Diagnostic Approach to Malignant and Nonmalignant Disorders of the Phagocytic and Immune Systems

This chapter introduces an approach to disorders that produce abnormalities of circulating blood cells, constitutional symptoms, or enlargement of lymph nodes or the spleen. The emphasis is on distinguishing benign from malignant disease. The disorders may take the form of (a) reactions to disease, particularly infections, resulting in changes in blood leukocytes, lymphadenopathy, and/or organomegaly; (b) neoplastic diseases (leukemias, lymphomas, and plasmacytic neoplasms and related diseases); and (c) inherited or acquired diseases that result in immunodeficiency.

Patients with disorders of the phagocytic or immune system usually come to medical attention with symptoms and signs suggestive of infection. Many patients with hematopoietic lymphoid neoplasms may also present with fever or other nonlocalizing constitutional signs and symptoms such as fatigue, generalized lymphadenopathy, abnormal bleeding, weight loss, bone pain, arthralgias, and pruritus. Suspicion of an underlying immune disorder, benign or malignant, may be raised during the course of a routine examination or during the evaluation of unrelated disorders by the detection of skin lesions, lymphadenopathy, splenomegaly, or hilar or mediastinal masses. In other instances, routine blood examination may disclose abnormalities in the numbers or morphology of circulating red cells, white cells, or platelets.

A detailed history should be obtained, and a thorough physical examination should be performed. Age of the patient, immunocompetence (focusing on types and number of infections), family history, travel history, animal exposure, and drug ingestion are particularly important areas to address. Complete blood cell count (CBC) and blood examination (including study of red cells, white cells, platelets, and the blood smear) may be diagnostic or help determine the next step in diagnosis. Chest x-ray and computed tomography (CT) may assist in identifying possible biopsy sites. Electrophoresis to characterize serum or urine immunoglobulins (Igs), immunophenotyping of peripheral blood, marrow examination, lymph node aspiration or biopsy, liver biopsy, and splenectomy may be necessary. In addition, evaluation of delayed type hypersensitivity and tests of neutrophil and/or lymphocyte function may be required. Clearly, not all or even most of these tests and surgical procedures are indicated for each patient who has the symptoms or signs described. Rather, a logical sequence is undertaken for each patient, tailored to the particular findings. A diagrammatic summary of a sequential approach is shown in Figure 62.1.

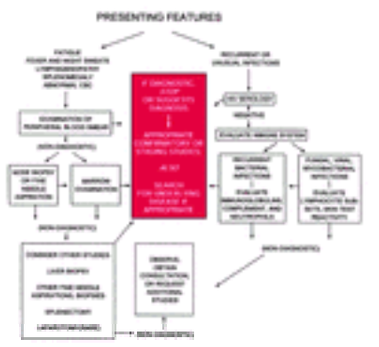

Figure 62.1. Diagnostic steps in diseases of the hematopoietic-lymphoid system. CBC, complete blood cell count; HIV, human immunodeficiency virus.

The examination of stained tissues by light microscopy remains the principal means of establishing a diagnosis in most of the benign and malignant conditions considered in Parts VI (Nonmalignant Disorders of Leukocytes, the Spleen, and/or Immunoglobins) and VII (Hematologic Malignancies). Other studies, however, including immunophenotypic studies ([1], [2]), cytogenetics, and molecular genetics, are proving increasingly valuable in making, confirming, and “fine-tuning” diagnoses as well as in determining certain subcategories of disease. Virtually all hematologic neoplasms are clonal tumors. Thus, if an expanded B-cell population is clonal by Ig light chain restriction, cytogenetics, or by gene rearrangement, the distinction between benign and malignant proliferation becomes easier. However, clonality does not always indicate malignancy ([3], [4] and [5]); oligoclonal and monoclonal populations have been identified in “benign” disorders, including lymphomatoid papulosis, monoclonal gammopathy, autoimmune disorders (e.g., Sjögren and Hashimoto), celiac disease, and lymphoid hyperplasias, particularly those in extranodal sites. Although these disorders may evolve into frank malignancy, they can remain clinically benign, regress spontaneously, or regress in the setting of antibiotics and removal of an antigen (*Helicobacter pylori* in gastric maltoma). Although the new techniques to identify clonality have astonishing sensitivity, the clinical, laboratory, and histopathology data must be correlated to distinguish benign from malignant disorders and determine therapy. In the next sections, the examination of the blood, marrow, nodes, and spleen are reviewed in the context of making a diagnosis, introducing the subsequent chapters, and outlining overviews of fever of unknown origin (FUO) and patients with recurrent infection.

EXAMINATION OF THE BLOOD

Physicians are too busy to examine peripheral blood smears in all of their patients. They usually do so in one of these circumstances: (a) patients with constitutional symptoms, particularly fever (see section on Fever of Unknown Origin) or weight loss, without an obvious underlying cause; (b) an abnormality in blood counts, either cytosis or cytopenia; or (c) as a part of the evaluation of a patient with clinical features of immunodeficiency.

The blood counts and peripheral smear are frequently abnormal in patients with constitutional symptoms, immunodeficiency, hematologic neoplasms, or a variety of other syndromes associated with lymphadenopathy or splenomegaly. Anemia, when present, usually is normochromic, normocytic. Most patients with chronic disease, myelodysplasia (MDS), multiple myeloma, and, rarely, acute leukemias have anemia but no other abnormalities. In patients with anemia of unknown origin, the evaluation begins with examination of the blood smear, red cell indices, and reticulocyte count. The evaluation proceeds based on the results of these simple tests as outlined in Chapter 27.

The major differential diagnosis of patients with thrombocytopenia includes (a) thrombocytopenia secondary to autoantibody-mediated platelet destruction [idiopathic thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE), drug-related thrombocytopenia, and perhaps human immunodeficiency virus (HIV)]; (b) primary marrow disease, particularly MDS or acute leukemia; and (c) peripheral consumption secondary to intravascular activation of clotting (e.g., disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, or hemolytic uremic syndrome). Although thrombocytopenia can be secondary to a nutritional deficiency (e.g., folate, vitamin B_{12}), usually the macrocytic anemia is the dominant clinical feature.

In ITP and drug-related thrombocytopenias, the peripheral smear red cell and white cell morphology should be normal and rare megathrombocytes are present. Thrombocytopenic patients with SLE may also be neutropenic and lymphopenic. Lymphopenia is often present in thrombocytopenia with HIV infection. MDS and leukemia rarely present with isolated thrombocytopenia. Most myelodysplastic patients are anemic and have white blood cell (WBC) abnormalities (e.g., blasts or hyposegmented or hypogranulated polymorphonuclear neutrophils) that indicate primary marrow disease. Schistocytes and polychromatophilic red cells in patients with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and hemolytic uremic syndrome are helpful in pointing away from marrow disease

or an autoimmune thrombocytopenia.

Bone marrow examination with cytogenetic studies is essential only in the cases of thrombocytopenia in patients with suspected MDS or acute leukemia or in those whom the diagnosis of autoimmune or consumptive thrombocytopenia is in doubt. In most children or young adults with otherwise normal counts and a normal blood smear, a bone marrow is probably not needed. So-called amegakaryocytic thrombocytopenias secondary to genetic or autoimmune disease are exceedingly rare.

Thrombocytosis with platelet counts of greater than 600,000 cells/µl are commonly seen on a transient basis during a variety of infections, after splenectomy, after acute blood loss, or during recovery from marrow injury or nutritional deficiency. The concern in persistent thrombocytosis is the presence of an underlying myeloproliferative disorder or occult malignancy. The presence of myeloproliferative disease is almost always suggested by the peripheral blood counts and smear [e.g., polycythemia in polycythemia vera, leukoerythroblastic changes in agnogenic myeloid metaplasia, and leukocytosis with immature myeloid precursors in chronic myeloid leukemia (CML)]. The one myeloproliferative disease in which thrombocytosis is often an isolated finding is essential thrombocythemia, a diagnosis that is best supported by the demonstration of megakaryocytic dysplasia on bone marrow examination.

Changes in blood leukocytes may provide the diagnosis (as in the leukemias) or may strongly suggest the correct diagnosis. Certain rare diseases associated with frequent infection can be recognized by morphologic changes in leukocytes (e.g., Chédiak-Higashi syndrome).

Leukocyte changes in the blood of patients with acute leukemia provide the diagnosis in more than one-half of this group and strongly suggest it in virtually all such patients ([6]). In approximately 60% of these individuals, the smear confirms the diagnosis by virtue of the presence of a large proportion of immature cells, whether or not the leukocyte count is increased. Blasts are easily demonstrable in blood smears of more than 90% of patients, and, even in patients whose blood smears have few blasts, anemia, thrombocytopenia, neutropenia, or combinations of these changes are suggestive of acute leukemia. For almost all such patients, bone-marrow aspiration proves diagnostic. Patients with two indolent leukemias, hairy cell leukemia, and leukemia of large granular lymphocytes (LGLs), often present with bacterial infections secondary to neutropenia. Circulating hairy cells may be few in number, but a bone marrow test is diagnostic. Identification of an increase in LGLs on blood smear should lead to confirmatory phenotypic studies and molecular genetic studies for clonality in LGL leukemia.

More than 10,000 small lymphocytes per µl of blood is usually indicative of chronic lymphocytic leukemia, especially if the patient is middle-aged or elderly. Characteristic signs and symptoms of chronic lymphocytic leukemia may be absent at a time when a diagnosis can be made by flow cytometric demonstration of light chain restriction, with small B lymphocytes coexpressing CD5 and CD23. Proceeding with other examinations in such patients, such as lymph node biopsy or bone marrow examination, is unnecessary.

The presence of CML is strongly considered in a patient with neutrophilic leukocytosis, particularly when the WBC count is greater than 50.0×10^9/L and is accompanied by an increase in circulating immature myeloids and basophilia. Additional findings suggesting the diagnosis of CML include (a) symptoms limited to fatigue, bone pain, left upper quadrant mass, or fullness; (b) sternal tenderness and splenomegaly revealed by physical examination; and (c) thrombocytosis. A “leukemoid reaction” must also be considered. Marrow examination confirms the diagnosis of CML by detecting the Philadelphia chromosome [t(9;22)] by cytogenetics or the chimeric bcr-abl gene by molecular analysis.

Patients with multiple myeloma usually have a few plasma cells in the blood, although occasionally large numbers are noted (plasma cell leukemia). Such patients almost invariably have other symptoms and signs of myeloma. A few plasma cells may also be observed in blood smears of patients with infectious mononucleosis or other viral infections. Plasma cells also are seen in the blood of persons recovering from bacterial infections or having allergic reactions, especially serum sickness. The next step when the diagnosis of myeloma is considered is to perform studies of serum and urine Igs. The technique of immunoelectrophoresis has largely been replaced by electrophoresis with immunofixation. This sensitive and specific technique identifies a monoclonal serum Ig and/or light chain in urine in more than 90% of patients with myeloma. The diagnosis is confirmed on bone marrow examination.

Blood leukocyte changes that are secondary to a variety of diseases usually consist of neutrophilia, eosinophilia, monocytosis, or abnormal-appearing lymphocytes. Changes in the distribution or appearance of circulating WBCs may provide important clues to the presence and type of an underlying infection. Eosinophilia is common in atopic individuals but can be seen in many parasitic infections. Atypical lymphocytosis is a helpful diagnostic clue in infections caused by Epstein-Barr virus, cytomegalovirus, and in primary HIV infections. In many parasitic diseases, such as malaria, acute Chagas disease, and filariasis, the infectious agent is easily demonstrated in peripheral blood. However, these three parasitic diseases are rarely autochthonous in North America, and the diagnosis is suggested by the nationality of the patient as well as the recent travel history of the patient ([7], [8], [9] and [10]).

Although in most infections the causative agents are not demonstrable in peripheral blood, there are certain notable exceptions. In HIV infection or in other severely immunocompromised patients, mycobacteria (Fig. 62.2A), fungi, such as histoplasmosis (Fig. 62.2B), or *Candida* may occasionally be identified on the peripheral blood smear. Residents of the Midwest (particularly Arkansas and Missouri) and Southeast may acquire ehrlichiosis through tick vectors. The typical inclusions of *Ehrlichia* in mononuclear cells (*Ehrlichia chaffeensis*) (Fig. 62.2C) or in neutrophils (*Ehrlichia phagocytophila*) are present in up to one-third of these patients, who often present with unexplained fever with accompanying leukopenia and elevated transaminases. The diagnosis of ehrlichiosis may be confirmed either serologically or by polymerase chain reaction methods ([11]). Babesiosis, first recognized in the 1890s as the cause of Texas cattle fever, has now been identified in febrile patients in the Northeast (Nantucket, Martha's Vineyard, Connecticut), Wisconsin, and on the West Coast. Infections can be life threatening in splenectomized patients. The diagnosis is suggested by the finding of single ring forms 1.0 to 3.5 micra in diameter in red blood cells (Fig. 62.2D) (characteristic tetrads are usually seen only in infected animals) ([12]). Although fungi, such as histoplasmosis, are rarely visible in the blood of nonimmunocompromised patients, in patients with indwelling venous catheters, *Malassezia furfur* (Fig. 62.2E), *Candida*, and *Torulopsis* (*C. glabrata*) may be identified in peripheral blood ([13], [14]). In bacterial sepsis, visible circulating bacteria are rare, but the presence of cytoplasmic neutrophilic vacuoles in a fresh finger stick blood smear is a specific clue to the diagnosis of septicemia (Fig. 62.2F). Toxic granulation (also seen in patients with sepsis) is often quite prominent in uninfected patients receiving granulocyte or granulocyte/macrophage-colony stimulating factor. Neutropenia may provide an explanation for the presence of infection and requires consideration of its various causes. Lymphopenia is produced by a wide variety of causes, but usually it is a transient phenomenon. Persistent lymphopenia suggests a defect in cellular immunity, such as that present in patients with Hodgkin disease or acquired immunodeficiency syndrome (AIDS).

EXAMINATION OF THE BONE MARROW

If a diagnosis is not established by examining the blood, bone marrow examination may be helpful (Table 62.1). Needle biopsy is usually performed in addition to aspiration, particularly if lymphoma, carcinoma, granulomatous conditions, or myelofibrosis are under consideration. To adequately triage marrow, the stained aspirate smear is reviewed along with clinical information and previous studies shortly after the procedure. This allows decisions about cytogenetics, molecular genetics, and

flow cytometry to be made when viable cells are still available and also limits inappropriate studies (Table 62.2). In the case of inaspirable marrows, sufficient cells for flow cytometry may be obtained by maintaining negative pressure on withdrawal of the biopsy or aspirate needle and then rinsing the needle in nutrient media or buffered saline.

TABLE 62.1. Indications for Bone Marrow Examination

Unexplained cytopenia
Evaluation of leukemia
Confirmation of myeloproliferative disorder
Unexplained lymphadenopathy
Splenomegaly without a diagnosis
Diagnosis or staging of lymphoid neoplasms
Constitutional symptoms (fever, weight loss) without a diagnosis
Bone pain with abnormal laboratory work (e.g., complete blood cell count, ? protein, ? lactate dehydrogenase, and ? uric acid)

?, increased.

TABLE 62.2. Suspected Diagnosis on Marrow Smear

Suspected Diagnosis	Flow Cytometry	Cyto-Chemistry	Cytogenetics	Molecular Genetics	Electron Microscopy
Acute leukemia	+	+	+	*a*	*b*
Suspected myelodysplasia	*c*	*d*	+	–	–
Myeloproliferative (particularly chronic granulocytic leukemia)	*e*	*e*	+	BCR	–
Lymphocytosis (small nondysplastic)					
Child	No	No	No	No	–
Adult	+	No	*a*	*a*	–
Suspected non-Hodgkin lymphoma (large cells ± dysplasia)	+	No	+	*a*	*b*

a If marrow transplantation is a therapeutic consideration, such baseline studies may be useful in assessing success of purging in autologous transplants and monitoring patients posttransplant.

b Marrow can be held pending completion of other studies.

c Potentially helpful but not well established in literature.

d Periodic acid-Schiff staining of erythroids is helpful diagnostically in myelodysplasia. Sudan black stains may reveal Auer rods, overlooked on Wright stain.

e Helpful only in blast crisis.

In cases of acute leukemia, cytochemistry allows classification of most cases of acute nonlymphocytic leukemia in which Auer rods are not easily identified. For acute leukemias in which the cells are Sudan black or peroxidase negative (FAB, M0 and M7; ALL), flow cytometry or other immunophenotypic studies are essential for classification ([15]). These account for approximately one-third of cases of acute leukemia at our institution ([16]). Flow cytometry may also be helpful in peroxidase/Sudan black–positive cases of acute nonlymphocytic leukemia in which immunophenotypic features suggest clinically important subtypes (e.g., DR negativity in acute promyelocytic leukemia). The flow cytometric profile of the blasts in which there is asynchronous antigen expression may allow diagnosis of relapse before morphologic relapse ([17], [18]). Cytogenetics are playing an expanded role in classification of acute leukemia and identifying prognostically important subsets of disease such as M3 with t(15;17), M4 with abnormal eosinophils (inversion 16), or M2 with 8;21 translocation ([15], [19], [20], [21] and [22]). In suspected MDS, cytogenetic studies are particularly helpful when morphologic abnormalities in hematopoietic cells are relatively subtle. Flow cytometry is of no help in the evaluation of myeloproliferative disease except when the presence of increased blasts on marrow smear point to an evolving acute leukemia.

Lymphocytosis on a marrow smear is common in very young children. Phenotypically, the lymphocytes are usually B cells in all stages of differentiation (so-called “hematogones”). In such cases, the numbers and morphology of the myeloid, megakaryocytic, and erythroid cell lines are usually normal, which is helpful in differentiating these cells from the blasts of the L1 subtype of acute lymphoblastic leukemia ([23], [24]). Lymphocytosis on marrow smear in an older adult should always have phenotypic studies by flow cytometry. Otherwise, important information about clonality and phenotype may not be retrievable from the paraffin-embedded tissues. In patients with dysplastic cells (large or small) on aspirate smear, material should be put up for electron microscopy in all cases. Flow cytometry and cytogenetics should be performed in those in whom morphology suggests the dysplastic cells are of hematologic or lymphoid origin.

Bone marrow examination should also be considered in patients who complain of bone pain whether or not bone lesions have been demonstrated radiographically and particularly if there is an abnormal CBC or abnormal chemistries, such as an elevated lactate dehydrogenase, total protein, or uric acid. Some processes, including myeloma, lymphoma, carcinoma, neuroblastoma, and granulomatous infections, may be quite focal and missed on marrow examination. Occasionally, radionuclide scans with gallium-67 or indium ^{111}, CT, magnetic resonance imaging, and/or positron emission tomography scans may be helpful in localizing various types of tumors and identifying specific marrow sites for biopsy ([25], [26], [27] and [28]). Again, serum and urine electrophoresis, with immunofixation (which allows detection of monoclonal Igs hiding in the Beta region) should be performed on adults with bone pain. Screening tests for neuroblastoma, including urine catecholamines, should be performed in children with bone pain and a nondiagnostic marrow examination.

EXAMINATION OF LYMPH NODES AND TISSUES

This section is concerned with the evaluation of the patient with palpable or visible enlargement of cervical, supraclavicular, axillary, inguinal, mediastinal, or hilar lymph nodes or tonsils. If the blood and marrow (when indicated, as discussed in the previous sections) fail to provide a diagnosis, the clinician should consider a fine-needle aspiration or biopsy of enlarged lymphoid tissue. The presence of a variety of signs and symptoms may modify and shorten the diagnostic evaluation. For example, if the clinical picture is fairly typical of a lymphoma, lymph node biopsy should be performed immediately.

How large must lymphoid tissue be before it is considered abnormal? Exact limits cannot be set. The answer varies with the age and occupation of the patient and the location of the lymph nodes. Careful physical examination by an experienced physician reveals palpable small lymph nodes and visible tonsillar tissue in most patients.

The most common cause of lymphoid enlargement is lymphocyte proliferation in response to antigenic stimulation. The frequency of trichophyton infection of toes and trauma to feet and legs is reflected in the frequency of palpable inguinal nodes (usually smaller than 1 cm in diameter). If the patient's occupation or hobby leads to frequent trauma of hands and arms, small palpable epitrochlear and axillary nodes are expected. Thus, the assessment of the lymphoid system in a laborer differs somewhat from that of an educator (unless the latter's hobby is gardening or hunting).

Children and adolescents commonly have more palpable nodes than do adults ([29]). This difference is presumed to reflect their more frequent exposure to new antigens and a larger total lymphoid mass in relation to body weight as compared to adults. Thus, significant generalized adenopathy has a more liberal definition in

the young than in adults. Prominently visible tonsils, protruding into the oropharynx, are expected in preschool children but are uncommon in adults.

Retroperitoneal lymphadenopathy must be extreme before an abdominal mass becomes palpable. CT scan and lymphangio-graphy (LG), provide complementary information concerning the status of retroperitoneal lymph nodes, although LG is no longer commonly used ([30]). Abdominal CT scan provides images of nodal areas that usually are not visualized with LG, such as pararectal, omental, and superior retroperitoneal images, and the hilus of the spleen and liver. LG may disclose qualitative abnormalities in small nodes, such as a “foamy” appearance in lymphoma or filling defects that may not be discerned by CT. Other imaging techniques, such as gallium scan, positron emission tomography scan, and radiolabeled monoclonal antibody scans, may further delineate worrisome lymph nodes.

Experience with many patients is the best guide in the selection and timing of lymph node biopsies. If doubt exists as to whether enlargement is significant, the choice between immediate biopsy or periodic observation to discover whether the nodes will enlarge or shrink should be made on the basis of ancillary findings. If other signs and/or symptoms are suggestive of lymphoma, biopsy of small, questionably enlarged nodes may yield a diagnosis. Biopsy should be performed after no more than 1 or 2 months of observation if the physician is still suspicious that the nodes are abnormal. Again, however, the physician's suspicion must be tempered by experience. Persistently enlarged lymph nodes considered abnormal in an adult may be well within the limits of normal in a child or adolescent patient.

Slap et al. ([31]) developed a simple means by which to determine whether biopsy of an enlarged lymph node will disclose a condition requiring treatment (primarily tumor and granulomatous conditions). A multifactorial, retrospective analysis involving 22 clinical findings was made of 123 patients, ages 9 to 25 years, in whom results of lymph node biopsies were known. Only three simple variables proved to have significant discriminatory function; nodes larger than 2 cm in diameter on physical examination and abnormal findings on chest radiographs favored the diagnosis of a disorder necessitating treatment, whereas a history of recent symptoms related to otolaryngologic disease in the presence of enlarged cervical nodes was strong evidence against the presence of a disease requiring therapy. With the use of these variables, 84 of 88 patients were categorized correctly in the retrospective review, as were 32 of 33 in a subsequent prospective study. The causes of enlargement of lymph nodes are extremely varied. Table 62.3 outlines the major categories of disease leading to lymphadenopathy. This table is in no sense exhaustive. The approach to lymphadenopathy is similar to that of FUO, with the most common broad diagnoses being infection, cancer, and immune disorders. The first step is determining whether adenopathy is localized or generalized, and this differentiation points to a local disease versus systemic illness.

TABLE 62.3. Conditions Leading to Lymph Node Enlargement

Lymphadenopathy primarily related to immune response
Infections
Pyogenic infections
Local enlargement of nodes draining areas of local infection (e.g., furuncles caused by staphylococci and oral infection)
Generalized enlargement from fairly indolent infections (e.g., *Salmonella* septicemia and bacterial endocarditis)
Viral infections
Local enlargement of nodes draining portals of entry of infection (e.g., cat-scratch fever and lymphogranuloma venereum)
Generalized lymphadenopathy with systemic infections (e.g., infectious mononucleosis, measles, infectious hepatitis, and acquired immunodeficiency syndrome)
Miscellaneous types of organisms
Local enlargement of nodes draining the portal of entry of such infections as cryptococcosis, primary chancre of syphilis, and tularemia
Generalized adenopathy (e.g., secondary syphilis and toxoplasmosis)
Lymphadenopathy primarily from infection of the node by organisms
Pyogenic infection; the classic example is the bubo of *Pasteurella pestis*; more commonly, abscess formation by staphylococcal invasion.
Granuloma formation. The entrance of tubercle bacilli or fungi, such as *Histoplasma capsulatum*, into nodes often results in granuloma formation as well as hypertrophy; identifiable organisms are present within the granuloma in many instances.
Neoplastic evolution or invasion of nodes
Primary neoplastic diseases of nodes
Non-Hodgkin lymphoma
Hodgkin disease
Secondary neoplastic processes occurring in nodes
Lymphoid leukemias: acute lymphocytic leukemia and chronic lymphocytic leukemia
Myeloid leukemias: acute myeloid leukemia and chronic myeloid leukemia
Idiopathic myelofibrosis with extramedullary hematopoiesis, producing lymph node enlargement
Metastases from carcinoma, producing lymph node enlargement
Diseases of unknown cause leading to lymph node enlargement
Autoimmune diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, and Hashimoto thyroiditis)
Reaction to drugs, such as the hydantoins
Miscellaneous diseases
Granuloma formation as seen with sarcoid or in patients exposed to beryllium
Reactive hyperplasia, as seen in hyperthyroidism
Kikuchi disease (histiocytic necrotizing lymphadenitis)
Kawasaki disease
Castleman disease

Certain physical characteristics of nodes aid in the diagnosis of the cause of lymphadenopathy. Infected nodes usually are tender, and the overlying skin often is inflamed. Such nodes may be matted together. In certain types of infection, such as tuberculosis (TB), aspergillosis, or actinomycosis, sinus tract formation is common. Infected nodes may be fluctuant. Nodes undergoing an immune response to infection also may be tender, but other signs of inflammation usually are absent. Tenderness may be related to other conditions, but this is uncommon. Carcinomatous nodes usually are hard and may be bound to one another and to surrounding tissue. Lymphomatous nodes are more often firm, rubbery, discrete, and freely movable; occasionally, Ki-1+ anaplastic large cell lymphoma has a significant inflammatory component.

The location of the nodes may be helpful in diagnosis, and, again, the age and immunocompetence of the patient are critical factors in determining the approach. Axillary and inguinal adenopathy are often enlarged due to trauma or infection distally. Cervical lymphadenopathy is also often due to localized infections but also can represent metastatic disease from the head and neck. Posterior occipital lymphadenopathy is classically seen in rubella (also toxoplasmosis) usually in conjunction with a maculopapular rash. Supraclavicular lymphadenopathy more often represents distant metastases than cervical adenopathy or contiguous spread from the mediastinum. Isolated mediastinal adenopathy in a young person is often Hodgkin disease. Large, bilateral hilar nodes without other detectable adenopathy are unusual in lymphomas and are more suggestive of sarcoidosis.

Infections may be either localized or generalized as the cause of lymphadenopathy. The most common forms of localized infections with cervical lymphadenopathy are pharyngitis and tonsillitis due to viral, mycoplasmal, and pyogenic infections (streptococcus, *Staphylococcus aureus*, and *S. epidermidis*) ([32]). Although the above usually cause bilateral adenopathy, unilateral adenopathy occurs with tonsillar abscesses, salivary adenitis, and dental abscesses ([32]). Systemic infections that may present with localized adenopathy include cat scratch disease, lyme disease, tularemia, toxoplasmosis, and bubonic plague, but these patients usually have constitutional symptoms and may give a history of animal or tick exposure, or have a characteristic rash (e.g., Lyme disease). TB involving the cervical lymph nodes (scrofula) is one of the more common presentations of extrapulmonary TB ([33]). Adenopathy in HIV patients tends to be generalized and painless and can be due to HIV alone or other infections (e.g., atypical mycobacteria, toxoplasmosis, syphilis, or lymphoma).

Immunologic disorders may present with adenopathy as a prominent clinical feature. Kikuchi disease (histiocytic necrotizing lymphadenitis) is a self-limiting illness characterized by cervical adenopathy and systemic symptoms; excisional biopsy is often performed to rule out neoplasia ([34], [35]). Kawasaki disease is a multisystem vasculitis of infants and children usually with mucocutaneous lesions and cervical adenopathy; therapy with intravenous gamma-globulin and aspirin can prevent or ameliorate coronary artery abnormalities ([36], [37]). Patients with SLE and rheumatoid arthritis may develop adenopathy but usually have characteristic clinical features and serology. Early lymph node biopsy should be considered in patients at increased risk for developing lymphoma such as those with an underlying autoimmune disorder (e.g., Sjögren syndrome and rheumatoid arthritis treated with methotrexate) or immunodeficiency (e.g., HIV infection and posttransplant). Drugs, such as phenytoin, can be associated with diffuse adenopathy that may regress with discontinuation of the drug.

In the event of a strong presumption of metastatic carcinoma or direct infection of the node, or in lymphadenopathy in areas difficult to biopsy (retroperitoneum), needle biopsy or aspiration may be considered. The procedure for lymph node puncture is simple and can produce diagnostic information in the time it takes to stain and examine the smears. However, the frequency of indeterminate or incorrect diagnosis is higher with needle biopsy than with excisional biopsy ([38]) as the histologic diagnosis often depends on changes in the overall architecture of the lymph node in addition to the cytology of individual cells. Excisional biopsy also yields more tissue for diagnostic studies, facilitating preparation of multiple histologic sections for routine and special stains as well as providing more adequate material for cultures and immunophenotypic and genetic studies. The smears from lymph node puncture or the touch preps from lymph node biopsy should be examined to guide the use of these ancillary studies.

For excisional biopsy, the largest palpable node available is given preference. More than one node should be removed, if possible, avoiding irradiated areas. When other considerations are equal, biopsy of cervical or supraclavicular nodes is preferable to biopsy of axillary nodes, and biopsy of nodes from any of these regions is preferable to that of inguinal nodes. As previously mentioned, inguinal nodes frequently are enlarged from chronic foot infection, in which case the architecture often is distorted. Axillary nodes, unless enlarged, may be difficult to find during surgical procedures because of the complex and changed anatomy during exposure of this area.

In the “good old days” when most diagnoses of disease involving marrow or lymph nodes were made (or not made) based solely on the morphology of smears and tissue sections, coordination of the efforts of the clinician, surgeon, and pathologist was less important and much less complex. Today, with a bewildering array of morphologic, cytochemical, immunologic, molecular genetic, and cytogenetic techniques available (and essential for many diagnoses), the clinician, surgeon, and pathologist must work closely together to optimize the diagnostic information of any biopsy and at the same time limit and control expense. The major pitfall in these efforts is improper specimen handling, precluding the use of important techniques available only in fresh tissue (i.e., cultures for pathogenesis, cytogenetics, and flow cytometry for surface markers).

The process of evaluation begins before the procedure. The studies that are done are guided by clinical information and review of previous biopsy material. At the time of biopsy or needle aspiration, the studies available within minutes of the procedure (i.e., the Wright-stained marrow aspirate smear of bone marrow or the hematoxylin and eosin stained smear of a lymph biopsy touch prep) are used to decide which diagnostic techniques will be applied to any given case. If the suspicion of infection is high, material for cultures is best obtained in the sterile environment of the operating room before sending it to pathology.

Table 62.4 includes guidelines for the diagnostic evaluation of tissue biopsies based on clinical information and the aspirate smear/touch prep appearance. The most important clinical information is the likelihood that a process is (a) a non-Hodgkin lymphoma (NHL), (b) Hodgkin lymphoma, (c) a carcinoma, or (d) a reactive process. The clinical information, including the age of the patient along with the touch prep or smear appearance, often helps in determining whether flow cytometry or cytogenetics is needed (as in many cases of NHL or leukemia).

TABLE 62.4. Guidelines for Evaluation of Lymph Node Biopsies/Fine Needle Aspiration

	Touch Prep Cytology							
Factors or Tests to Consider	**Small Lymphocytes**	**Mixed Small Lymphocytes and Large Lymphocytes (No Dysplastic Large Cells)**		**Mixed Small and Large Lymphocytes and Occasional Large Dysplastic Cells**		**Frequent Large Lymphocytes or Blasts**		
Age of patient	Child or young adult	Adult	Child or young adult	Adult	Child or young adult	Adult	Child or adult	
Freeze	+	+	+	+	+	+	+	
Flow cytometry	No	Yes	[a]	[a]	[b]	[b]	Yes	
Cytogenetics/molecular genetics	No	[c]	[d]	[d]	[d]	[d]	Yes	

[a] If clinical features are highly suggestive of non-Hodgkin lymphoma or tissue is from a site difficult to sample (e.g., mediastinum or retroperitoneum) a limited panel for B-cell monotypism and T-cell distribution may be helpful.

[b] If clinical features and gross appearance are typical for nodular sclerosing disease, do not do flow cytometry or perform cytogenetics.

[c] If patient is a transplant candidate, such studies may facilitate monitoring.

[d] Usually not helpful except if screening flow cytometric studies demonstrate an abnormal B- or T-cell population and patient is a transplant candidate.

NHL would be very uncommon in a child or young adult with a predominance of small lymphocytes on touch preps (Fig. 62.3A), but would more likely occur in an elderly patient. In a child or teenager, the major differential diagnosis would be a reactive node or lymphocyte-predominant Hodgkin disease. In neither would either immunologic typing studies or cytogenetics be of much help. On the other hand, in an older patient in whom a small B-cell NHL is more likely, immunophenotyping is of great help in proving monotypism and also identifying subsets of NHL of therapeutic and prognostic significance (e.g., hairy cell leukemia and mantle cell lymphoma). The role of cytogenetic studies is assuming increasing importance in the diagnosis of small B-cell lymphomas, particularly follicular [t(14;18)] and mantle cell [t(11;14)] lymphoma, and is prognostically important in subsets of extranodal marginal zone lymphoma [e.g., t(11;18)] ([39], [40] and [41]).

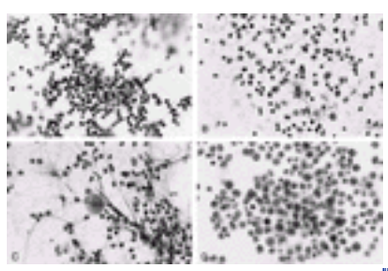

Figure 62.3. High power of hematoxylin eosin–stained touch preps of lymph node biopsies demonstrating **(A)** predominance of small lymphocytes in an adult with a small B-cell lymphoma; **(B)** mixed pattern of small and large lymphocyte macrophages, plasma cells, and neutrophils in a child with reactive ade-nitis; **(C)** mixed population of small and large lymphocytes with occasional large dysplastic cells in a patient with Hodgkin disease; and **(D)** predominance of large lymphocytes (many with polylobate nuclei) in a patient with large B-cell lymphoma of the mediastinum. See Color Plate.

In most older adolescents and young adults with touch prep showing a polymorphous mix of small and large lymphocytes and inflammatory cells (Fig. 62.3B), we do not perform flow cytometry. Most patients with touch preps with such mixed pattern will have a reactive process or Hodgkin disease (Fig. 62.3C); however, a few

B-cell NHL and peripheral T-cell lymphomas may show such patterns. If the clinical likelihood of NHL is high or in those patients with occasional large dysplastic cells who do not have clinical features of Hodgkin disease, a limited and inexpensive panel for B-cell monotypism and T-cell distribution (looking for aberrant T-cell phenotypes) can be performed. If these studies demonstrate an abnormality either in the small- or large-cell population, then more expanded panels can be run. If the case is not typed and on permanent tissue sections appears to be NHL, information about clonality (T and B) can be retrieved from frozen tissue or the paraffin-embedded tissue as needed ([42], [43]).

In patients with numerous large cells or blasts on touch preps (Fig. 62.3D) typing studies (and in many, cytogenetics) are essential in identifying prognostically significant patient subgroups. For example, in patients with blast cells on touch prep, the differential diagnosis would be lymphoblastic lymphoma (both B and T), blastic transformation of mantle cell lymphoma, and extramedullary acute leukemia. Flow cytometry is quite useful in the differential diagnosis and can provide an answer in hours (well in advance of other cytogenetic or immunohistologic techniques) (Fig. 62.4 and Fig. 62.5). Tissue should also be placed in glutaraldehyde for electron microscopy in these cases, because poorly differentiated tumors, such as neuroblastoma or rhabdomyosarcoma, may mimic hematopoietic neoplasms on touch prep.

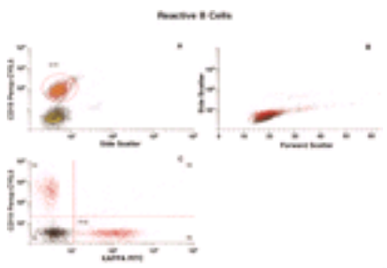

Figure 62.4. Flow cytometry of reactive B cells. **A:** Histogram (picture) of anti-CD19 antibody expression versus log side scatter (signal of cellular complexity), which is used to define and identify the B-cell lymphocytes. The CD19 $^{+}$ population is then focused on by using an isolation mechanism or *gate* (*R1*) to further describe this population. **B:** Histogram shows lymphocytes based on forward scatter signal (size) versus log side scatter signal (cell complexity or granularity). The red population represents the CD19 $^{+}$ B cells and their location in relation to the CD19 $^{-}$ population (*black dots*). **C:** A two-parameter histogram of anti-Kappa fluorescein isothiocyanate (FITC) versus anti-Lambda phycoerythrin. Red dots are the CD19 $^{+}$ B cells from histogram **A**; the black dots represent the CD19 $^{-}$ population. The pattern shown includes statistics of each population. The *R2 area* represents the anti-Lambda, CD19 $^{+}$ population and equals approximately 16.5% of the total cells present. The *R3 area* represents the anti-Kappa positive, anti-Lambda positive CD19 $^{+}$ population. This population is usually negative. The *R5 area* represents the anti-Kappa, CD19 $^{+}$ population and equals approximately 27.7% of the total cells present. *R4* represents the anti-Kappa– and anti-Lambda–negative population. Percp, peridinin chlorophyll protein. See Color Plate. (Diagrams courtesy of Bruce Grieg, MT, Vanderbilt University.)

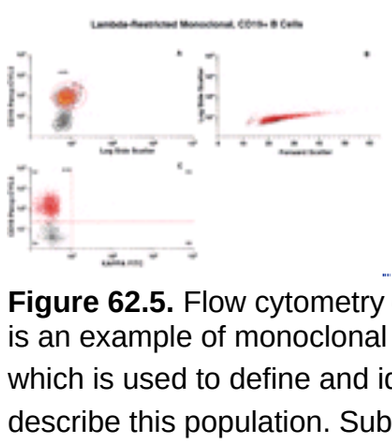

Figure 62.5. Flow cytometry of monotypic B cells. This set of pictures demonstrates CD19 $^{+}$ B cells that have a dominant expression of one particular light chain and is an example of monoclonal light-chain restriction. **A:** Histogram (picture) of anti-CD19 antibody expression versus log side scatter (signal of cellular complexity), which is used to define and identify the B-cell lymphocytes. The CD19 $^{+}$ population is then focused on by using an isolation mechanism or *gate* (*R1*) to further describe this population. Subsequent R1+ events are shown as red dots. Black dots represent CD19 $^{-}$ non-B cells. **B:** Histogram shows lymphocytes based on forward scatter signal (size) versus log side scatter signal (cell complexity or granularity). The red population represents the CD19 $^{+}$ B cells and their location in relation to the CD19 $^{-}$ population (*black dots*). **C:** A two-parameter histogram of anti-Kappa fluorescein isothiocyanate (FITC) versus anti-Lambda phycoerythrin. Red dots are the CD19 $^{+}$ B cells from histogram **A**; the black dots represent the CD19 $^{-}$ population. The pattern shown includes statistics of each population. The *R2 area* represents the anti-Lambda, CD19 $^{+}$ population and equals approximately 80% of the total cells present. The *R5 area* represents the anti-Kappa, CD19 $^{+}$ population and in this case is <1% of the total cells present. Percp, peridinin chlorophyll protein. See Color Plate. (Diagrams courtesy of Bruce Grieg, MT, Vanderbilt University.)

A histologic appearance of reactive hyperplasia or of nonspecific granulomatous changes does not rule out the possibility of Hodgkin disease or NHL at another site. For example, not all enlarged nodes from patients known to have Hodgkin disease show evidence of the disease ([44]); it is not surprising that the first biopsy may give negative findings in a patient in whom a second biopsy is diagnostic ([45], [46]). Similarly, analysis of surface antigens on cells from an initial biopsy may indicate that the B-cell population is polyclonal when later specimens showed a monoclonal proliferation ([47]). Molecular studies may identify monoclonal lymphoid populations earlier than flow cytometry or routine immunoperoxidase stains in selected cases. In equivocal or difficult cases, particularly those in which there are discrepancies between the histologic diagnosis, clinical picture, and the results of ancillary studies, consideration should be given to obtaining consultation in hematopathology ([48]). If more than one node is removed initially, the likelihood of positive findings is enhanced. In nondiagnostic biopsies, the decision to obtain more tissue for further study must be individualized. If no other nodes are enlarged and the patient has few or no symptoms, observation may be advisable. Prompt diagnosis and proper therapy are important in bacterial and fungal infections, Hodgkin disease, and aggressive NHL, but are less important for the eventual outcome of the other conditions listed in Table 62.3.

EXAMINATION OF THE SPLEEN

Many of the conditions that lead to lymphadenopathy also produce a palpably enlarged spleen. Consequently, the preceding discussion regarding evaluation of the patient with lymphadenopathy is equally applicable to the patient with splenomegaly. When splenomegaly is associated with systemic infection (acute splenic tumor), the spleen usually is barely palpable, soft to firm, but not hard, and splenomegaly disappears shortly after recovery from the infection. A palpable spleen usually indicates disease, but a soft spleen tip can be palpated by an experienced physician in approximately 1 to 2% of apparently healthy persons ([49]).

Splenic puncture may be helpful in the evaluation of patients with certain conditions (e.g., leishmaniasis and kala-azar), but is rarely used in North America ([50], [51]). Diagnostic splenectomy is required in some patients, especially those in whom the only palpably enlarged tissue is the spleen. Before this procedure is considered, however, numerous other studies should be made and may include liver/spleen scan and imaging studies to outline splenic vein patency, as well as hepatic blood flow, and any associated adenopathy. In many cases, results of these studies indicate the diagnosis. For instance, splenic hypertrophy owing to increased red cell destruction, such as occurs in hereditary spherocytosis and thalassemia, should be detected by means of appropriate blood and other examinations. Biopsy of enlarged nodes should always be carried out before splenectomy is undertaken. Examination of the marrow should also be considered. Liver function tests and needle biopsy of the liver also are warranted to exclude, among other considerations, the possibility that the splenomegaly results from hepatic disease, producing increased portal pressure.

Indications for splenectomy are discussed in Chapter 70 and elsewhere in relation to the various diseases associated with splenomegaly. If no explanation is found for splenomegaly, splenectomy should be considered to make or to exclude a diagnosis of lymphoma.

FEVER OF UNKNOWN ORIGIN

The classic definition of FUO proposed by Petersdorf and Beeson is a temperature elevation of 38.3°C (101°F) or higher persisting over 3 weeks in duration and without a diagnosis after 1 week of intensive in-hospital investigation ([52], [53]). There have been many attempts to modify the definition according to the host involved or length of fever, and the changing medical environment has required a shift to an initial outpatient evaluation; however, altering the definition dilutes its significance

and changes a valid approach to FUO ([52], [53], [54] and [55]). Still, because of changing medical practices and different types of patients with prolonged fever, FUO is currently subdivided according to four categories: (a) classic FUO, (b) nosocomial FUO, (c) immune-deficient FUO, and (d) HIV-associated FUO ([53]). Host factors (e.g., age of the patient and immunocompetence) and environment (e.g., socioeconomic status and geographic location) are factors in the evaluation of FUO.

The “big three” categories of FUO remain infections, autoimmune diseases, and malignancies (Table 62.5), although the incidence of cancer has declined probably due to improved diagnostic techniques ([56]). Miscellaneous diseases and undiagnosed conditions round out the main five categories of FUO. In a series of 167 patients from the Netherlands with classic FUO, 70% of the patients were accurately diagnosed, with 37% due to infections, 34% due to noninfectious inflammatory conditions, and 18% due to neoplasms ([57]). In developing countries, infections, particularly TB, often represent more than one-half the cases of FUO, whereas developed countries have a higher incidence of autoimmune diseases and neoplasms ([58], [59]). Undiagnosed conditions and infections are more common in younger patients, whereas autoimmune diseases, including temporal arteritis and polymyalgia rheumatica, are more common in the elderly ([59]).

TABLE 62.5. Diseases Causing Fever of Unknown Origin

Malignancy	Autoimmune disease
Common	Common
Hodgkin disease: classic Pel-Ebstein, lymphocyte depleted subtype	Still disease
	Temporal arteritis (polymyalgia rheumatica)
Non-Hodgkin lymphoma: usually advanced stage	Uncommon
Renal cell carcinoma: elevated sed rate, often encapsulated	Periarteritis nodosa
Metastatic carcinoma: liver, central nervous system	Rheumatoid arteritis
Uncommon/rare	Wegener granulomatosis
Hepatomas	Rare
Pancreatic carcinoma	Systemic lupus erythematosus
Acute leukemia/myelodysplasia	Vasculitis (Takayasu arteritis, hypersensitivity vasculitis)
Atrial myxoma	Felty syndrome
Neuroblastoma	Acute rheumatic fever
Central nervous system tumor	Pseudogout
Infection	Sjögren syndrome
Common	Behçet disease
Tuberculosis: extrapulmonary—renal, meningitis, miliary	Familial Mediterranean fever
Abscesses	Polymyositis
Intraabdominal	Tumor necrosis factor receptor–associated periodic syndrome
Subdiaphragmatic (periappendiceal, pericolonic, hepatic)	Miscellaneous
Pelvic	Common
Uncommon	Drug fever
Abscesses: splenic, perinephric, dental, brain	Cirrhosis
Subacute bacterial endocarditis (if culture negative, suspect right-sided endocarditis, intravenous drug abuse)	Alcoholic hepatitis
Cytomegalovirus	Uncommon: granulomatous hepatitis
Toxoplasmosis	Rare
Salmonella enteric fevers	Gastrointestinal: regional enteritis, Whipple disease
Rare	Endocrine: hyperthyroidism, hyperparathyroidism, pheochromocytoma, Addison disease, subacute thyroiditis, hypothalamic dysfunction
Localized, culture-negative infections: sinusitis, osteomyelitis, chronic meningitis, cholecystitis, urinary tract infection, mastoiditis	Granulomatous disease: sarcoidosis
Viruses: Epstein-Barr, hepatitis (all types), human immunodeficiency virus, parvovirus, other	Vascular related: pulmonary emboli, subacute dissecting aneurysm, giant hepatic hemangioma, occult hematomas
Cat scratch disease	Immune-related: hyper immunoglobulin D syndrome, pseudolymphoma
Brucellosis	Factitious fever
Listeriosis	Habitual hyperthermia
Spirochetal infections	Cyclic neutropenia
Relapsing fever	Other: Fabry disease, Kikuchi disease, Weber-Christian disease, mesenteric fibromatosis, malakoplakia, Castleman disease, hemophagocytic syndromes
Lyme disease	Undiagnosed conditions
Leptospirosis	
Rat bite fever	
Rickettsial infections: Rocky Mountain spotted fever, endemic typhus, Q fever, ehrlichiosis, trench fever, bacillary angiomatosis	
Parasitic disease: malaria, babesiosis, toxoplasmosis, trypanosomiasis, leishmaniasis, trichinosis, amebic liver abscess	
Fungal infections: blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis, candidiasis	
Yersinia infections	
Chlamydial infections: psittacosis, lymphogranuloma venereum	
Foreign object–related infections: vascular grafts, indwelling catheters, prosthetic devices	
Vascular infections: aortic aneurysm, jugular phlebitis	

Adapted from Cunha BA. Fever of unknown origin (FUO). In: Gorbach SL, Bartlett JB, Blacklow RN, eds. Infectious diseases, 2nd ed. Philadelphia: WB Saunders, 1996.

Nosocomial FUO is a particular problem for the patient in an intensive care unit and is related to the type of instrumentation, including indwelling vascular lines, Foley catheters, and endotracheal tubes ([60]), along with a specific spectrum of microorganisms and their antimicrobial sensitivity. More than 60% of FUO in the immunodeficient host is due to infections; the type and severity of infection correlates with the depth and length of neutropenia ([61]).

The initial exposure to HIV may cause FUO, and the HIV may go undetected due to lack of seroconversion ([62]). In general, FUO in HIV patients is usually diagnosed and is due to an opportunistic infection ([62]). Atypical and typical mycobacteria are the most common infections in HIV patients; other infections causing FUO in AIDS include cytomegalovirus, *Pneumocystis carinii*, toxoplasmosis, histoplasmosis, leishmaniasis, and cryptococcosis ([59]). Lymphoma and drug reactions may also be a cause of FUO in HIV patients. The use of highly active antiretroviral therapy (HARRT) in AIDS has accompanied a decline in FUO ([63]).

The pattern of fever has been extensively evaluated, but rarely is so specific to be diagnostic of a disease. Possible exceptions include a Pel-Ebstein pattern of

recurrent high fever and intermittent afebrile, asymptomatic periods in Hodgkin disease; the tertian and quartan patterns of malaria, the pulse-temperature dissociation of typhoid fever, the reversal of the normal diurnal pattern observed in disseminated TB, and a cyclical pattern (every 3 weeks) with cyclical neutropenia ([59], [64]).

In the evaluation of a patient with FUO, history and physical examinations often need to be repeated frequently ([65], [66] and [67]). Host factors (e.g., HIV, sickle cell disease, prior malignancy, organ transplant, cardiac valve disease, diabetes, and prior surgery) and external factors (e.g., occupation; travel; and exposures to infections, animals, and drugs) may point to the types of studies warranted to diagnose the etiology of FUO. The physical examination should pay particular attention to the skin (e.g., rashes, subcutaneous nodules, aphthous ulcers, and nailbeds), eyes (e.g., uveitis and Roth's spots and infections on funduscopic examination), sinuses, lymph nodes, heart (e.g., rubs and murmurs), lungs, organomegaly, and perirectal area. Bone, joint, and musculoskeletal examinations are important when symptoms of pain, limping, or weakness are associated with FUO.

The laboratory evaluation of FUO includes baseline screening (e.g., CBC, sedimentation rate, sequential multiple analysis, and chest x-ray) and examination of the blood smear for pathogenesis suggested by the history. Table 62.6 outlines possible etiologies as suggested by the findings on CBC and sedimentation rate. Improved blood culture techniques, serology for autoimmune disorders, and imaging studies (e.g., CT, magnetic resonance imaging, and radioisotope scans) have altered the distribution but not type of illnesses causing FUO ([65]). Autoimmune diseases that have remained a cause of FUO are those that are not readily diagnosed by serologic testing, such as temporal arteritis and Still disease ([65]). There are few “new” causes of FUO, but some include Kikuchi disease and hyperimmunoglob-ulinemia IgD syndrome ([65]).

TABLE 62.6. Complete Blood Cell Count Clues to Fever of Unknown Origin

Monocytosis	Eosinophilia	Erythrocyte sedimentation rate (>100 mm/h)
Tuberculosis	Trichinosis	Adult Still disease
Polyarteritis nodosa	Lymphomas	Temporal arteritis
Temporal arteritis	Drug fever	Hypernephroma
Cytomegalovirus	Addison disease	Subacute bacterial endocarditis
Sarcoidosis	Polyarteritis nodosa	Drug fever
Brucellosis	Hypersensitivity vasculitis	Carcinomas
Subacute bacterial endocarditis	Hypernephroma	Lymphomas
Systemic lupus erythematosus	Myeloproliferative diseases	Myeloproliferative diseases
Lymphomas	Thrombocytopenia	Abscesses
Carcinomas	Leukemias	Subacute osteomyelitis
Regional enteritis	Lymphomas	Polymyositis
Myeloproliferative diseases	Myeloproliferative diseases	Hyper immunoglobulin D syndrome
Atypical lymphocytosis	Relapsing fever	Basophilia
Epstein-Barr virus mononucleosis	Epstein-Barr virus	Carcinomas
Cytomegalovirus	Drug fever	Lymphomas
Brucellosis	Systemic lupus erythematosus	Pre-leukemias
Toxoplasmosis	Human immunodeficiency virus	Myeloproliferative diseases
Drug fever	Leukopenia	Lymphocytosis
Thrombocytosis	Miliary tuberculosis	Tuberculosis
Myeloproliferative diseases	Brucellosis	Epstein-Barr virus mononucleosis
Tuberculosis	Systemic lupus erythematosus	Cytomegalovirus
Carcinomas	Lymphomas	Toxoplasmosis
Lymphomas	Pre-leukemias	Non-Hodgkin lymphoma
Sarcoidosis	Typhoid fever	Lymphocytopenia
Vasculitis	Kikuchi disease	Human immunodeficiency virus
Temporal arteritis		Hodgkin disease
Subacute osteomyelitis		Whipple disease
Hypernephroma		Tuberculosis
		Systemic lupus erythematosus
		Sarcoidosis

Adapted from Cunha BA. Fever of unknown origin (FUO). In: Bartlett JB, Blacklow NR, eds. Infectious diseases, 2nd ed. Philadelphia: WB Saunders, 1996.

Rare, hereditary disorders characterized by recurrent episodes of fever and autoimmune features include familial Mediterranean fever, tumor necrosis factor-receptor–associated periodic syndrome, and the hyperimmunoglobulinemia D syndrome ([68]). Familial Mediterranean fever is an autosomal-recessive disorder and is caused by mutations in the pyrin-marenostrin gene, which provides inhibitory signals to inflammatory cells ([69]). Tumor necrosis factor-receptor–associated periodic syndrome is an autosomal dominant condition caused by missense mutations in the gene encoding type I tumor necrosis factor-receptor, which results in an exaggerated response to tumor necrosis factor ([70]). Hyperimmunoglobulin D syndrome is due to mutations in the gene mevalonate kinase, but the mechanism producing fever and autoimmune features is unknown ([71]).

After the initial evaluation, specific organ systems and diagnoses can usually be addressed. Bone marrow examination with cultures may be useful as well as liver biopsy if liver function tests are abnormal. Laparotomy is rarely performed unless there is adenopathy that is not easily approached by less invasive procedures, including fine-needle aspiration, mediastinoscopy, laparoscopy, and thoracoscopy. The goal is to identify treatable diseases as expediently as possible.

Empirical antibiotic trials are rarely warranted except in the immunocompromised patient with neutropenia and fever ([72]). Occasionally, antibiotics are given in culture-negative endocarditis; and antituberculosis therapy is used in the elderly with suspected miliary TB ([65], [73]). High-dose steroids with or without alkylating agents should probably only be given in biopsy-proven cases of vasculitis ([65]). Naprosyn has been advocated as a means to distinguish fever of malignancy from infection but should not prevent the search for infection ([65]). Treatment for malignancy should never be instituted without a tissue diagnosis.

RECURRENT INFECTIONS

The most common clinical presentation of immunodeficiency (either congenital or acquired) is infection (Table 62.7). More than one infection requiring hospitalization, infection with unusual pathogens, or an inappropriately delayed response to optimal therapy should all be tip-offs to possible underlying immunodeficiency. Occasionally, patients may present with sequelae of immunodeficiency (e.g., delayed growth or failure to thrive in children or unexplained chronic obstructive pulmonary disease). In some patients, particularly those with HIV infection, lymphoma or a nonhematologic malignancy may be the presenting manifestation. In congenital immunodeficiency diseases, such as IgA deficiency, or deficiency of classic pathway complement components, features of autoimmunity may dominate the clinical picture ([74], [75]).

TABLE 62.7. Clinical Approach to Immunodeficiency

Red flags for immunodeficiency
- More than one hospitalization for infection
- Infection with organisms not usually pathogenic
- Growth failure in children
- Delayed or absent response of infection on appropriate therapy

Initial evaluation
- History
  - Onset of infection
  - Family history
  - Type of infection
- Physical examination

Initial investigation for:
- Bacterial infection (implies B-cell, phagocyte, or complement deficiency)
- CBC and differential for neutrophil count and morphology, quantitative immunoglobulins, CH50
- Infection with intracellular organisms (implies deficient T cell/cellular immunity)
- Human immunodeficiency virus serology, CBC and differential for lymphocyte count, T-subset analysis, skin testing in adults

CBC, complete blood cell count.

The first test in any patient of any age with suspected immunodeficiency is HIV serology. In the HIV-negative patient, the type of infection or problem should dictate the tests ordered. In a patient with recurrent bacterial infection, the three major screening tests are a CBC and differential WBC, quantitative Igs, and a CH50 ([76]). Interpretation of quantitative Igs depends on an awareness of the variation in the normal ranges with age. IgG, IgA, and IgM are markedly decreased in children with physiologic hypogammaglobulinemia of infancy, common variable immunodeficiency, and X-linked agammaglobulinemia (Chapter 68). In the first two conditions, patients have circulating B cells by flow cytometry whereas in X-linked agammaglobulinemia, they do not ([77], [78] and [79]). Thymoma is another circumstance with decreased Igs and decreased or absent B cells ([80]). In hyper IgM syndrome, the presence of markedly elevated IgM with depressed IgG and IgA is virtually diagnostic ([81], [82]). Patients with Wiskott-Aldrich syndrome who respond poorly to encapsulated bacteria often have an isolated decrease in IgM or may also have increases in IgE and IgA ([83]). Marked elevations of IgE are seen in patients with chemotactic defects and recurrent staphylococcal skin disease ([84]).

In adults with low IgG, three major considerations include common variable immunodeficiency, chronic lymphocytic leukemia, and multiple myeloma. Patients with chronic lymphocytic leukemia have lymphocytosis and immunophenotypic studies demonstrating a monotypic $CD5^{+}$, $CD23^{+}$ B-cell population ([85]). In myeloma patients with a decreased IgA, IgM, or IgG, electrophoresis of serum identifies a paraprotein in more than 80% of patients, although immunofixation may be required to uncover IgA monoclonals hiding in the Beta region. Some myeloma patients have a negative serum electrophoresis with immunofixation. Most of these patients have a monoclonal light chain on urine electrophoresis ([86]).

Congenital complement deficiencies are rare. All patients with deficiency of C1, C2, C3, C4, C5, C6, C7, and C8 have a zero CH50 (also seen with improperly handled specimens and occasionally in patients with severe immune complex disease) ([87]). Patients with deficiency in the early classic pathway complement pathway deficiencies often have autoimmune disease (e.g., systemic lupus erythematosus and rheumatoid arthritis), which in part may be related to the physiologic role of the classic pathway in clearing immune complexes from the circulation ([87]). Patients with congenital C3 deficiency or acquired C3 deficiency (e.g., liver disease and autoantibodies that stabilize the C3 converting factor C3NEF) have severe bacterial infections as do patients with factor I deficiency ([88]). Deficiency of late components C5, 6, 7, 8, and 9 and properdin often present with fulminant infections with neisseria.

The CBC and differential will not only pick up patients with bacterial infections secondary to neutropenia, but review of white cell morphology identifies patients with Chédiak-Higashi syndrome ([89]). Small platelets may suggest a diagnosis of Wiskott-Aldrich syndrome. Persistent neutrophilic leukocytosis is frequently present in patients with leukocyte adhesion deficiency, which can be confirmed by flow cytometric analysis of neutrophils for the CD11b/CD18 (Mac1) ([90], [91]).

If quantitative Igs, CH50, the absolute neutrophil count, and neutrophil morphology are normal in a patient with recurrent bacterial infections, WBC functional studies for chronic granulomatous disease or other enzyme deficiencies are indicated (Chapter 64). The nitroblue tetrazolium test is abnormal in many, but not all, of these defects ([92]). Flow cytometry for the CD11/CD18 complex is diagnostic of rare patients with leukocyte adhesion deficiency ([90], [91]). In occasional patients with recurrent bacterial infection, measurement of IgG subclasses or responses to individual antigens (e.g., tetanus and diphtheria) may be helpful ([92]).

In HIV-negative children with infections suggesting defective cell-mediated immunity (viral, fungal, or mycobacterial), the evaluation begins with the absolute lymphocyte count (Chapter 68). Because 75% of circulating lymphocytes are T cells, moderate lymphopenia implies T-cell lymphopenia. In most forms of severe combined immunodeficiency, such as adenosine deaminase deficiency, both T and B cells are decreased ([93]). In X-linked severe combined immunodeficiency, T cells are absent whereas B-cell numbers are normal or may be elevated, masking T-cell lymphopenia ([93]). In DiGeorge syndrome (suggested by hypocalcemia and congenital heart disease), T-cell numbers are decreased whereas B cells are normal or elevated (sometimes masking T-cell lymphopenia) ([94]). In the bare lymphocyte syndrome in which either class I or class II HLA antigens are observed, the CD8 T-cell subset is decreased in defects involving class I HLA, and CD4 T cells are decreased in defects involving class II ([95]). Skin testing is of little value in children younger than 1 year because they are unlikely to have previously been exposed to antigen used in testing. In older children and adults, the presence of reactive skin tests to recall antigens virtually excludes a significant defect in cell-mediated immune response.

In HIV-negative adults, acquired defects in cell-mediated immunity with unusual susceptibility to viral, fungal, or mycobacterial infection are most commonly secondary to immunosuppressive therapy or malnutrition. Patients with sarcoidosis and neoplasms, such as Hodgkin disease, may be anergic on skin testing but usually do not develop infection before immunosuppressive therapy ([96], [97]). A rare group of HIV-negative patients with a profound decrease in CD4 T-cell numbers and low CD4/CD8 ratios present with opportunistic infections similar to those seen in AIDS. A second group of HIV-negative patients have CD4 T-cell lymphopenia and normal CD4/CD8 ratios, but do not usually have infection ([98], [99]).

Clinicians should be aware that absolute CD4 T-cell counts used in following HIV-positive patients are affected by several preanalytic factors. New therapies with interleukin-2 or proteosome inhibitors have more dramatic effects on CD4 T-cell counts than were seen with reverse transcriptase inhibitors such as zidovudine ([100], [101]). There is a diurnal and seasonal variation of CD4 T-cell numbers, so ideally the blood should be drawn for analysis at the same time of day ([102]). In addition, intercurrent viral infections, such as influenza, are associated with lymphopenia, so that testing is best avoided during acute infection and the month after infection ([103]). A portion of blacks are deficient in an epitope recognized by one of the commercially available CD4 antibodies and may have falsely low CD4 T-cell counts ([104]). The total lymphocyte count is usually performed by the hematology laboratory on ethylenediaminetetraacetic acid blood and should be performed within 6 hours of drawing the sample. The absolute $CD4^{+}$ cell count is the product of the percent CD4 lymphocytes and the total lymphocyte count. Substantial variation in the absolute lymphocyte count is possible if the WBC differential is done manually and less than 400 cells are counted. Management in AIDS patients is directed toward not only improving the CD4 count but also in decreasing the HIV viral load ([105]).

SUMMARY

This chapter is a brief overview and introduction to the subsequent chapters in Part VI on nonmalignant disorders of the phagocytic and immune system. A primary objective is to separate benign from malignant disorders. Identifying a specific defect in the immune system begins with a history and physical examination followed by tests to identify the defect. A single gene mutation may account for a congenital immune deficiency, and prenatal diagnosis may be possible by sex determination *in utero* if X-linked or by fetal blood sampling if the defective gene is known or if characteristic abnormalities in the peripheral blood can be identified. Some of the congenital immune deficiencies, such as severe combined immunodeficiency and its variants, represent medical emergencies. Acquired immune abnormalities, particularly functional asplenia, severe hypogam-maglobulinemia, and iatrogenic neutropenia or T-cell deficiency, can also be life threatening. Knowledge of the site

of the defect in a host's immune system—whether in the neutrophils, humoral, cell-mediated, or complement arms or combination of defects—is critical in predicting types of infections that can occur and instituting appropriate therapy.

Neutropenia

DEFINITION AND CLASSIFICATION

Neutropenia is defined as a significant reduction in the absolute number of circulating neutrophils in the blood. *Agranulocytosis* implies a severe form of neutropenia or total absence of circulating neutrophils. Neutropenia is described by the absolute neutrophil count (ANC), which is calculated by multiplying the total white blood cell count by the percentage of neutrophils plus bands noted on the differential cell count. Normal values are traditionally defined for a given population as the mean ± two standard deviations from the mean. Because the human neutrophil count varies by age, sex, race, and other factors ([1]), the lower limits of normal ANC differ somewhat in varied populations. Table 63.1 demonstrates the age-specific white blood cell counts and ANCs from birth to adulthood (see Appendix A). Normal values also exist for term ([2]) and preterm ([3]) infants. In general, 1500 cells/mm ^{3} is considered the lower limit of normal ANC for most children and adults and is used to define neutropenia in most populations. Blacks demonstrate slightly lower neutrophil counts than whites, with a lower limit of normal neutrophil counts of 1000 cells/mm ^{3} ([4], [5]).

TABLE 63.1. Normal Neutrophil Counts

	Total Leukocytes		Neutrophils		
	Mean	Range	Mean	Range	%
Birth	22.0	9.0–30.0	13.2	3.6–24.0	60
1–4 wk	12.0	5.0–21.0	4.8	2.0–8.4	40
6 mo	11.9	6.0–17.0	3.8	1.0–8.5	32
1 yr	11.4	6.0–17.0	3.5	1.5–8.5	31
2 yr	10.6	6.0–17.0	3.5	1.5–8.5	33
4 yr	9.1	5.5–15.5	3.8	1.5–8.5	42
6 yr	8.5	5.0–14.5	4.3	1.5–8.0	51
8 yr	8.3	4.5–13.5	4.4	1.5–8.0	53
10 yr	8.1	4.5–13.5	4.4	1.8–8.0	54
16 yr	7.8	4.5–13.0	4.4	1.8–8.0	57
21 yr	7.4	4.5–11.0	4.4	1.8–7.7	59

NOTE: Expressed as cells ×10 ^{3}/mm ^{3}; ranges expressed as 95% confidence limits. Neutrophils include band forms.

Data from Rudolph AM, ed. Rudolph's pediatrics, 19th ed. East Norwalk, CT: Appleton-Lange, 1991:1142; and Miller DR, Baehner RL, eds. Blood diseases of infancy and childhood, 7th ed. St. Louis: Mosby, 1995:39.

Often, neutropenia is classified as mild, moderate, or severe based on the level of ANC. Mild neutropenia corresponds to an ANC between 1000 and 1500 cells/mm ^{3}, moderate with 500 to 1000 cells/mm ^{3}, and severe with less than 500 cells/mm ^{3}. This classification is useful in predicting the risk of severe bacterial infection. In a classic study involving infection risk in patients with neutropenia complicating acute leukemia, Bodey et al. demonstrated that the risk of infection is directly correlated with the degree and duration of neutropenia ([6]). Figure 63.1, reproduced from Bodey's original report, shows that with ANCs below 100 cells/mm ^{3}, the infection rate was essentially 100% by 4 weeks of neutropenia, whereas with ANCs up to 1000 cells/mm ^{3}, three times longer exposure was necessary for comparable infection rates. In fact, with brief episodes of neutropenia (few days to weeks), the risk of serious infection is generally limited to patients with severe neutropenia ([7]). However, as detailed in the discussions that follow, the best classification of neutropenia is based on the infection history itself. Some patients with quantitatively severe neutropenia have few infections, whereas other patients with less severe neutropenia experience severe and recurrent infections.

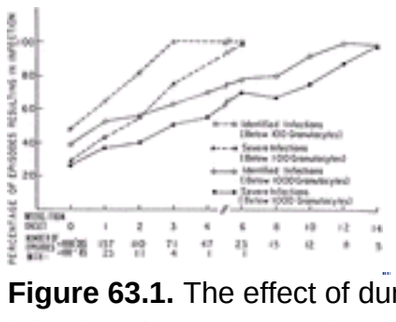

Figure 63.1. The effect of duration of neutropenia on the frequency of infection. The duration of neutropenia is plotted against the percentage of episodes resulting in infection. Along the x-axis are recorded the number of episodes of neutropenia (absolute neutrophil count below 1000 cells/mm ^{3}) or severe neutropenia (absolute neutrophil count below 100 cells/mm ^{3}) for each time interval. The risk of developing infection is directly related to the severity and duration of neutropenia. (From Bodey GP, Buckley M, Sathe YS, Freireich EJ. Quantitative relationships between circulating leukocytes and infection in patients with leukemia. Ann Intern Med 1966;64:328, with permission.)

CLINICAL PRESENTATION

In 1922, Werner Schultz ([8]) drew attention to a syndrome of unknown cause observed in middle-aged women and characterized by severe sore throat, prostration, extreme reduction or even complete disappearance of the granulocytes from the blood, and, in rapid succession, sepsis and death. He called this clinical entity *agranulocytosis*. Detailed reports of similar conditions were previously reported by Brown and Ophuls ([9]) in 1902 and by Türk ([10]) in 1907. In recognition of Schultz early work, older references to the fulminate form of severe neutropenia use the eponym *Schultz disease* ([11]). These early reports document the progressive, fatal

nature of severe neutropenia in the preantibiotic era.

Recurrent infections are the hallmark of significant neutropenia, and neutropenia in the absence of infections is not necessarily a disease state. Common sites of infection include the oral cavity and mucous membranes (Fig. 63.2), with mouth ulcers, pharyngeal inflammation, and periodontitis common. The skin is a second sentinel site of infection with rashes, ulcerations, abscesses, and poor wound healing. Perirectal and genital areas are also susceptible to repeated infections. The classic signs of local infection—especially swelling (tumor) and heat (calor)—are less evident in neutropenic patients than in nonneutropenic patients ([12]). With persistent, severe neutropenia, systemic infections of the lungs, gastrointestinal tract, and bloodstream appear and may prove fatal. Isolated neutropenia does not increase susceptibility to viral or parasitic infections.

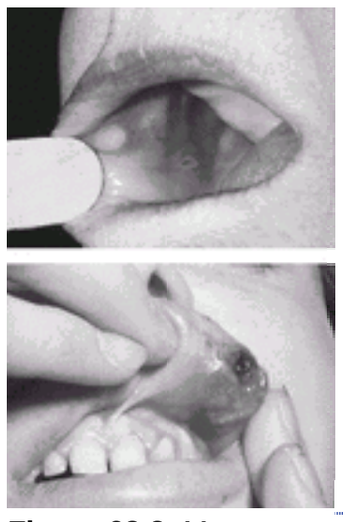

Figure 63.2. Mucous membrane lesions in neutropenia. Shown are oral ulcerations commonly noted in neutropenic patients. (From Sandoz atlas of clinical hematology. New York: Gower Medical Publishing, 1988, with permission.)

Endogenous bacterial flora are the most common pathogens: *Staphylococcus aureus* from the skin and gram-negative organisms from the gastrointestinal and genitourinary systems. Other rare bacterial pathogens, nosocomial organisms, and fungi are possible pathogens in cases of prolonged severe neutropenia, especially in patients with multiple antibiotic exposure, indwell-ing catheters, or prolonged hospitalization. As discussed in the section General Principles of Management of Neutropenia, initial and subsequent antibiotic choice must take these epidemiologic features into consideration.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of neutropenia includes congenital and acquired, benign and severe disorders and is outlined in Table 63.2. Neutropenia is also a common manifestation of more global marrow defects, such as the aplastic anemias, and acquired intrinsic marrow defects, such as leukemia and myelodysplasia. These global hematopoietic defects are discussed in Chapter 44. This chapter concentrates on disorders in which neutropenia is an isolated or predominant feature.

TABLE 63.2. Differential Diagnosis

- Pseudoneutropenia

    - Isoimmune neonatal neutropenia
    - Chronic autoimmune neutropenia
    - T-? lymphocytosis
    - Miscellaneous immunologic neutropenias
  - Felty syndrome
  - Neutropenia associated with complement activation
    - Dialysis, bypass
    - Extracorporeal membrane oxygenation
    - Anaphylactoid shock
  - Splenic sequestration
- Congenital or chronic neutropenias
  - Severe congenital neutropenia (Kostmann syndrome)
  - Cyclic neutropenia
  - Chronic benign neutropenia
    - Familial
    - Nonfamilial (chronic granulocytopenia of childhood)
  - Idiopathic chronic severe neutropenia
  - Neutropenias associated with congenital immune defects
    - Neutropenia with immunoglobulin abnormality
    - Neutropenia with defective cell-mediated immunity
  - Reticular dysgenesis
  - Neutropenias associated with phenotypic abnormalities
    - Shwachman syndrome
    - Cartilage-hair hypoplasia
    - Dyskeratosis congenita
    - Barth syndrome
    - Chédiak-Higashi syndrome
  - Myelokathexis

Lazy leukocyte syndrome
Metabolic disease

Pseudoneutropenia

An obvious initial step in the differential diagnosis of neutropenia is to ensure that the number of circulating neutrophils is actually low. In today's computerized society, many laboratories report white blood cell differential counts generated by automated counters. In all cases in which neutropenia is reported by automated examination, a manual differential white blood cell count is necessary to confirm automated data. Factitious neutropenia can occur if blood cell counts are performed at long periods after blood has been drawn. The presence of paraproteinemia or the use of certain anticoagulants can likewise result in neutrophil clumping and spuriously low neutrophil counts ([13]). A final cause of pseudoneutropenia is the asymmetric distribution of circulating neutrophils to the marginated pool ([14]).

Acquired Neutropenias

INFECTIONS Arguably, the most common cause of acquired neutropenia is infection. A wide variety of infections are associated with neutropenia (Table 63.3). In many instances, especially with viral infections, the neutropenia develops during the initial 1 to 2 days of illness in association with the peak viremic phase and persists for 3 to 7 days. The severity of neutropenia with common viral infections varies from mild to severe, but because it is usually short-lived, it rarely results in bacterial superinfection. Therefore, although very common, virus-mediated neutropenia is rarely clinically significant. The common mechanisms of virus-induced neutropenia include redistribution of neutrophils from the circulating to the marginating pool, aggregation and sequestration of neutrophils after activation by complement, and destruction of neutrophils by circulating antibodies ([42], [43] and [44]).

TABLE 63.3. Infections Associated with Neutropenia (Reference)

Rickettsial infections
Rickettsial pox (39)
Rocky Mountain spotted fever (40)
Typhus fever (41)

A few viruses produce more severe, protracted, and dangerous episodes of neutropenia. Hepatitis B virus, Epstein-Barr virus, and human immunodeficiency virus (HIV) are prime examples. The mechanisms of protracted neutropenia involve direct viral infection and damage of hematopoietic precursor cells, thus impairing production or replacement of granulocytes. Alternatively, autoantibody production of antineutrophil antibodies may result in protracted, infection-mediated neutropenia. HIV infection leads to significant cytopenias, including neutropenia, caused by both of these mechanisms ([45]). Severe cytopenias are often a hallmark of worsening HIV infection and present difficult management problems. The hematologic aspects of HIV-1 infection are discussed in detail in Chapter 69. Severe and clinically significant neutropenias are also associated with a number of bacterial, fungal, rickettsial, and protozoal infections (Table 63.3). Mechanisms of neutropenia in these infections include those discussed for viral infections. Additional mechanisms include direct bone marrow suppression of myelopoiesis by toxins derived from the infectious organisms, depletion of neutrophil marrow stores by release into the circulation, migration of neutrophils to sites of infection, and hastened neutrophil destruction by the infection via complement activation and by infection-mediated decreased myeloid growth factor production ([17], [46], [47]). Bacterial septicemia, particularly with gram-negative organisms, is one of the most serious causes of acquired neutropenia. Bacteremia and endotoxemia lead to increased neutrophil destruction and impaired production by the multitude of processes described in this section ([48], [49]). Patients with impaired bone marrow reserves, including neonates, the undernourished, alcoholics, and patients recovering from systemic chemotherapy or radiation, are especially prone to neutropenia when severe infection occurs ([50]). In these instances, the coexistence of septicemia and neutropenia carries a grave prognosis ([51]). The management of neutropenia complicating infection requires good supportive care, as discussed in the section General Principles of Management of Neutropenia. Attention should focus on proper therapy of the underlying infection if an antimicrobial agent is available. In many cases, the neutropenia is short-lived and does not require other specific therapy. In rare cases of progressive, overwhelming bacterial septicemia, especially in neonates, specific supportive therapy with granulocyte colony-stimulating factor (G-CSF) or white blood cell transfusions is indicated ([52], [53]). If the neutropenia is secondary to immune-complex–mediated destruction, blockade of autoantibodies with intravenous immunoglobulin (Ig) therapy has proved efficacious ([54]).

DRUG-INDUCED AGRANULOCYTOSIS AND NEUTROPENIA The second most common etiology of neutropenia is medication exposure (Table 63.4). Drugs and chemicals were first associated with agranulocytosis and neutropenia in 1931, when Kracke first noted a history of use of the analgesic aminopyrine (Pyramidon) in patients with agranulocytosis ([180]). Confirmation of the association of aminopyrine use and neutropenia led to the elimination of this agent from clinical use ([181], [182] and [183]). However, the introduction of new drugs into clinical use was followed by the recognition of new cases of drug-induced neutropenia, and today, drug use is

undoubtedly a common cause of isolated neutropenia.

TABLE 63.4. Drugs Associated with Neutropenia (Reference)

- Heavy metals
  - Gold (57)
  - Arsenic compounds (58, 59)
  - Mercury (60)
- Analgesics and antiinflammatory agents (61, 62)
  - Aminopyrine (63)
  - Dipyrone (64)
  - Phenylbutazone (65)
  - Indomethacin (66)
  - Ibuprofen (67)
  - Acetylsalicylic acid, diflunisal, sulindac (68)
  - Tolmetin (69)
  - Benoxaprofen (70)
  - Barbiturates (71)
  - Mesalazine (72)
  - Quinine (73)
- Antipsychotics, antidepressants, neuropharmacologic agents
  - Phenothiazines (chlorpromazine, methylpromazine, mepazine, promazine, thioridazine, prochlorperazine, trifluoperazine, trimeprazine) (74, 75)
  - Clozapine (76)
  - Risperidone (77)
  - Imipramine, desipramine (78)
  - Diazepam, chlordiazepoxide (79)
  - Amoxapine (80)
  - Meprobamate (68)
  - Thiothixene (81)
  - Haloperidol (82)
  - Riluzole (83)
  - Olanzapine (84)
- Anticonvulsants
  - Valproic acid (85)
  - Phenytoin (86)
  - Trimethadione (87)
  - Mesantoin (88)
  - Ethosuximide (89)
  - Carbamazepine (90)
  - Lamotrigine (91)
- Antithyroid drugs (92)
  - Thiouracil (93, 94)
  - Propylthiouracil (95)
  - Methimazole (96)
  - Carbimazole (97)
  - Potassium perchlorate (98)
  - Thiocyanate (98)
- Cardiovascular drugs
  - Procainamide (99)
  - Captopril (100)
  - Aprindine (55)
  - Propanolol (101)
  - Hydralazine (102)
  - Methyldopa (103)
  - Quinidine (104)
  - Diazoxide (105)
  - Nifedipine (106)
  - Propafenone (107)
  - Ticlopidine (108)
  - Vesnarinone (109)
  - Enalapril (110)
  - Amiodarone (111)
- Antihistamines
  - Cimetidine (112)
  - Ranitidine (113)
  - Tripelennamine (pyribenzamine) (114)
  - Methaphenilene (115)
  - Thenalidine (116)
  - Brompheniramine (117)
  - Mianserin (118)
- Antimicrobials (119)
  - Penicillins (120, 121 and 122)
  - Cephalosporins (123)
  - Vancomycin (124)
  - Chloramphenicol (125)
  - Gentamicin (126)
  - Clindamycin (127)
  - Doxycycline (128)
  - Flucytosine (129)
  - Nitrofurantoin (130)
  - Novobiocin (131)
  - Minocycline (132)
  - Griseofulvin (56)

Lincomycin (133)
Metronidazole (134)
Rifampin (135)
Isoniazid (136)
Streptomycin (137)
Thiacetazone (138)
Mebendazole (139)
Pyrimethamine (140)
Levamisole (141)
Ristocetin (142)
Sulfonamides (143)
Antimalarials (chloroquine, hydroxychloroquine, quinacrine) (144)
Ethambutol (145)
Dapsone (146)
Ciprofloxacin (147)
Trimethoprim (148)
Imipenem/cilastatin (149)
Antivirals [zidovudine (150), fludarabine (151), acyclovir (152), ganciclovir (153)]
Terbinafine (154)
Miscellaneous
Allopurinol (155)
Colchicine (156)
Aminoglutethimide (157)
Famotidine (158)
Bezafibrate (159)
Flutamide (160)
Tamoxifen (161)
Penicillamine (162)
Retinoic acid (163)
Metoclopramide (164)
Phenindione (165)
Dinitrophenol (166)
Ethacrynic acid (167)
Dichlorodiphenyltrichloroethane (168)
Cinchophen (169)
Antimony (170)
Pyrithyldione (171)
Rauwolfia (172)
Ethanol (173)
Oral hypoglycemic agents (chlorpropamide, tolbutamide) (174)
Thiazide diuretics (103)
Spironolactone (175)
Methazolamide (176)
Acetazolamide (177)
Intravenous immunoglobulin (178)
Omeprazole (179)
Levodopa (56)

Modified from Young NS. Agranulocytosis. JAMA 1994;271:935; and Vincent PC. Drug-induced aplastic anemia and agranulocytosis. Drugs 1986;31:52.

Many drugs, chemicals, and toxins produce hematopoietic toxicity, including neutropenia. With some, blood dyscrasias occur in all patients given the drug for sufficient time or in sufficient dose (e.g., the cancer chemotherapy agents). Because these agents rarely produce isolated neutropenia, but instead pancytopenia, they are discussed in Chapter 73. This section and Table 63.4 emphasize agents reported to cause isolated neutropenia and agranulocytosis unpredictably or in a minority of exposed patients. The pattern of association of drugs with the development of agranulocytosis or neutropenia is familiar and well described in this passage by John W. Athens from the ninth edition of this textbook:

> A new agent is described and in a few years it is widely used. At first, it is hailed as being nontoxic; ultimately a report appears describing the development of agranulocytosis in association with its use. This description is followed by another case, and another, and the circumstantial evidence becomes impressive. The drug loses popularity and is used with greater discrimination. The number of cases of agranulocytosis related to use of this agent decreases sharply, only to be replaced by other cases as new drugs are added to the therapeutic regimen.

The drugs listed in Table 63.4 are associated with the development of neutropenia or agranulocytosis. The list is probably incomplete, and in many cases, assignment of cause and effect to the temporal association of medication use and development of neutropenia is uncertain. The true incidence of drug-induced neutropenia is indeterminate because of variations in definition of agranulocytosis and neutropenia and inherent under-reporting. The best estimates of annual incidence come from the 10-year nationwide study in Sweden that predicted an annual incidence of drug-induced neutropenia of 1.0 case per million population per year (184), from a 5-year Dutch study that demonstrated an annual incidence between 1.6 and 2.5 cases per million (185), and from the International Aplastic Anemia and Agranulocytosis study, which found an overall incidence of all causes of agranulocytosis of 3.4 cases per million per year (186). Because a majority of cases of agranulocytosis are drug related, comparison of these estimates reveals close correlation. These estimates reflect the more severe forms of drug-induced neutropenia and thus underestimate the incidence of milder forms. The incidence is higher in women and the elderly, perhaps reflecting more frequent medication use or other genetic or physiologic traits in these populations. Several pathogenetic mechanisms for drug-induced neutropenia are postulated or supported by experimental evidence. These mechanisms include immune-mediated destruction of granulocytes or granulocytic precursors, dose-dependent inhibition of granulopoiesis, and direct toxic effect on myeloid precursors or the marrow microenvironment. With a given drug exposure, these mechanisms are not mutually exclusive. However, for categorization and descriptive purposes, representative agents in each category are discussed. Immune-mediated drug-induced neutropenia may occur by two mechanisms. In one mechanism, characteristic of neutropenia and agranulocytosis secondary to aminopyrine, penicillin, propylthiouracil, antithyroid drugs, and gold, the agent acts as a hapten to induce antibody formation, complement fixation, and neutrophil destruction. Physical presence of the drug is required to induce neutropenia, and antineutrophil antibodies are often identified by *in vitro* studies only when the drug is also present (187, 188). In a second immunologic mechanism, manifested by quinidine-induced neutropenia, circulating immune complexes are formed in response to the inducing drug. These immune complexes bind to neutrophils and result in granulocyte destruction. Once formed, the immune complexes do not require continued drug presence for destruction, and *in vitro* antineutrophil antibodies are often present even in the absence of the inducing drug (104). Another mechanism of drug-induced neutropenia is a dose-dependent inhibition of granulopoiesis. This mechanism is documented for ß-lactam antibiotics (189), carbamazepine (190), and valproic acid (85). In one representative study, val-proic acid was added at varying concentrations to normal donor marrow cells and colony-forming units granulocyte-macrophage (CFU-GM), quantified, and compared to controls in soft agar and plasma clot assays. At valproic acid concentrations of 60 µg/ml (mimicking low serum therapeutic levels), CFU-GM production was decreased 26 ± 4%. At concentrations of 120 and 240 µg/ml, CFU-GM production was inhibited by 67 ± 15% and 84 ± 27%, respectively (85). Both valproic acid and carbamazepine induce inhibition of CFU-GM in nearly all marrow samples at high concentration. However, the effects are more variable at lower drug concentrations, perhaps explaining patient-to-patient variability noted in clinical studies. The third general mechanism of drug-induced agranulocytosis and

neutropenia is direct damage to the bone marrow micro-environment or myeloid precursor cells by the drug or a drug metabolite. In a few cases, genetic or acquired factors predispose to toxicity with drug exposure. With sulfasalazine, individuals who inherit the slow-acetylator phenotype are at increased risk for agranulocytosis ([191]). Jewish people exhibit greater susceptibility to levamisole-mediated neutropenia ([192]). Captopril-induced agranulocytosis is more common in patients with renal insufficiency ([193]). These genetic predispositions probably relate to inherent differences in drug or drug metabolite clearance or metabolism. The granulocytopenia associated with phenothiazine use is based on a cumulative dose-dependent inhibition of granulopoiesis after 3 to 4 weeks of therapy ([194]). With chlorpromazine, the effect is based on inhibition of nucleic acid synthesis in myeloid precursor cells ([195]). The time of onset of drug-induced neutropenia is variable and depends in part on the mechanism of neutropenia. With immune-mediated neutropenia, the onset is rapid (hours to 1 to 2 days), especially in patients with previous drug exposure and prior antibody production ([196]). In contrast, agents that produce direct marrow suppression or toxicity often have delayed onset (weeks) of neutropenia ([194], [195]). The duration of neutropenia is also variable for the same reasons, with a range of 3 to 56 days (mean, 12 days) in one study ([197]). Bone marrow findings in drug-induced neutropenia are nonspecific and depend on the underlying pathophysiology. The bone marrow may manifest myeloid hypocellularity with neutrophil maturation arrest or hypercellularity with increased myeloid precursors ([198]). Diagnosis of drug-induced agranulocytosis or neutropenia is based on recognition of neutropenia during or immediately after drug exposure. Table 63.5 shows relative risk calculations for the most frequently invoked drugs and chemicals. Specific therapy for the drug-induced neutropenias begins with discontinuation of the suspect drug or agent. Supportive care follows the general principles of support outlined elsewhere in this chapter. In severe cases failing to respond to removal of the offending drug, treatment with recombinant human G-CSF is indicated and often effective ([199]).

TABLE 63.5. Risks of Agranulocytosis Associated with Select Drugs

Drug	Multivariant Relative Risk Estimate	Excess Risk [a]
Antithyroid drugs	97.0	5.30
Macrolides	54.0	6.70
Procainamide	50.0	3.10
Aprindine	49.0	2.70
Dipyrone	16.0	0.60
Trimethoprim-sulfamethoxazole	16.0	1.70
Thenalidine	16.0	2.40
Carbamazepine	11.0	0.60
Digitalis	2.5–9.9	0.10–0.30
Indomethacin	6.6	0.40
Sulfonylureas	4.5	0.20
Corticosteroids	4.1	—
Butazones	3.9	0.20
Dipyridamole	3.8	0.20
ß-Lactams	2.8	0.20
Propanolol	2.5	0.10
Salicylates	2.0	0.06

[a] Excess risk is expressed as number of cases per 1 million users in 1 week.

Data from the International Agranulocytosis and Aplastic Anemia Study. Risks of agranulocytosis and aplastic anemia. A first report of their relation to drug use with special reference to analgesics. International Agranulocytosis and Aplastic Anemia Study. JAMA 1986;256:1749.

NUTRITIONAL CAUSES OF NEUTROPENIA Severe, generalized nutritional deficiencies occurring in the setting of starvation, anorexia nervosa, marasmus, or cachexia may produce pancytopenia or selective hematologic defects including neutropenia ([200], [201], [202] and [203]). The pathogenesis is usually impaired blood cell production caused by lack of protein building blocks. Megaloblastic pancytopenia results from deficiencies of vitamin B_{12} or folic acid. Lack of these essential cofactors interferes with nucleic acid synthesis of myeloid precursors in the bone marrow and results in ineffective granulopoiesis ([204]). One morphologic hallmark of megaloblastic granulopoiesis is hypersegmented polymorphonuclear leukocytes with a lobe count of more than five per cell common. The administration of folic acid antagonists (trimethoprim-sulfamethoxazole, methotrexate) may mimic nutritional deficiencies. Copper deficiency is also reported to cause neutropenia ([205]), although the mechanism remains incompletely defined ([206]).

IMMUNE CAUSES OF NEUTROPENIA Neutropenia may result from the presence of specific antineutrophil antibodies that mediate destruction either by splenic sequestration of opsonized cells or by complement-mediated neutrophil lysis. Immune-mediated neutropenia is analogous to similar disorders of the platelet (immune thrombocytopenic purpura; see Chapter 53) and the red blood cells (immune hemolytic anemia; see Chapter 35 and Chapter 36). Selective immune-mediated neutropenia results from the presence and expression of unique neutrophil-specific antigens not shared with other hematopoietic cells. The most common and best characterized neutrophil-specific antigens are shown in Table 63.6 ([207], [208] and [209]). Neutrophils also express HLA antigens and several erythrocyte antigens, including the Kx antigen of the McLeod system ([210]). The leukocyte integrins CD11/CD18 are identified as autoantibody targets in some cases of neutropenia ([211]). Each of these antigenic determinants is associated with cases of immune neutropenia; in fact, most neutrophil-specific antigens have been identified through the investigation of immune neutropenia. The structure of several of the specific neutrophil antigens is known. For example, NA1 and NA2 are both isoforms of a neutrophil Fc receptor ([212]). Other antigens are identified only by molecular weight or remain unidentified ([213]).

TABLE 63.6. Human Neutrophil-Specific Antigens

Antigen	Phenotype Frequency (%)
NA1	54
NA2	93

Immune neutropenia may occur as an isolated condition involving mature neutrophils only, as a myeloid-specific neutropenia manifested by absence of some or all myeloid forms, or in association with other cytopenias. Autoimmune neutropenia is also classified as primary, if neutropenia is the sole abnormality, or secondary, if the neutropenia is a manifestation of a broader autoimmune condition. The clinical presentation depends on the lineage distribution of the antigen targeted by the autoantibody ([214], [215]). Recent studies suggest that in primary autoimmune neutropenia, the neutrophil autoantibody is specific for a single NA isoform, whereas in secondary autoimmune neutropenia, the antibodies react with all NA isotypes (panantibodies) ([216]). Another key determinant of the clinical course is whether the antineutrophil antibody is of restricted or nonrestricted clonality ([210]). Autoantibodies produced during the course of immune reaction to another foreign antigen by chance cross-reactivity are polyclonal in nature and thus are composed of mixtures of ?– and ?–light chain Igs. This is the usual pattern in self-limited neutropenias after or associated with infections or medication exposure. In contrast, antibodies associated with the loss of suppression of a clone of cells reacting with autoantigens are produced from a single clone (monoclonal) and express a single light-chain type. Monoclonal autoantibodies imply a more fundamental defect of the immune system and predict a longer and more severe degree of neutropenia. An example of neutropenia caused by neutrophil antibodies of restricted clonality is that associated with Graves disease ([217]), an autoimmune disease in its own right. Lalezari reported the first demonstration of circulating antibodies reactive against neutrophil-specific antigens in neutropenic patients in 1975 ([218]). Since that initial report, the methodology available to detect antineutrophil antibodies has markedly improved, allowing much of the progress in understanding the pathophysiology and antigenic targets of immune neutropenia. Table 63.7, adapted from reference [210], lists several methods used to detect antineutrophil antibodies. In general, antibodies can be detected directly on the neutrophil surface, or the effect of antibody binding to the neutrophil can be determined by indirect methods. Each method has its own strengths and weaknesses ([201], [219]), a discussion too complex for this text.

Further, technology continues to change and improve, and the superiority of one method today may not persist in the future. It is important to recognize the complexity and pitfalls of neutrophil antibody testing and invoke the help of expert laboratories when studying or evaluating specific patients.

TABLE 63.7. Methods to Detect Antineutrophil Antibodies

Category	Method
Detection of neutrophil surface Ig	Radiolabeled
	Anti-IgA
	Protein A
	Anti-IgM
	Intact staphylococci
	Immunofluorescence
	Flow cytometry
	Enzyme-linked immunoassays
Detection of antibody effects	Agglutination
	Opsonization
	Complement activation
	Antibodies to C3
	Cytotoxicity
	Antibody-dependent cytotoxicity

Ig, immunoglobulin.
Modified from Shastrik KA, Logue GL. Autoimmune neutropenia. Blood 1993;81:1984.

Immune-mediated neutropenia is clinically similar to other forms of acquired neutropenia. The ANC is usually below 500 cells/mm ^{3}. Bone marrow examination reveals variable results dependent on the lineage specificity of the antibody. In general, however, the bone marrow is hypercellular or normocellular and lacking in mature neutrophils ([220]). Only the finding of antineutrophil antibodies distinguishes cases of immune-mediated disease. Antineutrophil antibodies are involved in the pathophysiology of neutropenias occurring in several settings, including infection, drug exposure, and immune deficiencies. Each of these clinical presentations is discussed elsewhere. In addition, three distinct disorders in which the neutropenia is specifically caused by characteristic immune mechanisms are discussed here: isoimmune neonatal neutropenia, chronic autoimmune neutropenia, and T-? lymphocytosis.

Isoimmune Neonatal Neutropenia Isoimmune neonatal neutropenia is the neutrophil equivalent of Rh hemolytic disease of the newborn. During gestation, the mother is sensitized to antigens on fetal neutrophils that are not shared by the mother, resulting in production of IgG antineutrophil antibody able to cross the placenta and sensitize fetal neutrophils. The incidence is estimated at 3% of live births ([221]). The antigenic targets are those described earlier. The maternal neutrophils do not express the reactive antigen, but the father's neutrophils do. Thus, identification and characterization of the antibody are often aided by study of the father's neutrophils. Clinical manifestations include fever soon after birth, pneumonia, skin infections, urinary infections, and septicemia. Pathogens are those of the neonatal period and include gram-negative organisms, *S. aureus*, and group B *Streptococcus*. Neutropenia is especially dangerous in this age group because of the intrinsic risk of neonatal and perinatal infection. Deaths from overwhelming septicemia are reported ([222]). The duration of the neutropenia is related to the lifespan of the transplacentally conveyed Ig. The average duration of neutropenia is 7 weeks, but a range of 2 to 17 weeks is reported ([223]). The treatment of isoimmune neonatal neutropenia is primarily supportive, with antibiotic therapy chosen based on the clinical presentation and suspected pathogens. In life-threatening infections, other therapies including plasma exchange to remove the offending antibodies ([224]), transfusion of maternal neutrophils [which by definition lack the immunogenic antigen ([225])], intravenous Ig ([226]), or G-CSF ([227]) have been used individually or in combination.

Chronic Autoimmune Neutropenia In a subset of cases of chronic neutropenia, antineutrophil antibodies are identified that are presumed to have pathophysiologic significance. Age of onset varies from the neonatal period ([228]) to older than 70 years ([229]). These cases of antibody-mediated neutropenia are analogous to autoimmune hemolytic anemia or chronic immune thrombocytopenic purpura. Like these two more common immunologic diseases, the autoimmune process may be short-lived with benign clinical sequelae or may be associated with a more generalized autoimmune disorder having a prolonged course. Several disease states are associated with autoimmune neutropenia, including Wegener's granulomatosis, rheumatoid arthritis, systemic lupus erythematosus, and chronic hepatitis ([230]). These generalized autoimmune diseases are distinct from isolated autoimmune neutropenia. Autoimmune neutropenia of infancy and childhood is becoming more common. The estimated incidence in one study was 1 in 100,000 population per year in the age range of 6 months to 10 years. In contrast to isoimmune neonatal neutropenia, the infection risk appears to be less. Most patients manifest only mild infections, including otitis media, gastroenteritis, or cellulitis. Importantly, many of these children regain normal neutrophil numbers with time ([231]). Chronic autoimmune neutropenia is often recognized in adults of all ages. As many as 36% of adults with chronic idiopathic neutropenia have antineutrophil antibodies in the serum ([232]). Unless, as discussed previously, the neutropenia is a manifestation of a global autoimmune disorder, the problem is usually not life-threatening. Skin and lower respiratory infections predominate ([233]). Management decisions in autoimmune neutropenia are based on the presence or absence of associated autoimmune processes. Supportive care is indicated. If the immune neutropenia is isolated, specific therapy is usually not indicated because of the typically benign natural history. However, if the autoimmune neutropenia is one manifestation of a more generalized autoimmune disorder, specific therapy for the autoimmune illness is indicated. Corticosteroids are used to treat many immune-mediated cytopenias, including neutropenia ([234]). The primary mechanism of action of corticosteroids is decreased antibody production and reticuloendothelial blockade. Corticosteroids are not as effective in all types of immune neutropenia and should be prescribed with caution and understanding of the pathophysiology of the underlying defect.

T-? Lymphocytosis *T-? lymphocytosis* describes a group of patients with a syndrome of autoimmune neutropenia (and at times, thrombocytopenia and anemia as well) in association with infiltration of the bone marrow with large granular lymphocytes ([235]). *In vitro* evaluation of the lymphocytes and autoantibody reveals a clonal disorder of cytotoxic/suppressor T lymphocytes. This clonality identifies this syndrome as leukemia of large granular lymphocytes ([236]). The T-? lymphocytosis is also associated with other autoimmune diseases, including rheumatoid arthritis ([237]). The antineutrophil antibody associated with large granular lymphocytes or T-? lymphocytosis is usually high titer and complement activating, so the neutropenia is usually severe and long lived. Treatment in this disorder is directed not only at management and prevention of bacterial infections but also toward eradication or correction of the clonal disorder. Splenectomy has been used with some success in reducing infection risk and correcting the neutropenia but does not affect the lymphocytic infiltration ([238]). Corticosteroids have not produced good responses in this disorder and actually increase infection risk ([239]). G-CSF ([240]), cytotoxic chemotherapy, plasmapheresis ([241]), and cyclosporine ([242]) are all reported to have therapeutic benefit.

Miscellaneous Immunologic Neutropenias Autoimmune neu-tropenias also are reported after bone marrow transplantation and in association with reactions to transfused blood products. After bone marrow transplantation, autoantibodies directed against neutrophils develop in a minority of cases. The process of marrow transplantation, graft-versus-host prophylaxis, or treatment of manifestations of the underlying disease process all are potential immunomodulatory events equally able to result in autoantibody production ([243]). Nearly all cellular blood products are contaminated with neutrophils. With repeated transfusion, the recipient may become sensitized to antigens on the neutrophil surface (typically HLA antigens). Subsequent transfusion with blood products containing neutrophils of identical antigenic type may result in immunologic reaction, neutrophil damage, and occasionally complement fixation. If the antineutrophil antibody is directed against HLA antigens shared by the host, the circulating antibody may result in sufficient damage to host neutrophils to cause neutropenia ([244] , [245]).

FELTY SYNDROME *Felty syndrome* is the eponym used to describe the triad of rheumatoid arthritis, splenomegaly, and neutropenia ([246]). Patients with Felty syndrome are at increased risk of infection, with the risk related in large measure to the severity of neutropenia ([247]). The pathophysiology of neutropenia in Felty syndrome is multifactorial. Destruction of neutrophils by antineutro-phil autoantibodies ([248]) or immune complexes ([249]) plays a key role. Defective cell-mediated immunity with resultant T-lymphocyte–mediated immune destruction is also theorized ([250]). A further mechanism of accelerated neutrophil destruction is the splenomegaly itself ([251]). Finally, a neutrophil production defect manifested by defective granulopoiesis is reported ([252]). As expected, therapeutic interventions for this multifactorial disease process are many. Splenectomy is the oldest therapy, with the first reported use in 1932 ([253]). Initial response to splenectomy may approach 90%, but neutropenia recurs at a later date in 10 to 20% ([254] , [255]). In one series, the postoperative mortality rate was 4% ([255]). This fact must be kept in mind when considering splenectomy, especially in light of newer therapeutic options. Treatment of the underlying rheumatoid arthritis with gold therapy ([256]), D-penicillamine ([257]), cyclosporine ([258]), or other cytotoxic drugs ([259]) may be beneficial. Plasmapheresis has also been used with some success ([260]). Cortico-steroids ([261]) and intravenous Ig ([262]) have proved less useful. The hematopoietic growth factors granu-locyte-macrophage colony-stimulating factor (GM-CSF) and G-CSF are often reported as successful in ameliorating the neutropenia and infection risk ([263] , [264] and [265]). The preferred growth factor and duration of therapy remain incompletely defined ([266]). One important risk to consider with growth factor therapy of Felty syndrome is the effect of such therapy on the underlying autoimmune disease, rheumatoid arthritis. In several cases, arthritis symptoms are exacerbated during growth factor treatment ([263] , [267]).

NEUTROPENIA ASSOCIATED WITH COMPLEMENT ACTIVATION The exposure of blood to artificial membranes used in medical procedures including dialysis ([268]), cardiopulmonary bypass ([269]), apheresis ([270]), and extracorporeal membrane oxygenation ([271]) may result in complement activation *in vivo* ([272]). The complement is typically C3a or C5a produced by the classic complement activation pathway ([273] , [274]). Complement activation induces neutrophil aggregation and adherence to endothelial surfaces (often in the lung) with resultant neutropenia and cardiopulmonary symptoms ([275]). The onset of symptoms is soon after blood exposure to the membrane. The effect is transient but may result in severe symptoms. In hemodialysis, the incidence of this effect may be as high as 20% ([276]). The neutropenia of anaphylaxis manifests a similar pathophysiology.

SPLENIC SEQUESTRATION Enlargement of the spleen, irrespective of etiology, may result in neutropenia ([277]). The reduction in neutrophil number results from splenic trapping and destruction and often is mirrored by similar degrees of anemia and thrombocytopenia. The severity of neutropenia relates to the size of the spleen and the bone marrow's response to the call for increased production. Rarely is the neutropenia alone severe enough to cause severe infection. Therapy should be directed at correcting the underlying cause of the splenomegaly.

Congenital or Chronic Neutropenias

SEVERE CONGENITAL NEUTROPENIA (KOSTMANN SYNDROME) In 1956, Kostmann reported severe congenital neutropenia (SCN) in nine families in a remote, isolated region of northern Sweden ([278]). He named the disorder *infantile genetic agranulocytosis*. The syndrome is also known as *SCN* or *Kostmann syndrome*. In the highly inbred population initially described by Kostmann, consanguinity was common and the inheritance pattern probably autosomal-recessive ([279]). Similar cases of this disorder are reported from other geographic regions, where they are apparently sporadic in nature or follow autosomal-dominant modes of inheritance. The clinical presentation is remarkably consistent ([278] , [279]). The predominant manifestation is recurrent bacterial infections with the onset in early infancy in association with persistent severe agranulocytosis. Common initial bacterial infections include skin and soft tissue abscesses, boils and sores, omphalitis, otitis media, pneumonia, gingivitis, and urinary infections. The oral cavity and perirectal area are especially common sites of infection. The infections begin very early (often in the first days or weeks of life). Nearly all cases are apparent by 3 months of age. Fatal infections include septicemia, peritonitis, and enteritis. In initial reports, death from overwhelming infection occurred in infancy or early childhood. The most common bacterial pathogens are *S. aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa*. Granulocytopenia is universally severe, with the ANC typically less than 0.2×10^9/L. In many cases, no mature granulocytes are seen. Compensatory monocytosis is a common associated finding with or without variable degrees of eosinophilia. Bone marrow findings are typified by a myeloid maturation arrest at the promyelocyte-myelocyte stage (Fig. 63.3). There is a marked absence of mature granulocyte forms. Early reports noted prominent vacuoles in the myeloid progenitors that were present, although the etiology and significance of the vacuoles remain unclear ([280]).

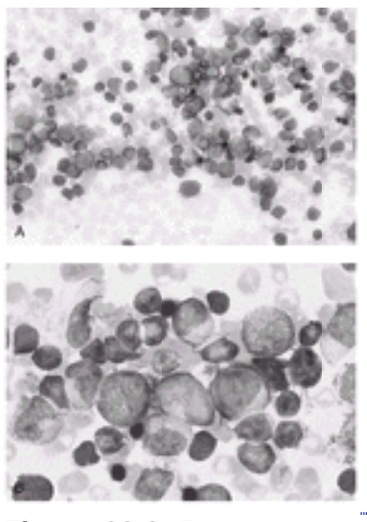

Figure 63.3. Bone marrow findings in severe congenital neutropenia (Kostmann neutropenia). Shown are a low-power view (×40) **(A)** and a high-power view (×100) **(B)** of a bone marrow aspiration from a child with severe congenital neutropenia. Note a cellular specimen with an apparent maturation arrest of myeloid differentiation at the promyelocyte stage. See Color Plate. (Photomicrographs courtesy of David Kelly, M.D.)

The underlying basis and pathophysiology remain incompletely defined despite aggressive global studies. As discussed in Chapter 6 and Chapter 10, myeloid maturation and differentiation depend on several cytokines with G-CSF, the most prominent and myeloid specific. G-CSF interacts with myeloid progenitor cells via specific high-affinity G-CSF receptors. The events after G-CSF binding to the G-CSF receptor that lead to myeloid maturation and differentiation remain incompletely defined. However, it is precisely these postbinding signal transduction pathways that appear to be dysfunctional in the SCNs. This assumption is based on the following findings:

- Normal numbers of myeloid colony-forming cells are found in the blood and bone marrow of affected patients, which fail to mature *in vitro* ([281] , [282]).
- The addition of extrinsic G-CSF to marrow cultures from patients with SCN results in normalized differentiation of myeloid colonies, although the concentrations of G-CSF required are higher than those required for normal marrow cells ([283]).
- The production of G-CSF by mononuclear cells from patients with SCN is normal compared with that of controls ([284]).
- Biologically normal to increased levels of G-CSF are found in the circulation of patients with SCN ([285]).
- G-CSF receptor number and function are normal to increased in patients with SCN before and after exposure to G-CSF ([286] , [287]).
- G-CSF (but not GM-CSF) ([288] , [289]) at pharmacologic doses administered to children with SCN may result in correction of neutropenia and improvement in clinical condition.

The data outlined above suggest that hematopoiesis in SCN is abnormal due to defective cytokine responses in primitive myeloid progenitor cells. These yet undefined defects are partially corrected *in vitro* with increased cytokine (predominately G-CSF) concentration ([290] , [291]). Knowledge of the molecular basis of SCN continues to expand. Two major groups of genetic mutations are described. The most frequently identified mutations in patients with sporadic and autosomal-dominant ([292]) but not autosomal-recessive ([293]) forms of SNC involve mutations of the gene encoding neutrophil elastase (ELA2 gene) on chromosome 19. It is hypothesized that the neutrophil elastase mutations result in accelerated apoptosis of myeloid progenitor cells and explain the defects of hematopoiesis outlined above. A second group of patients with SCN demonstrates mutations in the cytoplasmic component of the G-CSF receptor gene ([294]). These mutations appear to result in inability or altered ability to transmit a growth and differentiation signal from the G-CSF receptor to the myeloid cell. Importantly, the subset of patients with SCN and these G-CSF receptor mutations is at increased risk of developing acute myeloid leukemia ([295]). Figure 63.4 demonstrates one potential mechanism of leukemic transformation in such patients. Data suggest that the G-CSF receptor mutations are acquired ([296]) and that, over time, new mutations of the G-CSF receptor occur concurrent with the development of acute myeloid leukemia ([297]). Evidence shows that the receptor mutations result in impaired receptor internalization and sustained receptor activation with resultant prolongation of cell survival and resistance to apoptosis ([298]). Together, these mutations may play a role in leukemic transformation. The risk of myelodysplasia or leukemic transformation in SCN patients receiving G-CSF therapy is approximately 9%. The risk is associated with the presence of G-CSF receptor mutations or monosomy 7 but is not correlated with age of patient, gender, G-CSF dose, or G-CSF therapy duration ([299]). Thus, G-CSF therapy should not be withheld from patients with severe neutropenia because the potential clinical benefit of the therapy clearly outweighs the risk in most patients.

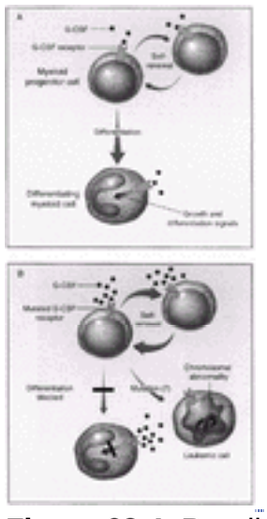

Figure 63.4. Possible mechanism for leukemic transformation. During normal, steady-state hematopoiesis **(A)**, only a small proportion of myeloid progenitors renew themselves. The majority differentiate into mature granulocytes. Granulocyte colony-stimulating factor (G-CSF) plays a major part in the process through an interaction with the G-CSF receptor that transmits the growth and differentiation signals. In cells with mutated G-CSF receptors **(B)**, more G-CSF is needed to activate the receptor. Abnormal proliferative signaling causes an accumulation of immature cells that do not differentiate. One such cell, constantly stimulated by G-CSF, may undergo a random mutation and acquire neoplastic properties. See Color Plate. (From Naparstek E. G-CSF, congenital neutropenia and acute myeloid leukemia. N Engl J Med 1995;333:517, with permission.)

Before the availability of genetically produced growth factors, multiple therapies were used to treat SCN. Treatment with corticosteroids ([300]), testosterone ([301]), splenectomy ([302]), vitamin B_6, and lithium ([282] , [288]) was ineffective. Allogeneic bone marrow transplantation is curative, but toxicity and donor availability problems limit its usefulness ([303]). Since the 1980s, recombinant human G-CSF has become the treatment of choice for patients with SCN ([298]). Data from the Severe Chronic Neutropenia International Registry (SCNIR) at the University of Washington provide the most complete information on the effects of G-CSF therapy in patients with SCN. More than 90% of patients respond to G-CSF therapy with an increase in total neutrophil count and ANC as well as a decrease in infection incidence ([304]). Most patients respond to doses of G-CSF between 3 and 10 µg/kg/day. Some patients, however, require higher G-CSF doses, and *nonresponders* are defined as those who do not to respond to doses of 120 µg/kg/day. For some nonresponding patients, the concurrent administration of prednisone with G-CSF may result in clinical and laboratory improvement ([305]). Figure 63.5 is a graphic demonstration of the effect of daily G-CSF therapy on the infection history of a patient with Kostmann neutropenia. GM-CSF, a related but distinct cyto-kine, is not as effective as G-CSF in SCN ([289]). For patients with severe neutropenia responding to G-CSF, the therapy must continue indefinitely. In some cases, the frequency of growth factor administration can be decreased to every other day or three times per week. However, in most patients, the drug must be administered daily to achieve therapeutic benefit.

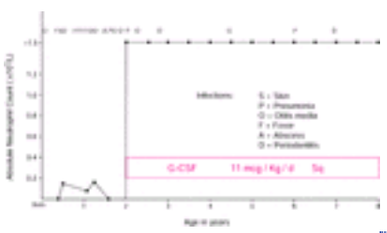

Figure 63.5. Effect of granulocyte colony-stimulating factor (G-CSF) therapy on infection history in a patient with severe congenital neutropenia. Shown are infections documented in a child with severe congenital neutropenia before and during therapy with G-CSF. Note the marked decrease in infection episodes with G-CSF therapy.

The chronic nature of G-CSF therapy for SCN brings into question the long-term safety of G-CSF. Review of data from the SCNIR defines possible long-term toxicities in patients with SCN treated with G-CSF ([306]). The relationship of G-CSF therapy to the reported toxicity is uncertain. Before cytokine therapy for SCN, mortality was high and life expectancy short. Thus, it is unclear whether some noted effects of G-CSF therapy in SCN represent medication side effects or an altered natural history of SCN. As discussed above, the most serious long-term concern with SCN and G-CSF therapy is myelodysplasia or acute leukemia. This complication occurs in approximately 9% of patients with SCN reported to the registry but not in patients with cyclic or autoimmune neutropenia. Acquired mutations of the G-CSF receptor or monosomy 7 are markers for leukemic transformation. The second most common complication of G-CSF therapy is osteoporosis, which may develop in as many as 50% of patients. The etiology of osteoporosis in SCN is unknown. Other less common associations include vasculitis, splenomegaly, hepatomegaly, and glomerulonephritis. Some authors recommend yearly evaluation of patients receiving G-CSF therapy for SCN to include renal and hepatic function tests, bone marrow for morphology and cytogenetics, and bone density study.

CYCLIC NEUTROPENIA *Cyclic neutropenia* is a rare defect of granulopoiesis characterized by regular periodic oscillations in the circulating neutrophil count from normal to neutropenic levels ([307] , [308] and [309]). The original case, reported by Leale in 1910, was an infant with repeated episodes of fever, stomatitis, skin infections, and neutropenia ([308] , [310]). Subsequently, more than 100 patients with a similar disorder were reported. In affected individuals, neutrophil counts drop to very low levels (ANC usually less than 200) followed by a recovery phase marked by return of nearly normal neutrophil numbers to the circulation (Fig. 63.6). During periods of neutropenia, patients experience repeated episodes of malaise, fever, skin, and oral mucosal infections and adenopathy. In the intervening periods of normal neutrophil numbers, patients typically are asymptomatic. This characteristic clinical syndrome usually presents in infancy or childhood either as a sporadic case or in a familial form. Most reported familial cases are inherited in an autosomal-dominant fashion ([311]). Acquired adult forms of the disease also are reported and are often associated with large granular lymphocytosis ([312]). The pathophysiology of these acquired adult cases appears distinct, and therapeutic approaches differ from apparent congenital cases. The discussion that follows deals primarily with the congenital forms of this disorder. The reader is referred to Chapter 92 and Chapter 93 for further information on large granular lymphocytosis.

