine labeling, or immunocytochemistry influences outcome in indolent and aggressive lymphomas ([274], [275] and [276]). In DLBCL, a high proliferative fraction, as defined by expression of the nuclear proliferation antigen Ki-67 (more than 60% of malignant cells), has identified patients at risk for early relapse and short survival ([276]). Similarly, loss of immune recognition structures on malignant cells, such as the histocompatibility antigens (e.g., HLA-DR), is thought to be associated with deficient local suppressor and cytotoxic T-cell response—that is, tumor-infiltrating T lymphocytes ([277]). Patients with HLA-DR negative lymphomas were initially reported to have a shortened survival, but some studies have not confirmed the correlation and have identified a favorable prognosis in NHL with increased CD4 $^{+}$ memory T cells ([278], [279], [280] and [281]).

Cell adhesion molecules are involved in lymphocyte homing and belong to adhesion receptor families, including selectin, integrin, Ig, and CD44 ([282]). Weak expression of the integrin ligand intercellular adhesion molecule 1 has correlated with dissemination and a poor prognosis in some, but not all, studies ([283]). Alternatively, increased CD44 expression has frequently correlated with a poor survival in DLBCL, even with limited-stage disease ([283], [284] and [285]). The variables of cell growth, T cells, and expression of cell adhesion molecules appear to have predictive prognostic value independent of clinical parameters and may be used to construct biologically relevant models of risk assessment ([275], [282], [286]).

Correlations between genetic abnormalities and disease entities are a central part of the WHO classification and the understanding of lymphomagenesis (Chapter 89). Immunoperoxidase stains can identify protein expression that correlates with a specific cytogenetic abnormality or prognosis, or both. Examples include cyclin D1 expression with t(11;14) of mantle cell NHL ([287]) and anaplastic lymphoma kinase (ALK) with the t(2;5) and its variants in T- or null-cell ALCL ([288]). Alternatively, BCL2 expression does not always coincide with the *BCL2* rearrangement [t(14;18)] of follicular lymphoma but may predict an inferior prognosis in DLBCL ([289], [290]). Although there is contradictory data on the impact of *BCL6* gene rearrangement on prognosis in DLBCL, increased BCL6 messenger RNA expression is associated with improved survival ([291]). Acquired chromosome 11q deletion involves the ataxia telangiectasia mutated (*ATM*) gene locus, is seen in a variety of NHL (B-cell, mantle cell, DLBCL, T-cell prolymphocytic leukemia), and is associated with a complex karyotype and a loss of tumor suppressor function ([292]).

Specific numerical abnormalities in NHL yield limited clinical data but should be correlated with pathology or other clinical factors. Favorable responses to therapy have been reported with normal metaphases and +3 or duplication of 3p, whereas chromosome breaks at 1q21-23, 1p32-36, 7, and 17p have been associated with a poor prognosis ([293], [294], [295] and [296]). Other correlations include 6q11-q16 with B symptoms, 11q13 with elevated LDH levels, and 3q21-q25 and 13q21-q24 with bulky disease ([294]). Inferior survival in follicular lymphoma was associated with deletions in 6q25-q27 or with complex karyotypes (two or more imbalanced chromosomal aberrations) ([297]). Trisomy 3 and normal metaphases were observed in less aggressive PTCL, whereas deletions in 6q, total or partial trisomy 7q, and monosomy 13 or changes in 13q14 were more common in the more aggressive PTCL ([298]). An increased number of chromosomal imbalances, gains of 3q or 12q, losses of 9p, and a loss of tumor suppressor genes are associated with an aggressive course in mantle cell NHL ([299], [300]).

Gene expression profiling by using DNA microarrays is yielding prognostic information in NHL and has subdivided DLBCL into prognostic groups according to a molecular profile ([301], [302]). Three gene expression subgroups, germinal center, activated B cell, and a third type, were identified and predicted prognosis independent of IPI (Fig. 90.9) ([302]). *BCL2* translocation and c-rel amplification were identified only in the germinal center subtype that had the best prognosis. Cell lines from the germinal center DLBCL have decreased activity of the nuclear factor-?B pathway, which blocks the apoptotic effects of chemotherapy and is increased in the poorer prognosis, activated B-cell type ([302]). Gene expression profiles have identified major differences between *de novo* DLBCL and transformation of follicular lymphoma to DLBCL with changes in expression of c-myc and its regulated genes in the latter ([303]).

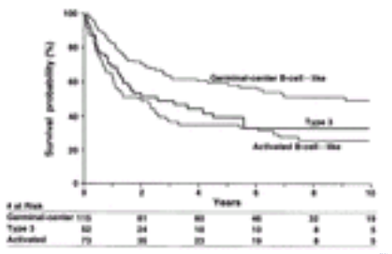

Figure 90.9. Kaplan-Meier survival curves of subgroups of diffuse large B-cell lymphoma according to gene expression profiles. Three subgroups of diffuse large B-cell lymphoma were identified, with the best prognosis occurring in the germinal center B-cell–like type. (From Rosenwald A, Wright G, Chan W, et al. The use of molecular profiling to predict survival after chemotherapy for diffuse large B cell lymphoma. N Engl J Med 2002;346:1937–1947, with permission.)

Treatment-associated parameters can also be applied to assess the probability of sustained remission. The relative dose intensity of the chemotherapy that is administered and the interval to attainment of complete remission (CR) influence the duration of remission ([304], [305], [306] and [307]). In one series, rapidly responding patients (i.e., CR in three or fewer treatment courses) had a risk of relapse that was one-half that of slower responders ([307]); however, slow responses in a later trial could not be used to accurately identify patients who could benefit from early transplantation ([308]). P-glycoprotein expression, which correlates with drug resistance, is uncommon (<5%) in untreated lymphoma patients but is often found in previously treated patients and can be a target for modifiers of drug resistance ([309]). Theoretically, therapy in the future will be directed at a drug-resistant phenotype that is defined by biologic parameters, specific genes, and protein expression.

THERAPEUTIC PRINCIPLES

Therapy follows assessment of the patient, the pathology, and the stage of the disease. The ability of the patient to tolerate therapy is dependent on age, performance status, and, if present, immunodeficiency due to a prelymphomatous condition. How advanced age adversely affects outcome in therapy is controversial, but comorbid illnesses and biologic differences of lymphomas can contribute to higher mortality in the elderly. Treatment-related toxicities are greater in elderly patients, but deaths from unrelated causes are also increased ([310]). Biologic differences of NHL between young and old patients are implicated by a greater lymphoma-related mortality in some series of elderly patients compared to younger cohorts ([311]) (see the section Therapy in the Elderly).

The type of therapy is based on pathology. One of the clinical disadvantages of the WHO and REAL classifications was the deletion of the WF grading system. Clinical schemas are being proposed to recognize the biologic behavior along with the cell of origin of the lymphoid neoplasm (Table 90.7).

TABLE 90.7. Proposed Clinical Schema for Malignancies of the Lymphoid System

B-Cell Lineage	T-Cell Lineage
Indolent lymphomas/leukemia (untreated survival measured in years)	
Chronic lymphocytic leukemia and small lymphocytic lymphoma	Large granular lymphocytic leukemia, T-cell and natural killer–cell types
Lymphoplasmacytic lymphoma, immunocytoma, Waldenström macroglobulinemia	Mycosis fungoides and Sézary syndrome
	Primary cutaneous anaplastic large cell
Hairy cell leukemia	Smoldering and chronic adult T-cell leukemia/lymphoma (human T-cell lymphotropic virus type 1 positive)
Splenic marginal zone lymphoma	

Marginal zone B-cell lymphoma
  Extranodal (mucosa-associated lymphoid tissue B-cell lymphoma)
  Nodal (monocytoid)
Follicle center lymphoma, follicular (small cell)—grade I
Follicle center lymphoma, follicular (mixed small and large cell)—grade II

Aggressive lymphomas (untreated survival measured in months)

Plasmacytoma, multiple myeloma
Mantle cell lymphoma
Follicle center lymphoma, follicular (large cell)—grade III
Diffuse large B-cell lymphoma (includes immunoblastic and diffuse large and centroblastic lymphoma)
Primary mediastinal (thymic) large B-cell lymphoma
Prolymphocytic leukemia
Peripheral T-cell lymphoma, unspecified
Angioimmunoblastic lymphoma
Angiocentric lymphoma (nasal type natural killer–cell and T-cell lymphoma)
Intestinal T-cell lymphoma
Anaplastic large cell lymphoma (T-cell and null-cell type)
Hepatosplenic ?d T-cell lymphomas (gamma delta)
Subcutaneous panniculitis-like T-cell lymphoma

Highly aggressive lymphomas and acute leukemias (untreated survival measured in weeks)

Precursor B-lymphoblastic lymphoma/leukemia
High-grade B-cell lymphoma, Burkitt-like
Burkitt lymphoma and B-cell acute leukemia
Plasma cell leukemia
Precursor T-lymphoblastic lymphoma/leukemia
Adult T-cell lymphoma/leukemia (human T-cell lymphotropic virus type 1 positive)

Adapted from Hiddemann W, Longo DL, Coiffier B, et al. Lymphoma classification—the gap between biology and clinical management is closing. Blood 1996;88:4085–4089.