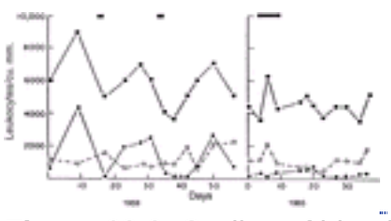

Figure 63.6. Cycling of blood elements in cyclic neutropenia. Shown are total leukocyte (squares), neutrophil (solid circles), and monocyte (open circles) counts in the patient over the period of observation, denoted in days. The black bars document episodes of mouth ulceration. (From Morley AA, Carew JP, Baikie AG. Familial cyclical neutropenia. Br J Haematol 1967;13:719, with permission.)

The average periodicity of neutrophil cycling in three-fourths of patients is 21 ± 3 days. In the remaining one-fourth, the period varies from as short as 12 days to as long as 36 days ([313]). Typically, the period of neutropenia lasts from 3 to 10 days. During the neutropenic period, the severity of infection tends to mirror the severity and duration of neutropenia. Most patients manifest mild infections of the skin and oral mucosa. When periods of neutropenia are long, more serious infections may occur, including sinusitis, mastoiditis, pneumonia, cellulitis, intraabdominal infections, and septicemia ([314]). These systemic infections are uncommon because the periods of neutropenia are usually brief. However, fatal infections occur in 10% of reported patients. A common pathogenic organism in fatal cases is *Clostridium perfringens* presenting as peritonitis and sepsis ([315]). Between episodes of neutropenia, most patients recover to nearly normal neutrophil counts and are generally well, without evidence of infection or systemic symptoms. Occasionally, sites of chronic infection and inflammation develop that may persist through several cycles. In general, cyclic neutropenia is a benign disorder and associated with prolonged survival. In several patients followed for a prolonged period of time, the cyclic nature of the disease became less prominent, and the condition came to resemble a chronic neutropenia ([316]). Detailed studies of other hematopoietic cells in cyclic neutropenia reveal cycling of platelets, reticulocytes, monocytes, and eosinophils as well ([317]). Based on this global cycling of hematopoietic elements, the term *cyclic hematopoiesis* is preferred by some authors. During the period of neutropenia, many patients manifest compensatory lymphocytosis, monocytosis, or eosinophilia ([318]). In contrast to the neutrophils, which cycle between normal and low numbers, the other blood cells oscillate between normal and elevated levels ([319]). The oscillatory cycle of the different blood elements may not coincide exactly, but the periodicity is usually similar. Sequential bone marrow studies in cyclic neutropenia demonstrate absence of granulocytes and granulocyte precursors or a maturation arrest before the onset of peripheral neutropenia. As hematopoiesis cycles, the myeloid precursor numbers return to normal before restoration of normal neutrophil counts ([320]). The cycling of blood neutrophils, platelets, reticulocytes, and monocytes in this disorder is attributed to fluctuating rates of marrow cell production. The basic mechanism responsible for the cycling remains largely unknown. Findings suggest that the disorder results from periodic failure of blood cell production, probably at a multipotent stem cell level. One proposed mechanism for the

cycling is impaired response of marrow progenitor cells to growth factor stimulation. *In vitro*, marrow precursor cells from patients with cyclic neutropenia demonstrate impaired CFU-GM growth in response to stimulation with either G-CSF or GM-CSF ([321], [322]). This defect is not caused by lack of specific growth factor receptors because G-CSF receptor number and affinity are normal ([286]). Available evidence suggests that the defect in cyclic hematopoiesis involves impaired survival of marrow progenitor cells ([323]). Further clues to the pathophysiology of cyclic neutropenia are obtained from study of a unique animal model of the disease. An autosomal-recessive form of cyclic neutropenia is described in gray collie dogs ([324]). The syndrome varies somewhat in mode of inheritance, duration of cycling, and associated pigmentary defects but otherwise is remarkably similar to the human disease. In dogs, oscillations of production of all hematopoietic cells are noted ([325]). The disease can be transmitted from affected to normal animals by bone marrow transplantation, and conversely, bone marrow transplantation of normal animal marrow into affected animals results in clinical cure ([326]). In humans, cyclic neutropenia was transferred by allogeneic bone marrow transplantation from one sibling to another concurrent with transplantation therapy for acute lymphocytic leukemia ([327]). Thus, available evidence supports the hypothesis of an intrinsic hematopoietic stem cell regulatory defect. The genetic basis of autosomal-dominant cyclic neutropenia was recently defined with the identification of point mutations in the neutrophil elastase gene on chromosome 19p13.3 ([328]). The mechanism by which neutrophil elastase mutations result in cyclic hematopoiesis remains uncertain but is hypothesized to involve accelerated apoptosis of myeloid precursors ([323]). In a single Chinese family with cyclic neutropenia and oligospermia, mutation of the Y chromosome was defined ([329]). Diagnosis of cyclic neutropenia is based on the findings of characteristic recurrent infections with cycling of blood elements, especially neutrophil numbers. Because the cycling periodicity may vary from patient to patient, twice weekly blood samples should be obtained for 4 weeks when seeking to document cyclic neutropenia. Therapy should include close attention to management of identified infections. Many short-lived fevers, aphthous ulcers, and upper respiratory infections require no therapy. However, a high index of suspicion must be maintained to identify and treat more serious bacterial infections. The specific therapy of adult onset cyclic neutropenia occurring in association with clonal large granular lymphocytosis is distinct. Treatment with daily or alternate-daily corticosteroids or cyclosporine has resulted in durable remissions of the hematologic manifestations of the adult forms of the disease ([330], [331]). In the congenital or pediatric onset forms of the disorder, therapeutic trials with corticosteroids, androgens, lithium, and splenectomy are generally ineffective ([307], [314]). Therefore, current specific therapy relies on the human growth factors G-CSF and GM-CSF. Daily intravenous or subcutaneous G-CSF therapy results in an increase in the mean neutrophil count, reduction in the duration of severe neutropenia, and amelioration of the number and severity of infectious episodes (Fig. 63.7) ([332]). Interestingly, G-CSF therapy does not prevent the cycling of blood elements and indeed accentuates the cycles. In contrast, GM-CSF therapy results in a less impressive increase in neutrophil number but does dampen or eliminate the hematopoietic cycling ([333]). Although these findings raise the possibility of combined cyto-kine therapy for patients with cyclic neutropenia, G-CSF therapy is considered the treatment of choice. Long-term (years) follow-up of patients with cyclic neutropenia treated with G-CSF therapy shows that the drug is generally well tolerated. One unique finding is of gradually increasing splenic enlargement, although no symptoms are reported attributable to the splenic size ([316]).

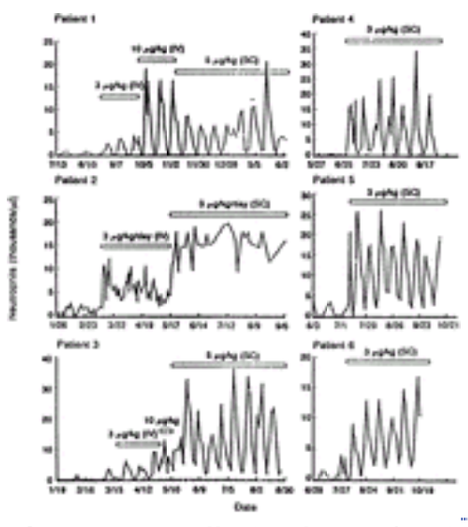

Figure 63.7. Effects of granulocyte colony-stimulating factor therapy on cyclic neutropenia. Shown are neutrophil counts performed every 1 to 2 days on patients with cyclic neu-tro-penia. The dosage of granulocyte colony-stimulating factor is indicated above each rectangle. (From Hammond WP 4th, Price TH, Souza LM, Dale DC. Treatment of cyclic neutropenia with granulocyte colony stimulating factor. N Engl J Med 1989;320:1306, with permission.)

CHRONIC BENIGN NEUTROPENIA *Chronic benign neutropenia* is a heterogeneous group of disorders sharing the common features of chronic neutropenia with little if any increased risk of infection in an otherwise healthy patient. Both familial and nonfamilial forms of this disorder are described.

Familial Chronic Benign Neutropenia Familial chronic benign neutropenia is an autosomal-dominant disorder found in families of Jewish Yemenite ([334]), African ([335]), and Western European ([336]) origins. Affected family members demonstrate moderate to severe neutropenia without associated leukopenia, relative monocytosis, and lymphocytosis with variable eosinophilia ([337]). Most patients are asymptomatic, and families are identified by chance. Infections, if present, typically are mild skin infections or oral cavity infections including gingivitis, periodontitis, and mouth sores ([338], [339]). Bone marrow studies reveal normal cellularity with reduced mature granulocytes. Neutrophil kinetic studies reveal a reduced bone marrow myeloid reserve pool, reduced mitotic pool size, and reduced concentration of colony-forming unit-culture. Based on these studies, the presumed defect is faulty release of mature neutrophils from the bone marrow ([340], [341]). Because the disease is benign in most affected families, therapy with cortico-steroids or growth factors is not indicated.

Nonfamilial Chronic Benign Neutropenia Other cases of chronic benign neutropenia are described in which no familial pattern is identified. Chronic neutropenia with a benign phenotype is described in all ages. The common feature of these heterogeneous disorders is the absence of severe or recurrent infections despite chronic neutropenia. In one form, chronic benign granulocytopenia of infancy and childhood, neutropenia with or without minor infections may be noted soon after birth ([342]). Unlike in SCN, life-threatening infections do not occur. The neutropenia is typically quantitatively severe, and a compensatory monocytosis and eosinophilia are noted. Bone marrow studies demonstrate hypercellularity and myeloid hyperplasia with maturation through the band stage. When stressed with severe infection or challenged with epinephrine or cortisol administration, the circulating neutrophil count increases. This response to stress explains why severe infections do not occur ([343]). In some cases of chronic benign neutropenia, careful evaluation reveals the presence of autoantibodies, thus suggesting an immune etiology ([344], [345]). In other cases, abnormal phagocytosis of mature neutrophils by marrow macrophages is documented ([346]). It is likely that multiple pathophysiologies result in the same clinical features. In the childhood form, spontaneous resolution of the neutropenia is noted by age 4 years in a majority of cases ([343]). G-CSF therapy has proved effective in elevating the neutrophil count in most patients ([347], [348]). However, because by definition, patients with this disorder manifest a benign course, specific therapy with steroids, androgens, splenectomy, or growth factors is not indicated.

IDIOPATHIC CHRONIC SEVERE NEUTROPENIA In some patients, chronic, symptomatic, severe neutropenia presents in later childhood or during adulthood. If the search for other underlying etiologies is not fruitful, the diagnosis of idiopathic chronic severe neutropenia is used ([349], [350]). This diagnosis probably represents a heterogeneous group of disorders. The distinction between chronic severe neutropenia and chronic benign neutropenia should be based on the natural history in a given patient. Thus, at presentation of a new patient, close attention to infection history and careful physical examination with emphasis on signs of chronic infection are crucial. The severity of neutropenia typically varies, and the infection risk depends in part on the degree of neutropenia ([351]). In the severe forms, the ANC is typically less than 500 cells/mm ^{3}. Bone marrow evaluation may reveal myeloid hypoplasia, maturation arrest, or normal morphology. Forms with myeloid hypoplasia have been called *chronic hypoplastic neutropenia* ([352]). Before diagnosing an idiopathic form of chronic severe neutropenia, careful evaluation for other forms should be concluded with emphasis on search for autoantibodies. Some forms of chronic severe neutropenia may represent a continuum of forms of benign neutropenia, but studies of this group of patients are not sufficient to define specific pathophysiologies. It is also possible that no true idiopathic forms exist and only reflect insufficient evaluation or insensitive laboratory methods. Clinically severe forms of chronic neutropenia deserve specific growth factor therapy.

NEUTROPENIAS ASSOCIATED WITH CONGENITAL IMMUNE DEFECTS As previously discussed, acquired immune deficiency secondary to HIV infection is often complicated by neutropenia of multifactorial origin. Likewise, patients with congenital primary immunologic defects of Ig production or cell-mediated immunity are at increased risk of symptomatic neutropenia. The coexistence of defects in immune function and neutropenia presents great danger to the patient.

Neutropenia with Immunoglobulin Abnormality As many as one-third of patients with X-linked agammaglobulinemia manifest symptomatic neutropenia at some time during their disease course ([353]). Many patients with hyper-IgM syndrome also manifest cyclic or persistent neutropenia ([354]). Neutropenia is reported to complicate dysgammaglobulinemia type I ([355]). Isolated IgA deficiency is reported to cause neutropenia via production of autoantibodies ([356]). Familial forms of hypo-gammaglobulinemia with neutropenia are described, including a father and daughter pair, suggesting autosomal-dominant inheritance ([357], [358]). Clinically, all patients with combined defects of neutrophil number and Ig synthesis are at high risk of infection. Therapy should include a trial of intravenous Ig, which may correct both defects ([359]). Specific growth factor therapy can also be used in patients who do not respond to Ig replacement.

Neutropenia with Defective Cell-Mediated Immunity A familial syndrome of severe neutropenia with associated defective cell-mediated immunity was reported in 1976, affecting three girls and a boy ([360]). The patients manifested eczema, poly-arthralgias, pneumonias, recurrent otitis media, and neutropenia with eosinophilia. Serum IgA levels were elevated, but antibody production in response to tetanus and poliomyelitis vaccines was impaired. The cell-mediated immune defect resulted in disseminated varicella infection in two of the four affected children.

RETICULAR DYSGENESIS This rare disorder results from an unidentified intrinsic failure of hematopoietic stem cells committed to myeloid and lymphoid development (both marrow and thymic derived). Red blood cell and platelet production are normal, but severe neutropenia, lymphopenia, agammaglobulinemia, and absent cell-mediated immunity result in extreme vulnerability to fatal bacterial or viral infection ([361], [362], [363] and [364]). Postmortem evaluation of affected patients reveals complete absence of lymphoid tissue, plasma cells, or splenic follicles. Bone marrow transplantation has proved curative in this disorder ([365], [366]). Reticular dysgenesis is one of the few causes of neutropenia that does not respond to G-CSF therapy ([367]).

NEUTROPENIAS ASSOCIATED WITH PHENOTYPIC ABNORMALITIES

Shwachman Syndrome *Shwachman syndrome*, initially described in 1964, is a rare autosomal-recessive disorder characterized by metaphyseal chondrodysplasia, pancreatic exocrine insufficiency, dwarfism, and neutropenia ([368]). Other associated findings include anemia, thrombocytopenia, developmental and mental retardation, diarrhea, weight loss, failure to thrive, eczema, recurrent otitis media and pneumonia, and neutrophil motility defects ([369], [370]). Patients with Shwachman syndrome are also at increased risk of bone marrow failure or leukemic transformation ([371]). The basic underlying genetic basis of the disorder remains undetermined. Bone marrow evaluation typically shows hypoplasia. Myelodysplasia or clonal cytogenetic abnormalities (usually monosomy 7) are found in up to one-third of patients. In one patient, increased spontaneous chromosomal breakage was noted in stimulated peripheral blood lymphocytes, suggesting a primary defect in DNA repair or protection similar to Fanconi anemia ([372]). In 2001, marrow failure in the Shwachman syndrome was linked to increased progenitor apoptosis mediated via the Fas pathway ([373]). The associated neutropenia appears to be secondary to marrow myeloid hypoplasia ([374]). The degree of neutropenia is usually moderate to severe with an average ANC between 200 and 800 cells/mm ^{3} ([375]). Most patients present in early infancy with failure to thrive, diarrhea, feeding problems, and recurrent bacterial infections. Growth failure and dwarfism usually are apparent by the second year of life. Chondrodysplasia, especially of the hip, appears with further growth. Death from infection is reported from septicemia, pneumonia, and osteomyelitis. The reported mortality rate in Shwachman syndrome is 15 to 25%, primarily from infection, bleeding, marrow failure, or malignancy ([376]). Treatment of the pancreatic insufficiency with dietary manipulation and pancreatic enzyme supplementation can improve the malabsorption but has no effect on the dwarfism or neutropenia. G-CSF therapy increases the neutrophil count and ameliorates the infectious predisposition of this disorder ([377]).

Cartilage-Hair Hypoplasia *Cartilage-hair hypoplasia* is an autosomal-recessive disorder noted primarily in the Amish ([378]) and Finnish populations ([379]). Characteristic findings include short-limb dwarfism, fine hair, moderate to severe neutropenia (ANC, 100 to 2000 cells/mm ^{3}), and defects of cell-mediated immunity ([380]). Other associated findings include anemia with macrocytosis and gastroesophageal defects (Hirschsprung disease, anal stenosis, esophageal atresia). The combination of neutropenia and cellular immunologic defects predisposes patients to infections, especially varicella-zoster virus infections. Linkage analysis studies have localized the gene responsible for cartilage-hair hypoplasia to the short arm of chromosome 9 ([381]). The underlying etiology of this constellation of findings remains unknown. Allogeneic bone marrow transplantation is reported to correct hematologic and immunologic defects ([382]). G-CSF would be expected to increase the neutrophil count, although no reports of its use in this disorder exist.

Dyskeratosis Congenita *Dyskeratosis congenita* is a rare multiorgan syndrome characterized by reticulated hyperpigmentation of the skin, nail dystrophy, and leukoplakia of the mucous membranes ([383], [384]). Originally described in 1906, this syndrome is also known as *Zinsser-Cole-Engman syndrome*. Other manifestations of the syndrome include mental retardation, growth failure, endocrine dysfunction, and minor defects of the eyes, ears, and bone ([385], [386], [387] and [388]). Hematologic manifestations include neutropenia, refractory anemia, thrombocytopenia, marrow failure syndromes, and cell-mediated immune dysfunction ([389]). The majority of reported cases are male patients, and the defective gene designated the *DKC1 gene* has been linked to Xq28 ([390]). Autosomal-dominant and -recessive pedigrees are also reported ([391]). The affected DKC1, dyskerin, is involved in RNA function and telomere maintenance. The exact pathophysiology of dyskeratosis congenita remains unknown, but the hematologic manifestations share remarkable similarity to Fanconi anemia ([392]). Like Fanconi anemia, dyskeratosis congenita is associated with defects of DNA repair or maintenance ([393], [394]). Also, as in Fanconi anemia, allogeneic bone marrow transplantation has been used successfully in dyskeratosis congenita to correct hematologic abnormalities ([395]). Patients with Fanconi anemia and dyskeratosis congenita require reduction in the intensity of the conditioning regimen for marrow transplantation ([389]). G-CSF or GM-CSF therapy can improve the neutropenia associated with dyskeratosis congenita ([389], [396]).

Barth Syndrome *Barth syndrome* is an X-linked recessive cardioskeletal myopathy with associated neutropenia ([397]). Affected male patients manifest skeletal myopathy, cardiomyopathy, short stature, and recurrent bacterial infection secondary to neutropenia ([398]). In most cases, dilated cardiomyopathy is the initial presenting symptom in infancy. The cardiomyopathy may be severe and fatal. The associated neutropenia is usually moderate to severe, with ANC from 0 to 500 cells/mm ^{3} ([399]). The neutropenia may be intermittent and tends to improve with advancing age. Infections tend to involve the skin and mucous membranes. Bone marrow evaluation usually reveals myeloid hypoplasia ([398]). In the original report by Barth, vacuolation of neutrophil precursors was noted ([397]), but this finding has not been noted in subsequent reports. The basic etiology of this syndrome is unknown. The gene for Barth syndrome is identified as the *TAZ gene* (previously *G4,5 gene*) located in the region of Xq28 ([400]). Metabolic abnormalities including low carnitine levels ([399]) and 3-methylglutaconic aciduria ([401]) are associated with Barth syndrome, but it remains uncertain whether these findings are primary or secondary defects ([398]). Genetic analysis of the TAZ gene sequence demonstrates homology to a family of acyltransferases, suggesting that defects of lipid synthesis or metabolism may be involved in disease pathogenesis ([402]). Primary clinical treatment of most patients with this rare disorder has focused on the cardiomyopathy. There are no reports of G-CSF or GM-CSF use in Barth syndrome, but these agents should prove effective if required for serious infections.

Chédiak-Higashi Syndrome *Chédiak-Higashi syndrome* (CHS) is a rare autosomal-recessive disorder characterized by recurrent infections, partial oculocutaneous albinism, and pathognomonic large lysosomal granules in nucleated blood cells, neurons, renal tubular epithelial cells, and tissue macrophages. Associated findings include photophobia, nystagmus, gingivitis, periodontitis, abnormal bleeding, mental retardation, neuropathy, immune dysfunction, and neutropenia ([403]). Neutropenia is present in at least 75% of reported patients with the degree of neutropenia moderate to severe ([404]). Infections include recurrent fevers, pyoderma, otitis media, gingivitis, and septicemia. The infection risk in CHS is magnified by coexistent defects of cellular and humoral immunity and neutrophil functional defects ([405]). The neutropenia of CHS appears to be secondary to increased destruction of granulocytes ([406]) and perhaps impaired bone marrow neutrophil release ([407]). The etiology of CHS is thought to be secondary to abnormal granule membrane fusion and function. In 2000, mutations in the lyso-somal trafficking regulator (LYST) gene on chromosome 1 were found in CHS patients from multiple families ([408]). Available data suggest that the pathophysiology of CHS involves defective trafficking of proteins to organelles. Many patients later develop an accelerated phase characterized by lymphomalike mononuclear cell infiltration of lymph nodes, spleen, liver, and bone marrow. This accelerated phase may be related to an abnormal immune response to Epstein-Barr virus infection ([409]). Treatment is primarily supportive. Bone marrow transplantation has resulted in apparent cure ([410]).

MYELOKATHEXIS *Myelokathexis* is a rare form of chronic neutropenia characterized by bizarre granulocyte nuclear morphology ([411], [412], [413], [414] and [415]). The mature neutrophils reveal cytoplasmic vacuolization, pyknotic nuclei, nuclear hypersegmentation, and thin nuclear strands connecting nuclear lobes (Fig. 63.8). Moderate neutropenia and recurrent bacterial infections are noted. Bone marrow studies demonstrate myeloid hyperplasia with degenerating granulocytes. Leukokinetic and morphologic studies suggest an intrinsic granulocyte abnormality resulting in increased intramedullary and systemic destruction of mature neutrophils as the basis of the disorder. Neutrophil lifespan is shortened in the circulation of affected patients as well as in the circulation of normal volunteers injected with myelokathexis neutrophils. Normal neutrophils injected into patients have a normal lifespan ([412]). Most reported cases are congenital with onset of symptoms in infancy. In a 1997 review, 80% of reported cases were female ([415]). An acquired form of myelokathexis as a paraneoplastic syndrome is the subject of one case report ([416]). The basic biochemical defect resulting in granulocyte destruction is uncertain. In one family, hypogammaglobulinemia was also present ([358]). Both GM-CSF and G-CSF are reported to correct the neutropenia and ameliorate infections in myelokathexis ([417], [418], [419] and [420]).

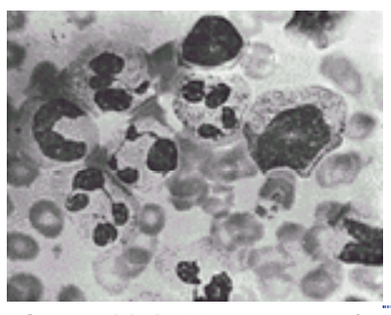

Figure 63.8. Marrow specimen from a patient with myelokathexis. Note the pyknotic nuclei, cytoplasmic vacuoles, and hypersegmented neutrophils with long, thin, intrasegmental chromatin strands. (From Krill CE, Smith HD, Mauer AM. Chronic idiopathic granulocytopenia. N Engl J Med 1964;270:973, with permission.)

LAZY LEUKOCYTE SYNDROME *Lazy leukocyte syndrome* was the term chosen by Miller et al. in 1971 to describe an apparently unique syndrome characterized by neutropenia, normal bone marrow granulocyte number, and defective neutrophil motility *in vitro* and *in vivo* ([421]). In the initial report, two unrelated children manifested severe neutropenia (ANC below 200 cells/mm ^{3}), normal bone marrow myeloid morphology, defective neutrophil chemotaxis and chemokinesis, and recurrent, primarily minor infections. Subsequently, a few similar cases have been reported ([422], [423], [424] and [425]). Most described cases present in infancy, although the diagnosis has also been made in adults ([423], [424]). In one infant, the neutropenia and neutrophil motility defect resolved before 2 years of age, suggesting a transient disorder ([425]). In general, described patients have manifested quantitatively severe neutropenia but have experienced few life-threatening infections. The etiology of

this syndrome remains unidentified. Defects of the neutrophil cytoskeleton have been hypothesized based on the findings of defective motility and the apparent inability of mature neutrophils to exit the bone marrow. However, no direct proof of cytoskeletal defect exists, and other patients with known neutrophil cytoskeletal defects (neutrophil actin dysfunction) do not manifest neutropenia ([426], [427] and [428]). Clinical management is primarily supportive. Most reported patients have responded well to appropriate antibiotic therapy. There are no reports of growth factor therapy in lazy leukocyte syndrome.

METABOLIC DISEASES Several congenital metabolic disorders, including glycogen storage disease type Ib ([429]), propionic acidemia ([430]), methylmalonic acidemia ([431]), and isovaleric acidemia ([432]), are complicated by chronic or intermittent neutropenia of variable severity. In glycogen storage disease type Ib, the neutropenia is a consequence of disturbed myeloid maturation ([433]) and is severe enough to result in recurrent infections beginning in the first year of life. G-CSF and GM-CSF are effective in correcting the neutropenia associated with glycogen storage disease type Ib and are worthy of trial in other metabolic disorders with symptomatic neutropenia ([434], [435] and [436]).

EVALUATION OF THE PATIENT WITH NEUTROPENIA

The clinical evaluation of neutropenia uses the diagnostic tools of history, physical examination, and selective laboratory studies to determine its chronicity and severity. An algorithmic approach to evaluation of a patient with severe chronic neutropenia is shown in Figure 63.9.

Figure 63.9. Diagnostic approach to neutropenia. ANC, absolute neutrophil count; CBC, complete blood cell count. (From Zeidler C, Boxer L, Dale DC, et al. Review: management of Kostmann syndrome in the G-CSF era. Br J Haematol 2000;109:490, with permission.)

The history should focus on a detailed evaluation of infection history; including type, severity, and frequency; duration of the recurrent infections or neutropenia; and age of onset of symptoms as clues to whether the disorder is congenital or acquired. Medication use and exposure must be carefully evaluated because drug exposure is a very common cause of transient, acquired neutropenia, and medication exposure is very common in our society. History of recent infections may provide clues to severity of the neutropenia, and infections may also be a cause as well as a result of neutropenia. Family history should focus on recurrent infections or unexplained sudden deaths. In neonatal neutropenia, maternal history is likewise important. Crucial but often overlooked historical information may require the assistance of other health care providers to obtain previous blood cell count values. Complete blood cell counts are often performed in physicians' offices while evaluating a myriad of complaints and often provide rapid confirmation that an episode of neutropenia is acquired or of recent onset.

The physical examination likewise focuses on delineation of evidence of current or recent infection. The skin and oral mucosa are especially common sites of chronic or recurrent infection and inflammation in patients with neutropenia. In children, growth and development should be documented. Recurrent, severe bacterial infection of long duration invariably results in growth failure. A thorough examination is indicated to evaluate for phenotypic abnormalities, especially bony defects. Specific areas of examination also include close attention for evidence of pallor or petechial bleeding suggesting deficiency of red blood cells or platelets and a search for adenopathy or splenomegaly. The perineum and perirectal area should not be neglected because the rectum is a common location of mucosal irritation and inflammation.

Laboratory evaluation, at a minimum, should include a complete blood cell count with manual white blood cell differentiation. The manual differential cell count offers important advantages over automated machine differential counts and is an early step in laboratory evaluation of presumed neutropenia. The complete blood cell count often offers important clues to guide further evaluation; for example, if concurrent abnormalities of red blood cells or platelet numbers are noted, bone marrow aspiration or biopsy is the next diagnostic test. If isolated neutropenia is noted, further laboratory evaluation should be based on the chronicity and severity of symptoms. For example, if mild or moderate neutropenia is noted in a healthy-appearing patient with recent or current viral infection or concurrent with suspicious exposure to medication (e.g., sulfonamides), clinical observation without further diagnostic study may be indicated. In contrast, if the history is chronic and severe, more detailed testing is in order. Table 63.8 lists some of the available laboratory investigations and major indications for each. Older tests of neutrophil mobilization, including the hydrocortisone stimulation test (which tests marrow myeloid reserve) ([437]), the epinephrine challenge test (which evaluates for the size of the marginating neutrophil pool) ([438]), and the Rebuck skin window (which evaluates neutrophil migration into tissues) ([439]), are rarely used in diagnosis of neutropenic syndromes.

TABLE 63.8. Laboratory Tests Useful in Evaluation of Neutropenia

Test	Indications and Use
Twice-weekly complete blood cell counts	Screen for cyclic neutropenia.
	Monitor for resolution of neutropenia.
Bone marrow aspiration/biopsy	Search for intrinsic marrow defects.
	Myelokathexis.
	Severe congenital neutropenia: maturation arrest at promyelocyte stage.
	Benign congenital neutropenia: maturation arrest at metamyelocyte stage.
	Morphologic identification of fungal infection.
	Evidence of megaloblastosis (vitamin B_{12}–folate).
Antineutrophil antibody screens	Autoimmune or isoimmune neutropenias.
	Evaluation of parents helpful in neonates.
Immune evaluation	Screen for defects of cellular or humoral immunity.
	Human immunodeficiency virus testing.
Metabolic studies	Copper, vitamin B_{12}, or folate levels.
	Diagnosis of inborn metabolic errors.
Radiographs of long bones	Evaluation for phenotypic forms of neutropenia.
Cytogenetic studies	Barth syndrome.
Chromosomal fragility/breakage studies	Fanconi anemia.
	Dyskeratosis congenita.
Pancreatic exocrine function study	Shwachman syndrome.
Bone marrow culture	Evaluation of colony-forming unit granulocyte-macrophage production.

GENERAL PRINCIPLES OF MANAGEMENT OF NEUTROPENIA

Management of neutropenia is based on the etiology of the neutropenia, if known, and assessment of the chronicity and severity of the disorder. Treatment of neutropenia after cancer chemotherapy or in the setting of bone marrow failure or bone marrow transplantation is a special topic discussed in detail elsewhere in this book. General and specific therapeutic options exist in isolated neutropenia and are discussed separately.

The general approach to treatment of neutropenic patients involves preventive measures to limit the number and severity of infections as well as direct efforts to rapidly identify and treat infections that do arise. Preventive measures begin with close attention to areas of high infection risk. Because the mouth and oral mucosa are common sites of infection, good oral hygiene is imperative, including cleaning and attention to and correction of dental problems. The perirectal area is protected by avoidance of trauma, such as rectal temperature measurement. If constipation is a concern, stool softeners are prescribed to minimize trauma and straining. Patients should be encouraged to report perirectal pain or irritation. The skin is the other common site of bacterial entry in neutropenic patients and should be kept clean. Skin abrasions or cuts need prompt cleaning and antibacterial topical therapy. Prophylactic antibiotics are used in some instances and may limit infectious risks in patients with severe chronic neutropenias. The most commonly used agent is trimethoprim-sulfamethoxazole.

Despite all of these efforts, infection is inevitable in patients with chronic, severe forms of neutropenia. Thus, the clinician must have a high index of suspicion for bacterial and fungal infections and initiate rapid diagnostic evaluation. Because the classic signs of infection, especially swelling (tumor) and heat (calor) may be absent or minimal ([440]), the examination may not reveal the usual clues of infection. Fever becomes a key systemic sign of infection, and the presence of fever in a severely neutropenic patient must provoke the presumption of infection. Febrile neutropenic patients should have samples of appropriate body fluids obtained for culture, and broad-spectrum antimicrobial agents should be initiated promptly. Because the common bacterial pathogens are *Staphylococcus* species and gram-negative enteric organisms, initial antibiotic therapy usually involves a combination of antibiotics with activity against the most common pathogens. As discussed elsewhere in this book, specific antibiotic choice depends in part on local patterns of drug sensitivity. In high-risk patients, therapy is usually initiated in the hospital setting. Lack of response to antibiotic therapy should initiate further diagnostic study or empiric antifungal therapy. In patients with benign clinical forms of neutropenia, clinical judgment is indicated, and outpatient management often appropriate. As previously discussed under individual disease entities, in some cases of mild acquired forms of neutropenia, no therapy at all is indicated.

Several specific therapies for neutropenia exist, dependent in large measure on the specific etiology of neutropenia. In neutropenia associated with drug exposure, an obvious specific measure is the discontinuation of the presumed causative agent. If the neutropenia is associated with gold or arsenic exposure, specific heavy metal therapy with British antilewisite (or dimercaprol) or penicillamine may help in correction of the neutro-penia ([441]). Specific therapies for immune-mediated neutropenias, including corticosteroids, intravenous Igs, and plasmapheresis, are discussed under specific disease entities. Further options for therapy include granulocyte transfusion or stimulation of neutrophil production with granulocyte growth factors.

Therapeutic transfusions of granulocyte concentrates (obtained initially by filtration leukapheresis and now by large-volume centrifugation leukapheresis) have been used for over two decades to treat neutropenic patients with documented, severe bacterial and fungal infections (see Chapter 24). The popularity of this therapy has waxed and waned through the years, and the clinical efficacy in individual patients or small studies remains controversial ([442]). Granulocyte transfusions are expensive, the short survival time of granulocytes necessitates frequent reinfusions, large numbers of granulocytes (1010) are necessary for clinical efficacy, and the transfusions are not without hazard. Risks include febrile reactions, transmission of viral infections (cytomegalovirus, hepatitis, HIV, and toxoplasma), pulmonary toxicity, and, potentially, transfusional graft-versus-host disease ([443]). Despite these risks, in selected neutropenic patients with severe bacterial or fungal infections that progress despite appropriate antimicrobial therapy, granulocyte transfusions may be life-saving ([442]). This therapeutic option appears especially useful in neonates with documented gram-negative septicemia and severe neutropenia ([444]). Once a decision to use granulocyte transfusions is made, large volumes of cells should be administered daily until the infection or neutropenia resolves. The use of growth factors to stimulate granulocyte number before leukapheresis may result in availability of high yields of granulocytes and stimulate a further revival of the popularity of this therapy ([445]).

The advent of recombinant human granulocyte factors and GM-CSFs has revolutionized the approach to the neutropenia patient. The pharmacology, pharmacokinetics, and historical development of these myeloid growth factors are the subject of several recent reviews ([304] , [446] , [447] and [448]). Both GM-CSF and G-CSF are hematopoietic growth factors that act primarily to stimulate proliferation and differentiation of committed progenitor cells into mature granulocytes. GM-CSF also stimulates monocyte and, variably, eosinophil maturation, whereas G-CSF stimulates primarily neutrophils. In treatment of the chronic severe neutropenias, these growth factors allow correction of neutropenia and thus prevention or amelioration of infection in many cases. The use of growth factors to hasten resolution of established infections is not as well defined as their preventive role. As detailed previously for individual disease states, G-CSF (and, less often, GM-CSF) is effective in increasing circulating neutrophil numbers and decreasing infection incidence in most forms of chronic neutropenia. Individual patient response varies, and the dosage range required in individual diseases and patients varies. However, most patients respond to G-CSF doses of 5 to 10 µg/kg/day. Equally important, the incidence of signs and symptoms of infections in these patients fell dramatically during G-CSF therapy (Table 63.9). The goal of G-CSF therapy is to prevent infections by maintaining a nearly normal blood neutrophil count. This goal is met in a majority of patients with severe neutropenia. Long-term treatment results remain incompletely defined. For patients with SCN, cyclic neutropenia, or chronic severe neutropenias, the duration of growth factor therapy is probably life-long. Because initial therapy with growth factors for these disorders did not begin until 1987, long-term follow-up remains limited. As outlined above in the discussion of G-CSF therapy for SCN, the most important long-term concerns include myelodysplasia or leukemic transformation, osteoporosis, and organomegaly. The growth and development of many patients with SCN are abnormal, but it remains uncertain whether growth failure is a stigmata of the underlying cellular defects in SCN or in some way associated with therapy for the disorder ([306]). Patients tolerate daily injections quite well.

TABLE 63.9. Incidence of Signs and Symptoms during Therapy with Recombinant Human Granulocyte Colony-Stimulating Factor (rHuG-CSF)

Symptom	Untreated (%)	rHuG-CSF (mo 0–5) (%)	rHuG-CSF (mo 5–17) (%)
Fever	77	27	28
Stomatitis	60	20	11
Sore throat	18	10	10
Lymphadenopathy	11	4	4
Abdominal pain	15	9	10
Cellulitis	8	2	1
Pustules	6	1	2
Diarrhea	18	15	6
Rash	4	10	6
Headache	24	17	24
Bone pain	6	17	5
Pain	10	25	11

From Dale DC. Hematopoietic growth factors for the treatment of severe chronic neutropenia. Stem Cells 1995;13:94, with permission.

Cost of the recombinant growth factors GM-CSF and G-CSF remains high. In 2002, the wholesale cost for a 300-µg/ml vial of G-CSF was approximately $200. Because G-CSF vials are single use only, the $200 represents the daily cost of therapy for patients up to approximately 60 kg (5 µg/kg/day). Thus, daily cost for 1 year of treatment for a patient with SCN is approximately $73,000. Obviously, costs depend on local pricing, daily dose, patient size, and other factors. Regardless, growth factor treatment of neutropenia is costly. In this era of cost control and justification, the decision to prescribe growth factor therapy must be based on an understanding of the natural history of the disorder and a careful evaluation of risk of infection.

Qualitative Disorders of Leukocytes

DISORDERS OF PHAGOCYTIC LEUKOCYTES CHARACTERIZED BY MORPHOLOGIC CHANGES

For the most part, the disorders considered here are rare, usually familial, and often reflect a general metabolic defect, the major manifestation of which may be more serious in tissues other than in leukocytes. Nevertheless, the leukocytic morphologic abnormalities may come to the attention of the hematologist, and familiarity with them and the associated diseases may facilitate diagnosis.

Pelger-Huët Anomaly

Pelger-Huët anomaly is a benign anomaly of leukocytes and is inherited as a nonsex-linked, dominant trait. It is characterized by distinctive shapes of the nuclei of leukocytes, a reduced number of nuclear segments (best seen in the neutrophils), and coarseness of the chromatin of the nuclei of neutrophils, lymphocytes, and monocytes. The nuclei appear rodlike, dumbbell-shaped, peanut-shaped, and spectaclelike (“pince-nez”) with smooth, round, or oval individual lobes (Fig. 64.1B and Fig. 64.1C), contrasted with the irregular lobes seen in normal neutrophils (Fig. 64.1A) ([1]). The incidence of this disorder in different studies has ranged from as high as 1 in 1000 persons ([2], [3]) to 1 in 4000 ([4], [5]), 6000 ([6]), or even 10,000 ([7]). Originally observed mainly in Holland, Germany, and Switzerland, the anomaly has now been described in other parts of the world, including individuals of Asian ([8]) and African descent and whites. The practical importance of identifying the Pelger-Huët anomaly lies in distinguishing this defect from the shift to the left that occurs in association with infection.

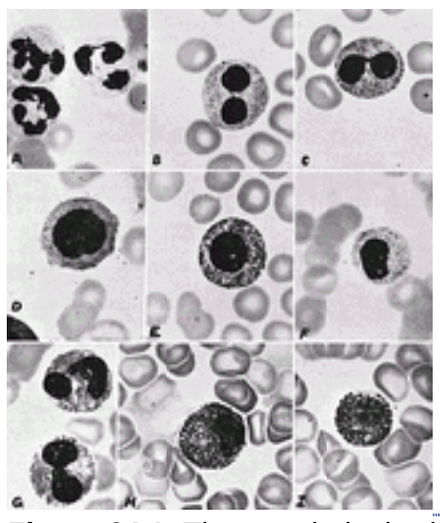

Figure 64.1. The morphologic changes of Pelger-Huët cells as compared with normal leukocytes. **A**, Normal neutrophils; **B** and **C**, neutrophils with bilobed or “pince-nez” nuclei; **D**, normal myelocyte, to contrast with **E** and **F**, mature Pelger-Huët neutrophils with round or indented nuclei; **G**, normal eosinophils; **H** and **I**, mature eosinophils with round nuclei. (From Skendzel LP, Hoffman GC. The Pelger anomaly of leukocytes: forty-one cases in seven families. Am J Clin Pathol 1962;37:294, with permission.)

The discovery of this anomaly in rabbits led to breeding experiments and the production of homozygotes ([2], [5]). These studies demonstrated that, in the heterozygote, bilobed, rod-shaped, and spectacle forms predominate, whereas in the homozygote, round nuclei with no evidence of segmentation are predominant. In rabbits, the homozygous form was often lethal, with most animals dying *in utero*; some survivors suffered skeletal malformations.

Two human homozygotes have been reported ([2], [9]). In them, the cytoplasm of the neutrophils appeared mature, but the nuclei were round or oval in all the neutrophils, in contrast to the fewer than 40% single-lobed neutrophils present in heterozygotes (Table 64.1) ([2], [6], [9]). In the homozygotes, the eosinophils, basophils, and megakaryocytes also were characterized by dense nuclear chromatin and rounded nuclear lobes; these individuals had fewer nuclear lobes than normal subjects ([2]). Examination of the bone marrow revealed normal morphologic features in myeloid precursors through the myelocyte stage, and electron

microscopy revealed persistence of nucleoli in the otherwise mature neutrophils that contained single oval nuclei ([9]). This finding was interpreted as indicating some retardation of nuclear maturation because no cytochemical defects were noted in the cytoplasm.

TABLE 64.1. Distribution of Nuclear Lobes in Neutrophils of Normal Persons and in Those with Pelger-Huët Anomaly

	Cases Examined	Number of Lobes [a]				
		1	2	3	4	5
Normals [b]	50	2.8 ±2.8	22.0 ±6.3	54.3 ±5.3	18.1 ±6.9	2.8 ±2.1
Pelger–Huët heterozygotes [b]	34	31.3 ±9.2	63.8 ±9.5	4.9 ±3.7	0.3 —	0 —
Pelger–Huët homozygotes [2,9]	2	100.0	—	—	—	—

[a] Mean and variance.

[b] Modified from Davidson WM, et al. The Pelger–Huët anomaly: investigation of family “A.” Ann Hum Genet 1954;19:1.

Pelger-Huët cells appear to be normal functionally ([9], [10] and [11]), are able to phagocytize and kill microorganisms ([5]), and survive normally in the circulation in both humans ([12]) and dogs ([13], [14]).

The Pelger-Huët heterozygote is recognized by finding (a) 69 to 93% of the neutrophils to be of the bilobed, pince-nez type; (b) few cells with three lobes (usually less than 10%); and (c) rare or no cells with four lobes (Table 64.1) ([4], [5] and [6]). In normal blood smears, no more than 27% of the cells are bilobed, and significant numbers of cells have three or more lobes (Table 64.1) ([5]). The presence of similar abnormalities in the blood smear in other family members also is helpful in establishing the diagnosis. In heterozygotes, mature neutrophils with round or oval nuclei of the type that is characteristic of the homozygous state may increase after stress such as the injection of colchicine ([15]) or pyripher ([3]). A shift toward increased numbers of neutrophil lobes was described in a patient with the anomaly who developed pernicious anemia ([16]).

Pseudo– or Acquired Pelger-Huët Anomaly

Cells with morphologic changes, such as those just described, have been observed occasionally in association with myxedema, acute enteritis, agranulocytosis, multiple myeloma, malaria, leukemoid reactions secondary to metastases to the bone marrow ([17]), drug sensitivity ([18]), or chronic lymphocytic leukemia ([3]). More commonly, pseudo–Pelger-Huët cells (Fig. 64.2) ([19]) are seen in patients with myeloid leukemia of either the acute or chronic type or in those with myeloid metaplasia ([20], [21]). In these subjects, the pseudo–Pelger-Huët cells tend to appear late in the disease, often after considerable chemotherapy has been administered. In addition, most of the nuclei are of the single oval type characteristic of the homozygous state ([20]).

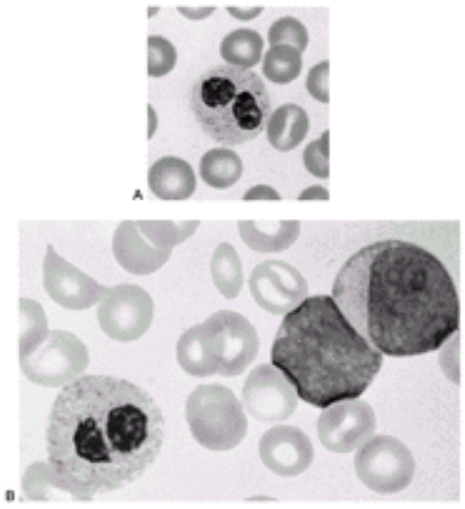

Figure 64.2. A: Pseudo–Pelger-Huët cells. **B:** From a patient with acute myeloblastic leukemia. See Color Plate.

Alder-Reilly Anomaly

Alder-Reilly anomaly, inherited as a recessive trait ([22]), apparently does not interfere with leukocyte function ([23]). It is characterized by the presence of larger-than-normal azurophil and basophil granules (Alder-Reilly bodies), which may be easily confused with granulations due to toxic states (Fig. 64.3). These granules stain dark lilac with Wright-Giemsa stains and are seen in patients with various types of bone and cartilage abnormalities ([24], [25], [26] and [27]). They are most common, however, in association with Hurler syndrome, Hunter syndrome, and Maroteaux-Lamy polydystrophic dwarfism ([28]).

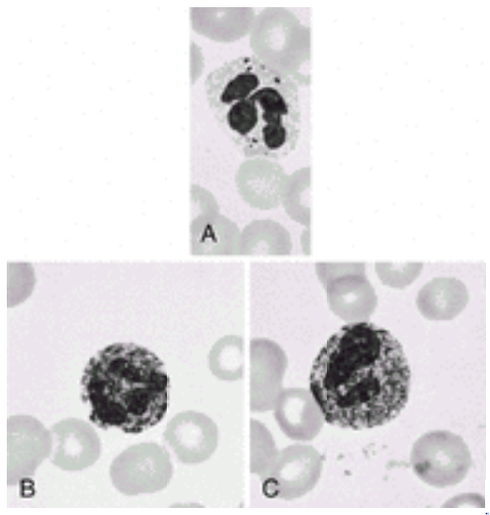

Figure 64.3. Neutrophils with Alder-Reilly bodies **(A)** compared with neutrophils exhibiting toxic granulation **(B,C)**. See Color Plate.

Similar inclusions may be seen in blood lymphocytes (Gasser cells) and monocytes ([26], [29]). The lymphocyte inclusions stain dark red or purple with May-Grünwald-Giemsa stain and metachromatically with toluidine blue; normal azurophilic granules do not stain at all ([26]). Such lymphocyte granules are found in all types of mucopolysaccharidoses except Morquio syndrome, but they are most common in the Hurler, Hunter, Sanfilippo, and Maroteaux-Lamy syndromes ([26], [28]).

They tend to occur in clusters rather than diffusely throughout the cytoplasm, are surrounded by vacuoles, and are shaped like a dot or comma. In one series of 19 patients, 8 to 50% of the lymphocytes contained the inclusions, and their presence was thought to be of diagnostic significance ([26]).

These inclusions are seen inconsistently in the blood but are more common in the bone marrow. For example, in a series of 18 patients with Hurler form of mucopolysaccharidosis, Alder-Reilly bodies were present in the blood of less than 10% of them. Careful examination of the bone marrow, however, revealed mucopolysaccharide granules in large mononuclear cells (Buhot cells) in 17 of 18 patients ([30], [31] and [32]).

The type of inclusion seen is not diagnostic of a particular type of mucopolysaccharidosis, and the frequency of the inclusions is not correlated with clinical severity ([33]). The basic defect in this group of diseases lies in the incomplete degradation of the protein–carbohydrate complexes known as *mucopolysaccharides*, and the different forms of mucopolysaccharidosis involve different enzymatic deficiencies ([28]). The accumulation of partially degraded mucopolysaccharide within lysosomes has been demonstrated by electron microscopy ([28]); the degradation of the protein core of the mucopolysaccharide appears to proceed normally, but catabolism of the carbohydrate side chains is impaired.

May-Hegglin Anomaly

The May-Hegglin anomaly is a rare, dominantly inherited disorder characterized by large (2 to 5 µm), well-defined, basophilic and pyroninophilic inclusions in granulocytes (neutrophils, eosinophils, basophils, monocytes) and accompanied by variable thrombocytopenia and giant platelets containing few granules ([34]). For the most part, affected family members have not been ill, but occasionally abnormal bleeding has occurred ([35], [36], [37] and [38]). Clot retraction time is prolonged, and the reaction to the tourniquet test may be positive. Platelet survival was short [half-life = 3 days as compared with the normal, which is 6.9 ± 1.5 (1 standard deviation) days] ([39]). Platelet aggregation and retraction were normal, but spreading and serotonin uptake was increased ([40]). Enzyme and substrate content per platelet was increased, but this value was decreased as related to platelet volume ([40]). The granulocyte inclusions (Fig. 64.4) are similar to Döhle bodies in appearance, but they often are larger, more round and discrete, and may be present in a large percentage of the cells. ([37], [38], [41]). It is claimed that these inclusions differ from the Döhle bodies of infection in morphologic appearance in that they are present in granulocytes other than neutrophils ([41]). Like Döhle bodies ([41], [37]), the inclusions were felt to consist mainly of RNA ([38], [42]), apparently derived from the rough endoplasmic reticulum. More recently, mutations of the NMMHC-A gene have been found in this syndrome ([43], [44] and [45]). NMMHC-A is a nonmuscle myosin heavy chain that is part of a family of genes coding for proteins that form part of the actin-myosin force generating complexes ([46]). In the bone marrow, clumping of the megakaryocyte cytoplasm has also been reported ([36]).

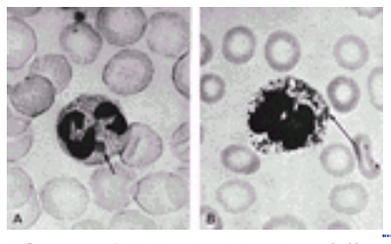

Figure 64.4. A: Neutrophil containing a typical May-Hegglin inclusion (*arrow*). **B:** Neutrophil showing a Döhle body of infection (*arrow*). Also note the toxic granulation in this cell. (From Cawley JC, Hayhoe FGJ. The inclusions of the May–Hegglin anomaly and Döhle bodies of infection: an ultrastructural comparison. Br J Haematol 1972;22:491, with permission.)

Chédiak-Steinbrinck-Higashi Anomaly (Congenital Gigantism of Peroxidase Granules)

Chédiak-Steinbrinck-Higashi anomaly, an autosomal-recessive disorder, has been reported in humans ([47], [48], [49] and [50]), mice ([51]), mink ([52]), cattle ([52]), cats ([53]), rats ([54]), and a killer whale ([55]). It is characterized by partial ocular and cutaneous albinism, increased susceptibility to pyogenic infections, the presence of large lysosomelike organelles in most granule-containing cells, and a bleeding tendency ([56]). The abnormal granules are most readily seen in blood and marrow leukocytes, especially granulocytes, (Fig. 64.5) and in melanocytes.

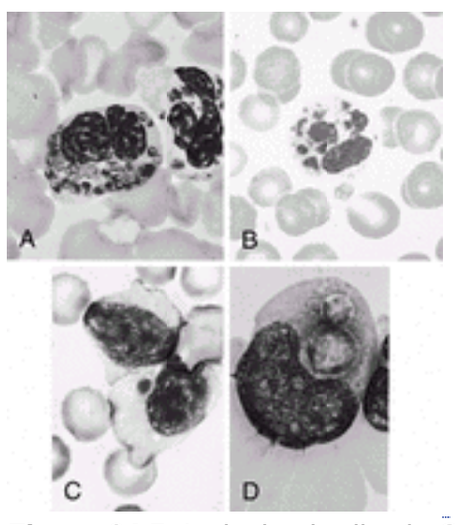

Figure 64.5. Inclusion bodies in Chédiak-Steinbrinck-Higashi anomaly. **A** and **B**, neutrophils; **C**, a lymphocyte; **D**, a monocytoid cell. See Color Plate.

In the first families that were reported with this anomaly, the mothers noted that some of their children exhibited pale hair (Fig. 64.6) and photophobia ([47], [48]). Because these children often had infections and adenopathy and died at an early age, the children born subsequently who were similarly affected were brought to medical attention in the hope of avoiding a fatal outcome ([48]). It was then that the large, peroxidase-positive granules were noted in their blood and marrow granulocytes ([47], [48] and [49]). Nevertheless, most patients die in infancy or early childhood; only a few survive into early adult life ([57], [58] and [59]).

Figure 64.6. The characteristic silver-gray hair of a child (*left*) with Chédiak-Steinbrinck-Higashi anomaly contrasted with that of her mother. (Courtesy of Dr. Dorothy Windhorst, National Institutes of Health.) See Color Plate.

During the 30 years after the first description of Chédiak-Higashi syndrome (CHS) ([60]), 59 cases were reported ([57]). The similar disorder in animals is of use in investigations of the pathogenic defect and is of significant economic impact in mink, in that affected animals, inbred for their unusual color, seldom survive more than

a year and exhibit increased susceptibility to a slow viral infection that produces hepatitis and a myelomalike illness (Aleutian mink disease) ([52]).

ETIOLOGY AND PATHOGENESIS The manifestations of this disorder appear to result from abnormal granule fusion with larger, fewer-than-normal, and perhaps defective granules being formed in most granule-containing cells throughout the body ([61]). Findings of a study of the formation of hepatic lysosomes in mice with the syndrome suggested that the abnormal granules arise from dilated portions of the Golgi–endoplasmic reticulum–lysosome apparatus, but whether this distortion reflects delayed granule detachment from the Golgi–endoplasmic reticulum–lysosome apparatus, abnormal granule membrane lipid, or some other defect remains unclear ([62]). The resulting abnormalities can be found in the hematopoietic tissues, hair, ocular pigment, skin, adrenal glands, pituitary gland, gastrointestinal organs, peripheral nerves, and elsewhere ([61]). In neutrophils, the anomalously large, peroxidase-positive granules seen by light microscopy ([47] , [48]) have been shown by electron microscopy to be abnormal primary (azurophilic) granules, the contents of which remain pleomorphic, the normal granule crystalloid structure not being formed ([61] , [63]). Characterization of the abnormal granules by means of immunofluorescence microscopy demonstrated that they were formed by the progressive aggregation and fusion of azurophilic granules ([64] , [65]). In a subsequent electron microscopic study, investigators demonstrated the presence of two types of giant, peroxidase-positive granules in CHS neutrophils: large, round, or oval granules with homogeneous internal structure similar to normal azurophilic granules; and irregular granules much larger than those of the first type. Because basophils and eosinophils from CHS patients do not contain type 2 granules, and because type 2 granules are less common in promyelocytes, myelocytes, and young neutrophils in the bone marrow than in blood neutrophils, the authors suggested that normal primary (azurophil) granules are formed, but progressive granule fusion occurs during maturation, especially in the blood. In this process, granules and bits of cytoplasm are trapped within the fused granules ([66]). An abnormal calcium uptake pump in CHS lysosomes may be the underlying defect ([67]). Also noted is an increased tendency to autophagic vacuole formation in Chédiak-Higashi neutrophils, perhaps because of increased permeability and leakage of injurious materials from the massive granules ([68]). The abnormal granules in monocytes result from granule fusion ([64]) and may be phagolysosomes. In lymphocytes and plasma cells, they may be primary granules. A secretory defect appears to prevent granule release in CHS T cells ([69]). Abnormal granules have been observed less often in erythroid cells, whereas in megakaryocytes and platelets, the granules appear normal by light microscopy ([61]). By electron microscopy, however, a decrease in dense bodies was seen ([61]), and decreased serotonin, adenosine triphosphate, and adenosine diphosphate levels were noted ([56]). Similar large granules containing a glycolipid have been observed in the Schwann cells of peripheral nerves, in neurons in the central nervous system ([68] , [70]), in renal tubular cells ([70]), and in the vascular endothelium and fibroblasts ([57] , [71]). In addition, giant pigment granules have been demonstrated in melanosomes ([70]) and in hair strands ([57] , [70]). In the several different tissues affected, the consistent feature is that the histochemical reactions of the large abnormal granules are those usually seen in normal granules of that cell line ([70]); no qualitative alteration in granule enzyme content is noted, but some decrease in granule enzymes and an increase in cytoplasmic enzyme content have been described ([72]). The effects of the abnormality in different tissues depend on granule function in that tissue. Thus, the large but fewer melanin granules produce pigment dilution, which explains the peculiar hair color, partial albinism, photophobia, and nystagmus ([70]). On the other hand, the abnormal large granules in neutrophils lead to increased susceptibility to infection. Infection occurs despite an above-normal rate of phagocytosis and a normal postphagocytic metabolic burst (H_2O_2 production) ([73]). Apparently, the intracellular destruction of some bacteria by Chédiak-Higashi leukocytes is delayed because the postphagocytic delivery of lysosomal enzymes into phagosomes is inefficient and incomplete ([74]). A similar defect in granule extrusion has been noted in the renal tubule ([75]). Chédiak-Higashi neutrophils from humans lack cathepsin G and elastase ([76]) and have reduced C3bi receptor expression ([77]). Because measurements of elastase and cathepsin G were normal in the bone marrow of beige mice, the primary lesion is thought not to be a gene defect but rather is likely a disorder of protein processing, protein synthesis, or granule assembly ([76]). In addition, a defect in cellular response to chemotactic stimuli both in *in vitro* and in *in vivo* skin windows has been demonstrated in humans, mice, and mink ([78] , [79]), and a neutrophil membrane abnormality consisting of spontaneous cap formation has been described ([80]). This defect appears to result from an absence of microtubule assembly (similar to that produced in normal cells by colchicine) and can be restored toward normal by agents such as cyclic guanosine monophosphate, cholinergic agonists ([81]), and ascorbic acid ([82]).

INHERITANCE In 1972, in families with 127 children, 59 were reported to be affected ([57]). Judging by this statistic and on the basis of animal studies ([52]), this disorder is almost certainly inherited as an autosomal-recessive trait. Male and female subjects are affected at a ratio of 0.87:1.00. A high proportion of marriages producing affected children have been consanguineous. Some heterozygotes may be identifiable by the presence of granulation in some of their lymphocytes ([83] , [84]).

CLINICAL FEATURES AND COURSE The partial albinism (more properly, pigment dilutional defect) ([70]), silvery hair (Fig. 64.6), and photophobia are usually noted early in infancy. The poor resistance to respiratory and cutaneous infection, especially by *Staphylococci* and other gram-positive organisms, soon becomes evident. Four patients studied for more than 1 year experienced 29 episodes of fever and pyogenic infection ([59]). Increased bleeding with abnormal platelet function has also been recognized ([85]). Many of the afflicted children die of infection during infancy or early childhood. In others, the disease remains quiescent. Eventually, in more than 85% of patients, it changes to an *accelerated* phase that is characterized by lymphadenopathy, hepatosplenomegaly, neuropathy, anemia, neutropenia, and, less often, thrombocytopenia ([86]). During this phase, infiltration of the tissues by mononuclear cells is widespread, a change that has been termed *lymphoma* by some, but is more likely a reactive lymphohistiocytic response ([57] , [87]). During the accelerated phase, neurologic manifestations (peripheral neuropathy) may become prominent, and hemorrhage may occur.

LABORATORY FINDINGS The characteristic microscopic findings are the large, often multiple, peroxidase-positive lysosomal granules in the granulocytes of the blood and bone marrow, and the large melanosomes in the hair. Less common are granules in the lymphocytes. Abnormal platelet aggregation can be demonstrated regularly ([56]). During the early phases of the disease, blood counts yield normal values, but as the disease progresses, anemia, neutropenia, and thrombocytopenia often develop. Immunoglobulin and complement levels are normal, as are cellular immune reactions. In the accelerated phase, erythrocyte and granulocyte survival may be shortened ([57]).

GENE DEFECT The origin of CHS in mice has been found to be a mutation in the Lyst gene, which codes for a lysosomal traficking regulatory protein ([88] , [89]). The human homolog CHS1 has since been cloned, and mutations of this gene have been found in patients with CHS ([89] , [90] , [91] , [92] and [93]).

MANAGEMENT Although unproven, some believe that the prophylactic administration of antibiotics may be beneficial ([59]). The administration of ascorbic acid corrected the defective leukocyte function *in vitro* and *in vivo* in several patients ([82] , [94]), and the administration of cholinergic agonists was effective in mice ([80] , [81]). The increased susceptibility to infection has been corrected in mice by the transplantation of normal bone marrow, and the hematopoietic defects can be transmitted to normal mice by transplanting marrow from an animal with CHS ([95]). In the accelerated phase, splenectomy has been only temporarily helpful ([57]); a few patients have been treated with a combination of vincristine and prednisone. Bone marrow transplantation appears to be a logical treatment, if possible ([96] , [97] and [98]).

Familial Vacuolization of Leukocytes (Jordan Anomaly)

Jordan anomaly is characterized by the presence of vacuoles in the cytoplasm of granulocytes, monocytes, and occasionally lymphocytes and plasma cells. In members of one family, all of the blood neutrophils and more than 70% of the monocytes contained 3 to 10 vacuoles ranging in size from 2 to 5 µm; fewer and smaller vacuoles were seen in eosinophils, basophils, and lymphocytes ([99]). By means of histochemical and fluorescence microscopic analysis, the vacuoles were shown to contain lipids. These lipids were seen in promyelocytes, myelocytes, metamyelocytes, and occasionally in plasma cells in the bone marrow, but they were not present in myeloblasts, erythroblasts, or megakaryocytes ([99]). This type of vacuolization must be distinguished from that characterized by fat-staining vacuoles occurring in people with serious infections, toxic hepatitis, or diabetic ketoacidosis ([100]).

The disorder appears to be familial. Two members were affected in each of two unrelated families ([99] , [100]). None of the four patients had acute disease, but in members of one family, progressive muscular dystrophy was present ([99]), whereas in members of the other, ichthyosis was associated ([100]).

Other Inclusions in Leukocytes

In an infant with congenital bile duct atresia, amorphous, round-to-oval bodies stained green or gray-green with Romanovsky stains in 3 to 13% of the blood neutrophils and in 1 to 5% of the monocytes ([101]). Similar inclusions were present in all stages of myeloid cells in the bone marrow but not in lymphocytes or plasma cells. Electron microscopic analysis showed that the inclusions were not enclosed in a phagocytic vesicle.

In the blood monocytes of patients with the Hermansky-Pudlak syndrome ([102]), a rare familial disorder characterized by albinism, mild bleeding related to platelet dysfunction, accumulation of ceroidlike pigment in marrow macrophages, and deficiency of the tetraspan protein CD63 in platelets ([103]), lipopigment bodies as well as another type of inclusion were demonstrated.

Abnormal Specific (Secondary) Granule Formation

A syndrome of recurrent staphylococcal skin and sinus infections associated with abnormal chemotaxis, impaired staphylococcal killing, and morphologic

abnormalities in the neutrophils was described in a 14-year-old boy ([104]). No other family members were affected. The patient's polymorphonuclear neutrophils exhibited bilobed nuclei with unevenly distributed chromatin, drumsticklike nuclear projections, and nearly absent cytoplasmic granules that stained with peroxidase but not with alkaline phosphatase. Electron microscopy revealed primary granules, but specific granules were small and reduced in number. These neutrophils were capable of phagocytosis, generated H_2O_2, reduced nitroblue tetrazolium (NBT) dye, and killed *Candida*, but staphylococcal killing was impaired.

Since the original report, at least five cases of specific granule deficiency (SGD) have been identified with both sexes affected, leading to the assumption that the disorder is an autosomal-recessive disease ([105] , [106]). SGD neutrophils exhibit decreased chemotaxis and bacterial killing *in vitro* and decreased migration into skin windows *in vivo*, and they fail to up-regulate CD11/CD18, laminin, or f-met-leu-phe (FMLP) receptors after activation ([105]), although oxygen radical generation is apparently normal. Myeloperoxidase (MPO)-positive primary granules are present, but the specific secondary granules appeared to be absent in Wright-stained blood smears and were decreased in number and small when viewed with electron microscopy ([104]). These structures do not stain with alkaline phosphatase. The specific granule constituents lactoferrin and B_{12} binding protein are reduced or absent.

Lactoferrin deficiency in patients with SGD is tissue specific (i.e., confined to myeloid cells, whereas lactoferrin is secreted normally in nasal secretions) and is secondary to a deficiency of RNA transcripts ([107]). Because morphologic changes have been described in the primary granule ([108]) and other granule proteins, such as primary granule defensin ([76]) and “tertiary” granule gelatinase, are also deficient in SGD neutrophils, one suggestion is that the basic defect in SGD is one of regulation of production of these proteins ([107]). Thus, this disorder may be one of incomplete granule synthesis rather than a true SGD ([108]).

Hereditary Giant Neutrophilia

Neutrophils with a diameter of approximatelyl 17 µm (as compared with a normal diameter of about 13 µm) are rare in blood smears from normal people (1 in 20,000 neutrophils or less). They may be seen with greater frequency in patients who are ill, but even then the number rarely exceeds 0.2% unless a disease involving leukocyte production is present or a reaction to a cytotoxic drug occurs ([109]). A family with giant neutrophils in healthy members of three generations has been reported ([109]). Over several years, the propositus had an average of 1.6% giant neutrophils in the blood. The large neutrophils appeared to be nearly double the normal cell volume and contained from 6 to 10 nuclear lobes. Therefore, it was suggested that the cells may have been tetraploid. This anomaly appeared to be transmitted as an autosomal-dominant trait.

Hereditary Hypersegmentation of Neutrophil Nuclei

Several families have been described whose members had a hereditary (autosomal-dominant) increase in the number of neutrophil nuclear segments (Fig. 64.7) ([110]). The proportion of neutrophils containing five lobes or more exceeded 10% in most heterozygotes and was greater than 14% in several suspected homozygotes, as compared with no more than 10% in normal controls ([110]). The bone marrow findings suggested a tendency toward nuclear indentation in early myeloid forms (eosinophils and basophils as well as neutrophils) ([110]). The normal size of these neutrophils was thought to provide evidence against tetraploidy, but in one study of five female family members, the mean number of nuclear drumsticks appeared to be increased above normal ([111]). The chief significance of this anomaly is in its differentiation from other causes of hypersegmentation such as folate or vitamin B_{12} deficiency.

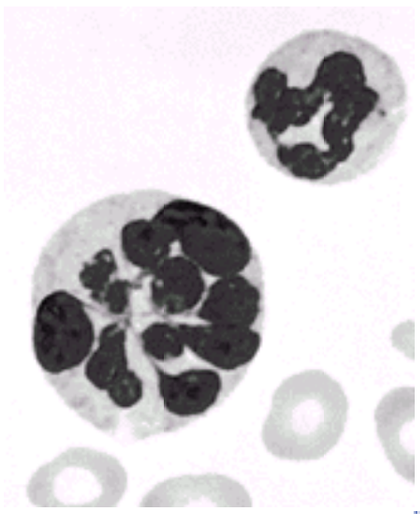

Figure 64.7. Hypersegmented neutrophil. See Color Plate.

Hypersegmentation of Eosinophils and Negative Staining for Peroxidase and Phospholipids

Hypersegmentation of eosinophils can be inherited as an autosomal-recessive trait, and the abnormality is characterized by a lack of sudanophilia and peroxidase activity in all of the eosinophils, whereas these histochemical reactions remain positive in the neutrophils and monocytes ([112] , [113]). In addition, the number of eosinophilic granules per cell appears to be reduced, and some hypersegmentation of the eosinophil nucleus may occur. No disease accompanies the disorder. This has been most commonly reported in people of Jewish (predominantly Yemenite) extraction, although members of other races have not been studied adequately.

FUNCTIONAL DISORDERS OF LEUKOCYTES NOT CHARACTERIZED BY MORPHOLOGIC CHANGES

The topic of neutrophil dysfunction is under active study. Several reviews summarize this topic ([114] , [115] , [116] and [117]); the reader is also referred to the current literature.

Chronic Granulomatous Disease of Childhood

Chronic granulomatous disease (CGD) is a rare clinical syndrome that results from inherited defects of leukocyte function ([118] , [119] , [120] , [121] , [122] , [123] and [124]). Recent reviews have been published ([114] , [115] , [123] , [124] , [125] , [126] , [127] , [128] and [129]).

CGD neutrophils are characterized by a defective respiratory burst during phagocytosis and an inability to generate superoxide. The impaired superoxide production usually occurs transiently in each phagosome with phagocytosis and leads to recurrent bacterial and fungal infections, most commonly at epithelial surfaces. CGD is characterized by recurrent infections with catalase-positive bacteria. CGD neutrophils can use H_2O_2 produced by ingested bacteria to generate HOCl via MPO and aid in killing the bacteria. Catalase-positive bacteria generate H_2O_2 levels in the phagocytic vacuole that are too low for generation of sufficient HOCl to contribute to significant bacterial killing via this mechanism ([125]). This syndrome can be the result of different genetic defects in the superoxide generating system. Variable inheritance patterns have been observed with approximately two-thirds of the pedigrees being X-linked and one-third autosomal recessive. Multiple molecular defects have been identified that result in the CGD phenotype ([114] , [115] , [125] , [126] , [127] , [128] , [129] and [130]). Potential treatments include prophylactic antibiotics and interferon-?. Knowledge in this field is changing rapidly.

CGD neutrophils, eosinophils, monocytes, and macrophages fail to generate superoxide, hydrogen peroxide, and other oxygen radicals after particle phagocytosis (or other stimulation), and thus have decreased microbicidal activity. CGD is associated with no leukocyte morphologic abnormalities and was first noted in male children with a history, beginning in early childhood, of recurrent suppurative infections caused by organisms of low-grade pathogenicity, including fungi, or by staphylococci. The eczematoid, granulomatous, and sometimes purulent skin infections recur repeatedly and clear slowly. Associated adenopathy develops and may persist. Pulmonary and other infections (e.g., osteomyelitis) also are common, and progressive granulomatous disease of the lungs, liver, and other sites develops. Hepatosplenomegaly is common, and biopsy reveals necrotizing granulomas, often with associated purulent inflammation. The disorder often progresses to death in early childhood ([131] , [132]), but some patients survive longer ([118] , [133]). Although rare, CGD has assumed great importance as a prototype of defects in leukocyte

bactericidal capacity.

HISTORY AND MODE OF INHERITANCE CGD was first described from 1954 to 1957 ([131] , [132]) as affecting only males. By 1970, more than 90 cases were reported ([121] , [133]). X-linked inheritance was established, and female heterozygotes were identifiable by the presence of defective leukocyte bactericidal capacity intermediate in degree between that of affected patients and that of normal individuals ([134]). Measurements of postphagocytic release of $^{14}CO_2$ from glucose-1- ^{14}C or reduction of NBT dye were used to detect the defect. By means of the NBT dye test, female carriers were found to have a mixed population of neutrophils, approximately one-half being NBT negative and one-half being NBT positive (Table 64.2). The defect is transmitted on an X chromosome, and the degree of deficit in female subjects varies according to random X chromosome inactivation. Consequently, one may expect to find an occasional female carrier with clinical disease as severe as that in male patients ([134] , [135]).

TABLE 64.2. Proportion of Postphagocytic Neutrophils That Are Nitroblue Tetrazolium–Positive in Family Members and Patients with Chronic Granulomatous Disease as Compared with Normal Subjects

	Number	% Nitroblue Tetrazolium–Positive Cells [a]
Patients (hemizygotes)	7	9.9 ± 4.2
Mothers and grandmothers (heterozygotes)	9	49.8 ± 5.4
Carrier sisters	7	51.3 ± 6.6
Fathers, brothers, and normal sisters	18	74.4 ± 5.4
Normal subjects	12	89.5 ± 5.4

[a] Mean ±2 SD.

From Windhorst DB, et al. The pattern of genetic transmission of the leukocyte defect in fatal granulomatous disease of childhood. J Clin Invest 1968;47:1026, with permission.

Because of the clinical and pathologic picture of chronic recurrent infection caused by low-grade pathogens and the resultant granuloma formation, it was suggested that a defect in inflammatory response results in lesions comparable to those that normal people develop after infection with tubercle bacilli or brucella ([120]). No abnormality in antibody response to diphtheria, tetanus, or poliovirus was demonstrated in these patients, and their delayed hypersensitivity response also was normal ([120]). In addition, leukocyte migration and surface phagocytosis were normal ([120]). Nevertheless, when leukocytes of CGD patients were incubated with bacteria, such as staphylococci, serratia, or other organisms causing infection in these patients, decreased bacterial killing and prolonged bacterial survival in the phagocytic vacuoles were observed ([136] , [137]). Decreased killing of fungi and incomplete inactivation of vaccinia and herpes virus also was reported ([120] , [138]), but streptococci were killed normally by CGD leukocytes ([137] , [139]). Although the mechanisms of bacterial killing by normal leukocytes are still incompletely understood, it is clear that phagocytosis is followed by fusion of lysosomes with the phagocytic vacuole, discharge of lysosomal enzymes into the phagosome, and a burst of postphagocytic metabolic activity. These events are usually accompanied by bacterial death and digestion (see Chapter 10). Early studies of CGD reported that a deficiency of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase or an abnormality in its activation is the underlying cause of this syndrome ([140]). The finding that iodination of bacteria in the phagosome appears to be one mode of bacterial killing, and that this process is defective in CGD leukocytes and can be partially repaired by the insertion of an oxidase into the phagosome, either carried on oxidase-coated polystyrene particles ([141] , [142]) or as part of the ingested bacteria ([143]), provided strong evidence incriminating defective generation of H_2O_2, superoxide ([144]), or related ions ([145]) as the pathogenic defect in this disorder ([141] , [146]). Although most studies have focused on neutrophils, it was recognized in the earliest reports that lipid-laden macrophages were present in the granulomatous lesions ([147]), and a defect in the mononuclear phagocytes ([148]) and in eosinophils ([149]) also has since been demonstrated. The platelets appear normal ([150]). In the late 1960s and 1970s, an autosomal-recessive form of CGD was described ([121] , [122]). It is clinically identical to the X-linked forms, with the exception that the parents of affected children usually have normal neutrophil function, and the clinical course may be milder ([119]).

MOLECULAR PATHOLOGY In 1978, a unique cytochrome *b*, termed b_{558} (named for its absorption spectrum) or b_{245} (named for its midpoint potential) present only in phagocytic cells, was described and suggested to be a primary component of the oxidase that normally generates superoxide but, when defective, results in CGD ([151]). This cytochrome was absent from X-linked CGD phagocytes (thus termed X^-) but was present in phagocytes from patients with autosomal-recessive inheritance patterns (A^+) ([151]). In 1985, a family with CGD and an autosomal-recessive inheritance pattern but with absence of cytochrome *b* was reported, thus identifying a third type of CGD (A^-) ([152]). In these studies, a somatic cell hybridization technique was used to demonstrate that fusing monocytes from any two of these three types of CGD (X^-, A^+, or A^-) restored their ability to oxidize NBT, thus defining three distinct molecular defects ([152]). Also in 1985, several groups demonstrated that both membrane and cytosolic components are necessary for superoxide generation, and deficiencies in either can result in CGD ([119]). In 1987, cytochrome *b* was purified and shown to be a heterodimer composed of two polypeptides, a heavily glycosylated, 91,000-dalton heavy chain (approximately 50,000 of the molecular weight is peptide) and a 22,000-dalton light chain ([153]). Antibodies to these two polypeptides showed them both to be absent from the phagocytes of two types of CGD (X^- and A^-). The defective gene in X-linked, cytochrome-negative CGD has been cloned and shown to encode for the polypeptide portion of the 91,000-dalton subunit of cytochrome *b* ([153] , [154]). Presumably, the gene for the 22,000-dalton subunit is on an autosome, and the absence of either gene (and/or gene product) results in cytochrome *b*–negative CGD ([154]). A large number of different genetic defects have now been described ([114] , [115] , [127] , [128] and [129] , [155] , [156] , [157] , [158] , [159] , [160] , [161] , [162] , [163] , [164] , [165] , [166] , [167] and [168]). Because postphagocytic activation of the respiratory burst with generation of superoxide and peroxide, as well as bacterial killing, involves complex reactions and multiple enzymes [e.g., phospholipases, protein kinases, NADPH oxidase, glucose-6-phosphate dehydrogenase (G6PD), glutathione peroxidase] ([119]), one might expect that defects other than those described in NADPH oxidase would result in a disorder phenotypically like that described in the section Variants .

CLINICAL AND LABORATORY FEATURES The clinical picture of CGD includes the development of recurrent infections, especially of the skin and lungs, with septic lymphadenitis, development of hepatosplenomegaly and granulomas, and ultimately death from infection ([118] , [120] , [131]). The blood neutrophil count is not reduced, and it increases appropriately with infection or after endotoxin injection; monocytosis is sometimes observed ([120]). Because chronic infection is common, the immunoglobulin levels often are elevated, and plasma cells may be present in increased numbers in the bone marrow. Immunoglobulin deficiencies have not been encountered, and antibody titers (both IgM and IgG) increase normally after antigenic stimulation. Reticuloendothelial clearance of colloidal gold also is normal. Peroxidase staining of blood cells demonstrates more intense dye uptake in CGD neutrophils than in normal cells ([149]). The simplest method for detecting the defect is the postphagocytic, intraphagosomal reduction of almost colorless NBT dye to blue-black formazan (Fig. 64.8) ([149] , [169]). When tests are properly standardized with respect to time of incubation of leukocytes with the dye-tagged zymosan particles, affected patients and most carriers are readily recognized (Table 64.2). When the reaction to this test is negative in suspected carriers, the reaction to the quantitative dye reduction test usually is positive ([149]).

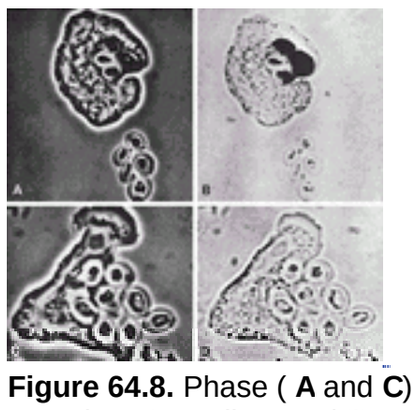

Figure 64.8. Phase (**A** and **C**) and bright field (**B** and **D**) photomicrographs of normal neutrophil (**A** and **B**) and a neutrophil from a patient with chronic granulomatous disease (**C** and **D**). In **A** and **B**, note nitroblue tetrazolium reduction (*black area*) that has occurred in the normal neutrophil 20 minutes after ingestion of zymosan granules and nitroblue tetrazolium dye. In **C** and **D**, zymosan ingestion is normal, but there is no dye reduction. (From Nathan DJ, et al. Failure of nitro blue tetrazolium reduction in the phagocytic vacuoles of leukocytes in chronic granulomatous disease. J Clin Invest 1969;48:1895, with permission.)

COURSE AND PROGNOSIS There is considerable heterogeneity in the severity of the clinical course of patients with CGD. Without treatment, this disease usually runs a progressive downhill course because of repeated infections and granuloma formation. The average life expectancy was reported to be 5 to 7 years in 1968 ([120]).

TREATMENT Treatment of infections with appropriate antibiotics and surgical procedures remains the cornerstone of management ([122], [170], [171]). Prophylactic use of antibiotics is generally recommended ([123], [124], [125] and [126], [171]). Trimethoprim-sulfamethoxazole alone or in combination with dicloxacillin can prolong the infection-free interval in many CGD patients ([170]). In some patients with CGD, the administration of interferon-? has induced partial correction of cytochrome *b* content and restored phagocyte bactericidal capacity toward normal, and reports have suggested that interferon-? increases the ability of CGD neutrophils to kill aspergillus and decreases the number of serious infections in patients with CGD ([171], [172], [173] and [174]). The exact mechanism by which interferon-? exerts its beneficial effect in CGD is unclear and may include other effects in addition to augmentation of the respiratory burst. Bone marrow transplantation has been tried, but its effectiveness is unclear ([170]).
VARIANTS Because the clinical picture of CGD results from delayed killing of catalase-positive bacteria, enzymatic defects in the bactericidal system other than decreased NADPH oxidase may produce an almost identical picture. Results of several studies demonstrate clearly that such biochemical variants exist. For example, in a brother and sister with the clinical picture of CGD, after phagocytosis of latex particles by their neutrophils, all oxidative metabolic reactions were absent. If the latex particles were opsonized with immunoglobulin, however, postpha-gocytic oxidative changes were stimulated dramatically ([175]). Another patient was reported in whom no oxidative changes (measured by chemiluminescence) occurred after phagocytosis of a variety of opsonized particles (latex, bacteria, or zymosan), but normal chemiluminescent responses occurred when the neutrophils were stimulated with soluble agents (concanavalin A and phorbol myristate acetate) ([176]). These patients appear to have a defect in signal transduction and activation of the oxidase system rather than in the oxidase enzyme(s). Another patient with clinically mild, X-linked CGD exhibited normal membrane depolarization (and therefore presumably normal activation), but NADPH oxidase apparently had a low affinity for NADPH and thus produced low but measurable amounts of superoxide ([177]).

Lipochrome Histiocytosis

A clinical variant lipochrome histiocytosis was described in three sisters with rheumatoid arthritis, hyperglobulinemia, splenomegaly, pulmonary infiltrates, and increased susceptibility to infection ([178]). No granulomas were found in tissue biopsies, but lipochrome pigmentation in large macrophages was present throughout the tissues. Studies of blood leukocyte function in two of the sisters revealed impaired postphagocytic respiration, NBT reduction, and hexose monophosphate shunt activity identical to that seen in patients with CGD ([179]).

Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH is the major substrate for the respiratory burst oxidase. A bactericidal defect similar to CGD has been described in a patient with a complete deficiency of G6PD, an enzyme important in the generation of NADPH ([180]). Apparently, almost complete absence of G6PD activity is necessary to interfere with bacterial killing because no difference from normal could be detected in cells with 25% activity or greater ([181]).

Glutathione Peroxidase Deficiency

Two unrelated 9- and 13-year-old girls presented a clinical picture similar to that of CGD and with decreased bactericidal capacity ([182]). The findings in these girls differed from those in males with CGD only in that no heterozygotes were detected in their families and their clinical course was somewhat more mild. These patients were reported before the nature of the NADPH oxidase was known, and it was suggested that the CGD phenotype was due to glutathione peroxidase deficiency, resulting in inhibition of the oxidase by accumulated peroxides. A recent study, however, suggested that glutathione peroxidase activity was normal in these patients and that both had mutations in the NADPH oxidase ([183]). Thus, there is no firm evidence that glutathione peroxidase deficiency is a cause of the CGD phenotype.

Glutathione Synthetase or Reductase Deficiency

Reduced glutathione (GSH) plays an important role in protecting neutrophils (including the NADPH oxidase system) from reactive metabolites, including H_2O_2. Because GSH levels are generated by both direct synthesis via glutathione synthetase and the reduction of oxidized glutathione by glutathione reductase, deficiencies of these enzymes might be expected to result in defective neutrophil function. The neutrophils of a normally growing infant with a relatively benign history of recurrent otitis and repeated episodes of neutropenia were found to have 5% of normal glutathione synthetase activity and 10 to 20% of normal glutathione content. The cells ingested particles and metabolized l-^{14}C glucose normally, but after phagocytosis, excess peroxide accumulated and impaired iodination and killing of bacteria were demonstrable. Electron microscopic examination showed damage to the microtubules and membranes of the neutrophils ([184], [185]). Neutrophil dysfunction resulting from a deficiency of glutathione reductase has also been reported ([186]). Patients with glutathione reductase deficiency or glutathione synthetase deficiency generally pursue a fairly benign clinical course. Vitamin E may be useful in patients with severe glutathione synthetase deficiency ([187]).

Catalase Deficiency

The neutrophil is protected from products of the NADPH oxidase not only by glutathione but also by superoxide dismutase, which generates H_2O_2 from superoxide, and by catalase, which converts H_2O_2 to H_2O and O_2. A deficiency in neutrophil catalase has been reported in which the surface of the neutrophil was more susceptible to damage by H_2O_2 than normal ([188]). These patients do not appear to have severe complications with infections ([188]).

Job Syndrome

Job syndrome was reported as occurring in two unrelated girls with red hair and fair skin who suffered from repeated staphylococcal cold abscesses, sinusitis, eczema, and pulmonary disease, a syndrome not unlike the affliction of Job ([189]). The leukocytes of these patients were capable of normal phagocytosis, bacterial killing, NBT reduction, and iodine fixation ([189], [190]), unlike those of patients with CGD. Subsequently, hyperimmunoglobulinemia E and defective chemotaxis were demonstrated, but the exact nature of the abnormality remains obscure ([191], [192]). It is now clear that this disorder is not limited to red-haired women, in that it is seen in both sexes and in patients of varied racial background and hair color ([191]). The common features are increased susceptibility to infection (usually evident in the first 6 weeks of life), chronic dermatitis, and hyperimmunoglobulinemia E.

Job syndrome is rare in that only 9 of 100 patients suspected to have it and referred to a major research center for further evaluation merited the diagnosis ([191]). Fungal, viral, and bacterial infections are common. Blood eosinophilia and elevated IgE levels are the most common laboratory findings; and the IgE, if directed against *Staphylococcus aureus*, is a relatively specific diagnostic parameter ([191]). Prophylactic treatment with dicloxacillin or trimethoprim-sulfamethoxazole may be helpful in managing afflicted patients. The role of interferon-? is unclear ([193], [194] and [195]). A primary defect of chemotaxis seems unlikely, and it is postulated that histamine released by the interaction of IgE with mast cells may interfere with neutrophil function ([192]) or that excess antistaphylococcal IgE production and a deficiency in synthesis of other protective antibodies are involved ([191]).

Myeloperoxidase Deficiency

An inherited deficiency of MPO was described in 1969 ([196]). The 49-year-old male propositus, one of his two sisters, and all four sons exhibited decreased MPO activity; no increased frequency of infections accompanied this defect. In two other families, apparently similarly affected, infection was also not a problem ([196]).

Until the late 1970s, this disorder was described in only rare cases (some familial, others apparently sporadic and acquired) ([197], [198] and [199]). This frequency seemed consistent with the apparently pivotal role of MPO in the oxygen-dependent killing of microorganisms ([196], [198]). With the development of flow cytometry and automated differential cell-counting techniques, however, MPO deficiency was often detected (approximately 1 in 2000 subjects) during routine hematologic evaluation of patients admitted to the hospital ([197], [199], [200]). From these studies, MPO deficiency clearly is the most common disorder of neutrophil function ([199]), and in those families studied, it appears to be an autosomally transmitted disorder ([199], [200]) (although the genetic defect is still not completely understood) ([198], [201]).

Most studies of MPO-deficient neutrophils reveal that bacteria and fungi are phagocytized normally, and ingestion is followed by a vigorous respiratory burst. Bactericidal killing, however, is somewhat delayed, reaching normal levels only after 1 to 3 hours ([198]). Findings of these studies and the rarity of clinical infections in MPO-deficient individuals support the concept of MPO-independent microbicidal mechanisms ([196], [198]). In contrast, although ingested normally, several *Candida* species and *Aspergillus* are killed poorly, if at all, and several MPO-deficient patients, including one of the first reported cases, suffered from disseminated fungal

infection ([196] , [198]).

The respiratory burst in MPO-deficient cells is actually prolonged and supernormal, and evidence exists that MPO normally acts to modulate and terminate the inflammatory response; for example, MPO oxidizes the methionine group in FMLP, thus modulating chemotaxis, and it also modulates NADPH oxidase activity ([198]).

Results of studies of the structure of MPO have shown it to be a tetramer (150,000 d) composed of two heavy and two light chains (a $_2$ß $_2$) of 55,000 to 60,000 and 10,000 to 15,000 daltons, respectively ([201] , [202]). Polymorphonuclear neutrophils from normal and MPO-deficient subjects contained an 89,000-dalton protein immunochemically related to MPO and thought to be a precursor protein ([198] , [201]). Normal neutrophils, however, contain several smaller peptides (59,000 and 13,500 daltons) that react with antibody to MPO and are thought to be the subunits of MPO. In one study, completely MPO-deficient neutrophils lacked all of these subunits but contained the precursor protein, whereas partially MPO-deficient neutrophils contained decreased amounts of the precursor protein and the subunits derived from it (Fig. 64.9). Because Southern blot analysis for MPO-related sequences showed the genomic DNA of MPO-deficient cells to be identical to that of normal neutrophils, and because mRNA from control and completely MPO-deficient subjects' myeloid precursors were of the same size and were present in the same amount, the genetic defect in these MPO-deficient patients likely results in the formation of a modified pro-MPO that undergoes defective posttranslational processing ([201]). In other studies, investigators did not detect the 89,000-d precursor protein and suggested that MPO deficiency results from a variety of defects, as in the case of thalassemia ([202]). Specific mutations in the MPO gene in MPO deficiency have been described ([203]).

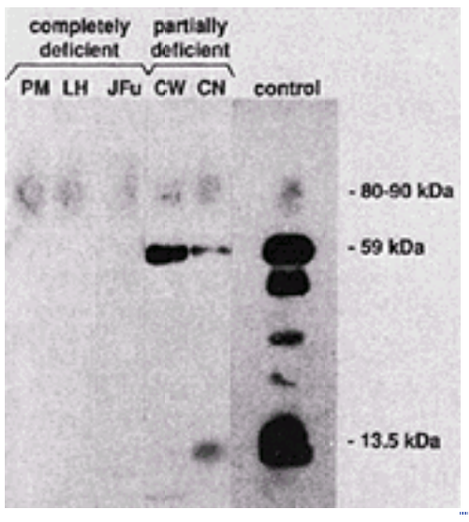

Figure 64.9. Immunoblot analysis of myeloperoxidase (MPO)-related peptides in neutrophils from control and MPO-deficient subjects. Neutrophils (5 × 10 ^{6}) were solubilized, and the proteins were separated by sodium dodecyl sulfate–polyacrylamide gel electrophoresis, blotted to nitrocellulose, and probed with monospecific polyclonal antibody to MPO. Neutrophils from completely deficient subjects (PM, LH, and JFu) lacked the normal MPO peptides but contained a diffuse band at 80 to 90 kd. Neutrophils from partially deficient subjects (CW and CN) contained small amounts (25 to 50%) of the normal subunits as well as the 80- to 90-kd band. For comparison, control neutrophils containing normal MPO activity and spectra have the major subunits of 59.0 and 13.5 kd. The bands at 39 and 24 kd are related to the 59.0- and 13.5-kd subunits, respectively. (From Nauseef WM. Aberrant restriction endonuclease digests of DNA from subjects with hereditary myeloperoxidase deficiency. Blood 1989;73:290, with permission.)

MPO deficiency also occurs as an acquired defect in a variety of situations (e.g., pregnancy, lead intoxication, Hodgkin disease, and activated coagulation) ([198]), but it is encountered most commonly in association with acute myeloblastic leukemia (up to 48% of patients), myeloproliferative states (20 to 60% in chronic myelogenous leukemia, 32% in myelofibrosis), and myelodysplastic syndromes (25%) ([198]). In many of these conditions, only some of the circulating myeloid cells are deficient, presumably those produced by the abnormal clone ([198]).

Other Enzymatic Defects

Two siblings with negative peroxidase, oxidase, and lipid reactions in the neutrophils and monocytes also have been reported ([204]).

Leukocyte Adhesion Defects

As described in Chapter 10, cell–cell adhesion plays an important role in neutrophil function. Two types of leukocyte adhesion deficiency (LAD) have been described.

LEUKOCYTE ADHESION DEFICIENCY-1 (CD11/CD18 DEFICIENCY) CD11/CD18 deficiency is a rare, inherited disorder of leukocyte function first reported in 1974. It usually is detected in infancy or early childhood as a result of frequent bacterial (and sometimes viral) infections or delayed umbilical cord separation, and high neutrophil counts ([205]). The infections are recurrent, often life-threatening or fatal, and usually involve the skin and subcutaneous tissues, middle ear, and oropharynx. Neutrophils are present in the blood in increased numbers (even between infections) and appear normal but fail to migrate into Rebuck skin windows or sites of infection in normal numbers. When studied *in vitro*, they exhibit defects in motility, phagocytosis, granule secretion, and particle-stimulated respiratory burst activity. Humoral (immunoglobulins and complement) and cellular immunity (skin tests and lymphocyte stimulation tests) otherwise appeared normal, and no specific enzyme deficiencies were detectable. The pathogenesis of this disorder was first suggested in 1980 when a patient's neutrophils were found to lack a high-molecular-weight glycoprotein ([206]). Subsequent work revealed the absence of CD11/CD18. As described in Chapter 2 and Chapter 10, the CD11/CD18 family consists of three heterodimeric proteins each composed of a noncovalently associated a (a $_L$, a $_M$, or a $_X$) and ß (ß $_2$) chain (Table 64.3). Translocation of a and ß chains to the cell surface requires assembly of the aß heterodimer. Mutations in the ß $_2$ chain prevent normal assembly of the aß heterodimer and subsequent translocation to the surface. CD11/CD18-deficient neutrophils roll normally on endothelial cells but do not adhere or migrate with chemotactic stimulation ([207]) (Table 64.3). Studies involving eight patients revealed two distinct phenotypes: patients with severe deficiency (less than 0.3%) and patients with moderate deficiency (2.5 to 31.0%) of CD11a/CD18 glycoproteins on the neutrophil surface. The severity of clinical manifestations correlated directly with the degree of glycoprotein deficiency ([208]). Results of other studies further expand the heterogeneity of defects causing this disorder in which mutations in CD18 have been identified ([205] , [209] , [210] , [211] , [212] , [213] , [214] , [215] , [216] , [217] , [218] , [219] , [220] , [221] and [222]). The disease has also been reported in cattle ([223] , [224] , [225] and [226]).

TABLE 64.3. Leukocyte ß $_2$ Integrins

Neutrophil Integrin	Expression	Ligand
a $_L$ß $_2$ LFA-1, CD11a/CD18	All leukocytes	ICAM-1 (CD54) ICAM-2 (CD102) ICAM-3 (CD50)
a $_M$ß $_2$ HMac-1, CD11b/CD18	Monocytes, neutrophils, some natural killer cells	ICAM-1, iC3b, fibrinogen, factor X
a $_X$ß $_2$ p150,95, CD11c/CD18	Monocytes, neutrophils	iC3b, fibrinogen

No specific therapy for this disorder is known. Some patients have demonstrated improvement after bone marrow transplantation ([205] , [227]).
LEUKOCYTE ADHESION DEFICIENCY-2 A second form of LAD has also been described in which the patients have severe mental retardation, short stature, a distinctive facial appearance, the Bombay (hh) blood phenotype, and recurrent bacterial infections, including pneumonia, otitis media, peridontitis, and localized cellulitis without the accumulation of pus, in association with an elevated white count ([207] , [228] , [229] , [230] and [231]). Phagocytosis was normal, but motility and homotypic aggregation were defective. Surface CD18 expression was normal. As described in Chapter 2 and Chapter 10, cell surface selectins, including CD62E (E-selectin), CD62P (P-selectin), and CD62L (L-selectin), and their ligands [carbohydrates whose structures appear to be related to sialyl-Le ^{x} (CD15s)], play an important role in

neutrophil adhesion. The critical structure of CD15s [NeuAc a 2?3 Gal ß 1?4, (Fuc a 1?3) GlcNAc] and the Bombay phenotype is a deficiency of Fuc a 1?2 Gal linkages, which serves as the core of the A, B, and O blood groups ([232]). LAD-2 neutrophils were found to lack CD15s expression and did not bind IL-1b–stimulated endothelial cells (which express E-selectin). Because these patients had deficiencies of several fucosylated carbohydrates, the syntheses of which depend on different fucosyltransferase genes, a general defect in fucose metabolism has been postulated ([228]). LAD-2 neutrophils do not roll well on endothelial cells and do not adhere under shear stress ([207]). However, under static conditions LAD-2 neutrophils can adhere and migrate ([207]). Few patients have been described, and these cases may represent different biochemical defects ([233], [234], [235], [236], [237], [238] and [239]). Oral fucose supplementation may be useful in some patients ([233], [234], [235], [236], [237], [238] and [239]). Bone marrow transplantation might be considered in some cases.

Fc?RIII Deficiency

Several patients who lack the IgG receptor Fc?RIIIB (CD16) ([240], [241], [242], [243], [244], [245], [246], [247] and [248]) have recently been reported. Two homologues of Fc?RIII (Fc?RIIIA and Fc?RIIIB) have been identified. Fc?RIIIB is glycosyl-phosphatidyl inositol–linked and expressed on neutrophils. Because Fc?RIII bears the NA1 and NA2 polymorphic neutrophil-specific antigens, these cells are NA1 and NA2 negative. The clinical expression of this deficiency ranges from a normal state to one characterized by multiple infections ([240], [241], [242], [243], [244], [245], [246], [247] and [248]).

Actin Dysfunction

A genetic disorder of neutrophil actin function (NAD), characterized by recurrent bacterial infections and defects in chemotaxis, adhesion, and phagocytosis, due to actin dysfunction also has been described ([249], [250], [251] and [252]). These cells appeared to have actin that did not polymerize well and had lower levels of F-actin in both the resting state and after stimulation. Subsequent studies after the death of the index case found that one, but not both, parent was heterozygous for LAD-1. Most patients with LAD-1 do not have abnormal actin polymerization. Patients with this syndrome and overexpression of 47- and 89-kd proteins (NAD 47/89) were also described ([252]). A more recent patient was described with overexpression of leufactin, an F-actin binding protein that regulates microfilaments, and neutrophil actin dysfunction with serious infections ([252], [253] and [254]). Leufactin was shown to be the 47-kd protein overexpressed in NAD 47/89. Overexpression of leufactin, also known as *lymphocyte specific protein 1*, can create the morphologic and motility abnormalities seen in leufactin-overexpressing neutrophils ([254]).

Localized Juvenile Peridontitis

Localized juvenile peridontitis is an adolescent disease characterized by alveolar bone loss, most prominently of the incisors and first molars ([255], [256]). Interestingly, these patients do not have demonstrable problems with extraoral infections. Abnormal neutrophil chemotaxis to FMLP and C5a in these patients has been reported ([255], [256]), and a similar chemotactic defect was also observed in siblings of patients before developing clinical disease. Neutrophils from patients with localized juvenile peridontitis have been reported to express CR2 (the C3d receptor) on the cell surface, in contrast to control cells, which do not ([257]). CR2 is present on normal immature neutrophils but is lost during maturation before release from the marrow. The mechanism of this abnormality has not been defined.

Desensitization

After previous exposure to a stimulus, neutrophils react less to subsequent stimulation by the same stimulus ([258], [259] and [260]). This phenomenon has been termed *desensitization*. In some cases, the desensitization appears specific to the original stimulus, but in other cases desensitization to different stimuli is also observed (cross-desensitization) ([257], [258], [259] and [260]).

Such desensitization has been observed in patients undergoing hemodialysis, in which exposure of blood to a cuprophane dialyzer membrane results in the generation of C5a which causes a transient neutropenia due to pulmonary leukostasis, as described in Chapter 10 ([261], [262]). Although C5a generation persists throughout dialysis, the neutropenia is transient ([263]). In contrast to neutrophils obtained at the start of dialysis, neutrophils obtained after 2 hours of dialysis (after the leukostasis has resolved) do not aggregate in response to plasma leaving the dialyzer membrane, demonstrating desensitization *in vivo* ([263]). A patient with cytomegalovirus infection, whose serum induced granulocyte aggregation (presumably due to C5a), did not experience neutropenia during dialysis, and his neutrophils did not aggregate in response to serum leaving the dialyzer, in contrast to control cells, also demonstrating *in vivo* desensitization ([263]). Similar desensitization was demonstrated in rabbits using the chemotactic peptide FMLP, wherein continuous intravenous infusion of FMLP reproduced a transient neutropenia due to pulmonary sequestration ([264]). It is likely that neutrophil desensitization may also occur in other pathologic states, including infection, trauma, and multiorgan failure syndrome, and may contribute to neutrophil dysfunction, although the clinical significance of this phenomenon is unclear.

Viral Infection

Neutrophil dysfunction has been reported to occur in response to influenza A exposure. Both influenza A virus and its purified hemaglutinin activate neutrophils and neutrophil responses to other stimuli are depressed after preexposure to influenza A and parainfluenza ([245], [246], [247] and [248], [265], [266], [267], [268], [269] and [270]). Neutrophils from patients with human immunodeficiency virus (HIV) infection also may exhibit abnormal function. In one study, neutrophils from patients with early HIV infection had enhanced superoxide production in response to bacterial products ([271]). Another study found evidence for neutrophil activation in patients with HIV infection as manifested by increased CD11b expression, decreased CD62L expression, increased H_2O_2 production, and increased actin polymerization ([272]). Interestingly, H_2O_2 production in response to FMLP after tumor necrosis factor and interleukin-8 priming was decreased, and CD62L down-regulation in response to FMLP was less complete; these abnormalities correlated with the clinical stage of disease. Whether these abnormalities are a direct effect of the HIV virus, a manifestation of desensitization as described in the previous section, or due to another mechanism is unclear. These observations suggest that neutrophil dysfunction may occur in response to other viral infections as well, although the clinical significance of such a phenomenon is unclear.

Hyperalimentation Hypophosphatemia

In the past, the use of hyperalimentation without adequate phosphate occasionally resulted in hypophosphatemia that was associated with neutrophil dysfunction, including impaired chemotaxis ([273]). The exact mechanism of this defect is unclear, and this syndrome is now rarely encountered, although evidence suggests that the impairment of phagocytosis seen in phosphate depletion may result from an increase in intracellular calcium ([274]).

Hyperglycemia

Abnormalities have been observed in several neutrophil functions in patients with poorly controlled diabetes, including phagocytosis, chemotaxis, adhesion, and the oxidative burst ([275], [276], [277], [278], [279], [280] and [281]). Improvement in glucose control is associated with an improvement in neutrophil function ([281], [282]). Improvement in neutrophil function can occur after incubation with insulin for as little as 15 minutes ([281]). In patients with non–insulin-dependent diabetes, neutrophil dysfunction is associated with an increased intracellular calcium that returns to normal in association with normalization of phagocytic function when glucose control is improved ([276]).

Miscellaneous

Other apparently unique neutrophil disorders have been reported. One patient with leukocytosis, severe bacterial infections, and impaired wound healing had neutrophils that appeared to have a defect in signal transduction ([283]). These cells had a severe defect in chemotaxis, activation of the respiratory burst, and azurophil granule release in response to a variety of chemotaxins. In contrast, FMLP induced a normal increase in intracellular free calcium and specific granule release. Actin polymerization was defective in response to FMLP but normal in response to some other stimuli. Phagocytosis of opsonized bacteria was normal. Presumably, these cells have a defect in the intracellular signal transduction pathway.

Neutrophil Dysregulation in the Systemic Inflammatory Response Syndrome

Although this chapter has primarily addressed disorders resulting in decreased neutrophil function, neutrophil activity may also be increased. For example, one study

reported increased neutrophil functional activity in patients with severe acute pancreatitis ([284]). The clinical significance of this phenomenon is unclear.

FREQUENCY OF IDENTIFIABLE QUALITATIVE NEUTROPHIL DISORDERS

Most patients suspected of having a defect in neutrophil function do not have a well-defined abnormality. In one study of 100 patients referred for evaluation of a suspected neutrophil abnormality, only four were identified as a described syndrome ([285]). Some degree of impaired chemotaxis or superoxide production was found in 53 of 100 patients, but no abnormality was found in 41 of 100.

Abnormalities of the Monocyte-Macrophage System: Lysosomal Storage Diseases

Abnormalities of the monocyte-macrophage system include certain of the inherited lysosomal storage diseases that result from specific defects in lysosomal function. Most of these disorders are caused by the deficiency of a particular hydrolytic enzyme, but others are due to impaired receptors or deficiencies of crucial cofactors or protective proteins. Prevalent among these disorders are the *sphingolipidoses*, which are a unique family of diverse diseases related by their molecular pathology. Here, the clinical, biochemical, and genetic features of three of these disorders are presented: Fabry disease due to defects in the a-galactosidase A gene on Xq21, Niemann-Pick disease (NPD) due to defects in the acid sphingomyelinase gene on 11p, and Gaucher disease due to defects in the acid ß-glucosidase gene at 1q. In each of these inherited disorders, a nucleotide-base substitution in a specific DNA segment that encodes a lysosomal enzyme results in a defective gene product (i.e., a noncatalytic enzyme), which is unable to perform its normal function as a hydrolase. The deficiency of these lysosomal hydrolases results in abnormal metabolism of the enzyme's specific sphingolipid substrate and accumulation of the sphingolipid within the cells of the monocyte-macrophage system. For example, in Gaucher disease and NPD, anemia, thrombocytopenia, leukopenia, or hepatosplenomegaly can be the presenting symptoms. Thus, these disorders are frequently diagnosed by the hematologist and must be included in the differential diagnosis for patients with monocyte-macrophage involvement.

PATHOPHYSIOLOGY OF LYSOSOMAL STORAGE DISEASES

The underlying defect in the inherited lipidoses is the accumulation of metabolites, including the glycolipids and sphingomyelin. The glycosphingolipids, which have a major structural function in many cells, are formed by the addition of various carbohydrates to a backbone of ceramide, an acylated sphingosine (Fig. 65.1). The fatty acid portion of ceramide consists primarily of stearic acid (C_{18}) in the brain, whereas in nonneural tissues, it is somewhat longer (C_{20} to C_{24}). Each sphingolipid is characterized by the nature of the compound that is esterified to the first carbon of the ceramide molecule. For example, the addition of hexoses and *N*-acetylneuraminic acid to ceramide forms the gangliosides, which are found in brain, and the neutral glycolipids, which are found more ubiquitously in cell membranes. The blood group antigens are also glycosphingolipids. In the lysosomal storage diseases, certain lipid compounds are present in different cell types, so their abnormal accumulation due to a specific lysosomal enzyme defect leads to a specific phenotype (Fig. 65.2).

Figure 65.1. Formulae of some of the sphingolipids.

GAUCHER DISEASE

Definition and History

Gaucher disease is a lipid storage disease characterized by the deposition of glucosylceramide in cells of the macrophage-monocyte system ([1]). It was first described by Gaucher in 1882, and the storage of glucocerebroside was first recognized by Epstein in 1924 ([1]). Brady et al. subsequently delineated the metabolic defect, the deficiency of the lysosomal hydrolase acid ß-gluco-sidase ([2]). There are three clinical subtypes that are delineated by the absence or presence and progression of neurologic involvement: type 1 or the adult, nonneuronopathic form; type 2, the infantile or acute neuronopathic form; and type 3, the juvenile or Norrbotten form. All three subtypes are inherited as autosomal-recessive traits. Type 1 disease is the most common lysosomal storage disease and the most

prevalent genetic disorder among Ashkenazi Jewish individuals, with an incidence of approximately 1 in 1000 and a carrier frequency of approximately 1 in 16 to 1 in 18 ([3]).

Etiology and Pathogenesis

All three subtypes of Gaucher disease result from the deficient activity of the lysosomal hydrolase acid ß-glucosidase. The molecular basis of Gaucher disease has been identified for 90 to 95% of Ashkenazi Jewish patients (Table 65.1). Genotype/phenotype correlations have been noted for the different subtypes and may provide the molecular basis for the remarkable clinical variation in type 1 Gaucher disease. Presumably, the amount of residual enzymatic activity determines disease subtype and severity. For example, type 1 patients homozygous for the milder N370S mutation tend to have a later onset and milder course than patients with one N370S allele and another mutant allele. However, the wide variability in clinical presentation among Gaucher disease patients cannot be fully explained by the underlying acid ß-glucosidase mutations. The lesions causing the severe type 2 (infantile) disease express little, if any, enzymatic activity *in vitro*.

TABLE 65.1. Molecular Genetics of Gaucher, Niemann-Pick, and Fabry Diseases

Disease	Chromosome Assignment	Molecular Characteristics	Comments
Gaucher	1q21	cDNA, functional and pseudogenomic sequences, >200 mutant alleles known	4 mutations (N370S, L444P, 84insG, IVS2 $^{+}$1) account for 90–95% of mutant alleles in Ashkenazi Jewish patients.
Niemann-Pick			
Types A and B	11p15.1 to p15.4	cDNA, entire genomic sequence, >30 mutant alleles known	4 mutations account for >95% of mutant alleles in Ashkenazi Jewish patients with type A disease.
Type C	18q11-q12 region	cDNA, entire genomic sequence, >100 mutant alleles known	Over 100 mutations in NPC1 gene.
Fabry	Xq22.1	cDNA, entire genomic sequences, >200 mutant alleles known	Over 200 private mutations detected occurring in single or a few families.

cDNA, complementary DNA.

Pathology

The pathologic hallmark in Gaucher disease is the presence of the Gaucher cell in the macrophage-monocyte system, particularly in the bone marrow (Fig. 65.3). These cells, which are 20 to 100 µm in diameter, have a characteristic wrinkled-paper appearance resulting from intracytoplasmic substrate deposition. Gaucher cells stain strongly positive with periodic acid-Schiff, and their presence in bone marrow, other tissues, or both suggests the diagnosis. The accumulated glycolipid, glucosyl-ceramide, is derived primarily from the phagocytosis and degradation of senescent leukocytes and, to a lesser extent, erythrocyte membranes. Glycolipid storage results in organomegaly and pulmonary infiltration. Neuronal cell loss in patients with types 2 and 3 disease presumably results from the accumulation of the cytotoxic glycolipid, glucosylsphingosine, in the brain due to the severe deficiency of acid ß-glucosidase activity. Glucosylceramide accumulation in the bone marrow, liver, spleen, lungs, and kidney leads to pancytopenia, massive hepatosplenomegaly, diffuse infiltrative pulmonary disease, and nephropathy or glomerulonephritis. The progressive infiltration of Gaucher cells in the bone marrow causes thinning of the cortex, pathologic fractures, bone pain, bony infarcts, and osteopenia. Central nervous system involvement occurs only in patients with types 2 and 3 disease.

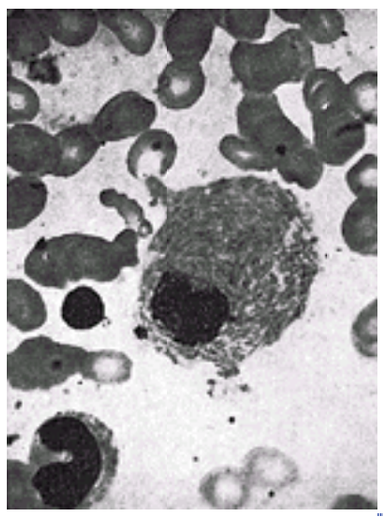

Figure 65.3. Typical Gaucher cell together with a lymphocyte and a juvenile neutrophil from the sternal bone marrow in a patient with Gaucher disease.

Clinical Manifestations

There is a broad spectrum of clinical expression among patients with type 1 disease, in part due to a combination of different mutant alleles. Onset of clinical manifestations occurs from early childhood to late adulthood, with the more severely affected patients presenting by adolescence. At presentation, patients may have easy bruisability due to thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated liver function tests, splenomegaly, and bone pain or pathologic fractures. Occasionally, patients present with pulmonary involvement. Patients who are diagnosed in the first 5 years of life are frequently non-Jewish and typically have a more malignant disease course. Patients with a milder form of the disease are identified later in life during evaluations for hematologic or skeletal problems or are found to have splenomegaly on routine examinations. In symptomatic patients, splenomegaly is progressive and can become massive. Clinically apparent bony involvement, which occurs in over 20% of patients, can present as bone pain or pathologic fractures. Most patients have radiologic evidence of skeletal involvement, including an Erlenmeyer flask deformity of the distal femur, which is an early skeletal change. In patients with symptomatic bone disease, lytic lesions can develop in the long bones, ribs, and pelvis, and osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis and bruising and is frequently overlooked until other symptoms become apparent. Children with massive splenomegaly are short of stature due to the energy expenditure required by the enlarged organ.

Type 2 disease, which is rare and panethnic in distribution, is characterized by a rapid neurodegenerative course with extensive visceral involvement and death within the first 2 years of life. The disease presents in infancy with increased tone, strabismus, and organomegaly. Failure to thrive and stridor due to laryngospasm are typical. The progressive psychomotor degeneration leads to death by 2 to 3 years, usually due to respiratory compromise.

Type 3 disease presents in infancy or childhood. Neurologic involvement is present in addition to organomegaly and bony manifestations. There is a high frequency of type 3 disease in Sweden (1 in 50,000), which has been traced to a common founder couple in the seventeenth century. Type 3 disease has been further classified as types 3a and 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Diagnosis

Gaucher disease should be considered in the differential diagnosis of patients who present with unexplained organomegaly, easy bruisability, or bone pain. Bone marrow examination usually reveals the presence of Gaucher cells; however, all suspect diagnoses should be confirmed by demonstrating deficient acid

ß-glucosidase activity in isolated leukocytes or cultured fibroblasts. For possible genotype/phenotype correlations, the specific acid ß-glucosidase mutation(s) may be determined, particularly in Ashkenazi Jewish patients. Carrier identification can be achieved by enzymatic assay confirmed with DNA testing in most Jewish families. Testing should be offered to all family members, keeping in mind that heterogeneity even among members of the same kindred can be so great that asymptomatic affected individuals may be diagnosed during such testing. Prenatal diagnosis is available by determining enzymatic activity or specific mutations in chorionic villi or cultured amniotic fluid cells.

Treatment

In the past, management of patients with type 1 disease was primarily symptomatic and included blood transfusions for anemia, partial or total splenectomy for severe mechanical cardiopulmonary compromise or hypersplenism, analgesics for bone pain, and orthopedic procedures for joint replacement. A small number of patients also have undergone bone marrow transplantation, which is curative if successful ([4]). However, a matched donor is required, and significant morbidity and mortality are associated with the procedure. No effective treatment is known for the neurologic involvement in types 2 and 3 disease. However, during the past 10 years, the safety and efficacy of enzyme replacement using recombinant acid ß-glucosidase have been clearly demonstrated in type 1 disease ([2]). Most of the extraskeletal symptoms are reversed by an initial debulking dose of enzyme (60 IU/kg) administered by intravenous infusion every other week. The effectiveness of enzyme replacement in reversing and preventing bone manifestations is still under study; however, the data indicate that enzyme replacement decreases the frequency of bone pain crises and stabilizes or improves the bone disease. In addition, early treatment is efficacious in normalizing linear growth and bone morphology in affected children. Efforts are also under way to develop gene therapy for type 1 disease.