The intensity of therapy is based on pathology and stage of disease. Advanced stage, tumor bulk as reflected by size (usually larger than 10 cm) and LDH, and number of extranodal sites of involvement were recognized early as independent prognostic determinants in NHL and now contribute to the IPI ([239], [312], [313] and [314]). The IPI has correlated clinical features into prognostic groups for indolent and aggressive lymphomas ([241], [243], [315], [316]).

After therapy is instituted, response needs to be assessed according to standardized criteria that were developed in 1998 by an international workshop of lymphoma investigators (Table 90.8) ([317]). Nodal masses should be smaller than or equal in size to 1.5 cm to be considered normal but should be smaller than or equal in size to 1 cm if they are initially clinically abnormal in the range from 1.0 to 1.5 cm ([317]). A common problem, particularly in large cell NHL, is a residual mass after therapy. A designation of unconfirmed complete response is given if there is a greater than 75% reduction in tumor size after therapy ([317]). Persistently positive gallium or PET scans after therapy suggest residual disease, but biopsy should be considered if a therapeutic decision is going to be made. FC studies, cytogenetics, and molecular markers are not presently required in the assessment of clinical response but are areas of ongoing investigations. The endpoints of clinical trials should also be well defined, and their importance may vary according to type of lymphoma ([317]). For example, progression-free survival (PFS) is more important in aggressive lymphomas than in indolent lymphomas, for which the time to the next treatment is more relevant. The problem with the latter end point is that guidelines for initiation of treatment need to be standardized as well.

TABLE 90.8. Response Criteria for Non-Hodgkin Lymphoma

Response Category	Physical Examination	Lymph Nodes	Lymph Node Masses	Bone Marrow
Complete response	Normal	Normal	Normal	Normal
Complete response unconfirmed	Normal	Normal	Normal	Indeterminate
	Normal	Normal	>75% decrease	Normal or indeterminate
Partial response	Normal	Normal	Normal	Positive
	Normal	=50% decrease	=50% decrease	Irrelevant
	Decrease in liver/spleen	=50% decrease	=50% decrease	Irrelevant
Relapse/progression	Enlarging liver/spleen, new sites	New or increased	New or increased	Reappearance

NOTE: See text for definitions of normal.

INDOLENT LYMPHOMAS

Indolent lymphomas are characterized by a long median survival and by a slow, but continuous, decline in survival. They are usually advanced in stage; respond to therapy, but relapse; may transform over time to a more aggressive course; and rarely spontaneously regress. With the availability of new chemotherapy agents and the advent of immunotherapy, the therapeutic options for indolent lymphomas are increasing in number (Table 90.9). Although the expansion of therapies represents a major advancement, the decisions of when to initiate therapy and what type of therapy to select are often controversial and confusing for the individual patient.

TABLE 90.9. Therapeutic Options for Indolent Lymphoma

Watchful waiting
Local radiation for limited stage disease
Chemotherapy
  Alkylating agent
  Nucleoside analog
  Combination chemotherapy
Immunotherapy
  Unconjugated monoclonal antibody
  Radioimmunotherapy
  Interferons
  Interleukins
  Vaccines
Combined modality
  Chemotherapy and radiation
  Chemotherapy and immunotherapy
Transplantation

- Autologous with or without purging
- Allogeneic
  - Myeloablative
  - Nonmyeloablative

Selected therapies
- Antibiotics in gastric lymphoma of mucosa-associated lymphoid tissue
- Splenectomy

Indolent B-cell lymphomas include follicular lymphoma, small lymphocytic lymphoma, lymphoplasmacytoid lymphoma and immunocytoma, and marginal zone lymphoma. Indolent T- and NK-cell lymphomas are less common and are less well recognized, other than CTCL (Chapter 94). T- and NK-cell lymphomas and leukemias, which can have an indolent phase, include large granular T- and NK-cell leukemia, smoldering HTLV-1–positive ATLL, and, more controversially, some types of PTCL. Follicular lymphomas formerly included follicular small cleaved lymphoma (FSCL), follicular mixed lymphoma (FML), and follicular large cell lymphoma and roughly correlate with cytologic grades I, II, and III, respectively. Grades I and II follicular lymphoma are considered indolent, whereas grade III is an aggressive lymphoma that is similar to DLBCL.

Follicular lymphoma (grades I and II) is the most common indolent lymphoma in the West, usually comprising 25 to 35% of lymphomas compared to 5 to 12% in Asia ([46], [318]). Most patients present with asymptomatic lymphadenopathy; B symptoms occur in approximately one-fourth of patients ([265]). The disease occurs primarily in the elderly (median age, 55 to 65 years), has a near equal male to female ratio, and usually is disseminated at diagnosis (stages III and IV =70%) ([265], [319], [320], [321] and [322]). Marrow involvement occurs in 40 to 60% of FSCL and in 25 to 35% of FML ([319], [320], [321] and [322]). Evaluating the marrow or blood for the *BCL2* translocation often identifies occult disease and can upstage patients by molecular criteria ([323]).

Before the recognition of different types of lymphomas by immunophenotyping and the prevalence of *BCL2* translocation in follicular lymphoma, extensive descriptions were made about pathologic differences among follicular lymphomas. The degree of nodularity in follicular lymphoma had been associated with a better prognosis in FSCL, but it was not of major significance without near complete absence of follicles, as in diffuse small cleaved cell lymphoma ([321], [322]). With present-day immunophenotyping, most of diffuse small cleaved cell lymphomas are more aggressive than follicular lymphomas and include mantle cell NHL and PTCL.

Along with cytologic grading, identification of *BCL2* translocations may further subclassify follicular lymphomas. Approximately 70% of patients have translocations at the major breakpoint region that is located in the untranslated region 3' of the last exon of the *BCL2* gene, and 10 to 15% of patients have translocations in the minor cluster region that is 30 kilobases downstream of the *BCL2* gene ([318], [324]). Lopez-Guillermo et al. ([324]) correlated survival with *BCL2* rearrangements: The 3-year failure-free survivals (FFSs) for minor cluster region, major breakpoint region, and germline cases were 95%, 76%, and 57%, respectively ($p < .001$). The impact of persistence of *BCL2* rearrangement in follicular lymphomas after therapy is controversial, because there are data indicating that its presence adversely affects clinical progression after therapy, and, alternatively, other series indicate that it has no effect on long-term survival ([251], [325], [326]). Median survivals for follicular lymphomas have been in the range of 8 to 11 years ([319], [320], [322]). Although survival has not changed substantially over the past two decades, preliminary data suggest that survival may be improving with the addition of immunotherapy.

Small B-lymphocytic lymphoma (SLL) is part of the spectrum of diffuse small B-cell lymphomas that includes lymphoplasmacytoid lymphoma, marginal zone lymphomas, and MCL (Chapter 88) ([327]). There is extensive clinical overlap with chronic lymphocytic leukemia (CLL) (Chapter 92), although there is more prominent lymphadenopathy and less lymphocytosis in SLL than in CLL ([328], [329]). An initial lymphocyte count of greater than 4×10^9 per L is considered diagnostic of CLL ([327]). Over time, 10 to 20% of patients develop a lymphocytosis that is consistent with CLL ([327]). SLL represents 4 to 6% of NHL in the West, is a disease of the elderly (median age, 55 to 65 years), and has a male to female ratio of approximately 2:1 ([327], [328] and [329]). Patients usually present with generalized adenopathy, and marrow involvement is found in most patients (70 to 80%) ([328]). Splenomegaly may be prominent, and SLL is often the underlying malignancy in primary splenic lymphoma ([327]). Median survivals have been variable, from a low of 4 to 6 years to more than 10 years, and probably depend on the criteria that are used to separate SLL from CLL ([328], [329] and [330]). Deletion at chromosome 6q is the most common cytogenetic abnormality in SLL but has had no effect on prognosis ([331]). Unmutated genes, as opposed to hypermutated genes, and expression of CD38 have been associated with a worse prognosis in CLL ([332], [333]). Between 1 and 15% of SLL and CLL evolve into an aggressive large cell process that is known as *Richter syndrome*, which is characterized by bulky retroperitoneal adenopathy, rising LDH, and a survival of less than 1 year ([334], [335]).

When SLL has plasmacytic differentiation, it is referred to as a *lymphoplasmacytic lymphoma (LPL)* and can clinically overlap with Waldenström macroglobulinemia (Chapter 100). LPL represents 1 to 2% of NHL, usually occurs in the elderly (median age, 60 to 65 years), and presents with lymphadenopathy and marrow involvement in most patients and splenomegaly in as much as one-half of patients ([336]). A paraprotein is found in 29 to 50% of patients, with IgM being the most prevalent type, and can contribute to hyperviscosity, neuropathy, and glomerular disease ([327], [336]). A positive Coombs test, cold agglutinin disease, cryoglobulinemia, and positive hepatitis C serology are associated with LPL and Waldenström macroglobulinemia ([337]). Translocation (9;14) involving the *PAX5* gene is the most common cytogenetic abnormality in LPL. Early reports using alkylating agents resulted in a median survival of only 5 years, but the introduction of nucleoside analogs and monoclonal antibody therapy has improved response and survival ([338], [339] and [340]).