NIEMANN-PICK DISEASE

Definition

NPD types A and B are lipid storage disorders that result from the deficiency of the lysosomal enzyme, acid sphingomyelinase, and the subsequent accumulation of its substrate, sphingomyelin ([3]). The original description of NPD referred to what is now known as type A NPD, which is a fatal disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by age 2 to 3 years. Type B is a nonneuronopathic form observed in children and adults. In addition, several other subtypes of NPD have been described, the major subtype being type C, which results from defective cholesterol transport. Previously, a type D disease was identified in patients from Nova Scotia. Studies have now shown that these type D patients have mutations in the major gene causing type C disease. All of the subtypes are inherited as autosomal-recessive traits and display variable clinical features.

Etiology and Pathogenesis

NPD types A and B result from deficient acid sphingomyelinase activity. In type C NPD, the genetic defect involves the defective transport of cholesterol from the lysosome to the cytosol. Two different genes causing the altered cholesterol transport in type C disease were recently identified, permitting more precise diagnosis, carrier detection, and prenatal diagnosis in affected families.

Pathology

The pathologic hallmark in types A and B NPD is the histochemically characteristic lipid-laden foam cell, often referred to as the *Niemann-Pick cell* (Fig. 65.4). These cells, which can be readily distinguished from Gaucher cells by their histologic and histochemical characteristics, are not pathognomic for NPD because histologically similar cells are found in patients with Wolman disease, cholesterol ester storage disease and lipoprotein lipase deficiency, and in some patients with GM_1 gangliosidosis, type 2. Sphingomyelin is the major lipid that accumulates in the cells and tissues of patients with types A and B NPD. In most normal tissues, sphingomyelin constitutes from 5 to 20% of the total cellular phospholipid content; however, in patients with types A and B NPD, the sphingomyelin levels may be elevated up to 50-fold, constituting approximately 70% of the total phospholipid fraction. Lysosomal sphingomyelin accumulation in brain, liver, kidney, and lungs has been documented with organs from types A and B NPD patients containing approximately the same amount of sphingomyelin, with the notable exception that type B NPD patients have little or no lipid storage in their central nervous systems. In general, patients with type A disease have less than 5% of normal acid sphingomyelinase activity when determined in cultured fibroblasts, lymphocytes, or both, whereas cells from type B patients typically have 10 to 20% of normal activity that presumably prevents the development of the neurologic symptoms.

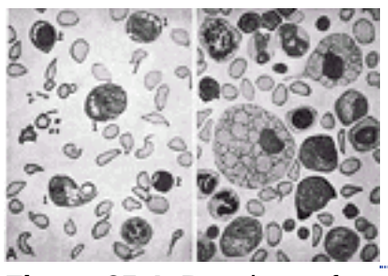

Figure 65.4. Drawings of representative cells in smears made from **(A)** peripheral blood and **(B)** sternal bone marrow in a patient with Niemann-Pick disease showing numerous vacuoles in the cytoplasm of monocytes (*1*) and lymphocytes (*2*) in the blood and foam cells in the marrow. (From Kato K. Sternal marrow puncture in infants and children. Am J Dis Child 1937;54:269, with permission.)

Clinical Manifestations

The clinical presentation and course of type A NPD is relatively uniform and is characterized by a normal appearance at birth, although the newborn period is sometimes complicated by prolonged jaundice. Hepatosplenomegaly, moderate lymphadenopathy, and psychomotor retardation are evident by 6 months of life followed by rapid neurodegeneration. The loss of motor function and the deterioration of intellectual capabilities are progressive. In later stages, spasticity and rigidity are evident with affected infants experiencing complete loss of contact with their environment.

In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most patients are diagnosed in infancy or childhood when enlargement of the liver, spleen, or both is detected during a routine physical examination. At diagnosis, type B patients also have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on chest roentgenogram. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth, the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients, the splenomegaly may not be noted until adulthood, and there may be minimal disease manifestations. In most type B patients, decreased pulmonary diffusion due to alveolar infiltration becomes evident in childhood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by age 15 to 20. Such patients have low pO_2 values and dyspnea on exertion. Life-threatening bronchopneumonias may occur, and cor pulmonale has been described. Severely affected patients also may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia due to secondary hypersplenism may necessitate partial or total splenectomy. Typically, type B patients do not have neurologic involvement and are intellectually intact.

Patients with NPD type C disease often have prolonged neonatal jaundice, appear normal for 1 to 2 years, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than in patients with type A or B disease, and they may survive into adulthood.

Diagnosis

Type A disease is diagnosed in the patient's first year of life by failure to thrive, organomegaly, and severe psychomotor retardation. In type B disease, splenomegaly is usually noted early in childhood; however, in very mild cases, the enlargement may be subtle, and detection may be delayed until adolescence or adulthood. The presence of the characteristic Niemann-Pick cells in the bone marrow supports the diagnosis. However, patients with type C disease also have infiltration of these cells in the bone marrow. Thus, all suspected cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the acid sphingomyelinase activity in peripheral leukocytes, cultured fibroblasts, or lymphoblasts. Patients with types A and B disease have markedly decreased levels of enzymatic activity (1 to

10% of normal), whereas patients with type C disease may have slightly decreased sphingomyelinase activity (50 to 75% of normal), and patients with Gaucher disease and other storage disorders characterized by hepatosplenomegaly, neurologic involvement, or both have normal or near-normal levels. The enzymatic identification of types A and B carriers is problematic. However, in families in which the specific molecular lesion has been identified, family members can be accurately tested for heterozygote status by DNA analysis (Table 65.1). Type C disease can be biochemically documented by demonstrating the cholesterol transport defect in cultured fibroblasts. Heterozygote identification for type C disease can be accomplished by DNA analysis in families whose mutations have been identified. Prenatal diagnosis of types A and B disease may be reliably made by measuring acid sphingomyelinase activity in cultured amniocytes or chorionic villi. In type C disease, the cholesterol defect can be demonstrated by filipin staining, but DNA diagnosis is most accurate. Thus, in types A, B, and C, prenatal diagnosis can be made by DNA analysis of fetal cells in families in which the specific molecular lesions are known.

Treatment

At present, no specific treatment is available for any of the NPD subtypes. Orthotopic liver transplantation in an infant with type A disease and amniotic cell transplantation in several patients with type B disease have been attempted without success. Bone marrow transplantation in a type B patient was successful in reducing the spleen and liver volumes, the sphingomyelin content of the liver, and the number of Niemann-Pick cells in the marrow and radiologically detected infiltration of the lungs. However, the patient experienced severe graft-versus-host disease, which complicated her quality of life. Future prospects for treatment of type B disease include enzyme replacement and gene therapy. Treatment of types A and C disease is presently precluded by their severe neurologic involvement.

FABRY DISEASE

Definition and History

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism that was first described in 1898 by two dermatologists, Anderson and Fabry, who independently reported patients with angiokeratoma corporis diffusum. The lipid storage nature of the disorder was subsequently established by Scriba, and although the familial occurrence of the disease was recognized earlier, it was not until 1965 that Opitz et al. ([5]) documented X-linked recessive inheritance by pedigree analysis. In 1967, Brady et al. ([6]) demonstrated that the enzymatic defect was in ceramide trihexosidase, or a-galactosidase A activity. The disease is characterized by the presence of angiokeratomas (telangiectatic skin lesions), hypohidrosis, corneal and lenticular opacities, acroparesthesias, and vascular disease of the kidney, heart, or brain. It has an estimated prevalence of approximately 1 in 40,000 males and is panethnic.

Etiology and Pathogenesis

Fabry disease is an X-linked recessive trait that is manifested in affected hemizygous males. Atypical male variants with residual a-galactosidase A activity may be asymptomatic or have late-onset, mild disease manifestations primarily limited to the heart. Heterozygous females are usually asymptomatic or exhibit mild manifestations. The disease results from the deficient activity of the lysosomal hydrolase, a-galactosidase A. Affected males who have blood group B or AB have a more severe disease course because the blood group B substance also accumulates as it is normally degraded by a-galactosidase A. The molecular basis of Fabry disease has been identified for a number of patients (Table 65.1).

Pathology

Fabry disease is characterized by the marked deposition of globotriaosylceramide and related glycosphingolipids with terminal a-galactosyl moieties primarily in the plasma and in the lysosomes of endothelial, perithelial, and smooth muscle cells of blood vessels ([4]). These glycosphingolipid deposits also are prominent in epithelial cells of the cornea, in glomeruli and tubules of the kidney, in muscle fibers of the heart, and in ganglion cells of the dorsal roots and autonomic nervous system. The skin lesions are telangiectases. Capillaries, venules, and arterioles show pathologic lipid storage, and there is marked dilatation of the capillaries of the dermal papillae just below the epidermis. The larger lesions are usually located in the upper dermis, where they may produce elevation, flattening, or hypertrophy of the epithelium with keratosis—hence the term *angiokeratoma*. Ultrastructurally, the glycosphingolipid inclusions in lysosomes have a concentrically arranged lamellar or myelinlike structure.

Clinical Manifestations

The angiokeratomas usually occur in childhood and may lead to early diagnosis. They increase in size and number with age and range from barely visible to several millimeters in diameter. The lesions are punctate, dark red to blue-black, and flat or slightly raised (Fig. 65.5). They do not blanch with pressure, and the larger ones may show slight hyperkeratosis. Characteristically, the lesions are most dense between the umbilicus and knees, in the “bathing trunk area,” but may occur anywhere, including the oral mucosa. The hips, thighs, buttocks, umbilicus, lower abdomen, scrotum, and glans penis are common sites, and there is a tendency toward bilateral symmetry. Variants without skin lesions have been described. Sweating is usually decreased or absent. Corneal opacities and characteristic lenticular lesions, observed in slit-lamp examination, are present in affected males as well as in approximately 70% of asymptomatic heterozygotes. Conjunctival and retinal vascular tortuosity are common and result from the systemic vascular involvement.

Figure 65.5. Typical skin lesions on the buttocks of a patient with Fabry disease.

Pain is the most debilitating symptom in childhood and adolescence. Fabry crises, lasting from minutes to several days, consist of agonizing, burning pain in the hands and feet and proximal extremities and are usually associated with exercise, fatigue, or fever. These painful acroparesthesias usually become less frequent in the third and fourth decades of life, although in some men, they may become more frequent and severe. Attacks of abdominal or flank pain may simulate appendicitis or renal colic.

With increasing age, the major morbid symptoms result from the progressive involvement of the vascular system. Early in the course of the disease, casts, red cells, and lipid inclusions with characteristic birefringent “Maltese crosses” appear in the urinary sediment. Proteinuria, isosthenuria, gradual deterioration of renal function, and development of azotemia occur in the second to fourth decades of life. Cardiovascular findings may include hypertension, left ventricular hypertrophy, anginal chest pain, myocardial ischemia or infarction, and congestive heart failure. Mitral insufficiency is the most common valvular lesion. Abnormal electrocardiographic and echocardiographic findings are common. Cerebrovascular manifestations result primarily from multifocal small vessel involvement. Other features may include chronic bronchitis and dyspnea, lymphedema of the legs without hypoproteinemia, episodic diarrhea, osteoporosis, retarded growth, and delayed puberty. Death most often results from uremia or vascular disease of the heart or brain. Before hemodialysis or renal transplantation, the mean age of death for affected men was 41 years ([7]).

Atypical male variants with residual a-galactosidase A activity who are asymptomatic or mildly affected have been described whose manifestations include late-onset, isolated cardiac disease and proteinuria but normal renal function for age. These cardiac variant patients do not have the early classic manifestations such as angiokeratoma, acroparesthesias, hypohidrosis, corneal opacities, and so forth. They have cardiomegaly, usually involving the left ventricular wall and interventricular septum, and electrocardiographic abnormalities consistent with cardiomyopathy. Others have had hypertrophic cardiomyopathy, myocardial infarction, or both. They develop proteinuria with age but usually have normal renal function and a normal lifespan.

Hematologic Features

Anemia that is probably due to decreased erythrocyte survival has been noted. A decreased serum iron concentration, normal erythrocyte fragility, and an elevated reticulocyte count also have been reported. Increased platelet aggregation and a high concentration of ß-thromboglobulin have been described. Lipid-laden foamy-appearing macrophages are present in the bone marrow.

Diagnosis

The diagnosis in classically affected males is most readily made from the history of painful acroparesthesias, hypohidrosis, the presence and distribution of the skin lesions, and the observation of the characteristic corneal opacities and lenticular lesions ([8]). The disorder is often misdiagnosed as rheumatic fever, erythromyalgia, or neurosis. The skin lesions must be differentiated from the benign angiokeratomas of the scrotum (Fordyce disease) and from angiokeratoma circumscriptum. Angio-keratomas identical to those of Fabry disease have been reported in fucosidosis, aspartylglycosaminuria, late-onset GM_1 gangliosidosis, galactosialidosis, a-*N*-acetylgalactosaminidase deficiency, and sialidosis. The diagnosis of the mild cardiac variants should be considered in individuals who present with left ventricular hypertrophy, cardiomyopathy, or both. The diagnosis of classic and variant patients is confirmed biochemically by markedly decreased a-galactosidase A activity in plasma, isolated leukocytes, or cultured fibroblasts or lymphoblasts.

Heterozygous females may have corneal opacities, isolated skin lesions, and intermediate activities of a-galactosidase A in plasma or cell sources. Rare female heterozygotes may have manifestations as severe as those in affected males. However, at-risk females in families affected by Fabry disease who are asymptomatic should be optimally diagnosed by the direct analysis of their family's specific mutation. Prenatal detection of affected males can be accomplished by demonstrating deficient a-galactosidase A activity or by detecting the family's specific gene mutation in chorionic villi obtained in the first trimester of pregnancy or in cultured amniocytes obtained by amniocentesis in the second trimester.

Treatment

Until recently, treatment for Fabry disease has been nonspecific and limited to supportive care. These measures included the use of phenytoin, carbamazepine, or both, which has been shown to decrease the frequency and severity of the chronic acroparesthesias and the periodic crises of excruciating pain. Renal transplantation and long-term hemodialysis also have become life-saving procedures for patients with renal failure. More recently, clinical trials with recombinant a-galactosidase (Fabrazyme, Genzyme Corporation, Cambridge, MA; Replagal, TKT Corporation, Cambridge, MA) have demonstrated the safety and effectiveness of enzyme replacement therapy for Fabry disease. A phase I/II dose-escalation trial demonstrated that the enzyme was well tolerated, and its use resulted in histologic, biochemical, and ultrastructural reductions in the levels of accumulated tissue globotriaosylceramide ([5]). The results of a recent phase III, multicenter, double-blind, randomized, placebo-controlled study of 58 patients with Fabry disease, half of whom received recombinant a-galactosidase and the other half placebo, showed that the treatment group had very significant clearance of globotriaosylceramide from the vascular endothelial cells of the kidney, heart, and skin ([9]). The placebo group had no change. After 20 weeks, patients in the placebo group were switched to recombinant a-galactosidase, and all had clearance to normal or near-normal levels of the vascular endothelial globotriaosylceramide in the kidney and skin and significant reductions in the heart. These studies demonstrated the safety and effectiveness of enzyme replacement therapy for this disease. Expert recommendations for the treatment of patients with Fabry disease were published recently ([8]).

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a disorder characterized by proliferations of cells in the mononuclear phagocyte system. Since the first case was described more than a century ago ([1]), LCH has often been a source of confusion. This is perhaps best demonstrated by the several labels given to the disorder during the past 100 years. Since 1985, *Langerhans cell histiocytosis* has been the preferred term ([2] , [3]), replacing *histiocytosis X*, which was coined in 1953 ([4]). The *X* demonstrated the lack of knowledge about the etiology and pathophysiology of LCH, and about how the different clinical syndromes were related. The term *histiocytosis X* did serve to bind the syndromes, which included Hand-Schüller-Christian syndrome, Letterer-Siwe disease, eosinophilic granuloma, Hashimoto-Pritzker syndrome ([5]), self-healing histiocytosis ([6]), and pure cutaneous histiocytosis ([7]), into one clinical entity. The term *Langerhans cell histiocytosis* was proposed to reflect the central role of the Langerhans cell in these diseases. LCH also distinguishes these disorders from other histiocytic syndromes, which include primary and secondary lymphohistiocytoses, and neoplastic disorders such as acute monocytic leukemia, malignant histiocytosis, and true histiocytic lymphoma ([3]). This chapter focuses on LCH.

HISTORY

The clinical triad of defects in membranous bone, exophthalmos, and polyuria in children, which became known as *Hand-Schüller-Christian disease* ([8]), was described in 1921 in a review by Hand ([9]). Hand described the first six cases, including those of Christian, Schüller, and his own first case reported in 1893 ([1]). All six patients had hepatosplenomegaly, lymphadenopathy, and bone lesions. However, not all had exophthalmos and polyuria. Attempts to link the disorder to xanthoma tuberosum, lipid storage disease, and the xanthomatoses proved unsuccessful, and to this day, no evidence exists that a specific biochemical defect is responsible for the condition. However, the foamy or xanthoma cell came to be regarded as a pathognomonic feature of the syndrome ([10]).

A different syndrome, consisting of fever, bilateral otitis media, hepatosplenomegaly, and adenopathy in a young infant who died was described by Letterer in 1924 ([11]). In 1933, Siwe described a 16-month-old girl who died after a 3-month illness characterized by fever, hepatosplenomegaly, lymphadenopathy, neutrophilia, and a destructive lesion in her fibula ([12]). At autopsy, massive infiltrates of large cells resembling histiocytes were found. Siwe reviewed five other cases from the literature (including that of Letterer) and concluded that they constituted a single clinical entity ([12]).

In 1940, two groups of investigators described a syndrome in which a characteristic feature was infiltration of bone by eosinophilic granulomas ([13] , [14]). In 1942, Green and Farber described a series of patients with eosinophilic granulomas of bone, which usually healed promptly after irradiation or curettage ([15]). They noted that these cases shared pathologic features similar to those of the Letterer-Siwe and Hand-Schüller-Christian syndromes. In 1953, because of the similarity of the histiocytes observed in these three disorders, Lichtenstein combined them into a single entity called *histiocytosis X* to indicate their unknown cause ([4]). The recognition that these three disorders were related was an important contribution. Understanding of these disorders improved, however, and the term *Langerhans cell histiocytosis* was proposed in 1985 ([3]). LCH also differentiates this group of diseases from reactive and malignant histiocytic processes of the mononuclear phagocyte system.

EPIDEMIOLOGY

Even with advances in the understanding of the central role played by the Langerhans cell in LCH, little is known about the etiology of LCH. The annual incidence has been estimated to be 4 per million ([16]), and there seems to be a slight predominance of cases in males ([17] , [18] , [19] and [20]). Most cases of LCH with multisystem disease occur before 2 years of age ([21] , [22]), whereas half of all cases in which LCH is limited to a single bony lesion occur after age 5 years ([23]). In an exploratory case-control study comparing 177 children with LCH to children with cancer and community controls ([20]), LCH was associated with a family history of benign tumors and less strongly with feeding problems during infancy. Other factors associated with LCH in this study were maternal urinary tract infections during pregnancy and blood transfusions during infancy. Factors not associated with LCH were the typical childhood viral infections and medication use. In a case-control study of 459 children with LCH, which compared risk factors in children with LCH to those in both community and cancer controls ([24]), LCH was associated with neonatal infections, solvent exposure, and thyroid disease in the proband or the family. Childhood immunizations appeared to be protective. Links with both solid tumors and leukemia have also been documented ([25]). Although some cancers after LCH may be secondary to therapy, this does not explain all cases because in some, cancer preceded the diagnosis of LCH. Patients with LCH may have a predisposition to cancer and vice versa. Patients with multisystem LCH are more likely to have chromosomal instability ([26]); this suggests a genetic predisposition to LCH, but further studies are needed to identify such a predisposition.

PATHOLOGY AND PATHOPHYSIOLOGY

The basic histologic lesion in LCH is granulomatous, with lesions containing histiocytes, mature eosinophils, and lymphocytes ([27]); other cells present may include giant cells, neutrophils, and plasma cells. Initially, lesions are proliferative and dominated by histiocytes, some of which are Langerhans cells. Although mitotic figures may occasionally be identified, the histiocytes are not neoplastic by histologic criteria. As lesions progress, necrosis may develop, and the number of eosinophils and phagocytic cells containing cellular debris increases. Ultimately, xanthomatous changes and fibrosis may occur, and late in the course of disease, Langerhans cells may no longer be demonstrable. Multinucleated giant cells occasionally are prominent, especially in bone and lymph nodes. The histologic findings do not correlate with the extent or aggressiveness of disease ([22] , [28]).

The Langerhans cell is the sine qua non of the diagnostic lesion. These pathologic Langerhans cells or LCH cells are similar to the normal Langerhans cells found in skin. Although its demonstration is essential for diagnosis ([22]), the Langerhans cell may constitute no more than a small proportion of histiocytes within lesions ([29]). Viewed by light microscopy, these cells appear as large mononuclear cells with few cytoplasmic vacuoles and little or no phagocytic material ([30]). The nuclei are irregularly shaped and contain a fine chromatin pattern. Electron microscopic or immunohistochemical studies may be required to identify Langerhans cells with confidence. The former demonstrate structures known as *Birbeck granules* (Langerhans bodies, X granules) ([29] , [30] and [31]), rod-shaped organelles with a central striation and occasional terminal vesicular dilation, giving them a tennis racket appearance (Fig. 66.1). They are thought to be produced by invagination of the cell membrane, and their function is not known. The percentage of histiocytes with Birbeck granules is not prognostic ([32]). The other feature that conclusively establishes the diagnosis of LCH is the demonstration of the CD1a antigen on the surface of LCH cells by immunohistochemical staining ([26]). Other distinctive features of Langerhans cells that can be demonstrated with immunohistochemical techniques include the demonstration of S-100 protein ([29] , [33]), Ia-like antigen ([34]), and membrane-bound adenosine triphosphatase activity ([35]). Paraffin-embedded tissue can be used to demonstrate S-100 protein ([33]) and a distinctive distribution of peanut agglutination ([36] , [37]). The cell surface also expresses CD101; this may be of use in frozen sections ([38]).

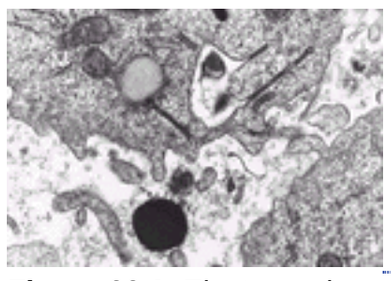

Figure 66.1. Electron micrograph of Langerhans cells from a bone lesion demonstrating characteristic Birbeck granules with a trilaminar structure. (Magnification ×45,000; courtesy of Roma Chandra.)

Langerhans cells are classified as dendritic cells because of their capacity to form long cytoplasmic extensions through which they establish intimate contact with other cells. The presence of fascin, a highly selective marker of dendritic cells, on the surface of Langerhans cells confirms their derivation from dendritic cells ([39]). Langerhans cells are found primarily in normal epidermis, but also are evident in lymph nodes and spleen. A hematopoietic progenitor of Langerhans cells has been identified in normal bone marrow ([40]). In the skin, Langerhans cells form a trap for external contact antigens and are involved in delayed hypersensitivity. Despite low phagocytic activity, they fix antigens for presentation to other cells, especially T lymphocytes ([41] , [42]). In tissue culture, Langerhans cells purified from bony LCH lesions secrete interleukin-1 (IL-1) and prostaglandin E_2, both of which induce bone resorption *in vitro* ([43]). These lesions also secrete angiotensin-converting enzyme, transforming growth factor-ß1 and IL-2 ([44]). These mediators are probably responsible for the osteolytic lesions that are a prominent clinical feature of LCH.

The focal accumulation of Langerhans cells, macrophages, lymphocytes, and eosinophils suggests that LCH is immunologically mediated. This reasoning is supported by both histologic abnormalities of the thymus and disturbances of immunoregulation in patients with active disease ([45]). Thymic abnormalities were noted by Letterer in his initial description of the disorder, later known as Letterer-Siwe disease ([11]). Abnormalities noted on pretherapy biopsy samples and postmortem material include dysmorphic changes, dysplasia, and nonspecific involution ([46] , [47] , [48] and [49]). In patients with LCH, the number of normal thymocytes (expressing CD6) and late differentiating suppressor lymphocytes (expressing CD8) is decreased ([50]). These abnormalities are noted even when the disease is limited in its distribution ([50]). Qualitatively similar alterations have been described in association with combined immunodeficiency ([51]), graft-versus-host disease ([52]), and acquired immunodeficiency syndrome ([53]).

Recognition of the possible pathogenic significance of thymic abnormalities prompted several studies of T lymphocytes in blood. The demonstration of decreased numbers of H_2 receptors on blood lymphocytes suggested loss of T-suppressor cells ([49]). This loss was confirmed by quantitation of T-cell subsets in patients with active disease. Both the relative and absolute numbers of suppressor T lymphocytes ($CD8^+$ cells) are decreased, resulting in an increase in the T4 to T8 ratio ([54]). Suppressor cell activity as measured by the concanavalin A and indomethacin stimulation assays also is poor ([54]). That T-suppressor cell deficiency may be causally related to a functionally abnormal thymus is suggested by the normalization of T4 to T8 ratios with thymic extract ([49]) and a synthetic peptide with thymic hormone activity ([55]). Moreover, the apparent ability of crude thymic extract to reverse disease activity in some patients suggests that the T-cell abnormalities may be of primary pathogenic significance ([49]). However, deficiency of blood T-suppressor lymphocytes is not specific to LCH ([56]).

Although less consistent, other abnormalities in immune regulation also have been described, including hypergammaglobulinemia ([57]), deficiency in antibody-dependent monocyte-mediated cytotoxicity ([58]), and abnormal *in vitro* response to mitogens and antigens ([47]). However, most investigators note normal mitogen-induced responses and normal delayed hypersensitivity ([59] , [60]). A deficiency in helper T cells rather than suppressor T cells was noted in one patient with LCH ([61]). Also, several cytokines are increased in LCH ([62]). Cytokines serve as mediators of inflammation, regulators of lymphocyte growth and differentiation, and activators of specialized effector cells. Cytokines that have been demonstrated to be increased in the serum of LCH patients include granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-8, and tumor necrosis factor-a. These cytokines are related to local activation of T lymphocytes and other inflammatory leukocytes. In addition, GM-CSF receptors are expressed by Langerhans cells ([63]). GM-CSF induces Langerhans cell proliferation and activation *in vitro*, and serum levels of GM-CSF have been correlated with the extent of disease ([63]). Thus, GM-CSF stimulation may be a critical element in the pathogenesis of LCH.

The link between proliferation of Langerhans cells and immune dysfunction has not entirely been worked out. One suggestion is that the disorder results from a physiologically appropriate response of the Langerhans cell to an external antigen or neoantigen, possibly infectious in origin ([33]). However, the lack of seasonal variation or geographic clustering argues against an infectious basis ([64]). In addition, no direct evidence for a viral etiology (viral particles or nuclear material) in LCH lesions has been demonstrated ([65] , [66]). Alternatively, LCH may result from an appropriate response of the Langerhans cell to abnormal signals from other cells in the immune system, perhaps from T lymphocytes. In either event, deficiency of T-suppressor cells may disrupt the mechanism for termination of immune responses. Failure of this homeostatic mechanism could result in unrestrained macrophage proliferation. Patients with interferon-? deficiency present with findings that mimic LCH ([67]). The Langerhans cells in LCH differ significantly from the Langerhans cell that normally occurs in the skin ([68]). Abnormal cellular adhesion molecules in LCH cells, suggested by the presence of CD2, CD11a, CD11b, and CD11d, may contribute to the migration of Langerhans cells into LCH lesions, as well as their abnormal persistence and proliferation ([69]). Compared to normal Langerhans cells, LCH cells are defective in their alloantigen-presenting activity ([70]).

Whether LCH is primarily a reactive or neoplastic process has long been debated. The predominant theory has been that LCH is a reactive process to an unknown stimulus ([71]). However, in 1994 two groups showed that the lesional cells are clonal ([72] , [73]); clonality occurred in patients with all forms of LCH, including acute disseminated LCH and unifocal LCH, and in those with intermediate forms of the disease. T cells within LCH lesions were polyclonal ([62]). However, at least some cases of pulmonary LCH are not clonal ([74]). Although the clonality of LCH cells has fueled the argument that LCH may be a neoplastic disorder, the debate continues.

CLINICAL FEATURES

LCH can present along a continuum of illness, ranging from indolent to explosive disease. In some disorders, pathologic lesions are solitary, whereas in others they are widely disseminated. Moreover, the distribution of lesions in a given patient may vary considerably over time. Although LCH can occur at any age, it occurs with greatest frequency in infants and children. The median age at diagnosis for all disease variants is 2 to 3 years ([75] , [76]). The acute disseminated form of the disease characteristically occurs in children younger than 3 years of age ([77]). The more indolent forms of LCH occur primarily in older children and young adults ([13] , [17]). The most commonly involved organ in adults is bone, often accompanied by an adjacent soft-tissue mass. Other organs that are involved less often in adults include lungs and pituitary gland ([78]). In adults, multisystem disease, including liver, lymph node, and bone marrow involvement, is extremely rare. Males are affected more often than females ([17] , [19] , [79] , [80] and [81]); in one large series of patients with localized bone disease, the male to female ratio was 1.8:1.0 ([82]), and in another, with all types of LCH, males outnumbered females by 3:1 ([81]).

The traditional classification of clinical variants was based on patterns of organ involvement ([4] , [8] , [77]). Eosinophilic granuloma was used to describe a syndrome characterized by single or multiple bone lesions in the absence of visceral involvement ([13]). When granulomas involved liver, spleen, lymph nodes, skin, central nervous system (CNS), or bone marrow as well as bones, the disorder was called *Letterer-Siwe disease* ([11] , [12]). The triad of multiple bone lesions, exophthalmos (resulting from retro-orbital granulomas), and diabetes insipidus (DI) (the result of hypothalamic or pituitary involvement) constituted Hand-Schüller-Christian disease (Fig. 66.2 and Fig. 66.3) ([9]). The separation of eosinophilic granuloma involving bone from syndromes characterized by visceral dissemination proved to be useful prognostically. However, the distinction between Letterer-Siwe disease and Hand-Schüller-Christian disease was often subtle and clinically irrelevant. The current classification is based on the number of organ systems involved and the number of sites involved within an organ system. The main classifications of disease are unifocal eosinophilic granuloma (i.e., single-system, single-site disease, usually in bone), multifocal eosinophilic granuloma (i.e., single-system, multiple-site disease, usually in bone), and acute disseminated histiocytosis (i.e., multisystem disease). The presence and degree of organ dysfunction are important distinctions in those with multisystem disease ([83]).

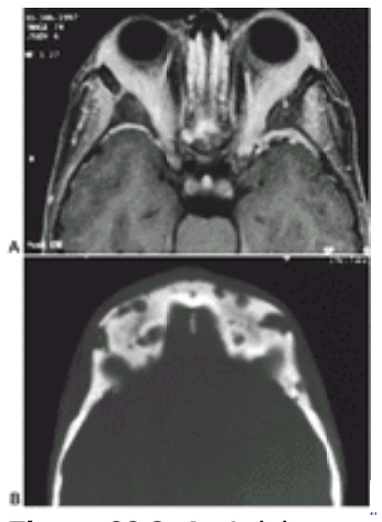

Figure 66.2. A: Axial magnetic resonance image of the orbits in a 4-year-old boy with recurrent disseminated Langerhans cell histiocytosis and marked proptosis. There are large orbital soft-tissue masses bilaterally. **B:** Computed tomography scan of same patient showing marked bony erosion of skull and orbit.

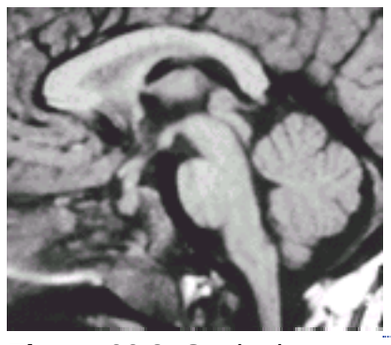

Figure 66.3. Sagittal magnetic resonance imaging scan showing thickened pituitary stalk in the same patient shown in Figure 66.2. He had a long-standing history of diabetes insipidus.

Bone is the most commonly involved organ, with the skull being the most commonly involved site in both children and adults ([84]). Unifocal eosinophilic granuloma of bone is the most common form of the disease ([10], [85]). Multifocal bone involvement may or may not be associated with visceral disease. The bones most commonly affected are shown in Table 66.1. Characteristically, patients note mild discomfort at the site of bone involvement. However, skull lesions are often painless and are found only because of a soft-tissue mass over the bony defect. Mandibular lesions are responsible for premature loss of teeth and faulty dentition. Involvement of the Petrus ridge of the temporal bone and mastoid is common, predisposing to chronic otitis media. Vertebral lesions pose special problems because of the risk of injury to the spinal cord. Vertebral collapse gives rise to vertebral plana ([86]). Extension of granulomas into the spinal space may compress the cord, causing permanent neurologic damage ([87]). Recurrent bony lesions in children are often associated with DI ([84]).

From Lieberman PH, et al. A reappraisal of eosinophilic granuloma of bone, Hand-Schüller-Christian syndrome and Letterer-Siwe syndrome. Medicine 1969;48: 375, with permission.

Radiographically, skeletal lesions are characterized by sharply demarcated rarefactions of the medullary portions of bone, producing a “punched out” appearance (Fig. 66.4) ([10], [84], [85]). Reactive sclerosis in surrounding uninvolved bone is unusual at diagnosis, but when present, signifies that healing has begun. Both tables of the skull characteristically are involved, the outer more so than the inner. Erosion of mandibular bone around unerupted teeth give them the appearance of floating in space. Skeletal lesions are well delineated with conventional radiography, computed tomography, and magnetic resonance imaging ([88]). Radionuclide studies, on the other hand, often are falsely negative ([89], [90] and [91]). As healing occurs, the sharp endosteal margins become less distinct, and sclerosis is often seen.

Figure 66.4. Skull radiograph showing active osteolytic lesions in a patient with disseminated Langerhans cell histiocytosis. Note absence of reactive sclerosis.

Head and neck involvement is common in young children, especially in those with multifocal lesions of the skull. Gingival swelling and inflammation, usually associated with cervical adenopathy, often are the first manifestations of disease. Premature eruption or loss of teeth and breakdown of the lower alveolar ridge result from involvement of the mandible ([92], [93] and [94]). Mandibular lesions may be palpable and painful, giving rise to facial swelling ([95]). The maxilla and upper gingival ridge are involved less often. Cervical adenopathy generally accompanies all forms of oral involvement.

Skin involvement is a common feature of acute disseminated histiocytosis ([96]). The lesions are vesiculopustular and may have a hemorrhagic crust. They are similar

in appearance to those of seborrheic dermatitis. LCH is often suspected after a seborrheic rash fails to respond to treatment. The rash has a predilection for the scalp, postauricular areas, and diaper area (Fig. 66.5). The back, axillae, and intertriginous areas also may be involved ([97], [98]). With advanced stages of the disease, the entire integument may be affected. Breakdown of severely affected areas is common, and concurrent thrombocytopenia imparts a hemorrhagic component to the rash.

Figure 66.5. Erythematous maculopapular rash in a boy with disseminated Langerhans cell histiocytosis. See Color Plate. (From Esterly NB, Maurer HS, Gonzalez-Crussi F. Histiocytosis X: a seven year experience at a children's hospital. J Am Acad Dermatol 1985;13:481–496, with permission.)

A rash indistinguishable from that seen in acute disseminated histiocytosis may occur as a congenital, self-limited phenomenon not associated with skeletal or visceral disease. This form of histiocytosis has been called *congenital self-healing histiocytosis* or *Hashimoto-Pritzker syndrome* ([5], [99]). The lesions are present at birth or appear within the first 2 or 3 weeks of life. They are most numerous over the scalp and face, but also may extend over the trunk and proximal extremities. Mucous membranes are spared. Langerhans cells present in biopsy material have the same immunophenotypic characteristics as those in the other variants of histiocytosis, although they contain fewer Birbeck granules ([99]). The lesions undergo spontaneous regression, with complete healing by the time the patient is 3 to 4 months of age. The prognosis is uniformly excellent without therapy.

CNS involvement is increasingly appreciated as a problem in LCH ([100], [101]). CNS involvement occurs by contiguous spread of skull lesions into brain substance or by granulomatous infiltration of deep structures. The disease demonstrates a predilection for the hypothalamic nuclei ([102]) and cerebellum ([103], [104]), although focal lesions may occur in the temporal lobe, occipital lobe, and spinal cord. Rarely, CNS lesions are found in patients who have no other evidence of histiocytosis. Focal cranial nerve involvement occurs rarely ([105]). Neurologic signs and symptoms include ataxia, nystagmus, dysmetria, seizures, dysphagia, and spastic paraparesis ([106], [107]). DI resulting from infiltration of the hypothalamus or pituitary stalk is common. Whereas mass lesions are satisfactorily visualized by computed tomography or magnetic resonance imaging, infiltrative lesions within the hypothalamus and elsewhere often are of similar density to adjacent brain tissue and produce little or no mass effect. Some of these lesions may be seen with magnetic resonance imaging ([99]). CNS involvement may leave survivors with permanent sequelae ([100], [101], [108]).

Of the endocrinopathies associated with LCH, DI is the most common ([109]), LCH is a common cause of DI in both adults and children ([110]). DI is caused by infiltration of the hypothalamus, pituitary stalk, or posterior pituitary by Langerhans cells. The prevalence of DI in large series of patients ranges from 10 to 50% ([10], [17], [77], [107], [109], [111], [112]). The cumulative risk of DI in 119 children with histiocytosis studied prospectively was 11% at 5 years by life-table analysis ([111]), substantially lower than the 42% at 4 years reported in an earlier study ([113]). DI is more common in patients with multisystem disease and in those with proptosis ([113]). DI is not a complication of unifocal bone disease. Characteristically, its onset is after the diagnosis of LCH is made; symptoms occur within 2 years of diagnosis in most children and rarely, if ever, after 4 to 5 years ([113]). Although most affected patients have complete absence of antidiuretic hormone, partial deficiency may occur. Progression from partial to complete DI may occur, and once complete DI has developed, it cannot be reversed ([114]).

Growth retardation resulting from growth hormone (GH) deficiency is another complication of LCH ([109], [111], [115]). Although GH deficiency is usually due to involvement of the hypothalamus or anterior pituitary by Langerhans cells ([116]), radiation therapy given for skull lesions may also contribute ([117]). Prospective studies of prepubertal children indicate that GH deficiency is less common than previously thought ([115], [117]). In 82 children with LCH and GH deficiency, GH replacement was safe and effective ([118]).

Thyroid involvement by histiocytosis gives rise to goiter and may lead to hypothyroidism ([97], [115]). Obstruction of the upper airway by diffuse enlargement of the thyroid gland has been described ([119]). Most children with thyroid involvement have DI and other evidence of disseminated disease ([109]).

Enlargement of the liver, often associated with abnormal liver function, is observed in many children with the disseminated form of LCH ([27], [120], [121] and [122]). In some patients, liver involvement leads to portal cirrhosis or intrahepatic cholestasis ([122]). For reasons that are not clear, death from progressive liver failure is observed less often now than previously, although liver transplant is sometimes required ([122]). Tissue from liver biopsies obtained from children with hepatomegaly infrequently shows the infiltrates of Langerhans cells, eosinophils, and lymphocytes that are hallmarks of the disease in other organs. Instead, subtle changes in the portal triads are observed, including triaditis, bile duct proliferation, and fibrosis ([122], [123]). Patients with triaditis alone at diagnosis are less likely to have abnormal liver function or progressive liver disease than those with fibrohistiocytic or cirrhotic changes. Persistent abnormality of liver function is a well-recognized adverse prognostic indicator ([17], [19], [75], [76], [124]).

Involvement of lymph nodes and spleen is often a feature of disseminated disease. Lymph nodes may be involved because of contiguous bone or skin disease or as a result of widespread histiocytic dissemination. Node enlargement occurs because of sheets of Langerhans cells that often have a syncytial arrangement ([27]). Splenomegaly is caused by portal hypertension or involvement of the spleen by large numbers of histiocytes. Curiously, Birbeck granules are rarely seen in otherwise characteristic Langerhans cells in the spleen and liver ([27]).

Although not common, the lungs may be involved with disseminated histiocytosis ([4], [125]). As with other forms of disseminated disease, lung involvement occurs primarily in infants and young children. In contrast, primary pulmonary histiocytosis is principally a disease of young and middle-aged adults ([126], [127], [128] and [129]), although it does occur in children ([114], [130]); smoking is often associated with pulmonary LCH ([131]). Affected patients are without apparent multisystem disease at diagnosis; with further evaluation, however, some patients have asymptotic bone lesions ([130], [132], [133]), and as many as 10% subsequently develop DI ([132]). Signs and symptoms of pulmonary involvement may be subtle or may include growth failure or weight loss, dyspnea, tachypnea, and hemoptysis. Recurrent pneumothoraces occur in as many as 20 to 25% of cases ([133]). Lung involvement is characterized radiographically by diffuse micronodular densities with cyst formation, sometimes giving rise to a picture of “honeycomb lung.” Lesions are usually prominent in the perihilar regions and the upper lung fields. Costophrenic angles are usually spared, and enlargement of hilar nodes is unusual. Permanent pulmonary sequelae often occur ([134]), and reactivation in the lungs may be associated with smoking ([135]).

Bone marrow involvement by Langerhans cells has been described most often in infants with disseminated disease ([10], [17], [19], [96], [136], [137]). It is characterized by anemia, neutropenia, and thrombocytopenia, occurring singly or together. Erythrophagocytosis may rarely be a factor in the pathogenesis of anemia ([138]). Because bone marrow and splenic involvement often occur together, splenic sequestration of blood cells may further exaggerate the cytopenia of bone marrow involvement.

PROGNOSIS

For most patients with LCH, the prognosis is excellent. Although LCH may wax and wane over many years, most patients improve over time. However, patients with

multisystem disease may experience organ failure, which can be fatal.

Most patients with unifocal bone disease experience complete resolution of lesions with or without treatment. Progression of bone erosion and recurrences at new sites are the exception rather than the rule ([17], [72], [139]). In the event of recurrence, the sites almost always are limited to the skeleton. In contrast, disease that is multifocal at the time of diagnosis usually is chronic and is characterized by one or more recurrences after disease control. In one large series, of patients who experienced disease exacerbations, final recurrences occurred within 1 year in 19%, between 1 and 4 years in 66%, and after more than 4 years in 15% ([75]). In another series, 72% of patients who initially responded to treatment experienced recurrent LCH 2 months to more than 5 years after cessation of therapy, and most recurrences were in previously uninvolved sites ([17]). Young children, especially those younger than 2 years of age at diagnosis, are at particular risk for multiple relapses ([17], [19], [123]). However, in most patients the disease appears to eventually burn out ([140]). On the other hand, approximately one-third of adults with pulmonary LCH die from the disease ([129]). After disease resolution, LCH survivors may be left with permanent complications, including DI, pulmonary difficulties, neurologic complications, neuropsychological impairment, dental problems, chronic otitis, or hearing impairment.

Several staging or scoring systems have been proposed as having prognostic and therapeutic relevance. Most cite age (age younger than 2 years being a liability), extent of disease, and the function of involved organs as the important prognostic variables. Perhaps the most widely accepted system is that proposed by Lahey, who assigned a point for each functional or anatomic abnormality involving the skin, liver, spleen, lymph nodes, lung, pituitary, skeleton, or bone marrow (i.e., anemia, leukopenia, or thrombocytopenia) ([19]). A nearly linear relationship between score and survival was observed. Subsequent staging systems introduced additional variables ([21], [22], [77], [141]). Although more elaborate, they did not have greater clinical utility. All staging attempts are confounded by what appears to be a change in the natural history of extraskeletal histiocytosis. Not only is acute disseminated histiocytosis less common now than formerly, but also it is lethal less often. In contrast to earlier analyses ([19], [77], [142]), recent experience fails to confirm a relationship between the extent of disease at diagnosis and survival ([17], [75], [143]). Age also may be of less prognostic significance ([17], [75]). The most important adverse prognostic factor clearly is functional compromise of the organs affected by histiocytosis ([17], [75], [124]). Jaundice related to liver involvement and cytopenias resulting from bone marrow invasion by histiocytes are associated with high mortality rates ([17], [124]). Disease limited to the skeleton is associated with a uniformly favorable prognosis ([17], [77], [82], [144]), and the number of bony lesions does not affect survival ([7], [17]). Skin involvement in the absence of deep visceral lesions also confers a good prognosis.

DIAGNOSIS

The clinical and radiographic features of LCH are distinctive enough to suggest the diagnosis in most patients. However, the diagnosis must be made pathologically, and for a definitive diagnosis, the presence of Birbeck granules or the presence of CD1a on the surface of LCH cells must be demonstrated.

Assessment of the extent of disease is critical. To help standardize the workup and management of LCH patients, the Histiocyte Society has published guidelines on how to evaluate and follow patients ([145]). Bony lesions may be diagnosed by either bone scan or skeletal survey. Each modality has been shown to discover lesions missed by the other. However, radionucleotide bone scan may miss osteolytic lesions that do not have any osteoblastic characteristics. This is particularly true for skull lesions ([146]). Other studies required include a chest radiograph, blood counts, assessment of liver function, and determination of renal concentrating ability. A bone marrow examination is required if cytopenias exist, and pulmonary function studies are helpful in documenting pulmonary involvement. Although not required to evaluate disease, some authors have recommended studies of T- and B-cell numbers, T-cell subsets, and lymphocyte function. New imaging modalities, including positron emission tomography and octreotide scans, may be useful in LCH, but they require additional study ([147], [148]).

MANAGEMENT AND TREATMENT

The first principle to remember when developing a treatment plan for a patient with LCH is that this is not a malignant disorder. Management is dictated by the likely natural history of the disease based on the location and extent of lesions and by the presence of specific organ involvement and/or dysfunction. Given that LCH tends to improve with time, most patients do not require treatment aimed at ablating the disease. Treatment decisions should be based on the number of systems involved and on whether a particular lesion is likely to result in disability. Children with single-system disease, particularly if they have a solitary lesion of bone (e.g., eosinophilic granuloma of bone), may require no therapy other than curettage ([139]). However, some patients have aggressive disease, warranting treatment similar to that required for neoplastic diseases ([125]). Also, a single patient may require different approaches at different points in time. Rarely are aggressive approaches, such as bone marrow or liver transplantation, justified.

Because unifocal bone disease is associated with a uniformly excellent prognosis, therapy with potential late effects should be avoided. The surgical procedure required for diagnostic purposes often is definitively therapeutic as well. Bone lesions are treated effectively with curettage ([139]). Lesions other than those for which curettage is performed for diagnostic purposes often heal spontaneously ([139], [149]). Lesions that progress or recur; those that threaten an important function, such as sight or hearing; and those that pose a risk of pathologic fracture or future disability may be treated effectively with low-dose radiotherapy. Doses of 600 to 1000 cGy in three to five fractions effect local control in most patients ([77], [143], [150], [151]). Lesions in weight-bearing sites, such as the neck of the femur, may require curettage and autologous bone grafting. Some advocate steroid injection into the lesion ([152]); however, the benefit of this treatment has never been proved in a randomized fashion. Skin lesions respond at least temporarily to radiation with ultraviolet light ([153]), and oral lesions may need surgery only ([154]).

Systemic therapy is required for soft-tissue disease and for multifocal skeletal disease that is progressive or recurrent. A notable exception is isolated histiocytosis of the skin in infants, a condition that regresses spontaneously ([5], [99], [155], [156]). Approximately 50% of patients requiring systemic therapy respond to corticosteroids alone ([157]). Because of the toxicity of corticosteroids when used for more than brief periods, however, other chemotherapeutic agents are now the mainstay of management. Vinblastine, vincristine, 6-mercaptopurine, methotrexate, alkylating agents, anthracyclines, and etoposide, singly or in combinations, are effective in controlling LCH ([157], [158]). Although multiagent regimens appear to have no advantage over monochemotherapy for many patients ([159], [160]), people with liver, lung, or bone marrow dysfunction probably are best treated with combination chemotherapy ([76]). In a clinical trial in which patients were stratified by risk, treatment included induction chemotherapy with vinblastine, etoposide, and prednisone followed by maintenance chemotherapy with etoposide, vinblastine, prednisone, 6-mercaptopurine, and methotrexate ([124]), two-thirds of those with organ dysfunction achieved a complete remission, as did approximately 90% of those with either multisite bony disease or soft-tissue disease without organ dysfunction. The Histiocyte Society has conducted multinational randomized clinical trials in LCH ([83]). In the first international trial (LCH I) ([83]), 143 patients were randomized to receive 24 weeks of vinblastine (6 mg/m ^{2} intravenously weekly) or etoposide (150 mg/m ^{2}/day intravenously for 3 days, every 3 weeks); all patients received a single dose of steroids. Both of those monotherapies were equivalent. Due to the risk of secondary leukemias with etoposide, subsequent studies have been built from the vinblastine arm. One robust finding in this study was that the response at 6 weeks was strongly prognostic, regardless of initial treatment. However, LCH I did not produce superior results compared to the earlier DAL studies ([161]). Survival was similar, but the DAL studies ([124], [161]) had superior reactivation rate and reactivation rate interval and less permanent disabilities. In most patients, disease manifestations are reversed with therapy that is far less intensive than that used for neoplastic disease. Courses of chemotherapy are generally limited to 3 to 8 months. As noted previously, multiple courses of treatment may be required for recurrences noted once therapy is discontinued. DI is not ameliorated by chemotherapy. Although some authors describe reversal of DI with radiotherapy directed to the hypothalamus-pituitary region soon after the onset of symptoms ([150], [159], [162]), the consensus is that radiotherapy, like chemotherapy, is without benefit in this situation ([111], [136], [143], [163]).

The demonstration of deficient suppressor T cells in patients with LCH prompted attempts to reverse the course of the disorder with immunotherapy ([49]). Most early clinical trials involved the use of suppressin, a hormone derived from calf thymus that induces differentiation and maturation of suppressor T cells ([164]). Other immunomodulating agents that have been used successfully in case reports or small case series include interferon alpha ([165]). Cyclosporine had shown some initial promise ([166]) but, when systematically studied in patients with reactivated LCH, did not have sufficient activity to be further developed ([167]). Conversely, the early promise of 2-CDA ([168]) has now been confirmed in several small series ([169], [170], [171] and [172]), and 2-CDA is being further evaluated by the Histiocyte Society ([172]).

Novel agents are needed, including those that might help differentiate the Langerhans cells ([173]). An improved understanding of the biology of LCH might also lead to targeted therapies.

A few patients with recurrent, progressive LCH refractory to conventional therapy have benefited from allogeneic bone marrow transplantation ([174], [175], [176], [177] and [178]

). In addition, a small number of patients have required liver transplantation ([179], [180]).

Infectious Mononucleosis and Other Epstein-Barr Virus–Related Disorders

Epstein-Barr virus (EBV) infects the majority of human individuals but usually results in subclinical infections. EBV has been etiologically linked to a wide spectrum of human disease, but it has been shown to be the etiologic agent in relatively few. Although infectious mononucleosis (IM) is a diagnosis made from a constellation of clinical and laboratory features, EBV has been identified as the etiologic agent. Classically, EBV has been associated with Burkitt lymphoma (BL), nasopharyngeal carcinoma (NPC), and the inherited immunodeficiency, X-linked lymphoproliferative disease (XLP). EBV has also been associated with many human malignancies, such as non-Hodgkin lymphoma (NHL) [B-cell, T-cell, and natural killer (NK)–cell phenotype], Hodgkin disease (HD), leiomyosarcoma, gastric carcinoma, hepatocellular carcinoma, and breast cancer, as well as oral hairy leukoplakia and lymphoproliferative disorders (LPDs) seen in patients with primary or secondary immunodeficiencies. In addition, EBV has been associated with several nonmalignant, but often fatal, human diseases such as virus-associated hemophagocytic syndrome (VAHS) and chronic active EBV infection (CAEBV). The role of EBV in the pathogenesis of these disorders remains to be fully understood. This chapter reviews the biology of EBV and IM in detail. Additionally, other diseases that have been associated with EBV infection are discussed, focusing on data pertaining to the role EBV may play in the pathogenesis.

HISTORICAL BACKGROUND

In the first decade of the twentieth century, several cases of glandular enlargement, sore throat, and increased numbers of mononuclear cells on the blood smear were described by Turk ([1]), Cabot, Marchant, and others ([2]). These cases were sometimes reported as acute leukemia that apparently resulted in spontaneous remission and cure. In the 1920s, Sprunt et al. ([3]) classified these cases and six of their own as *infectious mononucleosis*, emphasizing the peculiar blastlike cells present in the blood. In 1923, Downey et al. published a detailed morphologic description of these cells ([4]).

The search for the infectious agent responsible for IM included bacteria, spirochetes, protozoa, and several viruses ([2]). The relationship between EBV and IM began in 1958 when Denis Burkitt described an unusual, rapidly growing lymphosarcoma in children of Uganda and central Africa ([5]). In March 1961, Dr. Burkitt gave a lecture to medical students at Middlesex Hospital Medical School in London. The title of the lecture was *The Commonest Children's Cancer in Tropical Africa*, and it was about the epidemiology of this lymphoma that now bears his name ([6]). A young doctor named Epstein was in attendance at the lecture and became interested in the possibility of a viral etiology for this tumor. Dr. Epstein made arrangements for Dr. Burkitt to have biopsy specimens sent to his laboratory. For 3 years, Dr. Epstein and his colleagues were unsuccessful in finding viruses in the tumor tissue. However, in 1964, Dr. Epstein reported, along with Achong and Barr, the presence of viral particles in lymphoblasts cultured from tumor biopsies ([7]).

The discovery of EBV as the cause of IM was the result of a chance observation made in 1967 ([8]). The Henles noted that blood taken from a laboratory technician who had contracted IM led to the spontaneous establishment of a lymphoid cell line containing characteristic EBV particles, whereas previous attempts to establish cell lines from this individual's blood had been unsuccessful. They also discovered that sera obtained before the onset of IM had shown anti-EBV titers of less than 1:10 and a negative heterophil response. After the onset of clinical IM, however, anti-EBV and heterophil titers rose. On the basis of these provocative clues, the Henles and associates studied the sera of a number of students from Yale University, where a prospective study of IM had been in progress for many years. In all instances of clinical IM, the anti-EBV and heterophil titers rose together from a negative baseline. Of even greater interest was the observation that the anti-EBV titer remained persistently elevated, in contrast to the transient nature of the heterophil response. Other reports have provided further evidence that EBV is the etiologic agent in the majority of cases of IM ([9] , [10] , [11] , [12] and [13]).

PATHOPHYSIOLOGY OF EPSTEIN-BARR VIRUS INFECTION

EBV is one of eight known human herpesviruses and is subgrouped into the gamma-herpesvirus subfamily. Immature virus particles that measure 75 to 80 nm can be found in both the nucleus and the cytoplasm of infected cells. Mature, fully infectious particles, with a diameter of 150 to 200 nm, are found only in the cytoplasm ([9] , [14]). The infectious virus particle has three components: a nucleoid, a capsid, and an envelope. The doughnut-shaped central core, or nucleoid, contains the viral DNA in linear form. Surrounding the nucleoid is the capsid, which is icosahedral and is made up of hollow, tubular protein subunits called *capsomers*. Finally, the nucleocapsid (the capsid and the contained viral DNA) is enclosed in a protective envelope that is derived either from the nuclear membrane or the outer membrane of the host cell. The envelope contains a number of viral antigens (proteins) that are manufactured and inserted into the host cell membrane before the assembly of virus particles.

The EBV genome (Fig. 67.1) is a double-stranded DNA molecule of approximately 173,000 base pairs (bp) organized into a series of unique coding regions (U1 to U5), divided by interval repeat regions (IR1 to IR4) and terminal repeat (TR) domains ([15]). The genome encodes approximately 100 proteins ([16]). When EBV infects a cell, its linear genome circularizes to form an episome, an extrachromosomal element in the nucleus of the cell ([13] , [17] , [18]). Several of the EBV genes expressed during viral latency and replication are emphasized in Figure 67.1 and Figure 67.2 and are discussed in the section Epstein-Barr Virus Infection.

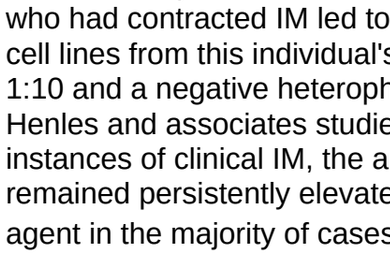

Figure 67.1. Epstein-Barr virus (EBV) genome and its organization. Schematic representation of linear EBV DNA showing the general organization in a series of unique (*U1* to *U5*), internal repeat (*IR1* to *IR4*), and terminal repeat (*TR*) domains. The location of several EBV genes expressed during viral latency and replication

is shown. EBER, EBV-encoded RNA; EBNA, EBV-determined nuclear antigen; gp, glycoprotein; LMP, latent membrane protein; ZEBRA, Z EBV replication activator. [From Tosato G, Tata K, Angiolillo AL, et al. Epstein-Barr virus as an agent of hematological disease. Baillere Clin Hematol 1995;8(1):165–199, with permission.]

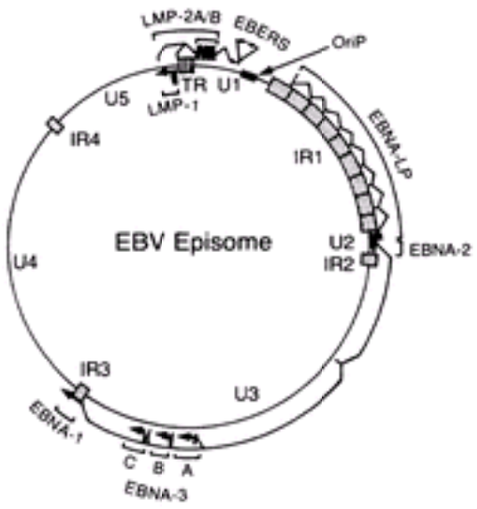

Figure 67.2. Circularized Epstein-Barr virus (EBV) genome; EBV DNA. Schematic representation of circular EBV DNA episomes, showing the general organization of unique (*U*) and major tandem internal repeat (*IR*) DNA domains and the location of latency genes within the circular DNA structure. EBER, EBV-encoded RNA; EBNA, EBV-determined nuclear antigen; LMP, latent membrane protein. [From Tosato G, Tata K, Angiolillo AL, et al. Epstein-Barr virus as an agent of hematological disease. Baillere Clin Hematol 1995;8(1):165–199, with permission.]

Although many variants have been reported, two major types exist: EBV-1 (A type) and EBV-2 (B type) ([9], [13], [16]). They are differentiated mainly by their differences in gene structure encoding the EBV-determined nuclear antigens (EBNA) 2, 3A, and 3C ([19]). Both types of EBV are found in most populations. Although EBV type B is frequently detected in the oropharyngeal secretions of individuals living in developed countries, recovery of EBV type B from peripheral blood lymphocytes is unusual ([20]). The relationship between these different strains and specific diseases remains to be determined. Recently, variants with differences in EBNA-1 have been reported to be associated with specific EBV-associated diseases, such as BL, but the incidence of these variants has been shown to be similar in the general population of a particular geographic region ([21]). Furthermore, mutations (so-called 30-bp or 69-bp deletions) of latent membrane protein (LMP-1), one of the viral proteins associated with cell immortalization, have been reported to be highly associated with the development of HD, certain forms of T- and B-cell lymphoma, and NPC ([22], [23], [24], [25] and [26]). But again, it has been demonstrated that these mutations are only reflective of regional EBV variations ([26], [27]). Therefore, caution must be exercised when attributing specific virus strains to particular diseases in the absence of geographically matched control isolates. Further studies are needed to clarify disease specificities of virus subtypes.

Epstein-Barr Virus Infection

The only host that the virus infects naturally is the human, although lymphocytes from other species, namely New World primates (i.e., cottontop marmosets, owl monkeys, and tamarins), are infectable ([28], [29]). EBV has been found in a variety of tissue types associated with disease (i.e., T lymphocytes, NK cells, HD, leiomyosarcoma, gastric carcinoma, hepatocellular carcinoma, and breast cancer) ([30], [31], [32], [33], [34], [35] and [36]). However, B lymphocytes and epithelium of the oronasopharnyx are the only natural cell targets of the virus. Cellular infection for herpesviruses requires two distinct events: cellular attachment and entry. Infection of B lymphocytes begins with attachment of the virus envelope glycoprotein (gp) 350/220 to the complement receptor C3d, also known as *CR2* or *CD21* ([16], [37], [38] and [39]). For entry into B lymphocytes, a complex of three viral proteins (gH-gL-gp42) is required, and HLA class II molecules serve as a co-receptor for gp42 ([40]). Attachment of EBV to epithelium is not via CD21, and viral entry is by infectious virions binding to polymeric immunoglobulin (Ig) A ([41]). EBV entry into epithelial cells does not require gp42/HLA class II but is mediated by a two-part complex of gH-gL. It has also been shown that virus that replicates in epithelial cells produces an abundance of gH-gL-gp42, favoring B-lymphocyte tropism, whereas virus produced by B lymphocytes lacks gp42, favoring epithelial tropism ([40]).

The life cycle of EBV in humans is illustrated in Figure 67.3. It is believed that virus contained in infectious saliva is produced by B lymphocytes of the oropharynx ([42], [43], [44] and [45]); therefore, virus in saliva would contain two-part complexes (gH-gL) and favor infection of the epithelium. Infection of epithelium leads to the lytic replication of the virus with the release of large quantities of viral particles ([37]), containing three-part complexes (gH-gL-gp42) that favor infection of HLA class II and CD21-expressing cells (i.e., B lymphocytes located in the oropharyngeal lymphoid tissues of the Waldeyer ring). These B cells may remain latently infected in the oropharnyx, but if viral reactivation and replication occur, cellular lysis and death result, and virus can be shed into the saliva. Salivary virus may then be transmitted to another host or may infect host epithelium, resulting in virus that may infect other B lymphocytes. Alternatively, infected B lymphocytes may disseminate throughout the body as resting memory B cells in secondary lymphatic organs (i.e., lymph nodes, spleen, and bone marrow) ([46]) and become the reservoir for latent EBV infection ([47]). The number of latently infected B cells is approximately 10^{-5} to 10^{-6} of all B cells and remains stable for the majority of the life of the infected individual ([47], [48]).

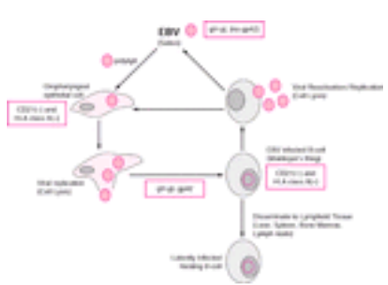

Figure 67.3. Life cycle of Epstein-Barr virus (EBV). gp, glycoprotein; Ig, immunoglobulin.

Latent infection is characterized by the expression of nine virally encoded proteins. Figure 67.1 and Figure 67.2 illustrate the transcriptions of the nine latent proteins of EBV (EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, leader protein, LMP-1, LMP-2A, and LMP-2B) ([9], [13], [16]). Nomenclature for the EBNAs varies such that EBNA-3A, -3B, and -3C are also known as *EBNA-3*, *-4*, and *-5*, respectively ([16]). The EBV-encoded RNAs (EBERs) EBER-1 and EBER-2 are seen in all latently infected cells, but they do not code for any proteins, and their function has not been determined. Additionally, the Bam HI-A rightward transcript (BART) is generally found in infected cells, but its function also remains to be fully delineated ([49]).

The state of latent infection is maintained by EBNA-1, which binds to a nucleotide sequence called *ori-P*, part of the DNA origin of EBV replication, thereby allowing the viral genome to be maintained in the nucleus of the latently infected B cell ([50], [51]). By this mechanism, the EBV DNA is assured of being maintained in B cells that undergo replication. EBNA-2, EBNA-3A, EBNA-3C, and LMP-1 appear to be required for B-cell immortalization. EBNA-2 transactivates the expression of two EBV LMPs—LMP-1 and LMP-2 ([52], [53], [54], [57]). EBNA leader protein augments the ability of EBNA-2 to up-regulate LMP-1 ([9], [13]). LMP-1 and LMP-2 are associated with a cellular tyrosine kinase ([56], [57]). The function of LMP-1 is similar to that of other members of the tumor necrosis factor (TNF) receptor family and is similar—but not identical—to that of CD40. LMP-1 interacts with TNF receptor–associated factors and the TNF receptor–associated death domain in infected cells and activates nuclear factor-?B and c-Jun *N*-terminal kinase pathways, resulting in B-cell activation and proliferation ([57], [58], [59] and [60]). Additionally, LMP-1 expression also induces bcl-2 expression and can prevent apoptosis in B cells ([61]). LMP-2 prevents viral reactivation by blocking tyrosine phosphorylation and promotes B-cell survival ([56], [62]). The EBNA-3 proteins regulate expression of cellular genes, including specific cellular receptors such as CD28, CD19, CD21, CD23, and CD30; T-cell co-stimulatory molecules CD80/CD86; adhesion molecules such as intercellular adhesion molecule-1, leukocyte factor antigen-1, and leukocyte factor antigen-3; and

a member of the src oncogene family, c-fgr ([9] , [13] , [63] , [64]).

Expression of EBV genes varies among the spectrum of EBV-associated diseases and often differs from *in vitro* immortalized B cells or normal human resting B cells infected by EBV ([55]). Briefly, EBV-positive BL cells commonly express only EBNA-1, EBER-1, and EBER-2 (type I latency), and type I latency is also observed in a portion of EBV-positive gastric carcinoma. EBV-positive NPC, T-cell NHL, and HD cells express EBNA-1, LMP-1, LMP-2, EBER-1, and EBER-2 (type II latency). However, EBV-infected cells of lymphoproliferative disease observed in immunodeficient patients resemble *in vitro* immortalized B cells; lymphoblastoid cell lines generally express all nine of the EBV-related latent proteins (type III latency). Recently, it has been shown that the peripheral resting CD23-positive B cells are the site of EBV latency in seropositive healthy individuals. These EBV-infected resting B cells express only LMP-2, EBER-1, and EBER-2 together with BART (type IV latency) ([65]).

Virus reactivation and replication are characterized by the expression of the EBV BZLF-1 gene product or ZEBRA (Z EBV replication activator) protein, an immediate early gene product that triggers viral replication in these cells ([16] , [66]). This protein also transactivates other immediate early genes, which then up-regulate the expression of early gene products essential for viral replication, including viral DNA polymerase and viral thymidine kinase. Late gene products follow, including viral capsid antigen (VCA), the major envelope glycoprotein (gp350), and the viral protein BCRF-1, 70% of whose structure is identical to that of interleukin (IL)-10 ([13] , [16] , [67]). Viral replication always results in lysis and death of the host cell.

Immune Response to Epstein-Barr Virus Infection

Understanding the immune response to EBV infection is essential to comprehend the pathogenesis of EBV-related disease. EBV is a very potent immune stimulus. The immune system controls lymphoproliferation in the normal host and maintains a host/virus symbiosis. Figure 67.4 illustrates the delicate balance between the host T-cell immune response and control of B-cell proliferation of latently infected B cells. In a healthy individual, although only 10^{-5} to 10^{-6} B cells are latently infected with EBV, approximately 1 to 5% of all circulating $CD8^{+}$ T cells are capable of reacting against EBV ([48] , [68] , [69] and [70]). Initially, there is B-cell proliferation, producing both EBV-specific and -nonspecific antibodies. The number of these virus-containing B cells rises during the acute phase of the infection but never exceeds 0.03 to 0.1% of the circulating mononuclear cells ([71] , [72] and [73]). A cellular immune response follows, which is comprised primarily of cytotoxic T lymphocytes (CTLs), that are again EBV-specific and -nonspecific. Figure 67.5 illustrates the pathologic consequences of an abnormal CTL response to EBV infection. A deficient CTL response, either quantitative or qualitative, results in an EBV-driven B-cell proliferative process. The lack of an appropriate CTL response can also result in an aggressive, predominantly T-cell and histiocytic reaction that is not EBV specific. This reaction is characterized by extensive infiltration of lymphoid and parenchymal organs with hemophagocytosis, and tissue destruction is often observed. If unchecked, this reaction can be rapidly fatal ([74] , [75]).

Figure 67.4. Balance of immune control in Epstein-Barr virus (EBV) infections. CTL, cytotoxic T lymphocyte.

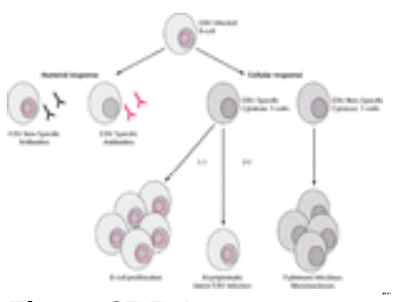

Figure 67.5. Immune response to Epstein-Barr virus (EBV) infection.

The humoral response to EBV is well characterized (Fig. 67.6) ([72] , [76] , [77] , [78] and [79]). VCA antibodies are the earliest to appear—first IgM and, later, IgG. IgM antibodies probably arise during the incubation period, peak with symptoms, and then decline rapidly ([80] , [81]). IgA anti-VCA antibodies are seen in some patients and, like IgM anti-VCA antibodies, are gone within several weeks ([82] , [83]). IgG anti-VCA antibodies reach a peak 2 to 3 weeks after their IgM predecessors and persist for life ([80] , [82]). The majority of patients also have a transient response to the EBV early antigen (EA), peaking usually within a month of infection ([80]). Antibodies to EBNA may appear several weeks after the onset of the illness in some patients but, in general, take several months to appear, and titers rise slowly over 1 to 2 years and persist for life. The majority of normal individuals have detectable IgG to EBNA by 6 months after EBV infections, although it may take years to develop detectable anti-EBNA titers. In young children, the anti-VCA and -EA responses may be much less intense, and anti-EBNA may take much longer to be seen ([84]).

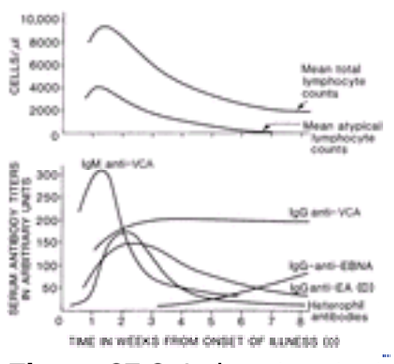

Figure 67.6. Laboratory tests I. Time course relationship between heterophil antibodies, various anti–Epstein-Barr virus antibodies, and the mean total and atypical lymphocyte counts. EA, early antigen; EBNA, Epstein-Barr nuclear antigen; D, diffuse component; Ig, immunoglobulin; VCA, viral capsid antigen.

An EBV-nonspecific humoral response also occurs with EBV infection. Paul et al. ([85]) first described this phenomenon in 1932 when they reported that the sera of patients with IM contained heterophil antibodies against sheep erythrocytes in concentrations far above normal. The use of heterophil antibodies in the diagnosis of IM is discussed in detail in the section Infectious Mononucleosis: Diagnosis . Many of these EBV-nonspecific antibodies function as autoantibodies and include cold reactive anti-i antibodies, Donath-Landsteiner cold hemolysins, and antibodies against smooth muscle, thyroid, and stomach ([86] , [87] , [88] and [89]). In addition, antinuclear antibodies have been found in the sera of some patients ([90] , [91]), as well as rheumatoid factors ([92]), including anti-Gm antibodies ([93]), anticardiolipin antibodies ([94]), and antiactin and anticytoskeletal antibodies ([94]). The serum of some persons with IM may contain cryoglobulins ([95] , [96]). Some of these autoantibodies have been reported to be monoclonal ([86] , [89]).

Although neutralizing antibodies produced after primary infection may play a role in thwarting the spread to additional B cells, EBV-specific antibodies are most useful for diagnosis, whereas the cellular response is the most important for control of EBV infections. NK cells and $CD4^{+}$ T cells have been shown to play a role, but $CD8^{+}$ memory cytotoxic T cells (EBV-CTL) are the primary defense in controlling EBV infections ([9] , [10] , [97] , [98] , [99] , [100] , [101] and [102]). Although the absolute number of NK cells may be increased, a decrease in NK function is usually observed, returning to normal gradually over several weeks ([98]). Initially, cytotoxic T cells are polyclonal and are neither EBV specific nor HLA restricted, evidenced by their ability to kill readily EBV-negative and major histocompatibility complex (MHC)–incompatible targets (

[99]). They resemble activated killer cells induced *in vitro* by the exposure of T cells to nonspecific mitogens or IL-2 ([13], [99]). These $CD8^+$ lymphocytes account for the majority of cells causing the lymphocytosis and the large, pleomorphic, atypical lymphocytes, or "Downey cells," characteristic of IM ([9], [13], [73], [97], [99], [103]). It is the amount of these T cells in the peripheral blood that correlates with symptoms seen in IM, not the number of EBV-infected B cells or the viral load ([104]). These cells disappear during convalescence ([99]) to be replaced by EBV-CTLs, which maintain a latent viral infection and control EBV-driven B-cell proliferation ([99], [100], [101] and [102]).

This symbiosis of EBV and the infected host is maintained by interactions between viral gene expression in latently infected B cells and host EBV-CTL surveillance. The reservoir of viral latency is found among the resting memory B cells ([47]). These resting memory B cells do not express high levels of adhesion molecules or T-cell co-stimulatory molecules, making them poor antigen-presenting cells. Also, these EBV latently infected resting B cells express only LMP-2, EBER-1, and EBER-2, together with BART (type IV latency) ([46], [65]). When these cells divide, EBNA-1 is expressed to assure passage of viral DNA to progeny cells ([105]). All attempts to demonstrate or produce EBNA-1–specific cytotoxic T cells have failed ([106]). It has been shown that the gly-ala internal repeats in EBNA-1 block their own degradation by proteosomes and, hence, peptide presentation through MHC class I molecules ([107]). Thus, resting EBV-infected B cells expressing EBNA-1 are not recognized by the immune system. However, activated EBV-infected B cells express MHC class I antigens; various adhesion molecules including CD44; leukocyte family antigens (CD18, CD58); intercellular adhesion molecules; and B-cell activation markers or co-stimulatory molecules such as CD23, CD30, CD39, CD40, CD70, CD80, and CD86 ([63], [64]), making these proliferating EBV-infected B cells good antigen-presenting cells. Proliferating, latently infected B cells express all latent proteins, including EBNA-2, EBNA-3A, EBNA-3C, LMP-1, and LMP-2 (type III latency). These proliferating EBV-infected B cells are highly susceptible to cellular lysis by EBV-CTLs and are eliminated during convalescence, whereas memory EBV-CTLs provide lifetime immunosurveillance against EBV-driven B-cell proliferation. The immunodominant epitope of the EBV-CTL response is highly restricted by the HLA type of the individual, making it difficult to develop vaccine strategies to prevent EBV infections ([99], [106], [108]) (Fig. 67.7).

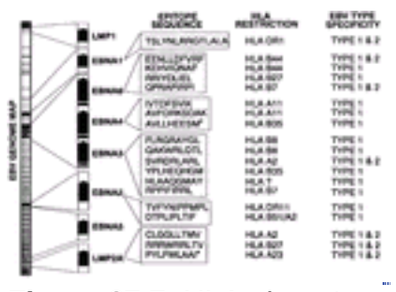

Figure 67.7. HLA phenotype and antibody specificity. Major histocompatibility complex class I– and class II–restricted cytotoxic T lymphocyte epitopes from Epstein-Barr virus (EBV) latent antigens defined at the peptide level. EBV types 1 and 2 are also referred to as *EBV types A* and *B*, respectively. EBNA, EBV-determined nuclear antigen; LMP, latent membrane protein. (From Khanna R. Microbiol Rev 1995:387–405, with permission.)

INFECTIOUS MONONUCLEOSIS

Epidemiology

The typical clinical syndrome associated with IM occurs most commonly in young adults, the peak incidence being in persons between 17 and 25 years of age (Fig. 67.8) ([72], [109]). Children often acquire immunity to EBV without developing the typical clinical manifestations of IM ([109], [110] and [111]). Because symptoms of EBV correlate with the nonspecific CTL response ([104]), this would suggest that young children generally respond with a more EBV-specific cellular response. The yearly conversion rate to EBV seropositivity among children in the United States is not known. Studies have shown that 51% of Yale University freshmen and 86% of Marine recruits, a population from a somewhat lower socioeconomic background, had antibodies to EBV ([12], [112]). Authors of a British study concluded that 30 to 40% of children had been infected by their fifth year ([64]). Generally speaking, the rate of seroconversion is high in developing countries, where socioeconomic conditions and standards of hygiene are relatively low ([72]). Under these circumstances, primary infection occurs in almost all children before 10 years of age, leaving few young adults susceptible to develop IM, and the observed incidence in such countries is very low ([72]). IM is sufficiently uncommon in individuals older than 30 years of age and is so rare in those older than 40 years of age that special care is needed when making the diagnosis in persons in their middle or late years. Nevertheless, well-documented cases of this illness in patients older than 40 years of age have been reported ([115], [116], [117], [118] and [119]). Complications such as protracted fever, jaundice, pleural effusion, and Guillain-Barré syndrome often dominate the clinical picture in these patients, detracting from the evidence that would allow the clinician to make the correct diagnosis ([117]).

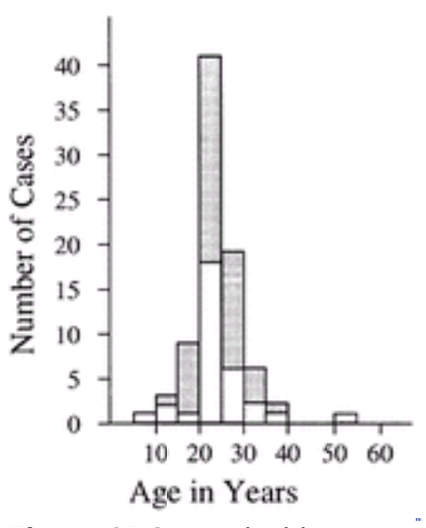

Figure 67.8. Age incidence. Age and sex of 82 patients with infectious mononucleosis at Johns Hopkins Hospital. Shaded columns, males; open columns, females.

Despite common opinion, the contagiousness of IM is quite low. It is rare for members of a patient's family, roommates of the same sex, and other close associates to develop symptoms of IM ([120], [121]). "Kissing disease," the colloquial term for IM, underscores the association of intimate kissing with IM ([72], [110], [122], [123]). Although oral shedding occurs throughout the life of a carrier ([69]), data suggest that acute infections are more likely to occur from a recently infected individual. Oral shedding in an immunocompetent individual peaks shortly after infection but is often readily detectable for 18 months or longer ([122], [124], [125]). Other modes of acquiring EBV infection include transplantation of organs or hematopoietic cells in which transmission to the transplant recipient is common ([126], [127], [128] and [129]). Although it is not thought to occur, there are anecdotal reports of transmission from blood transfusions ([130], [131]), *in utero*, or perinatally ([132], [133]). Although there are anecdotal reports of virus detected in cervical epithelium and semen, sexual transmission has never been demonstrated ([134]).

Clinical Features

Many individuals have held that the manifestations of IM are protean ([135]) and that many disorders may be simulated by this condition. IM is classically characterized by the clinical triad of fever, pharyngitis, and generalized adenopathy, with demonstration of an *atypical lymphocytosis*, defined as an absolute lymphocytosis with more than 50% lymphocytes and 10% or more atypical forms in the differential count, and the presence of heterophil antibodies ([110]). Usually, IM occurs only once in the lifetime of a host, although recurrences have been reported, and exacerbations of unresolved infection or transition to a chronic course may also occur. (See section Chronic Active Epstein-Barr Virus Infections.)

The signs and symptoms of IM are summarized in Table 67.1. The clinical course based on physical signs and symptoms is illustrated in Figure 67.9 and Figure

67.10. In most young adults, the symptoms are fairly abrupt in onset, although close questioning frequently elicits vague complaints of lassitude and ill-being for several days before the onset of more pronounced symptoms. Most of the early symptoms are nonspecific. Myalgias do occur, but they are usually mild and are often confined to the neck and upper back. Excessive fatigue and general malaise may be accompanied by fever, sweating, and chills. Severe rigors rarely occur, and the patterns of fever are generally moderate and nonspecific. The fever is of no characteristic type. It may be transient and slight in degree, but in as many as one-third of patients, it reaches a peak of 40°C ([135]). A secondary rise in temperature may occur after an initial drop to normal and may accompany the onset of glandular swelling or sore throat.

TABLE 67.1. Symptoms and Signs of Infectious Mononucleosis

Symptoms	%	Signs	%
Malaise and fatigue	90–100	Adenopathy	100
Sweats	80–95	Fever	80–95
Sore throat, dysphagia	80–85	Pharyngitis	65–85
Anorexia	50–80	Splenomegaly	50–60
Nausea	50–70	Bradycardia	35–50
Headache	40–70	Periorbital edema	25–40
Chills	40–60	Palatal exanthem	25–35
Cough (mild)	30–50	Liver or splenic tenderness	15–30
Myalgia	12–30		
Ocular muscle pain	10–20	Hepatomegaly	15–25
Chest pain	5–20	Rhinitis	10–25
Arthralgia	5–10	Jaundice	5–10
Diarrhea or soft stools	5–10	Skin rash	3–6
Photophobia	5–10	Conjunctivitis	5
Abdominal pain	5	Pneumonitis	3
Epistaxis	3

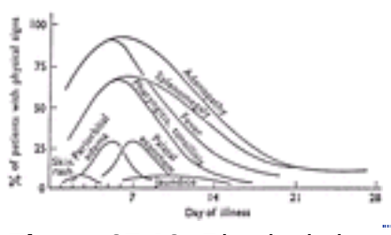

Figure 67.10. Physical signs. Usual frequency and duration of major physical signs in young adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969, with permission.)

Anorexia is a common early symptom. Its intensity and duration are often linked to the severity of sore throat and dysphagia. The anorexia often persists for several weeks. Nausea is equally common and may be one of the earliest symptoms of IM, but vomiting is rare. Sore throat and dysphagia are among the most important manifestations of IM and may be the only symptoms in some patients. These symptoms usually develop gradually and subside in 1 to 2 weeks. For most patients, the symptoms of pharyngitis are mild, but occasionally, even taking sips of water may be painful.

Lymph node enlargement is invariably present at some time ([136], [137] and [138]). Adenopathy usually appears during the first week of illness and slowly resolves thereafter. Anterior and posterior cervical node enlargement is almost always present, and palpable axillary and inguinal nodes are common. Radiographically detectable hilar adenopathy is rare (<1%) ([139]). Although splenomegaly is expected, the spleen is palpable in only one-half to three-fourths of all patients. Massive splenomegaly can be observed but is rare ([135], [138]). Hepatomegaly is detected in 15 to 25% of patients and is usually accompanied by percussion tenderness over the liver and discomfort on palpation. The course of hepatomegaly closely follows that of adenopathy and splenomegaly ([140]). Pharyngeal inflammation usually appears in the first week and then subsides rapidly. In approximately 25% of patients, pharyngitis first occurs after the initial week of illness, and there are no pathognomic features. It varies in intensity, but rarely, massive tonsillar and pharyngeal edema may cause virtually complete pharyngeal obstruction ([138]). Severe cough is relatively rare, although mild cough is common.

Headaches occur early, as well as photophobia, and ocular muscle pain can occur. Ocular manifestations occur in approximately one-third of patients and include eyelid edema, conjunctivitis, dry eyes, keratitis, uveitis, choroiditis, retinitis, papillitis, and ophthalmoplegia ([141]). Rashes are also common with primary EBV infection and may be the only symptom in young children ([142], [143]). Several observers have noted that patients experiencing IM are peculiarly prone to rashes when treated with ampicillin, which appear to be the result of vasculitis caused by circulating ampicillin-antibody complexes ([144], [145], [146] and [147]).

Laboratory Findings

Hematologic abnormalities in IM are observed in virtually all patients. The hematologic changes persist for a minimum of 2 weeks and usually for 1 to 2 months. One of the classic features of IM is the atypical lymphocytosis. The pleomorphism of the mononuclear cells found in the blood is usually striking. In addition to normal lymphocytes and monocytes, large mononuclear cells, or atypical lymphocytes, are observed in the blood (Fig. 67.11). Although nonspecific ([148]) because they may be found in the blood of patients with a variety of conditions, including other viral infections ([149]), they are a prominent feature of IM. The abnormal cells vary greatly in size and shape. They possess a nucleus that may be oval, kidney-shaped, or slightly lobulated and cytoplasm that most often is nongranular and vacuolated or foamy. The nuclear chromatin forms a coarse network of strands and masses and is not clearly differentiated from the parachromatin. The identity of these cells has been shown to be $CD8^+$ T lymphocytes, as discussed previously (see Immune Response to Epstein-Barr Virus Infection) ([9], [13], [73], [97], [103]). The rapid proliferation of these activated T cells is, in turn, responsible for the large numbers of atypical cells seen in the peripheral blood, as well as the generalized lymphadenopathy and hepatosplenomegaly, the tonsillar and adenoidal changes, and the cellular infiltration seen in many parenchymal organs, and is discussed in detail in the section

Infectious Mononucleosis: Histologic Findings .

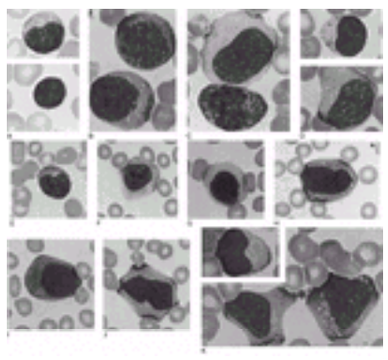

Figure 67.11. Lymphocytes and cells of infectious mononucleosis. **A:** Large and small lymphocytes from the blood of normal subjects. **B:** Lymphocytes resembling plasma cells (“plasmacytoid” cells) in the blood of a patient with viral pneumonia. **C:** Somewhat atypical lymphocyte and plasmacytoid lymphocytes in blood. **D:** Lymphocytes from the blood of a patient with viral infection; azurophilic granules are clearly seen in one of the cells. **E–J:** Infectious mononucleosis; lymphocytes showing increasing levels of atypia. **E:** Downey type I. **F, G:** Downey type II. **H–J:** Downey type III. **K:** Lymphocytes from blood of patient with infectious mononucleosis. See Color Plate.

Most patients with IM have slightly or moderately increased total white blood cell counts in the range of 10.0 to 20.0 × 10^9 cells/L, with approximately 15% of patients reaching levels in excess of 20.0 × 10^9/L ([76], [123]). The absolute lymphocyte count most often exceeds 5.0 × 10^9 cells/L; because the number of atypical lymphocytes usually is greater than 20% ([123]), minimum atypical lymphocyte counts of 1.0 × 10^9/L can be expected. Lymphocytosis begins toward the end of the first week of illness and reaches a peak corresponding to symptoms, as does the total leukocyte count (Fig. 67.12). Leukopenia has also been observed and can be manifested as lymphopenia or granulocytopenia ([150]). Most patients with IM have normal hemoglobin levels, and severe thrombocytopenia is rare, although mild depressions of platelet counts (=100 × 10^9/L) may be found in perhaps one-half of patients ([150], [151]). Neutropenia and thrombocytopenia may be very ominous signs, as they are frequently seen in the hemophagocytic reactions [VAHS or EBV–hemophagocytic lymphohistiocytosis (HLH)].

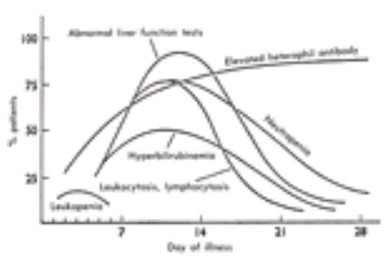

Figure 67.12. Laboratory tests II. Major laboratory findings in adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969, with permission.)

Nonhematologic abnormalities are also commonly observed in patients with IM. Many patients show mild to moderate abnormal liver function tests ([150]). The reported incidence varies from approximately 40 to 100%, depending on the severity of the disease, the time of testing, and the diligence with which the changes were sought. Reported enzyme changes include elevations of lactate dehydrogenase, alkaline phosphatase, glutamic pyruvate transaminase, phosphohexose isomerase, and aldolase, in roughly that order of frequency. Perhaps one-third of patients have mild to moderate elevations of serum bilirubin values; levels above 8 mg/dl (135 µmol/L) are exceedingly rare but have been reported ([150], [152]). Occasionally, proteinuria or hematuria is present, but renal function is usually unimpaired. When the patient is jaundiced, bile and increased concentrations of urobilinogen may be found. Lumbar puncture has been performed to evaluate patients with severe headaches. In these cases, the cerebrospinal fluid pressure may be elevated, and pleocytosis and increased levels of protein are often noted. The sugar content is normal. In a few patients, heterophil antibodies have even been demonstrated in the cerebrospinal fluid ([153]).

Histologic Findings

The main pathologic feature of IM is a notable proliferative response within the reticuloendothelial system, especially by the lymph nodes and the spleen. It can be difficult to distinguish between malignant lymphoma and nonmalignant disease associated with EBV infection, especially in the immunodeficient patient population ([75]). In summary, the histologic diagnosis of IM is one of suspicion rather than certainty ([154]).

The lymph node architecture is generally intact ([155], [156]) but may be distorted ([154], [155], [156] and [157]). Other morphologic features mimicking lymphoma include extensive immunoblastic proliferation in sheets and nodules and significant cellular atypia ([155]). Clonality studies are often necessary to differentiate IM from malignant disease. The germinal centers are usually identifiable, but follicular prominence is diminished, probably because of the irregular and vaguely defined borders that result from the lymphocytic and reticuloendothelial hyperplasia of paracortical structures and, to a lesser extent, the medullary cords. This intense proliferative activity within the paracortical areas is in keeping with the characterization of atypical lymphocytes as T cells ([157]). In addition, focal proliferations of macrophages are noted, as is, most characteristically, the presence of “typical” IM cells throughout the pulp, on the edges of germinal centers, and in the sinuses ([156]). Reed-Sternberg (RS)–like cells ([154], [155], [157]) are often observed in association with areas of necrosis ([75]). Because the presence of EBV has been demonstrated in approximately 50% of Hodgkin lymphoma specimens ([158], [159] and [160]), the identification of the virus or EBV-determined antigens is not particularly helpful in the differential diagnosis of these two disorders.

The spleen is striking for infiltration of its fibromuscular structures by mononuclear cells ([161]). Both the capsule and trabeculae are often thin and invaded by proliferating lymphocytes. This may explain the incidence of splenic rupture in this disease. *In vitro* hybridization studies can be used to track the distribution pattern of cells carrying the viral genome ([43], [154], [162]). Most labeled cells are found in the hyperplastic T-cell zones, the paracortical or interfollicular areas ([43], [154], [162]); smaller numbers are found within the epithelioid venules, the lymph node sinuses, and, occasionally, the germinal centers and the mantle zone ([162]). In the spleen, labeled cells are found mainly within pulp cords ([162]). Most of the labeled cells are small lymphocytes, but occasional labeled blasts, dendritic cells, and macrophages can be identified ([162]).

The bone marrow may be cellular with generalized hyperplasia of erythroid, myeloid, and megakaryocytic elements ([163]). With special techniques, sarcoidlike granulomas may also be demonstrated ([163], [164] and [165]). In most instances, however, routine marrow aspiration reveals no abnormalities of note.

Diagnosis

The diagnosis of IM rests primarily on documentation of a primary EBV infection. Because EBV cannot be cultured, the humoral response to EBV infection, which has been discussed in the section Immune Response to Epstein-Barr Virus Infection, is the usual method to discern infection. In summary, a recent, primary EBV infection is characterized serologically by (a) a positive heterophil antibody titer; (b) high titers of anti-VCA antibodies, both IgM and IgG; (c) high titers of anti-EA antibodies; and (d) the absence of anti–EBNA-1 antibodies. Convalescent sera demonstrate the disappearance of IgM anti-VCA antibodies and the appearance of anti–EBNA-1 antibodies ([79], [80]). Rapid test systems using recombinant EBV antigens and enzyme-linked immunosorbent or other assay technologies have been developed for use in clinical laboratories ([166], [167]), but false-positive tests, especially for anti-EBV IgM antibodies, are common ([168]).

Because so many antibodies have been linked to the development of IM, elevation of Ig levels in association with this disease is not surprising ([169], [170]). Although this change is especially true for IgM globulins, lesser elevations have also been seen in IgG and IgA globulins. The pattern of changes is similar to that seen in the

normal immune response: IgM is elevated first and IgG later ([171]). A general increase in titers of IgG antibodies and production of IgM antibodies against other infectious agents is common during the primary EBV infection ([172]) and must be taken into account when performing a diagnostic workup. Antibodies with recognized antigenic specificities, such as the heterophil antibody, make up only a small proportion of the total ?-globulins of the serum ([169] , [173]), and the antigenic specificity of most of the increased ?-globulins remains unknown.

A serologic diagnostic test for IM has been available since Paul and associates ([85]) discovered that the sera of patients with IM contain agglutinins against sheep red cells. They called the antibody *heterophil* because it reacted with a heterologous antigen that obviously had not elicited its production. Most authorities considered a positive response to the heterophil antibody test to be a *sine qua non* in the diagnosis of IM in adults. Investigators soon learned that the antibody reacted not only with sheep red cells but also with beef and horse erythrocytes ([171] , [174] , [175]). The heterophil antibody is an IgM globulin ([176] , [177] and [178]), which, in some studies ([179]), was shown to have ? light chains only. The Paul Bunnel (PB) antigen with which the heterophil antibody interacts is thermostable ([174] , [176]), in contrast to the Forssman antigen. Its immunologically reactive sites appear to be carbohydrate in nature ([180]). The carbohydrate nature of the antigen probably explains the observation that the antibody response is almost exclusively IgM. PB antigens are found also on cells other than heterologous erythrocytes ([176]). Of particular interest is the demonstration of PB-like antigens on murine T lymphocytes, Thy-1–positive murine lymphoma cells, and murine neutrophilic granulocytes ([176]). In addition, PB antigens have been demonstrated in various tissues of IM patients during the early stages of the disease ([176] , [181]), in cultures of some lymphoid cell lines ([182]), in fresh BL tissues ([183]), and in the spleens of some patients experiencing lymphoma or leukemia ([176]). The formation of PB antibodies by cultures of lymphocytes from IM patients also has been demonstrated ([184]).

Heterophil antibodies in titers of up to 1:28 are present in most normal persons and, occasionally, in titers of 1:56 ([185]). A study of more than 3000 IM patients showed the following age distribution of PB antibodies: 5 to 9 years of age, 4%; 10 to 14 years of age, 8%; 15 to 24 years of age, 80%; 25 to 29 years of age, 3%; and older than 30 years of age, 5% ([186]). For these reasons, the test for heterophil antibodies has been called “presumptive” ([187]), but in the presence of clinical and hematologic findings suggestive of IM and a titer of 1:256 or higher, the diagnosis of IM is likely. In patients with IM, positive heterophil reactions almost always appear during the first 2 weeks of the illness (Fig. 67.6). Highest titers usually are found during the second and third weeks. As a rule, positive reactions last 4 to 8 weeks, but they have been observed to persist for as short as 7 to 9 days or as long as 18 weeks ([185]). The titer bears no relation to the severity of the disease or to the leukocyte changes. Although elevated heterophil antibody titers are quite common in EBV infection, occasionally patients with other disorders produce elevated levels ([188]). Therefore, confirmatory EBV-specific antibody titers are warranted if the diagnosis is suspect (e.g., a previously documented case of IM, a young child or older adult, or unusually severe or persistent symptoms).

Molecular diagnostic techniques are useful for the demonstration of EBV in tissues and body fluids. *In situ* hybridization techniques ([154] , [162] , [189]), Southern blot analyses ([190] , [191]), and the polymerase chain reaction ([192] , [193]) are most commonly used. The use of quantitative EBV polymerase chain reaction has been evaluated for diagnostic and prognostic value in EBV-related diseases ([193] , [194] and [195]). It appears that the amount of EBV DNA detectable in the blood of a patient with EBV-related disease may be useful in monitoring response to therapy in some diseases, but its value for diagnosis or prognosis still remains to be determined.

Differential Diagnosis

The diagnosis of IM usually is not difficult. In most instances, a young adult complains of malaise, fatigue, anorexia, and a sore throat and is found to have fever, adenopathy, pharyngitis, and splenomegaly. Examination of the blood, a positive heterophil antibody test, or appropriate changes in EBV titers, or all three, confirm the diagnosis. Complications are rare, and signs of significant respiratory, cardiovascular, intestinal, urinary, or joint disease make considerations of other diagnoses mandatory.

The fever and general malaise can be seen in many infectious diseases including salmonella infections, listeriosis, brucellosis, subacute bacterial endocarditis, the lymphadenopathic form of toxoplasmosis, and malaria. Generalized lymph node enlargement, including the postauricular and occipital nodes, is also characteristic of rubella ([75]). The pharyngitis of IM must be differentiated from acute streptococcal pharyngitis, diphtheria, and acute viral pharyngitis of other types. Beta-hemolytic streptococci are isolated relatively often from patients with classic IM ([136]). Thus, a positive throat culture for streptococci does not make a search for an EBV infection unnecessary. In addition, a palatine exanthem may be present in patients with rubella, and atypical lymphocytes have been described in this condition. Drug fever and serum sickness–like reactions may also suggest IM, because they often are characterized by fever, jaundice, lymph node enlargement, and atypical lymphocytes ([75]).

Lymphocytosis, absolute or relative, may be encountered in association with diseases other than IM. These disorders include tuberculosis, tularemia, pertussis, dengue, mumps, chickenpox, German measles, typhoid fever, infectious hepatitis, serum sickness, and various other allergic states. In association with some of these conditions, abnormal lymphocytes resembling those of IM have been observed, as mentioned previously. Leukocytosis due to small lymphocytes of normal appearance and not associated with splenomegaly, lymphadenopathy, or a positive heterophil agglutination reaction, is suggestive of acute infectious lymphocytosis.

The hematologist may be called on to differentiate IM from other more serious hematologic diseases, such as acute leukemia, especially when the patient is heterophil negative. Under most circumstances, this is easily accomplished on the basis of clinical and laboratory data. Although many leukocytes of patients with IM appear abnormal, few contain nucleoli, and thrombocytopenia and anemia are rare in these patients. The appearance of the peripheral blood is constantly fluctuating in IM, whereas this fluctuation does not happen in leukemia. Bone marrow examination is rarely necessary to differentiate IM from acute leukemia. Patients who have had IM do not have a higher incidence of leukemia, but a few cases of concurrent IM and leukemia have been reported ([196] , [197] , [198] and [199]). The differentiation of the adenopathy seen in IM from that occurring regularly in HD and in NHL can be difficult. (See section Histologic Findings .)

A number of heterophil-negative, self-limiting diseases are associated with a peripheral blood picture that satisfies all of the morphologic criteria established for the diagnosis of IM; failure to recognize these illnesses can result in unnecessary lymph node or liver biopsies, bone marrow aspiration, or other irrelevant diagnostic tests. The most common causes of heterophil-negative mononucleosis-like illnesses include cytomegalovirus (CMV), rubella, hepatitis and adenoviruses, *Toxoplasma gondii*, trichinosis, human immunodeficiency virus (HIV), and human herpesvirus-6, as well as a number of bacterial infections ([200] , [201] , [202] , [203] , [204] and [205]). However, CMV is the most common ([200] , [204] , [206] , [207]).

When CMV-mononucleosis occurs, the illness is associated with fever (94%), sore throat (31%), splenomegaly (22%), prominent lymphadenopathy (17%), and myalgias (13%) ([200]). Blood smears are indistinguishable from those seen in EBV-induced IM; most patients have abnormal liver functions, and a surprising two-thirds have hemoglobin values of less than 120 g/L ([200]). Approximately one-half of anemic individuals have evidence of hemolysis ([200]). Lymphocytosis with atypical cells is the most characteristic laboratory feature of the syndrome, and the peripheral smear may be indistinguishable from that of IM. The white cell count usually does not exceed 15.0, but, occasionally, leukemoid reactions with counts of 35.0 to 75.0 × 10^9/L are observed ([208]). The bone marrow is stated to appear normal. Normochromic normocytic anemia with varying degrees of reticulocytosis is a routine finding and, in some instances at least, appears to be associated with a positive reaction to the antiglobulin test or with cold agglutinins ([208] , [209]). Other immunologic aberrations include rheumatoid factors, antinuclear antibodies, and cryoglobulins ([208] , [210]). Mildly to moderately abnormal tests of liver function are common ([204]). In most patients with CMV, the infection is mild and resolves within a few weeks; on occasion, the manifestations last for several months or longer. The diagnosis is confirmed by demonstrating the presence of IgM antibodies to CMV in virtually all cases ([136] , [200]). Most CMV-positive, heterophil-negative patients have no anti-EBV antibodies or have uncomplicated serologic data indicating long-past EBV infections ([200] , [205]). A few patients present with evidence of simultaneous CMV and EBV infection ([200]).

Complications

Unusual clinical patterns and serious complications are probably seen in no more than 1% of all patients ([138]). Misconceptions about a higher incidence stem from the fact that most of the medical literature concerning IM deals with complications and from impressions of subspecialists who usually do not see patients with uncomplicated disease. The most frequent reported complications are listed in Table 67.2 and Table 67.3 .

TABLE 67.2. Hematologic Complications of Infectious Mononucleosis [a]

Immune hemolytic anemia
Immune thrombocytopenia
Granulocytopenia
Marrow aplasia
Virus-associated hemophagocytic syndrome
Acquired immune deficiencies

[a] See text for references.

TABLE 67.3. Nonhematologic Complications of Infectious Mononucleosis

Splenic rupture (242, 243, 244 and 245)
Neurologic complications
  Guillain-Barré syndrome (246, 247, 248 and 249)
  Encephalitis (250, 251, 252, 253 and 254)
  Reye syndrome (255)
  Meningitis (247, 256, 257)
  Meningoencephalitis (247, 258, 259)
  Cranial nerve palsies (250, 259, 260 and 261)
  Optic neuritis (141, 262)
  Peripheral neuropathy (263, 264, 265, 266 and 267)
  Cerebellar ataxia (268, 269 and 270)
  Transverse myelitis (271, 272)
Cardiac complications
  Electrocardiography changes (142, 273)
  Pericarditis (274, 275 and 276)
  Myocarditis (87)
Respiratory complications
  Acute airway obstruction (277, 278)
  Pleural effusion (279, 280 and 281)
  Parenchymal changes (279, 280, 282)
Liver failure (242, 283, 284 and 285)
Pancreatitis (286, 287)
Renal failure (288)

Hematologic complications are the most common. The incidence of hemolytic anemia may be as high as 3% (211, 212 and 213). Hemolysis usually is mild; in approximately 70% of the patients with hemolytic anemia, the reaction to the antiglobulin test (or Coombs test) is positive, and in approximately the same number, the titers of cold agglutinins are increased (213), usually with anti-i specificity (217, 218). Occasionally, hemolysis has been attributed to anti-i antibodies (214), and occasional cases of hemolysis caused by Donath-Landsteiner cold hemolysins have been reported (215, 216). Although the cold agglutinins are specific for the red cell antigen i, a similar incidence of anti-i antibodies (70%) is found also in patients without hemolysis (217, 218), and the role of these antibodies in red cell destruction is therefore unclear. In summary, anti-i antibodies are extremely common, but hemolytic anemia is rare (217, 219, 220 and 221). Sometimes, however, no antibody of any kind is detectable. IM has been associated with accelerated hemolysis in patients with underlying hereditary spherocytosis (222, 223), elliptocytosis (224), or thalassemia (225), and in one patient, the onset of paroxysmal nocturnal hemoglobinuria coincided with the development of IM (226).

Hematologic cytopenias are common. Although mild depression of the platelet count (100 to 140 10^9/L) may be found in perhaps one-half of patients with IM (151), thrombocytopenic purpura is a rare complication that is seen primarily in younger children (227, 228 and 229). Thrombocytopenia occurring in acute IM has been attributed to increased destruction by an enlarged spleen or the production of platelet autoantibodies (230, 231). Occasionally, immune thrombocytopenia precedes the development of severe aplastic anemia (228). Mild granulocytopenia is a common finding in patients with IM (234, 243), but severe granulocytopenia is rare (232, 233, 234, 235, 236, 237 and 238). When marrow examination has been performed, myeloid hyperplasia has been noted with increased numbers of promyelocytes—but with depletion of more mature neutrophilic cells (232, 238). This picture is compatible with a proliferative response to an earlier marrow injury or peripheral destruction or increased use of granulocytes. Serious suppression of the entire marrow is rare (213, 239, 240 and 241). Fatal aplastic anemia has been noted after what appeared to be typical IM (191, 213) but is more commonly associated with hemophagocytic reactions (VAHS or EBV-HLH).

One of the most common reported complication is splenic rupture, which has led to death in several cases (242, 243 and 244) but has been reported to occur with an incidence of 0.1 to 0.2% in North America. Of the 107 cases reported in the world literature up to 1978, only 18 were considered “spontaneous” by one reviewer (244). The diagnosis of a ruptured spleen should be entertained whenever a patient with IM has severe or even moderate pain below the left costal margin, especially if the pain is accompanied by radiation to the left shoulder and supraclavicular area, or has evidence of impending peripheral vascular collapse. Other signs include those characteristic of peritoneal irritation, abdominal tenderness, and shifting dullness if massive intraabdominal bleeding has occurred. Frank rupture may be preceded by one or more episodes of subcapsular hemorrhage or minor capsular tears, which may be difficult to differentiate from rupture. Because potentially fatal bleeding may occur at any time, it is recommended that surgical intervention be pursued whenever the typical pain pattern is accompanied by signs of hemodynamic instability (243, 245). Delayed surgical intervention often is attributable to the misconception that abdominal pain is a common feature of the uncomplicated disease. Preservation of splenic function by surgical repair of the capsular tear (splenorrhaphy) or partial splenectomy has been recommended by some but is not generally recommended, as the altered splenic architecture in IM makes it unlikely that such interventions will be successful (243, 245).

Complications of almost all organ systems have been described in association with IM (289) and are listed in Table 67.3. Neurologic manifestations are not infrequent in IM and may occur in 1 to 2% of patients (244, 247, 249). When serious neurologic complications occur, the mortality rate may be as high as 8 to 11% (256), and, in addition, the incidence of serious residual damage may be as high as 12% (256). Cardiac complications are rare, although electrocardiographic abnormalities may occur in approximately 10% of patients (142, 273). A case of fatal myocarditis has been reported in association with IM (87). The most serious respiratory complication is acute airway obstruction, which usually is the result of extreme hyperplasia of the tonsils and other pharyngeal lymphatic tissue (277, 278). Pleural effusion and pulmonary parenchymal changes are exceedingly rare (279, 280, 281 and 282), but occasional cases are characterized by extensive interstitial infiltrates (lymphoid interstitial pneumonitis), and severe respiratory insufficiency has been reported (280). Evidence for some degree of hepatic involvement is found in most patients but is usually mild; the necrosis and inflammatory exudate seen in association with infectious hepatitis are encountered only rarely (242, 283, 284 and 285). Liver failure is rare (242, 283) but appears to be a prominent feature in fatal cases of IM [fulminant infectious mononucleosis (FIM) or EBV-HLH] (283), including those associated with subtle forms of immune deficiency (283). Acute pancreatitis has been associated with IM (286, 267). An association between IM and irreversible renal failure was postulated in one patient (288).

Treatment

Most patients experiencing uncomplicated acute IM require only symptomatic therapy. Bed rest is recommended for patients with fever, malaise, and myalgias.

Strenuous exercises, especially contact sports, should be avoided for at least 1 month or until resolution of splenomegaly. Nonsteroidal antiinflammatory drugs, such as acetaminophen or ibuprofen, should be used to control pain, although in patients with severe hepatitis, these agents should be used judiciously. It has been suggested that aspirin may prolong convalescence ([290]). Aspirin also interferes with platelet function, potentially increasing the risk of bleeding in thrombocytopenic patients, and Reye syndrome has been reported in association with IM, albeit rarely ([255]). Antibiotics are of no value in uncomplicated IM, but many patients show culture or serologic evidence of a recent streptococcal infection ([136]), and these should be treated with appropriate antibiotics. Ampicillin and amoxicillin should be avoided because they often cause a severe rash ([136] , [143] , [145] , [146]).

Corticosteroids have been used in cases of life-threatening complications such as airway obstruction, carditis, lymphoid interstitial pneumonitis, pleural effusions, or cerebral edema. Their efficacy is largely anecdotal and is presumably due to their antiinflammatory and lympholytic properties. The cumulative results of several small, controlled clinical trials suggest that corticosteroids hasten the resolution of fever and tonsillopharyngeal symptoms but do not provide significant benefits in the therapy of lymphadenopathy or hepatosplenomegaly ([13] , [291] , [292] and [293]). Caution should be exercised when using corticosteroids ([294]). There are reports of encephalitis or myocarditis in association with steroid use in IM ([293] , [295]), and secondary bacterial and fungal infections can occur. However, in the face of severe complications, the use of steroids may well be indicated and necessary ([290] , [294] , [296] , [297]).

Several antiviral agents such as acyclovir, ganciclovir, zidovudine, foscarnet, and the interferons (IFNs) have been shown to inhibit the replication of EBV *in vitro* ([298]). Only the linear form of the genome, not the latent circular form, is susceptible to inhibition. The efficacy of acyclovir in the therapy of uncomplicated IM has been assessed in several controlled trials ([299] , [300] , [301] , [302] and [303]). In general, acyclovir inhibited viral shedding during the time of therapy, but viral shedding resumed when therapy was discontinued ([13]). The trials documented few clinical benefits as measured by duration of illness and sore throat, weight loss, or absence from school or work, even when acyclovir was given in combination with steroids ([293] , [303]). IFN-a has been used in a few patients experiencing persistent EBV infection with severe complications of interstitial pneumonitis, encephalitis, or genital ulcers, apparently with some success ([304]). Patients with IM-associated immune thrombocytopenia have responded to therapy with large doses of intravenously administered ?-globulin ([231]). A viral protein vaccine has been developed, that protects marmosets from developing lymphoproliferative disease ([305] , [306]) but not from infection. Several groups are working on the development of EBV vaccines ([307] , [308] , [309] and [310]), but with the tight MHC restriction of the CTL response, large-scale population studies are problematic. Therefore, the use of the vaccine in the prevention of IM is controversial, but it may be beneficial in endemic areas of BL or NPC ([308] , [309]).

Prognosis

IM is rarely fatal, and the prognosis for a complete recovery within 2 months occurs in the majority of patients. Because recurrences of IM are extremely rare, one must question either the initial or the present diagnosis. IM is fatal in approximately 1 in 3000 cases, or approximately 50 cases annually in the United States ([78] , [311]). Penman ([242]), in reviewing the world literature on IM, catalogued 87 fatalities attributed to the disease or its complications. Only 20 of these reports, however, contained adequate evidence for an unequivocal diagnosis. Of these 20 cases, 9 fatalities were related to neurologic complications, 4 were related to respiratory failure from peripheral neuropathy of the Guillain-Barré type, and 5 were related to central respiratory paralysis; 3 were related to splenic rupture; and 3 were related to secondary infection. Other fatal complications included hepatic failure (two cases) and myocarditis (one case). In two cases, the cause of death was unrelated to IM. The majority of deaths associated with IM occur in patients who develop VAHS or EBV-HLH ([78] , [311]).

OTHER EPSTEIN-BARR VIRUS–RELATED DISEASES

Recently, methods for detecting infectious agents in human disease have become highly developed. Consequently, many ubiquitous infectious agents have been etiologically linked to certain human diseases (e.g., EBV infection has been associated with a wide spectrum of human diseases). Classically, EBV is associated with the development of human malignancies such as BL and NPC. EBV infection has also been associated with other human malignancies, such as NHL (B-cell, T-cell, and NK-cell phenotype), HD, gastric carcinoma, leiomyosarcoma, hepatocellular carcinoma, breast cancer, and LPDs, which may occur in patients with primary or secondary immunodeficiencies. In addition, EBV infection has been associated with several nonmalignant, but often fatal, human diseases, such as VAHS or EBV-HLH, and CAEBV, in which development of malignant lymphoma can occur. Although association has been demonstrated, it remains controversial whether EBV is causative in these disorders. The following discussion focuses on diagnosis of and evidence for the role of EBV in the pathogenesis of these diseases.

Chronic Active Epstein-Barr Virus Infection

EBV rarely causes recurrent or persistent symptomatic infections in apparently immunocompetent hosts. CAEBV is characterized by persistent or recurrent IM-like symptoms, such as recurrent fever, lymphadenopathy, and hepatosplenomegaly, and unusual anti-EBV antibody patterns ([317]). Diagnostic criteria for CAEBV have been proposed by Strauss ([318]) and Okano ([317]) and consist of (a) evidence of severe, progressive EBV illness beginning as a primary EBV infection and lasting more than 6 months with anti-EBV titers of IgG anti-VCA =1:5120, anti-EA =1:640, or anti-EBNA <1:2, or all three; (b) histologic evidence of major organ involvement; and (c) increased amounts of EBV in peripheral blood or affected tissues, or both. CAEBV occurs most commonly in patients who develop IM as older children or young adults ([317] , [319]). This entity may be more prevalent in Asia, as most of the published literature is from Japan. Recently, Kimura et al. reported 30 patients with CAEBV; the mean age was 14 years with a range from 5 to 31 years of age ([319]). Manifestations of CAEBV in this cohort were fever (100%), liver dysfunction (90%), splenomegaly (90%), lymphadenopathy (50%), thrombocytopenia (50%), anemia (50%), hypersensitivity to mosquito bites (43%), calcification in the basal ganglia (18%), and oral ulcer (18%). Only two-thirds of these patients had elevated anti-EBV titers fitting the diagnostic criteria mentioned above, but all had high levels of EBV DNA in the peripheral blood detected by the quantitative polymerase chain reaction.

In the peripheral blood of patients with CAEBV, high levels of EBV DNA have been found in $CD4^+$ T cells and NK cells, but not in B cells ([320]). The significance of this finding in the pathogenesis of CAEBV and the mechanism of infection of these cells, because they lack the CD21 receptors, remain to be elucidated. However, the predominant cell type infected by EBV may have prognostic value. One study showed that patients with a predominance of infected T cells have higher titers of anti-EBV antibodies and shorter survival than patients with a predominance of NK-cell infection ([319]). Although EBV is believed to be the etiologic agent in CAEBV, the precise underlying pathogenic mechanisms remain uncertain. However, it is believed that cellular immunologic abnormalities are responsible for the development of CAEBV because many patients showed defective NK-cell activity and extremely high levels of circulating cytokines such as IL-10 ([321]).

CAEBV can be lethal, with a 30 to 50% mortality within 5 years of diagnosis ([30] , [319]). Life-threatening complications include the hemophagocytic syndrome (21%), coronary artery aneurysm (21%), hepatic failure (18%), malignant lymphoma (16%), and interstitial pneumonia (12%) ([319]). The majority of deaths are due to hemophagocytic syndromes or hematologic malignancies, which may be of T-cell, B-cell, or NK-cell phenotype ([30] , [319]).

Jones et al. first reported three patients with T-cell lymphoma infected with EBV, who had grossly elevated antibody titers against EBV-replicative antigens such as VCA and EA ([322]). During the 1980s, approximately 30 similar patients were reported, mainly from industrialized countries. More recently, a distinct clinicopathologic syndrome was proposed, called “fulminant EBV-positive T-cell LPD following acute/chronic EBV infection” ([323]). This entity may overlap with severe or fulminant IM (FIM or EBV-HLH) and CAEBV. Further studies are needed to differentiate between these enigmatic disorders and determine the role of EBV infection in their pathogenesis.

A standard treatment approach to CAEBV has not been established. Most reports are anecdotal but include antiviral agents (acyclovir, ganciclovir, and vidarabine) ([317] , [319] , [324] , [325]) and immunomodulating agents (IFN-a or IL-2) ([319] , [326] , [327]). Immunochemotherapy (e.g., etoposide, corticosteroids, and cyclosporin A), which has been effective in treating the EBV-hemophagocytic syndrome, has been used to control symptoms and treat hemophagocytic complications ([319]). Hematologic malignancies have been treated with standard NHL therapy ([319]), but curative therapy for the severely affected patient appears to require the replacement of the patient's immune system with a normally functioning immune system to control the EBV infection—for instance, by an allogeneic stem cell or marrow transplant ([319] , [328]) or by allogeneic adoptive T-cell therapy ([329]).

CAEBV infections should be differentiated from the so-called chronic mononucleosis, or chronic fatigue syndrome. Due to the similar symptoms and reports of elevated anti-VCA and EA titers, EBV has been suggested to be the etiologic agent in the chronic fatigue syndrome ([330]). In controlled studies, no specific EBV serologies have been found that differentiate chronic fatigue syndrome patients from controls ([331]). In a randomized, placebo-controlled trial of acyclovir, clinical improvement was seen as frequently with the placebo ([332]). Chronic fatigue syndrome has been associated with other infections (viral and bacterial) and, therefore,

should not be considered a disease caused by EBV ([333], [334]).

Fulminant Infectious Mononucleosis or Epstein-Barr Virus–Associated Hemophagocytic Lymphohistiocytosis

The self-limited course of IM contrasts with the atypical responses that can occur in FIM, also called *VAHS* or *EBV-associated HLH* ([74]). Death occurs in approximately 1 in 3000 IM cases, or approximately 50 cases annually in the United States ([78], [311]). The median age at presentation of FIM/EBV-HLH is similar to that of uncomplicated IM (i.e., 13 years of age). Whereas FIM/EBV-HLH is the most common manifestation in males affected with XLP, it often occurs outside the context of XLP ([74], [75], [311], [335], [336]). In the latter cases, the male to female ratio is approximately 1:1 ([311]). VAHS has been associated with CMV, herpes simplex virus, and adenovirus, but EBV is the most common ([74], [337], [338]). Clinically, FIM/EBV-HLH is indistinguishable from other types of VAHS, familial HLH, and the accelerated phase of Chédiak-Higashi disease ([74], [75], [338]). Because FIM/EBV-HLH is rare, a search for a heritable immune deficiency in family members is mandatory.

Patients who progress to FIM/EBV-HLH initially present with the usual signs and symptoms of IM, but these symptoms are often more severe ([311]). The usual EBV antibody responses vary considerably and may be lacking or unusually high; therefore, it may be difficult to differentiate FIM/EBV-HLH from other hemophagocytic syndromes, CAEBV, acute leukemia, other malignancies, or even overwhelming sepsis ([75], [311], [335]). The course and progression of the disease are variable, ranging from multiorgan failure developing over hours to persistent or recurring symptoms of IM lasting for months. An atypical lymphocytosis usually is present at early stages of the disease, but patients subsequently develop severe, persistent pancytopenia, hepatic dysfunction resulting in fulminant hepatitis, meningoencephalitis, and varying degrees of myocarditis ([75], [311], [335], [339]). The development of hepatic dysfunction, often with coagulation abnormalities secondary to liver failure or disseminated intravascular coagulation, and pancytopenia is an ominous sign, as are other signs of hemophagocytic syndromes, such as hypofibrinogenia and elevated triglyceride levels ([74], [75], [311], [335], [336], [338]).

As discussed previously, EBV is a potent stimulus to the immune system, resulting in a massive EBV-specific and -nonspecific response of both the humoral and cellular immune systems (Fig. 67.5). In FIM/EBV-HLH, the EBV-nonspecific response, primarily the cellular immune response, is uncontrolled. FIM/EBV-HLH is characterized by extensive infiltration of parenchymal organs by lymphoid cells, primarily $CD8^+$ cells in varying degrees of transformation and histiocytes with surprisingly few B cells ([74], [337], [340]). The cells infected by EBV in FIM/EBV-HLH are usually T cells ([74], [320], [323]) and are generally $CD8^+$, as opposed to the $CD4^+$ or NK cells observed in CAEBV ([320]).

If this aggressive immune reaction proceeds unabated, all organs ultimately sustain extensive damage ([74], [75], [311], [335], [341]). Early in the course of the disease, the bone marrow may be hypercellular with few infiltrating histiocytes; erythrophagocytosis is seen best in smears of marrow aspirates. The marrow later becomes hypocellular with varying numbers of infiltrating histiocytes ([337]). Lymph nodes initially show an intense lymphoblastic proliferative response, again primarily T cells, but later, lymphoid depletion supervenes ([337]). Liver biopsies reveal active portal infiltration with lymphocytes and histiocytes, with occasional erythrophagocytosis in liver sinusoids ([337]). In the spleen, extensive necrosis of white pulp develops. Perivascular mononuclear cell infiltrates of the brain, mononuclear cell myocarditis, and interstitial nephritis also are observed ([75], [335], [336], [339], [342], [342a], [343]). The thymus shows thymocyte depletion and necrosis of thymic epithelia, reminiscent of that observed in experimental and human graft-versus-host disease (GVHD) ([344], [345]) and acquired immunodeficiency syndrome (AIDS) ([345]). Increased serum levels of IL-2, IFN-?, L-6, TNF-a, and soluble IL-2 receptors have been demonstrated ([74], [346]). The T cells that are activated in response to EBV are believed to stimulate and activate macrophages, the major source of IL-6 and TNF-a. This reaction culminates in the phagocytosis, tissue destruction, and cellular depletion seen in FIM/EBV-HLH ([74], [75]), and death usually follows shortly thereafter due to multisystem organ failure.

Once FIM/EBV-HLH develops, therapy is difficult and usually unsuccessful, with a median survival time of approximately 4 weeks ([311], [335]). Antiviral drugs, Igs, IL-2, IFN-a, IFN-?, plasmapheresis, corticosteroids, and most cytotoxic drugs have been ineffective ([74], [78]). There is one report of 20 patients with IM and hemophagocytosis, but lacking severe symptoms of FIM/EBV-HLH, successfully treated with chloroquine ([347]). The most consistent success in the treatment of FIM/EBV-HLH is with the early use of etoposide, which reduces the activity of stimulated macrophages *in vitro* ([348], [349] and [350]). Combinations of etoposide and intravenous Igs have been recommended by others ([74], [350], [351] and [352]). The best results appear to be obtained with a combination of etoposide and concomitant immunosuppression with corticosteroids and cyclosporin A or tacrolimus (FK506) ([74], [78], [350]). Therapy may have to be continued for 6 to 12 months. These patients are profoundly immunocompromised from their disease and the therapy. Therefore, a successful outcome is dependent on control of FIM/EBV-HLH symptoms as well as the prevention and successful treatment of life-threatening infectious complications. Even with remission of symptoms, recurrences are common and carry a poor prognosis. For the patient with severe or recurrent disease, curative therapy may involve replacement of the patient's immune system with a normal immune system by allogeneic stem cell or marrow transplantation ([350], [353]).

Epstein-Barr Virus–Associated Disorders in Immunodeficiency

In the mid-1970s, Purtilo et al. described XLP, in which affected males were thought to have a specific immunodeficiency to EBV, resulting in severe or fatal IM, malignant lymphoma, hypogammaglobulinemia or agammaglobulinemia, or aplastic anemia ([354]). Later, it was noted that patients with ataxia telangiectasia, a primary immunodeficiency, had high antibody titer responses against EBV-replicating antigens, and EBV genome–positive malignant lymphomas were observed ([355], [356]). Similar antibody patterns and EBV-associated B-cell LPDs (EBV-LPD) were also reported in patients with Wiskott-Aldrich syndrome ([357]). With more efficacious immunosuppression, EBV-LPD was also observed more frequently in recipients of organ and marrow transplants, whereas stopping or decreasing the dose of immunosuppressants sometimes resulted in the regression of EBV-LPD, suggesting that a deficiency of immunosurveillance was responsible for the development of EBV-LPD in such patients ([358]). In the late 1980s, an increased incidence of EBV-LPD, including BL, was reported in association with a growing number of patients with AIDS ([359]). In recent years, advances in the treatment of autoimmune disorders, the expanding number of organ transplants, and the spread of HIV have dramatically increased the number of patients at risk of EBV-associated diseases. However, not all LPDs seen in immunodeficient patients are associated with EBV. This raises the question of the specific role of EBV in the pathogenesis of LPD in immunodeficiencies.

PRIMARY IMMUNODEFICIENCIES As mentioned previously, the main immune defense against EBV-driven B-cell proliferation is EBV-CTLs. Patients with primary immunodeficiencies often lack T-cell functions, which may manifest as insufficient EBV-CTL activity. There are numerous reports of the occurrence of EBV-LPD in patients with a primary immunodeficiency disease (e.g., ataxia telangiectasia, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, severe combined immunodeficiency, and common variable immunodeficiency) ([360]). Generally, type III EBV latency is predominantly seen in these lymphomas ([30], [360]), suggesting a lack of appropriate EBV-CTL immunosurveillance (see section Immune Response to Epstein-Barr Virus Infection). Additionally, relapses are common and may not represent failure to eradicate the original clone, but a new clonal proliferation ([361]). These data underscore the role of immunosurveillance in the pathogenesis of these malignancies. The treatment is often difficult because of the underlying serious immunodeficiency and genetic susceptibility to chemotherapeutic agents. Antiviral therapy has had little effect in the treatment of EBV-LPD in primary immunodeficiency ([362]). Patients with antibody deficiencies, but at least partial T-cell immunity, have been treated successfully with IFN-a ([362]). Although complete remissions can be achieved with chemotherapy, immunodeficient patients with NHL have a far inferior outcome compared to those expected for immunocompetent children with NHL receiving similar therapy ([363], [364]). These poor results are due to increased toxicity of chemotherapy, especially in ataxia telangiectasia patients, but also increased fatal infections and NHL relapses. Because recurrences can be of different clonal origin, successful treatment depends on controlling B-cell proliferation by developing appropriate EBV-CTL immunity. In the majority of cases, the only way to achieve this is allogeneic bone marrow transplantation (BMT) ([353], [361], [362]).

X-Linked Lymphoproliferative Disease In 1974, there were two reports of maternally related boys dying of IM ([354], [365], [366]). In 1975, Purtilo described a kindred, in which 6 of 18 boys died of a lymphoproliferative disease associated with EBV infection ([365]). XLP has also been called *Duncan disease*, after the original kindred, or *Purtilo disease*. XLP is a rare disorder, affecting an estimated 1 out of every 1 million male individuals ([336]). Initially, three phenotypes were described in XLP patients, and these continue to characterize the majority of patients: FIM, malignant lymphoma (LPD), and dysgammaglobulinemia ([336]). Less commonly reported manifestations include disorders such as vasculitis, pulmonary lymphomatoid granulomatosis, and hematologic cytopenias, including aplastic anemia and pure red cell aplasia ([336], [341], [367], [368]). The “disease state” is capricious, as it may feature a single phenotype or two or more phenotypes, which may develop sequentially in susceptible individuals ([336], [369]). Reflecting on the ubiquitous nature of EBV infection, FIM is the most common XLP phenotype, affecting approximately 50% of patients in the XLP registry ([336], [368], [369]). FIM is decidedly the most lethal of the XLP phenotypes, as most of the boys die within 1 month and only 7% of FIM patients have survived ([367]). The median age of onset for XLP-associated FIM is 5 years of age, but the condition has occurred up to 40 years of age. The pathology and clinical findings of FIM associated with XLP are identical to those seen in patients without XLP, as discussed previously. Interestingly, 39% of XLP patients with

evidence of current or prior EBV infection never develop FIM ([369]). This observation puts into question the role of EBV and the immunologic defect caused by the genetic abnormality in XLP. Dysgammaglobulinemia is the second most common XLP phenotype, affecting approximately one-fourth of boys ([336] , [368] , [369]). Most boys developing this phenotype demonstrate global decreases of serum Ig levels. However, some featured increased levels of IgM or IgA, or both, as well as variable deficiencies in IgG1 and IgG3 subclasses ([370]). Although hypogammaglobulinemia often occurs after EBV infection, some XLP patients develop hypogammaglobulinemia without prior evidence of EBV infection ([369]). Mice with the XLP gene “knock-out” can manifest progressive hypogammaglobulinemia (J. Sumegi, personal communication, June 2002). The pathogenesis of dysgammaglobulinemia in XLP has not been delineated. An LPD develops in approximately one-fourth of XLP patients ([336] , [368] , [369]). Most lymphomas are of B-cell phenotype and are characterized by a small noncleaved (Burkitt) or diffuse large cell histology ([75] , [371]). Karyotypic analysis has not been extensively performed; however, the t(8;14) associated with BL is rare ([372] , [373]). Approximately 10% of LPDs are not of B-cell phenotype, including a small number of patients with HD or T-cell LPDs, including lymphoblastic lymphoma, lymphomatoid granulomatosis, or angiocentric immunoproliferative lesions ([75] , [367]). As in other immunodeficiencies, the role of EBV in the LPD of XLP is unclear, because approximately one-half of the boys with LPD have had no evidence of prior EBV infection, and EBV is detectable in only 25% of tumor specimens ([367] , [369]). Distinct from the marrow depletion seen with FIM, a limited number (4%) of boys have developed isolated hematologic cytopenias ([336] , [368] , [369]). Most manifest with suppression of two or more hematologic cell lines, including aplastic anemia, but pure red cell aplasia has also been observed. Again, the role of EBV in this manifestation of XLP is unclear, as 40% of cases observed in XLP have occurred without evidence of prior EBV infection ([369]). Initially, it was thought that males affected with XLP only manifested symptoms after primary EBV infection. Although IM is, by definition, caused by EBV, other XLP phenotypes developed in EBV-seronegative patients ([369] , [374]). Data from the XLP registry demonstrated that at least 12.5% of affected boys manifest symptoms of XLP before exposure to EBV ([336] , [368] , [369]). There is no difference in the age of onset of clinical symptoms between males that have or have not been previously exposed to EBV ([369]). Therefore, prevention of EBV infection in boys with XLP does not avert clinical manifestations. In addition, whereas approximately 40% of the boys develop FIM after primary infection with EBV, others develop LPD, dysgammaglobulinemia, and hematologic cytopenias, and a few have no symptoms ([369]). These data suggest that other genetic or environmental factors, or both, influence host susceptibility to EBV and are important in determining the clinical phenotype of XLP. Before the isolation of *SH2D1A*, the gene known to be absent or mutated in XLP, it was often difficult to make a diagnosis of XLP based solely on clinical or laboratory features. Laboratory investigations of lymphocyte numbers, immunophenotype, and function were generally unhelpful because results were either normal ([367] , [375] , [376]) or hard to interpret due to immune depletion resulting from primary EBV infection or lymphoma treatment. Evaluation of humoral responses gave inconsistent results, with some patients displaying normal values ([375]) and others demonstrating increases in IgA or IgM (or both), as well as variable deficiencies in the levels of total IgG or the IgG1 and IgG3 subclasses ([370]). The only consistent findings were lack of anti-EBNA responses in EBV-infected males and inability of IgM to switch to IgG after secondary challenge with FX174 bacteriophage ([377]), although these findings can be seen also in other inherited T-cell deficiencies. Investigations of EBV-specific immunity have been more controversial. Based on these issues, establishing an XLP diagnosis used to rely on the identification of two or more maternally related males demonstrating a characteristic phenotype usually after EBV infection ([378]). Now, the diagnosis can more easily be made based on the identification of an abnormal *SH2D1A* gene sequence ([369]) or protein expression ([379]). Although only 50% of their lymphocytes express *SH2D1A* on average, due to random X-chromosome inactivation ([380]), female carriers display no overt clinical manifestations of XLP. Molecular analysis should be pursued in females at risk of being a carrier to provide accurate genetic counseling. Recent genetic studies have also demonstrated that *SH2D1A* mutations can arise in affected boys whose mothers do not have a mutated gene ([381]). One might predict that mutations that delete the XLP gene or truncate the protein would be more likely to be associated with a severe phenotype, whereas missense mutations would occur preferentially in mildly affected patients. Attempts to correlate mutations of the *SH2D1A* gene and the clinical manifestations of XLP found that it was not uncommon to observe different phenotypes with identical mutations, even within the same family ([369]). No significant differences were observed in the phenotypes or severity of disease based on the type (missense, nonsense, truncating) or localization of *SH2D1A* mutations. The age of onset of clinical manifestations of XLP varied considerably, from younger than 1 to 40 years of age, as did survival, but there was no correlation with the type of mutation. Therefore, genetic analysis does not predict the phenotype or severity of disease. The *SH2D1A* gene codes for a protein of 128 amino acid residues that consists of an SH2 domain and a 25–amino acid *C*-terminal tail ([382] , [383]). *SH2D1A* is expressed throughout thymocyte development, as well as in $CD4^+$ and $CD8^+$ peripheral T cells ([384]). In contrast to T lymphocytes, *SH2D1A* has a more limited expression in B cells ([384]). The *SH2D1A* protein appears to function in the regulation of immune responses. The *SH2D1A* protein interacts with several proteins, including SLAM (*s*ignaling *l*ymphocyte *a*ctivating *p*rotein; CD150), also called *SLAM-associated protein* ([383]). SH2D1A/SLAM-associated protein also has been demonstrated to interact with members of the CD2 superfamily of molecules, including CD2, CD48, CD583, CD84, Ly-9, and 2B4, and with a new family of RasGAP adapter proteins such as p62Dok [Dok (*d*ownstream *o*f *k*inases)-1], p56Dok (Dok-2), and Dok-3 ([385] , [386] , [387] , [388] and [389]). The immunologic effects of *SH2D1A* interactions with these proteins are under investigation. Mice genetically deficient in *Sh2d1a* (the murine homolog) expression have been generated ([390]). Consistent with human XLP, mutant animals are viable and fertile, transmit the gene defect in an X-linked mendelian fashion, and display no significant defects in the number and phenotype of developing thymocytes or circulating T, B, or NK cells. After infection, however, *Sh2d1a*-deficient mice recapitulate important aspects of the human disease. For example, these mice exhibit abnormal lymphocyte responses to lymphocytic choriomeningitis virus, a virus that, like EBV, elicits large $CD8^+$ cytotoxic T-cell responses ([390]). In comparison to T-cell hyperactivation, B-cell responses appear to be blunted, with the numbers of total and lymphocytic choriomeningitis virus–specific antibody-secreting cells decreasing dramatically over time ([391]). Previous investigations of XLP patients have demonstrated elevated levels of IFN-? and IL-2 during IM ([367]), suggesting that a bias toward production of T-helper cell–type (Th1) cytokines may contribute to the overwhelming macrophage activation after primary EBV infection. In agreement with this human clinical observation, *Sh2d1a*-deficient mice produce more IFN-? after *in vitro* as well as *in vivo* stimulation ([390]). The increased T-cell activation, biased Th1 cytokine secretion, and defects in antibody production that occur in *Sh2d1a*-deficient mice suggest that they will provide a valuable tool with which to better understand FIM/EBV-HLH and how *Sh2d1a* may regulate *in vivo* immune responses to viral and other infectious agents. XLP is highly lethal; 75% of patients have died by 10 years of age, although the oldest known survivor is 49 years of age ([336] , [367]). Antiviral therapies, including acyclovir, ganciclovir, intravenous Ig, and IFN-a have been used to treat primary EBV infection; none has been particularly effective ([367]). The only therapy that has been consistently beneficial for males with FIM is etoposide and immunosuppression, as discussed previously ([336] , [367]). Recently, a patient with FIM was successfully treated with corticosteroids and monoclonal anti-CD20 antibody (K. Nichols, personal communication, June 2002). Even with remissions, relapses are invariable. Therefore, an allogeneic BMT is recommended once the patient's condition is stabilized and a suitable donor has been identified ([353] , [361] , [391]). Patients with hypogammaglobulinemia require regular Ig supplementation to prevent bacterial and viral infections. However, Ig infusions do not offer the guarantee of protection from primary EBV infection in an EBV-seronegative patient ([336] , [367] , [369]). For patients with lymphoma or hematologic cytopenias, standard therapeutic protocols suffice. Although treatment can induce disease remissions, relapses and other XLP phenotypes invariably occur, and allogeneic BMT is recommended ([353]). With definitive diagnosis by genetic mutational analysis, BMT now can be performed before the appearance of clinical manifestations of the disease ([391]).

SECONDARY IMMUNODEFICIENCIES It is well recognized that patients infected with HIV and experiencing AIDS, as well as transplant recipients, are at increased risk of developing LPDs that are often associated with EBV. Rarely, elderly patients, malnourished patients, and those with cancer develop EBV-associated atypical lymphoproliferation ([75] , [392]). EBV-induced LPDs have been reported in patients without severe immunodeficiency (i.e., individuals who received methotrexate as treatment for rheumatoid arthritis) ([393]). Therefore, a high index of suspicion is warranted in any patient who may be immunosuppressed.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome Patients with AIDS or the AIDS-related complex often show signs of EBV reactivation, including a transient elevation of antibodies to EBV antigens ([394]), an expanded pool of EBV-infected B cells in the peripheral circulation ([395]), and an increased production of the ZEBRA protein, that triggers viral replication and transactivates other genes that up-regulate the expression of early gene products essential for viral replication ([13] , [66] , [396]). In addition, there is an increase in EBV shedding in the saliva, especially in the presence of oral hairy leukoplakia, characterized by white, raised lesions with a hairy corrugated surface, 0.5 to 3.0 cm in diameter, occurring predominantly on the lateral margins of the tongue ([396]). EBV DNA has been found in the oral leukoplakia of HIV-infected patients ([396]). These wartlike lesions carry EBV-replicating cells in the upper five to six cell layers ([397]) and respond very well to oral therapy with acyclovir ([398]). EBV-positive monoclonal expansions of lymphocytes have been found in the lymph nodes of approximately one-third of HIV-positive individuals experiencing persistent generalized lymphadenopathy ([192] , [399]). Often, EBV-positive cells are increased five- to tenfold in lymphoid tissues of HIV-infected patients compared to non-HIV patients ([75]). Children with AIDS often develop lymphoid interstitial pneumonitis due to EBV-induced polyclonal B-cell proliferation ([400]). Adults with AIDS have a 100-fold increased risk of developing malignant lymphomas ([401]). It has been demonstrated that AIDS patients who develop EBV-associated lymphoma have a loss of EBV-CTL function ([402]). NHL is a common late manifestation of infection with HIV; the probability of developing such a complication has been estimated to range between 20 and 30% ([403]). Only 30 to 40% of these NHL tumors contain EBV genomes ([9] , [404]). It has been demonstrated that central nervous system lymphomas are almost always EBV positive ([405]), as are the rare lymphomas that involve preferentially the pleural, pericardial, and peritoneal cavities ([406]). As with NHL associated with other immunodeficiencies, most AIDS-associated NHL is of B-cell phenotype and tends to involve extranodal sites, especially the central nervous system (17 to 42%), the gastrointestinal tract (4 to 28%), the bone marrow (21 to 33%), and the liver (9 to 16%) ([9]). Histologically, many of these tumors are high grade and aggressive and most commonly are classified as small noncleaved (BL) or large cell diffuse ([9] , [399] , [407] , [408]). It appears that diffuse large cell NHL is more likely to develop in severely immunosuppressed patients, whereas BL is increased in less immunosuppressed patients with AIDS ([408]). Studies have demonstrated conflicting results on the effect of highly active antiretroviral therapy on the incidence of AIDS-associated NHL ([409] , [410] , [411] , [412] , [413] and [414]). Studies have shown that the incidence of central nervous system NHL and large cell lymphomas has decreased, but not that of BL ([411] ,

414). As for NHL associated with primary immunodeficiency, the prognosis for HIV-associated NHL is much worse than the prognosis for NHL occurring in immunocompetent individuals. Studies have demonstrated that survival may be improved with less-intensive chemotherapy (415). One study demonstrated that patients with EBV-positive tumors had a worse prognosis (416).

Posttransplant Lymphoproliferative Disease Figure 67.3 illustrates the importance of a qualitatively and quantitatively appropriate T-cell response in maintaining homeostasis and preventing EBV-driven B-cell proliferation. Therefore, after very immunosuppressive therapy and the transfer of EBV-infected B cells via blood, marrow, or organ grafts, complications due to EBV are frequently seen in transplant patients. Perhaps it is surprising that more patients do not experience EBV-related disease post-BMT. Posttransplant lymphoproliferative disease (PTLD) represents a spectrum of clinical and morphologic heterogeneous lymphoid proliferations (392, 417, 418, 419, 420 and 421). EBV lymphoproliferative disease posttransplant may manifest as isolated hepatitis, lymphoid interstitial pneumonitis, or meningoencephalitis or as an IM-like syndrome with peripheral adenopathy, fever, or hepatitis, or all three. Frequently, the definition of PTLD is limited to lymphomatous lesions (localized or diffuse) that are often extranodal (often in the allograft). Although less frequent, the most fulminant presentation of EBV-LPD in the posttransplant patient is as disseminated, systemic disease that clinically resembles septic shock and histologically resembles FIM. Histologically, EBV disease is quite heterogeneous as well. There have been several histologic classifications for PTLD over the years (417, 418, 420), but the World Health Organization has now proposed a classification, which includes (a) polymorphic hyperplasia, seen in IM presentations, (b) polymorphic PTLD, and (c) monomorphic PTLD. The last resembles intermediate- to high-grade NHL (422). Lesions associated with the IM presentation usually have a polymorphic histology with a mixture of B cells and infiltrating T cells. This pattern is also seen in EBV hepatitis, meningoencephalitis, and lymphoid interstitial pneumonitis lesions, in which the predominant cellular component consists of $CD8^+$ T cells (75, 419). PTLD is typically composed of plasmacytoid B cells, with few T cells, and, often, regional areas of necrosis. Distinguishing between a polyclonal and a monoclonal PTLD often requires lymphoid receptor gene analysis, because up to 50% of PTLDs do not express surface Ig (75, 419). The majority of PTLDs are $CD20^+$ and EBV early RNA (EBER)–positive by *in situ* hybridization, whereas immunohistochemistry staining for the LMP-1 protein is negative in 25% of cases (75, 423). Although PTLD may appear histologically identical to NHL or even HD, clinically and genetically, it appears differently. Cytogenetic abnormalities are rare in PTLD, even with Burkittlike histology, and abnormalities in genes observed in NHL (i.e., c-myc; N-, H-, and K-ras; p53; and bcl-2, bcl-6, etc.) are rare in PTLD (419, 420, 424, 425). Clonality and morphology have been poor predictors of outcome in PTLD, especially after BMT (127, 392, 426). More than 90% of early (<6 months posttransplant) PTLDs are EBV positive, when EBV-CTL immunity is lowest (392, 419, 426, 427, 428 and 429), whereas late (>2 years posttransplant) PTLDs are frequently EBV negative, can be of T-cell origin, and have a much poorer prognosis (430, 431, 432 and 433). The etiology of EBV-negative PTLD is not known, and no other virus has been identified as an etiologic agent. These late PTLDs may be a different disease and appear more akin to LPDs observed in other immunodeficient states (e.g., AIDS and primary immunodeficiencies), in which B-cell origin and EBV association are not universal. Currently, it is estimated that approximately 1000 new cases of PTLD a year are diagnosed in the United States (434). The risk factors for PTLD are well described and include the type of organ transplanted, frequency of rejection episodes requiring intensified immunosuppression (especially the use of T-cell antibody therapy or T-cell depletion with BMT), EBV seronegativity at time of transplant, the age of recipients (especially <5 years of age) in the case of organ transplants, and older age of donor in BMT (392, 417, 419, 426, 427, 435, 436). The incidence ranges from 1 to 5% in low-risk procedures (e.g., renal, heart, liver, and non–T-cell-depleted bone marrow transplants) to 10 to 30% in the high-risk procedures (e.g., lung, small bowel, and T-cell–depleted bone marrow transplants) (437). Because of the increased incidence in children receiving organ transplantation (435, 436), PTLD may soon become the one of the most common types of lymphoma in children in the United States. Successful treatment of EBV-LPD necessitates controlling the B-cell proliferation and facilitating the development of an appropriate memory cytotoxic T-cell (EBV-CTL) response to maintain an asymptomatic state of viral latency (Fig. 67.3). Additional factors that contribute to the difficulty of treating these patients include increased toxicity from therapy or secondary infections and the increased risk of organ rejection or GVHD due to the enhancement of alloreactive T-cell immunity. Surgery, radiotherapy, or both, are effective in curing localized disease, but this benefits only a small percentage of patients (392, 434). The use of antiviral agents such as acyclovir or ganciclovir and/or intravenous Ig may reduce viral replication and thereby limit the number of infected B cells and may be useful in prophylaxis or preemptive therapy (392, 437, 438 and 439). The efficacy of antiviral drugs in treating PTLD is controversial because they are seldom used without other interventions (e.g., reduction of immunosuppression); in addition, if viral replication, which is lytic to the infected B cells, is suppressed, B-cell proliferation could theoretically be enhanced. The approach most widely used as initial therapy is reduction of immunosuppression (392, 437). Many times, this is sufficient for controlling the disease, especially in localized, polymorphic cases or cases that present like IM. As opposed to PTLD after solid organ transplantation, immune suppression is rarely successful in BMT patients with PTLD, because the major immunosuppression after BMT is from delayed EBV-CTL recovery, not suppression of EBV-CTL function. Patients who do not tolerate reduction of immunosuppression because of graft rejection or GVHD, or who do not respond to immunosuppression reduction, require more aggressive therapy and have a much poorer prognosis (392, 417, 426, 427, 434, 437). IFN-a has been used successfully to treat PTLD (392, 426, 440, 441) but is not generally used due to apparent increased organ rejection and infections, the latter presumably from marrow suppression. Anti–B-cell monoclonal antibodies have been used successfully, including anti-CD21 and anti-CD23 (442) and, more recently, anti-CD20 (443, 444). Chemotherapy has also been used successfully for PTLD (434, 445, 446). This approach is attractive because it kills proliferating B cells and is immunosuppressive enough to treat or prevent GVHD or organ rejection (447). However, at conventional doses used in the treatment of NHL, posttransplant patients appear to have more end-organ toxicity and susceptibility to infection, especially after BMT (392, 434, 437, 445). Additionally, conventional dose chemotherapy may also inhibit the development of EBV-CTLs. Low-dose chemotherapy approaches have been shown to be at least as effective in controlling PTLD (434). Because the problem in most cases of PTLD is an inadequate number of EBV-CTLs, replacement of EBV-CTLs would be of great benefit. Infusion of donor leukocytes has been demonstrated to be successful in the treatment of PTLD post-BMT (448). However, severe GVHD has also been associated with infusion of donor leukocytes, death due to a “shock-like syndrome” has been reported, and the PTLD is not always controlled (448, 449). To avoid the GVHD and other associated toxicities, *ex vivo*–generated EBV-specific CTLs have been shown to be effective in treating and preventing PTLD post-BMT (450); however, this approach is not feasible for most centers due to the cost and regulatory oversight necessary to generate and administer the *in vitro*–generated EBV-CTLs. The use of adoptive T-cell therapy in an organ transplant recipient is complex. First, cadaver organs are most widely used; therefore, donor leukocytes are often not available. Second, as opposed to BMT, after organ transplant, the PTLD cells are usually of recipient origin, so the immunologic recognition, specificity, and efficacy of donor leukocytes are uncertain. Third, the use of closely matched relatives' leukocytes runs the risk of both rejection and GVHD. Finally, the *ex vivo* generation of EBV-specific CTLs takes several weeks (450, 451) and requires a high level of technology and cost.

Epstein-Barr Virus–Associated Malignancies

BURKITT LYMPHOMA The neoplastic cells in BL have a mature B-cell phenotype as demonstrated by the expression of B-cell–associated antigens (CD19, 20, and 21) and the presence of Ig on the cell surface (9). Approximately 95% of endemic African BLs contain EBV, as compared with 20% of sporadic BL occurring mainly in Europe and North America (10, 30). BL tumor cells express type I latency EBV gene expression (i.e., EBNA-1 and the EBERs, but not EBNA-2, EBNA-3, or LMP proteins) (13, 55, 452, 453). Also, many of the adhesion molecules and co-stimulatory molecules seen in latency type III infected cells are not expressed on BL tumor cells, making them less susceptible to immunosurveillance (30). EBV-positive lymphomas contain a single clone of episomal EBV genome, suggesting that virus infection preceded malignant transformation (454). Both endemic and sporadic forms of BL are characterized by specific chromosomal translocations that involve chromosomes 8 and 14 [t(8;14)] in 70% of cases, or 8 and 22 [t(8;22)] and 8 and 2 [t(8;2)] in the remainder (455, 456). As a result, the c-myc protooncogene becomes juxtaposed to one of the heavy or light chain Ig gene loci found on chromosome 14 (heavy chain), chromosome 22 (?–light chain), or chromosome 2 (?–light chain) (457, 458). As a consequence, the normal control of the c-myc oncogene expression is disrupted, and the oncogene is deregulated (458). Chronic B-cell stimulation by EBV, HIV, or malaria (340, 458) appears to play an additional, as yet undefined, role in the pathogenesis of BL. It has been postulated that EBV infection works as an initial trigger for B-cell proliferation and accounts for the increased incidence of BL in endemic areas. But EBV may not be required once the malignant transformation has been established (30). Interestingly, by analyzing EBV genome–positive and genome–negative clones originating from the same BL cell line, one study has shown that EBV infection was essential for malignant transformation (459). Others have suggested that EBERs were essential for transformation in BL cells (460). These findings suggest that EBV infection may be important not only in the development of BL but also for the maintenance of the malignant phenotype. Despite numerous attempts, the induction of the BL phenotype by infecting resting B cells with EBV *in vitro* has not been achieved. Therefore, the role of EBV in the pathogenesis of BL remains to be fully delineated.

NASOPHARYNGEAL CARCINOMA NPC is another important EBV-associated malignant disorder. This tumor is mainly observed in Southeast Asia, Southern China, and a few other limited regions of the world (10, 30, 461). In these areas, NPC is the most frequent malignant disorder. The evidence linking EBV to NPC is even more compelling than with BL (10, 461). The etiologic link between NPC and EBV was first suggested by serologic evidence (462, 463), especially IgA antibodies directed against EBV–EA diffuse or viral capsid antigens that are present in high titers in NPC patients as compared with matched controls, IM patients, and BL patients (10). Prospective screening for these IgA antibodies also appears to be useful in detecting preclinical NPC and in anticipating recurrences after therapy (464). The association between EBV and NPC was confirmed by demonstrating the presence of EBV DNA in NPC cells (314, 315 and 316). The finding of monoclonal EBV found in precancerous lesions of NPC is noteworthy, as it suggests EBV infection takes place early in the pathogenesis and is essential in the development of NPC (190, 465). As stated before, NPC tumor cells demonstrate type II viral latency gene expression (i.e., EBNA-1 but not EBNA-2 or EBNA-3 proteins); 60% also express LMP-1; LMP-2A can be detected in most, and LMP-2B is expressed in a smaller number of cases (55, 466, 467). EBERs have been demonstrated consistently in tissues derived from patients with undifferentiated NPC (468). A genetic predisposition appears to be an additional major factor in the development of this epithelial

malignancy. First-generation of southern Chinese immigrants to the United States have an incidence of NPC that is approximately one-half that of native Chinese, suggesting that both genetic and environmental factors contribute to the development of NPC ([469]). Other studies have identified loss of heterozygosity—that is, the deletion of genetic material from one of the chromosomes in tumor DNA; deletions at 3p25 and 3p14 have been identified ([470]). Putative tumor-suppressor genes at these sites remain to be confirmed ([461]). Other factors also may play a role in oncogenesis, including exposure to toxins contained in traditional Chinese medicines, such as *Euphorbia* plant extracts, which induce EBV replication, and the ingestion of nitrosamines or other oncogenic substances in salted fish ([10]).

HODGKIN DISEASE A pathologic link between EBV and HD has been suspected for some time on the basis of serologic studies that demonstrated unusually high titers of antibodies to VCA and EAs, as well as the observation that individuals with high antibody titers to EBV have an increased risk of developing the disease ([471], [472] and [473]). More recently, the presence of EBV has been demonstrated conclusively within the RS cells and their mononuclear variants in 40 to 50% of Hodgkin lymphoma specimens ([158], [159] and [160]). The virus appears to be monoclonal in any given individual, suggesting that infection occurred before the clonal expansion of RS cells ([474]). Nodular sclerosing and mixed cellularity types of HD are positive for EBV in more than 80 to 90% of cases, whereas lymphocyte-predominant and lymphocyte-depleted types are usually negative ([158], [159] and [160]). The pattern of latent gene expression is similar to that seen in most cases of NPC (i.e., type II latency) ([55], [159], [160], [475]). LMP expression in RS cells occurs at very high levels ([476], [477]). Furthermore, TNF receptor–associated factor-1, IL-10, and IL-6 have been reported to be overexpressed in EBV-positive RS cells ([478], [479] and [480]). These observations suggest a possible role for LMP-1 in the pathogenesis of HD. Because LMPs can elicit a cellular immune response, it has been suggested that factors within the microenvironment of the RS cells may induce a local suppression of EBV-specific immunity ([481]). Although the presence of viral genome does not prove the causative role of EBV in HD, these findings support that EBV infection is responsible or works as a cofactor in the development of EBV genome–positive HD.

T-CELL LYMPHOMA EBV genome–positive T-cell lymphoma was first described unexpectedly in three patients who had extraordinarily high IgG antibody titers to EBV-VCA and -EA ([322]). After this report, EBV genome–positive peripheral T-cell lymphoma had been increasingly reported mainly in Chinese populations ([482]). Type II latency is predominantly shown in these malignancies ([55]). The mechanism of EBV infection into human T cells still remains to be elucidated. CD21 expression has been reported on some T-cell lines ([483]); however, *in vitro* experiments have failed to demonstrate continuous presence of EBV in such T-cell lines. Variable clinical manifestations are observed in patients with T-cell lymphoma. This may be in part due to cytokine production and cytotoxic functions that can be observed in these tumor cells. Interestingly, this type of lymphoma is often associated with severe CAEBV ([317], [319]), as discussed previously. These malignancies are highly resistant, and the outcome is very poor.

NATURAL KILLER CELL LYMPHOMA/LEUKEMIA Patients with EBV genome–positive, CD3-negative NK-cell proliferations were initially reported by Japanese investigators ([484]). Type II latency is predominant in these malignancies as well ([30]). NK-cell lymphoma/leukemia has often been associated with mosquito bite sensitivity ([485]) and CAEBV (see discussion in section Chronic Active Epstein-Barr Virus Infection). Midline granuloma, which is predominantly of T-/NK-cell origin, was first reported in Asia ([486]), but now, cases in North America and Europe have been shown to be EBV genome–positive, with monoclonal viral episomes detected in virtually all tumor cells. In general, these malignancies have the same poor prognosis as EBV-positive T-cell malignancies.

GASTRIC CARCINOMA Gastric carcinoma is a leading cause of death due to cancer in Japan. Shibata and Weiss initially reported the presence of EBV genome by *in situ* hybridization ([32]). The incidence of the EBV genome in gastric carcinoma in Japan is approximately 7% ([43]). These cancerous lesions also contain a monoclonal EBV genome but express only EBNA-1, EBERs, and BART (type I latency), similar to EBV genome–positive BL ([487]). Therefore, EBV infection must occur before malignant cell proliferation. Due to the high percentage of EBV genome–negative cases, causality in regard to EBV and gastric carcinoma remains unclear, but the hypothetical mechanisms to genome-negative BL may apply.

MISCELLANEOUS EPSTEIN-BARR VIRUS–ASSOCIATED HUMAN CANCERS EBV genome–positive pyothorax-associated lymphoma has occurred uniquely in the pleural cavity of patients with long-standing pyothorax who have no obvious immunodeficiency, although lymphoma cells actually show type III latency, suggesting local immune suppression ([489]). There are anecdotal reports of several other human malignancies, in which the EBV genome has been detected. They include lymphoepithelial carcinomas of the salivary glands, tonsillar carcinoma, parotid grand carcinoma, and thymoma ([488]). EBV DNA has been found in leiomyosarcomas of children with AIDS ([35]) and organ transplant recipients ([36]). The precise etiologic role of EBV is not understood in these cases.

Primary Immunodeficiency Syndromes

The primary immunodeficiency diseases described in this chapter are mostly single gene defects and are rare, presumably because defenses against infection are an important requirement for survival. Immune responses, however, are complex and subject to multiple regulatory interactions. Polymorphisms for the many genes that contribute to immunity are likely to affect the speed or effectiveness of an immune response to an infecting agent, so there is plenty of scope for inheritable differences between individuals. The importance of complex inheritance traits is already clear in the case of autoimmune diseases, and they may eventually be recognized as causing definable immunodeficiencies. Secondary immunodeficiency is much more common than primary immunodeficiency and, worldwide, results principally from malnutrition or human immunodeficiency virus infection. This chapter concentrates on primary immunodeficiencies because of the insights that they give into the functioning of immune responses and because of their hematologic consequences. Disorders are principally grouped according to their clinical associations rather than their etiology.

The most familiar consequence of defective immunity is a delay in, or failure of, clearance of an infecting agent. Examples include the bacterial respiratory tract infections that complicate antibody deficiency syndromes and the mycobacterial infections seen when the interferon-? (IFN-?) pathway is defective. In a few instances [i.e., chronic cryptosporidiosis, *Pneumocystis carinii* (PC)], the identity of the infecting organism gives useful clues to the nature of the underlying immunodeficiency, but, in general, the correlations are not good enough to be clinically useful. Other consequences of immunodeficiency have been increasingly recognized over the past decade: lymphadenopathy, autoimmunity, and even periodic fever syndromes. Further developments in these areas may allow associations to be made with certain chronic infections and certain chronic diseases, raising the possibility that immunity to a restricted range of organisms may fail selectively.

Mechanisms of innate and specific immunity are reviewed in Chapter 16, Chapter 17 and Chapter 18, and knowledge of these makes the etiology of most immunodeficiency disorders easier to understand. Some of the principal associations are summarized in Table 68.1. Even when an immune response pathway has been well defined in mice, it is often not directly testable in humans. Confident diagnosis, in consequence, often requires a molecular approach.

TABLE 68.1. Principal Disorders Associated with Defective Innate Immunity

Complement Components	Associated Diseases
C1q, C1r, C1s, C4, C2	SLE-like syndromes, rarely infections
C3, factor D	SLE-like syndromes, pyogenic infections
Properdin	*Neisseria* infections
C5, C6, C7, C8, C9	Recurrent *Neisseria* infections, immune-complex disease
Toll and Toll-like receptor defects	—
Mannan-binding protein	Various bacterial, meningococcal infections
NOD2	Inflammatory bowel disease
Tumor necrosis factor, interleukin-12, interferon-?	Mycobacteria, including atypical species
Natural killer cells, perforin, SHP2	Herpesviruses, especially Epstein-Barr virus
Chédiak-Higashi syndrome, cathepsin C deficiency, other lysosomal defects	Periodontitis

SLE, systemic lupus erythematosus.

DISORDERS OF INNATE IMMUNITY

Complement

Immunoglobulin (Ig) G or IgM antibodies that are bound to cell surfaces activate the complement cascade of proteins. C3a and C5a fragments that are cleaved during activation attract neutrophils, whereas the C3b that remains on a bacterial surface can be bound by receptors on phagocytic cells. Deficiencies of individual proteins are symptomatic only when homozygous, which is rare. Lack of component C1, C2, or C4 is associated with immune complex disorders, particularly systemic lupus erythematosus, chronic glomerulonephritis, dermatomyositis, and cutaneous vasculitis (Table 68.1). Complete deficiency of C3 results in severe and recurrent bacterial infections because neither the classic nor the alternative pathways can opsonize bacteria for phagocytosis. Treatment is mostly with antibiotics. The heterozygous relatives of C3-deficient patients have had problems with nephritis. There is also an association with partial lipodystrophy, in which antibody to C3 (nephritic factor) is thought to stabilize and prolong the function of C3 convertase ([1]). Serum levels of C3 are occasionally low enough in conditions with a circulating C3 activator (nephritic factor) to increase susceptibility to infection.

Properdin is a plasma protein that binds to microbial surfaces and stabilizes the subsequent binding of C3b,Bb convertase. The gene is at Xp11, and a small number of families, totaling approximately 100 individuals with various mutations in the gene, are described. These families share an increased susceptibility to severe meningococcal infection ([2]).

Deficiencies of C5, C6, C7, C8, and C9 are associated with neisserial infections that disseminate, increasing the risk for arthritis in patients with gonorrhea and

recurrences of meningitis. Survivors of meningococcal meningitis should probably have their complement tested with a functional (hemolytic) assay to screen for a defect for which they should receive antibiotic prophylaxis.

Toll Receptors

A series of at least nine Toll-like receptors binds bacterial products that include endotoxin (bound through CD14 to Toll 4), flagellin (Toll 5), CpG dinucleotides (Toll 9), and certain carbohydrate conformations, including mannan. In the case of the mannan-binding lectin (MBL), binding can be followed by the activation of complement through the deposition of the membrane attack complex, or it can opsonize to enhance phagocytosis. Toll proteins have polymorphisms with variable function, and approximately 7% of the population has MBL alleles associated with reduced function. Some variants in MBL are associated with susceptibility to meningococcal meningitis ([3]). Susceptibility to other infections seems to fall with age in infants with low MBL levels ([4] , [5]). Polymorphisms in other Toll and Toll-like proteins may contribute to susceptibility to inflammatory bowel disease. For example, NOD2 protein with leucine-rich repeats was recently shown to be associated with susceptibility to inflammatory bowel disease ([6]).

Defects in the Interleukin-12 Interferon-? Pathway: Interferon-?, Tumor Necrosis Factor, and Interleukin-12 Defects

IFN-? is made principally by T and natural killer (NK) cells, and production is increased by signaling through the interleukin (IL)-12 receptor and IFN-a–signal transducer and activator of transcription–dependent pathways. A small number of subjects with mutations in both IFN-? genes has had severe infections from atypical mycobacteria, such as *Mycobacterium avium* ([7]). Analysis of other patients with atypical mycobacterial infections has disclosed a range of mutations affecting IL-12 ([8]) and the IFN-? receptors and signaling pathway that seems likely to account for the severe or prolonged mycobacterial infections. The failure of normal cytokine signaling interferes with the generation of memory CD4 T cells. Some of these patients have recovered from the mycobacterial infection after antibiotic treatment; others have required prolonged or continuous treatment to survive. One girl with complete IFN-? receptor-1 improved after BMT from an HLA-identical sister.

Cytotoxicity, by T or NK cells, is mediated through perforin, granzyme, and tumor necrosis factor–like cell surface ligands such as Fas. Defects of perforin and granzyme are both associated with enhanced susceptibility to infection. One population of NK cells arises in the marrow and another (NK T cells) in the thymus, and both appear to recognize nonpolymorphic major histocompatibility complex (MHC) determinants. NK cells lyse target cells by perforin-dependent mechanisms. Defects are most commonly associated with severe herpesvirus infections. Principal among these is Epstein-Barr virus, causing hemophagocytic lymphohistiocytosis in Chédiak-Higashi and Griscelli syndromes. A familial variety of hemophagocytic lymphohistiocytosis is now reported, resulting either from autoantibodies to NK cells or from lack of NK cell surface receptors for IgG. Symptoms result from infection, most notably, herpesvirus infections. Perforin deficiency appears to account for approximately 20% of familial hemophagocytic lymphohistiocytosis cases ([9]), and others result from defects in the SH2DIA gene that cause the X-linked lymphoproliferative syndrome. The lymphohemophagocytic component is associated with uncontrolled T-cell activation and cytokine secretion.

Other cytolysis defects follow defects of lysosomal trafficking, as in Chédiak-Higashi syndrome. This results from mutations in the gene for a large cytoplasmic protein (CHS1) that affects the sorting of proteins. Defective CHS1 gene function in humans is followed by the accumulation of secreted proteins in large nonfunctional granules and a clinical phenotype of partial oculocutaneous albinism. In the related Griscelli syndrome, a partial oculocutaneous albinism is accompanied by neurologic defects ranging from developmental delay to fatal neurodegeneration. The immunodeficiency also is variable, and some patients have developed a hemophagocytic syndrome with T-cell and macrophage activation. The phenotype is linked to 15q21, but mutations in two genes in this location appear to result in an almost identical phenotype ([10]). Chédiak-Higashi syndrome patients and cathepsin C–deficient humans (who have Papillon-Lefevre or Haim-Munk syndrome) have severe periodontitis.

IMMUNOGLOBULIN AND ANTIBODY DEFICIENCY SYNDROMES

Antibody-deficient patients with low levels of all Ig isotypes (IgG, IgA, IgM, and IgE) are described as having *hypogammaglobulinemia*, and they usually present as a consequence of recurrent infections, particularly of the respiratory tract. A small number of subjects make Igs that lack the quality required to bind to pathogens and to opsonize. These patients are more appropriately described as antibody-deficient because they are not truly hypogammaglobulinemic. A small number of single gene defects cause primary congenital hypogammaglobulinemia or agammaglobulinemia, of which the best known is the X-linked variety described by Bruton ([11]) that serves as the prototype for the following description. Antibody deficiency can also be acquired, occurring usually as a consequence of another immunodeficiency or an autoimmune syndrome (Table 68.2).

TABLE 68.2. Differential Diagnosis of Immunoglobulin Deficiency

Mechanism	Example	Comment
Secondary immunodeficiencies		
Protein loss from gut	Protein-losing enteropathy	Serum albumin is low.
Protein loss from kidney	Nephrotic syndrome	Loss may be selective.
Drug-induced	Phenytoin and other anticonvulsants, antimalarials, glucocorticoids, penicillamine	Phenytoin lowers IgA more than other isotypes. Levels recover when drug is discontinued.
Hypercatabolism	Dystrophia myotonica	IgG depression greatest.
Primary immunodeficiencies		
Antibody deficiency syndromes	X-linked agammaglobulinemia, X-linked hyper-IgM, common variable immunodeficiency	Isotypes differently affected.
Ataxia telangiectasia	IgG2, IgA	—
Severe combined immunodeficiency syndromes	Multiple types	Some make abnormal Igs.
After certain infections		
	Congenital rubella	—
	Epstein-Barr virus	Some X-linked lymphoproliferative syndrome patients.
	Human immunodeficiency virus	Hypergammaglobulinemia more common.
Malignancy		
	Thymoma, chronic lymphocytic leukemia, non-Hodgkin lymphoma, myelodysplastic syndrome with monosomy 7	Up to 10% of thymoma patients have hypogammaglobulinemia, some with impaired T-cell function. Chemotherapy contributes to Ig deficiency on other malignancies.
Other primary metabolic disorders		
	Transcobalamin II deficiency and hypogammaglobulinemia	Rare; neutrophils more affected.
	Immunodeficiency, centromere instability, and facial anomalies syndrome	—

Ig, immunoglobulin.

Congenital X-Linked Hypogammaglobulinemia

The underlying defect in congenital X-linked hypogammaglobulinemia interferes with B-cell development before birth. Newborns, however, are protected from most infections by transplacentally acquired IgG for the first 3 months of life. The respiratory tract is the principal site of infections, with pneumococci and *Haemophilus influenzae* causing recurrent otitis media and sinusitis. The skin is the second most common site for infections, presenting mostly as furunculosis, pyoderma, and

sometimes cellulitis. When the lower respiratory tract is infected and pneumonia develops, these children typically are ill, with high fever and rapidly progressing symptoms. Spread of the infecting organism is common, so that the boy originally described by Bruton had several episodes of septicemia and meningitis before a lack of Igs was recognized ([11]). Affected boys do not have visible tonsils or (by x-ray) adenoids, but there are no other useful physical signs. The response of infections to antibiotics parallels that seen in hosts with normal immunity, and recurrent antibiotic courses may keep an antibody-deficient subject sufficiently free from infections for the diagnosis to be delayed for years. Over the past decade, some opportunistic infections characteristic of antibody deficiency have been recognized. For example, *Mycoplasma* species, including *hominis*, can cause lung, abdominal, or bone infections that are remarkably hard to eradicate. Ureaplasma urealyticum infections are another possible cause for arthritis, urethritis, and pneumonia. *Helicobacter* species causing cellulitis, septicemia, or both have been a problem in some men.

Infections of the peripheral or central nervous system can be devastating. With the shift from live attenuated to killed poliovirus for immunization, cases of vaccine polio in hypogammaglobulinemic subjects should cease. Echovirus meningoencephalitis, in contrast, is likely to persist. This is a rare complication with a course ranging from rapid respiratory paralysis to a slow progression starting with optic atrophy. The complication is less common than previously, perhaps because the amount of IgG used to treat hypogammaglobulinemia syndromes has generally risen in the past decade.

Other Characteristics of Congenital Antibody Deficiency Syndromes

B-CELL TYROSINE KINASE DEFICIENCY The structural gene for B-cell tyrosine kinase (Btk) is on the X chromosome at Xq21.3, and mutations that interfere with enzyme function cause a spectrum of defects ranging from absence of B lymphocytes from blood and tissues to a selective failure to make antibody to carbohydrate antigens (in mice). Btk is a member of the Tec family of cytoplasmic tyrosine kinases and is required for B-cell transition from a cell making only µ heavy chains to one that expresses a heavy-light chain dimer on the cell surface. The clinical phenotype in affected boys includes a lack of tonsils and low to undetectable numbers of B lymphocytes in the blood. Diagnostic criteria include male gender with less than 2% $CD19^+$ B cells and either a mutation in Btk, absent Btk messenger RNA on Northern blot analysis of neutrophils or monocytes, absent Btk protein in monocytes or platelets, or maternal cousins, uncles, or nephews with less than 2% $CD19^+$ B cells. Often, the diagnosis is assumed if there is evidence for X-linked transmission and B cells are lacking in blood. Identification of the underlying Btk mutation becomes important in the context of chorionic villous biopsy analysis if antenatal diagnosis is desired. There is a small number of other gene defects that result in a clinical phenotype similar to XLA, but which also affect girls. They include defects in signaling pathways and, in two families, structural defects in the µ heavy chain gene ([12]).

TNFSF5 DEFICIENCY: HYPER–IMMUNOGLOBULIN M SYNDROME *Tnfsf5 deficiency* describes a failure of CD40 ligand production that results from mutations in the gene at Xq26 on the X chromosome. Affected boys are unique among subjects with selective antibody deficiencies in that they often present with PC or *Cryptosporidium parvum* (CP) infections ([13]). They commonly have episodes of lymphadenopathy, and, when this occurs in the retropharyngeal tissues, the respiratory tract can be obstructed. Blood counts show episodes of severe cytopenias, possibly as a consequence of autoantibody production. B lymphocytes are present, and T-cell numbers are generally normal. Tests for CD154 expression on activated T cells are of limited value for diagnosis because some affected individuals are able to express protein with impaired function on the cell surface. They usually have very low levels of IgG, IgA, and IgE with normal or raised levels of IgM and are described as having hyper-IgM syndrome (HIGM1). The receptor, CD40, is encoded at Xq26.3, and homozygosity for a null mutation should be a rare cause of an almost identical syndrome. Heterozygosity is more common and can result in a partial phenotype because CD40 functions as a trimer. Mutations that interfere with CD40 function are symptomatic when even one chain of the trimer is defective. Another X-chromosome–encoded gene, a nuclear factor-?B modifier, is downstream in the CD154 signaling pathway and, when mutated, causes a syndrome similar to HIGM1. Recessively inherited forms of HIGM1, named HIGM2 and HIGM3, result from mutations in an activation-induced cytidine deaminase gene or in CD40 itself.

CD40-CD154 SIGNALING DEFECTS CD40-CD154 signaling is important for the function of antigen-presenting cells as well as B cells, and NK cells may signal through CD154 too. When this pathway fails, impairment of certain aspects of cell-mediated immunity is added to the antibody deficiency. When Ig is replaced, the cell-mediated immunity defects persist, although they are not as severe as those that occur in the congenital combined immunodeficiency syndromes. *Candida* and papillomavirus infections are not usually a problem, although herpesvirus infections can be prolonged or severe. The failure to clear PC or CP infections can result in chronic inflammation of the lung or gut and biliary tree. T-cell cytokines could account for much of the pathology. PC infections respond well to standard antibiotics, but CP is less responsive. The chronic inflammation seems a likely contributor to the high incidence of bile duct cancers seen in these patients. The role of bone marrow transplantation for HIGM1 is still being evaluated. The prognosis for the subset of HIGM1 patients that develops bile duct disease is so poor that the risks of transplantation are well justified. Ig gene defects do not cause antibody deficiency unless they affect B-cell function, as do mutations of µ heavy chain or the surrogate light chain expressed on developing B cells. Mutations affecting individual heavy chains can impair or block synthesis of the corresponding isotype, but antibody function in other isotypes remains normal.

Other Characteristics of Acquired Antibody Deficiency Syndromes: Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is a diverse group of antibody deficiency syndromes with varying severity and variable Ig levels. When first described, the syndrome was subdivided on the basis of the individual isotypes that were deficient, but the better understanding of the isotype switch process has made these classifications mechanistically untenable. The principal advance in past years has been the association of CVID with the extended HLA A1B8DR3 haplotype that is also overrepresented in subjects with selective IgA deficiency ([14]). Whether the link is with a single gene in this region is not known, but the association clearly raises the possibility that the hypogammaglobulinemia results from disordered immunoregulation. In a subset of individuals, CVID arises several years after either selective IgA deficiency or systemic lupus erythematosus has been diagnosed. Many patients have impaired T-cell function in that delayed hypersensitivity skin responses may be negative or CD4/CD8 numbers in blood are abnormal. B-cell numbers in blood are generally normal, whereas germinal center formation in lymph nodes is abnormal, and few, if any, plasma cells are present in the marrow or the lamina propria.

Suggested diagnostic criteria include a decrease at least two standard deviations below the mean for age in two of three major isotypes (IgM, IgG, and IgA) in an individual aged greater than 2 years who lacks isohemagglutinins, has a poor response to vaccines, or both. Additionally, other defined causes of hypogammaglobulinemia must be excluded. The average age at diagnosis is 28 years, the prevalence is approximately 1 in 50,000, and both sexes are affected. The range of infections resembles XLA unless T-cell function is significantly impaired, in which case viral or fungal infections occur too. CVID significantly reduces life expectancy, with almost 20% of subjects developing some sort of lymphoma and another 10% developing respiratory failure from recurrent infections. Gastrointestinal symptoms are common, and hypertrophy of Peyer patches causes the appearance of nodular lymphoid hyperplasia on gut contrast x-rays. Some 20% of subjects have additional autoimmune-like disorders, including immune cytopenias, hepatitis, neuropathy, and endocrinopathies. Skin involvement ranges from alopecia and vitiligo to a granuloma annulare.

Treatment

IMMUNOGLOBULIN REPLACEMENT IgG has a half-life in the circulation of approximately 21 days, so intravenous infusions of approximately 600 mg of IgG per kg body weight given every 3 to 4 weeks maintain an IgG level of approximately 500 mg/dl (approximately 50% of levels in healthy adults, see reference [15]). This is usually sufficient to prevent upper respiratory tract infections as well as pneumonias, septicemia, and meningitis. The impact of lower levels of IgG replacement on recurrent bacterial infections of the upper respiratory tract is more variable, depending, perhaps, in part on the severity of damage to ciliated mucosal clearance that preceded diagnosis. Some patients seem to avoid sinusitis or productive cough when treated with 300 mg every 4 weeks. Persistence of sinusitis symptoms is a major clinical problem, and, when this occurs, it is worth trying more closely spaced infusions. The IgG is prepared from donor plasma and therefore contains antibody of the specificities common in the donor population. The IgG for intravenous infusions is stabilized with a sugar, and the rate of infusion is limited by reactions that generally comprise headache, chills, backache, and, if severe, hypotension. Activation of inflammatory pathways by complexes present either in the infusion or formed by antibody binding within the recipient seems a likely mechanism for these events. The rate and severity of reactions to intravenous formulations of IgG are greatly reduced by slowing the rate of infusion and by premedicating the recipient with paracetamol and an antihistamine. Subjects whose reactions persist may need 100 mg of cortisol at the beginning of the infusion, or they may be helped by switching to a different brand of IgG. IgG preparations are now generally free of hepatitis C virus, but previously infected individuals need to be followed for alanine tranaminases. IgG concentrates for intramuscular injection are still available but are less used than previously because of the large volumes that need to be injected. Slow subcutaneous infusions of the intramuscular formulations have not achieved much popularity with patients in the United States, but adequate levels can be achieved if IgG preparations are given at 10 to 30 ml/hour through 25-gauge needles by subcutaneous infusions over the lower abdomen.

OTHER ASPECTS OF MANAGEMENT Respiratory tract damage from chronic sinusitis or chronic bronchitis is important in the context of survival. At least, simple spirometry should be performed every 6 months, and any loss of function should be investigated by chest computed tomography scan. Bronchoalveolar lavage may be needed to identify unusual organisms, and courses of antibiotics may have to be prolonged to reduce lung damage. Stool exams for parasites of fastidious organisms are of relatively little value, and it is the increasing range of stool enzyme-linked immunosorbent assay tests for pathogens that has a higher diagnostic yield. Liver and bile duct enzyme tests can give an early indication of inflammation at these sites.

Complications of Hypogammaglobulinemia

The problems listed below are more the complications of the dysregulation responsible for antibody deficiency or the results of structural damage caused by recurrent infections than truly complications of the immunodeficiency itself. They are described separately here because they occur in only a subset of patients and because they may require different approaches to treatment.

CHRONIC GASTRITIS, ACHLORHYDRIA, AND PERNICIOUS ANEMIA Diarrhea, abdominal pain, and malabsorption are significant problems in approximately 10% of hypogammaglobulinemic patients. *Helicobacter pylori* was isolated from approximately 40% of antibody-deficient patients with gastrointestinal symptoms in one series ([16]). Overall, there are insufficient data to exclude immunoregulatory disorders as contributors to gastrointestinal symptoms. The complications of malabsorption are severe enough to justify endoscopy and biopsy, when appropriate. There are few, if any, treatments for the range of possible opportunists that includes corona and enteroviruses, microsporidia, and *Helicobacter* species. As the survival of antibody-deficient patients was prolonged by IgG replacement, it became clear that some developed B_{12} deficiency secondary to chronic gastritis. The incidence of gastric carcinoma was also increased in antibody-deficient subjects compared with healthy controls. The mechanism for the difference is not clear. The loss of intrinsic factor production is not generally accompanied by the production of autoantibodies to parietal cells, but the gastric mucosa does show an increased infiltrate of lymphocytes. Conceivably, these occur in response to an unidentified infection that might, for example, resemble the *H. pylori* infections associated with gastric ulcer.
DERMATOMYOSITIS AND CELLULITIS SYNDROMES A minority of subjects develop cutaneous ulcers, particularly on the legs, that associate with the recovery of opportunistic organisms, such as *Helicobacter cinaedi*, from the blood. These organisms are not well characterized and are able to develop resistance to multiple antibiotics. They are difficult to diagnose because they are not always detected by routine blood culture technologies that rely on CO_2 production from cultures. Treatment requires antimicrobial combinations that are selected on the basis of antibiotic sensitivities of the organism ([17]).
ECHOVIRUS MENINGOENCEPHALITIS SYNDROMES Encephalitis associated with echoviruses in the cerebrospinal fluid was recognized in the 1970s as a cause of death in approximately 10% of hypogammaglobulinemic boys. The incidence of this complication appears to have fallen greatly since the introduction of intravenous IgG replacement, perhaps because the recipient's plasma levels of IgG are so much higher. Some encephalitis cases have resolved after the dose of IgG was increased, whereas other cases have required treatment with ribavirin ([18]). IFN-a is another potential line for treatment.

Selective Immunoglobulin A Deficiency

With an incidence of approximately 1 in 1000, selective IgA deficiency is the most common primary immunodeficiency. The underlying mechanisms are poorly understood. Inheritance is polygenic, and there is a strong association with the HLA A1B8DR3 haplotype and with disorders such as celiac disease and type 1 diabetes. The symptoms of selective IgA deficiency stem more from the immunoregulatory disorder than from infections occurring secondary to a failure of host defense ([19]).

IgA has two isoforms and is made predominantly at mucosal surfaces. Subjects older than 4 years of age with serum levels consistently less than 7 mg/dl and whose levels of IgG and IgM are normal are described as *selectively IgA deficient*, with the term *partial IgA deficiency* sometimes used for adults with serum levels in the 7 to 20 mg/dl range. The condition is difficult to diagnose in childhood because adult blood levels of IgA (50 to 200 mg/dl) are not usually attained until 12 years of age or older. The frequency of cell-surface IgA-positive blood lymphocytes is normal in subjects with selective IgA deficiency. Up to 20% of IgA-deficient subjects have reduced levels of another Ig isotype—mostly IgG2.

IgA deficiency occurs occasionally in infants with congenital rubella and may develop during treatment with penicillamine or phenytoin—both drugs associated with the development of lymphadenopathy. IgA levels rise again when the drug is discontinued.

CLINICAL FEATURES Perhaps 50% of selectively IgA-deficient subjects have no symptoms that are clearly referable to their deficiency. When symptoms do occur, they range from allergy and arthritis to diarrhea, upper respiratory tract infections, and sinusitis. There are still no clear indications of the morbidity that might result directly from the IgA deficiency and that which might result from the underlying immunopathologic process. Sensitization to IgA itself is a problem for a minority of IgA-deficient subjects. One consequence is a reaction to nonpolymorphic determinants on a-chains that can cause severe anaphylaxis during blood transfusion. Overall, these are rare events, occurring in less than 1 in 20,000 transfusions.

Other Antibody Deficiency Syndromes

TRANSIENT HYPOGAMMAGLOBULINEMIA Maternal IgG is transported across the placenta at a rate that increases in the last month of pregnancy, so that newborns have IgG concentrations equal to their mothers'. The levels fall as the infant grows, and the IgG is catabolized to reach its nadir at 200 to 400 mg/dl around 4 months of age. Term infants whose levels dip below 200 mg/dl and subsequently return to control values are described as having *transient hypogammaglobulinemia*, so this is a diagnosis that can only be made in retrospect ([20]). The time to recovery can extend to 3 years but is generally less. The condition is usually recognized because frequent infections lead to Ig level measurement. One approach to management has been to immunize affected infants with killed vaccines and to start those who make no antibody response on replacement IgG. Infants who do respond to immunization with antibody production are usually safe with symptomatic management. Premature infants receive less maternal IgG, so they have low trough IgG levels. Although IgG replacement seems rational, it has been difficult to show the benefit clearly.
IMMUNOGLOBULIN G SUBCLASS DEFICIENCIES The roughly 1000 mg/dl of IgG in plasma is distributed between four subclasses, with approximately 60% as IgG1 and 30% as IgG2. IgG2 contains much, but not all, antibody to bacterial polysaccharides and does not normally reach adult levels before 2 years of age. Differences in the rate and ultimate levels of subclass appearance reflect immunoregulatory differences. The genes for these subclasses lie with the rest of the Ig genes on chromosome 14. Mutations affecting the surface expression and production of IgG2 are reported, although they are very rare ([21]). The link that is more commonly made between low levels of an IgG subclass and recurrent respiratory tract infections is not a consequence of heavy chain gene mutations but, in at least some cases, may result from a CVID-like process. IgA levels may be low in adults with chronically low IgG2 levels. Subclass deficiencies generally are not treated by IgG replacement.
Immunodeficiency, Centromere Instability, and Facial Anomalies Syndrome Children affected with immunodeficiency, centromere instability, and facial anomalies syndrome have facial dysmorphisms such as hypertelorism, a flat nasal bridge, and low-set ears. The immunodeficiency includes low IgA and, sometimes, low IgG or IgM with or without impaired lymphocyte proliferation. The centromeric instability describes breaks, deletions, isochromosomes, and triradial figures that typically affect chromosomes 1, 9, and 16 in karyotype spreads ([22]). Most cases are identified in developmentally delayed children. Recurrent or prolonged respiratory infections, diarrhea, and skin infections are reported. Many, but perhaps not all, cases are associated with deletions of one of three proteins responsible for maintaining DNA methylation. Although gene undermethylation is thought to be the unifying mechanism in the phenotype, the basis for the immunodeficiency and facial anomalies has yet to be established ([23]).

DEFECTS AFFECTING T LYMPHOCYTES

Combined Immunodeficiency Syndromes

Combined described the concurrence of impaired antibody production with failure of cell-mediated immunity as assessed by a lack of blood lymphocytes or proliferative response to mitogens. The term remains useful as a descriptor of a clinical syndrome characterized by diarrhea, malabsorption, and susceptibility to a range of infections that accompany hypogammaglobulinemia and a failure to make cell-mediated immune responses. These defects can result from a wide range of mutations in genes for enzymes, receptors, cytokines, or signaling molecules, in which case symptoms usually develop in infancy as a consequence of opportunistic infections. Typically, the infections are caused by PC, *Candida albicans*, or gram-positive cocci that cause bacterial skin infections. Affected infants are described as having a severe combined immunodeficiency (SCID) syndrome when their immunodeficiency is congenital. Comparably severe defects of antibody- and cell-mediated immunity are occasionally acquired in adults—these subjects are at the most severe extreme of the “common variable immunodeficiency” designator.

Infants presenting with SCID almost universally have diarrhea and may be diagnosed with multiple feeding intolerances. Changes in their formula feeding may bring short-lived remission of the diarrhea, but weight loss usually continues. Diagnosis is typically based on abnormal T-cell numbers in blood coupled with failure to make antibody in response to immunization. The great majority of syndromes (with the exceptions noted below) have both T lymphopenia and hypogammaglobulinemia. These defects are generally severe enough to be incompatible with successful host defense against infection, and their fatal outcome justifies the generic SCID descriptor. Diagnostic criteria for the congenital SCID syndromes include age of less than 2 years, less than 20% $CD3^+$ T cells (unless engrafted by maternal T

cells), an absolute lymphocyte count of less than 3000/mm ^{3}, and at least one of the following:

1. Mutation in the cytokine common ?-chain (?c)
2. Mutation in JAK3
3. Mutation in RAG1 or RAG2
4. Mutation in IL-7R?
5. Adenosine deaminase (ADA) activity of less than 2% of control or mutations in both alleles of ADA

The clinical features of X-linked SCID adequately describe those shared by this group of conditions. The differences in management are described in relation to the underlying gene defect.

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY X-linked SCID is the most common form of SCID, accounting for over 40% of cases. The condition results from mutations in the gene of the ?-chain that is shared by receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 ([24]). Affected infants have low counts of T and NK lymphocytes in their blood at (and before) birth. The percentage of B cells in their blood is very high, although the actual numbers are generally normal. The ability to make antibodies is nevertheless severely impaired, and the infants generally present with diarrhea, failure to thrive, and candidiasis. There are no useful physical signs other than a lack of palpable lymph nodes and reduced thymus size. Other presenting symptoms include pneumonia due to infection by PC, influenza, or adenoviruses. Congenital infections caused by herpesviruses can be fatal in these infants. Diaper rashes are severe, and perianal skin often breaks down as diarrhea continues. Progressive infections by bacille Calmette-Guérin or vaccinia were problematic when these were widely used as immunogens. Untreated, most infants with SCID-X1 die of infection within 1 year. A small number die of graft-versus-host disease after transfusion of unirradiated blood. Treatment by transplantation of HLA-matched sibling bone marrow effectively reconstitutes affected children (see Treatment of Severe Combined Immunodeficiency Syndromes). Infants without matched donors were offered reconstitution of autologous CD34 marrow cells in the first reports of a clearly successful gene therapy protocol for a combined immunodeficiency ([25]). Multiple cycles of transfection with retroviral vector encoding the common cytokine-receptor ?-chain gene were used to maximize the transfection rate. Six to twelve weeks after the transfected CD34 $^+$ cells were reinfused, transfected T cells appeared in the blood and have persisted for over 3 years. Although B-cell transfection rate was low, at least some Ig production followed. Recent reports of a T-cell lymphoproliferative disease in two infants treated with the retroviral vector for ?c have raised concerns that a vector that integrates randomly may pose unacceptable risks when marrow stem cells are transduced.

INTERLEUKIN-7R DEFICIENCY Among the cytokines whose binding requires ?c, IL-7 appears to play a unique role in the production of T cells. Mutations in the gene for the a-chain of the IL-7 receptor impair T-cell production but not the production of B or NK cells ([26]). The 16 subjects reported by Buckley ([27]) were ascertained in autosomal-recessive–inherited SCID who had intact ?c genes. Their phenotype was a T-cell deficient SCID with B cells and NK cells present in blood.

T-CELL RECEPTOR DEFICIENCIES Rearrangement of the V, D, J, and constant regions of T- and B-cell receptors requires a family of recombinase and DNA ligating/repair enzymes. A failure in one of these processes results in lymphopenia, but production of NK cells in the thymus generally continues. Most of these conditions are rare, although isolated instances of gene enrichment are recorded. One phenotypic variant of RAG1/RAG2 deficiency is Omenn syndrome. Affected infants typically develop a desquamative erythema after birth that is associated with the presence of oligoclonal, activated T cells. Some infants have high IgG levels. A few have been successfully treated with immunosuppressives, such as cyclosporine, followed by bone marrow transplantation. “Artemis” acts with a DNA-PK complex to open the hairpin ends that form after double-strand cuts in DNA. Artemis is encoded on 10p, and mutations occur in SCID patients whose fibroblasts are abnormally sensitive to radiation. There are substantial differences in severity of the immunodeficiency. A null mutation is associated with a severe phenotype that can present with noma. This accounts for a T/B-deficient SCID syndrome in the Na-dene (Navajo) population—a striking example of a founder effect ([28]). Many different mutations in artemis occur, as in affected families from Turkey, and alternative clinical phenotypes appear to include T-cell immunodeficiency with lymphomas ([29]). NK cell numbers are normal.

SIGNALING PATHWAY DEFECTS

JAK3 Deficiency JAK3 is the downstream signal transducer from the common cytokine receptor, and over 30 different mutations that impair signaling function are reported. They result in a phenotype generally resembling that of ?c deficiency, although up to one-third of patients is reported to make at least some T cells. In common with other defects in T-cell function, clones of abnormal T cells are sometimes produced, but they lack normal lifespan and function ([30]). T-cell development in the thymus requires cytokine signaling through phosphorylation of JAK3 and Stat1. Deficiency of either of these molecules impairs T-cell production to the levels seen in SCID-X1. T-cell lymphopenia, hypogammaglobulinemia, and opportunistic infections in a 4-month-old boy ([31]) were associated with a mutation in p56lck, and, more recently, CD4 lymphopenia in an adult was associated with low p56lck activity without a structural mutation. CD45 is a membrane glycoprotein present on most leukocytes. It has an intracellular domain that regulates Src kinases. Deletions affecting both CD45 alleles were responsible for a SCID phenotype in a very small number of T cell–deficient infants ([32]).

Adenosine Deaminase Deficiency ADA catalyses the conversion of adenosine triphosphate (ATP) and guanosine triphosphate (GTP) and their deoxy-counterparts to adenosine diphosphate and guanosine diphosphate. When enzyme activity is impaired or absent, intracellular levels of deoxy-ATP (dATP) rise to interfere with ribonucleotide reductase, such that DNA synthesis and repair are slowed. T-cell apoptosis is increased, so affected infants typically have very low numbers of T (and B) lymphocytes in blood. Clinical presentation with opportunistic infections is usual in the first year of life. In addition to the T-cell deficiency, skeletal abnormalities with osseochondrous dysplasia are common. The diagnosis is made by detecting high dATP levels in red cells and low enzyme activity. The gene is at 20q13.11, and sequence studies have identified many different mutations. Some 10% of cases present in childhood or young adult life. This phenotypic heterogeneity likely reflects the substantial range of mutations that is reported. ADA deficiency accounts for 20% or more of autosomal-recessive SCID cases. Aside from bone marrow transplantation, ADA-deficient infants can be treated with polyethylene glycol–conjugated ADA, which is injected subcutaneously once per week ([33]). Treatment efficacy is gauged by measuring red cell dATP levels. Enzyme treatment has the advantage of speed of response coupled with safety. The treatment is very expensive, costing approximately $100,000 per year in 2002. Bone marrow transplant has been successful in some, but not all, infants, with transplant rejection accounting for some of the failures. The first attempts at gene therapy used retroviral vectors to transfect the ADA gene into blood T cells, but this approach did not result in sustained T-cell reconstitution. The continued treatment of recipients with polyethylene glycol–ADA likely reduced the selective pressures on T cells that would have favored the survival of transfected cells. Nevertheless, follow-up of these early cases shows persistence of at least some transfected cells. More recently, the ADA gene has been transfected into the patient's own CD34 $^+$ stem cells, which were then reinfused. A first report that used a retroviral vector suggests that this approach may be successful ([34]), but recent experience with ?c deficiency has raised concerns about the safety of randomly integrating vectors.

Zap-70 Deficiency Zap-70 is a tyrosine kinase downstream of CD3 in the T-cell signaling pathway. The structural gene is at 2q12, and multiple mutations have been reported. Absence of functional enzyme results in a characteristic SCID phenotype with low numbers of CD4 cells in blood but few or no CD8 cells ([35]). Igs are low, and antibody responses are not made. The CD4 T cells that are present in blood do not respond to antigen or plant mitogens, but they do proliferate and make cytokines after stimulation by combinations of phorbol and ionomycin. Bone marrow transplantation has reconstituted immunity of some affected infants.

TREATMENT OF SEVERE COMBINED IMMUNODEFICIENCY SYNDROMES SCID was uniformly lethal in the first years of life until Good and colleagues successfully reconstituted an affected infant with a transplant of sibling bone marrow. Experience in subsequent years has shown that infants with T- and TB-cell–deficient SCID are reliably reconstituted for antibody- and cell-mediated immunity after intravenous infusion of 10 ^{7} HLA-matched-sibling nucleated bone marrow cells per kilo. Matching, in this context, requires identity at all HLA A, B, and D loci as occurs, on average, for one in four siblings. Many SCID infants have significant diarrhea and weight loss by the time they reach a transplant center, and management generally starts with prophylaxis for (or treatment of) PC pneumonia, IgG replacement, and intravenous hyperalimentation. Identification of an HLA-matched sibling and parental consent are followed by the infusion of freshly drawn marrow cells. Clinical improvement after HLA-matched sibling bone marrow transplantation is often apparent as soon as a week to 10 days, presumably because the mature T cells present in the donor marrow are able to function in their new environment. Rashes, often with the histology of mild graft-versus-host disease, are common in the first week but generally resolve spontaneously. Blood lymphocyte responses to phytohemaglutinin are usually detected as the lymphocyte count rises in the 3 months after transplantation, and antibodies are made after 6 to 12 months ([36]). Transplant treatment has the best outcome when used early, even in neonates. Freedom from infections and perhaps relative resistance to graft-versus-host disease contribute to the better outcome in comparison with delayed transplant treatment ([37]). The majority of SCID infants who lack matched siblings are generally treated by infusions of parental (haploidentical) bone marrow from which T cells have been depleted by immunologic or physical means. Graft-versus-host disease is a significant risk and is avoided only when less than 500,000 donor T cells are present in the infusion. It takes 3 or more months for counts of CD3 T cells to climb after grafts of T-depleted haploidentical marrow, and numbers in the normal range may not be achieved for 1 year or more ([38]). Cell-mediated immunity is normally sufficiently reconstituted to avoid opportunistic infections, but persistence of antibody deficiency means that these patients need long-term IgG replacement. Several experimental treatments have been tested in recent years. Flake et al. infused some 130 × 10 ^{6} CD34-enriched paternal marrow cells into a fetus between 16.0 and 18.5 weeks' gestation with ?-chain–deficient SCID and obtained engraftment with donor cells without much graft-versus-host disease ([39]). Intrauterine infusion of human fetal liver was followed by the appearance of donor-derived CD4 cells in one infant with X-linked SCID ([40]). Most SCID cases are diagnosed after birth, and some, in the long term, may be open to correction by transfection of intact genes into the recipient's own bone marrow stem cells. Development in the area of vectors with predictable insertion points facilitates these advances.

Other Syndromes with Severe Impairments of Cell-Mediated Immunity

CARTILAGE-HAIR HYPOPLASIA Cartilage-hair hypoplasia is a monogenic disorder resulting from mutations in the RMPG gene located at 9p21. The condition was first identified in Old Order Amish kindred and was subsequently found to have some geographic enrichment in western Finland. The principal clinical features include short-limb dwarfism, hypoplastic hair, and immunity defects that can result in fatal varicella infections. There is significant heterogeneity in the phenotype as regards effects on cartilage, gut innervation, and immunodeficiency that likely results from different underlying mutations. At its most severe, the immunodeficiency presents as a congenital SCID. Less severely affected subjects have problems only with herpesvirus infections or antibody production.

PURINE NUCLEOSIDE PHOSPHORYLASE DEFICIENCY Purine nucleoside phosphorylase is an enzyme that converts deoxyinosine to hypoxanthine. Mutations interfering with function cause deoxy-GTP accumulation and the inhibition of ribonucleotide reductase and DNA synthesis. T-cell function is impaired, increasing susceptibility to lethal DNA virus infections, particularly varicella. The increased deoxy-GTP levels are thought to inhibit ribonucleotide reductase, and, in a mouse model, they interfered with DNA repair ([41]). The earliest feature can be developmental delay and spasticity, often arising after the age of 4 years. Severe varicella is the most common presenting infection ([42]). The T-cell number in blood is very low; NK and B cells are generally normal, as are serum Igs. Approximately one-third of patients have developed autoimmune hemolytic anemia. Treatment with acyclovir or equivalent antiherpes agents may need to be continued for several weeks in the event of a varicella infection. Overall, the treatment of purine nucleoside phosphorylase–deficient children has been difficult. Allogeneic transplants have sometimes been rejected and did not reverse the neurologic disease even when successful ([43]). Approximately 10% of the small number of reported patients have died with malignant immunoblastic non-Hodgkin lymphoma. The mouse model suggests that enzyme replacement with polyethylene glycol–purine nucleoside phosphorylase may be useful.

WINGED HELIX NUDE The “nude” mouse is largely hairless and has a vestigial thymus that fails to support the development of T cells. The condition results from mutations in the winged helix nude gene. Two sisters with congenital alopecia, nail dystrophy, and T-cell immunodeficiency ([44]) were homozygous for a nonsense mutation in the winged helix nude gene, providing a human counterpart for the mouse condition. Bone marrow transplantation from an HLA-identical brother resulted in engraftment of T cells in the second winged helix nude -/- sister and the development of naïve and memory populations of CD8 cells. Antibody was made to hepatitis B immunization, but the numbers of donor CD4 cells declined during 6 years of follow-up, perhaps because no functional thymic tissue was available to support the development of new populations of naïve CD4 cells ([45]).

Thymic Hypoplasia: DiGeorge Syndrome

DiGeorge syndrome comprises congenital cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia, each in variable degree ([46]). Diagnostic criteria are given as a conotruncal cardiac defect (truncus arteriosus, tetralogy of Fallot, interrupted aortic arch, or aberrant right subclavian), hypocalcemia of greater than 3 weeks' duration that requires therapy, and deletion of chromosome 22q11.2 or possibly microdeletions at 10p12-13 ([47]). Other phenotypes arising from 22q11 microdeletions include the velocardiofacial syndrome and isolated conotruncal cardiac disease. The defective chromosome is usually inherited from the mother. The heterogeneity of the clinical phenotype may at least in part reflect differences in the expression of the VEGF isoform Vegf ^{164}. The hypocalcemia results from parathyroid hypoplasia, and the common major vessel abnormalities are truncus arteriosus, anomalous pulmonary venous drainage, or right-sided aortic arch. Clinically important issues include delayed speech acquisition and behavioral problems ([48]). Infants who have impaired rather than absent parathyroid or thymus function are often described as having partial DiGeorge syndrome. Clinical presentation usually results from cardiac failure or, after 24 or more hours, from hypocalcemia. Suggestive dysmorphisms include low-set, small ears and a short philtrum, small jaw, or both. Less than 500 per mm ^{3} CD3 $^{+}$ T cells in the blood is a criterion for diagnosis of complete DiGeorge syndrome.

The diagnosis is sometimes made during the course of cardiac surgery when no thymus is found in the mediastinum. Postoperative hypocalcemia can be severe and persistent, requiring both calcium and vitamin D supplements. Despite receiving fresh blood transfusions during cardiopulmonary bypass, patients do not usually develop graft-versus-host disease. The degree of thymic hypoplasia in infants diagnosed during surgery is variable, and, even if the number of CD3 $^{+}$CD4 $^{+}$ T cells in the blood is low in the postnatal period or after surgery, it may rise later. The susceptibility to infection is variable, and few infants with DiGeorge syndrome die with septicemia, although they may have chronic candidiasis.

A subset of patients with DiGeorge syndrome has severe problems with production of autoantibodies to red cells, white cells, and platelets ([49]). These patients may respond to intravenous IgG or to corticosteroids. Treatment of other features of DiGeorge syndrome may require surgery for the cardiac defects and vitamin D and calcium to correct hypocalcemia. Blood for these patients should be irradiated. Grafting thymic hypoplasia patients with thymic fragments or epithelial cells is followed by the production of new populations of naïve T cells and an improvement in the lymphocyte response to mitogens ([50]). This may be a valuable treatment option for infants who do not acquire normal T cell populations spontaneously. Infusion of HLA-matched sibling blood or marrow has been tried in a few patients who did not improve spontaneously, but this carries a risk for graft-versus-host disease. With increasing use of intrauterine ultrasound, congenital heart disease is more frequently defined before birth. Infants with abnormalities of the great vessels should probably be monitored postnatally for T-cell deficiency.

DEFECTS OF ANTIGEN PROCESSING/PRESENTATION: BARE LYMPHOCYTE SYNDROME

Assembly of the class I MHC with peptides cleaved from antigens occurs in the endoplasmic reticulum. Peptides that are generated in the cytosol are transported into the inner lumen of the endoplasmic reticulum by the proteins TAP1 and TAP2. Mutations in either of these, and of Tapsin to which they bind, have been identified. TAP mutations are associated with recurrent infections, particularly sinusitis and bronchitis. The diagnosis is usually suspected when serologic typing for HLA class I antigens fails to give interpretable results, although molecular typing indicates intact MHC DNA. Blood lymphocyte counts, including CD8 cells, have been normal in several subjects, whereas others have had low CD8 and NK cell numbers. Some of this heterogeneity is likely to reflect differences in the underlying mutation and in the gene affected. Survival into the third decade is described ([51]).

Defects that interfere with the assembly or cell-surface expression of the class II MHC–peptide complex are more severe than those affecting class I MHC, and clinical presentation usually occurs in infancy with diarrhea, failure to thrive, and a SCID-like syndrome. Affected children generally have normal or low numbers of CD4 cells in the blood, and these cells respond normally to mitogens. CD8 counts are normal. Reduced expression of class II MHC antigens on B cells and blood monocytes is the basis for the diagnosis. The combination of a positive lymphocyte response to mitogens and the presence of at least some CD4 T cells could delay the recognition of the syndrome.

OTHER BIOCHEMICAL DEFECTS SOMETIMES ASSOCIATED WITH IMMUNODEFICIENCY

Several primary errors of metabolism adversely affect immunity. Transcobalamin II deficiency causes a megaloblastic anemia with impaired bacterial killing by neutrophils and reduced serum Igs of all classes. Biotin-dependent decarboxylase deficiencies may be associated with convulsions, alopecia, candidiasis, low serum IgA, and a reduced number of T cells. Lymphopenia and impaired cell-mediated immunity are reported in hereditary orotic aciduria. A severe variant of the X-linked dyskeratosis associated with mutation in the DKC1 gene can be associated with a SCID variant with T cells but no B or NK cells in blood. A systematic listing of genetic disorders with immunodeficiency is given in the review by Ming and others ([52]).

Ataxia Telangiectasia

Ataxia telangiectasia is primarily a neurologic disorder, presenting with ataxia and progressing to choreoathetosis. Death in the second decade is common. The incidence is approximately 1 in 100,000 births, and the disorder is associated with mutations in a gene that maps to 11q23. Some 80% of affected individuals have low levels of IgG2, and 60% have low IgA. Most affected individuals have raised serum a-fetoprotein levels. Clinical presentation is usually between the ages of 2 and 5 because of cerebellar ataxia that is followed by unsteady walking ([53]). Telangiectases typically develop first on the conjunctivae and later are seen on the nose, ears, and shoulders. When infections are a problem, they involve the respiratory tract. The progressive neurodegeneration can compromise coughing, so it is hard to determine whether respiratory infections occur more as a result of the immunodeficiency or the motor defects. Malignancies are an important complication in the longer term, and the DNA repair defect that underlies ataxia telangiectasia likely has a major role in their etiology. Acute leukemias are common and are often T-cell in origin with translocations affecting rearranged T-cell receptor genes. Lymphomas are generally B-cell in origin and are associated with deletions in the 11q22-23 region. There is also an increase in frequency of epithelial tumors in both homozygotes and ataxia telangiectasia heterozygotes.

Bloom Syndrome

Bloom syndrome, in which mutations in a DNA helicase (RecQ proteinlike-3) result in excess sister chromatid exchanges, is associated principally with lymphoma and cancer ([54]). Multiple primary tumors occurring at an early age are common. Reduced growth in childhood results in a proportional dwarfism that, with cutaneous telangiectases, is a useful physical sign. Inheritance is autosomal and recessive, and the disease occurs with increased frequency in Ashkenazi Jewish populations. There is an increased frequency of life-threatening infections. Serum IgA and IgM are sometimes low, and lymphocytes respond abnormally in laboratory tests. No specific treatment is known to delay the onset of malignancies.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked disorder that usually presents in infancy on account of bloody diarrhea or stroke, recurrent upper respiratory tract infections, or eczema. Findings useful for diagnosis include thrombocytopenia and abnormally small platelets that fail to aggregate effectively. Serum Igs and T-cell numbers and functions are usually normal initially, and IgA levels are often high. Isohemagglutinins either fail to appear or have a very low titer. The disorder is caused by mutations in the Wiskott-Aldrich syndrome protein gene on the short arm of the X chromosome and occurs in approximately four live male births per million ([55]). Different mutations account for the spectrum of clinical disorders that, at their mildest, result only in thrombocytopenia. The Wiskott-Aldrich syndrome protein most likely functions as a signal transduction adaptor in a pathway that controls the Rho GTPases that affect cell membrane structure. The defect has adverse consequences for the function of antigen-presenting cells as well as for B, NK, and T lymphocytes. The most severe consequences for host defense arise from failure to clear bacterial infections and to protect from Epstein-Barr virus–associated lymphomas.

Clinical management has ranged from the provision of antibiotics to protect from infections by encapsulated microorganisms to splenectomy to increase the platelet count. Neither protects from lymphomas, so, in recent years, there has been increased interest in bone marrow transplantation as a means to restoring a fully functional immune system. Grafts from matched siblings have been substantially more successful than those from haploidentical or unrelated donors. Transfection of the individual's own marrow stem cells is currently being evaluated. Affected children should be evaluated for some form of intervention because survival without treatment is poor.

Autoimmune Lymphoproliferative Syndromes

Lymphocyte homeostasis requires the elimination of self-reactive cells and responder populations as pathogens are cleared. Both processes are accomplished through apoptosis, and they require members of the tumor necrosis family: Fas, Fas ligand, and the downstream caspases. Mutations in the structural genes of any one of these cause an autoimmune lymphoproliferative syndrome featuring lymphadenopathy, thrombocytopenia, autoimmune hemolytic anemias, and, occasionally, Guillain-Barré syndrome or panniculitis. There is a significantly increased risk for lymphoma. One affected boy experienced multiple bacterial infections before dying of pneumococcal meningitis at age 6 ([56]).

SCREENING FOR IMMUNODEFICIENCY

Although tests for immune responses have become relatively standardized, there is no clear indication as to who should be tested. Clues that can be useful are summarized in Table 68.3.

TABLE 68.3. Diagnostic Evaluation for Possible Immunodeficiency

Symptoms from	Type	Mechanism	Test
Infections	Atypical mycobacteria, some *Mycobacterium tuberculosis*	Interleukin-12 interferon-? pathway	Measure production
	Bacterial: *Staphylococcus* abscesses, *B. cepacia*	Complement, chronic granulomatous disease	Hemolytic assay, respiratory burst tests
	Helicobacter cinaedi, rappini cellulitis, arthritis	CVID/antibody deficiency	Serum immunoglobulins
	Viral: progressive varicella, fatal Epstein-Barr virus, severe warts	T cell, natural killer defects	Count, activation
	Fungal, apicomplexan: *Pneumocystis carinii, Cryptosporidium parvum*	CD40 signaling defects, SCID	T-cell activation, counts
Weight loss/failure to thrive	—	SCID in infants, CVID in adults	T-cell counts, repertoire (57), serum immunoglobulins
Skin changes	Granuloma annulare	CVID	Immunoglobulins

CVID, common variable immunodeficiency; SCID, severe combined immunodeficiency.

Acquired Immunodeficiency Syndrome

Despite significant strides in the prevention and treatment of human immunodeficiency virus (HIV) infection, acquired immunodeficiency syndrome (AIDS) remains a monumental problem, particularly in the developing world. According to the World Health Organization, 36 million people are currently living with AIDS globally, and 25 million of these live in sub-Saharan Africa. Within the United States and Western Europe, where highly active antiretroviral therapy (HAART) is available, the clinical picture and prognosis of HIV infection have changed. Still, in the United States, there have been more than 600,000 cases of AIDS diagnosed since 1981 and more than 400,000 deaths. Recently, because of HAART, many of the hematologic complications of HIV infections are less prominent. Cytopenias, once common, are now seen less frequently except in patients with advanced disease and in patients undergoing chemotherapy. Coagulation abnormalities are occasionally a clinical problem. Non-Hodgkin lymphoma (NHL) still poses challenges in management and leads to death in most of those affected. This chapter discusses diagnosis and management of the hematologic complications of HIV. A discussion of management of antiviral therapy and opportunistic infections (OIs) can be found elsewhere ([1], [2] and [3]).

BACKGROUND

HIV, a retrovirus first identified in 1983, is transmitted by sexual contact, transfusion or parenteral inoculation of infected blood, intravenous drug use, and vertical transmission from an infected mother to infant. Without treatment, HIV-1 infection generally progresses slowly, frequently becoming symptomatic years after initial infection. Currently, the Centers for Disease Control and Prevention (CDC) defines individuals as having AIDS using laboratory criteria: evidence of HIV-1 and CD4 counts less then 200 cells/µl. An earlier clinical classification system included individuals with a history of certain OIs and Kaposi sarcoma (KS) in the definition. Similar to other retroviruses, the HIV-1 genome contains *gag*, *pol*, and *env* genes that encode for viral core proteins, enzymes controlling replication (reverse transcriptase, integrase and aa viral protease), and envelope glycoproteins. Viral *rev* and *tat* genes encode proteins that regulate transcription and processing of viral messenger RNA. HIV-1 also contains a number of other genes that mediate interaction with the host cell and infectivity (*nef, vif, vpr, vpu*).

The mechanism of infection is still not completely understood but is influenced by host factors, the presence of specific receptors on individual cell lines, and the strain of virus. To gain entry into the cell, HIV gp120 binds to the cell membrane via the CD4 receptor as well as via a second chemokine receptor (CXCR4 in the case of T-cell lymphotropic viruses and CCR5 in the case of macrophage tropic viruses) (Fig. 69.1). The cognate ligands of these receptors are capable of inhibiting viral entry by these receptors ([4]). Modulation of expression of chemokine receptors is affected by cytokines. Chemokine receptor expression can influence the susceptibility of the cell to viral infection and may account for the vulnerability of hematopoietic cells of different lineages to HIV infection. Persons with inherited mutations in the gene coding for the CCR5 receptor appear to be relatively resistant to infection or, if infected, are among those who do not develop progressive disease ([5]). Expression of CD4 and a chemokine receptor may not be sufficient for HIV entry, however. Intracellular signaling events after the interaction between chemokine receptors and chemokines and the HIV envelope also may be important for viral entry.

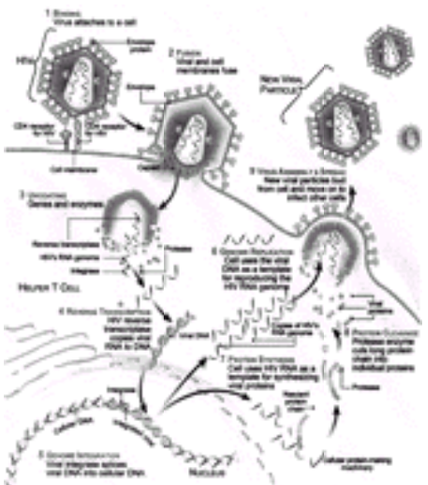

Figure 69.1. Human immunodeficiency virus (HIV) life cycle, deciphered with the help of genomic analyses, is unusually complex in its details, but all viruses undergo the same basic steps to infect cells and reproduce. See Color Plate.

After entry into the cell, HIV is uncoated in the cytosol, and viral RNA is transcribed into double-stranded DNA by reverse transcriptase and transported to the nucleus, where it circularizes and is inserted randomly into the host chromosomes. Expression of new virus involves transcription of the provirus into genomic RNA and then translation into viral proteins. *Gag* and *Pol* precursor proteins are then cleaved, and the virus assembles at the inner surface of the plasma membrane, leading to budding from the cell and release as an infectious particle (Fig. 69.1).

Initial infection is frequently associated with an illness that resembles acute aseptic viral meningitis, but more than 50% of individuals are asymptomatic. Immune response to the virus follows rapidly, resulting in increased populations of cytotoxic T cells; a humoral response with appearance of immunoglobulin (Ig) M, then IgG follows within 4 to 12 weeks (Fig. 69.2). Despite a vigorous immune response that may result in clearing of the virus from the circulation, viral replication continues in the lymph nodes and spleen, which act as a reservoir for infection even when effective antiviral therapy is given ([6]). Efforts to eliminate this virus from these sanctuaries have been unsuccessful.

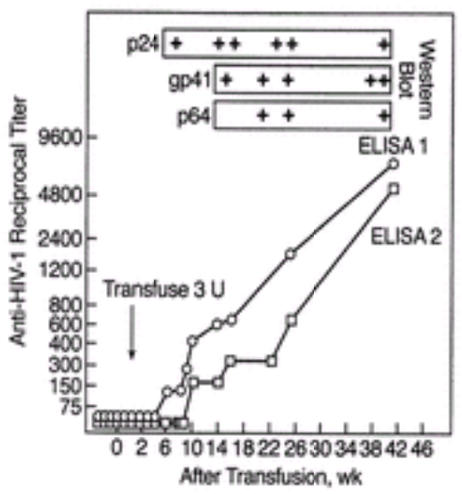

Figure 69.2. The human immunodeficiency virus (HIV) test results of a cardiac surgery patient who received 1 unit of HIV-1–infected blood and subsequently tested positive for HIV. In this case, the enzyme-linked immunosorbent assay (ELISA) first tested positive 6 weeks after transfusion at a time when only anti-p24 was demonstrated on immunoblot. This period during which the ELISA tests negative in an infected person is referred to as the "window period." Current ELISAs have narrowed the window period to less than 4 weeks, and polymerase chain reaction–based testing has narrowed it to 2 weeks.

Human Immunodeficiency Virus 1 Testing

Currently, most HIV testing procedures rely on detecting HIV-1 antibodies, although more recent procedures that have been implemented for testing blood for transfusion rely on detection of HIV-1 antigens or nucleic acids. Antibodies to HIV-1 proteins that develop during the course of infection include antibodies to viral core antigen (p24) and antibodies to viral envelope proteins (gp120, gp41). Antibodies to HIV-1 polymerase (p55) develop later, if at all. The most widely used test, the enzyme-linked immunosorbent assay (ELISA), is used in conjunction with a confirmatory test, the Western blot (WB), for HIV-1 antibody (Fig. 69.3). When a person becomes infected with HIV-1, viral genetic material is incorporated into the host T cell's genome before viral replication. The early stages of infection are generally associated with a short period during which free virus is usually present in plasma. This is followed by seroconversion, or the development of antibody, after which virus may be absent from plasma. Development of antibody usually occurs 4 to 5 weeks after infection ([7]). A person is classified as HIV-1-seropositive when a blood sample results in a positive result in two successive ELISAs and in one confirmatory WB (or an equally sensitive and specific confirmatory test). The CDC standards require that two of the three bands of p24, gp41, and gp120/160 be present on WB for a sample to be designated as positive for antibody to HIV-1 (Fig. 69.3). Only a fraction of persons testing positive for ELISA also test positive by WB. Assays for viral antigen and viral nucleic acids usually become positive at 16 and 11 days, respectively, after infection. A more thorough discussion of procedures used for testing blood for transfusion can be found in Chapter 24.

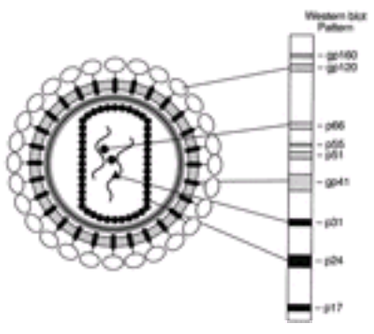

Figure 69.3. In Western blot testing, recombinant viral antigens are separated by electrophoresis into core proteins (p55, p24, p17), envelope proteins (gp120, gp160, gp41), and polymerase proteins (p66, p51, p31). The separated viral proteins contained in the gel are blotted onto nitrocellulose paper and incubated with tagged antihuman antibody.

Mechanism of Action of Antiretroviral Drugs

Infection with HIV results in the progressive destruction of CD4 T lymphocytes with the consequent development of immunodeficiency. The CD4 cells are destroyed through apoptosis or programmed cell death and through direct cytolysis by the virus. Apoptosis of lymphocytes results from many factors, including cytokine dysregulation, continued immune stimulation, and exposure to viral proteins ([8] , [9]). In the HIV-infected person, the half-life of peripheral blood T cells is markedly shortened, from approximately 82 days to 23 days. Although increase in CD8 production by the marrow compensates for their increased destruction, CD4 production is not increased; therefore, without therapy, the CD4 counts gradually decrease. Antiretroviral therapy increases the production of CD4 cells without improving the survival of these cells. The life cycle of the virus is depicted in Figure 69.1, which also shows the points targeted by drug therapy. The nucleoside reverse transcriptase inhibitors [zidovudine (ZDV), didanosine, zalcitabine, stavudine, and lamivudine] inhibit the reverse transcription of the viral RNA genome into a DNA form. This is a critical step in the life cycle of the retrovirus. Another group of drugs, the nonnucleoside transcriptase inhibitors (nevirapine, delavirdine), also inhibits the virus at this point. The protease inhibitors, yet another class of drug, suppress viral production by acting on the viral protease. Inhibition of this enzyme leads to aborted formation of the virus; defective particles that lack intact core protein are released instead of infectious virus. The hematologic effects of these drugs are discussed below and delineated in Table 69.1. These medications are generally given in combinations to avoid the emergence of resistance.

TABLE 69.1. Hematologic Toxicities of Antiretroviral Drugs

Medication	Type of Activity	Hematologic Toxicity
Zidovudine	Nucleoside analogs, antiviral	Anemia, neutropenia (dose-dependent)
Stavudine	Nucleoside analogs, antiviral	Anemia, neutropenia (dose-dependent)
Ganciclovir	Cytomegalovirus infection	Leukopenia, thrombocytopenia
Trimethoprim/sulfamethoxazole	Antibiotic, *Pneumocystis* pneumonia	Dose-related neutropenia, anemia; methemoglobinemia especially in persons with G6PD deficiency
Primaquine	Antibiotic, *Pneumocystis* pneumonia	Rare agranulocytosis, thrombocytopenia; methemoglobinemia especially in G6PD deficiency
Pentamidine	*Pneumocystis* pneumonia	Infrequent anemia, leukopenia, thrombocytopenia
Sulfadiazine	Toxoplasmosis	Leukopenia in 40%; thrombocytopenia in 12%
Clindamycin/pyrimethamine	Toxoplasmosis	Cytopenias in 31%
Amphotericin B	Antifungal, cryptococcal meningitis	Anemia

G6PD, glucose-6-phosphate dehydrogenase.

HAART has resulted in a reduction of AIDS-defining illnesses in patients with advanced immunodeficiency on this treatment and in a reduction in death rates. A patient on HAART should have repeated measurement of the viral load to assess potency of the drug regimen. Variability in adsorption, bioavailability, and viral resistance may make response rates different even in individuals who appear similar with respect to their degree of immunosuppression. Viral load may also increase with time, signaling the development of drug resistance and the need to change therapy. It may transiently rise in response to an acute infection or after vaccination. Residual HIV replication occurs in sanctuary sites and in peripheral mononuclear cells despite suppression of plasma viral load below the level of detection. After

starting HAART, viral load suppression is seen soon, whereas gradual increases in T cells occur in the ensuing months to years. The CD4 cells that remain are generally of the memory type ($CD45RO^+$ or $CD45RA^-$), with naive T cell numbers increasing slowly with time. Naive cells bearing the T-cell receptor excision circle do eventually appear with time. Thymic reconstitution that occurs in patients on HAART is an important step in immune reconstitution. Prophylaxis against OIs is associated with an improvement in survival independent of that produced by HAART.

Long-term survivors of HIV may have the widespread problems of hyperlipidemia, insulin resistance, and abnormal fat redistribution, which may or may not be related to the use of protease inhibitors or other antivirals. It is unclear at this point whether this lipodystrophy translates into increased frequency of cardiovascular disease. The role of lipid-lowering agents in this population is still conjectural. Multiple ongoing clinical studies are attempting to resolve these issues and examine the mechanism of hyperlipidemia and insulin resistance.

HEMATOLOGIC COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Anemia

Anemia, a significant clinical problem early in the AIDS epidemic when high doses of ZDV were widely used, is now much less prevalent. The Viral Activated Transfusion Study ([10], [11]) found that the frequency of transfusion for anemia decreased after institution of HAART when compared to historical controls ([12]). A number of studies, including the MultiCenter AIDS Cohort study, demonstrated that anemia was an independent predictor of survival ([13]). Cytomegalovirus (CMV), B19 parvovirus, or *Mycobacterium avium-intracellulare* suppress erythropoiesis and are potentially treatable causes of anemia in this population.

Although bone marrow failure is the likely cause of anemia, hemolytic anemia and anemia related to gastrointestinal bleeding also should be considered. Hemolysis is a rare cause of anemia in AIDS patients; antierythrocyte antibodies are frequent, but they are often clinically irrelevant and are also seen in many asymptomatic homosexual men ([14]). Although circulating erythropoietin (EPO) is often low, the degree of anemia nevertheless is often disproportionately severe for the EPO levels ([12]). Nutritional factors, such as B_{12} deficiency ([14a]) resulting from malabsorption or malnutrition, as well as deranged iron metabolism ([15]) have been reported as a frequent cause of anemia in patients with HIV infection. Blood loss from repeated phlebotomies and gastrointestinal bleeding also contributes. As previously mentioned, ZDV is commonly associated with marrow toxicity, particularly with long-term administration. Use of lower ZDV doses in combination with other nonmyelosuppressive antiviral drugs (e.g., the protease inhibitors or other nucleoside analogs) has significantly decreased the frequency of anemia, although patients with advanced disease taking doses of ZDV of less than 500 mg/day still demonstrate significantly decreased hemoglobin levels when compared to similarly immunosuppressed HIV-infected patients not taking the drug ([16]).

Parvovirus B19 infection can cause pure red cell aplasia and anemia in immunosuppressed HIV-1–infected patients ([17]). Although the seroprevalence of IgG antibodies against B19 parvovirus is 40 to 60% in the adult population ([18]), virus can generally be detected only in patients with active early or persistent disease. B19 infection is associated with anemia, absence of reticulocytes, and pure red cell aplasia of the marrow with normal leukocyte and platelet counts. Large vacuolated proerythrocytes or giant pronormoblasts and markedly reduced numbers of all red cell precursors are evident in the bone marrow. Typical manifestations of fifth disease are absent in AIDS patients but may be observed after treatment with immune globulin as a result of iatrogenic immune complex formation. B19 accounted for anemia in 17 to 31% of transfusion-dependent anemic HIV-1–infected patients ([19], [20] and [21]). Neither the presence of IgM to B19 nor the marrow morphology correlate with chronic B19 infection ([22]). Although a negative polymerase chain reaction examination of serum excludes the diagnosis, DNA dot blot hybridization is more specific for chronic infection ([19]). Positive serology is only indicative of past contact, and persistently infected patients usually lack serum antibodies to the virus.

TREATMENT Some patients with HIV infection have significant anemia requiring frequent transfusion. Clinical and experimental evidence suggests that transfusion may be associated with substantial morbidity in HIV-infected patients. In one study, transfused patients with advanced disease had an increased incidence of human CMV infection and death ([23]). Although these studies were retrospective, some *in vitro* evidence suggests that transfusion may be associated with viral activation. Busch et al. ([24]) demonstrated that allogeneic lymphocytes present in transfused blood components activate viral production by HIV-infected lymphocytes *in vitro*. Furthermore, a study using quantitative polymerase chain reaction (PCR) to measure circulating HIV demonstrated increases in viral load in transfused HIV-infected patients 5 days after transfusion ([25]). However, most blood in the United States is now leuko-depleted and should not pose this risk. Because of the potential for diminishing the hazards of transfusions in patients with HIV, EPO is a potentially attractive alternative. Previous studies of recombinant EPO showed that it increased the hemoglobin in patients with anemia, which complicates the administration of chemotherapy and anemia associated with renal failure. In HIV infection, EPO is effective in increasing the hemoglobin in patients receiving ZDV therapy ([26]). In HIV infection, as well in other anemic conditions, EPO has its greatest effect in patients with low endogenous EPO levels. In one multicenter study ([26a]), patients received EPO therapy at doses of 100 to 200 IU/kg (intravenously or subcutaneously three times weekly for a total of 12 weeks or until a hematocrit of 38% or higher was achieved). Patients with EPO levels below 500 IU/L demonstrated significant increases in hemoglobin levels, decreases in transfusion requirements, and improvement in quality of life; EPO was ineffective in patients with high EPO levels. No significant toxicities have been reported. In the case of parvovirus infection, commercial immune globulin infusion is almost always associated with marked improvement in hemoglobin levels with resolution of anemia after a course of 400 mg/kg/day for 5 to 10 days ([22]). HIV-infected patients frequently develop repeated episodes of B19 infection requiring repeated treatments with intravenous Ig.

Thrombocytopenia

Thrombocytopenia is also a common finding in patients with HIV infection and may be related to a number of factors. In patients with early disease, decreased platelet counts are more likely to be related to decreased survival than to marrow failure, whereas the reverse is true of patients with advanced disease ([27]). OI, splenomegaly, fever, and other undefined factors lead to decreased platelet survival. Although platelet-associated antibodies increase in prevalence with disease progression, their role in causing decreased platelet survival is dubious. The presence of platelet-associated antibodies has not been found to correlate with the presence or degree of thrombocytopenia ([28], [29]). One confounding factor in interpreting data on platelet-associated antibodies is that conditions associated with platelet injury promote nonspecific antibody binding to the platelet membrane [sepsis, infection, and thrombotic thrombocytopenic purpura (TTP)]. Nonetheless, specific antibodies have been identified by some investigators. In hemophiliacs, a 7S platelet-reactive IgG capable of binding to homologous and autologous platelets was detected in serum, and an inverse relationship between the concentration of platelet-associated antibody and the platelet count was demonstrated ([30]). In a group of HIV-1–infected intravenous (IV) drug users presenting with idiopathic thrombocytopenic purpura, immune complexes on the platelet surface have been identified ([27]).

Defective megakaryocytopoiesis may also contribute to thrombocytopenia, particularly in patients with advanced disease. Megakaryocytes can be infected with certain strains of HIV, some of which can be cytopathic for the megakaryocytes ([31]). In addition, megakaryocytes arising from HIV-1–infected $CD34^+$ progenitor cells are defective in their ability to produce platelets ([32]).