Marginal zone B-cell lymphomas (MZBL) include nodal-based disease (with or without monocytoid B cells), SMZL, and extranodal MALToma. Together, they represent 1 to 2% of NHL. Nodal MZBL occurs in the elderly (median age, 59 to 65 years), is the only indolent lymphoma in which women predominate (approximately a 2:1 female to male ratio), often presents with localized lymphadenopathy, and has less marrow involvement (29 to 43%) than other indolent lymphomas ([327], [341], [342] and [343]). Involvement of salivary glands and their adjacent nodes occurs in MZBL, usually in the setting of Sjögren syndrome ([342], [344]). Median survival has been variable owing to limited numbers of patients but has been recorded in the range from 9 to 12 years ([343], [345]). MALTomas are discussed in the section Management of Extranodal Lymphomas.

SMZL, with or without villous lymphocytes, occurs in the elderly (median age, 61 to 70 years), has a slight female predominance, and usually presents owing to symptoms of splenomegaly ([346], [347]). Cytopenias are common (46 to 60%), peripheral adenopathy is rare (10 to 15%), and marrow involvement is usually detected (73 to 100%) ([114], [347], [348] and [349]). A paraprotein may be present and is usually IgM. Despite disseminated disease, splenectomy plays a role in therapy by alleviating symptoms and improving cytopenias ([346], [347] and [348]). Median survival has been recorded to be 10.5 years but is shorter in the presence of a paraprotein, elevated $ß_2m$, or lymphocytosis (>9×10^9 per L) ([349], [350]). Patients with a more aggressive course have been reported to have unmutated genes with 7q deletion or to have *p53* mutations ([351], [352]).

Special Clinicopathologic Features

Clinicopathologic features that are unique to indolent lymphomas are histologic transformation and spontaneous regression. The forerunner and counterpart of histologic transformation is Richter syndrome of CLL and SLL ([334], [335]). Histologic transformation of indolent lymphomas usually is associated clinically with increasing adenopathy and LDH levels. All of the indolent lymphomas can undergo transformation, but the most common lymphoma to do so is FSCL; the transformation is characterized pathologically by a loss of a follicular pattern and an increase in the number of large noncleaved cells ([353], [354] and [355]). The median time from initial diagnosis to transformation is 4 to 6 years ([353], [354] and [355]). The incidence of histologic transformation is uncertain but has been estimated to be between 10 and 40% of indolent lymphomas, and the risk increases over time ([356]). Autopsy series of nodular lymphomas have identified diffuse morphologic changes, usually with increased large cells, in more than two-thirds of patients ([357]). Histologic transformation may involve the expression of additional cytogenetic abnormalities and oncogenes ([303], [354], [358], [359] and [360]). The disease course usually progresses rapidly after transformation, with a median survival of less than 1 year (Fig. 90.10) ([353]); occasionally, patients may attain a long remission after transformation ([355]). Patients with limited-stage disease and no prior chemotherapy at the time of histologic transformation are more likely to have prolonged survival ([355]).

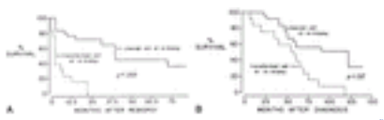

Figure 90.10. Histologic transformation of follicular center cell lymphoma. **A:** For patients with small cleaved cell lymphoma who underwent rebiopsy, median survival after transformation to large cell lymphoma was 2.5 months compared to 37.5 months in patients who had persistent cleaved cell lymphoma. **B:** Overall median survival was 56.5 months in the patients who transformed versus 89.2 months in the patients who had persistent cleaved cells at rebiopsy. (From Oviatt DL, Cousar JB, Collins RD, et al. Malignant lymphomas of follicular center cell origin in humans. V. Incidence, clinical features, and prognostic implications of transformation of small cleaved cell lymphoma. Cancer 1984;53:1109–1114, with permission.)

Spontaneous regression has occurred in indolent lymphomas, but its exact incidence is uncertain. Horning and Rosenberg reported regression in 19 (23%) of 83 untreated follicular lymphoma patients, including complete regression in six patients ([356]). Spontaneous regression occurs in approximately one-fourth of primary cutaneous ALCL cases (see the section Ki-1+ Anaplastic Large Cell Lymphoma). Spontaneous remission in diffuse large cell lymphoma (DLCL) has rarely been observed ([361]).

Additional clinicopathologic terms that are often misnomers are *discordant histology* and *composite lymphoma.* Both are related to the fact that lymphomas, particularly of FCC origin, are dynamic processes, and variations in morphology occur at different biopsy sites in patients. *Discordant histology* refers to the identification of different histologic grades of lymphoma in the same patient. The most commonly identified discordant histology is a peripheral node with predominantly large noncleaved cells and a marrow with small cleaved cells ([362]). Clinically, therapy should be directed at the higher histologic grade, although the risk of relapse may be higher ([362]). *Composite lymphoma* has also been used to describe a mixture of histologic grades but probably should be restricted to lymphomas that have two distinct histopathologic types—that is, two distinct diseases, preferably with immunophenotypic and molecular genetic differences ([363]).