TREATMENT Patients with idiopathic thrombocytopenic purpura and HIV infection respond to steroids with success equal to that of uninfected patients (60 to 80%). However, concern regarding the immunosuppressive effects of steroids is greater than for uninfected patients. If patients are not currently on antiretroviral therapy, its institution per se may result in improvement in the platelet count. Although most of the original work showed that ZDV increased the platelet production while not affecting the platelet survival, other antiviral regimens appear to affect the platelets in a similar fashion. Splenectomy remains an option, and concerns regarding its deleterious effect on the course of HIV infection appear to be unfounded ([33]). IV immune globulin also is effective, but its high cost, limited availability, and short duration of action make this a less attractive treatment. Similar to uninfected individuals, HIV-positive patients also appear to respond to anti-Rh immune globulin; this blood product has the advantage of subcutaneous administration, wide availability, and cheaper cost but, again, is limited by its short duration of action. Vincristine is effective when given monthly, although its administration is complicated by neuropathy. Recombinant thrombopoietin or the long-acting truncated form (referred to as the *pegylated recombinant human megakaryocyte growth and development factor*) has been evaluated in phase I/II clinical trials in uninfected patients. Administration of this agent increases circulating platelet count by severalfold in patients receiving chemotherapy ([34], [35]). Response is accompanied by significant increases in marrow megakaryocytes and marked mobilization of progenitor cells in the peripheral blood ([35], [36]). In HIV-infected chimpanzees ([37]), the pegylated form of thrombopoietin normalized platelet counts without increases in viral load. Development of antibodies to thrombopoietin with subsequent thrombocytopenia in normal controls has limited further study of thrombopoietin. Furthermore, patients with HIV infection and thrombocytopenia tend to have elevated thrombopoietin levels ([38]). Interleukin (IL)-11, a cytokine that promotes megakaryocyte maturation, is licensed for treatment of chemotherapy-related thrombocytopenia. In phase III studies in breast cancer patients receiving cytoxan and doxorubicin, patients receiving granulocyte colony-stimulating factor (G-CSF) and IL-11 (50 µg/kg/day) demonstrated a decreased requirement for platelet transfusions as well as a decreased time before platelet recovery ([39]). Undesired fluid retention reversed on discontinuation of the

drug. No studies using IL-11 in HIV-infected patients have been reported, and IL-11 is generally ineffective in patients with primary bone marrow disorders.

Neutropenia

Mild neutropenia is relatively common in patients with HIV infection. Although generally not of clinical significance, the limited bone marrow reserve that it reflects may become clinically apparent when administration of cytotoxic chemotherapy or other marrow suppressive drugs becomes necessary. Antineutrophil antibodies can frequently be seen ([40]), but their presence does not correlate with the degree of neutropenia. Progenitor cell numbers are generally normal except in patients with advanced disease when they are modestly decreased ([41]). Parenteral treatment with ganciclovir (GCV) or cytotoxic chemotherapy results in leukopenia in the majority of patients ([42] , [43]), frequently necessitating dose reduction and cytokine treatment ([44]).

TREATMENT Neutropenic (absolute neutrophil count, <1000 cells/µl) HIV-positive patients may experience increased frequency of significant bacterial infections. In a case controlled study, Tumbarello et al. ([45]) compared the neutrophil counts of groups of HIV-infected patients with and without bacteremia. Bacteremic patients were more likely to have an absolute neutrophil count of less than 1000 (38%) when compared with patients who are asymptomatic (19%). Another study ([46]), using a matched cohort analysis to evaluate the frequency of bacteremia in neutropenic and nonneutropenic patients, found that the frequency of bacteremia was increased in neutropenic patients (12.60 events per 100 patient months compared with 0.87 events per 100 patient months in the nonneutropenia control patients). In another study of 1645 patients with an absolute neutrophil count of less than 500 cells per µl, the risk of gram-negative infection increased eightfold ([47]). A number of studies have looked at the effect of recombinant growth factors on the incidence of infection and number of hospitalizations. (Doses and therapeutic effects of growth factors are listed in Table 69.2.) G-CSF enhances the proliferation and differentiation of neutrophils and improves neutrophil function, whereas granulocyte-macrophage colony-stimulating factor (GM-CSF) stimulates the proliferation and differentiation of a variety of myeloid progenitor cells and inhibits migration of neutrophils, enhancing the function of mature neutrophils and macrophages ([48]). G-CSF is the most widely used hematopoietic growth factor in HIV-infected patients, has fewer side effects, and increases the neutrophil count more rapidly. Although GM-CSF has been associated with an increase in HIV-1 replication *in vitro* ([49]), no consistent observation of acceleration of disease progression or increase in p24 antigen levels in patients receiving the drug has been demonstrated.

TABLE 69.2. Treatment of Human Immunodeficiency Virus (HIV) Patients with Hematopoietic Growth Factors

Drug	Dosage	Therapeutic Effect	Adverse Effects
Granulocyte-macrophage colony-stimulating factor	0.25–8.00 µg/kg/d	Improvement of leukocyte count and function	Back pain, myalgia, chills, nausea, headache, fever, rash, ?increase HIV replication
G-CSF	150 µg/m ^{2}/d	Improvement of proliferation and differentiation of committed progenitor cells	Bone pain
Erythropoietin	150 IU/kg 3 times/wk	Improvement in hemoglobin in patients with low erythropoietin levels	None
Stem cell factor	*In vitro* studies, 10 ng/ml	Improvement of white cell count when used with G-CSF	None
IL-3	*In vitro* studies, 10 ng/ml	Increase in erythropoiesis in presence of zidovudine and colony-forming unit granulocyte-macrophage	Fevers, headache, bone pain
Interferon-a	3 × 10 ^{6} U subcutaneously every other day	Variable response in prolonging platelet survival	Fever, myalgias, fatigue
IL-2	1.5 million U/m ^{2}, 2–3 times/wk	Increase in lymphopoiesis and decreased lymphocyte apoptosis; increase in CD4 count	? partial prothrombin time, proteinuria, fever, rash, capillary leak

G-CSF, granulocyte colony-stimulating factor; IL, interleukin; ?, increased.

Although beneficial effects, including decreased frequencies of OIs and increased tolerance for chemotherapy, have been reported with administration of G-CSF or GM-CSF, other studies have failed to reproduce these results, and no improvement in survival has ever been documented. G-CSF in combination with EPO leads to improvement in both leukocyte counts and hemoglobin levels. In one randomized, controlled trial of HIV-infected patients with life-threatening CMV retinitis, a group of investigators ([50]) used GM-CSF to ameliorate the myelotoxicity of GCV. In this study, there was a trend toward a decrease in the number of neutropenic episodes. GM-CSF administration resulted in a decrease in the number of times GCV therapy had to be interrupted as well as a longer mean time before progression of disease. Similar studies have been performed in patients receiving chemotherapy ([44]). In one study of patients receiving cyclophosphamide, hydroxydaunomycin, Oncovin (vincristine), and prednisone (CHOP) for NHL, the group receiving GM-CSF showed a reduction in the severity and duration of neutropenia, along with a reduction in the number of febrile neutropenic episodes and the duration of hospitalization. Other studies have failed to show decreased frequencies of OIs despite improvements in leukocyte counts ([51] , [52]). One study demonstrated an improved tolerance for chemotherapy in a group of patients receiving ProMACE-CytaBOM and G-CSF ([37]), but cytokine treatment did not result in a decreased incidence of fever, need for hospitalization, or an improved remission or survival rate. In another study using G-CSF in patients with advanced HIV disease with neutropenia (absolute neutrophil count, <1000), treatment decreased the frequency of bacterial infections by 31% and severe bacterial infections by 54%, requiring 26 fewer hospital days ([53]). A number of defects in neutrophil function have been demonstrated in HIV-infected patients. These include reduced L-selectin shedding and decreased H_2O_2 production ([54]) as well as defects in leukocyte migration, chemotaxis, and chemiluminescence during phagocytosis. These defects were more prominent in patients with advanced disease ([55]). G-CSF and GM-CSF both improve leukocyte function *in vitro*. A number of studies have looked at potential benefits of these cytokines in animal models of immunosuppression. In a murine model of *Pneumocystis carinii* pneumonia, CD4 $^+$-depleted immunosuppressed mice that received G-CSF after experiential pulmonary infection with *P. carinii* demonstrated improved survival when compared with control mice receiving placebo. Similar benefits were demonstrated using mouse models of disseminated *M. avium* infection, systemic candidiasis, and streptococcal pneumonia ([56]). No clinical study using either G-CSF or GM-CSF to enhance leukocyte function has been performed.

Lymphopenia

Increases in both CD4 and CD8 cell death and impairment in function are the *sine qua non* of HIV infection. IL-2 partially corrects the impaired lymphocyte proliferation and cytotoxicity seen in HIV infection *in vitro*. It also can partially block the enhanced tendency of lymphocytes obtained from HIV-infected patients to undergo programmed cell death (apoptosis) ([57]). In phase I trials of IL-2 in HIV-infected patients, it increased CD4 cell number and improved lymphocyte function ([57]). The development of a long-acting polyethylene glycol modified IL-2, which increases the half-life by 10- to 15-fold, allows for intermittent administration of the drug. Administration of doses of 1 to 5 million U/m ^{2}, two to three times weekly, resulted in modest but sustained increases in CD4 counts and improvement in natural killer activity in a patient with CD4 counts greater than 400 cells per µl ([58]) in 3 to 6 months. Fever, rash, and capillary leak are the most common toxicities ([59]). More recently, administration of very high doses of IL-2 (7.5 million IU twice daily to patients with early HIV infection) resulted in substantial increases in CD4 counts, compared with those seen in the group administered lower doses (1.5 million IU twice daily) ([60]). Of greater importance is the suggestion that intermittent administration of IL-2 in combination with HAART may lead to reduction in CD4 $^+$ T-lymphocyte cells that contain replication-competent HIV ([6]).

Thrombotic Thrombocytopenic Purpura

HIV infection is associated with an increased incidence of TTP and hemolytic-uremic syndrome, characterized by microangiopathic hemolytic anemia and thrombocytopenia with or without end-organ failure. Although no controlled studies comparing HIV-related TTP with classic TTP have been conducted, HIV-related TTP is generally thought to be associated with a milder course and a better response to therapy than classical TTP ([61]).

The pathogenesis of TTP and its relationship to HIV is still unclear, although a number of investigators have proposed different scenarios. HIV can infect endothelial cells, and viral p24 antigen has been detected by immunochemical stain in splenic endothelial cells, in spinal cord specimens, and in bone marrow microvascular endothelial cells ([62]). Whether infection results in vascular dysfunction has not been clearly demonstrated. Other factors, including cytokine dysregulation, can affect endothelial function. Tumor necrosis factor (TNF)-a and IL-1ß, two cytokines that are increased in HIV infection, could potentially lead to increases in endothelial expression of certain adhesion molecules, such as vascular cell adhesion molecule-1, intercellular adhesion molecule, and E-selectin, promoting localization of inflammatory cells to the endothelium with transmigration of lymphocytes through the endothelial wall. CMV, a virus that appeared to be associated with TTP in one

large AIDS Clinical Trials Group drug study, increases procoagulant activity in cultures of endothelial cells, potentially by binding and activating coagulation factor X/Xa ([62], [63]). Endo-thelial cells from small, but not large, blood vessels undergo apoptosis when exposed to plasma from patients with TTP ([62], [64]).

TREATMENT Although the treatment of choice for TTP is plasmapheresis or plasma exchange, successes with antiplatelet agents, vincristine, splenectomy, and plasma infusion have been reported ([33], [65]). Well-controlled clinical trials using a single treatment are lacking. In one study of HIV-TTP, most patients undergoing plasma exchange in addition to other therapies achieved a complete response ([62], [63] and [64], [66]). It is recommended that plasma exchange replace 35 to 40 ml per kg per exchange ([62], [67]). The frequency of exchanges should be governed by the clinical situation; lactate dehydrogenase (LDH) values may be used to monitor the course of the disease. The physician should attempt to keep the platelet count above 50,000 cells per µl and the LDH below 700 IU per dl. Platelets should not be transfused because doing so may lead to thrombotic events. Although antiviral agents have been reported as efficacious in this disease, no controlled trial has been performed. Early diagnosis and treatment appear important in producing good outcomes. TTP should always be suspected in an individual with thrombocytopenia, anemia, and a rising LDH.

Hematologic Effects of Drug Therapy

Drug-related hematologic toxicity is probably the most important clinical issue in the management of patients with AIDS (Table 69.1). Long-term administration of ZDV may be associated with marrow toxicity, particularly when given in higher doses as monotherapy, as was common practice in the early 1980s. Anemia is the most frequent manifestation of ZDV toxicity. More recently, when lower doses of ZDV were used in combination with other nonmyelosuppressive antiviral drugs, anemia became less of a clinical problem. The AIDS Clinical Trials Group showed that, although a ZDV dose of 500 mg/day did not affect hemoglobin levels in asymptomatic patients, that dose still could cause anemia in patients with advanced disease ([16]). Although the mechanism responsible for ZDV-associated anemia, inhibition of thymidine kinase, and DNA chain termination should theoretically also affect cells of other lineages, neutropenia is less frequent and thrombocytopenia very uncommon. The factors leading to preferential suppression of erythropoiesis are not clear. In addition, other nucleoside analogs like didanosine (ddI) or dideoxycytosine (zalcitabine; ddC), lamivudine (3TC), and stavudine (D4T) do not appear to have significant bone marrow toxicity ([68]). Protease inhibitors, such as indinavir, ritonavir, crixivan, and nelfinavir, alone or in combination with ZDV or other nucleoside analogs, also have little or no effect on hematopoiesis ([69]).

Trimethoprim/sulfamethoxazole (TMP-SMX), an antibiotic commonly used for the prevention of *Pneumocystis* pneumonia, is associated with a high rate of side effects, including fever, rash, and pancytopenia, in AIDS patients ([70]). Although there is no evidence that TMP-SMX induces folate deficiency in normal persons, the drug can cause megaloblastic anemia, leukopenia, and thrombocytopenia in patients with poor nutritional status and in combination with other predisposing factors ([70]). Bone marrow suppression, seemingly unrelated to folate deficiency, is a frequent side effect of TMP-SMX. In a comparative trial of patients treated with TMP-SMX or parenteral pentamidine, anemia was seen in 39% and 24%, respectively; mild neutropenia in 72% and 47%; and modest thrombocytopenia in 3% and 18% ([71]). TMP-SMX dose reduction to 20 mg/kg prevented development of neutropenia and thrombocytopenia. Dapsone (also used as prophylaxis of *P. carinii* pneumonia) is associated with fewer hematologic abnormalities than TMP-SMX (but is contraindicated in the presence of glucose-6-phosphate dehydrogenase deficiency).

Treatment of CMV infection with parenteral GCV may result in significant myelosuppression, producing leukopenia and thrombocytopenia after the second week of therapy ([42], [43]). Concurrent administration of hematopoietic growth factors may be necessary to prevent or improve severe neutropenia. Oral GCV (Valganciclovir) produces similar hematopoietic suppression to the intravenous form of the drug ([72]). Acyclovir, frequently used for treatment of recurrent herpetic lesions, has no bone marrow toxicity.

The antifungal amphotericin B is also frequently associated with myelosuppression. Hypochromic, normocytic anemia is the most common hematologic toxicity. In addition to direct effects on the bone marrow, amphotericin renal toxicity may result in diminished EPO production ([73]). Liposomal ampho-tericin products also produce anemia but to a lesser extent than the nonliposomal form of the drug.

Pathophysiology of Bone Marrow Suppression in Human Immunodeficiency Virus Infection

Diverse factors responsible for impaired hematopoiesis in HIV infection include suppression of the bone marrow by the virus or by viral proteins, immune dysregulation, actual infection of the bone marrow progenitor cells by HIV, and alteration of stromal cell elements. A number of studies demonstrate that CD34 cells have both HIV receptors necessary for infection (i.e., CD4 and CXCR4 or CCR5) ([74]). CD4 expression, as well as CXCR4 and CCR5 coreceptor expression, increases with maturation of the CD34 cell, and the expression of each correlates with potential infectability ([75]). In addition, CXCR5 may be up-regulated by a number of different cytokines. Although it is clear that the CD34 cell can be infected by HIV under a number of conditions, it appears that bone marrow progenitor cells do not represent a significant reservoir of infection ([76], [77]). In one study, HIV was detected in CD34 cells in only 14% of HIV-infected patients recruited in the United States and in 36% of HIV-infected persons in Zaire ([78]). When found, CD34 infection was present in those patients with far-advanced disease. Many investigators could not detect HIV infection in any stem cells ([79], [80]). In one study, purified $CD34^+$ cells were infected *in vitro* and cultured on allogeneic stroma for extended periods of time ([81]). A highly sensitive PCR failed to detect HIV-1 in the most primitive long-term colony-initiating cells (i.e., the secondary colonies generated from clonogenic cells harvested from stroma). Thus, it appears that although some committed progenitor cells can be infected with HIV-1 under some circumstances, the most immature stem cells appear not to be susceptible to HIV-1 infection.

The effects of HIV-1 on colony formation have been studied, either using bone marrow cells derived from HIV-1–infected patients ([79], [82], [83], [84] and [85]) or after *in vitro* infection of hematopoietic cells from bone marrow of normal donors ([86], [87] and [88]). Results have been surprisingly divergent. Although the growth potential of committed bone marrow progenitor cells in methylcellulose cultures after challenge with HIV-1 appears to be diminished, normal growth frequently has also been reported ([79]). Similar disparity exists in the results of studies performed with patient bone marrow. Such differences may be related to techniques in assaying colony growth (total bone marrow vs. purified $CD34^+$ cells), culture conditions (use of specific cytokines or growth factors), or patient selection. In some reports, inhibition of colony formation by virus was only observed in cultures of total bone marrow cells and not with isolated $CD34^+$ cells ([89]). Of interest is one report of abnormal progenitor cell function in HIV-negative infants born to infected mothers ([90]), implying that direct infection was not necessary for marrow suppression.

Marrow stromal function has been examined in patients with HIV infection. Stromal cells from some HIV-1–infected patients may be infected by the virus, demonstrating the importance of stromal infection in causing dysregulation of hematopoiesis. In one study ([91]), decreased colony formation has been observed when stroma infected *in vitro* was used to support growth of normal uninfected bone marrow progenitor cells. However, in another study, stroma obtained from HIV-infected patients supported growth of normal $CD34^+$ cells equally as well as stroma obtained from normal uninfected controls ([41]).

Although the stem cell compartment appears to be relatively well preserved early in the disease, in patients with low CD4 counts and history of OIs, there is a modest reduction of long-term colony-initiating cell numbers ([92]). However, the long-term colony-initiating cell numbers were far better preserved in this population than in patients with aplastic anemia with similar blood counts, implying that OIs, pharmacotherapy with antiparasitic, antimicrobial, antiviral, or cytotoxic agents, vitamin deficiencies, or poorly understood virally mediated immunomodulary changes were the major contributors to bone marrow failure in patients with advanced HIV disease.

Inconsistencies in the results of experiments attempting to demonstrate the role of direct infection of HIV-1 on hematopoiesis have stimulated further search for pathophysiologic mechanisms of bone marrow suppression. Several cytokines that are released during the course of HIV-1 infection are potent inhibitors of hematopoiesis. Not only native virus and productive infection ([89], [93]) but also viral products, such as gp120, gp160, and viral *tat* proteins, induce the secretion of an array of cytokines, including TNF-a, lymphotoxin-ß (TNF-ß), and IL-6 ([89], [94]). Perhaps the most prominent cytokine implicated in an array of pathophysiologic reactions in AIDS is TNF-a (or cahexin) ([95], [96]). In addition to its effect on body metabolism and immune system, TNF-a has inhibitory effects on hematopoiesis ([89], [97], [98]). High levels of interferon (IFN)-? were not only associated with a poor prognosis in HIV-1 infection but correlated with the degree of anemia ([99]). Although disordered cytokine production by both lymphoid tissue and bone marrow clearly occurs in HIV-1 infection, it is difficult to determine its ultimate role in suppression of hematopoiesis. Many inhibitory cytokines are produced in greatest quantities early in the course of HIV-1 infection when marrow suppression is least, and their levels decline as the disease progresses (when marrow suppression becomes most marked). In addition, increased levels of stimulatory cytokines have been observed in HIV-1 infection, and many cytokines never reach significant levels in the circulation. Local production of growth factors in bone marrow may be more important than systemically secreted factors. In support of this hypothesis, one study of genetically engineered stromal cells, designed to produce low levels of IFN-? constitutively, showed significant suppression of normal hematopoietic colony growth on IFN-? stroma, which could only be replicated by addition of large amounts of exogenous

IFN-? to marrow grown on normal stroma.

Apoptosis of hematopoietic progenitor cells through the Fas-L/Fas-R pathway is a mechanism by which activated T cells can kill virus-infected cells ([100]). It is likely that Fas-L and other cytokine products of activated T cells contribute to the hematopoietic inhibition seen in HIV-1 infection. Increased levels of Fas-L have been reported in patients with AIDS, and triggering of Fas-R on hematopoietic cells results in apoptosis ([101]).

Peripheral Blood and Bone Marrow Examination in Human Immunodeficiency Virus 1 Infection

Morphologic abnormalities can be found in the majority of bone marrow samples from HIV-1–infected patients, but most are nonspecific except in OI, in which the bone marrow examination provides valuable diagnostic information. Therefore, the bone marrow examination rarely yields substantial clinical information except in the diagnosis of concurrent *M. avium-intracellulare*, tuberculosis, or fungal infection or as part of staging for malignancy ([101a]).

The histopathologic findings in the bone marrow of HIV-1–infected patients are varied. In one large study of 216 bone marrow examinations performed in 178 HIV-1–infected patients for evaluation of cytopenia, 69% of patients exhibited hypercellular marrow, 69% showed myelodysplastic changes, and 20% showed significant fibrosis ([101a]); only 5% of the biopsies were hypocellular. Granulomas were found in 13% and lymphoid aggregates in 36% (but in other studies, in up to 50%) of specimens. Higher numbers of plasma cells and elevated numbers of eosinophils were also present, especially in conjunction with increased reticulin. Hyperplasia involving the granulocytic and erythrocytic lineages has been most commonly reported; the myeloid to erythroid ratio has varied from 2:1 to 5:1 ([102]).

Morphologic changes tend to be more pronounced in more immunosuppressed patients and increase in frequency as disease progresses. All lineages can be involved ([103] , [104]). Megaloblastic changes and ringed sideroblasts are frequent. Using the morphologic criteria established for primary myelodysplastic syndromes, dysplasia involving at least one lineage was diagnosed in 69% of patients. Dysplastic changes increase with disease progression. However, in one study, there were significant differences in the numbers of erythroid precursors and in the morphology of megakaryocytes, which clearly differentiated patients with AIDS from those with myelodysplastic syndrome ([105]). The cumulative effects of drug toxicities, direct HIV-1 infection of marrow cells, and dysregulated cytokine production may be responsible for the morphologic changes that occur late in AIDS. However, there is no correlation between the dysplastic changes in an individual lineage and specific cytopenias.

Coagulation Abnormalities

An increase in the incidence of thrombosis has been reported in uncontrolled, retrospective studies of HIV-infected patients. In one retrospective study, the prevalence of deep venous thrombosis among 4752 HIV-infected patients was 0.95%, or ten times that of the general hospital population ([106] , [107]). No analysis of the etiology of thrombosis was done in this study, making it difficult to interpret. Patients with HIV are, of course, subject to risk factors that affect other medically ill patients [e.g., inactivity, cancer, lymphedema, hypoalbuminemia, and medications that are associated with thrombosis (megace)] ([108]).

An increase in autoantibodies to phospholipids and to coagulation proteins has been reported in HIV-infected individuals. One study demonstrated lupus anticoagulant in 1% of patients with HIV infection ([109]). Antiphosphatidylcholine antibodies were present in 50% of patients; anticardiolipin autoantibodies were present in 64% of patients. Patients with far-advanced disease frequently lost their antibody because of their significant immunocompromised state. Unlike patients without HIV infection, these patients do not appear to exhibit an increase in the frequency of thrombosis ([110]).

Levels of functional protein S are decreased in a fair proportion of HIV-infected patients (27 to 73%) with as many as 12% developing thrombotic complications as a result ([111] , [112] and [113a]). Increased levels of complement binding protein 4, which binds protein S, can sometimes account for decreased functional protein S. Of interest is the statistically significant association of diminished protein S with thrombosis. No clear guidelines are available for treatment of these patients; however, most recommend anticoagulating patients with protein C deficiency for an undefined period of time. Decreases in heparin cofactor II ([114]) have also been described, but no examination has been done to correlate these laboratory abnormalities with a thrombotic tendency.

ACQUIRED IMMUNODEFICIENCY SYNDROME–RELATED MALIGNANCIES

KS, NHL, and Hodgkin lymphoma occur with increased frequency in patients infected with HIV ([115]). The development of these malignancies is related to a number of factors, including immunosuppression and concurrent infections with other viruses such as human herpesvirus 8 (HHV8) and Epstein-Barr virus (EBV), which foster malignant transformation. Although these malignancies also occur in the HIV-uninfected population, their presentation, as well as their appropriate treatment, is quite different in the HIV-infected patient. Designing a treatment plan for each patient with HIV infection must take into account the change in the aggressivity of the tumor, the effect of chemotherapy on the viral replication, drug interactions (should antiviral therapy be continued), and the limited hematopoietic reserve of these patients, which frequently necessitates modification of chemotherapeutic regimens. Despite our extensive experience in treating these disorders, the optimum therapy for many is still unclear, partially relating to the significant successes in the development of HAART therapy, which has prolonged the lives of patients with AIDS.

Non-Hodgkin Lymphoma

EPIDEMIOLOGY AND PATHOGENESIS NHL is the AIDS-defining condition in approximately 3% of HIV-infected persons. Although the frequency of NHL increases with the degree of immunosuppression [particularly for central nervous system (CNS) lymphoma], there is no correlation with the mode of HIV transmission. The relative risk of development of immunoblastic lymphoma is approximately 627-fold greater than what is expected in the general population, whereas the increase in diffuse large cell lymphoma is 145-fold greater ([116] , [117]). HAART has been associated with a significant decline in the incidence of OI and KS, as well as NHL. Although the incidence of small noncleaved (Burkitt) lymphomas (BL) has decreased, the number of patients with diffuse large cell lymphoma has increased. The average CD4 count at time of diagnosis of lymphoma has also declined over time so that the patient with NHL today is more likely to be significantly immunosuppressed. It is unclear if these changes are related to the changing management of patients with HIV infection. Genetic factors also play a role in the development of NHL; patients who are heterozygotes for the ([118] , [119]) CCR5 delta 32 are less likely to develop lymphoma, whereas those with stromal cell–derived factor 1 mutations are more likely to develop lymphoma. The three main pathologic types of HIV-NHL are the BLs and Burkitt-like lymphomas, B-cell immunoblastic lymphomas, and primary effusion lymphomas (PEL); each differs in clinical presentation, underlying pathogenesis, and response to therapy. The majority of HIV-related lymphomas are of B-cell origin. T-cell lymphomas are rare, as are PEL (which are of B-cell origin). BL and Burkitt-like lymphomas usually present with widespread disease and have a risk of CNS involvement ([120] , [121] and [122]). Other less common lymphomas include polymorphic lymphoproliferative disorders resembling posttransplant-associated lymphoproliferative disease and lymphomatoid granulomatosis. It is estimated that between 35 and 65% of all HIV-related NHLs are Epstein-Barr–positive ([123]). CNS lymphoma, which comprises approximately 18% of all HIV-related lymphomas, is virtually always associated with Epstein-Barr infection. In addition, BL is associated with EBV infection, and EBV is generally considered a predisposing factor for the development of lymphoma ([123] , [124] , [125] , [126] , [127] and [128]). Diffuse large cell lymphoma is also frequently associated with EBV in the preponderance of cases. PEL, on the other hand, is associated with HHV8 infection. The role played by these viruses in the pathogenesis of the disease is speculative. EBV encodes for a number of cytokines promoting cell growth, whereas HHV8 encodes for genes that inhibit detection of virally infected and transformed cells. AIDS-BL is associated with activation of the c *MYC* proto-oncogene, and many cases are associated with inactivation of p53 as well as point mutations in BCL-6.

CLINICAL MANIFESTATIONS Patients with HIV-NHL frequently present with advanced stage II or IV disease. The majority presents with a rapidly growing mass or the development of systemic B symptoms (i.e., fever, night sweats, unexplained weight loss). The clinical presentation is dependent on the site of involvement, and extranodal involvement, including the bone marrow (25 to 40%), gastrointestinal tract (26%), and CNS (17 to 32%), is common ([129]). Involvement of the small bowel and rectum is also prevalent, particularly in those with large cell histology. Several prognostic factors affect survival, including CD4 count, Karnofsky performance, age, LDH level, and response to therapy ([130]). Special attention should be paid to the patient with advanced HIV who presents with confusion, memory loss, and lethargy, as these may be the presenting symptoms of CNS lymphoma. Clinical evaluation of these patients may reveal multiple, heterogenous, or ring-enhancing lesions on computed tomography scan or magnetic resonance imaging, making it difficult at times to differentiate some lesions from those related to toxoplasmosis. Biopsy or cytologic evaluation of the CNS fluids is critical for diagnosis. There are also clinical features that help to distinguish the two conditions; larger lesions (>2 cm) and those that are periventricular or cross the brain midline favor a diagnosis of lymphoma. Diagnosis is based on biopsy or detection of EBV DNA or RNA transcripts in the cerebrospinal fluid. Should biopsy be impossible, a short trial of treatment for toxoplasmosis for several weeks with regular computed tomography scanning to assess size change would be a reasonable course of action. PEL, which generally occurs in patients with low CD4 count and advanced HIV disease, presents with pericardial and pleural effusions or ascites ([131]). Diagnosis is made by pericardiocentesis, thoracentesis, or paracentesis with cytologic examination of the fluid and immunohistochemical evaluation. PEL cells have a pleomorphic morphology and are negative for CD3 and CD19. Examination for Ig gene rearrangement

should show clonal rearrangement. Patients with CD4 counts less than 100 mm ^{3}, stage III or IV disease, age older than 35 years, history of drug abuse, and elevated LDH have a worse prognosis.

STAGING Staging evaluation for patients with AIDS-related lymphoma is similar to that for patients without HIV, except for the need to exclude CNS involvement and the necessity to exclude OI in the patient with B symptoms before starting therapy. All patients with AIDS-related lymphoma should undergo a head computed tomography scan or magnetic resonance imaging as well as a lumbar puncture.

THERAPY

Primary Central Nervous System Lymphoma The response to therapy in patients with primary CNS lymphoma has been very disappointing. Palliation with steroid and whole brain radiation (3000 to 5400 Gy) has response rates of 75%, and treatment with high-dose methotrexate has reportedly given similar results. Combination of radiation and chemotherapy is associated with unacceptable toxicity. The median survival is 2 to 4 months regardless of CD4 count ([132], [133]).

Primary Effusion Lymphoma Again, therapy is generally palliative in this condition. Therapy with CHOP extends life from 5 months to 10 to 14 months ([134]), but the decision to undergo therapy should be based on the functional status of the patient, the degree of immunosuppression, and the likelihood that the quality of life would be improved.

Disseminated Lymphoma Early in the AIDS epidemic, before institution of HAART, patients frequently tolerated standard-dose chemotherapy poorly, and only a minority of patients had a complete response. In addition, responses were of short duration. (The results of chemotherapy trials are listed in Table 69.3.) As a result, patients were treated with low-dose regimens with the expectation that patients would experience fewer OIs and less severe neutropenia. In one randomized, controlled trial comparing low-dose methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone (m-BACOD) ([135]) to the full-dose regimen, the survivals of each arm were comparable, although there was a substantial decrease in the incidence of febrile neutropenia in the low-dose group as well as a better quality of life. One difficulty in interpretation of these results is that patients were not stratified according to CD4 count or AIDS-defining illness to determine if the minority of patients with more intact immune systems would benefit from more intensive regimens.

TABLE 69.3. Results of Prospective Chemotherapy Trials in Acquired Immunodeficiency Syndrome–Related Lymphoma

Investigator	Regimen (Chapter 90)	Complete Response (%)	Median Survival (mo)
Little et al. (142)	Infusional EPOCH	79	Not yet reached
Weiss et al. (178)	CHOP low dose; CHOP full dose	30; 38	4.0; 20.8
Kaplan et al. (135)	mBACOD + granulocyte-macrophage colony-stimulating factor; mBACOD (low dose)	52; 41	7.0; 8.0
Sparano et al. (179)	Infusional CDE; infusional CDE + rituximab	42; 86	8.2; 9.0+

Treatment of HIV-related lymphoma has changed radically since the institution of HAART, and remission has been reported after institution of HAART alone ([136]). The French-Italian Cooperative Group subsequently examined the role of low- versus high-dose therapy in patients with moderate and severe immunosuppression ([137]). Patients with CD4 counts over 200 received a dose-intensified regimen of ACVB versus standard CHOP. Both groups of HIV-infected patients in this trial had comparable responses, but toxicity was less in the CHOP arm. Patients with one adverse prognostic factor were randomly assigned to dose-reduced CHOP. High-risk patients were treated with dose-reduced CHOP or vincristine plus prednisone. In the intermediate-risk group, standard-dose CHOP was superior to dose-reduced CHOP, but overall survival remained similar in the two groups. Tirelli et al. studied the impact of continuing HAART during CHOP chemotherapy in a case-controlled study. Responses were equivalent in the two groups, but toxicity was greatest in the group receiving HAART ([88], [138]) because of the overlapping toxicity of the antiviral medications with the chemotherapy; in this and other studies ([139], [140]), mucositis was a particular problem. However, despite this, patients receiving HAART had a survival advantage, and there was a trend toward an increase in OIs in the group not receiving HAART. A number of chemotherapy regimens using infusions of chemotherapeutic agents appear initially to allow for maximum cytotoxic benefit without increasing systemic toxicity. Cyclophosphamide, doxorubicin, and etoposide ([140]) given as an infusion produced remission rates of 58% with a median response duration of 18 months in patients with resistant disease. Subsequently, a National Institutes of Health trial of dose-adjusted EPOCH produced responses in 74% of patients; at 53 months of median follow-up, the disease-free and overall survival rates are 92% and 60%, respectively. Retroviral treatment was suspended during treatment. Although the CD4 cell counts declined and viral loads rose during chemotherapy, they returned to pretreatment levels after reinstitution of antiretinovial therapy at the termination of chemotherapy ([141]). Controlled, randomized trials still have not been done to compare these infusional regimens to standard chemotherapy. Anti-CD20 monoclonal antibody (Rituxan) has been used alone in patients with relapsed lymphoma and appears to be well tolerated and has some activity. Preliminary studies show that it can be added to EPOCH without evidence of added toxicity ([142]). Although in non–HIV-related lymphomas, CNS involvement generally occurs only in patients with BL and large B-cell lymphomas who have extranodal disease, involvement of the CNS frequently occurs in patients with HIV (15 to 20%) ([143]). Hence, CNS prophylaxis (methotrexate or cytarabine) is standard practice in patients with HIV-NHL. Administration of hematopoietic growth factors may be of use after chemotherapy. A small study using GM-CSF was performed in patients receiving CHOP for AIDS-related NHL. In that study, patients were randomized to receive either CHOP chemotherapy or CHOP chemotherapy plus GM-CSF beginning 3 days postadministration for 10 days ([144]). A reduced incidence of fever, neutropenia, and days of hospitalization was observed in the GM-CSF cohort, but the study size was too small to assess impact on survival or relapse.

Hodgkin Lymphoma

EPIDEMIOLOGY AND PATHOGENESIS The association between Hodgkin lymphoma and HIV has been supported by multiple studies. An Australian study showed a relative risk of Hodgkin lymphoma among HIV-infected persons of 8.5, whereas data from the United States and Puerto Rico revealed a relative risk of 7.6, and a more recent Italian study demonstrated a relative risk of 8.9 ([145], [146]). Hodgkin lymphoma appears to occur with decreased frequency in HIV-infected IV drug users ([147]). Hodgkin lymphoma in HIV-infected persons exhibits pathologic features different from those of Hodgkin lymphoma in the general population in that there is a preponderance of patients with unfavorable histologic subtypes—mixed cellularity is the most frequent histology, accounting for 41 to 100% of cases, whereas nodular sclerosis is the least frequent, accounting for 0 to 40% of cases. Some studies have described cases exhibiting a fibrohistiocytoid stromal cell proliferation, usually in bundles, surrounding nodular areas—a composition mimicking nodular sclerosis but distinguished from it by the absence of polarizable sclerosing reaction (and thus classified as having a mixed cellularity subtype). Another characteristic distinguishing the HIV-associated Hodgkin lymphoma from that not associated with HIV is the predominance of Reed-Sternberg cell–rich cases. The admixture of areas appearing as Hodgkin lymphoma alongside areas of NHL exhibiting large cell populations is not uncommon and can provide diagnostic as well as treatment dilemmas. Difficulties may also occur in distinguishing Hodgkin lymphoma from the CD30 $^{+}$ anaplastic large cell lymphomas as both consistently include CD30 $^{+}$ cells and expression of B cell–associated lymphoid antigens. However, Hodgkin lymphoma can be distinguished on the basis of a combination of activation markers and leukocyte common antigen LCA-CD45. Cellular markers, including CD30 $^{+}$, CD45 $^{-}$, and CD15 $^{+}$, are commonly expressed on Reed-Sternberg cells, whereas anaplastic large cell lymphomas usually express CD30 $^{+}$, CD45 $^{+}$, and CD15 $^{-}$. AIDS–Hodgkin lymphoma, like AIDS-NHL, is characterized by a high frequency of EBV infection when compared to Hodgkin lymphoma in the HIV-negative population. The pathologic role of EBV in Hodgkin lymphoma is evidenced by the Reed-Sternberg cell expression of EBV-transforming protein.

CLINICAL FINDINGS AND CLINICAL COURSE Unlike Hodgkin lymphoma not associated with HIV infection, persons with HIV–Hodgkin lymphoma frequently present with B symptoms and widespread disease at time of diagnosis. One study showed that 70 to 90% of patients present with B symptoms, and 74 to 96% of patients have advanced disease (stage III or IV) at the time of diagnosis with frequent involvement of extranodal sites (60%), including bone marrow, liver, and spleen involvement. Another characteristic of HIV–Hodgkin lymphoma is the high incidence of noncontiguous spread of disease; patients develop liver involvement without splenic disease and lung involvement without mediastinal adenopathy. Mediastinal involvement is present in far fewer patients than is seen in patients not infected with HIV ([145]). Bone marrow involvement occurs in 40 to 50% of patients and may be the first indication of the disease. Unlike patients with NHL, Hodgkin lymphoma develops in patients who have higher CD4 counts, ranging from 275 to 306 cells per µl ([148], [149]). Response to therapy is also decreased when compared to patients without HIV infection ([150]); the higher proportion of unfavorable histologies is not entirely responsible for these differences. Although HIV-infected patients tolerate chemotherapy far better than before the institution of HAART, patients still develop frequent OIs and bacterial infections, the bulk of which are due to gram-positive cocci and gram-negative bacilli. Significant predictors of prolonged survival include achievement of complete response, absence of prior AIDS diagnosis, and CD4 count greater than 250 cells per µl ([151], [152]). Patients with a CD4 count greater than 250 cells per µl have a survival of 38 months, whereas those with lower CD4 counts have a median survival of only 11 months; similar findings were found in those studies ([149], [153]).

THERAPY The major difficulty associated with treatment of HIV patients with Hodgkin lymphoma is the frequency of OIs during chemotherapy. CD4 counts tend to fall during chemotherapy, and leukopenias make standard doses of chemotherapy difficult to administer. The response to standard chemotherapy, including MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) and ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine), is lower than that of patients without HIV infection. One problem is that tolerance for chemotherapy is poor, resulting in a reduction of the doses or delay of chemotherapy. The median overall survival of

patients is approximately 1.5 years ([152], [154], [155]). Because 85 to 95% of Hodgkin lymphoma patients have widespread disease, there are no data on the impact of radiation therapy in treatment of AIDS-related Hodgkin lymphoma.

TRANSPLANTATION FOR HODGKIN DISEASE AND NON-HODGKIN LYMPHOMA Myeloablative transplants have been performed in patients with both NHL and Hodgkin lymphoma. Initial reports of patients receiving transplants without concomitant use of HAART have been punctuated with multiple OIs. At the City of Hope, 12 patients with NHL received stem cell transplants ([156]). Although 9 of 12 patients relapsed, three remained in remission. Patients received cytoxan (100 mg/kg), bischloroethylnitrosourea (450 mg/m ^{2}), and etoposide (60 mg/kg) as conditioning. OIs were seen in three patients; transient increases in viral load were seen in seven (related to HAART noncompliance). There were three deaths in this group (two with relapsed lymphoma); all others are currently alive at 18.5 months. Auto-logous transplantation has also been attempted. One study included eight patients with relapsed or resistant lymphoma, four with Hodgkin lymphoma, and four with NHL. Seven of eight continued HAART during transplant, and seven engrafted successfully. Although six of seven patients engrafted, only four patients went into complete remission ([157]). Nonmyeloablative transplantation has been used in patients with refractory disease and has produced short-term remissions (12 months) and was associated with little toxicity and few OIs ([158]).

Kaposi Sarcoma

KS, a disorder characterized by endothelial proliferation and spindle cell formation, was first described by Mortz Kaposi, a dermatologist. In 1872, he depicted both indolent and aggressive cases in elderly Eastern European men, wherein lesions usually involved the lower extremities and only rarely involved visceral organs. An aggressive form was then described in Africa, affecting infants and children with frequent fatalities. Later, KS was described in renal transplant recipients receiving immunosuppression; here, the disease was mild and found primarily in patients from Italy and Saudi Arabia or of Jewish descent. Lesions frequently regressed with withdrawal of immunosuppression. In the early 1980s, the disease was seen in a much more aggressive form in HIV-infected men with homosexuality as their risk factor; the disorder rarely affected HIV-infected women, drug abusers, or recipients of transfusion. Here, lesions were generalized and frequently affected viscera-lung, and gastrointestinal involvement led to death in some patients. Despite differences in clinical presentation, the histologic picture was similar to classic KS.

EPIDEMIOLOGY The occurrence of KS among HIV-infected homosexual males is 200,000-fold increased over that of the general population. Even HIV-infected persons in risk groups considered low risk for KS (i.e., hemophiliacs, transfusion recipients, and IV drug users) have an incidence of KS 1000- to 10,000-fold that of the noninfected population ([159]). Risk factors associated with KS include increased numbers of sexual partners, CD4 counts of less than 200 cells per µl, and intensity of HIV antiviral therapy. Individuals receiving HAART are less likely to develop KS than those receiving monotherapy. In the United States, up to 40% of homosexuals with AIDS in the early 1980s presented with KS at the time of the initial AIDS diagnosis. Subsequent to the introduction of HAART, the incidence of KS has declined dramatically. HHV8 infection appears to be present in all patients with KS and can be visualized within the KS lesions themselves. Of particular interest is the observation that KS regresses during pregnancy when it occurs in women; this phenomenon was explained by the fact that human chorionic gonadotropin appears to down-regulate activator protein 1, interfering with genes supporting cell growth. The decreasing number of individuals with KS taking HAART supports a significant role of the immune system in modulating the disease. Although HHV8 has been identified in KS lesions, it is unclear exactly what role viral infection has in producing KS lesions ([159], [160], [161], [162] and [163]).

PATHOGENESIS The KS lesion is composed of a proliferation of spindle-shaped cells with surrounding inflammatory cells of different origin and an increased angiogenesis with erythrocyte extravasation. There is some disagreement as to whether the disorder is a true malignancy. Early KS cells did not appear to have the characteristics of a malignancy. KS lesions occur in different noncontiguous locations, and one frequently sees KS lesions in many different stages of development. In most cases, these lesions demonstrate polyclonality. However, in patients with more advanced KS, the disease behaves in a more malignant fashion; in these lesions, there is evidence of clonality, and aneuploidy may be present. Furthermore, a number of oncogenes and oncosuppressor genes are expressed in lesions, including *bcl-2*, *c-myc*, and *TP53*. Studies performed in long-term KS cell cultures have implicated a number of cytokines important in KS cell growth. Some of these cytokines include autocrine growth factors, including IL-1ß, IL-6, and IL-8. Oncostatin M, basis fibroblast growth factor, and vascular endothelial growth factor also appear to be important in supporting growth. Transforming growth factor-ß, on the other hand, appears to suppress tumor growth. The KS lesion initiates as a granulation-like tissue, rich in inflammatory cells. Peripheral blood lymphocytes infiltrating the lesions produce inflammatory cytokines, including IFN-?, TNF-a, IL-1ß, IL-2, IL-6, and many others. These inflammatory cytokines may induce recruitment of additional cells into the tissues via adhesion and chemotactic molecules as well as the production of angiogenic factors that promote angiogenesis, edema, and activation of endothelial cells ([164]). Of interest is the observation by some investigators that administration of IFN-? and TNF-a to patients with HIV has led to the development of KS or to its progression. In addition, the onset of KS frequently occurs during OIs, which promote the secretion of inflammatory cytokines. HHV8 is ubiquitously associated with KS lesions and has been implicated as the factor that triggers this inflammatory process ([165], [166] and [167]). Data supporting the role of HHV8 in KS include serologic and PCR evidence of HHV8 infection in individual KS lesions; epidemiologic evidence shows that KS occurs more frequently in countries where HHV8 infection is most prevalent and in homosexuals with the highest antibody titers to HHV8. Despite this, other cofactors must be necessary to incite KS, as not everyone in high prevalence areas develops KS, and KS generally spares women with similar HHV8 antibody titers.

CLINICAL PRESENTATION KS most frequently presents as mucocutaneous disease characterized by purple raised lesions. Lesions on the limb may result in edema, ulceration, and bacterial infection. KS does not behave like many other tumors, as it may not spread to contiguous areas or metastasize by the lymphatics. Many different lesions at various stages of development can be found in many different areas of the body, seeming to indicate that each KS lesion develops *de novo* in response to a viral or related stimulus. Elimination of KS lesions by local treatment thus does not affect the eventual development of KS lesions in other parts of the body. KS often involves the head and neck, including the tip of the nose and the retroauricular and periorbital areas. Lesions of the hard and soft palate, as well as the gums, may destroy dentition and ultimately interfere with eating. Lymphatic involvement may result in edema of the limbs, periorbital area, and genitalia; cellulitis is a frequent complication of lymphatic involvement. Gastrointestinal involvement may result in gastrointestinal blood loss and obstruction. Involvement of the tracheobronchial tree, pulmonary parenchyma, and pleura may lead to death by respiratory failure.

TREATMENT All patients with KS should have a biopsy confirming the diagnosis, no matter how typical or atypical the lesion may look. Subsequent studies should include a chest x-ray and stool guaiac. Because HAART initiation may be associated with complete regression of the lesions, all patients with KS should be put on HAART and followed for a period of several months before other therapies are considered ([168], [169]). Patients with limited disease can have treatment addressing the local control and cosmetic treatment of individual lesions. The use of local interventions has increased because of the realization that no curative systemic therapy exists if the patient does not respond to HAART. Local control may be achieved by intralesional injection of dilute vinblastine, cryotherapy, radiation therapy, or laser therapy. Retinoids (alretinoin gel) have been modestly successful in producing remissions ([170]). Photodynamic therapy ([170], [171]) using intravenously administered photofrin before light exposure may be useful in small lesions. For patients with systemic disease that is too widespread to be amenable to local measures or who have pulmonary involvement, systemic therapy should be undertaken. One of the difficulties in performing therapeutic trials in patients with KS is assessing response to therapy. Frequently, people have a large number of lesions, and biopsy with histologic examination is necessary to document tumor cell death, as the lesions fade over the course of many months after effective treatment. IFN-a is an effective treatment for KS; it is associated with a 50% response rate in patients with a CD4 count greater than 200 cells per µl ([172]). However, many patients experience toxicity related to drug administration, including flulike symptoms, fever, and anemia. Thalidomide has been used in treatment of KS with the rationale that it decreases TNF-a, which may play a role in inducing KS, but results have been generally disappointing ([173]). A number of other agents possess activity against KS, including bleomycin, the vinca alkaloids, anthracyclines, paclitaxel, and etoposide. Patients respond well to liposomal anthracyclines that are generally comparable and less toxic than therapy with several agents (e.g., actinomycin D, bleomycin, and vincristine) ([168], [174], [175]). Paclitaxel in doses of 100 mg/m ^{2} every 2 weeks is effective in more than half of patients relapsing and unresponsive to other drugs. Current studies are investigating the efficacy of liposomal doxorubicin and paclitaxel ([28]). A phase II study comparing DaunoXome to triple drug therapy (actinomycin D, bleomycin, and vincristine) demonstrated comparable responses with considerably less toxicity with DaunoXome. Doxil has been shown to be effective in patients who have received prior systemic chemotherapy and to result in comparable response rates to actinomycin D, bleomycin, and vincristine. Patients not responding to these may be treated with paclitaxel, which is highly effective against KS but is not without significant toxicity. One group demonstrated that paclitaxel given in a dose of 100 mg/m ^{2} every 2 weeks was well tolerated and resulted in partial or complete responses ([28]). Current multicenter studies comparing paclitaxel to liposomal anthracyclines are now under way. Large trials using antiangiogenic agents, such as AGM 1470, thalidomide, and glufanide disodium, are in progress after initial studies showed encouraging responses. Retinoic acids appear to block angiogenesis as well as proliferation of KS cells *in vitro*. A multicenter trial to examine the efficacy of intravenous administration of liposomal tretinoin (all- *trans*-retinoic acid) demonstrated responses in persons receiving the drug three times weekly ([175a]). Retinoids have also demonstrated efficacy administered topically and a topical compound, alitretinoin gel, was licensed by the U.S. Food and Drug Administration in 1999. IL-4 has been investigated and failed to yield promising results. *In vitro* cell culture studies and a murine model for KS have shown that human chorionic gonadotropin-associated factor has antiproliferative and cytotoxic effects on KS cells without toxic effects on normal endothelial cells and lymphocytes. Preliminary results in patients showed a 30 to 40% response rate without significant toxicity ([176]). Some patients with very advanced disease were among the responders. Because of the association of KS with HHV8, the efficacy of a number of antiviral agents has been tested. An antiherpes drug, cidofovir, failed to produce a response when injected into KS lesions. Among patients with previous CMV disease, use of GCV and foscarnet was associated with a nonsignificant decrease in the incidence of KS. However, in the MultiCenter AIDS Cohort Study, acyclovir use was not protective against subsequent KS development ([177]). Patients who are more likely to respond are those with more intact immune systems.

FUTURE DIRECTIONS

Patients with HIV infections are living longer and experiencing better quality of life than ever before. Treatment of HIV-related lymphomas still represents a major challenge to the field. In the future, different strategies directed toward underlying inciting viral infections may perhaps be more successful than standard chemotherapy.

Efforts also need to be made to achieve immune reconstitution in infected persons. New and better antiviral medications not associated with viral resistance would help in this effort. In addition, studies directed toward altering bone marrow cells genetically so as to make them resistant to infection may be successful in promoting CD4 production and eliminating their early destruction. Additionally, work on development of better monoclonal antibodies active against HIV may help eradicate infected cells.

Disorders of the Spleen

The spleen is a small, purplish, spongelike organ found in the left upper abdominal quadrant ([1]). Although there is no mention of the spleen in the Bible, it receives considerable attention in the Talmud and post-Talmudic literature. Classically identified as the seat of laughter, there has been much debate over whether the spleen is truly necessary ([2]). It is said that Galen called it an “organ full of mystery” as early as the second century A.D. ([3], [4]). Although we have come to understand much about the structure and function of the spleen since those times, much of what intrigued Galen still remains a mystery today. For example, the basic question of which organ system the spleen belongs to remains a point of contention among authorities. Different investigators classify it as being a component of the circulatory system ([5]), the hematopoietic system ([6]), the mononuclear phagocyte system ([7]), or the lymphatic system ([8]). However, it is probably more accurate to describe the spleen as a clearinghouse for circulating cellular elements—a place where multiple organ systems converge in both structure and function. Through a careful study of splenic anatomy and physiology, as well as the consequences of splenectomy, much has been learned to help clarify these issues ([2]).

DEVELOPMENT AND ANATOMY

The spleen is derived from embryonic mesoderm ([6], [7], [9]). The developing organ first becomes apparent during the fifth week of gestation as mesodermal cells coalesce between the leaflets of the dorsal mesogastrium, posterior to the developing stomach ([7], [9], [10]). As development continues, independent lobules enveloped by mesogastrium become evident. In time, they fuse to form a multilobulated mass that eventually differentiates into a well-formed organ by late fetal life ([9], [10]). Occasionally, a stray lobule may fail to fuse with the others, develop independently, and give rise to an accessory spleen, a functioning mass of splenic tissue set apart from the body of the organ proper ([7], [9]). The mesogastrium enveloping the lobules eventually gives rise to the organ's capsule and trabecular skeleton, and the posterior and anterior attachments give rise to the primary supporting structures: the splenorenal and gastrosplenic ligaments, respectively ([9], [11]).

Gross Anatomy

Grossly, the spleen may appear in a variety of shapes. It may be wedge-shaped (44%), tetrahedral (42%), or triangular (14%) depending on its relationships with neighboring organs during development ([11]). Adjacent organs that affect the shape of the spleen include the stomach, left kidney, pancreas, and colon ([1], [12]). Corresponding depressions on the surface of the developing spleen give rise to the observed gastric, renal, pancreatic, and colic impressions ([1]).

The size of the spleen varies with age as well as immunologic and nutritional status ([1]). However, the average adult spleen measures 13 to 15 cm in length, 8 to 10 cm in width, and 4 cm in thickness, with a weight of 150 g and a corresponding blood volume of approximately 300 ml ([1], [8], [13], [14]).

The nonperfused organ appears purplish in color with a solid, spongelike texture throughout. It is covered by a fibrous connective tissue capsule that is 1.5 mm thick and composed of collagen and elastin fibers ([1]). This capsule surrounds all but the hilum of the spleen ([14]). Continuous with the capsule, involutions penetrate the body of the organ to form trabeculae, the fibrous supporting skeleton of the spleen ([1], [8], [14]). Finally, a serosal membrane, derived from peritoneum, covers the organ externally and adheres to the capsule. This mesothelial membrane covers the entire organ except at its hilum and the reflections of its primary supporting ligaments ([1]).

Beneath the capsule, the spleen may be divided into segments or lobes; two are found in most people ([15]). Although the exact nature of these segments remains to be defined, it is generally agreed that avascular planes separate them from each other and that they are defined by discrete nonanastomosing circulatory pathways ([1], [11], [15], [16]). The overwhelming majority of people have two lobes: a superior lobe and an inferior lobe ([15]). However, other lobes have been identified and include an intermediate or accessory lobe as well as numerous subsegmental lobes ([15], [16]).

LOCATION AND RELATIONSHIPS The spleen is located in the left upper quadrant of the abdominal cavity, posteriorly, at the level of the ninth to eleventh thoracic vertebrae ([1], [12]). The superior, or diaphragmatic, surface of the organ is convex in shape, smooth, and related to the left hemidiaphragm, whereas the inferior, or visceral, surface is somewhat triangular and rests on the splenic flexure of the colon ([1], [11], [12]). The medial portion of the spleen is concave and divided by a longitudinal ridge into a gastric surface anteriorly and a renal surface posteriorly ([1], [11]). The gastric surface contains the hilum of the organ and relates to the fundus of the stomach and the tail of the pancreas ([1]). The tail of the pancreas touches the spleen in 30% of cases and is within 1 cm of it in 73% of the population ([17]), contributing to the risk of pancreatic injury in patients undergoing splenectomy. The renal surface borders the superolateral surface of the left kidney and left adrenal gland ([11]). Figure 70.1 shows the gross appearance of the spleen as well as the relationship to the adjacent pancreatic tail and branch vessels of the splenic artery. The spleen's anterior, lateral, and posterior surfaces follow the contour of the left lower rib cage (ninth, tenth, and eleventh ribs) to which they are related, with the diaphragm and pleura intervening ([1], [12]).

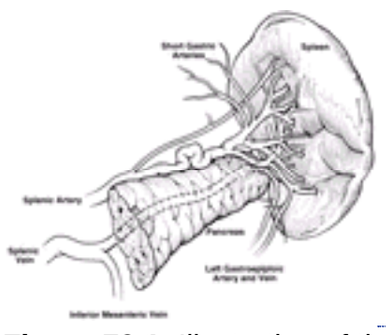

Figure 70.1. Illustration of the spleen and relationship to the adjacent pancreatic tail and branch vessels of the splenic artery and vein. (Redrawn and modified from Cameron JL, ed. Atlas of surgery. Philadelphia: BC Decker, 1990.)

The spleen is supported by a number of suspensory ligaments: the splenorenal posteriorly, the gastrosplenic anteromedially, the splenophrenic superiorly, and the

splenocolic inferiorly ([1]). Associated ligaments that help to support the spleen include the pancreaticosplenic, phrenicocolic, and pancreaticocolic ligaments as well as the presplenic fold ([11]). The splenorenal and gastrosplenic ligmary ([11]). The splenorenal ligament supports the organ posteriorly and servaments provide the majority of support to the organ and are considered pries as a conduit for the organ's neurovascular bundle, whereas the gastrosplenic ligament stabilizes the spleen anteromedially to the greater curvature of the stomach and contains the short gastric and gastroepiploic vessels ([1] , [11]). The other ligaments of the spleen play a secondary role in the support of the organ and are generally avascular ([1] , [11]). However, in certain pathologic states, such as portal hypertension, significant collateral circulation through these planes may occur ([7] , [11]). Certain surgical procedures (such as the distal splenorenal shunt) use these collateral pathways to decompress gastroesophageal varices in patients who have bleeding complications of portal hypertension and are not responsive to medical measures.

VASCULAR SUPPLY The spleen is a highly perfused organ. Although it represents only approximately 0.2% of the total body weight, it receives more than 5% of the total cardiac output ([18]). The main blood supply to the spleen is the splenic artery, which delivers 250 to 300 ml of arterial blood per minute ([10] , [18]). It arises as a branch of the aorta's celiac trunk in the midline and follows a tortuous course to the left, enveloped within the splenorenal ligament, to supply the organ ([1] , [12]). The splenic artery is a highly unpredictable vessel that displays variations in course and dimension ([11]). In 95% of the population, it travels along the upper border of the pancreas ([15]), but it may also travel in front of, within, or behind the pancreatic tissue ([11]). Along its tortuous course, the splenic artery gives rise to the left gastroepiploic artery and the short gastric arteries, both of which run within the gastrosplenic ligament ([7]). At its terminal end, the splenic artery branches into a number of smaller arteries, or segmental branches, before penetrating the hilum of the organ. These smaller arteries are also highly variable but are most often four in number and include the superior polar, superior middle, inferior middle, and inferior polar splenic arteries ([1] , [11] , [12]). The segmental branches penetrate the organ by traveling within the trabeculae (sheaths of fibrous connective tissue derived from the involution of the spleen's fibrous capsule) and ramify within the body of the organ ([8]). Additional sources of arterial blood to the spleen include direct tributaries and collateral circulation provided by branches of the pancreatic and short gastric arteries ([1] , [11]). Venous drainage is facilitated primarily by the splenic vein ([1] , [11]). It is formed by the coalescence of the segmental splenic veins, as they leave the hilum of the organ, and the left gastroepiploic vein ([7]). Occasionally, short gastric veins may also participate ([11]). Once formed, the splenic vein courses toward the midline along the superior border of the pancreas, where it joins the superior mesenteric vein to form the portal vein ([11]). Along the way, the splenic vein receives venous tributaries from the pancreas and, in 60% of cases, also receives the inferior mesenteric vein ([12]).

LYMPHATICS The spleen, which is considered by many to be a lymphatic organ ([8] , [9] , [19]), has no afferent lymphatics ([20]), yet a significant amount of lymph fluid is expressed by the organ and drains via efferent vessels that form around the arterioles. The lymphatics travel with the neurovascular bundle through the trabeculae, exiting at the hilum ([20]). In turn, the lymphatic fluid is directed toward the nodes of the splenic hilum, the splenic artery, and the pancreas (the pancreaticosplenic nodes) and eventually drains to the nodes of the celiac axis ([11]).

INNERVATION The innervation of the spleen remains controversial. Some authors argue that sensory, myelinated fibers play a role in splenic physiology ([11]). However, it is generally held that nonmyelinated autonomic fibers exist exclusively ([1]). The autonomic fibers that are observed in the spleen originate within the sympathetic chain at the level of T-6 to T-8 and pass with the greater thoracic splanchnic nerve to the celiac ganglion ([11]). From there, they pass to the organ via the arterial tree, with resulting vasomotor function ([1]). It is believed that, similarly to other mammals, the autonomic nervous system regulates changes in spleen volume, resulting in the expulsion of stored red blood cells during times of physiologic need ([14] , [21]). Of interest are studies that relate the sympathetic innervation of the spleen to the immune system ([22] , [23]). These studies suggest that the sympathetic nerves that travel along the arterial tree also provide branches to the lymphocytic tissue of the white pulp. In this respect, these investigators argue, the central nervous system is hard-wired to the immune system and may mediate the observed immunosuppressive effects of stress ([22] , [23]). It has been suggested that parasympathetic distribution to the organ exists, derived from the right posterior vagus nerve. The functional significance of this innervation is uncertain ([11]).

ACCESSORY SPLEENS An accessory spleen is a functioning lobule of splenic tissue set apart from the body of the spleen proper. It is an anatomic variant present in 10 to 30% of the general population ([7] , [9]) and appears to be found with greater frequency in patients with hematologic disorders ([10]). Figure 70.2 shows a typical example of an accessory spleen.

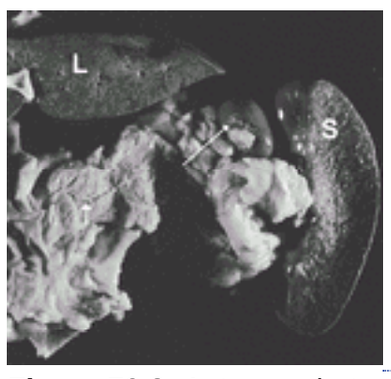

Figure 70.2. Autopsy photograph demonstrating accessory spleen (*large arrow*) and its relationship to the splenic hilum, pancreas (*small arrow*), and adjacent liver. L, liver; S, spleen. (Photograph provided by Hedi Wingard, M.D., Department of Pathology, Vanderbilt University Medical Center.)

These supernumerary organs arise during embryologic development when an encapsulated lobule of precursor cells fails to fuse with others forming the spleen proper ([9]); they are solitary in approximately 88% but can be multiple in 10% of cases ([10] , [24]). In the majority of cases, accessory spleens receive their blood supply from a tributary of the splenic artery and are found most often near the hilum of the organ or within one of the primary supporting ligaments ([10]). However, they may be found within secondary supporting ligaments or within the greater omentum or even in as remote a location as the pelvis of the female or the scrotum of the male ([10]). They may be mistaken for malignancy on imaging studies, such as computed tomography (CT) or endoscopic ultrasound ([24]), and can rarely develop abscesses just as a normal spleen ([25]). Because accessory spleens perform the same functions as the spleen proper, they are subject to the same pathologic conditions that affect the parent organ. Therefore, they may enlarge after splenectomy, causing a relapse of the disease process for which the spleen was removed ([20]). The presence of an unrecognized accessory spleen can account for failure of certain surgical procedures such as splenectomy for immune thrombocytopenic purpura (ITP). In patients who continue to have thrombocytopenia after splenectomy, search for a missed accessory spleen should be considered. Diagnosis may be made using abdominal sonography, CT, magnetic resonance imaging, nuclear scintigraphy, or Doppler sonography ([26]).

SPLENOSIS In addition to accessory spleens, extrasplenic tissue may occur via traumatic autotransplantation in the form of splenosis ([27]). This is the migration and subsequent proliferation of dislodged splenic tissue, and it is reported to occur in up to 75% of patients who undergo splenectomy for traumatic injury ([27]). Rarely, splenosis may be found in the gynecologic patient ([28]) or in the thorax after rupture of the spleen and left hemidiaphragm ([29]). In the era of laparoscopic splenectomy, there have been reports of splenosis at the retrieval port site ([30]). Histologic examination of splenetic tissue reveals the same elements of the parent organ: white pulp, red pulp, and marginal zones ([31]). It follows, therefore, that splenetic tissue should preserve at least some splenic function. Indeed, it has been observed that postsplenectomy patients with splenetic tissue do retain the ability to clear erythrocytes of undesirable inclusion bodies ([32]). However, it has not been demonstrated that this provides sufficient protection from postsplenectomy infectious complications ([33]).

WANDERING SPLEEN *Wandering spleen* refers to migration of the spleen from its normal location in the left upper quadrant ([34]). With an incidence of less than 0.5% in splenectomy series, the major complication of an ectopic spleen is torsion, either acutely or chronically. Signs and symptoms include vague or chronic abdominal discomfort and a tender abdominal mass, and CT assessment of viability leads to the decision of splenectomy versus splenopexy ([34]).

Microscopic Anatomy

Splenic tissue is supported by a scaffold of trabeculae, a dense, fibrous connective tissue skeleton that gives rise to an intrasplenic meshwork of collagen fibers ([1]). Vascular elements enter the spleen at the hilum, branch through the trabeculae, and penetrate the body of the organ to supply the microcirculation ([6]). As the arterial elements enter the parenchyma, they become surrounded by an aggregate of lymphoid tissue, which follows vessels in a sheathlike distribution ([1]). Aggregates of lymphoid tissue are collectively called the *white pulp*. White pulp may be arranged in this coaxial fashion, or it may appear as isolated follicles within the parenchyma of the organ ([19]). The balance of splenic tissue beneath the capsule is known as the *red pulp*. It is composed of vascular, circulatory, and mononuclear phagocytic elements ([1] , [35]). Additionally, an intermediate region can be observed at the junction between the white and red pulp; it is known as the *marginal zone* ([1]). Nerves and lymphatics follow the distribution of the larger vessels throughout the body of the organ ([3]).

WHITE PULP The white pulp represents roughly one-fourth of the splenic volume and is composed primarily of lymphoid elements ([3]). White pulp may be observed in one of two arrangements: a periarteriolar lymphatic sheath (PALS) or a lymphoid follicle ([1] , [35]). The *PALS* is a collection of (mostly) T lymphocytes that surrounds intraparenchymal arterioles and follows these vessels in a coaxial fashion for several millimeters throughout their terminal distribution ([1]). The *lymphoid follicles*, or

malpighian corpuscles, are spherical collections of B lymphocytes measuring 0.25 to 1.00 mm in diameter ([1]). These follicles are usually distributed along the length of the PALS in an eccentric fashion or may be found toward the terminal ends and branching points of the arterioles ([1]).

RED PULP The red pulp represents approximately three-fourths of the splenic volume ([1]) and is composed primarily of vascular elements surrounded by a fibrocellular reticulum that contains mononuclear phagocytic cell lines and circulating elements of blood in transit ([1, 35]). The chief vascular component of the red pulp is the *splenic sinus*, a preliminary venous element whose structure is unique to this organ ([3, 6]). The sinus is composed of an incomplete lining of elongated endothelial cells surrounded by a highly fenestrated basement membrane ([1]). The structure is supported externally by reticulin fibers wrapped in a transverse fashion ([1, 6, 19]). The unique architecture of the splenic sinus has been compared to the structure of a wooden barrel, with the elongated endothelial cells resembling the planks or staves and the external reticulin fibers representing the hoops ([19]). The splenic sinuses permeate the surrounding fibrocellular reticulum that supports them. Two-dimensional histologic observation reveals an intervening reticulum arranged in cords called *splenic cords* or *cords of Billroth* ([1]). These cords actually are a three-dimensional meshwork of densely packed elements (fibroblasts, collagen fibers, and cells of the mononuclear phagocytic lines) ([19]). Terminal arterioles and capillaries deliver circulating blood to this meshwork that percolates through the cord toward the sinuses. Thus, circulating elements of blood in transit are also packed within the cords: erythrocytes, platelets, macrophages, lymphocytes, plasma cells, and granulocytes ([1, 19, 35]).

MARGINAL ZONE The *marginal zone* is a transitional region between the white and red pulp and contains both lymphocytic and mononuclear phagocytic elements ([1, 35]). Within this transitional zone, three distinct regions can be identified. Moving from white to red pulp are the marginal sinus, the marginal zone proper, and the perimarginal cavernous sinus plexus ([36]). The *marginal sinus* is a vascular sinus that surrounds the white pulp and is a region where numerous arterioles terminate into an anastomosing complex of vascular spaces. External to the marginal sinus is the marginal zone. This transitional region contains elements of both white and red pulp and is where much of the circulating blood is presented to lymphocytic and mononuclear phagocytic cells ([1, 36]). Figure 70.3 illustrates a schematic view of the microcirculation within the spleen.

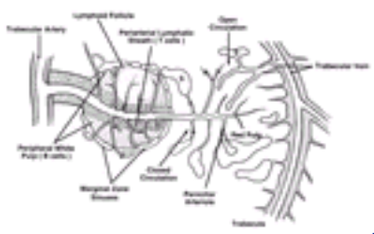

Figure 70.3. Schematic illustration of the microcirculation of the spleen. S, splenic sinus. (Redrawn and modified from Greep RO, ed. The spleen. New York: McGraw-Hill, 1966.)

MICROVASCULATURE As the splenic artery approaches the body of the organ, it divides into a series of branches, the *proper splenic arteries*. On average, four proper splenic arteries then enter the organ at the hilum ([1, 12]) and branch into *trabecular arteries*, so named because they run within the framework of the fibrous connective tissue skeleton, the *trabeculae*. Trabecular arteries leave the fibrous trabeculae and penetrate the parenchyma by branching into central arteries that immediately become surrounded by a cuff of white pulp, the PALS ([1, 35]). Some investigators argue that as long as central arteries are surrounded by white pulp, they do not give rise to tributaries ([37]). However, most researchers support the notion that as the central arteries pass through the white pulp, they give off lateral branches at right angles, most of which terminate in and supply the marginal sinuses, and others that terminate within the marginal zone or red pulp ([1, 38, 39]). The right angle by which these lateral tributaries branch off from the central artery is thought to mediate a plasma-skimming effect ([10]). In other words, as the flow is directed through the tributaries, it is hemoconcentrated, presenting the vessels and structures downstream with a greater number of cellular elements ([4]). This skimming effect may also have implications for the hypothesized role of the spleen in the regulation of plasma volume ([40]). Central arteries continue from the white pulp sheath through the marginal zone and eventually terminate in the red pulp, giving off additional lateral branches along the way known as *penicillar arterioles* ([1]). The penicillar arterioles, which are named for their resemblance to penicillium molds, terminate in one of three fashions: They may circle back and supply the marginal sinus; they may terminate in the red pulp, supplying the splenic cords; and a minority may terminate directly into the venous sinuses for direct venous return ([37, 38]). Eventually, the central artery itself terminates within the red pulp ([1, 19, 35]). Circulating elements of splenic blood flow begin their return by first entering the splenic sinuses, the preliminary venous vessels ([1]). Flow may enter the sinuses directly from arterial connections in a closed circulatory fashion. Alternatively, plasma and blood cells may reach the sinuses only after percolating through the reticulum of the parenchyma in an open circulatory fashion ([3]). Eventually, the venous sinuses coalesce and drain into trabecular veins that give rise to the segmental veins and, finally, the splenic vein ([1]). The exact details of splenic microcirculation remain under investigation. The currently accepted models that describe the flow of blood through the vessels of the spleen discuss this in terms of the pathway taken, or route, and the kinetics or speed of flow ([1, 38]). In terms of the pathway taken, blood flow through the spleen may follow a closed or open circulatory pathway ([1, 38]). A closed circulation implies that blood passes directly from artery to capillary to vein. In terms of the spleen, blood traveling along a closed circulatory path follows the terminal arterioles to capillaries and, eventually, into the venous sinuses. Indeed, such direct connections have been observed ([1, 37, 38, 41]) and do support some degree of direct transit within the organ. The term *open circulation* implies that cells and plasma spend at least some of their circulating time outside the endothelium-lined vascular channels. As it pertains to the spleen, circulating blood may follow one of two open pathways: It may leave the endothelium-lined marginal sinus, traverse the white pulp, and drain into the open-ended sinuses of the perimarginal cavernous sinus plexus ([38]); or it may leave penicillar arterioles that terminate in stroma of the red pulp, traverse the splenic cords, and reenter the venous sinuses through their fenestrations ([37]). Indeed, the unique vascular channels and microarchitecture of the spleen can support these open circulatory pathways, which also have been observed ([37, 38, 41]). Another model for discussing splenic microcirculation describes it in terms of kinetics or speed of flow ([1, 38]). Accordingly, intrasplenic circulation may be fast, intermediate, or slow, traversing the organ in seconds, minutes, or hours ([1]). Fast flow occurs along paths of low resistance, traverses the organ in seconds, and accounts for approximately 90% of splenic flow ([36]). Pathways that support fast flow include the open circulation of the marginal zone and, to a lesser extent, the closed circulation of direct arterial, capillary, and sinus connections ([38]). Elements that flow at an intermediate speed cross the circulation within minutes rather than seconds and represent approximately 9% of flow across the organ. These elements are thought to follow the open circulation through the cords where red cell processing—pitting and culling—occurs ([38, 41]). Finally, slow-flowing elements may take more than a day to traverse the organ and represent 1% of splenic flow. This is thought to represent a pool of maturing reticulocytes, which travel to the spleen from the bone marrow and undergo maturation before being released into the circulation ([38]). The role of the spleen in this function is well documented and supported by the fact that asplenic patients have a high concentration of immature reticulocytes in their peripheral circulation ([42]).

SPLENIC FUNCTION

The functions of the spleen are probably best understood in terms of its unique structure. Composed of several different tissue types, it lies at the crossroads between the arterial supply and venous return. In this respect, the spleen functions as a clearinghouse where elements of the circulatory, reticuloendo-thelial, and immune systems interact. Thus, it is ideally suited to play a critical role in the surveillance of circulating blood.

The spleen functions as a filter of the circulating blood, a coordinator of the immune response, and a reservoir for circulating cells and platelets. Additionally, the spleen may have a number of other responsibilities, including hematopoiesis, hemoglobin degradation and iron recovery, and plasma volume regulation ([1, 3, 7, 8, 10]).

Filter Function

According to most authorities, one of the primary functions of the spleen is to filter blood ([1, 6, 7] and [8, 10]). Elements removed from circulation by the spleen include aging or abnormal red cells, intraerythrocyte inclusions, and foreign particulate matter ([1, 7, 10]).

CULLING The removal of aging or abnormal red blood cells by the spleen occurs within the cords of Billroth and is known as *culling* ([37]). The mechanism by which this occurs is still under investigation. However, it is generally agreed that cells bound for destruction become trapped, or perhaps held, within the reticulum meshwork of the splenic cords, and, as their splenic transit time increases, they succumb to phagocytosis by resident macrophages ([1, 5]). Exactly how cells become delayed within the meshwork of the cords is not entirely clear, but several theories exist. Some argue that the hemoconcentration observed in the cords creates a limited pool of metabolites that is responsible ([10]). A low supply of metabolites, it is reasoned, results in decreased adenosine triphosphate production, failure of the Na^+/K^+ pump, and eventual swelling and entrapment of the cell within the meshwork ([1]). Older cells may be especially susceptible to this sequence of events because their complement of metabolic enzymes is lower than that of younger cells. However, investigators who have shown that an ample reserve of O_2 and glucose exists within the cords ([38]) have challenged this idea. Another theory to explain how red cells become trapped within the cords contends that as erythrocytes age, they lose

significant amounts of cytoplasmic membrane. Senescent cells therefore lack the deformability necessary to negotiate the meshwork and ultimately become trapped in this fashion ([5], [43]). Finally, it has been proposed that as erythrocytes age, they expose surface antigens that are recognized by self-directed antibodies ([1]). Once opsonized with antibody, senescent cells are easily trapped by cordal macrophages. Regardless of the mechanism by which aging and abnormal red cells become trapped within the cords, it is clear that as splenic transit time increases, the cells succumb to destruction by resident phagocytic cells. Similar events occur for erythrocytes that are morphologically abnormal secondary to congenital disorders such as sickle cell anemia and hereditary spherocytosis. These cells also are removed in the cords of the spleen by being trapped and phagocytized by resident macrophages ([7]). Splenic transit appears to be the common denominator and, thus, is currently viewed as an index of the organ's ability to clear red cells ([44]).

PITTING In addition to culling, the spleen also functions to remove intraerythrocyte inclusions from circulating red cells. The ability of the spleen to clear these inclusions while maintaining the integrity of the red cell itself is known as *pitting* and is an exclusive function of splenic tissue ([4]). Undesirable intracellular elements removed by the spleen include circulating particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules) ([3], [7]). Pitting occurs as cells within the cords attempt to reenter the circulation through the splenic sinuses. To do this, they must pass through slitlike fenestrations of the sinus endothelium. As this occurs, the deformable portion of the cell bends to negotiate the opening, whereas the inclusion, which is nondeformable, is unable to pass through the narrow passage; thus, it is left behind to be phagocytized by resident macrophages ([4]). The passage of red cells through the slits may also be mediated by active changes within the sinus endothelial cells ([1]). These cells have been shown to have cytoskeletons that include the contractile protein components actin and vimentin ([1]). Figure 70.4 is a schematic representation of the process of pitting.

Figure 70.4. Schematic representation of process of pitting by the spleen. This process is believed to be responsible for removal of undesirable elements from circulation, including particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules). **A:** Red blood cell (RBC) flows from open circulation and approaches fenestration of sinus. **B:** RBC begins to enter sinus through fenestration; note inclusion body within RBC. **C:** RBC transverses sinus; membrane-bound inclusion body lags behind. Sinus macrophage begins to approach inclusion body. **D:** RBC within sinus returns to venous circulation. Inclusion body succumbs to sinus macrophage. [Modified from Weintraub LR. Splenectomy: who, when, and why? (see comments.) Hosp Pract (Off Ed) 1994;29.]

Evidence that supports the role of the spleen in culling and pitting is found in the fact that, after splenectomy, asplenic and hyposplenic patients lose their ability to clear damaged red cells and intraerythrocyte inclusion bodies from the circulation. These patients display peripheral blood smears with an abnormal variety of erythrocytes, many with intracellular inclusions ([45]). In fact, evaluation of morphologic abnormalities in peripheral smears is a standard method of assessing splenic function ([42], [46]).

CLEARANCE OF PARTICULATE MATTER Another important filtering function of the spleen is its ability to remove particulate matter from the circulation ([1], [7]). As blood travels through the meshwork of the cords, foreign particles are exposed to splenic macrophages that clear them by phagocytosis ([35]). Experiments with injected carbon particles have confirmed this process and have identified the cells chiefly responsible for this function: the macrophages surrounding the splenic sinuses.

Immune Function

Because the spleen is composed of lymphocytic tissue, circulatory elements, and mononuclear phagocytic cell lines, it is ideally suited to play a coordinating role in the immune response. The organ's function in this respect includes its role in the nonspecific as well as the specific arm of the immune response. The nonspecific immune functions of the spleen include the clearance of pathogens, the clearance of opsonized erythrocytes and platelets, the production of complement, and the surveillance of malignant cells.

The spleen plays a significant role in the removal of bloodborne pathogens from the circulation. Once coated with complement, bacteria and viruses become circulating immune complexes. Although the liver clears some of these complexes, many others are delivered to and eliminated by the spleen ([47]). The contribution of the spleen to this process is supported by the fact that asplenic patients display a higher level of circulating immune complexes than do spleen-competent subjects ([48]).

The ability of the spleen to clear encapsulated bacteria is especially significant. Because these organisms have the ability to evade antibody and complement binding, their clearance depends on prolonged contact between pathogen and macrophage. This is most likely to occur in the cords of the spleen, where mononuclear phagocytic cells predominate and transition time is slow ([47]). Prolonged contact between pathogens and macrophages in the spleen may also help to protect patients with antibody or complement deficiencies ([47]). It is well recognized that asplenic or hyposplenic patients are prone to a syndrome of fulminant septicemia, most often involving encapsulated bacteria: overwhelming postsplenectomy sepsis ([47]).

The spleen also plays a major role in the removal of opsonized erythrocytes and platelets from the circulation. In certain pathologic states, such as autoimmune hemolytic anemia or ITP, circulating elements become opsonized with immunoglobulin (Ig) G antibody. The resulting cell–antibody complexes enter the spleen and encounter Fc receptor–laden macrophages in the marginal zone, where they are destroyed ([49]).

The role of the spleen in the production of complement remains controversial. According to one respected authority ([7]), mononuclear phagocytic cells of the spleen produce both properdin and tuftsin. *Properdin* is an opsonin that plays a critical role in the alternative pathway and has been detected in the monocytes of the spleen ([50]). Tuftsin stimulates interleukin-1 production and binds to granulocytes to initiate phagocytosis. Although these elements are also produced at other locations, the spleen's contribution is significant, and they are found in lower concentrations in the circulation of asplenic or hypo-splenic patients ([7], [51]). Patients who have lost their spleens also display a decreased concentration of C3 and factor B ([52]).

Another theory proposes that the spleen is not a major synthetic site of complement ([53]). It suggests that the decrease in alternative pathway components observed in splenectomized patients can be ascribed to a protein inflammatory response ([53]). These studies remain to be confirmed in the literature.

The role of the spleen in the surveillance and destruction of malignant cells is currently under investigation. According to some investigators, the ability of the spleen to destroy malignant cells is greatly underestimated ([7]). The spleen's high rate of perfusion and intricate meshwork of fibrocellular elements make it a likely candidate for metastatic foci. Over 50% of spleens removed from patients with solid primary tumors do indeed display micrometastases ([7]). The ability of the spleen to trap metastatic foci suggests that there may be destruction of malignant cells within the organ ([7]). Other studies support the antineoplastic role of the spleen and attribute this ability to the organ's reservoir of activated natural killer cells ([54], [55]).

SPECIFIC IMMUNE RESPONSE The spleen is also uniquely suited to play a coordinating role in the specific arm of the immune response. Because white pulp and vascular elements lie adjacent to each other, this may serve as an interface between the lymphocytic populations of T and B cells and the elements of circulating blood. As circulating blood enters the spleen, 90% of it passes through the marginal sinuses and surrounding zones ([36]). Here, foreign antigens are exposed to the lymphocytic tissue of the PALS and the follicles, stimulating them to respond. The cascade of events that follows involves both the humoral and cellular arms of the immune response. Ultimately, it results in the production of IgM, plasma cells, and memory cells tailored to the particular invader ([47]). It should be noted that although these functions also occur within lymph nodes, asplenic patients demonstrate a specific response to bloodborne antigens. For example, the production of IgM in asplenic patients is both delayed and diminished ([56]). On the other hand, specific immune factors that rise in the circulation after a splenectomy include IgE and self-directed autoantibodies ([48]).

Cellular Reservoir Function

The ability of the spleen to function as a reservoir for circulating elements has been the subject of much study. Platelet sequestration by the spleen is well documented ([3], [7], [10]), but its role as a reservoir for red cells remains controversial ([1], [57]). Some recent evidence supports the role of the spleen as a reservoir for white blood cells ([58], [59] and [60]).

The spleen is considered a reservoir for platelets because it can sequester large quantities of thrombocytes and, in turn, release them on demand. In nonpathologic states, the spleen sequesters approximately 30% of the body's platelets and can release them into the circulation in response to certain stimuli. For example, in response to an epinephrine challenge, the spleen may release significant numbers of sequestered throm-bocytes into the circulation. The exact mechanism of this response is not fully understood, but it may occur secondary to the effect of epinephrine on splenic circulation ([61]).

The role of the spleen as a platelet reservoir is most dramatically demonstrated by the fact that pathologically enlarged spleens sequester greater quantities of platelets. In splenomegaly secondary to portal hypertension, for example, the organ can sequester up to 90% of the body's reserves and result in severe thrombocytopenia ([4]). On the other hand, in the postoperative period after splenectomy, there is a significant rise in circulating platelet counts. Sometimes this effect is transient, possibly because the liver compensates by increasing its ability to sequester thrombocytes ([62]).

It has been demonstrated in other mammals that the spleen may sequester up to 50% of the total red cell volume during times of inactivity, reducing blood viscosity and heart workload. Although the human spleen sequesters comparatively fewer red blood cells, evidence suggests that it may perform a similar role ([14]). Nuclear medicine studies have been used to demonstrate a reproducible increase in the hematocrit after exercise, with the spleen as the source of the increased erythrocytes ([57]). A similar rise in hematocrit may be observed after serial apneas performed to simulate diving ([14]).

The mechanism of spleen volume change likely involves both direct innervation by autonomic fibers as well as the hormonal effects of catecholamines. a-Adrenergic blockade abolished the responses of the spleen to norepinephrine and direct neural stimulation ([14]).

Because of its role in the immune response, the spleen might be expected to serve as a way station for circulating leukocytes, but only recently has this been demonstrated. One study has shown that as blood enters the spleen, lymphocytes selectively migrate to their respective zones: T cells to the lymphatic tissue of the PALS and B cells to the follicles and red pulp ([58]). Another study demonstrates that the spleen is a reservoir for granulocytes, readily mobilized under stress ([59]). Finally, it was shown recently that splenic tissue may function as a reservoir for memory B cells ([60]).

Hematopoietic Function

The spleen produces red blood cells during fetal development and during certain pathologic states ([5]). During the fifth month of fetal development, it is a major source of red blood cell production, after which it loses this ability ([6]). Pathologic states associated with splenic hematopoiesis include myeloid metaplasia ([5]). However, the production of cells by the spleen under these abnormal conditions results not from the reactivation of fetal stem cells but from displaced bone marrow cells that take up residence in the confines of the organ ([63]).

Iron Metabolism

As red blood cells are destroyed within the splenic cords, their contents are degraded. The iron released in this fashion is recycled and sent to the bone marrow for use in the manufacture of new erythrocytes. Although other cells in the body can metabolize iron in a similar fashion, asplenic patients display lower serum iron levels for a considerable amount of time after loss of the spleen ([3]).

It is interesting to note that subpopulations of splenic macrophages have different abilities to recycle iron. For example, the macrophages that occupy regions bordering the splenic sinuses are quite adept at this function. In conditions that lead to red cell destruction in the cords, such as spherocytosis, iron salvage is well managed. On the other hand, in conditions that lead to the destruction of red cells by wandering macrophages, such as autoimmune hemolytic anemia, iron salvage is poor ([20]).

SPLENIC DISORDERS AND INDICATIONS FOR SPLENECTOMY

The causes of splenomegaly and indications for splenectomy can often be confusing. There are many potential causes of splenomegaly that must be considered in any patient undergoing evaluation with an unknown diagnosis. It can not be overstated that patients without a known cause of splenomegaly should rarely undergo splenectomy and then only after a thorough workup has been completed to assess the likely etiology of this finding.

Splenomegaly is often the result of some other condition, not the result of a primary pathologic state. The spleen rarely harbors a primary malignancy like lymphoma that is not apparent at other sites after a careful survey by history and physical examination and with limited imaging studies. The temptation to perform a splenectomy for diagnostic purposes early in the workup of the stable patient should be strongly resisted. It is unlikely to yield a diagnosis, and, in some situations, may entail significant risk to the patient with no benefit (as in splenomegaly resulting from portal hypertension).

It is important to remember that splenic size is not always a reliable guide to splenic function because palpable spleens are not always pathologic and abnormal spleens are not always palpable ([64]). In a survey of healthy first-year college students, 3% were found to have splenomegaly, and 5% of all hospitalized patients have been noted to have splenomegaly ([65]). Patients with cirrhosis and portal hypertension almost always have splenomegaly, but even with significant thrombocytopenia, which is often present, no specific therapy is indicated because this condition rarely results in specific complications. The important clinical issue involves determining when abnormal splenic function is occurring, ascertaining the responsible etiology, if possible, and only then assessing therapeutic options.

Chauffard introduced the concept of hypersplenism in 1907 ([3]), although the exact clinical definition remains confusing in practice even today. The criteria for this diagnosis generally include four features: cytopenia with anemia, thrombocytopenia, leukopenia, or some combination; compensatory bone marrow hyperplasia; splenomegaly; and improvement or resolution in these findings after splenectomy ([3], [7]). Hypersplenism has been further classified into *primary hypersplenism* when no etiologic factor for splenomegaly has been found and *secondary hypersplenism* when splenomegaly is the result of another recognized condition (such as portal hypertension or an infiltrative process). With continued progress in diagnosis of the causes of splenomegaly, there has been a continued drop in the frequency of cases of primary hypersplenism. Given the nonspecific nature of this diagnosis and uncertainties regarding its therapeutic implications, it is used less often today.

Primary hypersplenism is a diagnosis of exclusion and should be made only after a very thorough search has been made for a specific etiology. If no cause is found, corticosteroids or immune globulin may be effective in improving the cytopenia. Should these measures fail, splenectomy usually results in marked improvement in the hematologic derangement. Of note, lymphoma presenting with primary involvement of the spleen and no evidence of involvement at other sites occurs in less than 1% of patients with lymphoma. In this setting, there may be nonspecific splenic enlargement on CT scanning with no other intraabdominal findings.

Perhaps a more useful guide in the assessment of splenomegaly is to consider the mechanisms responsible for the splenic enlargement. Eichner et al. divided the causes of splenomegaly into six major categories, listed in Table 70.1 ([65]). The likely mechanisms for resulting cytopenias in specific disease states are shown in Table 70.2 ([7]). It is interesting that the degree of splenomegaly on physical examination, radiographic assessment, or at the time of splenectomy does not appear to correlate with the magnitude of cytopenia. This variability of cytopenia may be the result of differing degrees of red and white pulp infiltration depending on the specific disease state ([43]). Eichner et al. developed an algorithm to assist in diagnostic pathways in patients with splenomegaly ([64]), but given the complex and diverse disease conditions that may lead to splenomegaly, the algorithm is cumbersome for use in day-to-day practice.

TABLE 70.1. Classification of Splenomegaly by Mechanism

Mechanism	Causative Diseases
Immune response work hypertrophy	Subacute bacterial endocarditis
	Infectious mononucleosis
	Felty syndrome
Red blood cell destruction work hypertrophy	Spherocytosis
	Thalassemia major
	Pyruvate kinase deficiency
Congestive (venous outflow obstruction)	Cirrhosis and portal hypertension
	Splenic vein thrombosis
Myeloproliferative	Chronic myelocytic leukemia
	Myeloid metaplasia
Infiltrative	Sarcoidosis
	Amyloidosis
	Gaucher disease
Neoplastic	Lymphoma
	Chronic lymphocytic leukemia
	Hairy cell leukemia
	Metastatic carcinoma
Miscellaneous	Trauma
	Splenic cysts
	Hemangioma

Modified from Eichner ER (64, 65) and Sheldon, et al. (7).

TABLE 70.2. Etiology of Splenomegaly and Cytopenia in Selected Disease States

Disease Condition	Probable Mechanism
Portal hypertension	Increased pooling of blood cells
Hairy cell leukemia	Retention of hairy cells in splenic pulp
Felty syndrome	Immune system work hypertrophy
Thalassemia major	Reticuloendothelial system work hypertrophy
Gaucher disease	Increased pooling and flow-induced dilutional anemia
Agnogenic myeloid metaplasia	Extramedullary hematopoiesis

Modified from Eichner ER (64, 65) and Sheldon, et al. (7).

Although most attention regarding splenic dysfunction relates to splenomegaly and related cytopenias, occasionally patients develop hyposplenic conditions, usually from splenic infarction (such as sickle cell disease). In this group, consideration should be given to vaccination against encapsulated organisms, and potential infectious complications should be considered if unexplained fever or signs of sepsis develop, similar to postsplenectomy patients.

Indications for Splenectomy

A recent review of indications for splenectomy demonstrates the evolution of surgical management for splenic disorders. Over a 10-year period, the most common indications for splenectomy (trauma, incidental, hematologic malignancy, iatrogenic, and cytopenia) saw a drop of between 30 and 50%. In addition, the absolute number of splenectomies decreased over the period of review (66). Nevertheless, splenectomy is an accepted and often definitive treatment modality for a number of diseases, as discussed below.

IMMUNE THROMBOCYTOPENIC PURPURA *ITP* is a condition in which circulating antiplatelet antibodies bind to platelets and are cleared by phagocytic cells from circulation (see Chapter 53). The humoral cause of the disease was established in 1951 when a hematologist in training infused himself with the plasma from a patient with ITP and developed thrombocytopenia and platelet destruction (67). In addition, T cells appear to play a major role in the pathophysiology of the disease (68). Platelets are cleared mainly by the spleen and liver (67, 68). The spleen may have a dual role in this disease by both producing IgG and providing the location for platelets' removal from the circulatory system. The cause of this condition is unknown, although it likely involves cellular immune dysregulation (67). It most commonly presents in women in their 20s and 30s, and they often present with bleeding after minor trauma, with nosebleeds or petechiae. There are often no physical findings, and importantly, the spleen is almost always normal in size. The primary laboratory abnormality is thrombocytopenia with platelet counts typically less than 50,000 and sometimes as low as 10,000. There is evidence of immature platelets on peripheral smear, and bone marrow smears show increased numbers of megakaryocytes. Initial treatment of ITP is usually medical, with the goal of achieving and maintaining a hemostatic platelet count, usually defined as at least 10,000 to 50,000 per ml (69). Patients with mild to moderate thrombocytopenia do not require treatment. For those with more severe thrombocytopenia, initial treatment is with a short course of prednisone. However, in most cases, thrombocytopenia will recur after discontinuation of steroids. There is no consensus on the duration of long-term steroid therapy (69). Medical alternatives to steroids include anti-D (for Rh-positive patients), intravenous gammaglobulin (IVIg), and chemotherapy (70). A cost analysis of anti-D versus IVIg demonstrated similar efficacies but lower cost associated with the use of anti-D (71). For thrombocytopenic crises, a rapid increase in platelet count may be achieved with IVIg (1 g/kg) followed by platelet transfusion and steroid administration. Splenectomy is successful in the majority of patients who do not respond to medical measures or who initially respond but subsequently relapse (72). Initial response to splenectomy ranges from 40 to 86% (73). Over the long term, however, response rates appear to decline. Splenectomy can usually be performed electively unless patients have active, ongoing bleeding. Despite the thrombocytopenia, the circulating platelets function normally, and preoperative platelet transfusions are usually unnecessary and may be ineffective in raising the platelet count because of the rapid sequestration by the spleen. At the time of splenectomy, the surgeon should search for accessory spleens because they may later account for failure of splenectomy. Accessory spleens have been reported in 10 to 30% of patients with ITP (7, 9, 72). ^{99}Technetium sulfa-colloid scanning or ^{111}indium-labeled scanning may demonstrate accessory splenic tissue, although these studies are not recommended in the usual preoperative setting with newly diagnosed ITP. ITP can occur in childhood and often follows a viral illness. Most cases are acute and resolve spontaneously within 6 months to 1 year (69). However, a small number is at risk for major bleeding, and approximately 5% of children develop chronic severe thrombocytopenia that requires treatment, including splenectomy in some cases (74). Although ITP is thought to have a benign course, patient deaths do occur (75). These are usually related to bleeding (such as cerebral hemorrhage), which may be made worse by concomitant medical conditions, such as uremia or hemophilia, and may also result from infectious complications related to splenectomy or immunosuppressive medications. ITP occurs in the setting of human immunodeficiency virus infection in approximately 10% of patients. These patients can be treated in a similar fashion to non–human immunodeficiency virus patients with ITP, namely, with steroids, IVIg, and anti-D, and with splenectomy for medical treatment failures. In this setting, the severity of the underlying disease should be a factor in the decision regarding operative intervention. There are reports of increases in CD4 counts after splenectomy (76), suggesting that the spleen may sequester CD4 cells in some of these cases.

THROMBOTIC THROMBOCYTOPENIC PURPURA Thrombotic thrombocytopenic purpura (TTP) generally occurs between the ages of 20 and 60 years and is more common in women than in men (see Chapter 54). The exact etiology is often unknown, although a minority of cases are observed after therapy with ticlopidine or clopidogrel. The disorder occasionally occurs during pregnancy or in the postpartum period, and a familial form of the disease exists. TTP is characterized by thrombocytopenia, microangiopathic hemolytic anemia, neurologic abnormalities, renal failure, and fever (77). TTP is likely to be the result of the abnormal presence of a platelet-aggregating agent in the circulation. Studies suggest that this agent is von Willebrand factor, which is found in excess in patients with TTP. Platelet aggregation leads to microvascular thrombi, typically in the brain, heart, spleen, kidneys, pancreas, and adrenals. With appropriate treatment, nearly 90% of adults will respond. This consists of daily plasma exchange with plasmapheresis and transfusion of fresh frozen plasma. Steroids are also administered to decrease

autoantibody formation against the factor that cleaves von Willebrand factor ([78]). For treatment failures, other options include vincristine, azathioprine, and splenectomy ([77] , [78]). Surgical treatment is considered in patients who have frequent relapses of TTP and may prolong the disease-free interval ([79]). The rationale for splenectomy and the pathophysiology of its role in this disease are not well understood. Splenectomy generally plays a minor role in TTP, particularly in comparison to ITP, in which the spleen appears to be the major site of platelet destruction ([80]). Increasing experience with laparoscopic splenectomy may encourage surgeons to use this procedure more often in the treatment of chronic, relapsing TTP ([81]).

HODGKIN DISEASE *Hodgkin disease*, described by Thomas Hodgkin in 1832, is a malignant lymphoma characterized by typical multinucleated giant cells (Reed-Sternberg, Chapter 95). Most patients initially present with asymptomatic peripheral lymphadenopathy, most often in the cervical region (60 to 80%) ([7] , [82]). Other nodal regions, including the mediastinal, axillary, inguinal, and retroperitoneal regions, are less often involved at initial presentation. The presence of B symptoms, including fever, weight loss greater than 10%, and night sweats, is noted. Extralymphatic and splenic involvement is also used to stage patients, as outlined in Table 70.3 ([83]). Histologic subtypes fall into four categories: lymphocyte predominant, nodular sclerosing, mixed cellularity, and lymphocyte depleted ([82]).

TABLE 70.3. Ann Arbor Staging Classification for Hodgkin Lymphoma

Stage	Criteria
I	Involvement of a single lymph node region
II	Involvement of two or more lymph node regions on the same side of the diaphragm
III	Involvement of lymph node sites on both sides of the diaphragm
IV	Diffuse involvement of one or more extralymphatic organs with or without associated lymph node involvement
E	Involvement of adjacent extralymphatic site
S	Involvement of the spleen
A	Asymptomatic
B	Fever, night sweats, or weight loss

From Carbone PP, Kaplan HS, Musshoff K, et al. Report of the Committee on Hodgkin's Disease Staging Classification. Cancer Res 1971;31:1860–1861, with permission.

Historically, staging laparotomy has been used in patients with Hodgkin disease suspected to harbor disease below the diaphragm. In this procedure, lymph nodes are sampled from the paraaortic, paracaval, and iliac regions, and liver biopsies are performed along with splenectomy. More recent practice involves a shift away from the routine use of staging laparotomy ([84] , [85]). This has occurred for several reasons, including the enhanced accuracy of CT and other imaging studies for staging purposes, heightened concerns regarding postsplenectomy infectious complications, and the increased effectiveness of medical treatments. This practice has resulted in a general trend away from splenectomy in patients with Hodgkin disease. A 1999 survey of 47 centers showed that 68% no longer perform splenectomy for the staging of Hodgkin disease ([86]). Laparoscopy, with its reduced morbidity and mortality compared to open procedures, may result in a small resurgence of operative staging for the disease, but the overall trend is for nonoperative evaluation ([87]).

LEUKEMIA In chronic lymphocytic leukemia and less often in chronic myelocytic leukemia, massive splenomegaly can result in significant symptoms from the mass effect of the enlarged spleen, necessitating splenectomy (Chapter 84 and Chapter 92). Likewise, patients may develop significant cytopenia refractory to medical measures, and this may necessitate splenectomy. The decision to undertake splenectomy must be made with caution because these patients often are immunosuppressed and malnourished and have a higher operative mortality risk as well as a higher rate of perioperative complications. Hairy cell leukemia can lead to infiltrative splenomegaly and pancytopenia, which may limit cytotoxic chemotherapy ([3] , [5]) (see Chapter 93). In this setting, splenomegaly may allow for return of platelets and leukocytes to acceptable levels for the administration of chemotherapy. As discussed for chronic lymphocytic leukemia and chronic myelocytic leukemia, however, the surgeon and oncologist must weigh the increased perioperative risks against the possible benefits of splenectomy before making such a recommendation to any given patient.

HEREDITARY ANEMIAS Hereditary spherocytosis is inherited as an autosomal-dominant disease in which the red cell membrane includes a defective protein, spectrin ([3] , [4]) (see Chapter 32). The spleen destroys the resulting defective, spherical red cells. These patients have an anemia and significant reticulocytosis. Peripheral smears demonstrate spherocytes, and these patients have a negative Coombs test. Elective splenectomy will correct the anemia. Ideally, splenectomy is performed after the age of 5 or 6 years to minimize the potential risks of postsplenectomy infections. Because of the rapid red cell turnover, these patients often develop calcium bilirubinate gallstones, and consideration should be given to concomitant cholecystectomy at the time of splenectomy if they are present ([74] , [88]). Sickle cell anemia is an autosomal-recessive condition that also results in defective red blood cells ([3]) (see Chapter 40). Because of the frequency of sludging and thrombosis in small vessels, these patients more often develop infarcts in the spleen, which over time results in autosplenectomy. In rare patients, however, splenomegaly may develop, and, in these patients, splenectomy may be indicated if a significant cytopenia develops. Unlike hereditary spherocytosis, splenectomy has little effect on anemia related to the sickle cell condition. Thalassemia major is an autosomal-dominant condition in which abnormal hemoglobin forms protein precipitates in the red cell, recognized as Heinz bodies on a peripheral smear ([3]). These patients can develop significant splenomegaly with resulting cytopenia. In this condition, splenectomy can lessen the need for transfusion.

MALIGNANT TUMORS OF THE SPLEEN Lymphoma is a common tumor leading to splenomegaly or a splenic mass (see Chapter 90). Splenic marginal zone lymphoma often presents with massive splenomegaly and, clinically, is improved with early splenectomy. Other primary tumors of the spleen are exceedingly rare. Hemangiosarcoma and hemangiopericytoma of the spleen have been reported, as has plasmacytoma. All of these tumors may present with splenomegaly only.

BENIGN TUMORS OF THE SPLEEN The most common benign tumors of the spleen are lymphangiomas and hemangiomas (Fig. 70.5) ([7] , [10]). These tumors are most often incidental findings when imaging studies or laparotomy are performed, or they may be found at autopsy. Occasionally, the patient may develop significant splenomegaly and cytopenia, leading to the need for splenectomy. Usually, however, the diagnosis can be made on the basis of imaging studies alone and splenectomy avoided. In cases of doubt, follow-up imaging studies showing the absence of change over time may allow avoidance of splenectomy.

Figure 70.5. Computed tomographic scan **(A)** and gross photograph **(B)** of spleen in 35-year-old woman with marked splenomegaly from splenic hemangioma. The arrow demonstrates central hemangioma with surrounding uninvolved splenic parenchyma. This benign tumor had caused significant thrombocytopenia resulting in spontaneous bleeding before splenectomy. See Color Plate.

MYELOFIBROSIS *Myelofibrosis with myeloid metaplasia* describes a group of disorders characterized by prominent bone marrow fibrosis and disruption of normal hematopoiesis with enlargement of the liver and spleen due to extramedullary hematopoiesis ([89]) (see Chapter 86). Massive splenomegaly may lead to pancytopenia, portal hypertension, early satiety, and pain. Medical therapy, including blood transfusion, androgens, corticosteroids, erythropoietin, and interferon-a, has been generally disappointing. Reduction of splenic tissue may be accomplished by the use of cytotoxic agents, irradiation, or splenectomy ([86] , [89]).

SPLENIC CYSTS AND ABSCESSES Cystic lesions of the spleen are rare but are increasingly being recognized with the increased use of CT and other imaging techniques ([7] , [10]). These are most often asymptomatic and are usually classified as either true cysts or pseudocysts. Parasitic cysts are exceedingly rare in the United States but may occur in patients from other parts of the world. Splenic abscesses may occur when a simple cyst is secondarily infected or as a primary abscess, usually from a hematogenous source. True cysts of the spleen have an epithelial lining and are thought to be congenital in origin. Cystic lymphangiomas are occasionally found and fall into this category. They can derive from inclusions of splenic surface mesothelium lining into the splenic parenchyma during development or from an accelerated secretion of lining cells from an unknown cause. Cyst fluid can be thin and serous in nature or turbid and viscid ([90]). The majority of patients

with splenic cysts are asymptomatic and do not require specific treatment ([7], [10]). Nonoperative treatment is recommended for small cysts up to 5 cm in diameter ([90]). In patients with large cysts, excision of the cyst wall and free wall lining with splenic preservation, whenever possible, should be undertaken. There have been reports of laparoscopic partial splenectomy and partial cystectomy, and these will likely become the procedures of choice as more surgeons gain familiarity with these advanced laparoscopic techniques ([90]). Splenic pseudocysts lack an epithelial lining and are believed to result from trauma in the majority of cases (Fig. 70.6). They are derived from large, subcapsular or intrasplenic hematomas that have failed to organize in the usual manner and are much more common than true cysts of the spleen ([90]). Often when these are discovered, the affected patient has no recollection of the traumatic injury or recalls what was considered to be trivial trauma. Symptomatic large cysts may be successfully treated with percutaneous aspiration with or without placement of a drainage catheter for a short duration. These cysts may recur after aspiration, however, necessitating cyst excision or splenectomy.

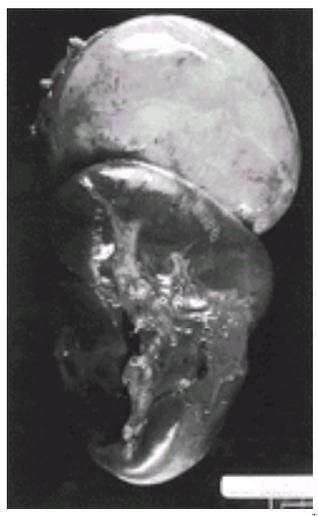

Figure 70.6. Large symptomatic splenic pseudocyst developing after blunt trauma to the spleen. See Color Plate.

Pancreatic pseudocysts have been reported to burrow into the substance of the spleen, and this should be kept in mind in the patient with a history of pancreatic trauma or pancreatitis ([91]). Assessment of cyst fluid amylase levels may provide a clue to the pancreatic origin in such a case. Management of cysts in these cases is usually directed toward treatment of underlying pancreatitis. Parasitic cysts in the spleen are usually the result of *Echinococcus granulosus* and are most often found in association with hepatic cysts. These parasites are found in endemic regions of Europe and the Middle East with sheep as an intermediate host, thus accounting for the finding in farmers from these regions ([7], [10]). CT scanning usually demonstrates daughter cysts in infected patients, and the diagnosis can be confirmed with serologic testing. Mebendazole is effective antiparasitic therapy, although splenectomy is required in a proportion of infected patients. Rupture or spillage of the cyst contents into the peritoneal cavity can lead to disseminated scoliceal infection as well as an anaphylactic reaction. For this reason, percutaneous aspiration of the cyst contents should not be undertaken in such patients, and splenectomy must be performed very carefully to avoid cyst spillage. Splenic abscesses usually develop from hematogenous seeding from endocarditis, from a distant site of infection, or in the setting of intravenous drug abuse ([7]). Often, these are present in immunocompromised patients and may also occur after a localized infarction, as in patients with sickle cell disease. There are rarely specific symptoms present suggesting the spleen as the specific site of infection, although left-upper-quadrant tenderness may be present in patients with significant abscess cavities. Abdominal CT scanning is the most helpful imaging technique, demonstrating low-density lesions in the spleen, which may contain gas and present peripheral enhancement ([92]). CT can also be used to direct placement of percutaneous drainage catheters, which can provide successful treatment in the majority of cases. Multilocular abscesses with thick septations or necrotic debris generally require surgery, although percutaneous catheter drainage may lead to improvement of the patient's general condition without adverse effect on subsequent operation ([92]). Antimicrobial therapy is based on aspirate culture data, with *Staphylococcus* and *Streptococcus* species being common pathogens.

FELTY SYNDROME *Felty syndrome* is a rare complication of rheumatoid arthritis, leading to splenomegaly, neutropenia, and other systemic manifestations such as leg ulcers, rheumatoid nodules, vasculitis, lymphadenopathy, and hepatomegaly ([93]). Antibody-coated neutrophils are cleared from the circulation in the spleen, and neutropenia can develop. Infection, a major source of morbidity, is due to the neutropenia as well as defects in neutrophil function ([93]). Treatment for rapid resolution of neutropenia begins with granulocyte colony-stimulating factor or granulocyte-macro-phage colony-stimulating factor. Low-dose methotrexate may be used for those who do not respond to growth factors, and splenectomy may be considered if no response is seen after 1 to 2 months ([93]).

SPONTANEOUS SPLENIC RUPTURE Patients with splenomegaly are at increased risk of splenic rupture when subjected to minor degrees of trauma. This probably occurs because of the increased capsular tension from the underlying parenchymal tissue. Patients with splenomegaly should be cautioned to avoid physical contact when possible. Occasionally, patients with rapid enlargement of the spleen experience spontaneous rupture. This is most often reported in the setting of acute mononucleosis ([94]) but can occasionally occur with leukemia and lymphoma. These patients usually develop acute left-upper-quadrant pain that may be associated with referred pain in the left shoulder. Initially, this may be contained beneath the splenic capsule as a subcapsular hematoma, but if intraperitoneal rupture occurs, patients may present with acute severe pain and hypovolemic shock. Ultrasonography or CT scanning is a confirmatory study, demonstrating intraperitoneal fluid (blood) and subcapsular hematoma. Urgent or emergent splenectomy is definitive treatment for these patients. Delayed splenic rupture has been reported in patients experiencing blunt abdominal trauma, a setting in which patients develop splenic hemorrhage more than 7 days after their original injury ([95]). This problem most likely represents an injury in evolution, when the initial imaging study (most commonly CT or ultrasound) at the time of the trauma fails to demonstrate a significant injury. These patients usually have an initial splenic contusion that continues to slowly enlarge and, at some later date, results in disruption of the splenic capsule. This is an uncommon occurrence but should be considered in any patient who develops significant left-upper-quadrant pain, distention, and signs of bleeding or shock after an episode of trauma ([95]).

SPLENECTOMY: SURGICAL TECHNIQUE

Open Splenectomy

Historically, splenectomy has been performed via a midline or left subcostal incision depending on the surgeon's preference and the presence or absence of significant splenomegaly. In patients with massive splenomegaly (more than 2000 g), a midline incision may be preferred to allow adequate mobilization and delivery of the spleen into the operative field.

Once the abdomen is entered, a careful search is made for accessory spleens, which may be present in 10 to 30% of patients ([7], [9], [72]). These may be found anywhere in the abdomen but are most often found in the splenic hilum or in the mesentery of the intestine. If present, they most often have the appearance of a 1- to 3-cm rounded nodule of tissue with texture and appearance similar to normal splenic tissue. If found, they are removed by ligating the vessels and lymphatics supplying this tissue.

In patients with significant splenomegaly, initial ligation of the splenic artery causes the spleen to decrease in size, lessen its distention, and decrease the risk of capsular avulsions and decrease splenic bleeding should a capsular tear occur. This is performed by dividing the avascular gastrohepatic ligament above the pancreas and isolating the artery near its point of origin from the hepatic artery. Care must be taken to avoid injury to the adjacent pancreas. This step is optional and can be omitted if the artery is not readily accessible because aggressive attempts at splenic artery ligation can result in pancreatic injury.

There are ligamentous attachments to the spleen that must then be divided before the inflow vessels in the hilum can be ligated. The phrenosplenic attachment is avascular and can be divided with sharp dissection. This is performed as the surgeon lifts the spleen away from the diaphragm and allows mobilization of the spleen into the open incision, greatly facilitating the remainder of the dissection. After this is performed, the gastro-splenic ligament (and short gastric vessels) and the splenocolic ligament are divided. Finally, the inflow vessels to the splenic hilum are individually ligated, taking care during this portion of the procedure to avoid injury to the tail of the pancreas, which may lie in close proximity to the hilum of the spleen. Closed suction drainage of the splenic bed is not routinely used, but a drain can be placed if there is suspicion of a possible pancreatic injury. If this occurs, evacuation of pancreatic fluid minimizes the risk of abscess formation and allows for a controlled pancreatic fistula that will usually seal with observation alone. Conversely, if a symptomatic fluid collection develops in the bed of an undrained spleen in the postoperative period, then a percutaneous drain can be placed under CT or ultrasound guidance.

Partial splenectomy is unlikely to be a realistic option for patients with marked splenomegaly but may be an option for patients with splenic pseudocysts in whom unroofing of the cyst is the primary objective. This may also be an option in patients with splenic trauma in whom splenorrhaphy may allow splenic preservation. Uranus et al. report successful partial splenectomy using a surgical stapler ([96]), and this may occasionally be helpful. Partial splenectomy has also been reported in

patients undergoing splenectomy for Gaucher disease ([97]).

Laparoscopic Splenectomy

Since the description of the first laparoscopic splenectomy in 1991 ([98]), the procedure has become increasingly common. Similarly to other laparoscopic procedures, minimally invasive splenectomy offers shorter hospital stays, decreased analgesic use, earlier return to work, and significantly less morbidity ([98]). One study has demonstrated an improved quality of life after laparoscopic splenectomy as compared to the open technique ([99]). Initial reports restricted the laparoscopic approach to patients with normally sized or small spleens ([74] , [100] , [101] and [102]). More recent reports have shown that this approach can be used successfully in the setting of massive splenomegaly ([103]). Further, the indications for laparoscopic splenectomy have been expanded and now include ITP, hereditary spherocytosis, hemolytic anemia, TTP, leukemias, splenic myelofibrosis, sickle cell disease, lymphomas, myelodysplastic syndrome, multiple myeloma, and accessory splenectomy ([81] , [104] , [105] , [106] , [107] and [108]).

After induction of general anesthesia, a nasogastric tube and Foley catheter are placed to decompress the stomach and bladder, respectively. The patient is placed in the right lateral decubitus position, and three or four working ports are placed for the introduction of the laparoscopic instruments. An angled laparoscope is used, and a careful examination of the abdomen is carried out to identify other disease or the presence of accessory spleens.

The dissection then proceeds in five stages: division of the short gastric vessels, division of the splenocolic ligament, ligation of the inferior polar vessels, hilar control, and division of the phrenic attachments of the spleen ([109]). Much of the dissection may be carried out with harmonic shears, and the hilar structures are ligated and divided with an endoscopic stapling device, clips, or suture ligatures ([110]). The spleen is then placed in an extraction bag, morcellated *in situ*, and the fragments removed. Some surgeons prefer to add a “hand port,” which allows the use of one hand without disturbing the pneumoperitoneum required for laparoscopic surgery. In this case, the spleen may be removed through this larger incision without morcellation.

COMPLICATIONS OF SPLENECTOMY

The most common complications of splenectomy include bleeding, injury to the adjacent pancreas with resulting pancreatitis, and pancreatic pseudocyst or fistula formation. These patients can also develop atelectasis, pancreatic abscess, or injury to the adjacent stomach or splenic flexure of the colon if care is not taken in dividing the ligamentous attachments to these structures.

Postoperative thrombocytosis can occur, and aspirin (one children's aspirin per day) should be considered if the platelet count is above 1,500,000 to minimize the risks of thrombosis or embolism. The thrombocytosis is usually transient with return of platelet counts to normal ranges by 2 years after splenectomy ([111]).

Infectious complications are increased after splenectomy, and this can occur both in the early postoperative period and after a significant time has passed. The rate of early postoperative infections is particularly high when multiple other procedures are performed (e.g., after complex injuries in the setting of multiple trauma) ([112]). The complication of overwhelming postsplenectomy infection (OPSI) has received significant attention.

Postsplenectomy Infection

One of the most important developments affecting the splenectomy procedure has been the recognition of the increased risk of sepsis after splenectomy. In 1919, Morris and Bullock concluded that removal of the spleen may lead to an increased susceptibility to infection ([113]). The first reported case of significant postsplenectomy infection occurred in 1929 ([114] , [115]), but it was not until 1953, when King and Schumacker observed five cases of sepsis in infants undergoing splenectomy for congenital spherocytosis ([115]), that this risk gained significant acceptance. In 1969, Diamond described a case of postsplenectomy fulminant bacteremia leading to rapid death and coined the term *OPSI* ([116]). In 1973, Singer further described this condition as a septicemia, meningitis, or pneumonia that was usually fulminant but not always fatal, occurring days to years after splenectomy ([114]). In 1983, Van Wyck described a syndrome with an extraordinarily fulminant course, often with absence of a defined septic focus: bacteremia, coma, shock, consumptive coagulopathy, and adrenal hemorrhage (Waterhouse-Friderichsen syndrome) ([117]). Other complications include purpura fulminans, extremity gangrene, and convulsions. Although cryptic infection is common in adults, focal infections, such as meningitis, are more common in children younger than 5 years of age ([113]).

PATHOPHYSIOLOGY In the early postoperative period, infection is usually caused by staphylococci and enteric gram-negative bacilli ([113]). Outside of this interval, the most common organisms responsible for OPSI are encapsulated bacteria ([6] , [8] , [118]), with pneumococcus being most common (incidence, 48%) ([114]). Other responsible organisms include *Neisseria meningitidis*, *Escherichia coli*, *Haemophilus influenzae*, *Staphylococcus*, and *Streptococcus* and occur at rates that range from 7 to 12% ([114]). Rarer organisms include *Capnocytophaga* (a fastidious gram-negative organism contracted after dog bites or scratches), *Bartonella*, and intraerythrocytic parasites (*Babesia* and *Plasmodium*) ([8] , [119]). The special susceptibility of the asplenic patient to *Pneumococcus*, *Meningococcus*, and *H. influenzae* is likely related to splenic clearance of encapsulated organisms ([8]). Three factors normally provided by the spleen that help to protect the body against encapsulated organisms are lost in the asplenic patient. They include the reticuloendothelial system/mononuclear phagocytic system meshwork of the splenic cords, complete and effective IgM-producing capability, and complete and effective opsonin-producing capability ([6] , [118]). Studies confirm that bacteria-specific IgM production in asplenic patients is both delayed and diminished ([6] , [56]). Also, it has been demonstrated that asplenic patients have lower circulating levels of certain complement factors, including properdin, tuftsin, C3, and factor B ([7] , [51] , [52]). There is also evidence that splenectomy results in defects of cellular immunity. After splenectomy for trauma, a cohort of patients was found to have a significant reduction in the percentage of $CD4^+$ T cells, specifically in the $CD45RA^+$ subset. This was accompanied by an impairment in primary immune responsiveness in a number of cellular and humoral assays ([120]).
INCIDENCE OPSI is most common in the very young, in patients with underlying malignancies or other medical conditions, and within the first 2 years after splenectomy, although it has been reported 20 to 40 years after surgery ([6] , [8] , [10] , [113] , [114] , [118] , [121] , [122] , [123] and [124]). The incidence of OPSI is greatest in the very young and diminishes with age: 15.7% in infants, 10.4% in children younger than 5 years, 4.4% in children younger than 16 years, and 0.9% in adults ([8] , [124]). Although the incidence in adults is similar to that of the general population, mortality from sepsis is 58-fold increased in the asplenic population ([113]). Underlying pathology, like youth, also imparts an increased risk of OPSI ([6] , [8] , [121] , [122]). The incidence of OPSI after splenectomy for trauma is approximately 0.5% ([10]). The incidence increases to approximately 1.5% if splenectomy is performed for diagnosis of lymphoma ([125]). Those who have undergone splenectomy for a serious primary disease (hepatic disease, Wiskott-Aldrich syndrome, storage diseases, and thalassemia major) are at even higher risk of OPSI ([121] , [122] , [126]). The highest risks of postsplenectomy sepsis appear to be associated with underlying immune disorders and Hodgkin disease, especially for those who receive chemotherapy ([6] , [113] , [114] , [123]).
CLINICAL COURSE OPSI generally pursues a rapid course with evolution to sepsis and disseminated intravascular coagulation. Any asplenic patient with fever should be evaluated for possible OPSI. Key to successful treatment is prompt administration of broad-spectrum intravenous antibiotics. A complete septic workup, including routine laboratory tests, appropriate imaging, and microbiology cultures, should be performed but should never delay the initiation of antibiotics. In fully developed OPSI, mortality rates of 50 to 70% have been reported; 80% of deaths occur within 48 hours ([113]).
PREVENTION OF OVERWHELMING POSTSPLENECTOMY INFECTION The guidelines for the prevention of OPSI center around vaccination, antibiotic prophylaxis, patient education, and strategies aimed at preserving splenic function. Recommendations for postsplenectomy patients include immunization against encapsulated bacteria ([10] , [127] , [128]) with additional antibiotic prophylaxis for all asplenic and hyposplenic children (oral penicillin, amoxicillin, amoxicillin-clavulanic acid, trimethoprim-sulfamethoxazole, or cefuroxime axetil daily) for at least 2 years. Some advocate continued prophylaxis for 5 years or even until the age of 21 ([129]). Cefotaxime and ceftriaxone have been recommended for use in empiric treatment of symptomatic patients who have been taking prophylactic antibiotics ([129]). There is some debate over which immunizations should be administered. Antipneumococcal vaccination is widely accepted, but there is disagreement over *H. influenzae* and *N. meningitidis*. Most patients receive immunization against *H. influenzae*, but *N. meningitidis* is not routinely recommended unless travel is anticipated to an area with increased risk of group A infection ([113]). Ideally, patients should receive the vaccinations 14 days before elective splenectomy ([8] , [118] , [130]). Patients who undergo emergent splenectomy should receive their vaccinations as soon as possible after surgery ([126]). With regard to revaccination (boosters), antipneumococcal vaccine should be administered every 5 to 10 years. Repeat antimeningococcal immunization is performed after 2 years. The requirement for reimmunization against *H. influenzae* is unclear ([113]). Regardless of the time frame, however, many patients do not receive any revaccination because of a general lack of understanding about their condition and the unclear role for revaccination ([112]). The ability of immunizations to reduce the incidence of OPSI has been well established ([6] , [8] , [119]). Nevertheless, the use of vaccinations and antibiotic prophylaxis is still the focus of much investigation. Some investigators question the existing regimens and have called for long-term randomized, controlled trials ([127]). Other investigators debate the efficacy and duration of immunization, citing numerous cases of OPSI in

“immunized” patients ([112]). Finally, others argue that the risks associated with vaccination may outweigh the risks of OPSI ([131]). One of the most important, and most overlooked, aspects of prevention is patient education. Up to 50% of asplenic patients are unaware of their increased risk of serious infection, and 30 to 40% do not recall being vaccinated ([113] , [129]). Few are provided with antibiotics to take empirically at the onset of fever, and one-half would not spontaneously tell an uninformed emergency department doctor about their splenectomies ([113]). Asplenic patients should be extensively counseled about their health risks, the need for reimmunization, and the importance of informing future caregivers of their condition.

AUTOTRANSPLANTATION OF SPLENIC TISSUE Extrasplenic tissue may emerge secondary to traumatic autotransplantation, known as *splenosis* ([27]). Splenic fragments may be intentionally implanted in the omentum at the time of splenectomy ([132]). Histologically, this tissue appears as normal spleen with white pulp, red pulp, and marginal zones ([31]). Extrasplenic tissue can preserve some of the functions of the parent organ (such as opsonin production) ([32]), but its ability to clear encapsulated organisms depends on blood supply and tissue mass and has not been fully established ([31] , [65] , [133]). In a study of pneumococcal vaccination after splenectomy, the development of humoral immunity based on antibody production was noted in those patients who underwent autotransplantation at the time of their surgery but not in patients who received only splenectomy ([134] , [135]). This suggests that in cases in which immunization has not preceded splenectomy, autotransplantation with follow-up immunization may provide some measure of protection against pneumococcus.

Hematopoietic-Lymphoid Neoplasms: Principles of Diagnosis

Leukemias and lymphomas are relatively common, affect all ages, and demonstrate extraordinary biologic, morphologic, and clinical heterogeneity ([1]). This complexity is due, in part, to the dramatic explosion in the last 25 years of our understanding of the hematopoietic-lymphoid system (HLS). Advances in monoclonal antibody technology, cytogenetics, and molecular genetics have revealed that the HLS is a heterogeneous population of cells organized into anatomically and functionally distinct compartments. These same techniques also have been applied to neoplasms and have provided insight into the diagnosis, classification, and pathogenesis of leukemias and lymphomas. As a result, many new types of leukemias and lymphomas have been described, each apparently representing the neoplastic counterpart of a specific functional compartment of the HLS. For example, the recent World Health Organization classification suggests as many as 30 distinct disease entities within lymphoid neoplasms, excluding Hodgkin lymphoma ([2]). It is not surprising, therefore, that the diagnosis and classification of these malignancies are challenging for pathologists, oncologists, and laboratory personnel.

This chapter describes the general principles of diagnosis and classification of HLS neoplasms (specific topics of classification and differential diagnosis of acute leukemias, non-Hodgkin lymphomas, and Hodgkin disease are included in Chapter 77, Chapter 88, and Chapter 95, respectively).

PRINCIPLES OF DIAGNOSIS OF HEMATOPOIETIC-LYMPHOID SYSTEM NEOPLASMS

The diagnosis of leukemias and lymphomas requires clear communication and close cooperation between the oncologist, the surgeon, and the pathologist. A thorough clinical evaluation by the oncologist should help direct the surgeon or operator (in the case of fine-needle aspiration or marrow biopsy) to the most appropriate tissue for biopsy in the patient suspected of having a hematologic or lymphoid malignancy. Likewise, the pathologist needs to instruct the surgeon or operator in the proper handling and triaging of the tissue sample.

Tissue removed from patients suspected of having hematopoietic or lymphoid neoplasms should be handled to ensure the highest yield of diagnostic information. Most mistakes made in lymph node and bone marrow examination are due to improper processing of tissue specimens ([3]). Ideally, fresh, intact tissue should be quickly delivered to the surgical pathology laboratory. In all cases, tissue should be processed according to a pathologist-supervised protocol that incorporates a multiparameter approach to diagnosis [an example of a protocol, modified from Collins ([4]), for the evaluation of lymph nodes is illustrated in Figure 71.1]. Some leukemias and lymphomas require a combination of routine morphologic examination and more sophisticated morphologic, phenotypic, or genotypic studies for precise diagnosis and classification. Collection and preservation of tissue for these studies require minimal initial time and expense, and, often, the necessity of a second biopsy to establish a diagnosis can be avoided.

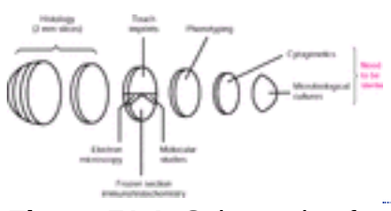

Figure 71.1. Schematic of protocol for processing lymph node biopsies from patients suspected of having lymphoid malignancies.

The diagnosis of hematopoietic and lymphoid neoplasms is based first and foremost on careful morphologic examination ([1]). General diagnostic criteria include pattern of growth of the infiltrate, degree of cytologic atypia, degree and type of differentiation of the predominant neoplastic cell population, and the presence of characteristic nonneoplastic, reactive cellular components. The recognition of these features is facilitated by the use of tissue fixatives, such as B-5, which preserve fine cytologic detail, and carefully prepared, well-stained sections or smears. Fine-needle aspiration biopsy and cytology are now widely used for evaluation of patients with known or suspected lymphomas ([5] , [6] and [7]). They are particularly useful in patients who are unable to undergo surgical excision and in patients with documented lymphomas suspected of having recurrent disease, especially in deep-seated nodes ([3]). Limitations include sampling errors and distinguishing reactive from malignant proliferations ([8]). Also, subclassification and grading of lymphomas can be problematic on fine-needle aspiration biopsy material. Molecular genetic analysis and immunophenotyping used in conjunction with fine-needle aspiration biopsy improve sensitivity and specificity ([9] , [10]). Electron microscopy is now used infrequently in diagnostic hematopathology, mainly due to improvements in immunohistochemistry, which can be performed more rapidly and at lower cost.

Correlation of morphologic and special studies is essential, as independent interpretations of various components of marrow or node examinations may lead to misinterpretations of the entire case ([1]). Although routine morphologic examination is the cornerstone for evaluation of marrows and lymph nodes, supplemental studies (Table 71.1) often are required for proper diagnosis or management of leukemias and lymphomas. Detailed descriptions of these modalities are presented in Chapter 76 and Chapter 77 for acute leukemias and Chapter 88 and Chapter 89 for non-Hodgkin lymphomas. However, a few general comments about limitations of their applications are in order.

Morphology, including histopathology, fine needle aspiration cytology, and electron microscopy
Immunohistochemistry
Cytochemistry
Cytogenetics
Molecular genetics
In situ hybridization

The recent development of commercially available monoclonal antibodies that react with antigens in routinely processed paraffin-embedded tissue sections (Table 71.2) ([11] , [12] , [13] and [14]) has made immunohistochemical evaluation of lymphomas and leukemias available to virtually all pathologists and has greatly improved diagnostic accuracy. As a cautionary note, none of these antibodies is 100% sensitive or specific for cell lineage. Other factors, such as type and length of time of tissue fixation and method of processing, may significantly affect the reactivity of these antibodies. If a laboratory chooses to perform immunohistochemistry, testing should be done with meticulous quality control, using panels of antibodies, and performed often enough for technicians and pathologists to acquire adequate experience in the performance and interpretation of the assays.

TABLE 71.2. Commonly Used Markers for the Characterization of Hematopoietic and Lymphoid Neoplasms in Paraffin-Embedded Tissue Sections

Category	CD Antigen or Antibody	Reactivity in Normal Cells	Reactivity in Neoplasms
Pan-leukocyte	CD45	B cells, most T cells, macrophages, and granulocytes	Most NHL and leukemias
T cell	CD1a	Cortical thymocytes and Langerhans cells	Precursor T-cell lymphoblastic leukemia/lymphoma, Langerhans cell histiocytosis
	CD2	T and NK cells	Many T-cell lymphomas and leukemias
	CD3	T cells	Most T-cell neoplasms
	CD5	T cells and subset of small B cells	Many T-cell lymphomas and leukemias and subset of diffuse small B-cell neoplasms, such as small lymphocytic lymphoma/chronic lymphocytic leukemia and mantle cell lymphoma
	CD7	Most T cells and NK cells	Many T-cell lymphomas and leukemias
	CD43	T cells, some macrophages, granulocytes, and plasma cells	Most T-cell lymphomas, some B-cell lymphomas, acute myeloid leukemias, and plasma cell neoplasms
	CD45RO	Most T cells, some macrophages, some myeloid cells	Most T-cell lymphomas, some B-cell lymphomas
	CD57	Some NK cells, subset of T cells	Some NK- and T-cell lymphomas/leukemias and some lymphoblastic lymphomas
	ßF1 (ß-chain of T-cell receptor)	T cells	Many T-cell lymphomas
B cell	CD10	Precursor B cells and follicular center B cells	Many precursor B-lymphoblastic leukemias/lymphomas, some precursor T-lymphoblastic leukemias/lymphomas, many follicular lymphomas, Burkitt lymphoma
	CD20	B cells	Most B-NHL, L & H R-S cell in LPHD; R-S cells in some cases of classic Hodgkin disease
	CD21	Mantle and marginal zone B cells, FDC	Some mantle and marginal lymphomas, FDC tumors
	CD23	Mantle zone B cells, some FDC	Chronic lymphocytic leukemia/small lymphocytic lymphoma
	CD45RA	B cells and subset of T cells	B-cell NHL, L & H cells in LPHD, some T-cell lymphoid and myeloid leukemias
	CD79a	B cells	Most B-cell NHL and many B-cell leukemias
	Antiimmuno-globulin	B cells, plasma cells	B-cell NHL and plasma cell neoplasms
Hodgkin related	CD15	Granulocytes and some macrophages	R-S cells in most cases of NS, MC, and LDHD; some T- and B-large cell lymphomas; some carcinomas
	CD30	Activated B and T cells, plasma cells	R-S cells in most cases of NS, MC, and LDHD; most cases of ALCL; other T- and B-cell NHL
Miscellaneous	CD34	Progenitor cells	Some acute myeloid leukemias and some precursor lymphoblastic leukemias/lymphomas
	CD56	NK cells, few T cells	Many NK-cell neoplasms
	CD68	Macrophages and granulocytes	True malignant histocytosis; many myeloid leukemias
	S100	Langerhans cells, interdigitating dendritic reticular cells, sometimes FDC	Langerhans cell histiocytes, sinus histiocytosis with massive lymphadenopathy, rare T-cell lymphomas, myeloid leukemias
	Terminal deoxy-ribonucleotidyl transferase	Precursor marrow cells, cortical thymocytes	Most precursor B- or T-lymphoblastic leukemias/lymphomas, some acute myeloid leukemias
	Ki-67	Proliferating cells (not in G_0-phase of cell cycle)	Proliferating cells
	Myeloperoxidase	Myeloid cells	Myeloid leukemias
	bcl-2	Nonfollicular center B cells, T cells	Most follicular lymphomas, many other diffuse NHL and leukemias
	Epithelial membrane antigen	Various epithelia, plasma cells	L&H R-S cells in LPHD, plasma cell neoplasms, ALCL, some other B- and T-large cell NHL and many epithelial tumors
	Cyclin D1	Minimal to no expression in normal lymphoid cells	Mantle cell lymphoma, hairy cell leukemia, and some cases of myeloma

ALCL, anaplastic large cell lymphoma; FDC, follicular dendritic cell; LDHD, lymphocyte-depletion Hodgkin disease; L & H, lymphocyte and histiocytic; LPHD, lymphocyte-predominance Hodgkin disease; MC, mixed cellularity; NHL, non-Hodgkin lymphoma; NK, natural killer; NS, nodular sclerosis; RS, Reed-Sternberg.

Flow cytometry is an important means of evaluating HLS neoplasms, especially for characterization of acute leukemias and the assessment of lineage and clonality of lymphoid proliferations ([15], [16], [17], [18] and [19]). Testing can usually be performed in several hours, is relatively inexpensive, and is widely available by transporting samples via overnight mail to reference laboratories. Performance and interpretation of flow cytometry testing require considerable expertise and experience. Correlation with histopathologic findings is essential, and diagnosing a process as leukemia or lymphoma based solely on flow cytometry should be avoided.

The cytogenetic and molecular characterization of leukemias and lymphomas using Southern analysis, polymerase chain reaction, *in situ* hybridization, karyotyping, and gene expression profiling has provided insight into the pathogenesis of these neoplasms, aided in diagnosis, classification, and prognosis, and improved recognition of minimal disease ([20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31], [32], [33], [34], [35] and [36]). These techniques rely on the fact that virtually all HLS neoplasms are clonal and demonstrate alterations of DNA. However, equating clonality with neoplasia requires caution. Nonneoplastic-appearing lymphoproliferative processes with “benign” clinical courses have been shown to contain clonal populations of lymphoid cells or alterations in DNA ([30], [37], [38], [39], [40] and [41]). Like phenotypic assays, molecular studies require that interpretation be correlated with histopathologic examination.

Complicated or uncommon cases of leukemia and lymphoma should be sent to a consultant who is experienced in hematopathology ([1]). Many pathologists find the field of hematopathology difficult ([5]) because of the complexity of the HLS, the lack of reliable diagnostic criteria for some neoplasms, the similarity of some reactive processes to neoplasms, and the lack of experience with uncommon disorders ([1]). Controversy over terminology and classification of leukemias and lymphomas also causes confusion for many pathologists.

CLASSIFICATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS

The approach to classification of leukemias and lymphomas should be comparable to that used for other neoplasms ([1]). An ideal classification should be scientifically accurate, reproducible by the average pathologist, and predict clinical behavior ([42]). It should incorporate the presumed site of origin of the tumor, the presumed cell of origin, the phenotype of the neoplastic cell, and the cell cycle or differentiation stage of the neoplastic population ([1]).

In no other area of oncology has the classification of tumors been more controversial than in the field of hematopoietic and lymphoid neoplasms, especially non-Hodgkin lymphomas. The existence of numerous classification systems, each with very different conceptual frameworks and terminology, coupled with rapid advances in immunologic and molecular genetic techniques used to identify new entities, has led to confusion and difficulty in communication ([43]).

In the past, classifications of non-Hodgkin lymphomas included the Working Formulation ([44]) and the Lukes-Collins system ([1]) in the United States, and, in Europe, the Kiel classification ([45]). Acute leukemias were generally classified by modifications of the French-American-British system ([46] and [47]).

Recently, the World Health Organization classification ([2]) of hematopoietic and lymphoid neoplasms (Table 71.3) was developed as a joint effort of American and European professional societies and was based, in part, on the earlier revised European-American lymphoma (or so-called "REAL") classification ([48]). This classification has gained wide acceptance and is a listing of distinct clinicopathologic, immunophenotypic, and genetic entities among hematopoietic and lymphoid neoplasms. Refinements and modifications of the World Health Organization classification are likely to occur in the future as our knowledge of the HLS continues to expand and new biologic observations are translated into new clinical entities.

TABLE 71.3. World Health Organization Classification of Hematopoietic and Lymphoid Neoplasms

- Chronic myeloproliferative diseases
  - Chronic myelogenous leukemia
  - Chronic neutrophilic leukemia
  - Chronic eosinophilic leukemia/hypereosinophilic syndrome
  - Polycythemia vera
  - Chronic idiopathic myelofibrosis
  - Essential thrombocythemia
  - Chronic myeloproliferative disease, unclassifiable
- Myelodysplastic/myeloproliferative diseases
  - Chronic myelomonocytic leukemia
  - Atypical chronic myeloid leukemia
  - Juvenile myelomonocytic leukemia
  - Myelodysplastic/myeloproliferative diseases, unclassifiable
- Myelodysplastic syndromes
  - Refractory anemia
  - Refractory anemia with ringed sideroblasts
  - Refractory cytopenia with multilineage dysplasia
  - Refractory anemia with excess blasts
  - Myelodysplastic syndrome, unclassifiable
  - Myelodysplastic syndrome associated with isolated del(5q) chromosome abnormality
- AML
  - AML with recurrent cytogenetic abnormalities
    - AML with t(8;21) (q22;q22) (AML1/ETO)
    - AML with inv(16)(p13q22) or t(16,16) (p13;q22) (CBFß/MYH11)
    - Acute promyelocytic leukemia [AML with t(15;17)(q22;q12), (PML/RAR-a) and variants]
    - AML with 11q23 (MLL) abnormalities
  - AML with multilineage dysplasia
  - AML and myelodysplastic syndrome, therapy-related
    - Alkylating agent–related
    - Topoisomerase II inhibitor–related
  - AML not otherwise categorized
    - AML minimally differentiated
    - AML without maturation
    - AML with maturation
    - Acute myelomonocytic leukemia
    - Acute monoblastic and monocytic leukemia
    - Acute erythroid leukemia
    - Acute megakaryocytic leukemia
    - Acute basophilic leukemia
    - Acute panmyelosis with myelofibrosis
    - Myeloid sarcoma
  - Acute leukemias of ambiguous lineage
- Precursor B-cell neoplasms
  - Precursor B-lymphoblastic leukemia/lymphoma
  - Precursor T-lymphoblastic leukemia/lymphoma
- Mature (peripheral) B-cell neoplasms
  - Chronic lymphocytic leukemia/small lymphocytic lymphoma
  - B-cell prolymphocytic leukemia
  - Lymphoplasmacytic lymphoma/Waldenström macroglobulinemia
  - Splenic marginal zone lymphoma
  - Hairy cell leukemia
  - Plasma cell neoplasms
    - Plasma cell myeloma
    - Plasmacytoma
    - Monoclonal immunoglobin deposition diseases
    - Heavy chain diseases
  - Extranodal marginal zone B-cell lymphoma (MALT lymphoma)
  - Nodal marginal zone B-cell lymphoma
  - Follicular lymphoma
  - Mantle cell lymphoma
  - Diffuse large B-cell lymphoma
  - Mediastinal (thymic) large B-cell lymphoma
  - Intravascular large B-cell lymphoma
  - Primary effusion lymphoma
  - Burkitt lymphoma/leukemia
  - Lymphomatoid granulomatosis
- Mature (peripheral) T-cell neoplasms
  - T-cell prolymphocytic leukemia
  - T-cell large granular lymphocytic leukemia

- Aggressive NK-cell leukemia
- Adult T-cell lymphoma/leukemia
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-type T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Blastic NK-cell lymphoma
- Mycosis fungoides/Sézary syndrome
- Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
  - Primary cutaneous anaplastic large cell lymphoma (C-ALCL)
  - Lymphomatoid papulosis
  - Borderline lesions
- Angioimmunoblastic T-cell lymphoma
- Peripheral T-cell lymphoma, unspecified
- Anaplastic large cell lymphoma

Hodgkin lymphoma
- Nodular lymphocyte-predominant Hodgkin lymphoma
- Classical Hodgkin lymphoma
  - Nodular sclerosis Hodgkin lymphoma
  - Mixed cellularity Hodgkin lymphoma
  - Lymphocyte-rich classical Hodgkin lymphoma
  - Lymphocyte-depleted Hodgkin lymphoma

Immunodeficiency-associated lymphoproliferative disorders
- Lymphoproliferative diseases associated with primary immune disorders
- Human immunodeficiency virus–related lymphomas
- Posttransplant lymphoproliferative disorders
- Methotrexate-associated lymphoproliferative disorders

Histiocytic and dendritic cell neoplasms
- Histiocytic sarcoma
- Langerhans cell histiocytosis
- Langerhans cell sarcoma
- Interdigitating dendritic cell sarcoma/tumor
- Follicular dendritic cell sarcoma/tumor
- Dendritic cell sarcoma, not otherwise specified

Mastocytosis
- Cutaneous mastocytosis
- Systemic mastocytosis
- Mast-cell sarcoma
- Extracutaneous mastocytoma

AML, acute myeloid leukemia; NK, natural killer.

Complications of Hematopoietic Neoplasms

Patients with hematologic neoplasms are at risk of complications from the neoplasms as well as from the treatment. Hematologic neoplasms commonly cause morbidity and mortality through three general mechanisms: (a) a deficit in cell number or function; (b) invasion of vital organs with impairment of organ function; and (c) systemic disturbance, as manifested by weight loss, fever, sweats, or pruritus, or metabolic alteration, such as tumor lysis. The frequency of these complications and their management vary according to the disease. For example, disseminated intravascular coagulation (DIC) commonly occurs in acute myeloid leukemia (AML), particularly acute promyelocytic leukemia (APL), whereas tumor lysis occurs in acute lymphoblastic leukemia (ALL), particularly with bulky disease as observed in T-ALL or Burkitt leukemia. Cytopenias are common to hematologic neoplasia and are addressed with the description of specific diseases in specific chapters (anemia, ; thrombocytopenia, Part V: ; neutropenia, Chapter 63 and Chapter 64). Deficient immunoglobulin (Ig) production is common in chronic lymphocytic leukemia (CLL) and multiple myeloma (MM) and contributes to the frequency and types of infection. Fever and infection, often the result of neutropenia, are among the most serious complications; their diagnosis and management are addressed in Chapter 75. Hemorrhage, often a result of thrombocytopenia, is another major problem associated with hematologic neoplasms. This chapter addresses defects in host defenses, hemorrhage, anemia, complications caused by invasion of vital organs, and metabolic disturbances associated with hematologic neoplasia.

DEFECTS IN HOST DEFENSE

The natural course of hematologic neoplasia often includes a phase of impaired host defense. Multiple factors may contribute to decreased resistance, including those related to the host and those related to the disease. It is helpful to divide opportunistic infections into those caused by impairment of phagocytosis (mainly neutropenia), defective production of circulating antibody (humoral immunity), and impaired cellular immunity, or by a combination of these defects. Table 72.1 outlines defects in host defense mechanisms associated with specific neoplasms. As discussed in Chapter 75, other host factors, such as disruption of the skin by catheters or ulcerations and anatomic obstruction of respiratory or gastrointestinal tracts, predispose patients to infections. Concomitant illnesses, such as diabetes, nephrotic syndrome, cardiac disease, and liver disease, may also contribute to infections, as well as influence management decisions ([1]). Moreover, chemotherapy, malnutrition, and, rarely, transfusions may play roles in the development of infections.

TABLE 72.1. Host Defects Predisposing to Complications in Hematologic Malignancies

Disease	Host Defect	Complications
Acute myeloid leukemia	Neutropenia	Bacterial infections, including perirectal abscess, typhlitis, sinusitis; superinfections when hospitalized; increasing problem of methicillin-resistant *Staphylococcus aureus* and coagulase-negative staphylococci; *Clostridium difficile* colitis; aspergillosis with prolonged neutropenia; viral infections (herpes simplex)
	Thrombocytopenia, disseminated intravascular coagulation	Hemorrhage
	Hyperleukocytosis	Leukostasis, tumor lysis
Acute lymphoblastic leukemia	Neutropenia	Bacterial infections (see Acute myeloid leukemia)
	Cellular immunity while on maintenance therapy	*Pneumocystis carinii*, disseminated varicella
	Thrombocytopenia	Hemorrhage
	Hyperleukocytosis	Tumor lysis, leukostasis
Chronic myeloid leukemia	Mild defects in neutrophil function	No increased risk of infections except in blast crisis
	Thrombocytosis, platelet dysfunction	Increased risk of thrombosis and hemorrhage, similar to other myeloproliferative disorders
CLL	Decreased immunoglobulins	Infections with encapsulated organisms (pneumococcus, *Haemophilus influenzae*, meningococcus)
	Cellular immunity	Mycobacteria, fungal, viral (herpetic), *Salmonella*
	Immune dysfunction	AIHA, ITP, red cell aplasia
Hodgkin disease	Cellular immunity	Viral (herpes zoster, other), *P. carinii*, fungal, mycobacteria, listeriosis, *Salmonella*
	Cytokine production	B symptoms, pruritus, eosinophilia
	Splenectomized	Encapsulated organisms (above), increased risk of leukemia
	Immune dysfunction	ITP, AIHA
	Mediastinal disease	SVC syndrome
Non-Hodgkin lymphoma		
Small B-cell lymphoma	Decreased Igs	Similar infections to CLL

PTCL, particularly angioimmunoblastic and subcutaneous panniculitis-like PTCL	Immune dysfunction	AIHA
	Cytokine production	B symptoms, hemophagocytic syndrome, eosinophilia
Large B-cell lymphoma	Mediastinal disease	SVC syndrome, pericardial disease
T-lymphoblastic lymphoma	Mediastinal disease	SVC syndrome, tumor lysis, CNS disease
Mantle-cell lymphoma	Colonic polyposis	Gastrointestinal bleed
Burkitt lymphoma	Gastrointestinal primary	Obstruction, perforation, tumor lysis, CNS disease with advanced stage disease
Multiple myeloma	Paraprotein	Hyperviscosity, hemorrhage
	Decreased Igs	Similar infections to CLL
	Osteoclast overactivity	Hypercalcemia
Waldenström macroglobulinemia	IgM paraprotein	Hyperviscosity, hemorrhage
Hairy cell leukemia	Neutropenia	Bacterial infections, fungal
	Cellular immunity	*P. carinii*, atypical mycobacteria
	Immune dysfunction	Periarteritis nodosa, lymphocytic vasculitis
	Monocytopenia	—
T-cell large granular lymphocyte leukemia	Neutropenia	Bacterial infections
	Immune dysregulation, positive rheumatoid factor, antinuclear antibody	ITP, AIHA, red cell aplasia
Adult T-cell leukemia/lymphoma	Cellular immunity	Opportunistic infections (*Strongyloides stercoralis*, *P. carinii*)
	Parathyroid hormone–related protein	Hypercalcemia

AIHA, autoimmune hemolytic anemia; CLL, chronic lymphocytic leukemia; CNS, central nervous system; Ig, immunoglobulin; ITP, immune thrombocytopenic purpura; PTCL, peripheral T-cell lymphoma; SVC, superior vena cava.

Neutrophil Defects

Neutropenia, defined as a decrease of the peripheral blood neutrophil count below 1000/mm ^{3}, predisposes to bacterial and fungal infections. The severity (<100/mm ^{3}) and length of neutropenia (>2 weeks) contribute to the risk of serious, overwhelming infections ([2]). Neutropenia is a common complication of acute leukemia (AL), is often prolonged during induction therapy, and predisposes the patient to specific sites and types of infections (Table 72.2). In patients with chronic myeloid leukemia (CML), neutropenia occurs only with blast crisis, in the face of developing myelofibrosis, or with therapy. In CLL, neutropenia is unusual in untreated patients ([3], [4]). Neutropenia is observed in myelofibrosis and may be mild in MM but is uncommon during untreated phases of other hematologic diseases. When neutropenia occurs in patients with Hodgkin disease (HD) or non-Hodgkin lymphoma (NHL), marrow invasion with tumor or fibrosis of marrow is usually present in conjunction with other cytopenias. In patients with hairy cell leukemia (HCL), opportunistic infections may occur as a result of neutropenia secondary to tumor cell invasion, splenomegaly, or both but may also result from defects in cell-mediated immunity, monocytopenia, and, more recently, decreased T cells after nucleoside analog therapy ([5]). Neutropenia may be the primary clinical problem in patients with T-cell large granular lymphocytic leukemia.

TABLE 72.2. Opportunistic Infections Associated with Defects in Immunity in Hematologic Neoplasia

Defect	Infections
Neutropenia	Gram-negative bacteremia (*Escherichia coli*, *Pseudomonas*, *Klebsiella*, *Proteus*)
	Gram-positive bacteremia (methicillin-resistant *Staphylococcus aureus*, coagulase-negative staphylococci, *Streptococcus viridans*)
	Fungemia (*Candida* species, aspergillosis)
Humoral immunity	Encapsulated organisms
	Streptococcus pneumoniae
	Haemophilus influenzae
	Neisseria meningitidis
Cellular immunity	Bacteria
	Listeria monocytogenes
	Mycobacteria
	Legionella species
	Nocardia species
	Salmonella species
	Viruses
	Herpes simplex
	Varicella zoster
	Parainfluenza, respiratory syncytial virus, cytomegalovirus
	Fungi
	Cryptococcus neoformans
	Coccidioides immitis
	Histoplasma capsulatum
	Parasites
	Pneumocystis carinii
	Toxoplasma gondii
	Strongyloides stercoralis

In any of the diseases under consideration, neutropenia is usually caused by decreased production. When neutropenia is severe, localizing signs and symptoms are often absent because of a lack of inflammatory response from absent granulocytes ([1], [6]). Fever remains the most common sign of infection associated with neutropenia and requires prompt attention (Chapter 75).

Functional defects in morphologically normal neutrophils have been described in hematologic malignancies, particularly myeloproliferative disorders and myelodysplasia (MDS); however, the effect of such defects on enhancing the susceptibility to infection is uncertain (Chapter 63). Neutrophils from untreated patients with CML may be mildly defective with respect to phagocytosis, oxygen consumption, and bactericidal capacity and tend to have decreased concentrations of

lactoferrin, elastase, collagenase, and peroxidase ([7]).

Alternatively, neutrophil superoxide (O_2^-)-producing capacity has been increased in myeloproliferative disorders, including CML ([8]). Decreased lobation and abnormal granulation in MDS may contribute to increased infections (Chapter 83).

Immature leukemic cells, as found in ALs, are of no benefit to the host against infection ([6]). Lysosomal enzymes of possible importance in bacterial killing, such as lysozyme, lactoferrin, and peroxidase, have been found in reduced concentrations in neutrophils of some patients with AML ([9], [10] and [11]). In ALs, bactericidal capacity and lysozyme content have been reported to be reduced, but phagocytosis was normal ([11], [12]). Neutrophil function generally is normal in CLL, HD, and NHL, although serum factors inhibiting chemotaxis have been described in some patients. Impaired adhesiveness of granulocytes has been reported in MM. A variety of functional neutrophil defects may also occur secondary to both chemotherapy ([13], [14]) and radiation therapy ([15]).

Deficient Immunoglobulin Production

Impaired humoral immunity is the second major cause of frequent and severe infection in patients with hematologic neoplasia. There is decreased Th2 CD4 T-lymphocyte–B-lymphocyte interaction, resulting in decreased antibody production, complement-mediated damage, and phagocytosis ([1]). Decreased Ig synthesis is a major cause of infection in patients with CLL ([16]) and MM ([17]) and in a smaller percentage of those with B-cell types of NHL ([18], [19] and [20]). Hypogammaglobulinemia is unusual in those with other lymphomas or HD except in severely ill patients. Patients who have had splenectomy for hypersplenism or for staging in HD have impaired antibody response, have reduced levels of tuftsin, and are at risk for infections similar to those of patients with hypogammaglobulinemia, particularly encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) ([21]). Igs tend to be toward the lower limit of normal in ALL but are normal or increased in AML and CML unless extensive therapy has been used ([22]). Polyclonal hypergammaglobulinemia has been described in HD and in T-cell neoplasms, including peripheral T-cell lymphomas and T-CLL ([23]).

Defective production of circulating Ig is often reflected in hypogammaglobulinemia and by reduction in naturally occurring Igs such as isoantibodies to red cell antigens. Hypogammaglobulinemia may be observed in the absence of extensive CLL or MM, and such patients may die of infection at a time when their disease is in an early stage. All classes of Igs may be depressed, or one class may be selectively depressed. Replacement of gammaglobulin is warranted in selected patients with hypogammaglobulinemia and recurrent severe infections ([24]).

Defects in Cellular Immunity

Depressed cell-mediated immunity is characterized by impairment of Th1 $CD4^+$ T lymphocytes or macrophage function or both, resulting in an increased risk of infections with intracellular bacteria, fungi, parasites, and viruses (Table 72.2) ([1]). The patient with HD who is anergic, as judged by loss of sensitivity to skin tests, has lymphocytes that fail to transform when exposed to phytohemagglutinin or pokeweed mitogen ([25]). Patients with HD often do not respond to new antigens and lose prior sensitivity as well ([26], [27]). Patients with CLL usually show reduced or absent lymphocyte transformation with phytohemagglutinin ([28]) but do not lose skin hypersensitivity to antigens such as old tuberculin. Patients with HD do not mount either a primary or a secondary immune response, whereas those with CLL maintain secondary responses but cannot mount a primary response. Cell-mediated immune responses may be abnormal in MM, but these responses have not been as well characterized as in CLL or HD. Depressed cellular immunity is uncommon in AL ([29]) except during maintenance therapy in ALL ([30]) or when patients are extremely ill ([31]).

The frequency and severity of impaired cellular immunity are variable and dependent on multiple factors. There may be differences in the stages of disease studied, the therapy used, and the sensitivity of the tests used to measure cellular immunity. In HD, a direct correlation exists between impaired cell-mediated immunity and the severity and stage of disease (Chapter 95). Although therapy with a wide variety of antitumor drugs produces anergy as a transient manifestation in either HD or CLL, treatment, if successful, may lead to eventual improvement of cell-mediated immunity ([26], [32]). In HD, after apparent eradication of disease by radiotherapy or chemotherapy, cell-mediated immunity as judged by either skin tests or phytohemagglutinin transformation may return to normal, although many months are required in most cases ([26], [33]). Herpes zoster often remains a clinical problem in patients cured of HD. As noted previously, patients with HCL are compromised by combined defects in host defense, and their clinical courses have been often characterized by multiple infections, including gram-negative organisms as a result of neutropenia and opportunistic infections because of decreased cell-mediated immunity ([34], [35] and [36]). Immunosuppression after bone marrow transplantation is a common problem and is dependent on the type of transplant (autologous vs. allogeneic) and the severity of graft-versus-host disease.

HEMORRHAGE

Serious, life-threatening hemorrhage is a common problem in the ALs and may occur in association with any of the diseases under consideration. Petechiae, purpura, and ecchymoses are the most common manifestations of hemorrhage and occur at diagnosis in 40 to 70% of patients with AL ([37], [38]). The most prevalent sites of hemorrhage are the skin, eyes, and mucosal membranes of the nose, gingiva, and gastrointestinal tract ([37], [39], [40]). Retinal bleeding occurs in approximately 15% of patients with AL at diagnosis and in up to 50% of patients as the disease progresses ([37], [38], [41]). Life-threatening hemorrhage is usually into the gastrointestinal tract or the central nervous system (CNS) but has also occurred in the lungs, uterus, and ovaries ([38]). Although infection has surpassed hemorrhage as the leading cause of death in AL, hemorrhage remains a prominent problem, contributing to death in approximately 40% of patients ([27], [37], [38], [40]).

Hemorrhage is less of a problem in both CML and CLL, although thromboses or thromboembolism frequently occurs in the chronic leukemias ([37], [39]). Hemorrhage by oozing from either the gastrointestinal tract or genitourinary tract may become a clinical problem in the chronic leukemias but is rarely life-threatening except during therapy or in advanced stages of the diseases, in blast crisis of CML, or marrow infiltration in CLL. Hemorrhage in hematologic neoplasia is most often caused by thrombocytopenia but may also occur as a result of platelet dysfunction, DIC, liver disease, fibrinolysis, and vascular defects. Table 72.3 outlines hemostatic defects in hematologic neoplasms ([37]).

TABLE 72.3. Defective Hemostasis in Hematologic Neoplasms

Thrombocytopenia

Thrombocytopenia

Reduced numbers of platelets in hematologic neoplasia are usually the result of chemotherapy or marrow infiltration; however, other less common causes include DIC, particularly in APL, infection-induced immune or nonimmune thrombocytopenia, idiopathic or immune thrombocytopenia, and hypersplenism secondary to splenomegaly ([37]).

The relationship of hemorrhage to the degree of thrombocytopenia has been defined in AL (Fig. 72.1) ([42]). Although the risk of severe hemorrhage has been decreased by the use of platelet transfusions, an optimal platelet count threshold for prophylactic platelet transfusion in patients with AL remains controversial. Platelet counts below 20,000/µl have been used as the threshold for transfusion, but life-threatening hemorrhage is unusual unless the count is less than 5,000/µl ([37] , [42]). Moreover, randomized studies comparing a threshold of 10,000/µl or less with one of 20,000/µl or less showed no major differences in morbidity in adults with AL ([43] , [44] and [45]). Thus, it is reasonable to use a platelet count threshold of less than 10,000/µl for prophylactic platelet transfusion in patients without risk factors for hemorrhage who have ready access to medical care. If serious hemorrhage occurs with platelet counts above 20,000/µl, a cause of hemorrhage other than thrombocytopenia should be sought (Table 72.3). Some authorities have advocated screening the urine and stool for bleeding and, if bleeding is not detected, transfusing patients only when platelets are below 5,000/µl ([37]). Patients with AL undergoing treatment require multiple platelet transfusions and have a risk of alloimmunization, which, in turn, can lead to platelet refractoriness. Platelets can be obtained from single donors or pooled from multiple random donors. The product can be modified by leukodepletion or by irradiation. The TRAP (Trial to Reduce Alloimmunization Study Group) compared the rate of alloimmunization in patients receiving unmodified pooled platelet from random donors, filtered (leukodepleted) pooled platelet from random donors, ultraviolet B-irradiated pooled platelet from random donors, and filtered platelets obtained by apheresis from a single random donor. They concluded that reduction of leucocytes by filtration was as effective as irradiated platelets in preventing alloantibody-mediated platelet refractoriness in patients undergoing chemotherapy for acute myeloid leukemia. Single donor platelets obtained by apheresis did not provide additional benefit ([46]). Platelet transfusion tends to fail in only two circumstances: in the febrile infected patient and in the patient who develops alloantibodies ([46]).

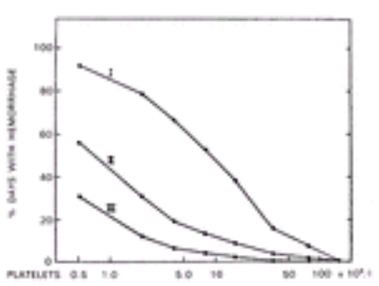

Figure 72.1. Relation between hemorrhage and platelet count. The percentage of days when hemorrhage occurred in the 92 patients combined is shown for each of the levels of platelet count. Curve I shows data for all hemorrhagic manifestations. In curve II, skin hemorrhage and epistaxis have been excluded. Curve III refers only to grossly visible hemorrhage. (From Gaydos LA. The quantitative relation between platelet count and hemorrhage in patients with acute leukemia. N Engl J Med 1962;266:905, with permission.)

DIC commonly complicates AL because of the release of procoagulant materials or enzymes from blasts; leukemic cells may also have fibrinolytic activity ([37] , [39] , [40] , [47]). The most common AL associated with DIC is APL [French/American/British classification (FAB) M3], followed by acute myelomonocytic leukemia (FAB M4), acute myeloblastic leukemia (FAB M1 and M2), ALL, and then the chronic leukemias, with CML more commonly associated with DIC than CLL ([37]). DIC may be worsened by the initiation of antileukemic therapy; however, the availability of *trans*-retinoic acid in APL has lessened the length and severity of DIC in this subtype of AL (Chapter 82). A reasonable approach to the treatment of other patients with AL who have severe DIC as part of their clinical picture is to institute induction chemotherapy as quickly as possible to reduce the leukemic cell population as the presumed cause of DIC. Antibiotics should be used if infection is suspected, and replacement therapy should be given if severe thrombocytopenia, coagulopathy, or hypofibrinogenemia is present. If biochemical or clinical evidence suggests DIC is continuing or worsening, there may be a role for the use of heparin ([48]).

Immune thrombocytopenic purpura (ITP) (Chapter 53) is being recognized in an increasing number of patients with hematologic malignancies ([49]). Autoimmune destruction of platelets is assumed to be the causative mechanism, and platelet-bound IgG has been demonstrated in some patients ([50]). This syndrome complicates the course of 2 to 5% of patients with CLL ([49] , [50] and [51]) and has also occurred in HD, MM, NHL, and ALL ([49] , [51] , [52] , [53] and [54]). Simultaneous ITP and autoimmune hemolytic anemia (Evans syndrome) have been observed in a few patients ([51]). The time of onset of ITP bears little relation to the duration, severity, or state of activity of the neoplasm and, except for the hazard posed by ITP itself, has no adverse prognostic implications. The ITP syndrome has also occurred in patients previously splenectomized for HD ([52]). In hematologic neoplasia, therapy with prednisone, intravenous gammaglobulin, splenectomy, and other modalities is similar to that used in other forms of ITP (Chapter 53). Platelet sequestration resulting from hypersplenism and splenomegaly is another mechanism of thrombocytopenia common to CLL (Chapter 92) and some NHL (Chapter 90); its management with splenectomy is discussed in Chapter 70.

Platelet Dysfunction

Platelet dysfunction is often present in the myeloproliferative disorders regardless of the platelet count and may contribute to hemorrhage ([54]). Bleeding caused by platelet dysfunction occurs more commonly in polycythemia vera (PV) (approximately 70%) followed by idiopathic myelofibrosis (50%) and then CML (30%) ([55] , [56]). The most common defects are impaired aggregation to adenosine diphosphate and epinephrine, defective release of platelet factor 3, and deficiency of a-granules ([57]). Although similar defects have been reported in some patients with AL ([40] , [58]), bleeding as a result of platelet dysfunction is believed to be less of a problem in ALs than in the myeloproliferative disorders. Platelet transfusions should be administered with bleeding secondary to platelet dysfunction when the platelet count is normal or decreased. Platelet cytapheresis can decrease bleeding when platelet dysfunction is associated with thrombocytosis (>700,000/µl) ([37]).

Other Causes of Hemorrhage

Coagulation protein abnormalities caused by liver disease or circulating inhibitors, fibrinolysis, and vascular defects may contribute to hemorrhage in hematologic neoplasms ([37]). Liver infiltration is more common in ALs followed by CLL and then CML and results in decreased synthesis of vitamin K–dependent clotting factors (factors II, VII, IX, and X) ([39] , [40]). Decreased fibronectin in AL is more commonly caused by DIC ([59]). Cholestasis in AL may contribute to decreased synthesis of clotting factors and, occasionally, to DIC ([39] , [40]). Viral hepatitis and hepatotoxicity from therapy are other complications that can cause liver failure and decreased synthesis of clotting factors.

Acquired inhibitors to clotting factors have been associated with a variety of hematologic neoplasms, particularly lymphoid in origin, and may become difficult clinical management problems (Chapter 60). Patients develop a sudden bleeding tendency, and coagulation tests usually show a prolonged partial thromboplastin time. Specific clotting factors have to be tested, with factor VIII and von Willebrand factor the most commonly recognized deficiencies ([37] , [60] , [61] , [62] and [63]). Inhibitors of thrombin or factor X deficiency may develop in patients with MM and amyloidosis because of the binding of calcium-dependent clotting factors by amyloid ([64]). Therapy for the underlying malignancy may correct the bleeding tendency and eradicate the inhibitor. Other measures may also be required, including replacement therapy, immunosuppression, and plasmapheresis. The use of deamino-8-d-arginine vasopressin may decrease bleeding tendency in patients with acquired von

Willebrand syndrome ([37]).

Changes in the fibrinolytic system have been reported more commonly in ALs than in chronic leukemias. The findings are inconsistent, with both increased and decreased activity being reported ([37]). The role of fibrinolysis in clinical hemorrhage in hematologic neoplasms and its management are controversial. In primary fibrinolysis, hemorrhage is caused by plasmin-induced degradation of many clotting factors, including fibrinogen, factor V, and factor VIII:C ([37]). The use of antifibrinolytics, e-aminocaproic acid, or tranexamic acid has been advocated for bleeding believed to be caused by excessive fibrinolysis, but their use is contraindicated in patients with DIC, a more prevalent problem in hematologic cancers ([37]).

Vascular defects more commonly develop in ALs than in chronic leukemias, and paraproteins in Waldenström macroglobulinemia and myeloma may contribute to hemorrhage, as well as thrombosis. Increased vascular permeability can occur in AL as a result of (a) infiltration of the vessel wall by blasts, (b) leukostasis with hyperviscosity of the vasa vasorum, and (c) extramedullary hematopoiesis within the vasculature ([37]). The incidence of hemorrhage related to paraproteins is partially dependent on the type of disease. Approximately 15% of patients with IgG myeloma, approximately 40% with IgA myeloma, and over 60% with Waldenström macroglobulinemia (IgM) experience hemorrhage during the course of their illness ([37] , [65]). Whereas paraproteins are often associated with hyperviscosity, other factors that can contribute to hemorrhage include organ failure (uremia, liver failure), platelet dysfunction, low-grade DIC, fibrinolysis, or vascular infiltration with amyloid.

ANEMIA

Anemia is often a part of the clinical course of hematologic neoplasms and contributes to symptoms of fatigue and dyspnea. The mechanisms causing anemia vary according to the type of neoplasm (Table 72.4). In the ALs and myeloma, it is such a common part of the clinical picture that making a diagnosis in the absence of anemia is unusual. Other mechanisms of anemia besides marrow replacement must be considered in hematologic neoplasms because the therapy may be dependent not only on the underlying neoplasm, but also on the mechanisms involved.

TABLE 72.4. Anemia Associated with Hematologic Neoplasms

Mechanism of Anemia	Associated Neoplasms
Marrow replacement	More prevalent in acute leukemias than in chronic leukemias
	Advanced stage lymphomas
	Myeloma (amyloidosis)
Blood loss	
Caused by thrombocytopenia (DIC)	Acute leukemias
Caused by gastric ulcers	Myeloproliferative disease, lymphomas
Caused by gastrointestinal perforation	High-grade lymphomas (Burkitt)
Anemia of malignancy (chronic disease)	Hodgkin disease
Pure red cell aplasia	CLL, T-cell large granular lymphocyte leukemia
Hemolytic anemia	
Warm antibody–mediated	CLL, lymphomas
Cold agglutinin disease	Waldenström macroglobulinemia, lymphomas
Microangiopathic hemolytic anemia	Acute leukemias with DIC
Hypersplenism	CLL, lymphomas, myelofibrosis
Macrocytic anemia	Myelodysplasia, acute myelocytic leukemia
Hemophagocytic syndrome	Lymphomas (peripheral T-cell lymphoma), leukemias

CLL, chronic lymphocytic leukemia; DIC, disseminated intravascular coagulation.

The primary cause of anemia is marrow replacement by neoplastic cells, although other causes may contribute. Hypochromic, microcytic anemia suggests iron deficiency from chronic blood loss usually from gastrointestinal bleeding, but iron deficiency may also occur in the anemia of chronic disease. Serum iron levels are often low in many patients with CLL, HD ([37] , [66] , [67]), or MM, transferrin levels tend to be decreased, and serum ferritin levels are often increased. Pathophysiologic mechanisms in the anemias of malignancy and chronic disease include a shortened red blood cell survival, a hypoproliferative response to erythropoietin, and an impaired release of iron ([37] , [68]). Cytokines, including tumor necrosis factor and some interleukins, probably contribute to the anemia of malignancy ([37] , [68]). Erythropoietin in doses larger than those needed in the treatment of anemia of renal failure may improve anemia associated with hematologic neoplasms, particularly MM and CLL ([37] , [68]). Pure red cell aplasia is an unusual complication in hematologic neoplasms; it is most commonly associated with CLL, less commonly with other B-cell lymphoproliferative neoplasms, and rarely with other hematologic malignancies ([37] , [69] , [70]). It may respond to the use of intravenous gammaglobulin or to therapy for the underlying neoplasm.

Hemolytic anemias may be the presenting feature or may precede or follow the diagnosis of hematologic cancer; they do not correlate with prognosis. Warm antibody–mediated hemolytic anemia (Chapter 35) complicates the course of 10 to 20% of patients with CLL and may occur in patients with other hematologic cancers ([37] , [71] , [72] , [73] and [74]). The onset is often sudden, and hemolysis can be so severe that death from cardiac failure may occur ([37] , [75] , [76]). Therapy is directed at decreasing the production of antibody and splenic destruction of red blood cells. Adrenocortical steroids, transfusions, therapy for the underlying neoplasm, and splenectomy are used in autoimmune hemolytic anemia of warm antibody type. In cold agglutinin disease, the anemia is usually mild; steroids and splenectomy have little benefit. Avoiding cold exposure, plasmapheresis, and treatment of the underlying lymphoproliferative disorder may be effective in improving the anemia associated with cold agglutinin disease (Chapter 35). Microangiopathic hemolytic anemia is seen most often as part of the DIC syndrome but has been reported in patients with hematologic neoplasms without evidence of DIC. Hypersplenism, the trapping or destruction of erythrocytes in an enlarged spleen, may contribute to anemia in hematologic cancers, particularly some low-grade lymphomas and CLL. Although there is little correlation between the size of the spleen and evidence for splenic pooling of erythrocytes, splenectomy has been used extensively in some centers for treatment of nonautoimmune hemolytic anemias in lymphoid malignancies ([37] , [77] , [78]).

Macrocytic anemia with marrow cells resembling megaloblasts can be found in patients with erythroleukemia (Di Guglielmo syndrome), MDS, and some AML, in which the predominant cell is a myeloblast rather than the proerythroblast of erythroleukemia. The most common cause of macrocytic anemia is cytotoxic chemotherapy and the resultant inhibition of DNA synthesis. Agents whose primary effect is inhibition of DNA synthesis, such as the folic acid antagonists, cytosine arabinoside, 6-mercaptopurine, hydroxyurea, and procarbazine, are most commonly associated with macrocytic anemia. The abnormal nucleated red cells that may appear in AML in the absence of such drugs or occur as part of the terminal phase of myeloproliferative disorders have certain morphologic features that often allow their differentiation from megaloblasts resulting from vitamin deficiency. The nuclear chromatin is not as fine as in true megaloblasts, and a greater proportion of the erythroid precursors are more immature in most patients with erythroleukemia than in those with vitamin B_{12} or folate deficiency. Furthermore, bi- and trinucleated erythroblasts are more numerous in erythroleukemia than in patients with vitamin B_{12} and folate deficiency. Macroovalocytes and the changes in neutrophils characteristic of these vitamin deficiencies, such as hypersegmentation, giant metamyelocytes, and macropolycytes, are usually absent.

Hemophagocytic syndrome is rare and can be associated with viral infections and lymphoid neoplasia, particularly peripheral T-cell lymphoma [angiocentric T-/natural killer (NK) lymphoma and subcutaneous panniculitic peripheral T-cell lymphoma] (Fig. 72.2) ([37] , [79] , [80] and [81]). The mechanism of macrophage activation is unknown, but its presence is often associated with a poor prognosis.

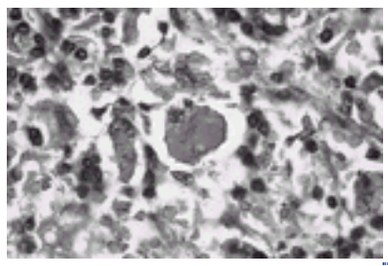

Figure 72.2. In the center of the field, two macrophages are stuffed with red blood cells (hemophagocytosis) in this high magnification view of spleen involved by a hepatosplenic ?d T-cell lymphoma (hematoxylin and eosin stain). See Color Plate. (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

Therapy for anemia in hematologic malignancy is directed at the underlying mechanism and disease. Transfusions should be used when required for control of symptoms and signs caused by the anemia. Studies may be indicated to rule out deficiency of iron, vitamin B_{12}, or folic acid as a cause of the anemia, but therapy with these agents as a routine procedure is of no benefit. Splenic irradiation may lead to reduction of anemia in patients with massive splenomegaly, but splenectomy is usually more effective. As noted previously, erythropoietin may improve the anemia caused by malignancy. In many cases, therapy for the underlying hematologic malignancy improves the anemia.

ORGAN INFILTRATION AND DYSFUNCTION

Infiltration of organs by tumor is one of the most important causes of morbidity in patients with hematologic neoplasms. However, asymptomatic tumor infiltration diagnosed at autopsy is much more common than symptomatic organ dysfunction during life (Fig. 72.3). Organ infiltration from leukemia, lymphoma, myeloma, and related conditions is, in general, less likely to be symptomatic than organ infiltration from carcinoma. Organs may also have impaired function from paraneoplastic phenomena.

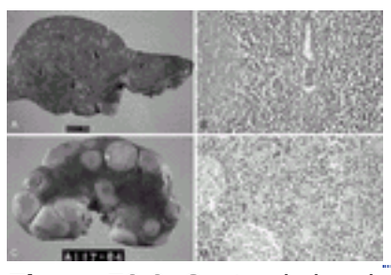

Figure 72.3. Systemic involvement of lymphoma at autopsy. **A:** Pale nodules of follicular small cleaved cell are present on the cut surface of the liver. **B:** Microscopically, the liver shows a pronounced periportal lymphocytic infiltrate that surrounds a residual bile duct (hematoxylin and eosin stain) (*upper center*). **C:** Numerous lymphomatous nodules are also present on the external surface of the kidney. **D:** Extensive interstitial lymphocytic infiltrates obliterate the renal tubules, whereas two residual glomeruli can be seen on the left (hematoxylin and eosin stain). See Color Plate. (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

Therapy for organ infiltration and dysfunction includes systemic chemotherapy; local therapies, including surgery, radiation, and topical therapy for skin lesions; or both. In diseases such as the ALs, HD, and the aggressive lymphomas in which the therapeutic goal is cure, therapy of symptomatic organ infiltration consists of systemic chemotherapy with or without local therapy. Therapies for specific neoplasms are discussed in Chapter 76, Chapter 77, Chapter 78, Chapter 79, Chapter 80, Chapter 81, Chapter 82, Chapter 83, Chapter 84, Chapter 85, Chapter 86, Chapter 87, Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93, Chapter 94, Chapter 95, Chapter 96, Chapter 97, Chapter 98, Chapter 99, Chapter 100 and Chapter 101. In diseases such as CLL or some low-grade B-cell lymphomas in which the therapeutic goal is often palliation, local therapy alone may be used. All of the hematologic neoplasms are sensitive to radiation; radiotherapy alone may be an excellent choice for cure of localized disease, particularly HD, or for palliation.

Intravascular Complications: Leukostasis and Intravascular Tumors

Two distinct entities can occur as a result of intravascular tumor cells. The first, termed *leukostasis*, is caused by “sludging” of leukemic cells in capillaries and is seen with extremely high white blood cell counts (hyperleukocytosis). This entity occurs in the leukemias. The second form occurs when tumor cells lodge and grow within vessels, which can lead to the formation of macroscopic tumors with secondary hemorrhage and thrombosis. Intravascular tumor may complicate AML and occurs in a rare form of NHL.

Increased serum viscosity without hypercellularity occurs in patients with increased quantities of monoclonal or polyclonal Igs. It complicates Waldenström macroglobulinemia, MM, and disease processes that are associated with polyclonal hyperglobulinemia such as human immunodeficiency virus (HIV) infection. The syndrome is usually manifested as bleeding or mental status abnormalities and is managed with plasmapheresis. Hyperviscosity is discussed in Chapter 98, Chapter 99 and Chapter 100.

Leukostasis is a common postmortem finding in patients with AML or CML. McKee and Collins divided the pathologic findings into leukocyte thrombi and leukocyte aggregates based on the presence of fibrin in the former ([82]). The lesions were present in 40% of patients with AML and in 36% of patients with CML. The lesions were far more common in patients with CML in blast phase (15 of 30) than in patients in chronic phase (2 of 17). The lesions of leukostasis were rare in patients with lymphocytic leukemias, being present in 3 of 33 CLL patients and 0 of 39 ALL patients. The most common sites of involvement in this autopsy series were lung and brain. A direct correlation between the leukocyte count and risk of leukostasis was found in the myeloid leukemias.

Leukostatic sludging is believed to be related to increases in blood viscosity (cellular hyperviscosity). The viscosity of whole blood increases markedly with extreme elevations of the leukocyte count. A leukocrit of 20 to 25% is required to increase whole blood viscosity (Fig. 72.4A). This requires approximately 400,000 to 600,000 myeloblasts/µl or 500,000 to 1,000,000 lymphoblasts or lymphocytes/µl because of the increased size of myeloblasts. In addition, the blasts in AML are less deformable than other cells and may therefore have an increased tendency to sludge in capillary beds ([83], [84]).

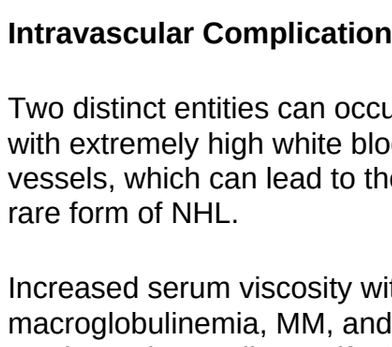

Figure 72.4. Hyperleukocytosis and leukostasis. **A:** An elevated leukocrit is present in this tube of centrifuged peripheral blood from a patient with T-cell acute lymphoblastic leukemia who had a peripheral blood blast count of 250,000/µl. **B:** Pulmonary alveolar capillaries are expanded by leukocyte aggregates indicative of leukostasis in a patient with acute myeloid leukemia (hematoxylin and eosin stain). **C:** Ring-enhancing lesions on magnetic resonance imaging were attributed to hemorrhage in a patient with chronic granulocytic leukemia, hyperleukocytosis, and blurred vision (T1-weighted image). See Color Plate.

Clinically, leukostasis is difficult to prove, and no agreed-on diagnostic criteria exist (Table 72.5). The symptoms are nonspecific and include dyspnea and hypoxemia from lung involvement (Fig. 72.4B) ([85], [86]). Hypoxemia, however, may be artifactual as a result of oxygen consumption by leukocytes *in vitro* ([87]). CNS involvement

may be manifested by headache, confusion, tinnitus, papilledema, ataxia, stupor, and obtundation and can progress to CNS hemorrhage and death (Fig. 72.4C). The syndrome should be suspected in patients with any of these symptoms and a blast count of greater than 50,000/µl.

TABLE 72.5. Management of Leukostasis

Leukostasis should be suspected in leukemia in descending order of diagnosis: most prevalent in acute myelocytic leukemia, then in chronic myelocytic leukemia, then in acute lymphocytic leukemia, and least prevalent in chronic lymphocytic leukemia.
Blasts are usually over 50,000/µl.
Symptoms of lung or brain involvement are medical emergencies.
Allopurinol and hydration should be initiated.
Red cell transfusions should be minimized early to avoid increasing viscosity.
The white count should be decreased rapidly.
If asymptomatic, hydroxyurea can be used.
If symptomatic or if blasts are markedly elevated, consider leukapheresis; platelet transfusions will be needed.
Initiate chemotherapy as soon as possible.

The syndrome is best prevented by institution of emergency therapy for hyperleukocytosis. In asymptomatic patients, hydroxyurea is generally used. This antimetabolite rapidly lowers the leukocyte count and whole blood viscosity ([88], [89] and [90]). For symptomatic patients, leukapheresis has been used. It has the advantages of having immediate onset of action and of not inducing the acute tumor lysis syndrome (ATLS) for which patients with hyperleukocytosis are at risk ([91], [92] and [93]). Nevertheless, some centers manage such patients conservatively with good results ([94]). Definitive antileukemic therapy should be initiated as soon as possible. Transfusions of red blood cells should be avoided, as they may increase whole blood viscosity and worsen the syndrome ([95]). However, if the patient is thrombocytopenic, platelet transfusions are warranted, as platelets are removed during leukapheresis.

It is unclear how to manage patients with CLL and hyperleukocytosis. Symptomatic leukostasis is rare, and some patients may have hyperleukocytosis without other indications for therapy. Baer and co-workers reported three cases of cellular hyperviscosity among 16 patients with CLL and a sustained leukocyte count of more than 500,000/µl ([96]). Thus, it may be reasonable to institute cytoreductive therapy for patients with CLL and a leukocyte count of more than 500,000/µl.

Intravascular formation of tumors is currently rare; they occurred more frequently before the introduction of effective therapies for leukemia. The most common presentation is massive intracranial hemorrhage from intracranial tumors. A sharp rise in the leukocyte count appears to be associated with the presence of this syndrome. The formation of such tumors seems to be more common in monoblastic leukemia, in which they may occur without hyperleukocytosis ([97]).

Symptoms from intravascular tumor may also occur in NHL. *Angiotropic large cell lymphoma* is a large B-cell lymphoma that has also been called *malignant angioendotheliomatosis*, *intravascular lymphomatosis*, and other names. It consists of malignant large B lymphocytes within vessels (Fig. 72.5). The clinical manifestations are protean and result from vascular occlusion or thrombosis. Neurologic or pulmonary symptoms and skin lesions are the most common presenting features. This entity may present as fever of unknown origin. Most cases are diagnosed postmortem, but there are reports of response to systemic chemotherapy ([98], [99], [100], [101] and [102]).

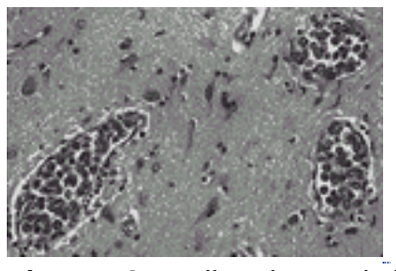

Figure 72.5. Dilated vessels in the brain are filled by intravascular lymphoma in a patient with angiotropic large B-cell lymphoma (hematoxylin and eosin stain). (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

Neurologic Complications

Neurologic complications are common in hematologic malignancies. Here, involvement of the meninges, brain, and spinal cord are discussed as are rare paraneoplastic phenomena.

MENINGEAL INVOLVEMENT The meninges are a common site of involvement in hematologic neoplasms, including ALL, AML, and NHL ([103], [104], [105] and [106]). The clinical syndrome produced is generally related to increased intracranial pressure: headache, lethargy, nausea, and vomiting. As this meningeal syndrome progresses, papilledema and signs and symptoms of meningeal irritation, such as stiff neck and Kernig and Brudzinski signs, develop. Seizures and altered mental status are late sequelae. This constellation of symptoms in conjunction with involvement of the meninges has been called the *meningeal syndrome* and is in contrast to many patients with AL who have meningeal involvement without symptoms at diagnosis. Cranial nerve palsies are present in approximately 20% of patients with clinical meningeal syndrome ([107]). Involvement of the trigeminal nerve can lead to the “numb chin syndrome.” Unusual syndromes have been reported that are likely related to involvement of the hypothalamus. These include hyper-phagia and obesity as well as abnormalities of insulin and growth hormone secretion ([108], [109]). The CNS is a “sanctuary” into which most drugs penetrate poorly, and isolated meningeal relapses may occur even after aggressive systemic therapy ([110]). In ALL and, to a lesser degree, in AML and NHL, prophylactic therapy is used to prevent isolated meningeal recurrence. Specific strategies include the use of intrathecal chemotherapy, cranial or craniospinal radiation, and high-dose chemotherapy designed to penetrate into the cerebrospinal fluid (CSF). Meningeal involvement is common in ALL and may be present at diagnosis or at any time in the course of the disease. In the late 1960s, Evans and co-workers described a 3.8% per month incidence during the first year that decreased to 2% over the second and third years (110a). Pavlovsky and colleagues reported that the risk of meningeal involvement was similar in age-matched patients with AML and ALL ([111]). Meningeal involvement was found in 7 of 39 newly diagnosed patients with AML who had a lumbar puncture (LP) as part of routine evaluation; of note, all seven had acute myelomonocytic leukemia ([112]). Acute myelomonocytic leukemia, particularly when eosinophilia and an inversion of chromosome 16 are present, appears to have a high incidence of meningeal involvement ([113], [114]). The use of high-dose cytarabine (ara-C) consolidation appears to decrease this occurrence ([115]). Infiltration of the meninges occurs in certain types of NHL ([105], [116], [117]). CNS involvement is associated with high-grade lymphomas and extranodal disease ([118]). It is particularly common in T-cell lymphoblastic lymphoma ([119], [120]); small, noncleaved “Burkitt-like” NHL; and Burkitt lymphoma. CNS prophylaxis is generally a component of therapy for these diseases (Chapter 89). In a case series at the National Cancer Institute, meningeal involvement has been reported in 24% of patients with small, noncleaved “Burkitt-like” lymphoma ([121]). Meningeal disease may occur in association with Burkitt lymphoma even when the disease is limited to the jaw ([122]). The incidence of meningeal involvement in mantle-cell lymphoma is variable ([123], [124] and [125]). Although meningeal involvement is less common with other types of NHL, sinus and testicular NHLs have a higher predilection for meningeal spread at either diagnosis or relapse ([115], [116]). Lymphomatous involvement of the meninges is common in patients with HIV infection ([126], [127] and [128]) or in posttransplant lymphoproliferative disorders ([129]). This is likely also true of HIV-infected patients with HD ([130]). Other hematologic neoplasms occasionally involve the meninges. CML in chronic or, more commonly, blast phase can involve the meninges ([131], [132]). Meningeal involvement appears to be more common in the lymphoid form of blast phase ([133], [134]). It is rare that MM and plasma cell leukemia ([135], [136]), CLL ([137]), and HD ([130]) have meningeal involvement. The diagnosis of meningeal involvement with a hematologic neoplasm is made by LP and examination of the spinal fluid. LP should be performed early in patients at risk or who have symptoms of the meningeal syndrome. In thrombocytopenic patients, there is a small risk of hematoma complicating LP, and platelet transfusion immediately before the procedure is recommended. It is reasonable to instill methotrexate (MTX) or ara-C at the time of LP in patients suspected of having the meningeal syndrome to avoid the need for

repeat LP if cytology returns positive. The demonstration of tumor cells in spinal fluid by cytology proves meningeal involvement. The sensitivity is enhanced by the use of centrifugation of the CSF ([138]). More recently, immunophenotyping techniques have been investigated ([139] , [140]). In particular, staining for terminal deoxynucleotidyl transferase is helpful in distinguishing reactive from leukemic lymphocytes in ALL ([140] , [141]). Metaphase cytogenetics have also been performed on CSF samples. The classic criteria for diagnosis of meningeal leukemia are a CSF cell count of greater than 5 cells/mm ^{3} and presence of a recognizable blast form on a cytospin preparation. A more refined definition of CNS leukemia classifies CSF into three categories ([142]). *CNS1* indicates a clear CSF. *CNS3* represents unequivocal CSF leukemia. *CNS2* is defined by presence of a blast cell with a total cell count of less than 5 cells/mm ^{3}. The presence of blasts even with a cell count of fewer than five white blood cells (CNS2) indicates a risk for future meningeal involvement; conversely, some patients with fewer than ten blast cells on a routine LP and a history of leukemic meningitis do not go on to develop clinically apparent leukemic meningitis ([143] , [144]). In ambiguous cases, an LP should be repeated in 1 to 2 weeks. The diagnosis of meningeal involvement is usually straightforward, but several difficult situations may occur. One such situation arises when meningeal malignancy and infection occur simultaneously. Also, the diagnosis of meningeal leukemia in patients with a past history of meningeal involvement is difficult ([145]).
Therapy for patients with meningeal involvement of a hematologic malignancy depends on the clinical situation. The goal may be either temporary control or complete eradication of meningeal involvement. High-dose systemic chemotherapy (usually with ara-C or MTX) and craniospinal radiation are useful in eradicating meningeal disease. They are discussed in Chapter 78 as they relate to ALL. The same principles may be applied to other diseases. Here, we discuss intrathecal therapy designed to control local symptoms. The mainstay of therapy for the meningeal syndrome involves instillation of chemotherapeutic agents directly into the CSF ([146] , [147]). The most widely used agent is MTX, although other antimetabolites, such as ara-C and 6-mercaptopurine, steroids, and the alkylating agents diaziquone ([148]) and thiotepa ([149]), have all been studied. Intrathecal dexamethasone can rapidly improve symptoms, presumably via an antiinflammatory effect. It may be a good choice for patients with refractory disease for whom short-term palliation is the goal of therapy. Intrathecal MTX should be injected slowly after an atraumatic LP. Immediately after the injection, the patient should be placed supine with the foot of the bed elevated to improve drug distribution ([150]). The drug should be sterile and in a saline or balanced salt solution. Preservative-free drug is generally used, but the advantage of this approach, if any, is unclear. Clinicians should be extremely vigilant when administering intrathecal agents so as to avoid overdose. More recently, a sustained release preparation of ara-C (DepoCyt) has been approved for treatment of neoplastic meningitis. It is given at a dose of 50 mg, intrathecal or intraventricular, every 2 weeks. Pharmacokinetic studies have shown therapeutic concentrations of ara-C in excess of 14 days. An open-label study in 110 patients with neoplastic meningitis who were treated for 1 month showed a response rate comparable to twice weekly intrathecal MTX. The adverse effects were low grade and transient and included headache and arachnoiditis ([151]). Agents administered intrathecally are distributed to the CNS. The volume of CNS varies with age rather than body size, so age- rather than body surface area–based dosing is appropriate for intrathecal drugs (Table 72.6) ([152]). There is no advantage to increasing the dose of MTX beyond 12 mg.

TABLE 72.6. Pharmacokinetically Derived Dosing Schedules for Intrathecal Methotrexate

Age (yr)	Dose (mg)
<1	6
1	8
2	10
=3	12

Neither the optimal schedule nor the route (lumbar or intraventricular) of MTX is known, nor is the role of combination therapy such as “triple therapy,” consisting of a steroid, MTX, and ara-C ([153]). MTX given every 2 or 3 days induces a CSF remission in most patients; however, relapse is often a problem ([154]). Although there is no clear proof of its superiority, most patients with meningeal involvement with a hematologic neoplasm receive intraventricular therapy via an Ommaya reservoir ([155]). This is better tolerated by patients and allows a more reliable and consistent CSF level of MTX. Care should be taken to avoid complications of the Ommaya reservoir ([156]). The procedure should be done under sterile conditions to avoid infections. Perioperative antibiotic use is important to prevent infections. Positioning of the reservoir is important to prevent intraparenchymal delivery of chemotherapy, which can lead to leukoencephalopathy. Most centers use single-agent MTX given twice weekly until all leukemic cells have cleared. The CSF protein concentration generally remains elevated. It is reasonable to give continued intrathecal therapy, craniospinal radiation, or high-dose systemic consolidation to those patients whose systemic disease is controlled. Toxicity is common after administration of intrathecal chemotherapy, although it is difficult to determine whether drug or disease cause a particular complication. Toxicities have been reported with MTX, ara-C, and intrathecal drugs combined with radiation. A transient, mild arachnoiditis is common ([157]). It may be associated with headache, nausea, and vomiting; reversible paresis and paraplegia have been reported. Severe and sometimes irreversible toxicities, including dementia, seizures, coma, and death, have been reported but are less common. A mild syndrome of fever and somnolence may occur 5 to 7 weeks after intrathecal therapy ([157]). Myelosuppression may occur after intrathecal chemotherapy, particularly in patients with renal failure. The risk of leukoencephalopathy is higher in older patients who have received brain irradiation.

BRAIN INVOLVEMENT The most common cause of brain masses in hematologic malignancy is NHL; intracerebral tumors related to hyperleukocytosis in AL were discussed previously. The lesions may occur in association with systemic lymphoma or may be primary CNS lymphomas. Primary CNS lymphoma is common in patients who are immunodeficient; this can be either iatrogenic (e.g., after organ transplantation) or related to HIV infection. The frequency of primary CNS lymphoma appears to be increasing rapidly in both immunocompromised and immunocompetent patients ([158]). Although rare, parenchymal brain masses have been reported in HD and MM.

Spinal Cord Compression Impingement of the spinal cord with associated neurologic signs or symptoms is a true medical emergency (Table 72.7). It can occur when a hematologic neoplasm involves the cord, meninges, dura, or a vertebra with compression of the cord. This complication occurs often in patients with MM and is not uncommon in patients with NHL and HD. Lymphoma is a common cause of spinal cord compression in children ([159]). Leukemia is a rare cause; a 1981 review of spinal cord involvement in leukemia found only 70 well-documented cases ([160]), although others have since been reported. Cord compression has resulted from extramedullary hematopoiesis. Cord compression may occur at any time in the course of a hematologic malignancy.

TABLE 72.7. Management of Spinal Cord Compression

The diagnosis should be suspected in patients who have multiple myeloma or non-Hodgkin lymphoma.
Pain and weakness are the most common symptoms; urinary incontinence and constipation occur later and confer a poor prognosis.
Leg weakness, hyperreflexia, and a Babinski reflex are common signs.
Total spine magnetic resonance imaging is the preferred imaging technique.
Steroids should be administered early, preferably as soon as the diagnosis is known.
Definitive therapy may involve surgery, radiation, and/or chemotherapy.

Pain is the most common symptom of cord compression in both adults and children. Pain that is not relieved when the patient is supine is particularly worrisome, as is pain with a radicular component. Weakness is the next most common symptom. It may be most often manifested as proximal muscle weakness preventing patients from ascending stairs or rising off the commode. Autonomic symptoms, such as urinary frequency, urgency, retention, or constipation, generally occur late in the course and are associated with a poor prognosis. Physical examination may reveal leg weakness; hyperreflexive deep tendon reflexes and a Babinski reflex may be present. Careful sensory examination may show a discrete sensory level. Patients with severe back pain or other symptoms suggestive of spinal cord compression should have an imaging procedure performed and appropriate referrals made rapidly. If the index of suspicion is high, then empiric corticosteroids may be administered before an imaging procedure, particularly if a patient is being transferred to a different facility; however, in cases without a known diagnosis, steroids may prevent or obscure the ability to make a tissue diagnosis because of necrosis. Magnetic resonance imaging has largely replaced myelography and computed tomography (CT) scanning as the imaging procedure of choice (Fig. 72.6) ([161] , [162]). Ideally, magnetic resonance imaging should image the entire spine, as multiple areas of compression are possible ([163]). Of note, plain radiographs are quite insensitive for detecting cord compression caused by lymphoma ([159]).

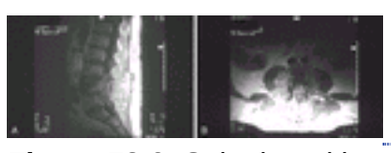

Figure 72.6. Spinal cord involvement shown by magnetic resonance imaging. **A:** Epidural mass on sagittal view is posterior to L4 and L5 vertebral bodies with invasion of the spinal canal (T1-weighted image). **B:** On axial view, the mass involves the L4 vertebral body, surrounds the thecal sac, and elevates the inferior vena cava and aorta (T1-weighted image). The diagnosis by biopsy was Hodgkin disease. (Courtesy of Dr. Kathleen Helton, Department of Radiology, Vanderbilt University School of Medicine, Nashville, TN.)

Therapy for cord compression consists of supportive measures, including corticosteroids (generally dexamethasone), and definitive therapy to shrink or remove the compressing tumor. The optimal dose and value of dexamethasone are controversial. High-dose therapy has been associated with increased life-threatening gastrointestinal complications ([164], [165]). A dexamethasone schedule of 10- to 100-mg initial bolus followed by at least 16 mg daily has been recommended ([166]). In patients with aggressive lymphomas, ATLS may occur after dexamethasone therapy (*vide infra*). After diagnosis and administration of dexamethasone, radiation and surgery are the mainstays of therapy. Surgery is the modality of choice for patients without a previous diagnosis of malignancy, as it allows tissue sampling while relieving cord compression; it can also be used for areas that have been previously irradiated. Hematologic neoplasms are largely radiosensitive, and radiation should be part of initial therapy for most patients with cord compression. As cord compression is a sign of progressive disease or relapse, chemotherapy is often used after radiation. In patients with highly chemotherapy-sensitive tumors who present with cord involvement, chemotherapy may be used alone ([167]). Patients with myeloma or lymphoma have a good prognosis even if they present with cord compression. Many will be alive with no functional impairment 5 years after diagnosis if treated appropriately.

OTHER NEUROLOGIC SYNDROMES Peripheral neuropathies may occur in a variety of hematologic neoplasms. They are most common in monoclonal gammopathies ([168], [169] and [170]). It appears that, in many of these disorders, an IgM monoclonal protein binds to myelin-associated glycoprotein causing a demyelinating neuropathy ([168], [171]). A similar neuropathy may be seen in patients whose paraprotein forms a cryoglobulin. These neuropathies may respond to plasmapheresis. Peripheral neuropathy has long been recognized as a complication of osteosclerotic myeloma ([172], [173]). This neuropathy seems to respond well to chemotherapy for myeloma ([173]). Peripheral neuropathy can occur in NHL and HD ([174], [175]). Vital et al. have described eight distinct types of lymphoma-associated neuropathy ([176]). Peripheral neuropathies have also been reported in leukemia ([175]). The most common cause of peripheral neuropathy in patients with hematologic neoplasms is chemotherapy-induced toxicity ([177]). Other rare, neurologic complications can occur. Granulomatous angiitis of the CNS has been reported in patients with HD ([178]); the otherwise fatal disorder has responded to chemotherapy. Progressive multifocal leukoencephalopathy, which is common in HIV infection and other immunosuppressive conditions, has occurred in patients with hematologic neoplasms ([179]).

Ocular Complications

The orbit and globe are uncommon but important sites of involvement by hematologic neoplasms. As in the case of the meninges, the eye is a sanctuary into which chemotherapy penetrates poorly ([180]) and can be the sole site of relapse in ALL ([181]) or AML ([182]). Autopsy studies suggest that subclinical involvement of the eye with AL is common and correlates with the peripheral blood count ([183]). Eye involvement has been reported in a variety of other hematologic neoplasms, including HD, MM, and CML ([184], [185] and [186]).

However, NHL is the hematologic malignancy that most commonly involves the eye. Although various aggressive NHL types have been described ([187]), the most common ocular lymphocytic infiltrates are low grade ([188], [189]). There has been some controversy about the classification of these lymphoid infiltrates. Medeiros et al. have performed a careful analysis of 61 patients with lymphocytic infiltrates of the orbit or conjunctiva. Using histology alone, they were able to identify 20 patients with definite low-grade malignant lymphoma, 14 patients with a definite benign, inflammatory infiltrate, and 27 patients with an indeterminate infiltrate. Twenty of these infiltrates had monotypic Ig expression and were classified as low-grade lymphoma. A correlation existed between evidence of clonality and the likelihood of dissemination and death ([190]). More recently, it has become apparent that many of these low-grade lesions should be classified as marginal zone lymphomas of the mucosa-associated lymphoid tissue (MALT) type ([191], [192]) using the International Lymphoma Study Group classification system ([193]), which has been adopted by the World Health Organization classification. Ocular lymphoma may complicate HIV infection ([194], [195]) or organ transplantation. Therapy of ocular lesions involves radiation with or without chemotherapy. Patients with high-grade lymphomas should usually receive chemotherapy and often have a poor prognosis ([196]).

Head and Neck Involvement

The other organs of the head and neck are rarely involved by hematologic neoplasms, with several exceptions. The gums are typically involved by FAB M4 and M5 AML (Chapter 79). There is a distinct clinicopathologic entity of nasal lymphoma ([197], [198]). This is a NK- or T-cell lymphoma that frequently expresses the NK cell–associated antigen CD56, often has angiocentric histology, and is associated with Epstein-Barr virus infection ([199], [200]). Many cases of “midline granuloma” likely were, in fact, cases of this entity ([201]). The ideal treatment strategy is unknown but usually involves chemotherapy and radiation ([202]). B-cell lymphomas may also involve the mouth, nose, or paranasal sinuses ([203]). Waldeyer ring is a common site of involvement by both T/NK-cell and B-cell lymphomas, including mantle-cell lymphoma, and by lymphomas involving the stomach ([204], [205]).

Other rare complications include reports of rhinophyma, hearing and vestibular dysfunction, sinus involvement, and upper airway obstruction ([206]) as complications of hematologic neoplasms. Patients with Sjögren syndrome may develop lymphomas of the MALT type in their salivary glands ([207], [208]). Lymphoma may also complicate autoimmune (Hashimoto) thyroiditis ([209], [210]).

Thoracic Complications

LUNG INVOLVEMENT Involvement of the lung is relatively common in patients with HD and NHL ([211]). Filly et al. described radiographic evidence of parenchymal disease in 11.6% of HD patients and in 3.7% of NHL patients at the time of diagnosis ([212]). Diehl et al. have demonstrated that the spread of HD in the thorax occurs in a stepwise manner from the mediastinal nodes to the hilar nodes and then to the lung parenchyma either by direct extension or hematogenously with the development of nodules ([213]). Secondary involvement with NHL is less predictable. Primary pulmonary HD is rare and generally has a nodular appearance on chest radiograph ([214]). Although more common than primary pulmonary HD, primary pulmonary NHL is also a rare disorder. Furthermore, various disorders that had been previously classified as “pseudolymphomas” are now considered malignant lymphomas; MALT lymphoma and lymphomatoid granulomatosis (principally a B-cell process) are examples ([215], [216] and [217]). Cordier et al. described 70 cases of primary pulmonary lymphoma that they classified according to the updated Kiel classification. They reported 61 cases of low-grade and 9 cases of high-grade NHL; the rare high-grade lesions had markedly worse prognoses ([218]). Lung involvement is common in patients with HIV-associated lymphomas ([219]). Radiographically, NHL and HD can be nodular, bronchovascular-lymphangitic, or pneumonic-alveolar in appearance. Nodularity is the most common presentation ([211]). Many patients with NHL or HD of the lung are asymptomatic, and their disease is discovered only on a routine radiograph or CT scan. However, cough, chest pain, fever, hemoptysis, and dyspnea may all be presenting features ([214], [218], [219]). Patients with leukemia are at risk for a variety of pulmonary complications ([220]). Pulmonary symptoms in AL with hyperleukocytosis were discussed previously. A diffuse, interstitial process has also been described in the absence of leukocytosis ([221]). Alveolar proteinosis may occur in myeloid malignancies ([222]). Pulmonary hemorrhage may be a cause of diffuse infiltrates ([223]). Lung involvement in other hematologic neoplasms is rare. Other pulmonary diseases may occur in patients with hematologic neoplasia. Pulmonary embolus occurs even in thrombocytopenic patients. Alveolar deposition of paraproteins has been reported to cause respiratory failure ([224]). The most common pulmonary complication in patients with hematologic neoplasms is infection with bacterial or opportunistic pathogens. Patchy or focal infiltrates are likely to be bacterial, whereas diffuse infiltrates are likely to be caused by opportunistic infections. Management of pulmonary abnormalities depends on the entire clinical picture, including whether the underlying neoplasm is controlled. Patients with signs and symptoms that suggest bacterial infection can be treated presumptively. Those in whom the diagnosis is uncertain and for whom management depends on precise data should undergo bronchoscopy, open lung biopsy, or both.

SUPERIOR VENA CAVA SYNDROME The superior vena cava syndrome (SVCS) occurs when this central vessel is compressed, invaded, or thrombosed, leading to occlusion of venous flow. The resultant clinical syndrome consists of facial edema, plethora, cyanosis, and venous distention. Tachypnea and headache may occur. In the first part of the twentieth century, aortic aneurysms and tuberculous mediastinitis were the most common etiologies. However, although benign entities continue to occasionally cause SVCS, in the second half of the twentieth century, malignancies became the most common cause ([225], [226]). As a cause of SVCS, NHL trails only lung cancer in incidence (Fig. 72.7). Of a total of 915 cases of NHL seen at the M.D. Anderson Cancer Center, 3.9% were associated with SVCS at presentation ([227]). Classified according to the Working Formulation ([228]), 23 patients had diffuse large-cell lymphoma (7% of all diffuse large-cell lymphoma patients), and 12 patients had lymphoblastic lymphoma (21% of lymphoblastic lymphoma patients). One patient with follicular large-cell lymphoma had SVCS. No patients had SVCS among the 474 other patients with follicular or small lymphocytic lymphoma, indicating that this is a rare occurrence in patients with low-grade NHL. The presence of SVCS in patients with low-grade NHL should prompt a search for other causes such as lung cancer or infection.

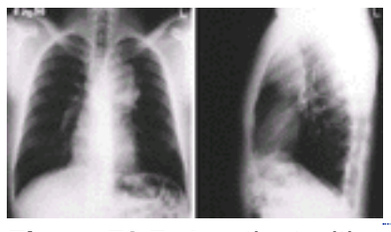

Figure 72.7. A patient with anterior mediastinal mass due to large B-cell lymphoma developed superior vena cava syndrome. Hematologic neoplasms associated with superior vena cava syndrome include lymphoblastic lymphoma, Hodgkin disease, and large B-cell lymphoma.

It is likely that many patients with SVCS who had diffuse large-cell lymphoma according to the Working Formulation would be reclassified as having primary mediastinal (thymic) B-cell lymphoma in the World Health Organization classification. This entity is often associated with SVCS ([229], [230]); therapy is controversial but generally consists of combination chemotherapy with or without radiation. Although results have been variable, adults with primary mediastinal B-cell lymphoma can have a good prognosis, with approximately 50% of patients achieving long-term disease-free survival ([231], [232]). In the pediatric population, SVCS is unusual. When SVCS caused by an underlying malignancy occurs in children, lymphoma is the most common cause, followed by ALL and HD ([233]). Although almost all children with mediastinal NHL have lymphoblastic lymphoma, a minority has primary mediastinal B-cell lymphoma. Prognosis for these children is good. SVCS from other hematologic neoplasms is rare but has included extramedullary myeloid tumor/granulocytic sarcoma (AML), malignant histiocytosis, angioimmunoblastic lymphadenopathy with dysproteinemia, and plasmacytoma. An increasingly common cause of SVCS in patients with hematologic neoplasms is thrombosis related to indwelling catheters. Therapy consists of anticoagulants and thrombolytics ([234]). Thrombosis can also complicate malignant obstruction of the superior vena cava ([235]). Although discussions of SVCS are often included under the title “oncologic emergencies,” recent reviews have emphasized the fact that life-threatening complications of SVCS are exceedingly rare (Table 72.8) ([236]). Thus, the focus of management has shifted from empiric radiation therapy to careful diagnostic evaluation. Physical examination should focus on potential sites of extrathoracic disease that may be suitable for biopsy. CT scanning has largely replaced venography as the imaging modality of choice. Although there is a concern about invasive procedures, particularly mediastinoscopy, in patients with SVCS, these procedures are, in fact, quite safe even in areas of high venous pressure ([237]).

TABLE 72.8. Management of Superior Vena Cava Syndrome (SVCS)

Accurate diagnosis and specific therapy are necessary for the optimal care of the patient who presents with SVCS. The following is a diagnostic approach to a patient who presents with SVCS.
Assessment of respiratory status. Radiation therapy should not be given empirically except for the <5% of patients who are in extremis at presentation. Steroids should be avoided until diagnosis is made.
History and physical examination. The examination should be focused on identifying extrathoracic sites for diagnostic biopsies, including the peripheral lymph nodes and testes.
Laboratory studies. A complete blood cell count and routine chemistries, including liver tests, should be obtained. A serum ß human chorionic gonadotropin and a-fetoprotein should be obtained in young men. The peripheral blood should be examined for lymphoblasts.
Appropriate imaging studies. All patients should have a chest radiograph, and most should have a chest computed tomography scan. Imaging studies of the abdomen should be obtained as dictated by the above studies.
Extrathoracic biopsies. Biopsies of extrathoracic sites found by the above studies should be taken (e.g., excisional lymph node biopsy of a palpable node). Bone marrow aspiration and biopsy should be performed on patients with cytopenias.
Mediastinoscopy and/or thoracoscopy. A thoracic surgeon should evaluate patients who do not have a definitive diagnosis.

Thus, management of SVCS should focus on prompt diagnosis and specific therapy. Many patients with a hematologic neoplasm as the etiology of their SVCS have a chance to be cured with combination chemotherapy.

PLEURAL EFFUSION Pleural and peritoneal effusions are common complications in patients with advanced HD or NHL ([238]), particularly in children (Fig. 72.8). Effusions and pleural involvement from tumor have been reported in patients with AL ([239]), CLL, CML, HCL, Waldenström macroglobulinemia, and MM ([240]). Recently, a primary body cavity–based NHL has been described in patients with HIV infection. It presents as a serous effusion, has immunoblastic or anaplastic large cell cytology and a B-cell immunophenotype, and is associated with infection with human herpesvirus type 8 (Kaposi sarcoma–associated human herpesvirus 8) ([241], [242]). Another primary pleural lymphoma occurs in patients with long-standing tuberculous pyothorax. These so-called pyothorax-associated lymphomas are associated with Epstein-Barr virus infection and appear to arise in the setting of a polyclonal B-cell reaction ([243]).

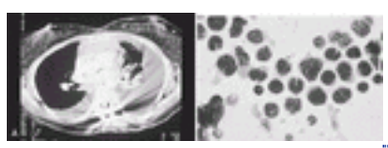

Figure 72.8. A large left pleural effusion and smaller right pleural effusion can be seen in this computed tomography scan from a patient who also has a large anterior mediastinal mass **(A)**. Pleural fluid cytology (Papanicolaou stain) shows numerous convoluted lymphoblasts characteristic of T-cell lymphoblastic lymphoma, a diagnosis confirmed by flow cytometric phenotypic analysis of the effusion **(B)**. See Color Plate. (Courtesy of Dr. Michael T. Lomis, Department of Pathology, Vanderbilt University School of Medicine, Nashville, TN.)

In a series of patients with pleural effusion complicating lymphoma, 17 of 19 had evidence of pleural involvement, suggesting that direct involvement rather than obstruction of pleural lymphatics or the thoracic duct is the major mechanism of pleural effusion. Pleural fluid cytology, however, was diagnostic in only two patients, and many required thoracoscopic biopsy to obtain diagnostic material ([244]). The yield of pleural fluid cytology may be improved with immunophenotyping and molecular techniques. Care should be taken in making a cytologic diagnosis of HD as Reed-Sternberg–like cells have been described in the pleural fluid of a patient with pulmonary embolus and infarction ([245]). Management of malignant pleural effusions can be vexing. They generally recede if systemic disease is controlled. However, they can be a source of great discomfort to patients with refractory disease in whom the goal of therapy is to maximize comfort. Therapy for pleural effusions caused by hematologic neoplasms is similar to that for other malignant pleural effusions and ranges from repeated thoracentesis for palliation to aggressive measures like pleurodesis done bedside or under thoracoscopic guidance ([246], [247]).

Cardiac Complications

The most common cardiac complications in patients with hematologic neoplasms are related to therapy. These include pericarditis and premature coronary artery disease ([248], [249]) from mediastinal radiation (usually for HD), arrhythmias related to ATLS (*vide infra*), and chemotherapy-induced cardiomyopathy. Infiltration of the heart and pericardium by hematologic neoplasms is not an uncommon finding at autopsy ([250], [251]). However, it rarely causes symptoms.

Infiltration of the myocardium by amyloid fibrils with resultant diastolic dysfunction is common in patients with AL amyloidosis and is discussed in Chapter 99. Symptomatic infiltration of the myocardium or pericardium is occasionally seen in NHL ([252]). Cardiac lymphoma has been reported as a primary tumor and as a metastatic site in patients who are immunosuppressed secondary to HIV or organ transplantation ([253], [254] and [255]). Similar infiltrations of the heart may also occur, but quite rarely, in HD, leukemia, and plasmacytoma.

Infiltration of the pericardium is often asymptomatic, but cardiac tamponade, arrhythmias, or, rarely, myocardial rupture can be the clinical presentation. This can occur either at diagnosis or later in the course of the disease. A few patients have been reported in whom hematologic neoplasia led to a symptomatic stenosis of a coronary artery ([256], [257]).

Infiltration of the heart is generally diagnosed by echocardiography; magnetic resonance imaging and thallium scintigraphy may also be of value ([258]). A diagnosis of hematologic neoplasia can be made by pericardial fluid cytology or by endomyocardial biopsy ([259]), although the diagnosis may be elusive.

Nonbacterial thrombotic (marantic) endocarditis has occasionally been reported to complicate hematologic neoplasms ([260]). Eosinophilic (Löffler) endocarditis has been described in a number of patients with high peripheral blood eosinophil counts preceding the overt development of ALL ([261]). The eosinophilic endocarditis

resolved with therapy for ALL and appears to be prevented by the administration of hydroxyurea to patients with the hypereosinophilic syndrome. Löffler endocarditis has also been reported in patients with NHL and eosinophilia. High-output heart failure has been described in association with plasmacytic neoplasms ([262]).

Breast Involvement

Involvement of the breast occurs in NHL and may be the only site of detectable disease. The most common histology is diffuse large B-cell lymphoma, although other types, including MALT lymphomas, occur ([263] , [264] and [265]). Presentation is similar to carcinoma of the breast, and the lesions may appear similar on mammography. An accurate diagnosis is best accomplished by core needle biopsy. Treatment should be similar to that used for stage IE NHL of other sites.

Breast involvement has been reported to occur in AL, HD, and MM. However, breast masses in patients with a history of hematologic neoplasia should be considered a primary breast cancer until proven otherwise, particularly in women who received irradiation for HD ([263] , [264] and [265]).

Abdominal Complications

GASTROINTESTINAL COMPLICATIONS Symptomatic involvement of the esophagus is rare in hematologic neoplasms. It has been most commonly reported in NHL ([266] , [267] and [268]) and has also been reported in HD ([269] , [270]) and leukemia. Bronchoesophageal fistulae may occur ([270]). The stomach is the most common site of extranodal NHL, which is discussed in Chapter 90 and Chapter 91. Gastric involvement may occur in HD ([271]), granulocytic sarcoma ([272]), MM ([273]), and amyloidosis ([274]). The intestines are often involved by NHL (Fig. 72.9). Burkitt lymphoma often presents with abdominal pain, obstruction, and a mass involving the ileocecal region of the gastrointestinal tract. Two distinct entities in the World Health Organization classification scheme typically involve the small bowel. Intestinal T-cell lymphoma is a complication of gluten-sensitive enteropathy (nontropical sprue) and has been called *enteropathy-associated T-cell lymphoma*. Intestinal T-cell lymphoma can occur without a history of nontropical sprue. Immunoproliferative small intestinal disease or Mediterranean lymphoma is a B-cell process that is rare in the West. Mantle-cell lymphoma may present with lymphomatous polyposis of the colon, which can be mistaken for familial polyposis. These and other gastrointestinal NHLs are discussed in Chapter 90 and Chapter 91.

Figure 72.9. A large mass near the ileocecal valve produced symptoms of intestinal obstruction in a patient with small, noncleaved cell (Burkitt) lymphoma. See Color Plate. (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

The intestines may be involved with leukemia, HD, or myeloma. Ischemic bowel resulting from angiocentric T/NK-cell lymphoma has been described ([275]).
NEUTROPENIC ENTEROCOLITIS (TYPHLITIS) One of the most serious complications of intensive chemotherapy for hematologic malignancies is neutropenic enterocolitis (typhlitis) (Table 72.9). Clinically, the syndrome has been defined as fever, abdominal pain, and abdominal tenderness occurring in a neutropenic patient ([276]). Other authors include radiographic evidence of right-sided colonic inflammation in the clinical definition ([277]). The syndrome has become increasingly common, probably because of intensification of therapy ([277]). In an autopsy series of 37 children with neutropenic enterocolitis, 7 had cecal involvement alone, 13 had cecal and other intestinal involvement, and 10 had cecal involvement with scattered ulcerations throughout the gastrointestinal tract. The bowel wall consisted of a denuded mucosa with hemorrhagic necrosis ([278]).

TABLE 72.9. Management of Typhlitis

Typhlitis tends to occur in an acute leukemia patient with prolonged neutropenia.
Fever and abdominal pain are common symptoms. The abdomen is tender, and bowel sounds are decreased or absent.
Imaging studies (flat plate and upright of abdomen, computed tomography scan) often indicate right-sided colonic inflammation; the bowel wall may be distended, edematous, and have air within the wall. Free air indicates perforation.
Therapy should be individualized.
Administer broad-spectrum antibiotics and include anaerobic coverage; consider growth factors.
Nasogastric suction can be used to decompress the gastrointestinal tract.
Surgical consultation should be obtained early. An operation should be performed if perforation has occurred or if there is a question of necrotic bowel.

Neutropenic enterocolitis may be related to neutropenia of any cause but has most commonly been associated with AL. No association has been made with particular chemotherapeutic agents, although several recent reports have mentioned patients treated with taxanes ([279]), and ara-C may cause gastrointestinal toxicity ([280] , [281]). Although infection is believed to be the cause, this has not been proven pathologically ([282]). Neutropenic enterocolitis is a life-threatening complication; some have recommended immediate surgery for all patients ([283]), whereas others have reported good results with supportive therapy ([277]). Supportive treatment may be the best approach, with surgery reserved for patients who have evidence of bowel perforation or clinical deterioration.
SPLENIC INVOLVEMENT: SPLENOMEGALY AND SPLENIC RUPTURE The spleen is a common site of involvement with hematologic neoplasms. Splenomegaly with resultant abdominal fullness and pain as well as cytopenias may occur with direct involvement, or secondarily. The complications of splenomegaly can be improved with splenectomy or splenic irradiation ([284] , [285]). A life-threatening complication of splenic involvement is *spontaneous rupture*, which is defined as rupture of the spleen without trauma; it has also been called *pathologic splenic rupture* (Fig. 72.10). In 1981, Bauer et al. described 5 cases of splenic rupture at the University of Nebraska and reviewed 48 cases from the English language literature. Of these 53 cases, 11 had AML, 9 had ALL, 6 had CML, 6 had HD, 3 had CLL, and 1 patient was reported with MM, macroglobulinemia, and HCL. The survival rate was 38%, and no patient survived without surgery ([286]). Guth et al. used conservative management prospectively in an intensive care unit for 11 patients who had grade one to four spontaneous splenic rupture (i.e., those without a completely shattered spleen) ([287]) and who did not require numerous immediate transfusions. All 11 survived without operation, suggesting that nonoperative management may be appropriate for selected patients with contained splenic rupture ([288]). Spontaneous splenic rupture can occur at any time during the disease course, including at presentation.

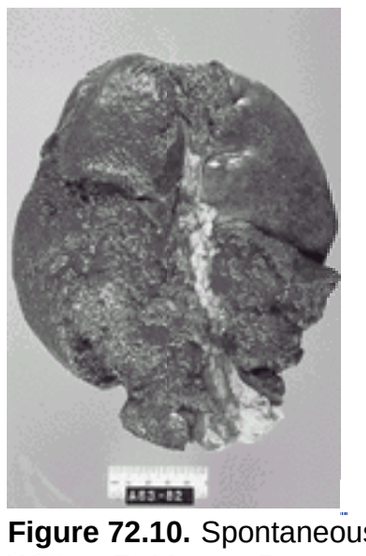

Figure 72.10. Spontaneous rupture of this friable spleen caused exsanguination of a patient with acute lymphocytic leukemia. See Color Plate. (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

HEPATIC COMPLICATIONS The liver is commonly involved by hematologic neoplasms, but patients rarely die from liver disease. NHL and HD may involve the liver.

The prognosis depends on histology and overall staging and is not adversely affected based only on liver involvement. Liver disease is rare in MM but has been reported ([289]). Thrombosis of the portal vein leading to portal hypertension and bleeding esophageal varices is a potential complication of myeloproliferative and lymphoproliferative disorders ([290]). Hepatic vein thrombosis and the Budd-Chiari syndrome may also complicate myeloproliferative disorders ([291]) or lymphoid malignancies ([292]). If feasible, patients with Budd-Chiari syndrome caused by a myeloproliferative disorder can be considered for orthotopic liver transplantation. Molecular or cell culture techniques to study erythroid colony formation *in vitro* suggest that a high percentage of patients with "idiopathic" hepatic or portal vein thrombosis have an occult myeloproliferative disorder ([291]).

RENAL COMPLICATIONS Renal complications are common in MM and in other diseases associated with paraproteins. These are discussed in Chapter 96, Chapter 97, Chapter 98, Chapter 99, Chapter 100 and Chapter 101. The kidneys may be infiltrated by leukemias or lymphomas. However, fewer than 10% of patients with kidney infiltration at autopsy had renal impairment in life. Renal failure may accompany ureteral obstruction from NHL or HD. Enlarged kidneys may occur in patients with leukemia even after successful therapy and do not correlate with disease activity. Renal failure associated with the tumor lysis syndrome, urate nephropathy, and hypercalcemia is discussed later in the chapter. Nephrotic syndrome and glomerulonephritis may occur in conjunction with a variety of hematologic neoplasms. The association of nephrosis and HD is a well-established paraneoplastic syndrome ([293]). Most patients have minimal-change (nil) disease on renal biopsy. The renal lesion often precedes the diagnosis of HD and is steroid resistant. Successful therapy for HD generally leads to resolution of nephrosis. Patients with CLL or small lymphocytic lymphoma may present with membranoproliferative nephrotic syndrome and glomerulonephritis, generally in association with a paraprotein or cryoglobulin ([294]). The association of nephrotic syndrome and glomerulonephritis with other hematologic malignancies is less clear.

UROLOGIC AND GYNECOLOGIC COMPLICATIONS Infiltration of the prostate with resultant urinary retention may occur in lymphoma or leukemia. Priapism can complicate the leukemias (especially CML) or myeloma. Lymphoma has been reported to involve almost any part of the female genital tract, including the ovaries, uterus, and vulva. Leukemias, myeloma, or HD may also involve the female genital tract. The testes are commonly involved with hematologic neoplasms. Like the CNS, the testes are sanctuaries into which chemotherapy penetrates poorly; they can be the sole site of relapse in ALL ([295]) or AML ([296]). Initial testicular involvement in ALL may portend a poor prognosis ([297]). The testicles can also be involved by NHL, which is the leading cause of testicular enlargement in elderly men. In the Danish Lymphoma Study Group database, 39 of 2687 cases of NHL had testicular involvement. Twenty-four of these 39 had disease limited to the testicle. Most patients had diffuse large B-cell lymphoma. Combination chemotherapy appeared to be beneficial as adjunctive therapy in localized disease. The value of this approach is supported by data from the University of British Columbia in Vancouver ([298]). Patients with testicular lymphoma should have a CT scan of the abdomen to rule out retroperitoneal lymph node involvement. Patients with disseminated disease at presentation and testicular involvement appear to have a poor prognosis because they are at risk for both CNS and late, contralateral testicular relapses ([299]). Patients with testicular lymphoma should receive CNS prophylaxis with intrathecal chemotherapy and radiation to the contralateral scrotal contents.

Skin Involvement

The skin can be involved by NHL as a primary site or secondary to previously documented nodal/extranodal or marrow involvement. Cutaneous T-cell lymphoma (Chapter 94) and cutaneous-only anaplastic large cell lymphoma (typically anaplastic large cell kinase expression–negative) tend to be indolent. More recently, primary cutaneous B-cell lymphoma (no extracutaneous involvement) has been described. The prognoses of these depend on the histology. Many of the therapeutic modalities primarily used for patients with cutaneous T-cell lymphoma, such as topical chemotherapy or electron beam radiation, may be of use in palliating patients with skin involvement from other hematologic neoplasms.

Infiltration of the skin may occur in the ALs and the lymphomas, and it is rare in myeloma and HCL. Most skin lesions in patients with these neoplasms are infectious or reactive in nature. Extramedullary hematopoiesis has been reported to cause skin lesions ([300]). Skin involvement in systemic HD is rare; it complicated the course of only 0.5% of 1844 patients seen between 1944 and 1977 at the M.D. Anderson Cancer Center ([301]). Primary cutaneous involvement is extremely rare when methods are used that can exclude CD30-positive T-cell cutaneous lymphomas.

Cutaneous eruptions are fairly common in patients with leukemia. These can be divided into hemorrhagic lesions, infectious lesions, reactive or paraneoplastic lesions (e.g., Sweet syndrome), drug reactions, complications of bone marrow transplant, and leukemia cutis. Desch and Smoller reviewed 123 skin biopsies performed on patients with leukemia ([302]). Leukemia cutis was present in 37 of the biopsies (30%), and 23 of these patients had AML or MDS. Of note, however, was the fact that most patients who had skin biopsies with AML had a cutaneous process other than leukemia cutis, mainly infection or drug reaction. When graft-versus-host disease was excluded, leukemia cutis accounted for 50% of diagnoses in patients with CLL or ALL and for 88% of diagnoses in patients with CML ([302]). Thus, most cases of leukemia cutis occur in patients with AML, who are also at high risk for other cutaneous complications.

In Boggs et al.'s large series of patients with AL, leukemia cutis occurred in 11.0% of the patients with AML and in 1.3% of the ALL patients. Acute monocytic leukemia (FAB M5) is disproportionately represented ([38]). Clinically, leukemia cutis can present in a number of forms. Papules, nodules, plaques, and macules are the most common, although ulcerations, ecchymoses, bullous lesions, erythroderma, and vasculitic lesions may occur. Like other forms of extramedullary disease, leukemia cutis usually portends a poor prognosis in patients with AML.

Paraneoplastic skin disorders commonly occur in patients with hematologic neoplasms. The most common of these is Sweet syndrome or febrile neutrophilic dermatosis. Of patients with malignancy-associated Sweet syndrome, 85% have a hematologic malignancy, most commonly AML ([303]). Paraneoplastic pemphigus, which can be fatal, and pyoderma gangrenosum may also occur.

Another serious cutaneous complication of CLL and NHL is the increased risk of skin cancer in these patients. The risk applies to both basal cell carcinoma and squamous cell carcinoma ([304]). The latter may be aggressive and difficult to control and may lead to morbidity and death.

Musculoskeletal Complications

Osteolytic skeletal lesions are common in myeloma and are discussed in Chapter 98. Bone lesions are also common complications of adult T-cell leukemia lymphoma (ATLL) ([305]). Radiographic evidence of bone involvement is not uncommon in NHL and HD. Primary NHL of bone is most often a diffuse large B-cell type ([306]). Second to skin, bone lesions are a metastatic site for T-anaplastic large cell lymphoma ([307]). Therapy for NHL or HD involving bone is generally a combination of chemotherapy with or without radiation. Bone destruction with pain can occur in CML in blastic phase, CLL, HCL, and Waldenström macroglobulinemia.

Bone pain is an extremely common presenting symptom of AL, particularly in ALL in children ([308]). This is presumably caused by massive proliferation of blasts in the medullary canal and under the periosteum. At presentation, a variety of radiographic abnormalities may be seen, including osteopenia, lytic lesions, sclerotic lesions, and radiolucent metaphyseal bands in long bones.

Osteoporosis can occur in ATLL or myeloma and can result from therapy for hematologic neoplasia as a result of ovulatory failure. Bisphosphonate therapy may be beneficial ([309]).

Muscle complications of hematologic neoplasms are rare. Primary lymphoma of muscle has been reported ([310]). Polymyositis has occurred in association with MM, NHL, HD, and CLL.

Metabolic Complications

Patients with hematologic neoplasms often have metabolic derangements. Many are caused by the complex interactions of disease, toxic therapies, and other complications such as infection or hemorrhage. Many of these derangements are common in other critically ill patients and are not covered here. However, several metabolic problems are either unique to patients with hematologic neoplasms (such as ATLS) or are the result of direct effects of the neoplasm.

ACUTE TUMOR LYSIS SYNDROME ATLS occurs when neoplastic cells are killed and the intracellular contents are released into the circulation (Fig. 72.11). Clinically, it is marked by hyperphosphatemia, hyperkalemia, hyperuricemia, hypocalcemia, and acute, often oliguric renal failure. Patients are generally critically ill ([311]). ATLS most often occurs in patients with rapidly proliferating neoplasms, such as ALs, and high-grade NHL in response to aggressive therapy.