Stages I and II Indolent Lymphoma

Limited-stage disease in indolent lymphomas is infrequent and may be as low as 6%, as reported by the National Cancer Institute (NCI) series of pathologically staged patients ([364]); most series that involve clinical staging report between 10 and 20% of patients with limited-stage disease ([322] , [365]). Immunophenotyping and molecular genetic studies may identify more advanced-stage disease, as well as predict the clinical course, but their impact on therapeutic decisions is controversial. Radiation therapy has achieved disease-free survival (DFS) in 31 to 85% of limited-stage patients with follow-up over 10 years, including a report from Stanford University of relapse-free survivals (RFSs) of 44% and 37% at 10 and 20 years, respectively ([366] , [367] , [368] and [369]). Although these reports suggest that some limited-stage patients may be curable, there is not a clear plateau on the survival curves. Most relapses have occurred outside the radiation field. The best results have been in young patients (younger than 50 years of age), in patients with a small amount of disease (less than 2.5 cm), and in stage I disease ([365]).

More extensive radiation (total lymphoid irradiation vs. involved field or extended field) has been associated with a better survival in a multivariate analysis, but no significant difference was noted in survival based on the extent of radiation in clinically or pathologically staged patients ([367]). Although extended field radiation is used frequently, no conclusive data are available to support more extensive radiation than involved field for localized low-grade lymphomas. The role of adjuvant chemotherapy for localized low-grade lymphomas has not been evaluated thoroughly. Results of small series have indicted fewer relapses in patients who receive combined chemotherapy and radiotherapy ([370] , [371]), but adding chemotherapy has not improved survival in localized, indolent lymphomas ([372]).

Rituximab (anti-CD20 monoclonal antibody) was initially approved for relapsed indolent lymphomas with response rates in the 50% range but is now being used as front-line single-agent therapy, with response rates of 70 to 76% ([373] , [374]). The rationale for its use in limited-stage patients includes its efficacy with low tumor burden, better PFS with molecular responses, and the fact that most limited-stage patients actually have advanced-stage disease.

Stages III and IV Indolent Lymphoma

Many investigators advocate initial watchful waiting for the advanced-stage indolent lymphomas, because of a continual risk of relapse, and early chemotherapy has not improved overall survival (OS) ([321] , [367] , [375] , [376]). Although stages III and IV usually are considered together, stage III has a tendency toward better survival than stage IV ([322] , [365]). Radiation alone and combined modality therapy are associated with an RFS of more than 50% at 5 years in stage III patients, but there are continued relapses with longer follow-up ([377] , [378]). Adverse prognostic factors in series that evaluate stage III patients include B symptoms, more than four sites of involvement, bulky disease, and elevated serum LDH levels ([377] , [378]).

Among the most controversial aspects in the management of indolent lymphomas are the initiation of therapy and the selection of type of therapy (Table 90.9). The choices of therapy are multiple and vary widely from no initial therapy to various chemotherapy agents (single or combination), with or without monoclonal antibody therapy, to transplantation ([319] , [321] , [367] , [379]). Clinical features that usually warrant therapy include B symptoms, bulky lymphadenopathy, nodal encroachment on vital organs, massive organomegaly, cytopenias, or transformation ([319] , [367]). Age of the patient, performance status, comorbid illnesses, patient preference, and physician training and bias influence therapeutic decisions. Most studies that evaluate the therapy of indolent lymphoma are compromised owing to small patient numbers, the lack of randomized trials, the combination of different histologies and stages, and premature reporting. Because these diseases have long median survivals, long follow-up is required, and, ideally, randomized trials need to be developed to determine optimal therapy.

Prospective trials at Stanford University have evaluated different therapies in indolent lymphomas and the approach of watchful waiting before initiating therapy ([367] , [375]). In a randomized series of 51 patients, no significant differences were noted in CR, RFS, or OS among three different treatments: chlorambucil; cyclophosphamide, vincristine, and prednisone (CVP); or irradiation ([375]). In a series of 83 patients with advanced disease who initially were not treated, a median actuarial survival of 11 years was reported; 61% of patients required therapy for progressive disease at a median time of 3 years ([356]). The median time to treatment was significantly shorter for FML (16.5 months) than for FSCL (48 months) or SLL (72 months), and the OS at 10 years was significantly poorer for FML (60%) as compared to FSCL (80%) ([356]).