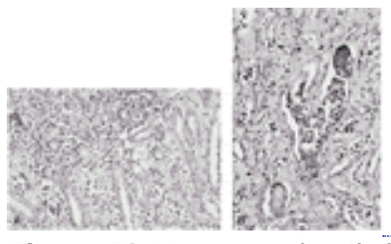

Figure 72.11. Karyorrhectic lymphoblast nuclei are present throughout the kidney in a patient with acute tumor lysis syndrome in whom cytolysis was initiated by administration of corticosteroids **(A)**. Renal tubules contain calcium phosphate precipitates that contributed to acute tumor lysis–associated renal failure (hematoxylin and eosin stain) **(B)**. See Color Plate. (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

Hande and Garrow have drawn a distinction between laboratory tumor lysis syndrome and clinical tumor lysis syndrome ([312]). They found that an asymptomatic change in two of four laboratory parameters (serum phosphate, urate, potassium, and blood urea nitrogen) occurred in 42% of patients receiving chemotherapy for intermediate- or high-grade NHL, but they also found only a 6% incidence of clinical ATLS, marked by renal failure or severe hyperkalemia. Thus, laboratory evidence of tumor lysis is far more common than the symptomatic clinical syndrome. ATLS has been reported in a variety of hematologic and solid tumor types. However, it is most common in bulky, rapidly proliferating tumors. Patients with small, noncleaved B-cell lymphoma (Burkitt and Burkitt-like types) and T-cell lymphoblastic lymphoma appear to be at highest risk. Patients with high lactate dehydrogenase and renal insufficiency are at high risk for developing clinical tumor lysis and should be monitored carefully. Although ATLS usually occurs with aggressive combination chemotherapy, the syndrome has been reported to occur spontaneously ([313]), in response to fever, and in patients treated solely with corticosteroids, intrathecal chemotherapy, or radiation. Several recent reports have described ATLS in patients with CLL who were treated with the newer purine analogs cladribine or fludarabine ([314] , [315]). It has been described with a variety of other single agents. Monoclonal antibody therapy, like rituximab, has rarely caused tumor lysis ([316]). The etiology of the renal failure in ATLS is multifactorial. Urate nephropathy is a major cause. The ionization constant of uric acid is 5.6, so, at normal blood pH, the majority of uric acid is in its more soluble ionized form. However, the hyperosmolality and acidity of the kidney's collection ducts and distal tubules can lead to precipitation of uric acid crystals. This, in turn, can lead to mechanical obstruction of urine flow and a “postrenal” acute renal failure. Uric acid can also precipitate as renal calculi and cause frank hydronephrosis. Tumor breakdown leads to purine catabolism, which culminates in production of hypoxanthine and xanthine. Xanthine oxidase converts xanthine to uric acid, which, as mentioned above, precipitates in the renal milieu. Allopurinol is a competitive inhibitor of the enzyme xanthine oxidase and prevents the formation of uric acid. It is administered in a dose of 300 to 800 mg daily. Important drug interactions include the prolongation of the half-lives of 6-mercaptopurine and azathioprine. It can also cause life-threatening allergic reactions, including Stevens-Johnson syndrome. Allopurinol is available as an intravenous formulation, which is safe and efficacious in patients unable to take oral medications ([317]). It is usually given at a dose of 200 to 400 mg/m ^{2}/day in either a single infusion or divided over 6 to 8 hours. Even at appropriate doses of allopurinol, increased uric acid production can be seen after chemotherapy. Humans lack the enzyme uricase that converts uric acid to allantoin, which is water soluble. *Rasburicase* is a novel recombinant form of uric acid oxidase. In recent pediatric trials, rasburicase was shown to decrease uric acid production compared to allopurinol, despite intensive chemotherapy ([318]). Similar experience has been seen in the adult population ([319]). Hypersensitivity reactions were rare and did not recur on retreatment. The dosing schedule used in these studies was 0.2 mg/kg as a 30-minute intravenous infusion for the first 5 to 7 days after starting chemotherapy. Patients at high risk for ATLS should receive prophylactic therapy in an effort to prevent the syndrome (Table 72.10). This generally consists of intravenous hydration to promote a brisk urine output, alkalinization of the urine, and allopurinol to prevent renal and metabolic complications. Intravenous allopurinol and rasburicase are important developments in the management of tumor lysis.

TABLE 72.10. Management of the Acute Tumor Lysis Syndrome

A clinician should consider the likelihood of tumor lysis when instituting therapy in any patient with a hematologic neoplasm. Those at low risk need no preventive therapy. The following measures should be undertaken for patients at risk.

All patients at intermediate or high risk (acute leukemia, intermediate- or high-grade lymphoma, chronic lymphocytic leukemia, being treated with fludarabine or cladribine) should receive allopurinol, 600 mg by mouth on the day before therapy and 300 mg daily during the first cycle of therapy.

Patients at high risk (acute leukemia or high-grade lymphoma with bulky disease or renal impairment) should be admitted to the hospital. Volume depletion should be corrected, and patients should receive 0.9% saline hydration at 250 cc/h overnight. Urine output should be monitored carefully. Alkalinization of urine may be indicated.

Patients at high risk should have electrocardiographic monitoring during institution of therapy. Serum calcium, phosphorous, magnesium, potassium, and uric acid should be monitored every 2–6 h for 2–3 d.

Plans for emergent hemodialysis should be in place before institution of chemotherapy.

Chemotherapy should be given even if dialysis is necessary. Less intensive therapy may be needed for debulking purposes before initiation of definitive chemotherapy.

Supportive care continues to remain a critical part of the management. Therapy for hyperkalemia and dialysis are often required. Hemodialysis is preferred over peritoneal dialysis because of its superior clearance of phosphate and urate ([311]). Continuous arteriovenous dialysis and venovenous hemofiltration have been reported to be beneficial. For patients at very high risk for ATLS such as those with bulky high-grade NHL, nephrology consultation and plans for therapeutic or prophylactic dialytic treatments should be made before institution of chemotherapy.

ALTERATIONS OF POTASSIUM METABOLISM Low serum potassium levels are a common complication of AML. Ten percent of severely hypokalemic patients have AML, a 22-fold increase over the expected value ([320]). Hypokalemia in AML is a result of decreased whole-body potassium. Although lysozymuria and alterations of the renin-angiotensin-aldosterone axis have been implicated, the exact pathophysiology is not defined in all cases. Antibiotic and antineoplastic therapy may contribute to low serum potassium Pseudohyperkalemia caused by *in vitro* hemolysis is often encountered in patients with hematopoietic neoplasms and markedly elevated leukocyte or platelet counts ([321]).

ALTERATIONS OF SODIUM METABOLISM Hyponatremia may be encountered in patients with hematologic neoplasms and is likely caused by inappropriate vasopressin release. Antineoplastic agents, including cyclophosphamide, vincristine, and biologic agents, can also cause hyponatremia ([322]). Pseudohyponatremia is a sequela of paraproteinemia and is commonly seen in MM ([323]). Hypernatremia is rare except in patients with CNS disease and central diabetes insipidus.

ALTERATIONS OF URIC ACID METABOLISM Uric acid is produced during purine metabolism. Its production is increased in hematologic malignancies with rapid tumor cell turnover. Thus, hyperuricemia or, more commonly, increased urate excretion is often seen at diagnosis in patients with AL, CML, PV, and idiopathic myelofibrosis. Less commonly, hyperuricemia may be seen in patients with newly diagnosed HD, NHL, and MM. Rapid cell killing by cytotoxic chemotherapy causes increased urate production and hyperuricemia, which are manifestations of ATLS (discussed previously). Hyperuricemia has two main sequelae: urate crystal–induced arthritis and urate nephropathy. Urate crystal–induced arthritis (gout) is a relatively rare complication of hematologic neoplasia. The exception to this rule can be found in men with PV, in whom gout is common ([324]). Gout in women with PV is less common but more severe. Urate nephropathy, gout, or both can be the presenting complaint in patients with hematologic neoplasia. It has even been reported to precede the overt manifestations of AL. Nevertheless, the majority of cases occur in patients with clinically evident disease as a manifestation of ATLS. The Polycythemia Vera Study Group has recommended that allopurinol be administered to all patients with PV and hyperuricemia ([325]). Allopurinol is also reasonable therapy for patients with other myeloproliferative disorders who develop gout. Hypouricemia is rare. It has been reported in patients with HD as a result of a renal tubular defect ([326]).

ALTERATIONS OF CALCIUM METABOLISM Hypercalcemia is one of the most common complications of malignancy. It occurs in 5 to 10% of patients with solid tumors and generally portends a poor prognosis. It is less common in patients with hematologic neoplasms with two prominent exceptions. Hypercalcemia occurs in approximately one-third of patients with MM and in two-thirds of patients with human T-cell leukemia virus type 1–associated ATLL (Chapter 98 and Chapter 90 , respectively). Hypercalcemia occurs less often in other types of NHL and HD. It is a rare occurrence in leukemias but has been reported in all subtypes. The symptoms of hypercalcemia—anorexia, nausea, pain, fatigue, constipation, weakness, polyuria, and altered mental status—are nonspecific and common in patients with hematologic malignancy. Therefore, hypercalcemia should be suspected in patients with a variety of complaints. Lowering of the serum calcium in hypercalcemic patients is readily achievable and provides effective palliation ([327]). Calcium metabolism is complex and involves the interplay of parathyroid hormone, vitamin D metabolism, bone resorption, gastrointestinal absorption, and renal excretion. All of these mechanisms may be perturbed in malignancy-associated hypercalcemia. However, hypercalcemia from hematologic neoplasms generally results from one or more of three underlying mechanisms. First, the hypercalcemia of MM results from cytokine-mediated bone destruction. *Osteoclast-activating factor* (OAF) is a descriptive term used to denote the substance(s) elaborated by normal or neoplastic hematopoietic cells that results in activation of osteoclasts with resultant bone destruction and impaired bone formation ([328]). Interleukin-1ß, lymphotoxin, and tumor necrosis factor-a appear to be the major molecules with OAF activity. Interleukin-1ß appears to be the most important in MM and may be important in disease progression ([329]). A second mechanism is conversion of 1-OH vitamin D to 1,25-OH vitamin D (calcitriol). In normal calcium homeostasis, this conversion occurs in the kidney, and the calcitriol so produced causes increased gastrointestinal calcium absorption and increased resorption of calcium from bone. In both NHL and HD, an ectopic production of calcitriol can occur in the tumor. The increased levels of calcitriol lead to increased calcium absorption and hypercalcemia ([330]). The third

mechanism of hypercalcemia in hematologic neoplasms is elaboration of parathyroid hormone–related peptide. This is the major mechanism of hypercalcemia in solid tumors. Like parathyroid hormone, parathyroid hormone–related peptide causes hypercalcemia by increasing release of calcium from bone. This mechanism of hypercalcemia appears to be important in human T-cell leukemia virus type 1–associated ATLL ([331]) and is the likely mechanism of action in occasional cases of CML in blast phase, AL, NHL, HD, and MM. There is no specific therapy. Patients with hematologic neoplasms may have hypercalcemia for reasons unrelated to their tumor. Primary hyperparathyroidism is the most common cause of hypercalcemia in outpatients and should be suspected in patients whose neoplasm is in good control. Immobilization is a cause of hypercalcemia and may cause worsening hypercalcemia in patients with MM or other hematologic neoplasms. Therapy of hypercalcemia consists of hydration and loop diuretics to increase calciuresis, corticosteroids for patients with hypercalcemia believed to be caused by OAF or calcitriol production, and therapies to prevent release of calcium from bone such as bisphosphonates (Table 72.11) ([332]). Therapy for the underlying hematologic neoplasm should be undertaken.

TABLE 72.11. Management of Hypercalcemia

Patients with symptomatic hypercalcemia and an underlying hematologic neoplasm can be effectively palliated. The approach consists of history and physical examination to look for other causes of altered mentation and a laboratory evaluation to assess renal function. Specific therapy to lower the serum calcium consists of the following.

Immediate vigorous hydration with 0.9% saline. The rate should be individualized based on assessment of the patient's volume status and cardiac function. Most patients require 3–5 L of saline to normalize his or her intravascular volume.

Intravenous furosemide should be used if signs or symptoms of volume overload develop. Diuretics should not be given to volume-depleted patients. Thiazide diuretics should be avoided.

Pamidronate, 90 mg intravenously over 4 h, should be given.

For patients with multiple myeloma or lymphoma, corticosteroids should be given. Prednisone, 60–100 mg daily, or an equivalent dose of dexamethasone or another steroid is effective.

In severe symptomatic hypercalcemia, calcitonin, 4 units/kg subcutaneously every 12 h for 4 doses, may be added to pamidronate and corticosteroids.

Hypercalcemia induces an osmotic diuresis, and patients are often markedly volume depleted. Volume depletion can lead to a decreased glomerular filtration rate, decreased calcium excretion, and worsening hypercalcemia. Thus, the mainstay of antihypercalcemic therapy is aggressive rehydration with isotonic saline. Other electrolytes, including sodium, potassium, and magnesium, should be monitored and repleted as necessary. Loop diuretics, such as furosemide, may increase calciuresis slightly. However, they should be withheld until the patient's intravascular volume status has been normalized, as they may worsen prerenal azotemia. Thiazide diuretics should be avoided. Corticosteroids impair release of OAF and ectopic production of calcitriol. They are useful as adjuncts to other therapies in patients with MM, HD, or NHL. They are ineffective in hypercalcemia because of other mechanisms. Bisphosphonates are now widely used as the main therapy for hypercalcemia. In the United States, pamidronate is most widely used. Pamidronate was originally given as 60 or 90 mg intravenously over 24 hours. However, a 4-hour infusion is safe and effective ([333]). Zoledronic acid is a new intravenous bisphosphonate that can be given safely and effectively over a 15-minute period and is not associated with more side effects than pamidronate ([334]). Rapid infusions of doses greater than 8 mg have been associated with an increased risk of renal dysfunction ([335]). Patients with creatinine of greater than 3 mg/dl should not be treated with this agent, as these patients have typically been excluded from clinical trials using zoledronic acid. There is less experience with bisphosphonates in children. Calcitonin results in a rapid lowering of serum calcium, but tachyphylaxis is common. Its use in combination with a bisphosphonate is reasonable for patients with severely symptomatic hypercalcemia. Gallium nitrate and mithramycin are also effective agents. However, the nephrotoxicity of the former and the marrow suppression of the latter limit their use. Hypocalcemia is a component of ATLS (discussed previously). Administration of calcitriol may be useful if hypocalcemia is prolonged. Hypocalcemia has also been reported in osteosclerotic myeloma and AL. In summary, as more antineoplastic agents are added to the arsenal, the diversity of complications arising from these agents will continue to increase. Physicians caring for patients should be astute in recognizing complications arising from the hematologic neoplasms and those that develop due to treatment. Some of these complications, including acute tumor lysis and leukostasis, can be life-threatening. Timely management of symptomatic cytopenias, using appropriate blood products, antibiotics, and growth factors in the case of febrile neutropenia, is important.

Principles and Pharmacology of Chemotherapy

PRINCIPLES OF CHEMOTHERAPY

The modern era of chemotherapy began shortly after World War II when investigators at Yale successfully used nitrogen mustard to treat lymphomas ([1]), and Sidney Farber in Boston used folic acid antagonists to treat children with acute lymphocytic leukemia ([2]). Over the past six decades, the number of drugs available to treat various malignancies has grown at a steady rate. Knowledge of how these drugs work, their kinetics, and toxicity has increased dramatically. A common pathway for tumor cell kill by anticancer drugs (apoptosis) has been recognized. To optimally use antineoplastic agents, clinicians must understand the principles of cancer chemotherapy as well as the specific drugs used to treat cancer. The first section of this chapter reviews the current understanding of (a) cancer biology, (b) mechanisms of antineoplastic drug action, (c) mechanisms of drug resistance, (d) drug toxicities, (e) pharmacologic principles (common and unique), and (f) potentials and limitations of therapy for individual patients. Specific drugs used to treat hematologic malignancies are summarized in the last section of this chapter.

Cancer Biology

When children with acute leukemia were first treated with folic acid antagonists in the 1940s, there was initial enthusiasm as all malignant cells were cleared from the bloodstream ([2]). However, the rapid return of leukemia with cells resistant to further therapy led to disappointment. We now understand this common situation: the difficulty presented by the large numbers of tumor cells at diagnosis and the development of tumor cells resistant to antineoplastic agents (discussed later in the chapter). A tumor that is 1 cm in diameter (rarely are tumors detected this early) contains 10^{9} cells. A lethal tumor burden is only 3 logs higher (10^{12} cells). Chemotherapy can be modeled as killing a specific fraction of tumor cells present ([3], [4]). The fractional cell kill (e.g., 90%, 99%, 99.99% cell kill) depends on the sensitivity of cells to the antineoplastic drug and the dose of drug administered. The cell kill is proportional regardless of tumor burden. Although not completely accurate, this model helps us to understand two important principles regarding chemotherapy. First, because of the large number of cells present at diagnosis (e.g., 10^{11}), multiple courses of treatment may be required for therapy even if a drug or a combination of drugs produces a 99.9% cell kill (i.e., kills 999 of every 1000 cells present). One treatment with a 99.9% cell kill reduces a tumor population from 10^{11} to 10^{8} cells. At least four treatments are therefore necessary to eliminate the final cancer cell, assuming that there is no tumor cell growth during the treatment period. In fact, because of toxicity to normal tissues and time needed for normal tissue recovery, cancer chemotherapy must be spaced out in treatment cycles. During the period between cycles, tumor regrowth occurs. Thus, most curative treatment regimens require multiple courses of chemotherapy, with the number depending on the tumor mass at the time of diagnosis and the sensitivity of the tumor to the drugs. A second principle from this model is that recurrent disease after “complete remission” (disappearance of all detectable disease) can be explained by our inability to detect fewer than 10^{3} to 10^{4} tumor cells in the body even by the most sensitive means. Chemotherapy that kills several logs of tumor cells (e.g., from 10^{11} to 10^{4}) eliminates all evidence of cancer and prolongs survival, but the malignancy will recur at a later time. Examples of possible clinical treatment courses are illustrated in Figure 73.1.

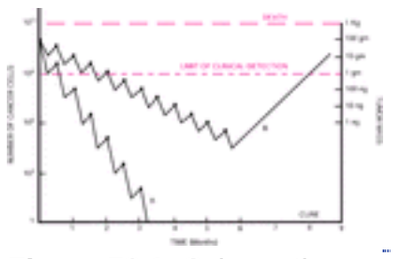

Figure 73.1. Schematic representation of clinical course of two patients with Hodgkin disease. Both patient A (*A*) and patient B (*B*) are diagnosed with a clinically detected tumor mass (10^{11} cells). Both patients are treated with ABVD (doxorubicin, bleomycin, vincristine, and dacarbazine) every 2 weeks. One course of therapy for patient A results in a 2-log tumor cell kill. Patient B's therapy results in only a 1-log tumor cell kill. Some tumor growth occurs while waiting for normal tissue recovery before initiation of the next treatment. Three months into therapy, neither patient A nor patient B has clinically detectable disease. Treatment is stopped after 6 months of therapy. Patient A is cured, whereas disease recurs in patient B 3 months after stopping therapy.

The growth fraction of a cancer represents the percentage of cells actively progressing through the cell cycle. A cell cycle is marked by two observable events. During *S-phase* (synthesis), DNA replication occurs, and during *M-phase* (mitosis) cellular division into two daughter cells is seen ([4]). G_1 (gap) is the time between the end of mitosis and the start of the next S-phase. G_2 is the time between the completion of S-phase and the start of M-phase. Cells that have ceased to proliferate for prolonged periods have entered a G_0*-phase* (or resting phase) of the cell cycle (Fig. 73.2). Some drugs cause cytotoxicity when exposed to cancer cells in any phase of the cell cycle. Some agents are phase-specific; that is, they are cytotoxic to cells only in a particular phase of the cell cycle. Cytarabine, for example, is an S-phase–specific agent, whereas vincristine is M-phase specific. For cells to be killed by cytarabine, the drug must be present when the cell is synthesizing DNA.

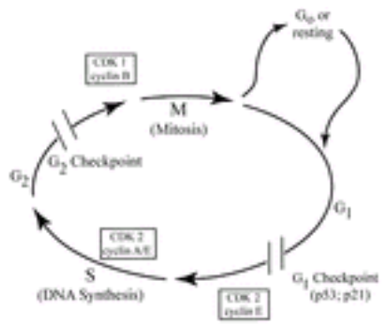

Figure 73.2. The cell cycle. The cell cycle is marked by two observable events. During *S-phase* (synthesis), DNA replication occurs, and during the *M-phase* (mitosis), cells divide. *G 1* and *G 2* are times between completion of M-phase and the start of S-phase and between the completion of S-phase and beginning of M-phase, respectively. During G 1 and G 2, the cell prepares for the S- and M-phases of the cell cycle. Cells may temporarily cease to divide and enter a resting or G 0-phase of the cell cycle. The G 1-S checkpoint is a critical phase in the cell cycle when directions for entering S-phase or committing to apoptosis (programmed cell death) are given. CDK, cyclin-dependent kinase.

Many cancers do not grow in an exponential manner but exhibit Gompertzian kinetics ([3], [4]). Gompertzian growth is sigmoid. In the Gompertzian model, the growth fraction of the tumor reduces as the tumor enlarges. In large cancers, not all cells are susceptible to chemotherapy as many drugs are effective only against dividing cells, and a proportion of cells in a large tumor mass are often in a resting or dormant phase, presumably due to lack of adequate nutrients or oxygen. The best opportunity for cell kill by chemotherapy is in the early portion of the growth curve when all cells are dividing.

Mechanisms of Antineoplastic Drug Action

Antineoplastic agents interfere with some essential step required for cell growth or division. The initial target of antineoplastic drugs varies widely, from direct attack on the DNA molecule to inhibition of the formation of the mitotic spindle needed for cell division. However, all antineoplastic agents cause a disruption in a normal cellular process so significant that it requires the cell to either quickly repair the damage or initiate the process of apoptosis (programmed cell death). Essentially, all antineoplastic agents result in cell death through initiation of apoptosis ([5]). *Apoptosis* is the normal physiologic process of cellular suicide, which occurs in all living organisms to eliminate unwanted, functionally abnormal, or harmful cells. In apoptosis, in contrast to cellular necrosis, the cell shrinks and condenses, fragmenting into multiple membrane-bound bodies (apoptotic bodies), which are engulfed by surrounding cells without inflammation or damage to the surrounding tissues. Biochemically, apoptosis is characterized by fragmentation of nuclear DNA, demonstrated by a typical ladder pattern on agarose gel electrophoresis.

To understand how cytotoxic agents initiate apoptosis, an understanding of the events occurring in the normal cell cycle is important. As previously mentioned, DNA synthesis is not continuous from one mitosis to the next but takes place in only a specific period of the cell cycle, the S-phase. Similarly, mitosis, or the M-phase, takes up only a small part of the cell cycle ([4]). In most, if not all, cells, the cell cycle is temporarily halted during the G 1-S-phase checkpoint and at the G 2-M-phase checkpoint. At these times, cells determine whether to continue into the S-phase, initiate the process of apoptosis, or undergo DNA repair ([6]). Passage into a new phase of the cell cycle requires activation of a series of enzymes called *cyclin-dependent kinases*, which activate another group of enzymes (the cyclins) ([7]). If cells are damaged by chemotherapeutic agents and are unable to repair the damage, apoptosis is initiated at the G 1-S or G 2-M checkpoint, provided that the mechanisms for apoptosis are in place. The critical factors needed for apoptosis remain an intense area of study, but some important components have been recognized. Two important factors are p53 and p21. *p53* is a nuclear phosphoprotein capable of binding to specific DNA sequences and activating selected target genes. Cells with a mutated p53 gene have a relative resistance to cancer chemotherapeutic agents and are unable to properly initiate apoptosis ([8]). *p21* is a protein induced by p53 that binds to and inactivates the cyclins required for progression of cells into the S-phase. Other factors are known to affect the apoptotic pathway. A protein originally found in B-cell lymphomas, bcl-2, blocks apoptosis. Its exact site of action is under investigation, but this protein acts late in the apoptosis pathway. Caspases are the key machinery causing the breakdown of DNA and proteins. *Caspases* are specialized proteases existing as proenzymes, which can be rapidly activated by a number of factors. The Fas ligand and tumor necrosis factor stimulate the protease cascade. The apoptosis pathway is under intense investigation, and our understanding of essential control points in this pathway will increase ([9]). It is clear that antineoplastic agents provide the initial trigger for beginning the pathway to programmed cell death (Fig. 73.3). However, the presence, or absence, of apoptotic proteins is as important as the initial interaction between a cytotoxic drug and its effector in determining whether tumor cell kill occurs.

Figure 73.3. Potential pathways involved in cytotoxicity induced by chemotherapy. Chemotherapeutic drugs or growth factor deprivation damages cells. Cells are arrested at the G 1-S checkpoint. If the damage is sublethal, it may be repaired, and the cell proceeds into the S-phase. If significant DNA damage is present, the process of programmed cell death is initiated. Critical factors, such as p53 and p21 gene products, are required for the cell to undergo apoptosis. G 1, gap; S, S-phase or synthesis.

Resistance to Anticancer Drugs

The presence of cancer cells resistant to chemotherapeutic agents is a common clinical occurrence. This vexing problem in cancer therapy is related, in part, to the many ways in which cells can become resistant to an antineoplastic agent. Steps in antineoplastic drug disposition within the cell are schematically represented in Figure 73.4. For an anticancer drug to be active it must (a) be taken up into a cancer cell and (b) be converted into an active agent. It must then make its way within the cell to its target without being (c) metabolically inactivated, (d) chemically inactivated, or (e) excreted from the cell. Once it interacts with its cellular target, the cell must not be able to (f) alter the target or (g) repair the damage to the target. Finally, (h) mechanisms for apoptosis must be in place as discussed in the preceding section. Examples of drug resistance at all of these steps have been described (Table 73.1). A tumor cell can become resistant to a particular drug in many ways. For example, resistance to methotrexate (MTX) has been described in some cell lines with altered folate transport limiting MTX uptake into cells. In other cell lines, MTX resistance results from the overexpression of the target enzyme, dihydrofolate reductase (DHFR).

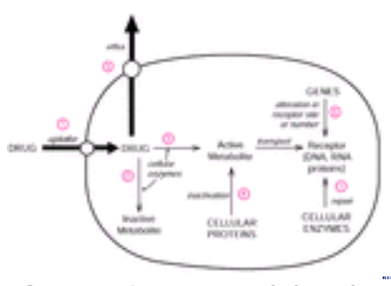

Figure 73.4. Potential pathways for antineoplastic drug disposition within tumor cells. For a drug to be effective, the drug or its active metabolite must reach its target site within the cell. Possible steps required for a drug to reach its receptor include (*1*) uptake into a cell through a particular transport protein, (*2*) enzymatic conversion of the drug to an inactive metabolite, (*3*) enzymatic conversion of the drug to its active metabolite, (*4*) binding of an active metabolite by a cellular protein or thiol, thereby inactivating drug, (*5*) excretion of the drug from the cell via an efflux transport pump, (*6*) alteration in the genetic makeup of the cell, changing the drug receptor site or number, and (*7*) changes in the ability of a cell to repair damage of a drug at its receptor.

TABLE 73.1. Mechanisms of Cancer Cell Resistance to Chemotherapeutic Agents

Resistance Mechanism	Example	Affected Drugs	Reference
Decreased drug uptake	Altered folate receptor	Methotrexate	10
Decreased metabolic activation	Decreased concentrations of deoxycytidine kinase	Cytosine arabinoside	11
Increased catabolism	Thiopurine methyltransferase excess	6-Mercaptopurine	12
Increased drug detoxification	Increased glutathione production	Alkylating agents, platinum analogs	13
Increased drug efflux	Multidrug resistance	Vincas, epipodophyllotoxins, anthracyclines, paclitaxel	14
Increased DNA repair	O ^{6}alkylguanine alkyltransferase	Nitrosoureas, procarbazine, dacarbazine	15
Alteration of drug target	Topoisomerase II mutations	Anthracyclines, epipodophyllotoxin	16

Cancer cells may become simultaneously resistant to several types of chemotherapeutic drugs. Cells expressing the multidrug resistance (MDR) gene produce a glycoprotein of 170-kD weight known as *p-glycoprotein* or *p170* (14). Originally described in 1976, this protein is a drug transporter that sits in the cell wall of resistant tumor cells. P-glycoprotein transports a number of antineoplastic agents, most of which are hydrophobic, including vinca alkaloids, epipodophyllotoxins, anthracyclines, actinomycin, and taxanes. Cells in which the MDR gene is activated develop simultaneous resistance to all of these antineoplastic agents. The presence of p-glycoprotein on tumor cells has been correlated with poor prognosis in hematologic tumors, sarcomas, small cell lung cancer, and carcinomas of the breast and ovary (17, 18). Because of the potential role of MDR in tumor resistance, efforts have been directed at blocking this transporter. A number of agents, including analogs of verapamil and cyclosporine, are inhibitors of MDR. Clinical trials of combinations of these inhibitors with anticancer drugs have been undertaken. MDR inhibitors may alter either the hepatic or renal excretion of several anticancer drugs, thereby increasing drug toxicity (19). Clinical effectiveness of these MDR inhibitors has not been clearly demonstrated.

Other cell lines have been characterized that do not overexpress p-glycoprotein but display a similar cross-resistance pattern. Some of these lines have a different type of transport protein called *MRP* or *MDR-associated protein* (20). MRP, like p-glycoprotein, is a member of the adenosine triphosphate (ATP)–binding cassette gene superfamily. However, MRP is structurally dissimilar to p-glycoprotein and has different inhibitors. The clinical significance of MRP is under study, but, like p-glycoprotein, its presence may be a poor prognostic factor.

In summary, tumor cells can develop resistance to antineoplastic drugs by numerous mechanisms. Resistance occurs as a result of random mutational changes in a population of cancer cells. Mutations to a drug-resistant cell line are estimated to occur at population size of 10^{4} to 10^{6} tumor cells, a size smaller than clinically detectable (21). Therefore, drug-resistant cancer cell populations are present in the majority of tumors at diagnosis. The early presence of resistant tumor cells leads to the rationale for (a) early treatment of cancers to avoid multiple resistant populations and (b) use of multiple agents with differing mechanisms of action.

Drug Toxicity

As opposed to many other classes of drugs, the therapeutic window for chemotherapeutic agents is narrow (Fig. 73.5). The dose of drug needed to achieve adequate tumor cell kill often causes toxicity to normal tissues. For many antineoplastic agents, a sigmoidal curve defining the relationship between myelosuppressive toxicity and the dose of drug administered [or the area under the plasma drug concentration (AUC) vs. time curve] has been demonstrated. At low drug concentrations, no cytotoxicity is observed. With increasing concentration, cell kill is proportional to dose. At higher concentrations, the effect plateaus. Relationships correlating the dose of drug and antitumor response have also been demonstrated (Fig. 73.5C) (22). A positive relationship between the drug dose administered and tumor response rate has been demonstrated for many tumors, including the lymphomas. Higher response rates and an increased chance for cure are achieved with higher doses of selected agents (23, 24). For this reason, clinicians generally try to push doses of agents to toxicity to maximize the chance for cure. The optimal dose or AUC for an individual patient with a particular cancer is unknown.

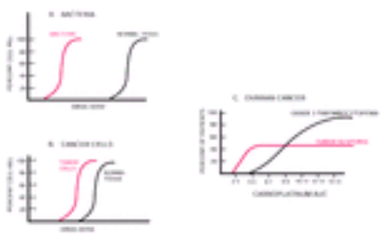

Figure 73.5. Schematic representation curves relating drug concentrations to response. Antibacterial agents **(A)** have a wide therapeutic window with a significant difference in the dose that produces bacterial cell kill and the dose that causes toxicity to normal tissues. For antineoplastic drugs **(B)**, the therapeutic window is narrow (e.g., doses adequate to produce tumor cell kill usually produce toxicity to normal tissues). For a few cancers, such as ovarian **(C)**, the shape of the dose response curve has been defined (22). For most tumors, however, a specific dose response (or AUC response curve) has not been defined.

Chemotherapeutic agents cause a wide variety of toxicities (Table 73.2). Myelosuppression and nausea are seen, to some degree, with many anticancer drugs. Nausea and vomiting, although generally self-limited and not life-threatening, are very distressing to patients. The emetogenic potential of antineoplastic agents varies from drug to drug and is dose-dependent (25) (Table 73.3). The emetogenic potential of combination chemotherapy regimens can be estimated. Serotonin receptors, located within the vagal and splanchnic nerves of the gastrointestinal system and in the brain, are critical in the initiation of nausea by chemotherapeutic agents (26). The development of specific type 3 serotonin (5-hydroxytryptamine or 5HT $_{3}$)–receptor blockers, such as ondansetron, dolasetron, and granisetron, has resulted in major improvement in control of chemotherapy-induced emesis (27). Combination therapy with a 5-HT $_{3}$–receptor blocker and a steroid, such as dexamethasone (Decadron), has become standard preventive therapy for highly emetogenic combination chemotherapy regimens.

TABLE 73.2. Antineoplastic Drug Toxicity

Nausea/Vomiting	Bone Marrow	Mucositis	Alopecia	Neurologic	Diarrhea	Hepatic	Vesicant	Pulmonary	Renal

TABLE 73.3. Emetic Potential of Selected Antineoplastic Agents

Grade	Emesis Frequency (%)	Drug
5	>90	Carmustine >250 mg/m ^{2} Cisplatin Cyclophosphamide >1500 mg/m ^{2} Dacarbazine Mechlorethamine
4	60–90	Carboplatin Carmustine =250 mg/m ^{2} Cyclophosphamide 750–1500 mg/m ^{2} Cytarabine >1 g/m ^{2} Doxorubicin >60 mg/m ^{2} Methotrexate >1000 mg/m ^{2} Procarbazine (oral)
3	30–60	Cyclophosphamide =750 mg/m ^{2} Cyclophosphamide (oral) Doxorubicin 20–60 mg/m ^{2} Epirubicin =90 mg/m ^{2} Idarubicin Ifosfamide Irinotecan Methotrexate 250–1000 mg/m ^{2} Mitoxantrone
2	10–30	Docetaxel Etoposide 5-Fluorouracil Methotrexate 50–250 mg/m ^{2} Paclitaxel Topotecan
1	<10	Bleomycin Busulfan Chlorambucil (oral) 2-Chlorodeoxyadenosine Fludarabine Hydroxyurea L-Phenylalanine mustard (oral) Thioguanine (oral) Vinblastine Vincristine Vinorelbine

NOTE: When considering combination chemotherapy regimens, identify the most emetogenic agent. Each grade 3 or 4 agent increases the emetogenic potential of the most emetic agent by one grade. All grade 2 drugs combined increase the emetogenic potential of the combination one level. Grade 1 agents do not add to the emetogenic potential.
Adapted from Hesketh PJ, Kris MG, Grunberg SM, et al. Proposal for classifying the emetogenicity of cancer chemotherapy. J Clin Oncol 1997;15:103–109.

Myelosuppression is the most common dose-limiting antineoplastic agent toxicity. The suppression of hematopoietic cell lines is determined by the kinetics of the specific cell line in the peripheral compartment. Anemia occurs as a late effect because of the long half-life of red blood cells (120 days). Thrombocytopenia occurs in an intermediate time frame (platelet half-life, 5 to 7 days), whereas granulocyte suppression occurs earliest. Granulocytopenia is a more frequent occurrence than thrombocytopenia or anemia. The white blood cell count usually drops 5 to 14 days after drug administration with recovery by 7 to 21 days. Several exceptions are recognized such as a predominant thrombocytopenia seen with carboplatin and delayed myelosuppression with busulfan and the nitrosoureas (occurring 4 to 5 weeks posttherapy). The degree and duration of bone marrow suppression are directly related to the dose of drug administered. High-dose chemotherapy regimens used with marrow transplantation generally result in 15 to 25 days with a neutrophil count less than 500 per mm^3 and thrombocytopenia lasting for a more extended period if growth factors are not used. An increased risk of infectious complications occurs that is directly related to the degree and duration of granulocytopenia ([28], [29]). The development of recombinant hematopoietic colony-stimulating factors (CSFs), such as erythropoietin, thrombopoietin, granulocyte-macrophage CSF, and granulocyte-CSF, has shortened the duration of bone marrow suppression but not eliminated it ([30]). CSFs are now commonly used with regimens expected to produce an incidence of febrile neutropenia greater than 40%. Guidelines for the use of these important, yet expensive, factors are available and should be used ([31]).

The range of toxicities associated with antineoplastic agents is too great to review in detail in this chapter. Readers are referred to reviews on oral ([32]), renal ([33]), neurologic ([34]), hepatic ([35]), pulmonary ([36]), cardiac ([37]), and cutaneous ([38]) toxicities of antineoplastic agents. Physicians must also remember that most antineoplastic agents have teratogenic and mutagenic potential. Alkylating agents are the most damaging to testicular and ovarian function. Damage is dependent on drug dose, age of patient (older patients are more likely to have toxicity), and sex (males greater than females) ([39]). Second malignancies (primarily acute leukemia) have been associated with alkylating agents, epipodophyllotoxins, nitrosoureas, and anthracyclines ([40]). Concomitant radiation therapy increases the risk of second malignancies (generally sarcomas) 5 to 9 years after therapy.

General Pharmacologic Principles

Antitumor activity of an antineoplastic agent is better correlated with the concentration of drug that reaches the site of drug action than with the dose of drug administered. As noted in the section Resistance to Anticancer Drugs, several factors may affect what happens to a drug within the cell. Similarly, drug disposition within the body from the time it is administered until it reaches its target site is also critical to achieving an antitumor response (Fig. 73.6). Knowledge of the absorption, distribution, biotransformation, and excretion of a drug (its pharmacokinetic properties) helps physicians make adjustments in the dose, route, or schedule of drug administration to achieve the optimal drug effect. Pharmacokinetics represents an attempt to quantitatively predict how a patient will handle a given dose of drug ([41]). The four most important pharmacokinetic parameters are (a) bioavailability, (b) volume of distribution, (c) clearance, and (d) drug half-life.

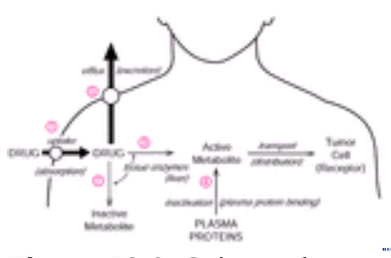

Figure 73.6. Schematic representation of drug disposition within the body. For a drug to function, it must be taken into the body (*1*) and avoid being cleared from the body by metabolism (*2*) or excretion (*5*). It must reach its site of action in active form (*3*) without being inactivated by protein binding (*4*).

Bioavailability, the percentage of a dose of drug that reaches the plasma compartment, defines drug absorption. Drugs given intravenously, by definition, have 100% bioavailability. Factors that decrease the bioavailability of orally administered drugs include poor solubility in aqueous solutions and metabolism of the drug in the intestine or liver before entry into the systemic circulation (first pass effect). Bioavailability of poorly soluble etoposide decreases at high oral drug doses ([42]). Bioavailability of orally administered 6-mercaptopurine (6-MP) and 5-fluorouracil is low because of extensive, first-pass, hepatic drug metabolism ([43], [44]). With poor or widely variable bioavailability of a particular agent, an intravenous route of administration is preferred. The most important factor regarding bioavailability is the variation from patient to patient of the amount of oral drug absorbed (coefficient of variation). If bioavailability of an oral anticancer drug were 50% in all patients, simply doubling the drug dose would produce an equivalent response to intravenously administered drug. However, the variation from patient to patient in the AUC achieved is usually greater with oral than intravenously administered drug ([45]). Therefore, variation in toxicity is also greater.

After a drug reaches the bloodstream, it is distributed into tissues. Figure 73.7 shows a plasma concentration versus time curve for a drug with a typical two-phase (distribution and elimination) decline in plasma concentration. Distribution may be affected by drug binding to plasma proteins (usually albumin or a $_1$-acid glycoprotein). Only free drug is biologically active. Decreasing the percentage of bound drug by a decrease in the amount of albumin or displacing drug from its binding site may increase toxicity (seen with etoposide) ([46]). Distribution of drug into a “third-space,” such as ascites or a pleural effusion, may slow clearance and increase toxicity, as noted with MTX ([47]).

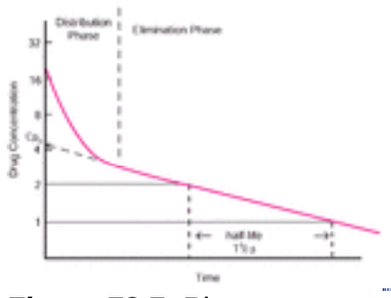

Figure 73.7. Plasma concentrations of a typical drug at various times after intravenous administration. After an early distribution phase, drug concentrations decrease in a log-linear manner. *Cp* $_0$ is the hypothetical drug plasma concentration at time zero if equilibrium were achieved instantaneously. The drug's half-life is the time required for its concentration to decrease by half.

Clearance is expressed as the volume of biologic fluid (usually plasma) from which a drug can be removed per unit of time. Clearance of most drugs is constant over a range of plasma concentrations, which means that the mechanism for elimination is not saturated. However, some drugs, such as paclitaxel, demonstrate saturable elimination at high plasma concentrations ([48]). This means a greater proportional drug effect is noted when high doses are increased. Clearance measurements allow physicians to maintain a particular plasma concentration, as the dosage rate = clearance × desired plasma concentration. Removal of drugs from the circulation occurs primarily by metabolism, renal elimination, or hepatic excretion. If urinary excretion is an important route of elimination, renal failure results in slower removal of the drug from the body. Administration of the usual dosage of a renally excreted drug to a patient with renal insufficiency leads to greater drug accumulation and an increased likelihood of toxicity. In such cases, drug dosage should be modified so that a similar drug concentration–time profile is achieved in the plasma of the patient with renal insufficiency. Using available data on drug clearance, the appropriate dose in renal insufficiency may be calculated as follows:

Dose in renal insufficiency = normal dose × clearance in renal insufficiency ÷ normal clearance

In contrast to a predictable decline in renal drug clearance when glomerular filtration is reduced, it is not possible to make a general prediction of the effect of liver disease on hepatic biotransformation of drugs. Even in advanced hepatocellular disease, the magnitude of impairment in drug clearance usually is only two- to fivefold. The extent of such changes cannot be predicted by common tests of liver function. Consequently, even when it is suspected that drug elimination is altered in liver disease, there is no quantitative base on which to adjust the dosage regimen other than assessment of clinical response. Antineoplastic drugs for which dose modifications are indicated for renal or hepatic insufficiency are listed in Table 73.4.

TABLE 73.4. Drugs Requiring Dose Alterations for Organ Toxicity

Nephrotoxicity	Hepatic Toxicity
Bleomycin	Daunorubicin [a]
Carboplatin [a]	Doxorubicin [a]
Cisplatin [a]	Epirubicin [a]
Cladribine	Idarubicin
Cyclophosphamide (if CrCl <20 ml/min)	Irinotecan
Deoxycoformycin	Paclitaxel [a]
Etoposide	Taxotere [a]
Fludarabine	Vinblastine [a]
Hydroxyurea	Vincristine [a]
Ifosfamide	Vinorelbine [a]
Methotrexate [a]	
Mithramycin	
Mitomycin [a]	
Nitrosoureas [a]	
Pentostatin	
Streptozocin	
Topotecan	

[a] Major dose adjustment.

The hepatic metabolism of drugs may be altered by genetic deficiency of a metabolizing enzyme or by inhibition of metabolism by another drug. Examples include the inherited deficiencies of dihydropyrimidine dehydrogenase, the enzyme that degrades 5-fluorouracil ([49]), and thiopurine methyltransferase, the enzyme degrading azathioprine and 6-MP ([50]). Individuals lacking these enzymes experience excessive drug toxicity. Certain antineoplastic drugs are metabolized by the hepatic P-450 microsomal enzyme system (vincas, epipodophyllotoxins, cyclophosphamide, and the taxanes). The activity of the microsomal enzyme systems may be increased with concomitant use of phenobarbital or other drugs. Use of anticonvulsants has been shown to increase the catabolism of teniposide, a drug eliminated from the body through hepatic microsomal metabolism ([51]). Clearance of drugs metabolized by the hepatic P-450 enzyme system, such as paclitaxel or docetaxel (Taxotere), can be decreased with concomitant use of P-450 inhibitors such as some antiretroviral agents.

It is important to recognize the unpredictable variation in the way chemotherapeutic drugs are handled by the body. Mean values for bioavailability, clearance, and volume of distribution of anticancer agents have standard deviations of 20%, 50%, and 30%, respectively. This means that target drug concentrations may vary widely from patient to patient, even those whose renal and hepatic function appears similar. This is particularly important for drugs with a low therapeutic index and necessitates that all patients receiving chemotherapy be carefully monitored.

Approach to the Patient with Cancer

Before initiating cancer chemotherapy, a physician should (a) verify the accuracy of the diagnosis, (b) understand the natural history of the illness, and (c) identify, with the patient, the goals of therapy. Verification of the diagnosis, in nearly every case, requires histologic documentation of cancer. Once the diagnosis is established, the physician and patient must decide whether cure is possible or palliation is the optimal goal. If cure is the goal, the patient and physician may be willing to tolerate more severe toxicity. The patient must be a partner in such decisions. In many cases, several options may be reasonable, and an informed patient can direct the physician as to whether intensive, potentially toxic therapy should be tried for a relatively small chance of cure ([52], [53]). Fortunately, curative therapy, even for disseminated disease, is available for many hematologic malignancies, including Hodgkin disease, non-Hodgkin lymphomas, and acute and chronic leukemias. In some illnesses, such as chronic lymphocytic leukemia and low-grade lymphomas, curative therapy is not available, and the disease is often indolent. A discussion of these illnesses and their natural histories can reassure patients and help them understand why chemotherapy is not being immediately initiated. If high-dose, aggressive curative chemotherapy is planned, patients and their families need to be aware of anticipated and potential toxicities.

The use of chemotherapy for treatment of an individual requires a detailed knowledge of the patient, including his or her medical and psychological status, specific knowledge of the drugs to be used, and the availability of appropriate laboratory and hospital support services. Combination chemotherapy (use of several drugs simultaneously) is usually used and multiple cycles of drugs administered to achieve adequate tumor cell kill without life-threatening toxicity or the development of tumor cell resistance. Certain patient selection factors are important in planning treatment. Age alone is seldom a reason to exclude patients from chemotherapy ([54], [55]). However, age-related changes in organ function, including reduced marrow reserve and decreased renal function, are commonly seen and may increase the risk of toxicity. The performance status of a patient (either on the Karnofsky or American Joint Committee on Cancer scale) usually correlates with response to chemotherapy (Table 73.5). The nutritional state of a patient is important. Malnourished patients with hypoalbuminemia may have increased toxicity when highly protein-bound drugs are used ([46]). Appropriate dosing guidelines for obese patients are not available ([56]). Doses based on actual body weight appear appropriate when the goal for therapy is cure ([57]), whereas doses based on ideal body weight, with potential escalations later, are reasonable when palliation is the intent. Altered organ function may eliminate the opportunity to use certain drugs (e.g., doxorubicin in patients with heart failure and bleomycin in patients with severe pulmonary toxicity). Drug doses are routinely modified for decreases in blood counts (Table 73.6) and also for changes in renal and hepatic function (see section General Pharmacologic Principles). The patient must be carefully observed for toxicity and response to chemotherapy. It is common to reevaluate patients after two to three cycles of chemotherapy to determine treatment effectiveness. If a response is seen, therapy is usually continued for a set number of courses or two cycles past a complete response. If tumor progression is noted, therapy should be discontinued. For patients with stable disease, an assessment of drug toxicity is important. If therapy is tolerable, a decision to continue treatment is reasonable with the understanding that disease progression will eventually occur.

TABLE 73.5. Karnofsky and American Joint Committee on Cancer (AJCC) Performance Status Scales

Karnofsky Scale (%)	Corresponding Description	AJCC Scale	Corresponding Description
100	Normal; no complaints; no evidence of disease	0	Normal activity
90	Able to carry on normal activity; minor signs or symptoms of disease	—	—

80	Normal activity with effort; some signs or symptoms of disease	1	Symptomatic and ambulatory; cares for self
70	Cares for self; unable to carry on normal activity or to do active work	—	—
60	Requires occasional assistance but is able to care for most of own needs	2	Ambulatory more than 50% of time; occasionally needs assistance
50	Requires considerable assistance and frequent medical care	3	Ambulatory 50% or less of time; nursing care needed
40	Disabled; requires special care and assistance	—	—
30	Severely disabled; hospitalization indicated, although death not imminent	—	—
20	Very sick; hospitalization necessary; active supportive treatment necessary	4	Bedridden; may need hospitalization
10	Moribund, fatal processes progressing rapidly	—	—
0	Dead	—	—

TABLE 73.6. Generalized Dose Adjustment Guidelines for Hematologic Toxicity [a]

	100% Dose	75% Dose	50% Dose	Omit
Granulocyte	>2000	1500–1999	1000–1499	<1000
White blood cells	>3500	3000–3500	2500–2999	<2500
Platelet	>100,000	75,000–100,000	50,000–74,999	<50,000

[a] In selected circumstances, such as in the treatment of leukemia, these guidelines do not apply. Specific guidelines accompanying individual protocols should be sought.

DRUGS USED TO TREAT CANCER

A comprehensive review of the pharmacology of all drugs used in the therapy of malignancies is beyond the scope of this chapter. The focus is a brief review of those agents most commonly used in the therapy of hematologic malignancies. Important information necessary for the optimal use of these drugs includes (a) mechanism of action; (b) pharmacology, including bioavailability, routes of elimination, and important drug interactions; and (c) toxicities. Table 73.7 summarizes important information for most antineoplastic agents. A more detailed summary of the most commonly used antineoplastic agents for the therapy of hematologic malignancy follows.

TABLE 73.7. Chemotherapeutic Agents

Drug Name (Synonym)	Drug Class	Action	Clearance Route [a]	Major Toxicity
Altretamine (Hexalen); Hexamethylmelamine	Nonclassical alkylating agent	Unknown, may alkylate DNA.	Hepatic metabolism	Hypersensitivity reaction, deficient synthesis of key proteins (clotting factors, insulin), CNS depression, pancreatitis
Arsenic trioxide (ATO)	Arsenical	Degrades PML-RAR fusion protein, allowing cellular differentiation.	Hepatic metabolism	Hypokalemia, QT prolongation, retinoic acid syndrome
Asparaginase (Elspar)	Enzyme	Breaks down the amino acid asparagine. Sensitive lymphocytes lack ability to synthesize asparagine.	Hepatic metabolism	N & V, neurotoxicity, myelosuppression, diarrhea
Bexarotene (Targretin)	Retinoid	Binds to RXR nuclear receptor, inducing apoptosis.	Hepatic metabolism	Hyperlipidemia, hypercholesterolemia, headache
Bleomycin (Blenoxane)	Antibiotic	Single-strand DNA breaks.	Renal	Hypersensitivity reaction, pulmonary fibrosis, skin and mucocutaneous reactions, fevers
Busulfan (Myleran)	Alkylating agent	Forms DNA cross-links.	Metabolism	Myelosuppression, hepatotoxicity (venoocclusive disease), pulmonary fibrosis
Carboplatin (CBDCA, Paraplatin)	Platinum complex	Produces DNA cross-links like alkylating agents but with platinum bridging.	Renal	Thrombocytopenia, leukopenia, nephrotoxicity, ototoxicity, neuropathy, N & V
Carmustine (BCNU)	Nitrosourea	Alkylates DNA at O^6 position of guanine.	Hepatic metabolism	Delayed (4–6 wk) myelosuppression, pulmonary toxicity, hepatotoxicity
Chlorambucil (Leukeran)	Alkylating agent	Cross-links DNA.	Metabolism	Myelosuppression, pulmonary toxicity, hepatotoxicity
Cisplatin (CDDP, Platinol)	Platinum complex	Produces DNA cross-links with platinum similar to alkylating agents.	Protein binding, renal	Nephrotoxicity, N & V, ototoxicity, alopecia, neuropathy
Cladribine (Leustatin, 2-Chlorodeoxyadenosine)	Antimetabolite (purine analog)	Incorporation into DNA; NAD consumption.	Renal	Myelosuppression, fever, renal toxicity (high dose)
Cyclophosphamide (Cytoxan, Neosar)	Alkylating agent	Cross-links DNA strands.	Hepatic metabolism (renal)	Myelosuppression, N & V, cystitis, cardiac (high dose)
Cytarabine (Cytosar, ara-C, cytosine arabinoside)	Antimetabolite (pyrimidine analog)	Incorporates into DNA; inhibits DNA poly-merase.	Hepatic metabolism	Myelosuppression, N & V, mucositis, ocular, hepatic
Dacarbazine (DTIC)	Nonclassical alkylating agent	DNA methylation.	Renal (hepatic metabolism)	Vesicant, myelosuppression, N & V, hepatic
Dactinomycin (Cosmegen, Actinomycin-D)	Antibiotic	DNA intercalation.	Biliary	Myelosuppression, N & V, vesicant, mucositis
Daunorubicin (Cerubidine)	Antibiotic (anthracycline)	Topoisomerase inhibition, DNA intercalation, free radical formation.	Biliary excretion, hepatic metabolism	Myelosuppression, N & V, cardiomyopathy, vesicant, red urine, mucositis
Denileukin difitox (Ontak)	IL-2–linked toxin	Binds to the IL-2 receptor; the diphtheria toxin is internalized.	Unknown	Hypersensitivity reaction, N & V, myalgias, headache, vascular leak syndrome
Docetaxel (Taxotere)	Plant alkaloid	Mitotic spindle inhibitor.	Hepatic metabolism, biliary excretion	Myelosuppression, hypersensitivity (steroids needed), fluid retention, neuropathy
Doxorubicin (Adriamycin, Rubex)	Antibiotic (anthracycline)	Topoisomerase inhibition, DNA intercalation, free radical formation.	Biliary excretion, hepatic metabolism	Myelosuppression, N & V, cardiomyopathy, vesicant, red urine, mucositis

Etoposide (VePesid, VP-16); etoposide phosphate (Etopophos)	Plant alkaloid	Inhibits topoisomerase II.	Renal, hepatic metabolism	Myelosuppression, mucositis, hypersensitivity reaction
Fludarabine (Fludarabine phosphate, Fludara)	Antimetabolite (purine analog)	Inhibits DNA polymerase; incorporation into DNA and RNA; NAD depletion.	Renal	Myelosuppression, mucositis, hypersensitivity reaction, neurologic
Fluorouracil (5FU, Adrucil)	Antimetabolite (pyrimidine analog)	Inhibits thymidylate synthetase; incorporated into DNA and RNA.	Hepatic metabolism	Myelosuppression (more with bolus), diarrhea and mucositis (more with continuous infusion), stomatitis, cardiac ischemia, CNS (cerebellar ataxia)
Gemcitabine (Gemzar)	Antimetabolite	Inhibits ribonucleotide reductase; incorporated into DNA as false nucleotide.	Metabolism	Myelosuppression, nausea, diarrhea, hepatic fever
Hydroxyurea (Hydrea)	Antimetabolite	Inhibits ribonucleotide reductase.	Hepatic metabolism, renal	Myelosuppression, mucositis
Idarubicin (Idamycin)	Antibiotic, anthracycline	Similar to doxorubicin.	Hepatic	Similar to doxorubicin
Ifosfamide (Ifex, IFOS)	Alkylating agent	Cross-links DNA strands through alkyl groups.	Hepatic metabolism, renal excretion	Myelosuppression, N & V, neurologic, alopecia, cystitis (must be given with Mesna)
Imatinib mesylate (Gleevec, STI-575)	Signal transduction inhibitor	Inhibits the tyrosine kinase of the bcr-abl and c-kit oncogenes.	Hepatic metabolism	Nausea, diarrhea, fluid retention, abnormal liver function tests
Interferon-a (INF-a); Intron A, (a2b); Alferon, (an); Roferon, (a2a); Welferon, (an)	Biologic	Degradation of messenger RNAs; modulation of oncogene expression; increase in natural killer cells and other immunoregulatory elements.	Renal metabolism	Fever, chills, myalgias, headache, fatigue, anorexia, myelosuppression, hepatic, CNS
Irinotecan (Camptosar, CPT-11)	Camptothecin analog	Inhibits topoisomerase I.	Metabolism, biliary excretion	Myelosuppression, diarrhea, pneumonitis, stomatitis
Levamisole (Ergamisol)	Biologic	Unknown.	Hepatic metabolism	Nausea, hepatic, fever, chills
Lomustine (CeeNU, CCNU)	Nitrosourea	Same as carmustine.	Same as carmustine	Same as carmustine
Mechlorethamine (Nitrogen mustard, Mustargen)	Alkylating agent	Cross-links DNA via alkylation.	Tissue binding	Vesicant, ototoxicity, myelosuppression, N & V
Melphalan (Alkeran, L-PAM, Phenylalanine mustard)	Alkylating agent	Cross-links DNA strands via alkylation.	Spontaneous degradation, protein binding	Myelosuppression, pulmonary fibrosis (rare), N & V (high dose)
Mercaptopurine (6MP, Purinethol)	Antimetabolite (purine analog)	Incorporation into DNA.	Hepatic metabolism	Myelosuppression, hepatotoxicity
Methotrexate (MTX, Amethopterin, Folex, Mexate)	Antimetabolite (folic acid analog)	Inhibits dihydrofolate reductase with decreased thymidylate and protein synthesis.	Renal excretion	Myelosuppression, mucositis, hepatotoxicity (chronic low dose), renal (high dose), pulmonary
Mitomycin (Mutamycin, Mitomycin-C)	Antibiotic	Cross-links DNA strands.	Hepatic metabolism	Myelosuppression, N & V, vesicant, pulmonary, hepatic, renal
Mitoxantrone (Novantrone, DHAD)	Anthraquinone	Similar to doxorubicin.	Hepatic metabolism	Similar to doxorubicin; blue-green urine
Paclitaxel (Taxol)	Plant alkaloid	Mitotic spindle inhibitor stabilizes microtubulin.	Hepatic metabolism, biliary excretion	Myelosuppression, hypersensitivity syndrome (use with steroids, antihistamines), mucositis, neuropathy
Pentostatin (Nipent, 2-Deoxycoformycin)	Antimetabolite (purine analog)	Adenosine deaminase inhibitor.	Renal	Myelosuppression, fever, rash, hepatotoxicity, pulmonary, CNS
Procarbazine (Matulane, Natulan)	Nonclassical alkylating agent	Alkylates DNA, DNA strand breaks.	Hepatic metabolism	Myelosuppression, N & V, CNS (confusion, depression), monoamine oxidase inhibition, hepatic, pulmonary
Streptozocin (Zanosar, Streptozotocin)	Nitrosourea	Methylation of O^6-guanine of DNA.	Renal	Myelosuppression, N & V, renal, diabetes, vesicant
Teniposide (VM-26, Vumon)	Plant alkaloid	Binds to topoisomerase II, causing DNA strand breaks.	Hepatic metabolism	Myelosuppression, hypersensitivity reactions
Thioguanine (6-Thioguanine, 6TG, Lanvis)	Antimetabolite (purine analog)	Incorporates into DNA as fraudulent nucleotide.	Hepatic metabolism	Myelosuppression, hepatic venoocclusive disease
Thiotepa (Thioplex)	Alkylating agent	Trifunctional alkylating agent; cross-links DNA.	Metabolism	Myelosuppression, stomatitis
Tretinoin (Retinoid Acid, *Trans* Retinoid Acid, Vesanoid)	Retinoid	Induces differentiation.	Hepatic metabolism, biliary excretion	Mucocutaneous, headache, fever, neurologic, hepatic, pulmonary
Vinblastine (Velban)	Plant alkaloid	Binds to tubulin, prevents formation of mitotic spindle.	Hepatic	Myelosuppression, vesicant, neurotoxin
Vincristine (Oncovin, Vincasar)	Plant alkaloid	Binds to tubulin, prevents formation of mitotic spindle.	Hepatic	Neurotoxin, vesicant, CNS
Vinorelbine (Navelbine)	Plant alkaloid	Binds to tubulin, prevents formation of mitotic spindle.	Hepatic	Myelosuppression, vesicant, neuropathy

CNS, central nervous system; IL, interleukin; N & V, nausea and vomiting; NAD, nicotinamide adenine dinucleotide.

[a] Minor routes of elimination are indicated by parentheses.

Alkylating Agents

MECHANISM OF ACTION Alkylating agents (busulfan, chlorambucil, cyclophosphamide, ifosfamide, melphalan, mechlorethamine, nitrosoureas, procarbazine) covalently bind alkyl groups (one or more saturated carbon atoms) to cellular molecules, including DNA, RNA, and proteins. Alkylating agents form reactive carbonyl groups in plasma and within tissues. Attack at electron-rich sites on adenine or guanine in the DNA molecule is the primary mechanism for cytotoxicity ([58]). Many alkylating agents (chlorambucil, cyclophosphamide, ifosfamide, mustard, melphalan) contain two reactive nitrochlorethyl groups, which allow them to react with both strands of DNA, forming cross-linkage (Fig. 73.8). Other agents (procarbazine, dacarbazine) produce only single-strand alkylation. The site of alkylation varies with the type of drug. Most alkylators preferentially attack the N_7 position of guanine. Nitrosoureas, procarbazine, and dacarbazine attack the O^6 position. Repair of alkylation sites on DNA by O^6methyltransferase produces resistance to the nitrosoureas but not to nitrogen mustard or cyclophosphamide ([59]). Formation of DNA adducts, particularly DNA cross-links, leads to direct interference with cellular replication ([60]). Alkylating agents are cell cycle nonspecific. The most widely used alkylating agents are the nitrogen mustards, of which five are commonly used: mechlorethamine, cyclophosphamide, ifosfamide, melphalan, and chlorambucil. Thiotepa is an aziridine closely related to the mustards. Busulfan is an alkyl sulfonate that has a poorly understood selective toxicity for myeloid precursors.

Procarbazine, hexamethylmelamine, and dacarbazine are metabolized to reactive intermediates that decompose to produce methyl diazonium, which covalently binds DNA. The basis of cytotoxicity of these nonfunctional alkylating agents is probably the formation of DNA strand breaks ([60]).

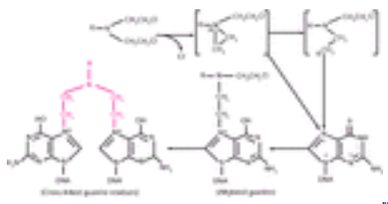

Figure 73.8. Mechanism of attachment of alkylating agents to DNA. Alkylating agents (in this case, those with two nitrochlorethyl groups) form reactive intermediates that bind to the N7 position of guanine. Bifunctional alkylating agents can bind to two guanine molecules, resulting in cross-linkage of DNA strands.

Cellular thiols can provide nucleophilic targets, which bind alkylating agents before they reach their DNA target. Increasing the concentration of these thiols impairs antineoplastic drug activity, toxicity, or both. Buthionine sulfonamide decreases glutathione synthesis (a naturally occurring thiol) and increases drug cytotoxicity ([61]). The radioprotective agent amifostine (WR2721) provides an exogenous nucleophilic thiol that can decrease alkylating agent toxicity ([62]). An important mechanism of cellular resistance to alkylating agents is through enhanced DNA repair mechanisms.

CLINICAL PHARMACOLOGY Binding of alkylating agents or their reactive intermediates to sulfhydryl groups on glutathione or proteins is the primary route of drug clearance. Dosage alterations for hepatic or renal function impairment are therefore usually not needed. Mechlorethamine rapidly degrades in solution and must be reconstituted just before administration. Cyclophosphamide and ifosfamide require activation via the cytochrome P-450 system to produce 4-hydroxy derivatives, which are taken up in tumor tissue ([63]) and decompose to form the active metabolite, phosphoramide mustard (Fig. 73.9). Drugs that alter the microsomal enzyme system, such as phenobarbital, can alter the plasma kinetics of cyclophosphamide and its metabolites. However, these kinetics changes do not appear to have any effects on the toxicity of this drug. Ifosfamide, a structural analog of cyclophosphamide, is activated less readily than cyclophosphamide, so higher drug doses are required ([64]). Although only a small amount of a dichlorethyl metabolite is formed with cyclophosphamide, this metabolite is generated to a significant extent with ifosfamide and may account for the central nervous system (CNS) toxicity seen with this drug. The release of acrolein and dichlorethyl metabolites into the bladder results in cystitis. Mercaptoethane sulfonate (Mesna) is administered to all patients receiving ifosfamide and to patients receiving high-dose cyclophosphamide to prevent cystitis by binding these reactive urinary metabolites ([65]). In plasma, Mesna circulates in an inactive dimesna form so that antineoplastic activity is not affected. Oral bioavailability of cyclophosphamide is excellent, whereas the bioavailability of melphalan (30%) and chlorambucil (50%) is less and more variable. The AUC of melphalan is reduced by concomitant use of cimetidine ([66]).

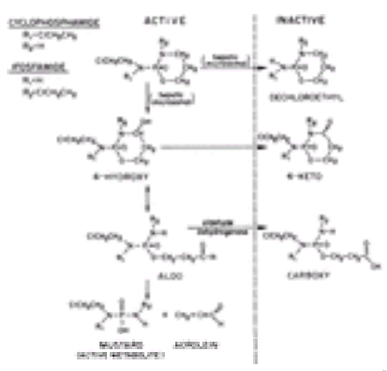

Figure 73.9. Metabolism of cyclophosphamide and ifosfamide. These drugs can be metabolized to active agents (vertical metabolism) or to inactive metabolites (horizontal metabolism).

TOXICITY Although alkylating agents share a common mechanism of action, toxicity of alkylating agents varies significantly due to differences in pharmacokinetic features, lipid solubility, membrane transport properties, and presence of specific DNA repair mechanisms. Marrow suppression occurs in all cell types with the alkylating agents. However, the pattern of suppression varies from drug to drug. A relative platelet- and stem cell–sparing effect occurs with cyclophosphamide. In contrast, busulfan is especially damaging to stem cells. The hematopoietic depression produced by the nitrosoureas is delayed (3 to 6 weeks). Nausea and vomiting are frequent with high doses of alkylators but decrease with low-dose oral regimens. Alopecia is seen primarily with cyclophosphamide. Pulmonary fibrosis can be seen with all alkylating agents but particularly with busulfan and the nitrosoureas ([67]). Bladder toxicity is seen with ifosfamide and cyclophosphamide. Hepatic toxicity is noted with high-dose thiotepa, cyclophosphamide, busulfan, or carmustine (BCNU) therapy used in stem cell transplant regimens ([68]). Ifosfamide, busulfan, and the nitrosoureas cause CNS toxicity, more frequently at high doses ([69]). Renal toxicity is seen with the nitrosoureas and ifosfamide ([70]). High-dose cyclophosphamide produces water retention. All of the alkylating agents result in gonadal atrophy, and permanent loss of reproductive function can occur ([71]). All are teratogenic and carcinogenic ([39]). An increased risk of second cancers (usually acute myelogenous leukemia) has been reported with melphalan, procarbazine, and cyclophosphamide.

Antimetabolites

Antimetabolites disrupt the synthesis of essential compounds required for DNA synthesis. Antimetabolites are cell cycle–specific agents that must be present during the S-phase of the cell cycle to produce toxicity, which explains the schedule-dependent nature of these agents. Most antimetabolites are prodrugs that require metabolism to express their cytotoxic effects.

METHOTREXATE

Mechanism of Action MTX, an analog of folic acid (Fig. 73.10), is a tight-binding inhibitor of DHFR, the enzyme required for converting folate to its active (tetrahydrofolate) form ([72]). In the presence of MTX, tetrahydrofolates, needed as cofactors for purine and thymidine formation, are depleted leading to inhibition of DNA synthesis and cell death. Cytotoxicity is related to the time MTX or MTX polyglutamate concentrations are present within the cell at concentrations great enough to inhibit DHFR ([73]). 5-Formal tetrahydrofolate (calcium leucovorin or citrovorum factor) administered 24 hours after the administration of MTX can rescue normal cells from the effects of MTX by providing a reduced form of folic acid to the cells. Resistance to MTX has been related to the presence of increased levels of the target enzyme, DHFR, in cells as the result of increased expression or amplification of the DHFR gene.

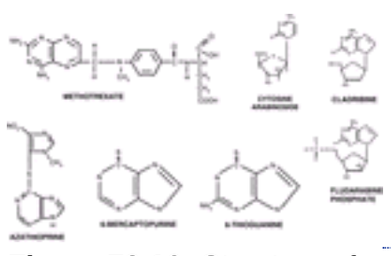

Figure 73.10. Structure of selected antimetabolites used for treatment of hematologic malignancies.

Clinical Pharmacology MTX can be given orally, intravenously, or by intrathecal injection. With standard oral doses (7.5 to 20 mg/m ^{2}), absorption is variable, with bioavailability decreasing at higher doses ([74]). MTX is primarily eliminated by glomerular filtration and renal tubular secretion. In patients with renal dysfunction, MTX clearance is delayed, resulting in prolonged exposure and increased toxicity ([75]). Patients with renal insufficiency should not be given MTX or must have plasma drug concentrations closely monitored with leucovorin rescue used if clearance is delayed ([76]). Retention of drug in ascites or pleural effusions can prolong MTX half-life and increase toxicity ([47]).

Toxicity The primary toxicities associated with MTX are myelosuppression and mucositis ([76]). High-dose MTX can result in renal failure as a consequence of drug precipitation in renal tubules in the presence of acidic urine. The routine use of adequate prehydration, alkalinization of the urine, and measurement of MTX concentrations after high-dose therapy are required ([77]). Chronic MTX administration can be associated with liver disease, manifested by portal fibrosis and occasional cases of cirrhosis ([78]). MTX is also associated with the development of pulmonary toxicity ([79]). CNS toxicity has been reported with MTX, particularly with high doses of MTX and concomitant cranial irradiation. Intrathecal MTX administration may cause arachnoiditis ([80]).

CYTOSINE ARABINOSIDE

Mechanism of Action Cytosine arabinoside (ara-C, cytarabine and liposomal ara-C, DepoCyt) is an analog of deoxycytidine with substitution of an arabinose sugar for the normally occurring deoxyribose sugar (Fig. 73.10). Ara-C must undergo metabolic activation to cytosine arabinoside triphosphate by a series of

enzyme-mediated phosphorylation steps (Fig. 73.11). Cytosine arabinoside triphosphate competitively inhibits DNA polymerase alpha. Cytosine arabinoside triphosphate is also incorporated into DNA, a feature that correlates closely with cytotoxicity. Incorporated ara-C inhibits both DNA template function and chain elongation ([81]). Ara-C–mediated DNA damage then induces apoptosis. Several mechanisms of resistance to ara-C have been described, including (a) deletion of deoxycytidine kinase, the initial enzyme involved in ara-C activation; (b) increased levels of cytidine deaminase in tumor cells, resulting in rapid conversion of ara-C to inactive uracil arabinoside (ara-U); and (c) decreased presence of nucleoside transport sites on tumor cells.

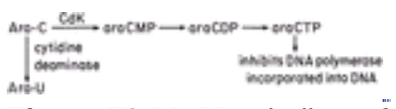

Figure 73.11. Metabolism of cytosine arabinoside (Ara-C) by tumor cells. Ara-C is phosphorylated to its active metabolite, cytosine arabinoside triphosphate (araCTP), by a series of enzymatic steps, beginning with deoxy-cytidine kinase (CdK). Metabolism via the enzyme cytidine deaminase converts Ara-C to the inactive metabolite uracil arabinoside (Ara-U). araCDP, cytosine arabinoside diphosphate; araCMP, cytosine arabinoside monophosphate.

Clinical Pharmacology Ara-C is rapidly converted to the inactive metabolite, ara-U, by the degradative enzyme, cytidine deaminase, present in great quantity in the liver. The large capacity of the liver for metabolizing ara-C results in (a) a short plasma half-life of ara-C (2 to 3 hours), (b) adequate capacity for clearance of ara-C even in the presence of hepatic damage, and (c) urinary excretion of high concentrations of ara-U ([82]). Because of the short drug half-life and the S-phase specificity of ara-C, prolonged infusion or multiple-day administration schedules are required for cytotoxicity. Cytarabine encapsulated into multivesicular lipid-based capsules (DepoCyt) has been developed as a means of sustaining cytotoxic ara-C concentrations at the tumor site. It acts as a depot form of ara-C. DepoCyt has been found useful in the therapy of neoplastic meningitis ([83]).

Toxicity Single high-dose boluses of ara-C are well tolerated but clinically ineffective because of the rapid inactivation of the agent. Continuous infusion or repeated administration of ara-C for 24 to 48 hours results in significant myelosuppression ([84]). Nausea, vomiting, and diarrhea often occur after ara-C administration, especially with high-dose regimens. These symptoms typically subside quickly after the treatment. High-dose ara-C regimens (doses of 3 g/m ^{2} every 6 to 12 hours for 12 doses) have been associated with the development of cholestatic jaundice and elevations of hepatic transaminases. In addition, cerebral and cerebellar dysfunction have been reported in approximately 20% of patients receiving high-dose ara-C ([85]). This toxicity is more common in patients older than than 50 years of age and usually is reversible. A steroid-responsive conjunctivitis noted after high-dose ara-C has led to the routine prophylactic use of saline or steroid eye drops in patients receiving the high-dose regimens. Intrathecal injection of ara-C or DepoCyt is associated with chemical arachnoiditis (headache, fever, nausea, vomiting).

HYDROXYUREA

Mechanism of Action The principal use of hydroxyurea is as a myelosuppressive agent for myeloproliferative syndromes, such as chronic myelogenous leukemia (CML) or polycythemia vera, or for treatment of sickle cell anemia. Hydroxyurea inhibits ribonucleotide reductase, the enzyme responsible for the conversion of ribonucleotide diphosphates to their deoxyribonucleotide forms used for DNA synthesis and repair ([86]). Hydroxyurea kills cells selectively in the S-phase of the cell cycle. Hydroxyurea blocks human immunodeficiency virus DNA synthesis also. Doses of 0.5 to 2.0 g/day result in a rapid (2 to 5 day) decrease in peripheral white blood cell counts. Doses are then titrated to clinical response. The rapid onset of effect on circulating leukemia cell populations and the brief duration of action have led to the routine use of this agent in patients with significantly elevated leukemic blast counts or in those with elevated platelet counts ([87]).

Clinical Pharmacology Hydroxyurea is well absorbed orally (90 to 100% bioavailability) with minimal patient-to-patient variability ([88]). It is excreted mostly in the urine with a plasma half-life of 4 hours ([89]). Although precise guidelines are not available, patients with renal failure should have drug doses reduced.

Toxicity The main toxicity of hydroxyurea is myelosuppression, which is rapidly reversible once the drug is discontinued ([87]). Reversal of myelosuppression is rapid after discontinuation of the drug. Nausea, vomiting, anorexia, and diarrhea can be seen but are typically mild. Skin changes (hyperpigmentation, rash, and banding of nail beds) have been noted with long-term therapy ([90]). Uncommon toxicities include pulmonary fibrosis, hepatotoxicity, and fever. Hydroxyurea-induced leg ulceration has been reported ([91]).

6-MERCAPTOPURINE, 6-THIOGUANINE, AND AZATHIOPRINE

Mechanism of Action 6-MP is used in maintenance therapy for children with acute lymphoblastic leukemia. 6-Thioguanine is a second-line agent for therapy of acute myelogenous leukemia. Azathioprine, a prodrug of 6-MP, is used as an immunosuppressant. The mechanisms of action of these three agents are similar ([92]). All are purine analogs. 6-MP is an analog of hypoxanthine (Fig. 73.10). It is converted intracellularly to 6-MP ribose triphosphate, which is incorporated into DNA (Fig. 73.12). 6-MP kills cells primarily by incorporation into DNA, compromising subsequent replication. 6-Thioguanine is activated in a manner similar to that outlined for 6-MP. Azathioprine is rapidly cleaved by nonenzymatic mechanisms to 6-MP and methyl-4-nitro-5-imidazole derivatives. 6-MP is incorporated into DNA. The imidazole derivatives react with glutathione and cysteine residues. The alkylation of lymphocyte thiol groups may be important in azathioprine immunosuppression ([93]). Azathioprine also interferes with cytokine synthesis ([93]).

Figure 73.12. Mechanism of activation and catabolism of azathioprine and 6-mercaptopurine (6-MP). Active metabolites are indicated by surrounding boxes. Inactive (or less active) metabolites are indicated by italic print. HGPRT, hypoxanthine-guanine phosphoribosyltransferase; TPMT, thiopurine methyltransferase; xo, xanthine oxidase.

Clinical Pharmacology Azathioprine is rapidly cleaved to 6-MP after absorption. Clearance of 6-MP occurs primarily through two routes of catabolism. 6-MP is oxidized to the inactive metabolite, 6-thiouric acid, by xanthine oxidase (Fig. 73.12). 6-MP also undergoes S-methylation by the enzyme thiopurine methyl transferase (TPMT) to yield less active 6-methyl mercaptopurine. Oral absorption of 6-MP is incomplete and highly variable. The low bioavailability (5 to 37%) is a result of a large first pass effect as drug is absorbed into the portal circulation and metabolized by xanthine oxidase in the liver. The use of concomitant allopurinol (an inhibitor of xanthine oxidase) increases 6-MP bioavailability fivefold, increasing toxicity ([94]). This important drug interaction must be remembered for 6-MP and azathioprine. Patient-to-patient variation in TPMT activity can result in significant changes in 6-MP metabolism and drug toxicity. One in 300 subjects has absent TPMT activity. Patients with low TPMT activity are susceptible to severe 6-MP– and azathioprine-induced myelosuppression ([95]). Patients with high TPMT concentrations may be at greater risk for relapse due to rapid drug inactivation. Genetic testing for the TPMT gene is available ([95]).

Toxicity The dose-limiting toxicity of 6-MP, 6-thioguanine, and azathioprine is myelosuppression, occurring 1 to 4 weeks after onset of therapy and reversible when the drugs are discontinued ([92] , [96]). Immunity to infectious agents or vaccines is subnormal. Gastrointestinal mucositis and stomatitis are modest but appear to be more common in adults than in children. Hepatotoxicity is seen in a small number of patients receiving 6-MP ([97]). It is usually mild and reversible with a clinical picture of cholestatic jaundice, although elevations of transaminase may be seen. Frank hepatic necrosis and venoocclusive disease can occur. 6-MP and azathioprine are potentially teratogenic. Acute leukemia with karyotypic changes of 7q/-7 has been seen after 6-MP use, with a greater risk associated with longer duration of therapy ([98]).

FLUDARABINE

Mechanism of Action Fludarabine (Fig. 73.10) is a fluoridated analog of 9-ß-D-arabinofuranosyladenine (ara-A). When administered, fludarabine is dephosphorylated in plasma, enters cells, and then is again phosphorylated to 2-fluoro-ara-ATP (F-ara-ATP) (Fig. 73.13) ([99]). F-ara-ATP inhibits DNA polymerase, ribonucleotide reductase, DNA primase, and DNA ligase I, resulting in DNA deletions and mutations ([100]). Fludarabine is also incorporated into DNA where it is an effective DNA chain terminator. Although the effects of F-ara-A on DNA synthesis account for its activity in dividing cells, fludarabine is also cytotoxic to cancers with very low growth fractions such as indolent lymphoma. Although the specific mechanism by which fludarabine induces cell death among quiescent cells is under investigation, proposed mechanisms of action include fludarabine's ability to inhibit RNA polymerase and to deplete nicotinamide adenine dinucleotide with resultant decrease in cellular energy stores and interference with normal DNA repair processes ([101]).

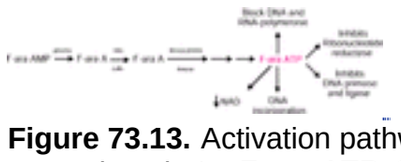

Figure 73.13. Activation pathway and mechanism of action of fludarabine. F-ara-A, fluoroarabinofuranosyladenine; F-ara-AMP, 2-fluoro-ara–adenosine monophosphate; F-ara-ATP, 2-fluoro-ara–adenosine triphosphate; NAD, nicotinamide adenine dinucleotide.

Clinical Pharmacology Fludarabine undergoes rapid (2 to 4 minutes) conversion to 2-F-ara-A. 2-F-ara-A is excreted primarily in the urine with few metabolites noted. In patients with renal function impairment, total body clearance of 2-F-ara-A decreases significantly ([100]). Dose reduction is recommended for patients with renal dysfunction. Oral bioavailability is roughly 75%, and oral formulations for commercial use are being developed.

Toxicity The dose-limiting toxicity of 2-F-ara–adenosine monophosphate is myelosuppression occurring a median of 12 to 16 days after the beginning of therapy.

Other toxicities include mild nausea and vomiting (36% of patients), fever (60%), infection (33%), peripheral sensorimotor neuropathy (rare), autoimmune hemolytic anemia (rare), and hepatocellular toxicity with elevations in serum transaminase (rare) ([92], [100]). An irreversible neurotoxicity syndrome has occurred in patients receiving high doses (greater than 40 mg/m ^{2}/day for 5 days). Mild, reversible neurotoxicity has been seen at lower doses with increased frequency and severity in older patients ([102]). Pulmonary toxicity, characterized by fever, cough, hypoxia, and diffuse interstitial pneumonitis, has also been reported. Fludarabine is immunosuppressive and associated with an increased risk of opportunistic infections ([103], [104]). CD4 and CD8 T-lymphocyte subpopulations drop to 150 to 200 per mm ^{3} after therapy.

PENTOSTATIN

Mechanism of Action Pentostatin (deoxycoformycin, DCF) is a potent inhibitor of adenosine deaminase. It is active in the treatment of chronic lymphoid malignancies, particularly hairy cell leukemia ([105]). Inhibition of adenosine deaminase results in inability of the cell to catabolize adenosine and deoxyadenosine. Intracellular concentrations of deoxyadenosine triphosphate increase and exert a negative feedback on ribonucleotide reductase, resulting in an imbalance in deoxynucleotide pools. This imbalance inhibits DNA synthesis and impairs replication with arrest of cells in the G_1- and S-phases of the cell cycle. These mechanisms are relevant to proliferating cells. The mechanism of action of pentostatin on nonproliferating cells is unclear.

Clinical Pharmacology Plasma pentostatin concentrations greatly exceed those needed to inhibit adenosine deaminase. Pentostatin's terminal half-life is 3 to 15 hours in humans. Only 40 to 80% of the drug is excreted unchanged in urine within 24 hours ([106]). Plasma clearance correlates with creatinine clearance. Dosage reduction should be considered for patients with impairment in renal function. Pentostatin is not bioavailable by the oral route as a result of its acid lability.

Toxicity At doses used in hairy cell leukemia (4 mg/m ^{2} biweekly), therapy is usually well tolerated ([107]). Toxicities include worsening of neutropenia, mild to moderate lethargy, anorexia, rash, and reactivation of herpes zoster late in therapy. Nausea, although often mild, can occasionally be severe. Delayed emesis is seen.

CLADRIBINE

Mechanism of Action Cladribine (2-chlorodeoxyadenosine, 2-CdA) is an adenosine analog found to be more cytotoxic against lymphocytes than fludarabine (Fig. 73.10). The 5'-triphosphate metabolite [2-chloro-2'-deoxyadenosine 5' triphosphate (2-CdATP)] accumulates in cells rich in deoxycytidine kinase, primarily lymphoid cells. 2-CdATP is incorporated into DNA, producing DNA strand breaks and inhibition of DNA synthesis in dividing cells ([108]). Several mechanisms for drug toxicity to resting cells have been suggested. It is postulated that lymphocytes at rest are continually breaking and rejoining DNA, a process that is balanced by nicotinamide adenine dinucleotide consumption for repair of cellular breaks. By interfering with DNA repair, cladribine stimulates increased nicotinamide adenine dinucleotide use, triggering apoptosis ([109]).

Clinical Pharmacology Bioavailability of subcutaneously administered cladribine is excellent. Oral bioavailability averages 50% ([110]). Cladribine is primarily cleared by the kidneys (50% of total dose) via a cation organic carrier system. Although dose-adjustment guidelines for patients with renal insufficiency are not available, caution should be used in giving cladribine to patients with renal insufficiency. Significant patient-to-patient variability (±28%) exists in the AUC achieved after administration of drug by any method ([111]).

Toxicity The dose-limiting toxicity of cladribine is myelosuppression. Grade 3 or 4 neutropenia occurs in one-half of treated patients at standard doses. Fever (above 100°F) has been seen in two-thirds of patients, often beginning 5 to 7 days into therapy or during the period of neutropenia ([112]). Cladribine suppresses $CD4^+$ lymphocytes. The CD4:CD8 ratio may remain depressed for up to 16 months after therapy, with associated opportunistic infections including *Candida* or *Aspergillus* ([104]). After high-dose cladribine therapy (5 to 10 times the recommended therapeutic dose), renal failure and progressive irreversible motor weakness with paraparesis have been reported. Betticher et al. ([113]) have shown that reducing the dose of cladribine from 0.7 to 0.5 mg/kg/cycle decreased the rate of grade 3 myelosuppression (33 to 8%) and the infection rate (30 to 7%). No change in lymphoma response rate was noted with this dose reduction.

Topoisomerase Inhibitors

MECHANISM OF ACTION DNA topoisomerases are nuclear enzymes that use ATP to modulate DNA topology by passing an intact helix through a transient break in the DNA backbone through a number of discrete steps. These enzymes make the transient strand breaks in DNA to allow the cell to manipulate its topology ([114]). DNA topoisomerase I makes single-strand breaks in the DNA, whereas the type II enzyme makes double-strand breaks and passes double-stranded DNA through the nick to allow relaxation of overcoiled DNA. Topoisomerase II functions in DNA replication, chromosome condensation, and chromosome segregation. Topoisomerase inhibitors (doxorubicin, daunorubicin, epirubicin, idarubicin, etoposide, and teniposide) act by poisoning these enzymes to prevent the enzyme from religating cleaved DNA (Fig. 73.14) ([115]). This converts topoisomerase into a toxin, which introduces high levels of transient protein-associated breaks in the genome of treated cells. Failure to repair the DNA break by the cell results in apoptosis.

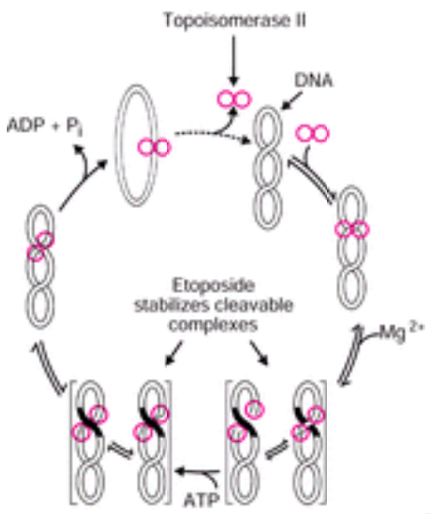

Figure 73.14. The catalytic cycle of topoisomerase II. Dimeric topo-isomerase II binds to DNA. In the presence of magnesium and adenosine triphosphate (ATP), an intact DNA helix can pass through a temporary break in DNA with subsequent relegation. Topoisomerase II inhibitors block this cycle at the stage of DNA cleavage. ADP, adenosine diphosphate. (From Osheroff N, Zechiedrich EL, Gale KC. Catalytic function of DNA topoisomerase II. Bioassays 1991;12:269–275.)

Currently available topoisomerase I inhibitors are irinotecan (CPT-11) and topotecan. As these agents are not frequently used in treatment of hematologic neoplasms, they are not further discussed in this section. U.S. Food and Drug Administration (FDA)–approved topoisomerase II inhibitors are etoposide, teniposide, doxorubicin, idarubicin, epirubicin, and mitoxantrone.

ANTHRACYCLINES

Clinical Pharmacology Anthracyclines include doxorubicin, daunorubicin, epirubicin, and idarubicin. Anthracycline elimination occurs through hepatic metabolism and biliary excretion. Urinary excretion accounts for approximately 10% of anthracycline clearance ([116], [117]). Dose reduction for patients with jaundice is required, although specific dose-reduction guidelines are not available. Studies with doxorubicin in patients with hepatic dysfunction showed no increase in cardiac toxicity, although an increase in mucositis and myelosuppression occurs. Liposomal encapsulated anthracyclines [doxorubicin hydrochloride liposome injection (Doxil) and liposome-encapsulated doxorubicin (Myocet)] act as a depot form of free drug ([118], [119]).

Toxicity The acute dose-limiting toxicity of the anthracyclines is myelosuppression, with a nadir in leukocytes expected around day 10 to 14 and recovery usually completed by day 21 to 28. Other acute systemic toxicities include nausea, vomiting, alopecia, and mucositis. Anthracyclines cause severe local tissue reactions if extravasation occurs during infusion. The most serious toxicity associated with anthracyclines is cardiotoxicity. Anthracyclines cause a dose-dependent congestive cardiomyopathy that often leads to congestive heart failure. Late-onset cardio-myopathy can appear months to years after treatment is completed ([120]). The mechanism underlying the cardiotoxic effects of anthracyclines is generally accepted to be via formation of free radicals generated by iron–doxorubicin complexes that damage cardiac cellular membranes ([121]). The cardiac damage caused by anthracyclines is cumulative. With total doses of doxorubicin less than 500 mg/m ^{2}, heart failure is seen in less than 7% of cases. The risk of toxicity is related to the peak plasma concentration, so continuous infusions reduce the risk of heart failure compared to administration by large bolus injections. At equally myelosuppressive doses, epirubicin is less cardiotoxic than doxorubicin ([117]). Liposomal formulations of doxorubicin and daunorubicin have been investigated in the hopes of increasing tumor selectivity, allowing an increase in the tolerated dose. Liposomal formulations of doxorubicin have reduced cardiotoxicity. Liposomal formulations of doxorubicin and daunorubicin are, however, associated with a unique toxicity: palmar-plantar erythrodysesthesia syndrome ([118], [119]).

MITOXANTRONE Efforts to synthesize compounds with better antineoplastic activity and less toxicity than doxorubicin led to the discovery of mitoxantrone.

Toxicity The primary dose-limiting toxicity of mitoxantrone is myelosuppression. Other potential toxicities include nausea, vomiting, alopecia, and cardiotoxicity. At doses that produce equivalent drops in white blood cell and platelet counts (75 mg/m ^{2} of doxorubicin vs. 15 mg/m ^{2} of mitoxantrone), nausea, vomiting, and alopecia are less frequent with mitoxantrone than with doxorubicin ([122], [123]). With commonly used dosages, approximately twice as much mitoxantrone can be given before heart failure develops when compared with doxorubicin. Acute leukemia is a potential serious side effect of therapy using mitoxantrone.

Clinical Pharmacology Mitoxantrone is highly protein bound (78%) ([122]). Hepatic metabolism is the primary mechanism for mitoxantrone clearance, with only 6 to 11% being cleared by the kidney.

EPIPODOPHYLLOTOXINS

Toxicity Common toxicities of epipodophyllotoxins etoposide and teniposide include bone marrow suppression, dose-dependent nausea or vomiting, and alopecia ([124]). Myelosuppression is the dose-limiting toxicity at usual therapeutic doses. At very high doses, such as those used with bone marrow transplantation regimens, mucositis becomes the dose-limiting toxicity. Liver toxicity, fever, and chills are also seen with high-dose therapy. Hypersensitivity reactions, including vasomotor changes related to the pulmonary and gastrointestinal systems, can also be observed. These allergic reactions, although infrequent, can be life-threatening and are likely due to hypersensitivity to the polysorbate 80 (Tween 80) needed to solubilize the intravenous etoposide preparation. These reactions can usually be ameliorated with histamine blockade, by using a slower infusion, or both. Etoposide phosphate, a water-soluble prodrug that is rapidly changed to etoposide by endogenous phosphatases, may reduce the risk of a hypersensitivity reaction because no solubilizer is required ([125]). The most serious adverse event associated with etoposide and teniposide is the development of acute nonlymphocytic leukemia ([126]). Therapy-related acute myelogenous leukemia also occurs with other topoisomerase II inhibitors, but at a lower frequency. Leukemia develops relatively early after etoposide therapy (2 to 3 years) and can be distinguished from other therapy-related malignancies by a unique molecular marker: a balanced translocation involving the mixed-lineage leukemia gene on chromosome 11 band q23.

Clinical Pharmacology Etoposide is poorly soluble in water. It is dissolved in a solubilizer composed of polysorbate 80, polyethylene glycol, and alcohol and diluted to a concentration less than 0.4 mg/ml to avoid precipitation. These additives are believed to induce the hypersensitivity reactions occasionally seen with etoposide infusion. Approximately one-third of administered intravenous etoposide is excreted in the urine, and hepatic glucuronidation may account for another 25% of etoposide's metabolism ([127]). Etoposide clearance is modestly decreased in patients with renal dysfunction but not in those with hepatic obstruction. Biliary drug excretion is minimal, and little or no dose adjustment is required in the presence of obstructive jaundice. Etoposide is highly bound to plasma proteins, with only 6 to 8% unbound. Because free drug is biologically active, conditions that decrease protein binding or decrease albumin increase the pharmacologic effect of a given drug dose. Teniposide has less water solubility and decreased renal clearance (10%) and is more tightly bound to plasma proteins than etoposide, with less than 1% of the total teniposide concentration unbound. Teniposide has a longer drug half-life and increased biliary clearance compared to etoposide. Anticonvulsants, such as phenobarbital and phenytoin, increase teniposide clearance, presumably by increasing hepatic metabolism ([128]). This increased clearance has been found to result in a lower efficacy of chemotherapy in children with acute lymphocytic leukemia receiving teniposide chemotherapy. Etoposide is available as an oral capsule. Bioavailability of oral etoposide ranges from 40 to 80% and varies with the drug dose ([124]). Oral etoposide absorption is linear up to doses of 250 mg but decreases with doses of greater than 300 mg. Oral etoposide administration results in significantly greater variability in drug exposure than does intravenous administration ([129]).

Bleomycin

MECHANISM OF ACTION Bleomycin is a mixture of low-molecular-weight glycopeptides, of which bleomycin A_2 is the major species. Bleomycin can be administered subcutaneously, intramuscularly, and intravenously and has been instilled into pleural and pericardial spaces to act as a sclerosing agent in patients with malignant effusions. Bleomycin produces single- and double-strand DNA breaks, which result in chromosomal deletions and fragmentation ([130]). The DNA strand breaks are generated by the production of free radicals by an Fe (II)–bleomycin complex, which functions as a ferrous oxidase to catalyze the formation of a hydroperoxide ([131]).

CLINICAL PHARMACOLOGY Absorption after intramuscular or subcutaneous injection of bleomycin is nearly complete. Renal clearance accounts for 65% of total drug clearance. Patients with renal failure have a prolonged drug half-life ([132]) and an increased risk of developing pulmonary toxicity ([133]). A 75% dose reduction has been recommended for patients with a creatinine clearance less than 25 ml/min. Approximately 45% of an intracavitary dose of bleomycin is absorbed into the systemic circulation, and 30% is excreted in urine ([134]).

TOXICITY Unlike many antineoplastic agents, bleomycin is not myelosuppressive. Fever occurs within 48 hours of drug administration in approximately 25% of patients. Rare acute allergic reactions have been noted with this drug, which have led to the use of a 1-unit test dose of bleomycin in patients receiving the drug for the first time ([135]). The most prominent toxic effect of bleomycin is a chronic interstitial pneumonitis, which may continue on to fibrosis, hypoxia, and death ([136], [137]). Pulmonary toxicity, manifested by cough, dyspnea, and pulmonary infiltrates, occurs more often at higher cumulative drug doses but can occur after any dose. Approximately 10% of patients who receive a total drug dose of more than 450 mg develop pulmonary toxicity. Risk factors for pulmonary toxicity include individual doses over 25 U/m^2, advancing age, underlying lung disease, and previous radiation therapy to the chest. Patients who receive high oxygen concentrations during anesthesia have an increased risk of lung toxicity ([138]). No specific therapy is effective other than stopping the drug. Bleomycin can also result in cutaneous toxicities of hyperpigmentation, erythema, desquamation, nail changes, and alopecia ([139]). Raynaud phenomenon has been reported. Skin and lung, tissues with the greatest susceptibility to bleomycin damage, have low concentrations of bleomycin hydrolase, an enzyme that cleaves bleomycin to inactive metabolites.

Platinum Analogs

MECHANISM OF ACTION The platinum analogs cisplatin, carboplatin, and oxaliplatin are heavy metal complexes that induce tumor cell kill by cross-linking DNA strands in a manner analogous to the alkylating agents. Reactive aquated intermediates are formed within cells, which directly and covalently bind to DNA, leading to DNA cross-links ([138]) (Fig. 73.15). Cisplatin is more reactive in water than carboplatin or oxaliplatin. Chloride-containing solutions are required to stabilize cisplatin. The difference in aqueous stability, differences in the reactive groups, and spatial differences between platinum compounds appear to account for the variations in pharmacokinetics and toxicity among platinum agents. Cisplatin, carboplatin, and oxaliplatin form the same total amount of similar DNA lesions, although the time frame for forming DNA adducts varies, with oxaliplatin and carboplatin taking more time than cisplatin ([141]). These compounds are very effective in treating a variety of solid tumors and are also used as second-line agents in the treatment of lymphomas ([142]).

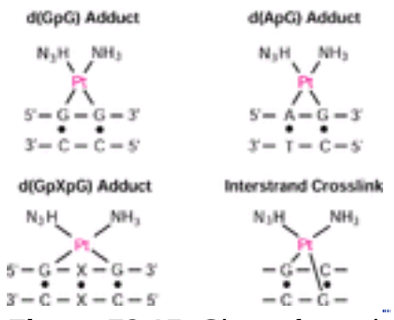

Figure 73.15. Sites of covalent binding of cisplatin to DNA. After forming an aquated reactive intermediate, cisplatin binds to guanine (and, occasionally, adenine) bases within the DNA molecule. Some adducts result in interstrand DNA cross-links.

CLINICAL PHARMACOLOGY The reactive intermediates of the platinum analogs rapidly bind to proteins and other nucleophilic compounds. Only the free (unbound) species are cytotoxic ([143]). Over 90% of cisplatin is protein bound and inactivated within 2 to 4 hours. ([144]). Thus, protein binding represents the major route of carboplatin elimination. In contrast, only 20 to 40% of carboplatin is protein bound at 2 hours after administration. Renal excretion is the primary route of carboplatin elimination (70 to 90% of total clearance). Carboplatin clearance is highly correlated with creatinine clearance ([145]). Carboplatin doses should be calculated based on an individual patient's creatinine clearance ([146]). Oxaliplatin is also extensively cleared by the kidney (50%) but to a lesser degree than carboplatin. Oxaliplatin dose reductions are needed for individuals with renal insufficiency ([147]).

TOXICITY The toxicity profiles of cisplatin, oxaliplatin, and carboplatin differ. Myelosuppression is rare with cisplatin, although moderate anemia is common ([140]). Nausea and vomiting are common cisplatin toxicities, but the incidence can be reduced with pretreatment therapy using dexamethasone and serotonin antagonists ([27]). Nephrotoxicity, manifested by azotemia and electrolyte disturbances (primarily hypomagnesemia and hypokalemia), is dose related ([148]). Although pre- and posttreatment hydration (with chloride-containing solutions) and diuresis reduce the incidence and severity of cisplatin nephrotoxicity, moderate and permanent reductions in the glomerular filtration rate may still occur ([149]). Neurotoxicity from cisplatin is cumulatively dose related and usually begins as a “stocking-glove”–type peripheral neuropathy. Hearing loss, cortical blindness, and seizures also have been reported. The toxicity profile of carboplatin is different from that of cisplatin, with dose-limiting myelosuppression being the major toxicity after carboplatin administration ([150]). Renal, neurologic, and ototoxicities noted with cisplatin are infrequent after carboplatin administration. Dose reductions of carboplatin must be made in patients with impaired renal function, with formulas available for calculating dose adjustments based on creatinine clearance and desired nadir platelet count ([145]). Nausea and vomiting usually are mild to moderately severe after carboplatin. Reversible, cumulative peripheral sensory neuropathy is the primary dose-limiting toxicity with oxaliplatin therapy. Hematologic and gastrointestinal toxicities occur but are mild to moderate. Ototoxicity and nephrotoxicity are uncommon ([151]).

Antimicrotubule Agents

VINCA ALKALOIDS

Mechanism of Action The vinca alkaloids vinblastine, vincristine, and vinorelbine bind to tubulin and prevent the formation of microtubulin, a protein that is essential for maintenance of cellular shape and for formation of the mitotic spindle ([152]). Vinca alkaloids bind to a site on microtubulin distinct from the taxanes. Cells treated with vinca alkaloids are arrested in metaphase ([153]). Disruption in microtubular formation leads to initiation of apoptosis. Differences in activity and toxicity of the vinca alkaloids result from differences in their pharmacokinetics, their differential effects on various tubulin isoforms, and variations in tissue penetration and cellular retention. Resistance is a result of the presence of p-glycoprotein or reduced tubulin binding due to mutations in tubulin.

Clinical Pharmacology All vincas are rapidly taken up into cells. However, the various agents differ in cellular retention (vinblastine greater than vincristine). All vincas are extensively bound to tissues and to proteins ([154]). Their terminal half-lives are long (20 to 60 hours). CNS penetration is poor. All of the vinca alkaloids are metabolized by the liver (via hepatic cytochrome P-450 3A4) and excreted into the bile. Drugs blocking CYP 3A4 may inhibit vinca clearance, causing increased toxicity ([155]). Doses of the vinca alkaloids should be reduced in patients with hepatic dysfunction but not in patients with renal insufficiency. Specific dose-reduction guidelines for hepatic function impairment are not available.

Toxicity Vincristine causes little myelosuppression. Its dose-limiting and most frequent toxicity is neurotoxicity ([153] , [156]), manifested by a symmetric, distal, sensory-motor neuropathy. Loss of deep tendon reflexes in the lower extremities and paresthesias of the fingers and toes are common early findings. Continued use of the drug can result in further motor neuropathy, manifested by foot-drop or wrist-drop, which may be only partially reversible or irreversible when the drug is stopped. Neuropathies of the motor cranial nerves have also been reported, as have constipation, cramps, and paralytic ileus. Hair loss is common after vincristine administration. The dose-limiting toxicity of vinblastine is hematopoietic, with thrombocytopenia and leukopenia commonly occurring after administration of the drug ([157]). The onset of myelosuppression tends to occur earlier with this agent than with other antineoplastic agents, with the leukocyte nadir typically seen by day 4 to 7 and recovery by day 10 to 14. Severe neurotoxic symptoms are unusual with vinblastine, but use of the drug is associated with myalgias and an autonomic neuropathy manifested by orthostatic hypotension or paralytic ileus. Vinorelbine shows toxicities similar to other vincas ([158]). Its dose-limiting toxicity is myelosuppression. Vinorelbine is less neurotoxic than vincristine. Injection site reactions of erythema, pain, and vein discoloration occur in one-third of patients with severe toxicity, which is seen in 2% of patients treated with vinorelbine. Respiratory reactions have been reported. All vincas are potent vesicants, with severe local tissue damage associated with extravasation of these drugs into soft tissues.

TAXANES

Mechanism of Action Taxanes paclitaxel and docetaxel are antineoplastic agents that exert their cytotoxic effects by binding to a unique site on microtubulin (distinct from the vinca alkaloids) that causes increased assembly and stabilization of microtubulin ([159]). Docetaxel binds with slightly greater affinity than paclitaxel. The bundling of microtubules induced by the taxanes blocks cells in metaphase and induces apoptosis ([160]). The taxanes are potent radiation therapy sensitizers.

Clinical Pharmacology Paclitaxel is primarily cleared from the body by hepatic metabolism via cytochrome P-450 2C8 and 3A4 enzymes ([161] , [162]). This route of elimination can be saturated, so nonlinear kinetics are noted at high paclitaxel doses ([163]). Inhibition of the P-450 system can delay drug clearance and increase toxicity. Docetaxel also undergoes microsomal metabolism, although primarily via CYP 3A4 ([164]). Dose reductions of both paclitaxel and docetaxel are needed in patients with hyperbilirubinemia. Many drug interactions with the taxanes have been recognized ([165]), including those with anthracyclines, carboplatin, and anticonvulsants due to the effect of these drugs on cytochrome P-450 metabolism.

Toxicity Myelosuppression is the principal toxicity of both paclitaxel and docetaxel, although they have differing nonhematologic side effects. Hypersensitivity reactions with paclitaxel (dyspnea, urticaria, hypotension) were found in 25% of patients initially treated ([166]). With prophylactic use of dexamethasone and antihistamines, these reactions are uncommon (1%). Paclitaxel induces a peripheral neuropathy. Transient myalgias are seen in over one-third of patients and occur 2 to 5 days after treatment at doses over 170 mg/m ^{2}. Nausea and vomiting are uncommon, but alopecia is seen. Docetaxel induces edema formation due to fluid retention and an erythematous maculopapular rash ([167]). Both the rash and fluid retention are prevented by premedication with dexamethasone. Peripheral neuropathy is also seen with docetaxel. Neuromuscular toxicity is less severe than with paclitaxel.

Asparaginase

MECHANISM OF ACTION Certain cells, in particular those of lymphocytic origin, lack the capacity to synthesize the amino acid asparagine. L-Asparaginase is an enzyme derived from bacteria that reduces blood asparagine to undetectable levels, thereby depriving cells of this amino acid. The cytotoxic effects of L-asparaginase on lymphoblasts result from the inhibition of protein synthesis when cells are depleted of asparagine ([168]).

CLINICAL PHARMACOLOGY After intravenous enzyme administration, plasma asparagine levels fall rapidly and remain low for up to 10 days ([169]). Asparaginase is detectable in the blood for 1 to 3 weeks, but as antibodies are formed, clearance of the drug is greatly accelerated. Asparaginase is degraded by protein metabolism.

TOXICITY Toxic effects of asparaginase related to inhibition of protein synthesis include a decrease in circulating levels of albumin, clotting factors, insulin, and lipoproteins ([170]). Synthesis of anticoagulant proteins, such as antithrombin III, protein C, and protein S, is also reduced. Hypersensitivity reactions (urticaria, anaphylaxis, serum sickness, and so forth) are common, with frequencies ranging from 20 to 40%. Factors that increase the risk of developing a reaction include type of administration (intravenous vs. intramuscular), dose, and repeated treatments. Changes in the source of the enzyme from *Escherichia coli* to *Erwinia* may be required when hypersensitivity develops to the commonly used *E. coli* preparation ([171]). Conjugation of polyethylene glycol to asparaginase (pegaspargase, Oncaspar) at sites other than the active site of the enzyme prevents uptake of the drug by the reticuloendothelial system, making it less immunogenic and prolonging its circulating half-life. The incidence of hypersensitivity reactions to pegaspargase in patients who have had reactions to *E. coli* asparaginase is approximately 30%. The relative effectiveness and toxicity of asparaginase and pegaspargase remain to be established ([172]). Toxic reactions to both asparaginase and pegaspargase include cerebral dysfunction (25% of patients), vomiting, chills (often an immediate reaction), pancreatitis (15% of patients), and liver function abnormalities (frequent) ([173]).

Biologic Therapies

INTERFERONS

Mechanism of Action Interferons (IFNs) are a family of glycoproteins, of which some are inhibitors of viral replication and tumor growth. At present, several INF-a preparations are available. IFN-a2b (Intron A) and IFN-a2a (Roferon) are recombinant products differing by 1 amino acid out of 166. IFN-an (Welferon) and IFN-an (Alferon) are naturally occurring IFNs purified from cell cultures. IFNs have multiple effects on cytokine production and regulation of tumor oncogenes and antioncogenes. The specific mechanism of antitumor activity for the IFNs is unclear, but the IFNs produce direct antiproliferative effects on tumor cells, increase host-mediated immune defenses, and inhibit angiogenesis ([174] , [175]).

Clinical Pharmacology The IFNs can be administered subcutaneously, intramuscularly, or intravenously. After exposure to IFN, expression of over 20 genes is altered ([174] , [176]). The optimal dose and administration route of IFN are not clear. IFN-a is filtered through the glomeruli and undergoes rapid proteolytic degradation during tubular reabsorption.

Toxicity IFN-a use is associated with many potential toxicities, including a flulike syndrome manifested by myalgias and fatigue in patients not premedicated with antipyretics ([177] , [178]). The severity of myalgias decreases with continued drug use. Nausea and vomiting are noted less often. Somnolence and lethargy occur when higher doses of IFN are used. Other side effects include myelosuppression, diarrhea, mild alopecia, skin rashes, and elevated hepatic enzymes. Depression, anxiety, and suicidal ideation may occur with IFN therapy ([179]). These toxic effects are readily reversed when administration of the IFN is stopped. Some of the immediate systemic toxicity associated with the use of this agent can be prevented by administration of acetaminophen or megestrol ([180]).

DENILEUKIN DIFITOX

Mechanism of Action Denileukin difitox (DAB $_{389}$IL-2, Ontak) is a fusion protein containing peptide sequences for human interleukin (IL-2) and for diphtheria toxin ([181]). The IL-2 portion of this fusion protein binds to cells that express IL-2 receptors. Once bound to the IL-2 receptor, the diphtheria toxin protein is internalized, inhibits cellular protein synthesis, and results in cell death. Three types of IL-2 receptors exist: high affinity, intermediate affinity, and low affinity. The fusion protein is internalized only with intermediate- or high-affinity IL-2 receptors. Expression of high-affinity IL-2 receptors is normally restricted to activated T lymphocytes or leukemias and lymphomatous cells of T- or B-cell origin. Denileukin difitox has been approved for use in cutaneous T-cell lymphomas.

Clinical Pharmacology There is wide variation in serum concentrations of denileukin difitox after intravenous administration (coefficient of variation, >50%) ([182]). A terminal half-life of roughly 75 minutes is seen with initial therapy, but this decreases to 43 minutes with continued therapy as antibodies to denileukin difitox appear.

Toxicity Hypersensitivity reactions, such as dyspnea, back pain, rash, hypertension, and chest tightness, occur during or within 24 hours of drug infusion in 60% of patients ([181] , [182]). These symptoms can be controlled with the use of steroids or antihistamines or by slowing the drug infusion. Constitutional and gastrointestinal symptoms (nausea/vomiting, asthenia, myalgias, headache, diarrhea) are seen in 92% of patients (grade 3 or 4 in one-third). A vascular leak syndrome occurs in 25% of treated patients. Myelosuppression is uncommon.

RETINOIDS

All- Trans-Retinoic Acid

Mechanism of Action A specific cytogenetic abnormality within the retinoic acid receptor (RAR) gene locus exists in patients with acute promyelocytic leukemia (APL) ([183]). In APL, the RAR gene is translocated next to a nuclear protein gene (PML). Fusion of RAR protein with the nuclear protein, PML, prevents normal differentiation of the myeloid cell ([185]). Retinoids are vitamin A derivatives essential for normal controlled cellular growth and development. All- *trans*-retinoic acid (ATRA, tretinoin) induces remission in patients with APL ([184]). Pharmacologic concentrations of ATRA (1 μM) reverse inhibition of differentiation and induce remission of APL.

Clinical Pharmacology Peak plasma ATRA concentrations of 350 ng/ml are achieved 1 to 2 hours after dosing and drop rapidly ($t_{1/2}$ = 50 minutes). ATRA is metabolized by the hepatic P-450 microsomal enzyme system. Use of ATRA stimulates this degradative pathway. ATRA plasma concentrations, therefore, decrease with prolonged drug use ([186]). Variations in hepatic microsomal metabolism account for significant patient-to-patient and day-to-day variation in ATRA clearance ([183]).

Toxicity ATRA has been administered with low morbidity. Patients may develop transient bone pain, dry skin, nasal stuffiness, and elevated levels of hepatic transaminases ([184], [187]). Pseudotumor cerebri has been observed. Some patients with APL treated with ATRA develop a syndrome of fever, pulmonary infiltrates, and leukocytosis ([188]). These symptoms usually respond readily to the administration of corticosteroids. ATRA, like other retinoics, has significant teratogenic properties, particularly during the first trimester of pregnancy ([189]).

Bexarotene

Mechanism of Action Bexarotene (Targretin) is the only retinoid approved for therapy of cutaneous T-cell lymphoma. Reti-noid modulation of tumor growth is mediated through binding to nuclear receptors, which subsequently function as transcription factors to regulate gene expression. Two receptor families, reti-noic acid nuclear receptors and retinoid X nuclear receptors, have been identified ([190]). Bexarotene selectively binds and activates retinoid X nuclear receptors. Binding to the retinoid X nuclear receptor can induce apoptosis in selected cell types, through triggering of a variety of downstream events ([191]).

Clinical Pharmacology Bexarotene is available as a topical gel for application to skin lesions or as an oral capsule for systemic therapy. Peak plasma concentrations are seen 2 to 3 hours after oral administration. Drug half-life is 3.5 hours. Bexarotene, like other retinoids, undergoes metabolism by the hepatic cytochrome P-450 enzyme system (3A4). Drug interactions with other CYP3A4-metabolized drugs may occur. Gemfibrozil increases bexarotene concentrations and toxicity ([192]).

Toxicity The most common bexarotene-associated toxicities are hyperlipidemia (82%), hypercholesterolemia (30%), hypothyroidism (29%), headache (20%), asthenia (16%), pruritus (13%), and leukopenia (11%) ([192]). Side effects are more common at higher drug doses. Pancreatitis may result from hyperlipidemia. Use of lipid-lowering agents is often required. Thyroid function tests must be monitored ([193]).

CORTICOSTEROIDS

Mechanism of Action Several cancers are dependent on specific hormones for growth and cellular maintenance. Altering the hormonal balance can cause tumor regression in such patients. A comprehensive review of all hormonal therapies is beyond the space limitation of this chapter. Corticosteroids (prednisone and dexamethasone) are often used in the treatment of hematologic malignancies and are briefly reviewed. Steroids are also useful in managing complications of cancer, including chemotherapy-induced emesis, hypercalcemia, and increased intracranial pressure. The mechanism of corticosteroid cytotoxicity to lymphocytes is mediated via binding to the glucocorticoid receptors, which induces apoptosis in these hormone-sensitive cells ([194], [195]).

Clinical Pharmacology Prednisone is an inactive prodrug that requires hepatic activation to produce prednisolone, the active moiety. Oral bioavailability of corticosteroids is excellent (greater than 80%). Corticosteroid half-life ranges from 0.5 to 2.0 hours. Both prednisolone and dexamethasone are inactivated via hepatic metabolism ([196]).

Toxicity Common corticosteroid toxicities include increased appetite, centripetal obesity, immunosuppression, myopathy, osteoporosis, aseptic necrosis, peptic ulceration, pancreatitis, psychiatric disorders, cataracts, hypertension, precipitation of diabetes, growth failure, amenorrhea, impaired wound healing, and atrophy of subcutaneous tissue ([196]). Many of these toxicities are seen only with long-term therapy.

ARSENIC TRIOXIDE

Mechanism of Action The mechanism by which arsenic trioxide (ATO, Trisenox) is effective in the treatment of promyelocytic leukemia is not fully understood ([197]). It is thought that ATO degrades the fusion protein, PML-RAR. Degradation of PML-RAR allows malignant promyelocytes to overcome a maturation block ([179]). ATO also induces apoptosis. ATO appears to promote opening of the permeability transition pore of the mitochondria causing caspase activation. Several other biochemical changes are noted with ATO therapy, which may induce apoptosis ([198]).