Combination chemotherapy has been evaluated in randomized trials without evidence of superiority of any one regimen and without comparing therapy to watchful waiting, except in a single trial at the NCI. Although the Eastern Cooperative Oncology Group (ECOG) reported a better 5-year RFS in stages III and IV FSCL that received a combination of COPP (cyclophosphamide, vincristine, procarbazine, and prednisone) (57%) as opposed to a combination of BCOP (bischloroethylnitrosourea, cyclophosphamide, vincristine, and prednisone) (26%) and a combination of chlorambucil and prednisone (22%; p =.02); no difference was noted in OS ([380]). The Southwest Oncology Group (SWOG) and Cancer and Leukemia Group B have similarly found no significant differences in response or OS in patients with indolent lymphomas when comparing the combination of CHOP [cyclophosphamide, hydroxydaunomycin, Oncovin (vincristine), and prednisone] with or without bleomycin to less aggressive regimens ([381] , [382] and [383]); however, the M. D. Anderson Cancer Center (MDACC) group has advocated using doxorubicin in treating indolent lymphomas because of better CR and survival with CHOP when compared retrospectively to CVP ([384]). Using intensive non–cross-resistant regimens, the MDACC group achieved CR rates of 65% in stage IV indolent lymphomas; some of these patients achieved molecular remissions with the loss of *BCL2* gene rearrangements by PCR analysis ([385]). CHOP plus rituximab has achieved response rates of 95% [55% CR plus 40% partial response (PR)] in indolent lymphomas and molecular remission in seven of eight patients who were previously positive for *BCL2* by PCR ([386]). Still, no randomized trial has shown a survival benefit of CHOP or other intensive regimens over less aggressive therapy in advanced-stage indolent lymphoma ([383] , [387]).

In an effort to answer the controversy between watchful waiting and initial combination chemotherapy, the NCI group prospectively randomized patients to a watch-and-wait arm with palliative involved field radiation or to an aggressive combined modality arm [ProMACE (prednisone, methotrexate, Adriamycin [doxorubicin], cyclophosphamide, and etoposide)] and MOPP [mustard, Oncovin (vincristine), procarbazine, and prednisone]; plus total lymphoid irradiation] ([388]). In a report of 104 patients, 83% were eligible for randomization, and 17% required therapy at diagnosis. No difference was noted in OS between the two groups (greater than 75% survival at 5 years), but there was a difference in DFS (51% vs. 12%; p <.01), favoring initial therapy. Despite these results, no conclusive data support intensive chemotherapy as initial therapy for advanced-stage indolent lymphomas; however, patients, particularly those with poor prognostic features, can benefit from therapy and should continue to be evaluated in clinical trials.

Although alkylating agents have been the backbone of the early trials in indolent lymphomas, nucleoside analogs, particularly fludarabine, have been increasingly used because of high response rates in previously treated and subsequently untreated patients. Responses were reported in a range from 40 to 50% in previously treated patients with 10 to 20% CR and in a range from 60 to 90% in untreated patients with 37 to 50% CR ([319], [389], [390] and [391]). In general, these agents are well tolerated, with little gastrointestinal side effects and no alopecia, but cause prolonged decrease in T-cell immunity and contribute to immune-mediated cytopenias. In a phase III randomized trial of fludarabine versus CVP in patients with relapsed indolent lymphomas, there were no differences in response rates or OS; but fludarabine slightly improved PFS (11 months vs. 9.1 months; $p = .03$) and treatment-free survival (15 months vs. 11 months; $p = .02$) and had higher scores for social function ($p = .0008$) ([392]).

Combinations of nucleoside analogs with other agents, particularly alkylating agents and the anthracenedione mitoxantrone, have been used in indolent lymphomas. In phase I and II trials of fludarabine plus cyclophosphamide in untreated indolent lymphomas and CLL, the response rates have been 92 to 100%, including CR rates of 47 to 89% ([393], [394]). The estimated 5-year DFS and OS in an ECOG trial were 53% and 66%, respectively ([394]). Despite these encouraging results, opportunistic infections are increased with the combination, there may be an increased incidence of myelodysplasia, and phase III trials have not established the combination of cyclophosphamide and fludarabine as a superior regimen ([393]).

The combination of fludarabine, Novantrone (mitoxantrone), and dexamethasone (FND) has been established as an effective combination with response rates greater than 90% (CR, 43 to 67%) in treated and untreated indolent lymphoma ([395], [396] and [397]). In previously untreated patients, the 2-year PFS was 63%, and the OS was 93% ([396]). Steroids that contribute to opportunistic infections may not increase efficacy and have been dropped by some investigators. In a randomized trial that involved patients with stage IV indolent lymphoma, FND was compared to an intensive alternating triple therapy (ATT) regimen. Maintenance therapy with interferon (IFN) and dexamethasone was given for 1 year to both arms. Although the 5-year FFS was better in ATT than in FND (50% vs. 41%; $p = .02$), there was no difference in OS (82% vs. 84%), and there were much higher grade III and IV toxicities with ATT ([398]). The controversy in indolent lymphoma is identifying an optimal treatment regimen that achieves high response rates, prolonged PFS, and mild toxicity.

Immunotherapy

The role of IFN in indolent lymphomas has been mixed owing to conflicting data in randomized trials. In the 1980s, IFN-a as a single agent had response rates that varied from 30 to 50% in NHL, depending in part on the amount of prior therapy ([399], [400]). No survival advantage was identified in most randomized trials that compared alkylator-based therapy to an alkylator with IFN-a ([401], [402]); however, randomized trials with intensive regimens, often with anthracyclines, favored the IFN-a arm with better DFS and, usually, OS ([403]). Although other trials did not find a survival advantage to IFN-a, the U.S. Food and Drug Administration approved its use in combination with anthracyclines for aggressive follicular lymphomas in 1997 ([404]).

Rituximab (Rituxan) is an unconjugated antibody against the CD20 antigen and has emerged as an effective component in the therapy of all types of B-cell lymphomas. In a phase I dose-escala-tion trial, Maloney et al. ([405]) determined a dosage of 375 mg/m ^{2} weekly for four doses as the dosage for subsequent phase II trials ([406]). In a multicenter trial that involved 166 patients with relapsed indolent NHL, McLaughlin et al. reported a 48% response and a median time to progression of 13 months for responders ([407]). This study led to rituximab's approval by the U.S. Food and Drug Administration for relapsed follicular, indolent NHL in 1997. Humanized antibodies undergoing trials in B-cell NHL include epratuzumab and apolizumab, which are directed toward the CD22 receptor and a polymorphic determinant of HLA-DR, respectively ([408], [409]).

Radioimmunotherapy has paralleled the development of unconjugated monoclonal antibody therapy and has led to the approval of two radioisotopes (yttrium 90 and iodine 131) that are conjugated to anti-CD20. The first radioimmunotherapy that was approved for the treatment of relapsed or refractory follicular and indolent or transformed NHL was yttrium 90 ibritumomab tiuxetan (Zevalin, IDEC Pharmaceuticals, San Diego, CA) ([410], [411]). In a randomized trial that compared ibritumomab tiuxetan to rituximab, in relapsed and refractory follicular or CD20 $^+$ transformed NHL, Witzig et al. ([412]) reported that the radioimmunotherapy arm had a higher response rate (80% vs. 56%, $p = .002$; 30% vs. 16% for CR, $p = .04$). Although there was no difference in the median duration of response (14.2 months vs. 12.1 months; $p = .6$), durable responses of greater than or equal to 6 months were statistically more frequent with radioimmunotherapy (64% vs. 47%, $p = .03$).

Iodine 131 tositumomab (Bexxar, Corixa, Seattle, WA; Glaxo Smith Kline, Philadelphia, PA) has been in clinical investigation since 1990 ([413]). Kaminski et al. ([414]) reported response rates of 65% in patients with chemorefractory indolent or transformed NHL compared to a 28% response after their last chemotherapy ($p <.001$). The median duration of response was 6.5 months for iodine 131 tositumomab compared to 3.4 months after chemotherapy ($p <.001$) ([414]). When used as initial therapy in patients with follicular lymphoma, the response rate was 97%, including 63% CR, and the median duration had not been reached ([415]).

Transient myelotoxicity has been the primary toxicity of radioimmunotherapy, but myelodysplasia has been reported in 5 to 7% of patients and remains a concern ([410], [414]). Although new radioimmunoconjugates are under development, trials are ongoing to establish the optimal timing and use of radioimmunotherapy in NHL and whether combining it with chemotherapy or transplantation may improve responses and survival ([410], [416], [417]). The ultimate form of immunotherapy for lymphoma is vaccination, which was pioneered in clinical trials by Levy et al. at Stanford University. Their studies and other aspects of immunotherapy are reviewed in Chapter 74.

MANTLE CELL LYMPHOMA

MCL has previously been referred to as *centrocytic*, *intermediate lymphocytic*, and *mantle zone lymphoma* and was given its present name in 1992 ([418], [419]). MCL represents approximately 2 to 8% of NHL in the West, occurs in the elderly (median age, 60 to 68 years), and has a male predominance (male to female ratio is 2 to 6:1) ([420], [421] and [422]). Most patients present with diffuse lymphadenopathy (75 to 100%), and splenomegaly is common (35 to 75%) ([420], [421] and [422]). B symptoms are present in 25 to 50% of patients, and 15 to 30% have or develop a unique gastrointestinal presentation with multiple lymphomatous polyposis ([216], [420], [421] and [422]). Bone marrow involvement is detected in 60 to 90% of patients, and as many as 25% have a leukemic phase ([420], [422]). CNS involvement has been documented in 9% of patients during the course of the illness ([423]).