Clinical Pharmacology The pharmacology of ATO has been poorly studied. Plasma concentrations of 1.5 to 7.0 μM are achieved after an intravenous dose of 0.08 to 0.15 mg/kg. Arsenic trioxide is presumably methylated in the liver and then excreted in the urine as metabolites. No dosage guidelines for patients with hepatic or renal insufficiency are currently available.

Toxicity Grade 3 or 4 toxicity occurs in the majority (68%) of patients treated with ATO ([199]). The most common life-threatening toxicities include hypokalemia (13%), hyperglycemia (10%), neutropenia, and cardiac toxicity. The cardiac toxicity is primarily manifested by QT prolongation on the electrocardiogram, but torsades de pointes and sudden death have been reported ([200]). The “retinoid acid syndrome,” similar to that noted after ATRA treatment, is frequently seen (25% of patients). Leukocytosis after ATO therapy is common (50%). Other toxicities include neuropathy, nausea (75%), fatigue, fever, headache, diarrhea, and skin rash.

Signal Transduction Inhibitors

IMATINIB MESYLATE Imatinib mesylate (Gleevec, STI571), approved by the FDA in 2001 for the treatment of CML, is the first signal transduction inhibitor to be used in the therapy of cancer.

Mechanism of Action CML is characterized by a reciprocal exchange of genetic material between chromosomes 9 and 22 (t9;22). A new gene is formed, the BCR-ABL protooncogene, which encodes a signal transduction protein that is autonomous. Increased activity of the BCR-ABL protooncogene leads to cellular proliferation, decreased apoptosis, or both ([201]). The intracellular component of the BCR-ABL signal transduction protein contains a tyrosine kinase, which activates subsequent signaling molecules by taking a phosphate from ATP and transferring it to a second signaling molecule. Imatinib mesylate binds to the ATP-binding site of the BCR-ABL oncoprotein and prevents transfer of phosphate from ATP to the second messenger (Fig. 73.16). Imatinib inhibits the tyrosine kinase of the BCR-ABL, c-kit, and PDGF oncogenes ([202]).

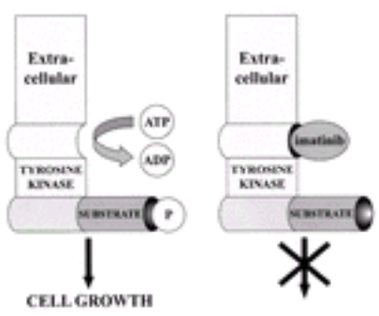

Figure 73.16. The BCR-ABL oncoprotein is schematically shown. This is a transmembrane protein with a tyrosine kinase on the intracellular part of the molecule. Imatinib mesylate (Gleevec) binds to the tyrosine kinase, preventing activation of second messenger proteins. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P, phosphate.

Clinical Pharmacology Imatinib mesylate is given orally at doses of 400 to 800 mg/day. Bioavailability is 98% with a drug half-life of 18 hours. Imatinib is cleared by hepatic microsomal cytochrome P-450 metabolism (CYP3A4) to a metabolite that has similar potency ([203]). Biliary excretion of parent drug and metabolite accounts for 70% of drug clearance. No dosage guidelines are available for patients with hepatic or renal insufficiency. Drugs that inhibit CYP3A4 (e.g., ketoconazole) may slow imatinib clearance.

Toxicity Mild nausea (70%), diarrhea (56%), and fluid retention are the most common toxicities associated with imatinib ([203], [204]). Edema can usually be managed with diuretics or dose reductions. Hematologic toxicity is mild and associated with more advanced stage (e.g., CML blast crisis). Severe toxicity (grade 3 or 4) is rare (15% of patients). Abnormal liver function tests have been reported but require discontinuation of therapy in fewer than 0.5% of patients.

Pharmacology of High-Dose Chemotherapy

As noted previously in this chapter, increased doses of an anticancer drug usually produce progressively greater tumor cell kill. However, the dose of drug that can be given is limited by its toxicity to normal tissues. For many antineoplastic agents, myelosuppression is the initial dose-limiting toxicity. With the use of bone marrow transplantation and good supportive care, dose-limiting myelosuppression can be abrogated. Drugs used for bone marrow transplant can have dose escalations until nonhematologic toxicities are noted. One basis for selecting drugs used for high-dose chemotherapy with marrow transplantation is the dose ratio of the drug to be considered ([205], [206]). The dose ratio is the maximum tolerated dose in the transplant setting divided by the standard dose. Most anticancer drugs with a high dose

ratio are alkylating agents. These drugs have a steep dose–antitumor response relationship over a wide dose range and have predominant marrow toxicity. Other chemotherapeutic drugs used in high-dose regimens include etoposide, carboplatin, ara-C, and mitoxantrone. Many other agents have a dose ratio close to one. Table 73.8 indicates the drugs used in stem cell rescue regimens, dose ratios, and extramedullary dose-limiting toxicities.

TABLE 73.8. Dose Escalations and Major Nonhematopoietic Toxicities of Drugs Used in High-Dose Chemotherapy with Stem Cell Support

Drug	Standard Dose (mg/m ^{2}) [a]	Transplant Dose (mg/m ^{2})	Dose Ratio	Extramedullary Toxicity
Carmustine	175	1000	5.7	Lung, liver
Busulfan	70	640	9.0	Mucositis, liver
Carboplatin	400	2000	5.0	Kidney, liver
Cisplatin	100	200	2.0	Kidney, nerve
Cyclophosphamide	1200	7000	5.8	Cardiac
Etoposide	400	3200	8.0	Mucositis
Ifosfamide	6000	16,000	2.7	Renal, CNS
Melphalan	35	140	4.0	Mucositis
Mitoxantrone	36	75	2.0	Mucositis, cardiac
Paclitaxel	250	725	3.0	Mucositis, CNS, renal
Thiotepa	32	1000	31.0	Mucositis, CNS, liver

CNS, central nervous system.

[a] Approximate.

From Jones RB, Matthes S, Dalton C. Pharmacokinetics. In: Armitage JO, Antman KH, eds. High-dose cancer therapy: pharmacology, hematopoietins, stem cells. Baltimore: Williams & Wilkins, 1995:49–69, with permission.

Agents listed in Table 73.8 have been combined in various myeloablative regimens. Drugs with nonoverlapping, nonhematopoietic toxicities should be selected to avoid serious new additive or synergetic toxicity. Depending on the regimen used, significant hepatic, gastrointestinal, renal, and pulmonary toxicities are encountered (206, 207). Correlations between extrame-dullary toxicity and the plasma pharmacokinetics of busulfan (208), cyclophosphamide (209), and BCNU (210) have been found, suggesting that therapeutic drug monitoring could reduce the frequency of nonmarrow toxicity associated with bone marrow transplantation (211). Potential toxicities associated with high-dose chemotherapy are so significant that this therapy should only be used in a center with adequate facilities and physicians experienced in this type of therapy.

ACKNOWLEDGMENT

The author would like to thank Mrs. Sharon Stokes for her help in the preparation of this manuscript.

Immunotherapy

HISTORY

There probably is no field in medicine that has provided as much hope, or as much disappointment, as the field of tumor immunology. A major relationship between the immune system and the oversight of neoplasms was postulated in the early part of the century by Paul Ehrlich ([1]). This theory of immunosurveillance envisioned that in long-lived animals, inheritable genetic changes in somatic cells must be common, and some proportion of these changes must represent steps toward malignant transformation. It was considered an evolutionary necessity, therefore, that some mechanisms exist for eliminating or inactivating such potentially dangerous mutant cells. This mechanism was thought to be immunologic. The theory of immunosurveillance was restated in the 1950s by Lewis Thomas ([2]), then popularized and championed by Sir Macfarlane Burnet ([3]). Supported by these powerful figures in medicine, the theory of immunosurveillance was so inherently appealing that it often was accepted uncritically, and evidence to the contrary often overlooked ([4]). For instance, although patients or animals who are immunosuppressed tend to have an increased incidence of tumors, these tumors are disproportionately of lymphoid origin or associated with an oncogenic virus. The development the common epithelial neoplasms (with the exception of certain skin cancers) in these patients occurs with much less impressive frequency ([5]).

The most obvious evolutionary necessity of the immune system was to survey a variety of infections, especially viral infections. In fact, the immunologic assault on viral infections is directed not so much against the virus as against virally infected cells. This is certainly true of the T-lymphocyte–mediated immunity against viruses. Early evidence seemed to indicate that immunity played a significant role in eradicating virally induced tumors ([6] , [7]). On the other hand, it appeared to play a less significant, or less effective, role in prevention of tumors induced by physical or chemical carcinogens ([8] , [9]).

Experimentation in the early part of the twentieth century demonstrated that spontaneously arising tumors in outbred animals could occasionally be transplanted from one animal to another of the same species and propagated in that fashion. Attempts to immunize against transplantable tumors soon followed. Animals injected with a small number of tumor cells often were able to eliminate those tumor cells—that is, there appeared to be a threshold number of tumor cells required for tumor propagation. Animals that had eliminated a sublethal inoculum of tumor cells were often able to withstand inoculation with a large number of tumor cells that would have been lethal in a naive animal. Furthermore, preexposure to normal tissue of the donor often rendered the recipient resistant to challenge with a lethal number of tumor cells ([10]). These experiments brought into question the idea of tumor-specific antigens and ultimately led to the discovery of major histocompatibility complex (MHC) genes and their products ([11] , [12]).

Modern tumor immunology finds its roots in the classical experiments of Prehn and Main ([13]). These investigators demonstrated, in genetically identical mice, that previous exposure to a chemically induced sarcoma rendered animals resistant to challenge with the same tumor, but that these animals would accept normal, nonneoplastic tissues transplanted from the tumor donor animal. Similarly, prior exposure to normal tissues from the donor animal did not render the recipient animal resistant to tumor challenge. These experiments revived the notion that tumor-specific (transplantation) antigens did exist. Subsequent experiments demonstrated that protection afforded by prior exposure to tumor was tumor specific ([14]). Thus, tumor transplantation behaved like an immune system, demonstrating memory and specificity.

Tumor immunity could be passively conveyed from one animal to another by transfer of lymphoid cells ([15]). The relevant cells for protection were shown to be T lymphocytes ([16]). Thus, it should have been clear to workers in the field that the relevant tumor antigens were those that could be recognized by T lymphocytes. However, as this work was beginning there was little understanding of how T lymphocytes recognized antigens or how those antigens were processed and presented to the T lymphocyte by antigen-presenting cells or the tumor target cells. Much time and effort was expended in search for membrane structures or tumor cell products that would distinguish the tumor from all others. Particularly after the description of monoclonal antibody technology ([17]), a fervent search was undertaken to define structures on tumor cells that would be tumor specific and potential targets for therapeutic intervention. Although many cell-surface structures were defined and the contribution to the understanding of biology cannot be overstated, this adventure produced only a single truly specific tumor antigen, the idiotype of clonally distributed immunoglobulin present on certain lymphomas.

Only recently has convincing evidence for an effect of immu-nosurveillance been produced ([18] , [19]). This new evidence relies, in great measure, on the availability of genetically manipulated animal systems. A variety of knock-out mice with defects in components of immune activation or effector function develop, at high frequency, spontaneous tumors or tumors after carcinogen exposure. Interferon-? receptor–deficient mice are more likely to develop methylcholanthrene-induced sarcoma and more susceptible to spontaneous development of sarcomas and lymphomas after loss of p53 alleles ([20] , [21]). One in two aged perforin-deficient mice develop disseminated lymphomas ([22]). These tumors are rejected by histocompatible wild-type mice through a mechanism dependent on $CD8^+$ T lymphocytes. A high incidence of lymphoma is also seen in aged mice deficient in Fas/Fas ligand interactions ([23]). Aged mice doubly deficient in STAT1 and RAG2 develop adenocarcinomas (colon, breast, and lung) with high frequency. The frequency and distribution of tumors are increased in the doubly deficient mice over the frequencies and distributions seen in singly deficient mice ([24]). Many of these observations have been interpreted as evidence that the primary (both first and predominant) mechanism underlying tumor immunosurveillance is the system of innate immunity ([25]).

INNATE IMMUNITY

The innate immune system is a widespread and evolutionarily ancient ([26] , [27]) form of host defense against infection ([28]). The importance of the system is underscored by the fact that most defects in the system are lethal ([28]). Therefore, this system was not revealed in the same way that “experiments of nature” illuminated important aspects of the adaptive immune system. In recent years, there has been an explosion of information regarding innate immunity, including its role in host defense and its regulation of inflammation and adaptive immunity ([29]).

The innate immune system is made up of many cells. These include dendritic cells, macrophages, mast cells, neutrophils, eosinophils, natural killer (NK) cells, and a subset of T lymphocytes that bear certain NK structures, NKT cells ([30] , [31]). Cells of the innate immune system bear receptors that detect “danger” ([32] , [33]) in the form of pathogen-associated molecular patterns (PAMPs). Examples of PAMPs include bacterial lipopolysaccharide, lipoprotein, peptidoglycan, and lipoteichoic acids ([34]) and bacterial CpG DNA ([35]). The innate immune system is said to distinguish “infectious non-self” from “non-infectious self.” The pattern recognition receptors of the innate immune system are encoded in the germline. Unlike genes of the T-cell antigen receptor and the immunoglobulins, these genes do not undergo rearrangement. They are fixed and detect critical microbial components. Ten toll-like receptors, each with specificity for a different PAMP, have been describe in humans and mice ([28] , [34]).

Cells of the innate immune system become activated during an inflammatory response. They rapidly differentiate into short-lived effector cells to rid the host of infection. They usually succeed without recourse to the system of adaptive immunity. However, when unable to effectively deal with the invaders, the innate immune system can instruct the adaptive immune system about the nature of the pathogen invader. This role is played primarily by dendritic cells (and other antigen-presenting cells, such as macrophages), which through antigen processing and up-regulation of co-stimulatory molecules (particularly CD80 and CD86), present antigen fragments in the context of MHC and, with appropriate second signals, to activate T lymphocytes (Fig. 74.1) (see section T-Lymphocyte Activation and Response).

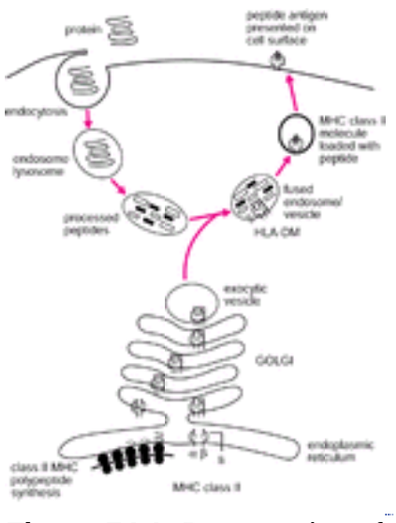

Figure 74.1. Presentation of extracellular antigens on class II major histocompatibility complex (MHC) products. Extracellular proteins are taken up by the antigen-presenting cell and processed to peptide fragments in endolysosomes. Class II MHC proteins are synthesized in the endoplasmic reticulum and associated with the chaperone Ii. Fusion of endosomes and exocytic vesicles provides an environment in which peptides are loaded, in the presence of HLA-DM, into the antigen-presentation cleft of the MHC class II molecule. The antigen–MHC complexes are then exposed on the cell surface.

It has been recognized for a long time that NK cells kill MHC class I–deficient tumor cells *in vivo* and *in vitro* ([36]). However, the identity and characterization of receptors mediating NK activation proved elusive for many years. Activation of NK cells now is understood to be dependent on the balance of activating and inhibitory signals emanating from activating and inhibitory receptors on the NK cell surface. These receptors fall into two major structural classes, those of the immunoglobulin superfamily (KIRs and LIRs) ([37]) and those of the C-type lectinlike family (NKG2D, CD94/NKG2A, and Ly49) ([38]). An activating receptor on NK cells, NKG2D, has now been shown to recognize a variety of stress-induced MHC class I–like molecules ([39] , [40] , [41] and [42]). Inhibitory receptors (e.g., CD94/NKG2A and KIR) recognize classic MHC molecules ([43]).

It is now possible to speculate that the innate immune system is involved in defense of the organism against tumor initiation ([25] , [44] , [45]). Cells have evolved complex mechanisms to assure successful repair of errors in the genome and survival, or alternatively, recognition of failed repair and programmed cell death. Cells that fail to repair damage yet escape apoptosis would present signs of cellular stress to the innate immune system in the form of heat shock proteins ([46]) and/or down-regulation of MHC class I molecules. NK cells and other innate effectors would be activated to kill the renegade cell. Some direct evidence for this model has been provided. Kusunoki et al. ([47]) demonstrated that after x-irradiation, MHC class I–deficient lymphocytes appear and then disappear. In animals depleted of NK cells, the disappearance of MHC class I–deficient lymphocytes was inhibited, suggesting that NK cells mediate elimination of this population of cells ([47]). These effects may be active in the clinic in the setting of acute myelogenous leukemia (AML) patients who receive HLA haplotype–mismatched transplants. Clinical trials, using KIR epitope–mismatched NK cells to facilitate engraftment of mismatched stem cells with reduced intensity conditioning and NK cell inhibitory receptor blockade have been proposed ([45]).

ADAPTIVE IMMUNITY

Tumor Antigens

Tumor antigens are like all other antigens of adaptive immunity. That is, with few exceptions, they are peptides that are presented to T lymphocytes in the cleft of an MHC-encoded protein ([48]). These peptides are derived from two distinct pathways ([49]). Peptides representing proteins sampled from the extracellular world are presented in the context of class II MHC proteins. Peptides resulting from intracellular synthesis of proteins are presented in the peptide groove of the class I MHC proteins. The binding cleft of MHC molecules has a ß-pleated sheet floor and a-helical sides. An immunogenic peptide must be capable of forming noncovalent attachments to key residues along the cleft and interacting with the T-cell antigen receptor with other residues. The MHC contact residues of the peptide tend to be near the amino and carboxy terminal ends of the peptide. The cleft of the class I MHC molecule has closed ends and accommodates only a peptide of proper length, 9 to 11 amino acids. The cleft of the class II MHC molecule, on the other hand, is open ended and can bind peptides of more diverse lengths, 10 to 30 amino acids, with most being 12 to 19 ([50]).

Peptides located in class II MHC molecules are derived from proteins that have been consumed by antigen-presenting cells ([51]) (Fig. 74.1). The proteins are taken up by phagocytosis, or receptor-mediated endocytosis in clathrin-coated pits, or engulfed by pinocytosis. Once internalized, the antigens are located in membrane-bound vesicles called *endosomes*. The endosomes then become continuous with lysosomes. The enzymology of the endo-lysosome has been described in some detail ([52]). There, in an acidic environment, proteases cleave the proteins to peptides. The endosome fuses with an exocytic vesicle budding from the Golgi apparatus that contains newly made class II MHC molecules associated with invariant chain, which has been shown to play a critical role in the assembly, intracellular transport, and function of MHC class II molecules ([53] , [54]). In addition a chaperone, HLA-DM, plays a critical role in the loading of peptides onto MHC class II molecules. HLA-DM is a peptide exchange factor that binds with empty and peptide-loaded class II molecules in endosomal and lysosomal compartments ([55] , [56]). In the fused vesicle, peptides are loaded into the class II MHC molecules. Fusion of the endosome with the plasma membrane ultimately displays the class II MHC molecule–peptide complexes on the cell surface.

Peptides are prepared for presentation on class I molecules in a different fashion (Fig. 74.2). These peptides are derived from intracellular protein synthesis ([57]). After protein synthesis, proteins introduced into the cytoplasm become the target of the proteasome, a cytoplasmic organelle whose major function is the degradation of proteins tagged for turnover by the addition of ubiquitin ([58]). These peptides are then transported into the exocytic pathway by the transporter associated with antigen-processing (TAP) proteins ([59]). Within the endoplasmic reticulum, assembly of class I MHC heavy chain molecules with ß $_2$-microglobulin requires the presence of peptides. In fact, the tripartite assembly of MHC class I a-chain, peptide, and ß $_2$-microglobulin is required for dissociation of the MHC class I a-chain from its chaperone. Tapasin is a transmembrane protein that tethers empty class I molecules in the endoplasmic reticulum to the transporter associated with antigen processing, TAP. Emerging evidence suggests that tapasin (and HLA-DM for MHC class II processing) retain unstable MHC molecules in peptide-loading compartments until they bind with high-affinity peptides. The assembled MHC class I–peptide complex transits the Golgi apparatus, proceeds in a vesicle to the cell surface, and is displayed on the cell surface after fusion of the vesicle membrane with the plasma membrane. Tapasin, therefore, promotes the surface expression of long-lived MHC-peptide complexes ([55] , [56]). Defects in MHC class I and class II antigen-processing machinery have been found in association with malignant transformation ([60]). These may account, to some degree, for escape of tumor cells from T-cell recognition.

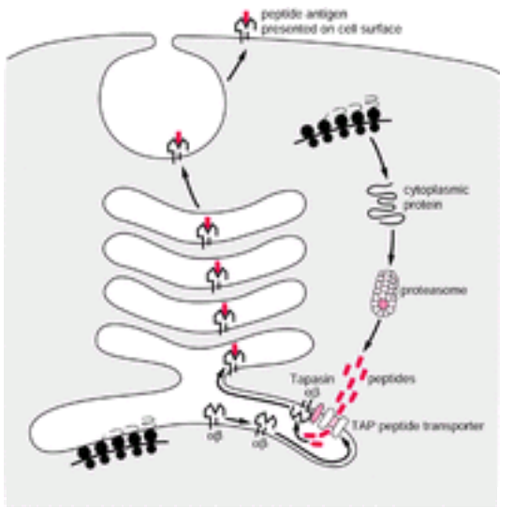

Figure 74.2. Presentation of intracellular antigens on class I major histocompatibility complex (MHC) products. Proteins synthesized within the cell are broken down to peptides in the proteasome. Resulting peptides are carried by the transporter associated with antigen processing (*TAP*) peptide transporter into the site of class I MHC product synthesis. There they are loaded, in the presence of tapasin, into the antigen presentation cleft of the MHC class I molecule. The antigen–MHC complexes are then exposed on the cell surface.

The nature of peptide antigens responsible for immune responses to tumors has been described in a classic set of experiments ([48], [61], [62] and [63]). In essence, two approaches were used. Neither made assumptions regarding the nature of the antigenic peptides. In the first approach, tumor-derived cloned cytolytic T lymphocytes (CTLs) were established. Next, a library of tumor complementary DNA or genomic DNA was constructed and used to transfect cells expressing appropriate MHC molecules but lacking the tumor-specific epitope. Transfected cells were tested for their ability to activate the tumor-specific CTLs. The transfected DNA was then recovered and sequenced, thus identifying the gene of origin ([64]). In the second approach, tumor-cell MHC molecules were isolated. Subsequently, peptides were eluted from the MHC molecules and fractionated chromatographically. These peptide fractions were then used to load antigen-presenting cells and presented to tumor-specific CTL. Peptide fractions that stimulated T-cell responses were then sequenced using conventional Edman degradation ([65], [66]) or tandem mass spectrometry ([67], [68]). These approaches have revealed some surprising characteristics of tumor-specific antigens. Most tumor-specific antigenic peptides, discovered thus far, have been derived from proteins not usually expressed in any normal adult tissues ([69]) (with the exception of testis), such as P1A ([70], [71]) and MAGE-1 ([72], [73]), or they represent differentiation antigens characteristic of the cellular lineage of the tumor, such as tyrosinase ([74], [75] and [76]), gp100 ([68], [77], [78]), and MART1/Aa ([79], [80]) in melanoma.

Early definition of tumor antigens focused on MHC class I–restricted peptides ([81]). This seemed to be the obvious approach because most tumors express MHC class I structures, but few express MHC class II molecules. Also, the point of immunotherapy was to eliminate tumors—a job for cytolytic cells (i.e., for $CD8^+$ cytotoxic lymphocytes that recognize antigen in the context of class I MHC molecules). Early clinical immunization trials ([82], [83] and [84]) demonstrated the feasibility and the potential efficacy of immunotherapy with peptides recognized by $CD8^+$ T cells. However, immune responses were, in general, weak and short-lived. At the same time that the trials were being conducted, there was a growing realization of the importance of $CD4^+$ T cells in the immune response against tumors ([85], [86] and [87]). Techniques, similar to those used to define antigens recognized by CTLs, have been used to define antigens for $CD4^+$ T cells. However, these techniques are slow and labor intensive. A genetic targeting expression system has been designed to expedite antigen screening ([88]). It is likely that incorporation of both MHC class I– and II–restricted epitopes in tumor vaccines will be required to generate potent antitumor responses ([89]).

While this direct approach to tumor antigen recognition has proceeded, other investigators have asked whether certain appealing target proteins could be immunogenic. In particular, molecules involved in the process of malignant transformation provide attractive targets for therapeutic intervention ([90]). Because loss variants of tumor cells bearing these oncogenic proteins would presumably be nonmalignant ([91]), an immunologic assault on these proteins might be particularly effective. Evidence has been provided that immune responses to both mutated and overexpressed oncogenic proteins can occur in patients with malignancy or can be elicited in animals. Target oncogenic proteins include mutated ras ([92], [93], [94], [95] and [96]), Her-2/neu ([97], [98]), bcr-abl ([99], [100]), pml-RARa ([101]), and mutated p53 ([102]).

A new approach to definition of tumor-specific antigen targets for humoral immunity, termed *SEREX*, has been introduced ([103], [104]). In the SEREX approach, a complementary DNA library is prepared from a patient's tumor specimen, packaged into phage vectors, and expressed in bacteria. Recombinant proteins from bacterial clones are transferred to nitrocellulose membranes and identified as relevant antigens by reactivity with immunoglobulin G (IgG) antibodies present in the patient's serum. Early studies defined three classes of antigens: (a) known tumor antigens, such as MAGE-1, MAGE-4a, and tyrosinase; (b) products of known genes, such as restin; and (c) unknown gene products ([105], [106]). Because the cellular and humoral arms of immunity work in concert, it is likely that targets of antibody production will also prove to be targets of cellular immunity. The SEREX approach provides a direct approach to the definition of potentially relevant tumor antigens.

T-Lymphocyte Activation and Response

The goal of antigen processing and presentation is the activation of appropriate T lymphocytes to proliferate, produce cytokines, and promote an immunologic reaction or become cytotoxic cells. The molecular basis of T-cell response has been elucidated since the 1980s. A number of groups contributed to the recognition of the T-lymphocyte antigen receptor, some using antibody detection ([107], [108], [109] and [110]), others taking a genetic approach ([111], [112] and [113]). This receptor is unique in that it does not recognize its ligand (antigen) in solution, but only in the context of an MHC molecule. Thus, T-cell responses are said to be restricted by products of the MHC ([114]). The a and ß chains of the receptor, which have immunoglobulin-like domains, are sufficient for recognition of both the MHC molecule and the antigenic peptide. Although the interaction of T-cell antigen receptor and antigen-MHC provides specificity of response and initiates the crucial events of activation, the interactions are few and of low affinity ([115]). The interaction between T-lymphocyte and antigen-presenting cell or target cell is initially stabilized by a number of nonspecific receptor–counterreceptor interactions ([116]), leading to development of an immunologic synapse with its central supramolecular activation cluster ([117]). Chief among these interactions is the coupling of CD2 on the T lymphocyte with lymphocyte function antigen-3 on the antigen-presenting cell. Also involved is the interaction of the lymphocyte function antigen-1 molecule with intercellular adhesion molecule-1 and intercellular adhesion molecule-2. Once the cells have been apposed, the specific interaction of the T-cell antigen receptor and the antigen-MHC can occur. It now appears that the T cell proceeds toward activation only if certain threshold numbers of T-cell receptor (TCR)-MHC/antigen interactions occur ([118]).

The T-cell antigen receptor is made up of a number of polypeptide chains (Fig. 74.3). The expression and aggregation of all of the subunit parts are required for membrane display of the receptor ([119]). The a and ß chains of the T-cell antigen receptor have very short intracytoplasmic portions that lack known signal transduction motifs. Therefore, the other components of the T-cell antigen receptor–CD3 complex are responsible for signal transduction. These chains include the immunoglobulin-like CD3-?, CD3-d, and CD3-e, which are arranged in heterodimers of ?–e and d–e, and the TCR-? family of chains, which may be arrayed as ?–? homodimers or heterodimers of ?–?. Each of these chains contains one or more signal transduction motifs called *immunoglobulin receptor family tyrosine-based activation motifs* (ITAMs). These motifs have the structure (D/E)XXYXXLX $_{7–8}$ YXX(L/I) and were predicted to have important structural significance long before this fact could be demonstrated ([120]). In addition to the chains of the TCR-CD3 complex, the co-receptor CD4 and CD8 structures take part in the initial step of T-lymphocyte activation. These structures bind to nonpolymorphic portions of MHC class II and class I proteins, respectively.

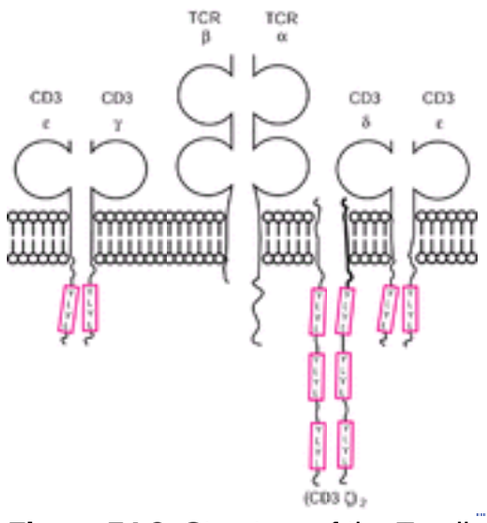

Figure 74.3. Structure of the T-cell antigen receptor (*TCR*). Immunoglobulin-like antigen recognition units TCR-a and TCR-ß are associated with components of the CD3 complex, CD3-?, CD3-d, and CD3-e, arranged as heterodimers of CD3-?–CD3-e, and CD3-d–CD3-e, and with homodimeric TCR-?. TCR-? and the CD3 components contain multiple immunoglobulin receptor family tyrosine-based activation motifs characterized by YXXL–YXXL domains.

The earliest observable event of activation after ligation of the TCR is a wave of tyrosine phosphorylation ([121]) (Fig. 74.4). A number of nonreceptor protein tyrosine kinases (PTKs) are involved. Two members of the src kinase family are recruited immediately ([122]): pp56 ^{lck}, which is physically associated with the CD4 or CD8 structures ([123]), and pp59 ^{fyn}, which appears to associate directly with the TCR-CD3 complex ([124] , [125]). Enzymatic activity of these two PTKs is dynamically regulated by their phosphorylation state ([126]). Phosphorylation of the carboxy-terminal tyrosine of each PTK promotes a closed (inactive) conformation, the product of interaction between the phosphotyrosine and an SH2 domain. Phosphate transfer to the src family kinases is dependent on the cytoplasmic PTK, CSK ([127]). Dephosphorylation results from the action of the transmembrane protein tyrosine phosphatase, CD45 ([128]). Cell lines lacking CD45 exhibit markedly impaired T-lymphocyte activation, and animals lacking CD45 exhibit profound defects in thymocyte development and T-lymphocyte activation.

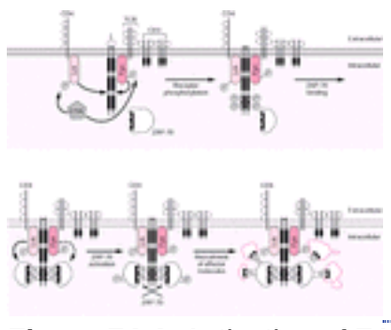

Figure 74.4. Activation of ZAP-70, a critical early event in T-lymphocyte activation. After antigen–major histocompatibility complex binding, the src-like protein tyrosine kinases (PTKs) pp56 ^{lck} and pp59 ^{fyn}, whose activation is regulated by CSK, phosphorylate tyrosine residues contained in the immunoglobulin receptor family tyrosine-based activation motifs (ITAMs) of T-cell receptor (TCR)-? and the CD3 components. Doubly phosphorylated ITAMs provide docking stations for the T-cell–specific PTK, ZAP-70. ZAP-70 activation depends on phosphorylation by the src-like PTKs and from cross-phosphorylation. Subsequently, scaffolding and effector molecules are recruited to the signalsome.

The Src family kinases are responsible for phosphorylation of the tyrosine residues within the ITAMs of the TCR-? chain and CD3 components. Tandemly phosphorylated tyrosines provide a docking site for the two SH2 domains of ?-associated protein, ZAP-70, a member of the syk family of PTKs ([129] , [130] and [131]). Experiments in reconstituted systems suggest that the combination of an src-family PTK and the ZAP-70 (or syk) kinase is required for activation ([129] , [132]). One variant of severe combined immunodeficiency syndrome has been associated with defects in ZAP-70 expression ([133]).

In addition to the src and syk families of PTKs, another family of PTKs, the Tec family, becomes activated after TCR engagement ([134]). These cytosolic PTKs contain pleckstrin homology domains that mediate interactions with membrane phospholipids, in addition to SH2, SH3, and kinase domains. Tec PTK knock-out mice exhibit abnormal T-lymphocyte activation ([135]).

Activation of ZAP-70 leads to recruitment of two scaffolding molecules to the receptor complex or signalsome ([136] , [137] and [138]). These scaffolds provide sites on which many SH2-containing proteins can assemble. Among the signaling molecules known to associate with the signalsome are pp59fyn ([124] , [125]), syk kinase, phospholipase C?-1 (PLC?-1) ([139]), PI3-kinase (PI3-K) ([140]), FAK-related PTK ([141]), Grb2 ([142] , [143]), vav ([144]), and cbl ([145]). The first scaffold, LAT (linker of activated T cells) is a 36-kd integral membrane protein ([146] , [147]). Its cytoplasmic tail contains several tyrosine residues arrayed appropriately to bind the SH2 domains of other proteins. After stimulation, LAT becomes associated with Grb2, GADS, PLC-?, and PI3-K. LAT-deficient cell lines fail to transmit activation signals beyond ZAP-70 phosphorylation ([148]). Knock-out mice lacking LAT demonstrate abnormal T-lymphocyte development, reduced numbers of thymocytes, and absence of T cells in peripheral lymphoid organs ([149]). The second, SLP-76 participates in multiple, complex interactions with PLC? and LAT ([150]), and with vav (see below).

Several signaling pathways proceed from the activation of ZAP-70. The first described and best understood of these involves changes in inositol lipid metabolism (Fig. 74.5). PLC? becomes tyrosine phosphorylated and activated ([151]) as it associates with a 36-kd membrane protein, LAT ([138] , [139]). Activation of PLC? leads to the hydrolysis of a minor membrane lipid, phosphatidylinositol bisphosphate (PIP $_2$), to yield inositol trisphosphate (InsP $_3$) and diacylglycerol (DAG) ([152]). Each of these products activates downstream events. InsP $_3$ leads to release of intracellular stores of calcium ([153]), whereas DAG activates the serine-threonine kinase protein kinase C (PKC). PKC-? plays a central role in T-cell activation ([154]). After engagement of the TCR, PCK-? translocates to the supramolecular activation complex ([155]). Peripheral T cells in PKC-?–deficient mice fail to activate nuclear factor-?B (NF?B) and AP-1, and fail to produce interleukin-2 (IL-2) ([156]).

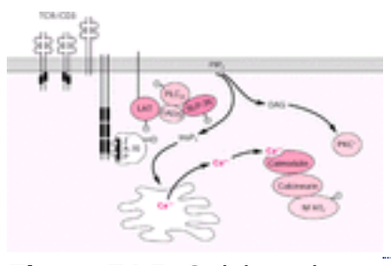

Figure 74.5. Calcium-dependent pathway of T-lymphocyte activation. Phospholipase C?-1 (PLC?-1) becomes associated with the T-cell receptor (TCR)-CD3–associated signalsome through complex interactions of LAT (linker of activated T cells), GADS, and SLP-76, and is activated by tyrosine phosphorylation. PLC?-1 catalyzes the hydrolysis of a phosphatidylinositol bisphosphate (PIP $_2$) to the second messenger molecules, InsP $_3$ and diacylglycerol (DAG). DAG activates protein kinase C (PKC). Inositol trisphosphate (InsP $_3$) releases intracellular stores of calcium. Increased intracellular calcium activates calmodulin and ultimately the cytoplasmic phosphatase calcineurin. Calcineurin action on the nuclear factor of activated T cells (NFAT $_c$) allows its translocation to the nucleus, where it serves a critical role in cytokine gene expression.

At the same time, phosphatidylinositol 3-kinase (PI3K) becomes tyrosine phosphorylated and activated ([157]). PI3K catalyzes the phosphorylation of phosphoinositides

on the 3' position of the inositol ring, yielding PtdInsP, PtdInsP $_2$, and PtdInsP $_3$. These phosphorylated phosphoinositides are involved in regulation of several cytosolic serine/threonine kinases ([158]). Full activation of PI3K requires co-stimulation (described in section Exploitation of Co-Stimulation) ([159]).

Coupling of TCR occupancy and PTK activation to downstream events appears to be dependent on a number of adaptor proteins, the prototype of which is Grb2 ([147]). This molecule is made up of two SH3 domains and one SH2 domain, the function of each being protein interaction. Grb2 couples the mammalian SOS (son of sevenless, mSOS) to the activation complex ([142]) (Fig. 74.6). Two pure adaptor molecules are particularly important in T-lymphocyte activation. GADS, a Grb2 family member, joins LAT to SLP-76 ([137]) (Fig. 74.5) and interacts with a Tec family kinase ([160]). The Src-like adaptor protein, SLAP, associates with CD3?, ZAP-70, SLP-76, vav, and LAT. SLAP is involved in TCR endocytosis and is a negative regulator of TCR signaling ([161], [162]).

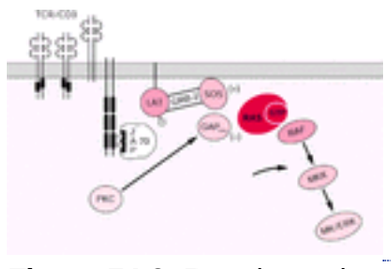

Figure 74.6. Ras-dependent pathway of T-lymphocyte activation. Through a series of scaffolding and adaptor molecules, the guanine nucleotide exchange factor, SOS, becomes associated with the signalsome. SOS positively regulates the g-protein, Ras. Simultaneously, activated protein kinase C (PKC) reduces the negative regulatory effects of guanosine triphosphatase activating protein of ras (GAP $_{ras}$). Ras activation drives a cascade of mitogen-activated protein kinase activity, leading toward the nucleus. GTP, guanosine triphosphate; LAT, linker of activated T cells; MK, MAP kinase; MKK, MAP kinase kinase; TCR, T-cell receptor.

mSOS is a guanine nucleotide exchange factor that, when interacting with ras, promotes activation of ras in the guanosine triphosphate (GTP)-bound state ([163]) (Fig. 74.6). Ras activation also results from the negative regulatory influences on the guanosine triphosphatase activating protein of ras (GAP $_{ras}$) ([164]). GAP $_{ras}$ stimulates the enzymatic activity of ras to dephosphorylate GTP, leaving ras in the guanosine diphosphate–bound, or inactive, state. Although GAP $_{ras}$ is a target of tyrosine phosphorylation in T cells, negative regulation of GAP $_{ras}$ appears to result from a PKC-dependent interaction ([165]). Activation of ras sets off one or more cascades of mitogen-activated protein (MAP) kinase activity ([166]) (Fig. 74.6). The best characterized of these cascades involves the ras proximal protein kinase, raf, which acts as a MAP kinase kinase kinase, activating the MAP kinase kinase MEK 1/2, which in turn activates the MAP kinase ERK 1/2. MAP kinases positively regulate the activities of several transcription factors, leading to increased production of the components of the AP-1 transcription complex ([167]).

Another phosphoprotein appears to play an important role in early T-lymphocyte signaling. The product of the protooncogene, vav, is a 95-kd protein that has been associated with ZAP-70 ([168]) and SLP-76. This remarkable protein contains two SH3 domains, an SH2 domain, a cysteine-rich domain that forms zinc fingers, a pleckstrin homology domain, and a guanine nucleotide exchange factor domain. Vav-deficient mature B and T lymphocytes from chimeric mice derived from blastocysts lacking the recombinase-activating gene and embryonic stem cells deficient in vav expression show profound defects in proliferation and cytokine production ([169], [170]). Vav increases IL-2 expression ([168]).

The previously described increases in intracellular calcium and production of DAG contribute to the activation of PKC. PKC activation directly or indirectly activates phospholipase D, tapping a large reservoir of membrane lipid for further production of DAG from phosphatidic acid resulting from the action of phospholipase D on phosphatidylcholine ([171], [172]). PKC also plays an important part in the activation and translocation of the transcription factor NF-?B by the targeted phosphorylation of its cytoplasmic inhibitor, I-?B ([173]), and in the activation of MAP kinases ([174]).

Increased intracellular calcium concentration, through the multipurpose calcium receptor calmodulin, regulates the action of a cytoplasmic phosphatase, calcineurin ([175]). Calcineurin action on the cytoplasmic form of the nuclear factor of activated T cells (NFAT $_c$) allows its translocation to the nucleus as NFAT $_n$. The critical nature of calcineurin action is underlined by the observations that calcineurin is the target of the immunosuppressive actions of cyclosporine and FK506 bound to their cytoplasmic binding proteins ([176]). There is evidence that cytoplasmic-to-nuclear shuttling of NFAT $_c$ family members determines the duration of TCR occupancy necessary for IL-2 production ([177]).

The net result of this extremely complex activation system is the expression of new proteins, the acquisition of functional capacity, or the ability to proliferate. Recycling TCR-? chains and bound ZAP-70 appear to relocate and associate with elements of the cytoskeleton ([178]). These observations suggest that these components of the T-cell signaling mechanisms may play an important part in the reorganization of cellular structures required for change of function in cytotoxic cells and also correlate with the ability of cells to produce IL-2 and proliferate.

T-lymphocyte activation is best understood as a culmination of events leading to IL-2 production ([179]) (Fig. 74.7). The constraints on production of this cytokine are more rigorous than those relevant for production of other gene products (such as IL-2 receptor a-chain and transcription factors). The promoter of the IL-2 gene is made up of a number of binding sites for transcription factors, including two NFAT sites, an NF-?B site, and an AP-1 site ([180]). Fos and jun components of AP-1 produced primarily as a result of the MAP kinase pathways bind to the AP-1 site. In addition, these components associate with NFAT $_n$, which has translocated to the nucleus after dephosphorylation by calcineurin, to occupy the NFAT sites. The NF-?B site is occupied by the NF-?B liberated from its inhibitor by the action of PKC. The combination of production of IL-2 receptor a-chain and IL-2 provides an adequate stimulus for the T lymphocyte to successfully proliferate, giving rise to the antigen-specific clonal expansion of lymphocytes characteristic of immunologic responses. However, there are extraordinary controls against inappropriate activation of T lymphocytes ([181]). In addition to a first signal delivered via the T-cell antigen receptor complex, full activation of T cells also requires a second signal ([182]). The best characterized origin of these second signals is the interaction of CD28 on the T-lymphocyte surface with its cognate ligand, CD80 (B7) on the antigen-presenting cell, the most potent of which is the dendritic cell. Failure to receive a second signal can lead the T lymphocyte to anergy or apoptosis.

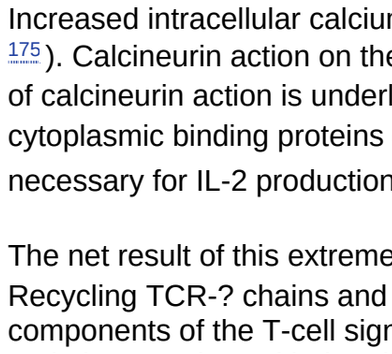

Figure 74.7. Overview of T-lymphocyte activation leading to cytokine production and proliferation. The calcium-dependent and Ras-dependent activation pathways, in association with vav-dependent pathways and synergizing with signals emanating from CD28, converge in the nucleus, providing a number of transcription factors required for new gene expression. ERK, extracellular signal-regulated kinase; I-?B, inhibitor-?B; IL-2, interleukin-2; JNK, jun kinase; MK, MAP kinase; NFAT $_c$, nuclear factor of activated T cell; NFAT $_n$, nuclear factor of activated T-cell nucleus; NF-?B, nuclear factor-?B; PKC, protein kinase C; PTK, protein tyrosine kinase; TCR, T-cell receptor.

Defects in T-cell signaling associated with loss of TCR-? protein have been described in patients with neoplasms ([183], [184]). TCR-? is a substrate for caspase 3 and caspase 7 ([185]) as well as granzyme B ([186]). Loss of TCR-? in tumor-infiltrating lymphocytes (TILs) is predictive of poor outcome for the patient from whom the tumor was taken ([183]). Loss of TCR-?, signaling abnormalities, reduced proliferation, and apoptosis were associated with high levels of Fas ligand expression in the tumor (

[184]).

APPROACHES TO IMMUNOTHERAPY

Antibody Approaches

UNCONJUGATED ANTIBODIES Unaltered antibodies have been used since the earliest trials of monoclonal antibody therapy in humans ([187], [188] and [189]). In early trials, success was limited by the absence of suitable tumor cell-surface targets, antigenicity of first generation (murine) monoclonal antibodies in humans, modulation of the target structure from the tumor cell surface, and poor recruitment of immune effector mechanisms ([190], [191]). However, enthusiasm for this approach was rekindled by the enormous success of genetically engineered, chimeric, or fully humanized versions of monoclonal antibodies, most notably rituximab for lymphoid malignancies and trastuzumab in solid tumors ([191]). Rituximab is a chimeric monoclonal antibody with humanized framework and Fc regions. It is directed against the CD20, pan B-cell antigen. CD20 is present on pre-B cells and mature B cells, but not on precursor cells or terminally differentiated plasma cells. The function of CD20 remains poorly understood ([192]), although it has been implicated in B-cell activation, regulation of B-cell growth, and regulation of transmembrane calcium flux. The antibody fixes human complement and elicits antibody-dependent cellular cytotoxicity. Rituximab was approved for use as monotherapy in patients with low-grade or follicular CD20 $^{+}$ non-Hodgkin lymphoma (NHL). The pivotal study, involving 166 patients, was reported by McLaughlin et al. ([193]). All patients had relapsed or chemotherapy-resistant disease that, in the opinion of the treating physician, required antilymphoma therapy. The study excluded patients with chronic lymphocytic leukemia and patients with extremely bulky disease (larger than 10 cm diameter). Patients received four weekly infusions of rituximab at 375 mg/m ^{2}. In this patient population, rituximab produced a tumor response in one-half of the patients. Median duration of response was 11.8 months, comparable to the patients' response duration on the last chemotherapy treatment. Human antichimeric antibody responses were uncommon. The most common adverse experience associated with rituximab was a constellation of acute infusion-related events, including chills, fever, headache, rhinitis, pruritus, vasodilation, asthenia, and angioedema. This syndrome can progress to hypotension, urticaria, bronchospasm, and, rarely, death. The risk is particularly great in patients with high circulating white cell counts ([194]). Other toxicities were, in general, mild and infrequent ([195]). Neutropenia and thrombocytopenia were unusual. Eighty-six percent of patients had no cytopenias. Circulating B cells were depleted and remained low until recovery at a median of 12 months. Immunoglobulin levels, however, remained normal. No increased incidence of infections was seen. Rituximab was evaluated again in the relapsed, refractory, low-grade or follicular NHL patient population, using eight weekly infusions rather than four ([196]). This extended regimen produced a response rate of 57% and a time to progression (TTP) in responding patients of more than 19.4 months. Adverse event reporting was commensurate with the longer treatment period. No unexpected toxicities were noted. The use of rituximab has quickly spread to other clinical situations. Davis et al. ([197]) reported results of the standard four-infusion regimen in patients with low-grade or follicular NHL who had bulky disease. The antibody produced a response rate of 43% and a TTP of 8.1 months in the patients with a significant poor prognostic factor. This is an important observation, as antibody penetration into bulky tumors had been a concern. Davis et al. ([198]) also reported on the use of rituximab as retreatment in patients who had progressed after an initial response to rituximab. Rituximab produced an overall response rate (ORR) of 40%. Estimated median TTP for responding patients was 17.8 months. The safety profile of the antibody in retreatment was not different than that associated with first treatment. Rituximab has been used in the first-line treatment of patients with low-grade lymphoma, both as monotherapy and in combination with chemotherapy. Hainsworth ([199]) reported the results of rituximab as monotherapy in 39 previously untreated patients. Patients received rituximab × 4 at the usual dose and schedule. Response was evaluated at week 6. At that time, 54% of patients were noted to be in response. Patients who had responded or who had stable disease were treated with an additional four weekly treatments of rituximab at 6-month intervals to a maximum of four treatment cycles. The ORR rose to 72% after the second course of treatment. Progression-free survival at 1 year was 77%. Toxicities were as expected. The addition of rituximab to cyclophosphamide, hydroxydaunomycin, Oncovin (vincristine), and prednisone (CHOP) chemotherapy produced impressive results. Patients were treated with six infusions of rituximab, one associated with each of six cycles of CHOP. In 40 patients with newly diagnosed (N = 31) or relapsed/refractory (N = 9) low-grade or follicular NHL, rituximab plus CHOP produced an ORR of 95%, complete response (CR) rate of 55%. With a median follow-up of 29 months, median duration of response and median TTP had not been reached. Eight of 18 patients tested for the bcl-2 (t(14;18)) translocation by polymerase chain reaction (PCR) testing were positive at initiation of therapy. Seven of these eight patients, after therapy, became negative for the translocation. The authors concluded that the addition of rituximab to CHOP produced benefits in efficacy parameters without significant additional toxicity. Elimination of PCR positivity for the t(14;18) translocation had not been previously reported with CHOP alone. Rituximab also has been used with success in patients with more aggressive lymphomas. Vose et al. ([200]) reported the results of rituximab plus CHOP chemotherapy (again using six infusions of rituximab in association with six cycles of CHOP) in 33 previously untreated patients with advanced aggressive (Working Formulation types D to H, excluding patients with mantel cell lymphoma, lymphoblastic lymphoma, and Burkitt lymphoma) B-cell NHL. The combination produced an ORR of 94% and a CR rate of 61%. With a median observation time of 26 months, 29 of 31 patients achieving a remission were in continuing remission at the time of the report. Thirteen patients were bcl-2 positive at study entry. Eleven of these 13 patients became bcl-2 negative after treatment, and 10 of the 11 remained bcl-2 negative. The authors concluded that the results were achieved without significant added toxicities above those expected with CHOP. The Groupe d'Etude des Lymphomes de l'Adulte undertook a study to compare the utility of CHOP with that of rituximab plus CHOP in elderly patients with diffuse B-cell lymphoma ([201]). The elderly were chosen for study because though CHOP is the standard of care for initial therapy of younger patients with aggressive lymphoma, it induces complete remissions in only 40 to 50% of elderly patients, with a 3-year event-free survival of 30%. Attempts to increase CHOP efficacy in this population by adding other cytotoxic drugs had been unsuccessful. Patients between the ages of 60 and 80 years with untreated, diffuse large B-cell lymphoma were eligible for the study. Patients were randomly assigned to receive eight cycles of CHOP chemotherapy (197 patients) or to receive eight cycles of CHOP, each given after an infusion of rituximab (202 patients). Rituximab plus CHOP produced a superior rate of remission, 76% versus 63% (p = .005). With a median follow-up of 2 years, event-free and overall survivals were significantly higher in the rituximab plus CHOP group (p <.001 and p = .007, respectively). These results were achieved without a significant incremental increase in toxicity. The addition of rituximab to CHOP reduced the risk of treatment failure [risk ratio, 0.54; 95% confidence interval (CI): 0.44, 0.77] and the risk of death (risk ratio, 0.64; CI: 0.45, 0.89). The addition of immunotherapy to standard chemotherapy had accomplished what 25 years of chemotherapy manipulation had failed to do (i.e., improve on the results of CHOP chemotherapy) ([202], [203]). Rituximab has been used with limited success in patients with multiple myeloma ([204], [205] and [206]). This lack of success might be expected given the limited expression of CD20 on plasma cells, although the possibility of affecting proliferating precursor cells made trials worthwhile. The suggestion that a subset of patients with CD20 expression on bone marrow plasma cells may benefit from rituximab is provocative ([206]). The mechanism by which rituximab produces these impressive results is less clear. A number of possible mechanisms have been considered: initiation of complement-mediated cell lysis, induction of antibody-dependent cellular cytotoxicity, and signaling via CD20 leading to programmed cell death and/or sensitization to cytotoxic drugs. Indeed, there is no reason to believe that only a single mechanism is operative. There is, however, some evidence to suggest that induction of complement-mediated lysis may play a less important role. Pretreatment lymphoma cells from 29 patients were examined by flow cytometry for expression of complement inhibitors CD46, CD55, and CD59 ([207]). Expression of these cell-surface inhibitors of complement activation was not predictive of outcome to rituximab therapy. The authors point out that these data do not rule out a role for complement fixation in the genesis of the B-cell depletion or the side effects profile of the antibody. Considerable evidence suggests that induction of antibody-dependent cellular cytotoxicity plays an important role in rituximab's antilymphoma effects. A rituximab-like antibody for which an IgG4? framework was substituted for the IgG1 framework of rituximab was incapable of producing B-cell depletion in primates ([208]). Rituximab was relatively ineffective in eliminating Raji B-cell implants in FcR? $^{-/-}$/nu/nu knock-out mice compared to nu/nu mice ([209]). These mice lack the activating receptor for Fc portions of antibodies, a critical component of the antibody-dependent cell-mediated cytotoxicity mechanism. In patients, response to rituximab has been shown to be associated with homozygosity for the high-affinity allotype of the Fc?RIIIa receptor ([210]). Evidence also exists that rituximab signaling or interference with normal signaling via CD20 may directly induce apoptosis or sensitize cells to the deleterious effects of chemotherapeutic agents ([211]). A direct, growth inhibitory effect of rituximab, with accompanying apoptosis, on cell lines cultured in the absence of complement was demonstrated ([212]). Anti-CD20–associated apoptosis has been associated with up-regulation of the pro-apoptotic protein, Bax ([213]), and down-regulation of antiapoptotic protein Bcl-2 through inactivation of signal transducer and activation of transcription (STAT) 3 ([214]). Down-regulation of STAT3 appears to be a result of down-regulation of an IL-10 autocrine pathway ([215]). These changes and/or others may be responsible for increased sensitivity to chemotherapeutic agents ([216]). In the wake of the stunning success of rituximab, a number of other antilymphoma monoclonal antibodies have entered the clinic ([217]). Alemtuzumab is a humanized IgG1? monoclonal antibody directed against the CD52 cell-surface antigen. Precursors of the molecule were among the first monoclonal antibodies to be explored in humans. However, development in rheumatoid arthritis was abruptly abandoned when substantial acute toxicity and significant immunosuppression were encountered without substantial efficacy ([191]). CD52 is expressed on normal and malignant lymphocytes of B- and T-cell lineage, as well as NK cells, monocytes, and macrophages. Alemtuzumab is indicated for the treatment of B-cell chronic lymphocytic leukemia in patients who have been treated with alkylating agents and who have failed fludarabine therapy. The pivotal clinical trial was carried out in 93 patients with fludarabine-refractory chronic lymphocytic leukemia ([218]). Alemtuzumab produced a response rate of 33%. Virtually all of the responders were partial responders; the CR rate was 2%. Median duration of response was 7 months. Median TTP was 4.7 months for the group as a whole; 9.5 months for responders. The most common adverse events were infusion related—most were grade 1 or 2 in severity, including rigors in 90% of patients (grade 3 in 14%), fever in 85% of patients (grade 3 or 4 in 20%), nausea in 53% of patients, and vomiting in 38% of patients. Infusion-associated side effects declined with subsequent infusions. During the study, 28% of patients experienced dyspnea, 17% experienced hypotension, and 3% experienced hypoxia. Overall, 55% of patients developed an infection during the study. Approximately one-half of these infections were considered serious (grade 3 or 4). Septicemia occurred in 15% of patients, and two deaths resulted. Opportunistic infections occurred in 12% of patients. Ten percent of patients died during or within 30 days of treatment—one-third of these were attributed to progressive disease. Twenty-four percent of patients discontinued treatment because of a drug-related side effect. Most patients who discontinued had not responded to therapy. Serious infusion-related events

associated with alemtuzumab appear to result from ligation of CD16 on NK cells resulting in what has been termed *cytokine storm*—release of IL-6, tumor necrosis factor-a, and interferon-? ([219]). Prolonged immunosuppression after use of alemtuzumab can result in opportunistic infections ([220]). Treatment schemas now use the routine use of prophylaxis with both antibiotics and antivirals. Two other monoclonal antibodies with potential utility in the treatment of lymphoma are in early clinical development ([217] , [221]). Epratuzumab is a humanized IgG1 monoclonal antibody directed against the CD22 antigen. CD22 is a pan B-cell antigen with distribution similar to that of CD20. Epratuzumab has a favorable safety profile in early trials. Approximately 50% of follicular lymphoma patients and 25% of diffuse large-cell lymphoma patients responded in a small phase II trial. Some of the responses have been long-lived. Apolizumab is a humanized IgG1 monoclonal antibody that binds to a variant of the HLA-DR ß-chain. The antibody induces complement-mediated lysis, antibody-dependent cellular cytotoxicity, and tyrosine phosphorylation signaling events in cell lines *in vitro*. The antibody binds to approximately 70% of lymphoma specimens. Administration of the antibody to patients results in typical infusion-related side effects. Four of eight patients with follicular lymphoma responded to apolizumab.

ANTIIDIOTYPE THERAPY Much time and energy were expended searching for tumor antigens, particularly after the development of monoclonal antibody techniques ([17]). These brute-force immunization, hybridization, and screening procedures yielded little. They defined only a single truly tumor-specific antigen. That was the idiotype of clonally distributed antibody expressed on the surface of certain B-cell lymphomas. Because it represents a unique protein structure within the combining site of antibody, the idiotype can serve as an antigen for antibody production. This fact was demonstrated by Sirisinha and Eisen ([222]) in the early 1970s. Furthermore, they demonstrated that an immunologic response to idiotype could lead to tumor protection ([223]). Levy and Miller ([224]) have explored the utility of antiidiotype strategies in indolent B-cell lymphoma over many years. Initially, these investigators raised custom-made antiidiotype monoclonal antibodies ([225]) for passive administration. A first patient with far advanced, chemotherapy-refractory disease received antiidiotype monoclonal antibodies. Gradual reductions in serum idiotype and tumor volume were noted. The patient then entered a long-term complete remission ([226]). In an initial series of patients treated with antiidiotype therapy, 11 patients were reported ([227]). In this group, a second near-complete remission, four partial remissions, and five insignificant responses were seen. There was little toxicity associated with administration of the antiidiotype antibodies. The most common side effects were chills and fever. Transient shortness of breath, headache, nausea, emesis, diarrhea, and myalgias were occasionally observed. Unusual toxicities included transient leukopenia or thrombocytopenia and transient elevations of hepatic enzymes. Several interesting problems of antiidiotype therapy were noted in this early series: the interfering effect of circulating idiotype, the development of human antimouse antibody, and the emergence of idiotype-negative tumor cell variants ([228] , [229] , [230] and [231]). An attempt to reduce the incidence of emergence of idiotype-negative lymphoma variants with a short course of chlorambucil was unsuccessful ([232]). The cumulative experience suggests that antiidiotype therapy can result in a 15% CR rate and a 50% partial response rate. The mechanism of tumor response in these trials remains unclear. However, response in these trials correlated with antiidiotype–induced signal transduction events in the lymphoma cells, suggesting that activation of apoptotic pathways may lead to lymphoma cell death after interaction of the antiidiotype antibody with the lymphoma surface-bound immunoglobulin receptor ([233]). This group has turned to active immunization strategies in indolent lymphoma (see Immunization Strategies section).

RADIOIMMUNOTHERAPY The use of immunoglobulin–radionuclide conjugates in cancer treatment represents appropriation of a classic guided-missile strategy. In theory, the antibody homes to its antigenic target and delivers a cytotoxic assault on the cell to which it attaches. Radionuclides offer certain advantages over other cytotoxic agents. They do not have to be internalized. Radioactive particles can deliver their effects over distances of 1 to 5 mm, thus limiting collateral damage to normal tissues while still potentially providing antitumor effects against antigen-negative variants in the vicinity in what has been termed a *cross-fire effect*. The principles of radiation physics underlying radioimmunotherapy have been reviewed by Press and Rasey ([234]). Radiolabeled antibodies deliver continuous, exponentially decreasing, low-dose-rate radiation. Traditional external beam radiotherapy delivers intermittent, fractionated radiation at higher dose rates. The most commonly used isotopes for radioimmunotherapy have been iodine 131 and yttrium 90. These radionuclides kill cells primarily through emission of ß particles, resulting in DNA strand breaks. The ß particles of yttrium 90 are more energetic than those of iodine 131. They affect cells in a radius of approximately 5 mm compared to approximately 1 mm for those of iodine 131. Iodine 131 also emits ? rays. This allows direct imaging of the distribution of the radioconjugate but raises issues regarding shielding and health care worker and family member safety. This field is poised on the threshold of widespread use, with one agent approved for use and others apparently close behind. Several recent reviews attest to the emergence of this field ([217] , [235] , [236] and [237]). A number of theoretical and experimentally generated concerns with radioimmunotherapy appear to have been overcome in the successful clinical studies described below. There had been concern that effective delivery of radioimmunoconjugates would be impeded by heterogeneous tumor vasculature, slow diffusion of these large molecules in interstitial spaces, heterogeneous biodistribution in tumor nodules, and high intratumoral pressures. The two products in the most advanced stages of development, yttrium Y 90 ibritumomab tiuxetan and iodine I 131 tositumomab, are both directed against the anti-CD20 antigen of B lymphocytes, the same structure targeted by rituximab. Both products are based on murine monoclonal antibodies. Both are administered after infusion of unconjugated anti-CD20 antibodies—rituximab in the case of yttrium 90 ibritumomab tiuxetan and tositumomab in the case of iodine I 131 tositumomab. Both use nuclear medicine imaging as a preparatory step to administration. Biodistribution of yttrium 90 ibritumomab tiuxetan is predicted by scans taken after administration of indium 111 ibritumomab tiuxetan. Simple dosimetry is accomplished for iodine I 131 tositumomab by capturing whole-body gamma counts after infusion of a 5 mCi “dosimetric dose” of the agent. Imaging is carried out in yttrium 90 ibritumomab tiuxetan–treated patients to assure normal biodistribution. Whole-body dosimetry is carried out in iodine I 131 tositumomab–treated patients to allow calculation of a patient-specific activity (mCi) to deliver a desired total-body dose of radiation (cGy). Both have been studied most extensively in indolent lymphoma. Yttrium Y 90 ibritumomab tiuxetan was recently approved for the treatment of patients with relapsed or refractory low-grade, follicular, or transformed B-cell NHL, including patients with rituximab refractory follicular NHL. The approval for ibritumomab tiuxetan rested primarily on two clinical studies. The first was a randomized controlled comparison of the effectiveness of yttrium 90 ibritumomab tiuxetan to that of rituximab in patients with relapsed or refractory low-grade, follicular, or transformed B-cell NHL ([238]). The study involved 143 patients; 73 randomized to yttrium 90 ibritumomab tiuxetan (single administration), and 70 randomized to rituximab (weekly × 4). Patient characteristics were balanced between the arms. Median number of prior therapies was two. Approximately one-half of the patients failed to respond to or had a TTP of less than 6 months to their last chemotherapy regimen. Yttrium 90 ibritumomab tiuxetan produced a statistically superior response rate (using the response definitions of the International Workshop), 80% versus 56% ($p = .002$). The number of durable responders at 6 months favored yttrium 90 ibritumomab tiuxetan–treated patients, but the significance of the observation was lost at 9 months and 12 months. Median TTP (estimated by Kaplan-Meier methods) was 11.2 months for patients treated with yttrium 90 ibritumomab tiuxetan and 10.1 months for patients treated with rituximab ($p = .173$). Grade 3 and 4 nonhematologic adverse events were unusual in both groups. Yttrium 90 ibritumomab tiuxetan produced grade 3 or 4 neutropenia in 57% of patients, grade 3 or 4 thrombocytopenia in 60% of patients, and grade 3 or 4 anemia in 2% of patients. One patient in the yttrium 90 ibritumomab tiuxetan–treated group developed myelodysplasia. One patient in the rituximab-treated group developed pancreatic carcinoma. The second trial was a phase II experience in 57 patients who had failed to respond to rituximab or had a TTP of =6 months ([239]). These patients had a median of four prior therapies, and 74% had bulky tumors (greatest diameter =5 cm). In this patient population, yttrium 90 ibritumomab tiuxetan produced a response rate of 74% and CR rate of 15%. The median TTP was estimated at 6.8 months. Grade 4 neutropenia occurred in 35% of patients, grade 4 thrombocytopenia in 9% of patients, and grade 4 anemia in 4% of patients. An extensive experience with iodine I 131 tositumomab also has been reported. The pivotal study enrolled 60 patients with refractory low-grade or transformed low-grade NHL who had been treated with at least two different qualifying chemotherapy regimens ([240]). Patients must also have failed to achieve an objective response or relapsed within 6 months after completion of their last qualifying chemotherapy (LQC) regimen. The patients in this study had multiple poor prognostic characteristics, including median age of 60 years and a median of four prior chemotherapies, as well as clinical conditions such as presence of bulky disease, bone marrow involvement, elevated serum lactate dehydrogenase, advanced stage, and transformation from an initial low-grade histology to a higher-grade histology in 38% of the patients. The primary endpoint was a comparison of the number of patients having a longer duration of response after iodine I 131 tositumomab therapy to the number of patients having a longer duration of response after their LQC regimen. Secondary efficacy endpoints included ORR, CR rate, and TTP. A statistically significant improvement in the primary endpoint was achieved: there were significantly more patients with a longer duration of response (>30 days) after iodine I 131 tositumomab therapy (N = 26) than patients with a longer duration of response after their LQC (N = 5; $p < .001$). Improvements in secondary efficacy endpoints after iodine I 131 tositumomab compared to those after LQC were also achieved: overall response (47% vs. 12%; $p < .001$), duration of response (11.7 vs. 4.1 months; $p < .001$), and CR (22% vs. 2%; $p = .002$). Fifteen of 60 (25%) patients were classified as long-term responders (patients with a MIRROR Panel–assessed TTP of a year or more). Nine (15%) of the 60 patients are still in CR, with TTP ranging from 41+ to 57+ months. A second trial examined the incremental benefit of the radioconjugate (iodine I 131 tositumomab) compared to the nonradioactive antibody (tositumomab) ([241]). This study was a randomized, two-arm, open-label, multicenter study that enrolled patients with chemotherapy-relapsed or refractory low-grade or transformed low-grade NHL. Patients were randomized to receive either iodine I 131 tositumomab therapy or unlabeled tositumomab alone. The primary endpoint was a comparison of the rates of CR. Secondary endpoints included ORR, duration of responses, and TTP. A total of 78 patients (18% with transformation) participated in the study. Patients had been previously treated with one to three chemotherapy regimens. One or more therapies must have included an anthracycline, anthracenedione, or alkylating agent. A significant difference was observed for the primary efficacy endpoint. The CR rate was 33% (14 of 42 patients) for the patients treated with iodine I 131 tositumomab compared to 8% (3 of 36) for patients treated with unlabeled tositumomab ($p = .012$). In addition, the ORR was greater after treatment with iodine I 131 tositumomab: 23 of 42 (55%) patients compared to 7 of 36 (19%) patients ($p = .002$). Nineteen patients initially treated with the unlabeled antibody crossed over to receive iodine I 131 tositumomab after disease progression. A CR then was observed in 42% (8 of 19 patients) and an ORR in 68% (13 of 19 patients) in the crossover patient population. A total of 20 patients (33%) from the iodine I 131 tositumomab–treated populations, including patients in the crossover arm, were classified as having a long-term response, including ten patients continuing in CR, with TTP ranging from 23+ to 59+ months. The efficacy of iodine I 131 tositumomab was also evaluated in patients who had progressed after rituximab ([242]). The objectives of the study were to assess the response rate, duration of response, and safety of iodine I 131 tositumomab therapy in patients whose disease had not responded or had progressed soon after rituximab therapy. Forty-three patients were enrolled in the study, and 40 patients received the study drug. All patients were required to have prior treatment with at least four doses of rituximab without an objective response, or to have progressed during or after treatment. Twenty-four patients did not respond to their last treatment with rituximab, and, of the 16 patients who did respond to rituximab, four patients had a duration of response exceeding 6 months. A response occurred in 27 of 40 (68%) patients, with a median duration of response of 14.7 months (95% CI; 10.6 months no response). A CR occurred in

12 of 40 (30%) patients; the median duration of CR has not been reached (95% CI; 11 months no response). Outcomes after iodine I 131 tositumomab and after previous rituximab were compared. Of the 40 patients, 24 patients had a longer (at least 30 days) duration of response after iodine I 131 tositumomab than after rituximab, five patients had a longer duration of response after rituximab than after iodine I 131 tositumomab, nine patients had equivalent durations of response, and two patients were censored (p <.001). A total of 14 patients (35%) had a TTP of 12 months or longer. Radioiodinated tositumomab also has been used at myeloablative doses, with stem-cell rescue in patients with relapsed B-cell lymphomas ([243], [244] and [245]). Radioiodinated tositumomab was used initially as a single agent ([244]). Twenty-five patients were imaged after a tracer dose of radioiodinated tositumomab. Twenty-two of these 25 patients achieved favorable biodistributions (i.e., had tumor doses in excess of doses to normal organs). These 21 patients received therapeutic infusions of radioiodinated tositumomab (345 to 785 mCi) followed by reinfusion of autologous hematopoietic stem cells. All patients achieved bone marrow engraftment (19 with bone marrow stem cells, two with peripheral blood stem cells). However, two patients died before full neutrophil recovery; one of sepsis, one of progressive lymphoma. Nonhematologic toxicities included nausea in most patients, mild mucositis in five patients, and partial alopecia in four patients. One patient experienced reversible cardiomyopathy and interstitial pneumonitis. Eighteen patients responded to this therapy; 16 patients experienced a CR. With a median follow-up of 2 years, 2-year progression-free survival was estimated at 62%, with overall survival estimated at 93%. Press et al. ([245]) then combined radioiodinated tositumomab with chemotherapy and autologous stem cell transfusion in a series of patients with relapsed B-cell lymphomas. Fifty-two patients received the planned therapy. Patients were again given tracer doses of radioiodinated tositumomab and underwent sequential gamma camera imaging. Absorbed doses of radiation to tumor sites and normal organs were determined. Thereafter, patients received a therapeutic infusion of radioiodinated tositumomab calculated to deliver between 20 and 27 Gy to normal organs (e.g., liver, kidneys, and lungs). Patients then received etoposide, 60 mg/kg, and cyclophosphamide, 100 mg/kg, followed by reinfusion of autologous hematopoietic stem cells. The maximal tolerated dose of radioiodinated tositumomab to be combined with chemotherapy was determined to be that dose that delivered 25 Gy to normal organs. Eight patients experienced 13 grade 3 or 4 toxic events. These included three patients with acute respiratory distress syndrome, three patients with severe mucositis or gastrointestinal toxicity, one patient with venoocclusive disease, and four patients with fatal infections. At 2 years, the Kaplan-Meier estimates of overall and progression-free survival for all treated patients were 83% and 68%, respectively. These findings were considered superior to results previously observed in patients who had undergone conventional external beam total-body radiation with etoposide/cyclophosphamide preparation for transplantation in the same institution.

IMMUNOTOXINS AND FUSION TOXINS This category of treatment reagents resembles those guided missiles of radioimmunotherapy. In this case, however, the warheads are chemical rather than nuclear, and the targeting is provided by antibodies or by lymphokines, growth factors, and so on that specifically bind receptors on the surfaces of target tumor cells. Attached to the targeting moiety is the cytolytic moiety. This is usually a toxin, derived from plants or bacteria, which works by inhibiting protein synthesis. They kill either resting or dividing cells and require fewer than ten molecules in the cytosol to be effective ([246], [247]). Toxins of this type tested in phase I trials include ricin A chain, blocked ricin, saporin, pokeweed antiviral protein, *Pseudomonas* exotoxin A, and diphtheria toxin. Recently, calicheamicin, a highly potent antitumor antibiotic that cleaves double-stranded DNA at specific sequences ([248]) has been successfully targeted to leukemia cells ([249]). A number of factors influence the efficacy of immunotoxins. These include the binding affinity of the ligand for its target and the target density on the tumor cell surface ([250]). The epitope to which binding occurs can affect the potency of the immunotoxin ([251]). Membrane-proximal epitopes appear to confer greater efficacy. Immunotoxin binding must lead to internalization of the target structure and the attached immunotoxin ([252]). Once internalized, the toxin moiety must translocate to the cytoplasm to be effective. This process is aided by certain translocation sequences in the toxin. This need for translocation signals provides the rationale for using blocked ricin toxin; targeting via the binding subunit is eliminated but translocation signals are preserved ([253]). The site of translocation may vary for different toxins. Increasing lysosomal pH protects cells from *Pseudomonas* exotoxin and diphtheria toxin but increases sensitivity to ricin ([254], [255] and [256]), suggesting that ricin may undergo translocation in the Golgi apparatus. Finally, these toxins affect protein synthesis by ADP-ribosylating elongation factor 2 ([257]) in the case of diphtheria toxin and *Pseudomonas* toxin, or by alteration of the 60s ribosomal subunit in the case of ricin ([258]). A number of phase I clinical trials using ricin-based, anti-pan B-cell antibody immunotoxins have been reported in B-cell lymphoma ([259], [260], [261], [262], [263], [264], [265] and [266]). These trials demonstrated that therapeutic doses of immunotoxins can be delivered with tolerable, reversible side effects. Toxicities include systemic symptoms of fever, nausea, vomiting, headache, and muscle aches; evidence of hepatocyte damage with transaminase elevations; and significant problems with capillary leak syndrome ([267]). Again recognized were the problems of human antimouse antibody formation and rapid clearance of immunotoxin in the presence of circulating antigenemia. Sporadic responses were seen in these trials, with response rates perhaps approaching 25% and CRs approaching 10%. There were hints that targeting via CD22 might be more useful than targeting via CD19 ([268]). Some experts have suggested that these agents will not become useful clinical tools until problems of their immunogenicity have been solved ([190], [247]). However, recent success has been reported for two agents of this class. A recombinant immunotoxin containing the anti-CD22 variable domain (Fv) fused to a truncated pseudomonas exotoxin has produced CRs in patients with hairy cell leukemia (HCL) ([269]). Sixteen patients whose disease was resistant to nucleoside analogs were treated by intravenous infusion every other day for three doses. Thirteen of 16 patients responded—11 had CRs. The treatment was generally well tolerated. Common side effects included transient elevations of liver enzymes and hypoalbuminemia. Median follow-up was 16 months, during which 3 of the 11 complete responders relapsed. These three patients were retreated with the immunotoxin. Two of the three developed hemolytic uremic syndrome. Another immunotoxin has been approved for the treatment of elderly patients with CD33-positive acute myeloid leukemia in first relapse. This approval suggests that agents of this type may prove useful sooner than expected. Gemtuzumab ozogamicin is an immunotoxin composed of a recombinant human IgG4? monoclonal antibody conjugated with a cytotoxic antitumor antibiotic, calicheamicin ([270]). The antibody is directed against the CD33 antigen found on the surface of leukemic blasts and normal immature cells of myelomonocytic lineage, but not on hematopoietic stem cells. CD33 is a sialic acid–dependent adhesion molecule. In a phase I dose escalation trial, treatment with gemtuzumab ozogamicin resulted in elimination of leukemic cells from peripheral blood and bone marrow in 8 of 40 patients ([271]). These results were achieved with acceptable toxicity. The basis for approval of the drug was the experience in 142 patients participating in one of three similar trials designed to examine the efficacy and safety of gemtuzumab ozogamicin in patients in first relapse of AML ([272]). Two of the studies enrolled patients 18 years of age or older. The third enrolled only patients 60 years of age or older. Across the three studies, 80 patients were 60 years of age or older. The median duration of first remission for the group was 11.1 months. Most patients had received aggressive initial induction therapy. All 142 patients received a first dose of drug, 109 patients received two doses (the recommended treatment course), and five patients received three doses. Roughly 40% of patients were treated as outpatients. Median duration of hospitalization was 24 days. The ORR was 30%. This included patients achieving a CR [defined as (a) leukemic blasts absent from peripheral blood, (b) bone marrow blasts <5% of cellular elements, (c) recovery of neutrophils and platelets, and (d) rbc transfusion independence] and patients achieving a CRp (CR as defined except delayed platelet recovery). Median survival for the group as a whole was 5.9 months. Median relapse-free survival for responders was 6.8 months. Essentially, all patients had grade 3 or 4 neutropenia and thrombocytopenia. Fifteen percent of patients experienced grade 3 or 4 bleeding events. Infusion-associated events occurred in approximately 10% of patients. Sepsis occurred in 16% of patients; pneumonia in 7%. Grade 3 or 4 hypotension was seen in 9% of patients. Twenty-three percent of patients experienced grade 3 or 4 elevation of serum bilirubin levels, and 17% of patients had grade 3 or 4 elevations of hepatic transaminases. Two deaths were associated with liver abnormalities. Eleven patients died during the treatment period of causes other than disease progression. There was no treatment-associated cardiotoxicity, cerebellar dysfunction, or alopecia. Neoplasms bearing the high-affinity IL-2 receptor have been approached with a genetically engineered, bacterially expressed IL-2-diphtheria toxin fusion protein, denileukin diftitox ([273]). Denileukin diftitox was approved in 1998 for the treatment of patients with relapsed cutaneous T-cell lymphoma (CTCL). This was the first approval for drugs of the recombinant fusion toxin class. The development of this molecule is detailed in a recent review ([274]). The basis of approval was a pivotal trial conducted in 73 patients with disease that was refractory to other therapy (patients having received three or more previous treatments) ([275]). Patients were randomized to either a low dose (9 µg/kg/day) or high dose (18 µg/kg/day) of the fusion toxin. Patients were treated on 5 consecutive days in 21-day cycles for up to eight cycles. Seventy-one patients received a drug. The ORR was 30%, and CR rate was 10%. Rates and durations of response did not differ between the two treatment groups. Adverse events included flulike symptoms, acute infusion-related events, and vascular leak syndrome. Approximately three-fourths of the patients experienced transient elevations of hepatic transaminase levels and hypoalbuminemia; approximately 15% of patients experienced grade 3 or 4 elevations of liver enzymes or hypoalbuminemia. The success of this trial, to some extent, allays concern that a major problem with this family of fusion toxins would be previous immunization of most of the American population with diphtheria toxoid in childhood. Although approximately one-half of patients had antibodies against diphtheria toxin at baseline and almost all patients had antibodies after treatment, these did not appear to affect treatment outcome ([275], [276]).

BISPECIFIC ANTIBODIES Bispecific antibodies are antibody constructions that recognize a tumor-associated antigen (TAA) with one arm and recognize and activate an immune effector cell structure with the other arm ([277], [278] and [279]). In theory, approximation of a tumor cell with an activated immune effector could result in tumor cell elimination. These bispecific antibodies can be obtained either by chemical heteroconjugation or by fusion of two hybridomas of desired specificity to yield a tetradoma. With either approach, chromatographic or other separation techniques are required to isolate the desired product. Strategies using antibodies to activate phagocytic cells, NK cells, and T lymphocytes have been examined. In preclinical models, antiidiotype × anti-CD3 bispecific antibodies have demonstrated the ability to inhibit tumor cell growth ([280], [281] and [282]). Recognizing the need for co-stimulation in T-cell response, other investigators have used a combination of bispecific antibodies, anti-CD3 × anti-TAA and anti-CD28 × anti-TAA, with interesting results ([277]). A phase I trial of anti-CD3 × anti-CD19 (a pan B-cell surface antigen) bispecific antibody treatment in patients with B-cell lymphoma has been reported ([283], [284]). Little treatment-related toxicity was observed, and some evidence of efficacy was seen. Bispecific antibodies have been used in the treatment of patients with refractory Hodgkin disease ([285], [286]). In an initial phase I/II trial ([286]), 15 patients were treated with an NK cell-activating bispecific monoclonal antibody directed against the Fc?-receptor III (CD16 antigen) and the Hodgkin-associated CD30 antigen. The antibody was administered every 3 to 4 days × 4. Dose-limiting toxicity was not encountered up to and including the highest dose administered, 64 mg/m^2. Side effects were unusual, but included fever, pain in involved lymph nodes, and maculopapular rash. Nine of 15 patients developed a human antimouse antibody response that resulted in allergic reactions in four patients who were retreated. One complete and one partial remission were observed. Duration of CR was 16 months, and partial responses endured for a median of 3 months. These results prompted a second trial to investigate the effects of different administration schedules

and the concomitant administration of cytokines on the effectiveness of the bispecific antibody ([287]). Sixteen patients were treated with 25 mg of the construct four times either as a continuous infusion for 4 days or a 1-hour infusion every other day. Patients who exhibited response were retreated at 4-week intervals, if possible. Patients with stable disease received retreatment after administration of IL-2 and granulocyte-macrophage colony-stimulating factor (GM-CSF). Four patients responded to the treatment (three partial remissions and one complete remission). Durations of response were from 5 to 9 months. Bispecific antibodies, as an approach to immunotherapy, appear to have garnered more enthusiasm and engendered more activity in the treatment of solid tumors. Relatively minor results have not given rise to large-scale trials.

Cytokines

INTERFERONS The interferons constitute a family of cytokines that were initially recognized by their abilities to interfere with viral replication ([166]). Two major classes of interferons exist: type I, consisting primarily of interferon-a and interferon-ß; and type II, consisting of interferon-?. Type I interferons are produced by many cell types. Type II interferon is produced by T lymphocytes. The biochemistry and structure of interferon receptors have recently been elucidated, as have the signal transduction pathways that emanate from those receptors. Signaling in this system involves the janus kinase (Jak) family and the STATs ([288]). Transmission of interferon-specific signals results in induction of a number of genes, including several transcription factors, MHC class I and class II (primarily in response to interferon-?) molecules, and a number of proteins that are responsible for the antiviral activity of the interferons, including the (2'–5') oligoadenylate synthase–nuclease system ([289]). Promoters for these genes share an interferon-stimulated response element that has a consensus structure of AGTTTCNNTTTCNC/T ([290]). The nature of the interferon antitumor action is as yet ill defined. Early observations involving virally induced tumors demonstrated that interferons could inhibit tumor growth ([291]). These observations were later extended to nonvirally induced tumors ([292]). The marriage of molecular biology and the entrepreneurial biotechnology industry produced recombinant interferons early on, and these molecules have been used extensively in clinical trials since the early 1980s. Interferon-a has found its way into the therapeutic armamentarium, but interferon-? has not. The most successful applications of these substances have been in chronic myelogenous leukemia (CML) and HCL. In chronic-phase CML, interferon-a has demonstrated the ability to control blood counts and to induce complete hematologic response in perhaps 70% of patients and complete cytogenetic responses in 25% of patients ([293] , [294] , [295] , [296] , [297] , [298] , [299] and [300]). Typical administration schedules have been 5×10^{6} U/m^{2}/day or three times weekly. These results have been achieved with significant side effects, including initial flulike symptoms that abate at approximately 2 weeks, then later fatigue, weight loss, neurotoxicity, depression, and insomnia. Rare cardiac and autoimmune side effects have occurred, including arrhythmias and congestive heart failure as well as hemolytic anemia, thrombocytopenia, rheumatologic disorders, hypothyroidism, and nephrotic syndrome. The role of interferon-a in the treatment of CML and its effect on remission duration and survival are controversial. One large multicenter trial failed to demonstrate a correlation between cytogenetic response to interferon-a and remission duration or survival ([296]), but in a head-to-head comparison of interferon-a with hydroxyurea, significantly improved survival was seen in the interferon-a–treated group ([298] , [301] , [302]). In this study, most of the benefit of interferon-a appeared to accrue to the patients who achieved a major cytologic response, all of whom were in the interferon-a–treated group. In the era of imatinib mesylate, the role for interferon-a remains to be defined ([299] , [300]). In HCL, interferon-a became the first effective, nonsurgical treatment; splenectomy was the first treatment approach. A number of studies conducted with partially purified, then recombinant interferon-a demonstrated that approximately 75% of treated patients achieved a complete or partial response ([303] , [304] , [305] , [306] and [307]). Median durations of response were 12 to 24 months, with virtually all patients eventually relapsing. However, most patients respond to a second treatment course of interferon-a. The mechanism of interferon-a action in this disease is unknown. Both antiproliferative ([308]) and immunomodulatory ([309] , [310]) events have been demonstrated in treated patients. Although interferon-a is an active agent in HCL, the remarkable effectiveness of short courses of cladribine in inducing sustained complete clinical remissions in this disease make it the treatment of choice for most patients with the disease. Interferon-a also has been used in the treatment of NHL ([190]). As a single agent, interferon-a has modest activity in indolent lymphomas, but toxicities are significant (at the doses generally used) and remission durations are generally short. Therefore, a number of studies have investigated the ability of low-dose interferon-a to enhance the CR rate of standard chemotherapy or to sustain chemotherapy-induced remissions. In general, the effect of interferon-a in this setting has been modest, with little effect on response rates and perhaps a reduction in the rate of transformation to higher-grade lymphoma ([311]), moderate prolongation of remission durations, but, with one exception ([312]), no effect on overall survival. Interferon-a may also be a useful agent in the treatment of multiple myeloma ([313] , [314]). When used in combination with chemotherapy, interferon-a may improve initial response rate and progression-free survival. A pilot trial conducted by the Eastern Cooperative Oncology Group suggested that interferon-a treatment in combination with chemotherapy led to increased response rates and prolonged disease-free interval, over that expected, by 12 months ([315]). In a large randomized trial of 256 patients ([316]), interferon-a maintenance treatment produced improved disease-free survival of 17.8 versus 8.2 months for the control group and overall survival of 50.6 versus 34.4 months. Both differences were statistically significant. Inclusion of interferon-a during induction therapy appeared to confer further benefit. However, in a large cooperative group trial ([317]), no benefit was seen to interferon-a maintenance therapy. A metaanalysis of 24 randomized studies involving more than 4000 subjects indicated that interferon-a improves relapse-free survival to a moderate degree and overall survival to a marginal degree in multiple myeloma. Therefore, the role of interferon-a in the treatment of multiple myeloma remains controversial. Its cost and side effects must be considered when contemplating the use of interferon-a. Furthermore, its usefulness has been questioned in melphalan-prednisone–treated patients ([318]), in patients receiving high-dose steroids ([319]), and in the elderly ([320]).

INTERLEUKIN-2 IL-2 was first recognized as a growth factor for T lymphocytes ([321] , [322]). Its discovery allowed the cloning and long-term propagation of antigen-specific T-cell clones ([323] , [324]). In addition, it was determined that IL-2 treatment led to gain of function, particularly increased cytotoxicity in T lymphocytes ([325]) and NK cells ([326]). The possibility of generating or potentiating specific immune responses for clinical applications made the production of IL-2 one of the earliest targets of the biotechnology industry. Recombinant IL-2 was available for clinical application by 1983 ([327]), only 5 years after the activity was first described. IL-2 binds specifically to receptors (IL-2R) on target cell surfaces ([328]). Most resting lymphocytes display only intermediate-affinity receptors made up of IL-2Rß and IL-2R? polypeptide chains. A number of stimulatory signals lead to production of IL-2Ra chains and the display of high-affinity heterotrimeric receptors of IL-2Ra, IL-2Rß, and IL-2R? chains. IL-2Ra contributes a rapid association rate with IL-2, whereas the IL-2Rß and IL-2R? chains provide a slow dissociation rate. The resulting rapid on rate and slow off rate results in an equilibrium dissociation constant ($K_{d} = 10^{-1}$ mol) ([329]). With approximately 750 receptors per cell surface, an endocytosis-related half-life of approximately 15 minutes, and an apparent requirement of 10,000 occupied receptors before commitment to cell cycle progression, it is likely that optimal treatment strategies will require prolonged, continuous administration of the cytokine ([330]). Early experience with IL-2 used increasing doses, seeking optimal effect. However, at high intravenous dose (greater than 10^{-8} mol peak concentration, attempting to saturate intermediate affinity IL-2R on target cells), IL-2 produced significant, life-threatening toxicities ([331]). These side effects included fever and chills initially followed by a constellation of problems resulting from a capillary leak syndrome, including hypotension requiring pressor support in a majority of patients, significant weight gain, respiratory distress occasionally requiring intubation, oliguria, renal dysfunction, and death in approximately 1% of patients. Additional side effects included nausea, vomiting, diarrhea, cardiac arrhythmia, liver dysfunction, mental status changes, anemia, and thrombocytopenia. Because of these severe side effects, arbitrary *ad hoc* dose adjustments and well-controlled clinical trials have attempted to reduce dose while maintaining clinical efficacy. At doses approximately 300 to 500 times less than those initially used, marked increases in circulating levels of NK cells without induction of immune-mediated pathology have been demonstrated ([332]). Continuous intradermal and intermittent subcutaneous administration schedules have been evaluated ([330]). IL-2 has been used in the treatment of AML. A few studies have been conducted in patients with active disease ([333] , [334] , [335] and [336]). Of these patients, a small minority had complete remissions, which were generally of brief duration. However, in several instances the IL-2–induced/maintained remission duration exceeded that of previous remission durations. This experience prompted an examination of IL-2's ability to prolong remission after chemotherapy ([337]). Seventeen patients with AML were treated with IL-2 or IL-2 plus lymphokine-activated killer (LAK) cells after autologous bone marrow transplantation (BMT). Five of these patients relapsed between 2 and 10 months, one died in therapy, but 11 remained in complete remission 12 to 54 months after BMT. All of the surviving patients demonstrated remission inversion. Similar results were reported in seven patients treated with polyethylene glycol–conjugated IL-2 administered as the sole postremission therapy after induction of a second complete remission ([338]). More recently, a pilot study of IL-2 in patients in first remission has been reported ([339]). The results suggest that more patients were alive at 3 years than would have been predicted by observations in historical controls. These results suggest that consolidative IL-2 administered early in remission induction can decrease relapse rate and suggest that prospective randomized comparisons are warranted. Despite difficulty meeting accrual goals in several studies ([340]), some experience has been gained using IL-2 in NHL, Hodgkin disease, and CTCL. In general, response durations in these diseases are brief and clinically insignificant ([190]). However, a few remissions of prolonged duration have been reported. European investigators examined continuous-infusion high-dose IL-2 alone in patients with heavily pretreated lymphomas of various subtypes ([341]). In 24 patients with low-grade lymphomas resistant to anthracycline-containing regimens, one CR was seen. In 23 patients with intermediate- or high-grade lymphomas refractory to primary therapy or salvage therapy, three complete remissions and two partial remissions were documented. No responses were seen in seven patients with Hodgkin disease. In seven patients with mycosis fungoides refractory to chemotherapy, one complete remission and four partial remissions were seen. These authors concluded that further testing with IL-2 in patients with aggressive lymphoma and CTCL was warranted. This experience with CTCL is particularly provocative because a direct effect of IL-2 on tumor cells, which often bear the IL-2R, is likely and may relate to the mechanism by which the IL-2 effect was manifest in this trial. Use of IL-2 has been investigated in myelodysplastic syndrome ([342]). Its utility, in this setting, remains to be defined.

Cellular Approaches

GRAFT-VERSUS-LEUKEMIA EFFECT Despite the fact that early studies in murine leukemia suggested that allogeneic transplantation would confer a lower risk of relapse than syngeneic transplantation ([343]), and this information was used as part of the rationale for early clinical transplantation ([344]), the reality of a graft-versus-leukemia effect in human transplantation was slowly recognized ([345] , [346]). Significant indirect evidence for a graft-versus-leukemia effect can now be cited ([347]). Anecdotal reports have documented remission reinduction after a flare of graft-versus-host disease ([348]) or on rapid withdrawal of immunosuppression ([349]). Furthermore, a number of studies have confirmed that syngeneic BMT is associated with a higher risk of relapse than allogeneic BMT ([350] , [351]). Other studies, including large retrospective analyses by the International Bone Marrow Transplant Registry ([352]), have demonstrated a protective effect of graft-versus-host disease. Non–T-cell–depleted transplant recipients with acute, chronic, and acute plus chronic graft-versus-host disease had a lower likelihood of relapse than did patients receiving non–T-cell–depleted transplants who had no graft-versus-host disease. Patients who received non–T-cell–depleted transplants and experienced no graft-versus-host disease still had a lower likelihood of relapse than patients receiving syngeneic transplants. These data have been interpreted to support the notion that graft-versus-leukemia effects can be seen in the absence of graft-versus-host disease. Of note, it appears that the potency of the graft-versus-tumor effect differs among neoplasms ([353]). The graft-versus-tumor effect is obvious in AML and CML, has been suggested in lymphoma ([354]), but at least in one study was absent in acute lymphocytic leukemia ([355]), and has been less apparent in myeloma ([356]). The molecular and cellular mechanisms that underlie the graft-versus-leukemia effect are becoming better understood ([347] , [353] , [357] , [358]). Furthermore, the relationship between the graft-versus-leukemia effect and graft-versus-host disease is becoming better defined. Some antigens relevant to these processes have been identified. Although MHC differences have long been associated with graft-versus-host disease, the role of minor histocompatibility antigen expression in graft-versus-host disease and graft-versus-leukemia effect is becoming apparent ([353] , [355] , [356] , [359] , [360]). In a murine model, administration of allogeneic T cells specific for a single minor histocompatibility antigen resulted in an antileukemic response without a graft-versus-host response ([361]). Other antigens may be important as well. Immune responses against the neoantigens expressed from the bcr/abl fusion in CML ([362] , [363]) and the pml/rara fusion in acute promyelocytic leukemia ([101]) have been demonstrated. Their relevance is suggested by the disease-specific efficacy of donor leukocyte infusions, but their true relevance in the clinical setting remains to be defined. The immunologic effectors of graft-versus-host disease and graft-versus-leukemia effect also are being dissected. It is apparent that T lymphocytes must play a large role in these reactions, for their removal results in marked decrease in graft-versus-host disease and marked increases in relapse frequencies ([364]). NK cells may also be involved in the graft-versus-leukemia effect ([365]). Recent evidence suggests that CD4 $^{+}$ T lymphocytes may be particularly important in the graft-versus-leukemia effect ([366] , [367]). Allografts selectively depleted of CD8 $^{+}$ T lymphocytes (CD4 $^{+}$ T-lymphocyte preserved) demonstrated a low incidence of graft-versus-host disease yet a preserved graft-versus-leukemia effect similar to that seen with unfractionated transplants in patients with CML. These clinical findings are supported by similar findings in animal models ([368]) and by the demonstration of donor-derived, HLA-identical, cytotoxic CD4 $^{+}$ T-cell clones of multiple specificities in a patient with severe graft-versus-host disease after transplantation for CML ([369]). T-helper subset 2 and T-cytotoxic subset 2 may be particularly important in the regulation of graft-versus-host disease and mediation of graft-versus-leukemia effects ([370]). Development of MHC-tetramer technology had provided a means to visualize antigen-specific T-cell responses ([371]). This technology can be used to correlate individual T-cell responses with clinical course. In an early application of the approach, Mutis et al. ([372]) demonstrated that the frequencies of T cells specific for the HY and HA-1 minor histocompatibility antigens correlated with severity of graft-versus-host disease. A number of strategies have been proposed to enhance the graft-versus-leukemia effect and reduce graft-versus-host disease ([353] , [373]). These include a reduction in the total number of T lymphocytes used in transplantation, delayed transfusion of donor lymphocytes ([374]), CD8 $^{+}$ T lymphocyte depletion, ablation of thymidine kinase gene–transfected donor T lymphocytes with ganciclovir administration in case of graft-versus-host disease ([375] , [376]), administration of IL-2 ([377]), functional depletion of antihost lymphocytes without depletion of antimyeloid lymphocytes ([378] , [379]), and *ex vivo* generation of leukemia-specific T lymphocytes ([380]). The approach that has garnered the most attention recently has been mini-allografting ([357] , [381] , [382]). High-dose chemotherapy with stem-cell rescue has proven to be an effective, potentially curative approach to the treatment of several malignancies. However, this technique is associated with significant morbidity and mortality. The success of donor leukocyte infusions (see section Donor Leukocyte Infusions) for the treatment of CML and other hematologic malignancies has suggested that much of the benefit of allogeneic transplantation is mediated by the graft-versus-malignancy effect. Several groups have evaluated the effects of safer, less toxic approaches to transplantation. Shimoni et al. ([381]) described their experience with allogeneic hematopoietic transplantation using nonmyeloablative regimens in 116 patients. These low-dose regimens were designed, not to eradicate host hematopoiesis, but to allow induction of the graft-versus-leukemia effect as the primary treatment mechanism. Forty-six patients with advanced age or significant organ dysfunction and diagnoses of CML, AML, or myelodysplasia, were treated with purine analog/cytarabine combinations to provide sufficient immunosuppression to allow engraftment of allogeneic progenitor cells. Thirty-six of 40 evaluable patients receiving related-donor transplants engrafted with donor cells—23 patients—achieved complete donor chimerism, and 13 patients were mixed chimeras. Death attributed to treatment-related causes occurred in eight patients. Twenty-eight of 31 evaluable patients with AML or myelodysplastic syndrome achieved a CR. Three patients died in remission. Fifteen patients relapsed. Six of the 15 patients received donor leukocyte infusion, but none responded. Eleven patients had CML. Eight of nine patients who received related-donor grafts achieved complete hematologic and cytogenetic remission. Two-thirds of patients treated in chronic phase were alive at 2 years. Seventy patients were treated with purine analog/melphalan nonmyeloablative regimens in an attempt to improve outcomes for patients with active chemorefractory leukemia at the time of transplantation. Sixty-two of 64 evaluable patients had engraftment of donor hematopoietic cells. Treatment-related mortality was estimated at 45%. Median survival for the group was 4.5 months. Survival at 1 year was 37% and at 2 years was 31%.

DONOR LEUKOCYTE INFUSIONS A number of authorities consider the success of donor leukocyte infusions to be the most compelling proof of a graft-versus-leukemia effect ([383]). In 1990, Kolb et al. ([384]) reported three patients with relapsed CML after marrow transplantation who were treated with infusion of buffy coat leukocytes from the donor and interferon-a. Complete hematologic and cytogenetic responses were seen in these patients. Since then, the phenomenon has been replicated and extended by many investigators ([383] , [385] , [386]). A broad experience of 25 North American transplant centers has been reported ([387] , [388]), confirming the remarkable efficacy of this approach in patients with relapsed chronic phase CML and the less impressive response rates in advanced CML and acute leukemia. The collective experience suggests that in cytogenetic relapse or clinical chronic phase relapse of CML, complete cytogenetic remission can be attained in 80% of patients. However, patients with more advanced disease have a much lower, perhaps 25%, chance of remission. When the technique has been applied to patients with AML, relapsing after allogeneic BMT, response rates have been only 15 to 20% ([386]). Anecdotal reports of responses have been generated in multiple myeloma, chronic lymphocytic leukemia, Fanconi anemia, and polycythemia vera ([386]). When applied to patients with acute lymphocytic leukemia, Hodgkin disease, and NHL, few responses have been seen ([386]). Donor leukocyte infusions are not without complications. The two most worrisome are graft-versus-host disease and pancytopenia occurring weeks after infusion. Predictors of graft-versus-host disease after donor leukocytes were T-lymphocyte depletion in the original transplant marrow and concomitant interferon-a usage. The graft-versus-host disease induced by donor leukocyte infusions appears to respond more readily to immunosuppressive measures than does the graft-versus-host disease seen with transplantation. Predictors of myelosuppression include frank hematologic relapse and T-lymphocyte depletion ([383] , [387] , [388] and [389]). The optimal dose and timing of donor leukocyte infusions have yet to be determined ([390]). Administered dosage of leukocytes does not necessarily correlate with response ([383] , [391] , [392]), but there is some evidence that the incidence of graft-versus-host disease does correlate with dosage ([392]), making the notion of infusing fewer cells attractive. Regarding timing, the ability to detect relapse with molecular biologic techniques, such as PCR, allows definition of relapse long before it becomes hematologically apparent. Yet whether donor leukocyte infusions should be used before hematologic relapse remains a matter for clinical investigation because transient molecular relapses have been documented ([390]). Similarly, the requisite concomitant use of interferon-a has been questioned. In the European trials, use of interferon-a did not appear to improve the response rate to donor leukocyte infusions ([383]), and a number of studies have documented responses without the use of the cytokine ([389] , [392]).

ADOPTIVE CELLULAR IMMUNOTHERAPY The field of immunotherapy was rejuvenated in the early 1980s by reports of clinical trials with transfer of antitumor cells to tumor-bearing patients ([393] , [394]). Rosenberg et al. pioneered the use of LAK cells plus IL-2 ([395] , [396]). LAK cells were derived from resting, autochthonous, peripheral blood mononuclear cells by culture *ex vivo* in high concentrations of IL-2. After culture, these cells were capable of lysing fresh tumor cells in an MHC-nonrestricted fashion ([397]). They were returned to tumor patients with concomitantly administered high-dose IL-2. Although the tumor target structure remains undefined, these determinants appear to be broadly distributed on fresh and culture tumor cells and not expressed on normal cells *in vivo*. LAK cells appear to be derived from the NK subset of human T lymphocytes, bearing the NK markers CD16 and CD56, and usually lacking the CD3 structure ([398] , [399]). Initial reports with LAK plus IL-2 in patients suggested a significant response rate in NHL, but most emphasis has been given to solid tumors, particularly renal cell carcinoma (RCC) and melanoma ([400] , [401]). Studies suggested that LAK cells do not consistently home to the site of tumor involvement, significantly limiting their therapeutic efficacy ([402]), and have demonstrated no advantage for the administration of LAK plus IL-2 over administration of IL-2 alone ([400]). A search for more potent killer cells resulted in the description of TILs ([403]). These cells could be isolated and grown from single-cell suspensions of tumor specimens in IL-2. They have the phenotype of classical cytotoxic T cells and kill tumor cells in an MHC-restricted manner. In animal studies, TILs are approximately 50 to 100 times more potent killers than are LAK cells. TILs also more efficiently home to and accumulate in tumor deposits ([404] , [405]). Pilot trials ([394] , [406]) have demonstrated a response rate of approximately 35% in patients with melanoma. The rather modest response rates, extremely labor-intensive nature of these treatments, and the serious toxicity of systemically administered IL-2 have markedly limited enthusiasm for these approaches to treatment, but they stand as important milestones on the road to effective immunologic treatments for neoplastic hematologic diseases and solid tumors. The remarkable success of adoptively transferred virally specific, *ex vivo*-expanded T lymphocytes for control of cytomegalovirus infection in patients after allogeneic BMT ([407] , [408] and [409]) suggests that, if appropriate tumor cell antigens can be found and exploited, this form of therapy may become a useful modality in the treatment of hematologic malignancies ([410] , [411]).

Immunization Strategies

ACTIVE IMMUNIZATION AGAINST IDIOTYPES A natural outgrowth of the studies involving passive administration of antiidiotype antibodies has been an attempt to induce active immune responses against idiotype ([412]). The feasibility of this approach was first demonstrated in animal models ([413]) and later in a pilot trial in patients with indolent B-cell lymphomas ([414]). A more complete evaluation was reported by Hsu et al. ([415]). Forty-one patients (32 in first remission and nine in subsequent remissions) with B-cell lymphoma received a series of injections of tumor-specific idiotype protein coupled to keyhole limpet hemocyanin emulsified in immunologic adjuvant. Toxicities, immune response, and tumor status were evaluated. Twenty patients (49%) developed demonstrable immune responses against the idiotype protein. Two patients with residual disease achieved CRs coincident with development of antiidiotype immunity. Median TTP and overall survival were significantly prolonged in patients who developed an immune response compared to those who did not. Similar results have been reported from the National Cancer Institute group ([416]). These investigators used idiotype protein coupled to keyhole limpet hemocyanin injected with free GM-CSF, given monthly × 4. Clearance of PCR evidence of t(14;18) was accomplished in 8 of 11 evaluable patients. A number of other antiidiotype immunization strategies have been explored in animal models and patients. Protective antiidiotype antibody responses have been induced in mice using a fusion protein immunogen containing murine idiotype determinants and constant region backbones appended to murine ([417]) and using intramuscular injection of a naked DNA construct coding for a similar idiotype–GM-CSF fusion ([418]). In a pilot clinical trial involving ten patients ([217] , [419] , [420]), autologous dendritic cells pulsed *ex vivo* with tumor-specific idiotype protein were infused intravenously. This procedure was followed by injection of idiotype antigen 2 weeks later. The cycle of pulsed dendritic cells and antigen was repeated two times at monthly intervals and again at approximately 6 months. Each of four patients reported in the study developed measurable tumor-specific cellular immune responses. Most impressively, two clinical CRs were seen. Durations of the responses were 44 and 54 months. Based on these impressive results, the study was extended to involve patients with follicular lymphoma in first remission ([420]). Id protein coupled to keyhole limpet hemocyanin was used to pulse the dendritic cells based on evidence of improved immunogenicity and tumor protection in a murine model ([421]). Revaccination with idiotype protein coupled to keyhole limpet hemocyanin at the time of lymphoma recurrence has resulted in tumor regression, in some cases ([422]). Dendritic cell–based idiotype vaccine strategies also have been explored in patients with multiple myeloma ([204] , [423] , [424] , [425] and [426]).

CYTOKINE-DRIVEN CELLULAR VACCINES A number of studies demonstrated that creation of locally high concentrations of cytokines in proximity to tumor cells can lead to immunoinflammatory responses that are capable of tumor elimination, induction of specific resistance to tumor challenge, and, in certain cases, to eradication of established tumor ([427]). In early reports, Tepper et al. ([428] , [429]) and Fearon et al. ([430]) demonstrated that transfection of tumor cell lines with genes for the IL-4 and IL-2, respectively, led to elimination of injected tumor cells by host animals. Subsequently, induction of specific tumor immunity, which resulted in the ability of challenged animals to reject wild-type tumor cells, was demonstrated. Thus, local destruction of cytokine gene–transfected tumor cells can lead to systemic immunity against nontransfected tumor cells. Golumbek et al. ([431]) then demonstrated that injection of cytokine gene–transfected cells led to elimination of established tumor at a distant site. This observation was a unique departure from previous tumor immunization studies and suggested that immunotherapy might be clinically relevant. An extensive evaluation of many cytokines in a single tumor model in mice was carried out ([432]). B16 melanoma cells were transfected with genes for several cytokines. Expression of none of the cytokines except IL-2 led to primary elimination of tumor cells. However, IL-2 failed to induce protective tumor-specific immunity in this model. Systemic toxicities of several cytokines were seen in animals bearing cytokine gene–transfected tumors. When cytokine gene–transfected B16 cells were irradiated before injection in mice, GM-CSF–producing cells stimulated potent, long-lasting tumor-specific immunity. IL-4 and IL-6 also demonstrated some ability to induce immunity. Although the ability of GM-CSF to induce tumor-specific immunity was somewhat unexpected, it has been speculated that locally high concentrations of GM-CSF led to the recruitment of professional antigen-presenting cells, such as macrophages and perhaps dendritic cells, which are particularly effective in presenting tumor antigens in the context of MHC products and display appropriate co-stimulatory molecules ([427]). An additional cytokine, not examined in the work described above, may hold promise as a inducer of antitumor immunity ([433]). IL-12–transduced adenocarcinoma cells ([434]) and myeloid leukemia cells ([435]) have produced impressive regressions of established tumors and protection against tumor challenge in animal model systems. Some studies in mice suggest that cytokine-driven immunotherapy approaches can be applied to lymphoma ([436] , [437]). These and other studies have led to the initiation of a clinical immunotherapy trial using cytokine gene–transfected tumor cells in RCC ([427] , [438]). Results of a phase I trial evaluating this strategy for safety and the induction of immune responses in patients with metastatic RCC have been reported ([439]). Patients were treated in a randomized, double-blind dose-escalation study with equivalent doses of autologous, irradiated RCC vaccine cells with or without *ex vivo* human GM-CSF gene transfer. The replication-defective retroviral vector MFG was used for GM-CSF gene transfer. No dose-limiting toxicities were encountered in 16 fully evaluable patients. GM-CSF gene–transduced vaccines were equivalent in toxicity to nontransduced vaccines up to the feasible limits of autologous tumor vaccine yield. No evidence of autoimmune disease was observed. Biopsies of intradermal sites of injection with GM-CSF gene–transduced vaccines contained distinctive macrophage, dendritic cell, eosinophil, neutrophil, and T-cell infiltrates similar to those observed in preclinical models of efficacy. Histologic analysis of delayed-type hypersensitivity responses in patients vaccinated with GM-CSF–transduced vaccines demonstrated an intense eosinophil infiltrate that was not observed in patients who received nontransduced vaccines. An objective partial response was observed in a patient treated with GM-CSF gene–transduced vaccine who displayed the largest delayed-type hypersensitivity conversion. No replication-competent retrovirus was detected in vaccinated patients. This study demonstrated the feasibility, safety, and bioactivity of an autologous GM-CSF gene–transduced tumor vaccine for RCC patients but failed to live up to the high expectations that attended its initiation. A similar strategy was used in a phase I study in patients with multiple myeloma ([440]). Although 33 patients entered the trial, only 21 completed the planned immunization protocol. Metastatic lesions, biopsied after vaccination, demonstrated dense infiltration with T cells and plasma cells and extensive tumor destruction with fibrosis and edema. A single patient developed a partial remission. Three other patients were rendered free of disease with surgery or radiotherapy and remained without evidence of disease at 20 to 36 months. Although elegant in concept and execution, gene therapy approaches are not required for induction of cytokine-driven host antitumor responses. Depot forms of cytokine injected with irradiated tumor cells appear to be equally efficacious. Coinjection of microencapsulated GM-CSF with irradiated tumor cells led to induction of systemic immunity and elimination of preexisting tumor in a manner comparable to injection of GM-CSF gene–transfected tumor cells in the B16 model ([441]). Nongene-therapy approaches to tumor immunotherapy offer significant advantages by avoiding the uncertainties of tissue culture adaptation of tumor explants ([438] , [439] and [440]) and the custom-made, labor-intensive nature of each tumor transfectant. Recombinant products are available for several human cytokines. These products could be used off the shelf or after derivation to provide a more pharmaceutical approach to therapy.

EXPLOITATION OF CO-STIMULATION As noted in the discussion of T-lymphocyte activation, stimulation of the T-cell antigen receptor complex by antigen and MHC is required, but not sufficient, for commitment of the cell to IL-2 production and proliferation. This second signal requirement can be provided by the interaction of the CD28 cell-surface structure with its cognate ligands, CD80 (B7-1) and CD86 (B7-2), on the antigen-presenting cell ([442]). Few tumor cells express CD80 or CD86. Therefore, the tumor cell could be considered a poor antigen-presenting cell, a quality that might contribute to the poor immunogenicity of many tumors. A number of investigators have demonstrated in animal models that injection of tumor cells transfected with the gene for CD80 can elicit host responses, exhibiting enhanced immunogenicity capable of tumor elimination and induction of resistance to subsequent tumor challenge ([443] , [444] and [445]). This approach also has been shown to lead to elimination of preexisting tumors ([446] , [447] and [448]). However, the approach has not been universally successful and appears to be useful only in the enhancement of responses to tumors with poor but existent immunogenicity ([449]). The CD28 co-stimulatory system appears to be counterbalanced by a negative regulatory system mediated through the CTLA-4 cell-surface structure ([450] , [451]). T-cell activation promotes expression of CTLA-4, which binds CD80 and CD86 with affinities orders of magnitude greater than the affinity with which CD28 binds these ligands. Cells expressing CTLA-4 appear refractory to activation, perhaps through interference with co-stimulation when amounts of CD80 and CD86 are limiting ([452]). Therefore, it was argued that blockade of CTLA-4 stimulation might promote antitumor responses. This appears to be the case. *In vivo* administration of anti–CTLA-4 antibodies accelerated rejection of $CD80^{+}$ colon carcinoma, including preexisting tumors, in mice and resulted in systemic immunity protective against subsequent challenge ([453]). CTLA-4 blockade has been incorporated into phase I clinical trials in patients with prostate cancer and melanoma ([454]). Safety was a major concern in these studies as the CTLA-$4^{-/-}$ mouse develops a lethal lymphoproliferative syndrome ([455]), and CTLA-4 blockade had been shown to exacerbate autoimmune disease in experimental models. For clinical studies, humanized anti–CTLA-4 was used. The prostate trial involved hormonal refractory patients who had progressed after at least one systemic therapy. The treatment was well tolerated, with no increase in activated T cells peripherally and no clinical signs of autoimmunity. Two of six patients who had not received chemotherapy showed clinical responses (>50% decreases in prostate-specific antigen) that lasted from 3 to 5 months. The melanoma trial involved patients who had refractory, progressive, unresectable metastatic disease. Adverse events in the trial were generally mild. Several patients showed mixed responses, and biopsies of tumor tissue post-therapy showed extensive tumor necrosis with inflammatory infiltrates in the tumor mass. These trials provide evidence that CTLA-4 blockade promotes antitumor effects as a single agent in two solid tumors. The most straightforward approach to the exploitation of co-stimulation is the use of dendritic cells in immunization schemes ([456] , [457] , [458] , [459] and [460]). Dendritic cells are a small population of cells that occupy the blood and tissues. Two types exist—one of myeloid origin, one of lymphoid origin ([461]). Stimulated immature dendritic cell precursors become mature dendritic cells that express many adhesive and co-stimulatory molecules, including CD40, CD50, CD54, CD80, CD86, and others. These cells are the most potent stimulators of T-lymphocyte activation, capable of transmitting all the requisite signals to cause resting or naïve T lymphocytes to undergo proliferation, produce cytokines, and acquire effector function. Dendritic cells can be generated *ex vivo*, either from $CD14^{+}$ peripheral monocytes or from $CD34^{+}$ hematopoietic precursor cells. A number of cytokines can contribute to expansion, differentiation, and terminal maturation of dendritic cells, but GM-CSF appears to be the most important factor for all of these functions. The professional antigen-presenting cells can be loaded with tumor-associated antigen in a number of ways. These include peptide pulsing, gene transfection, tumor cell-dendritic cell heterokaryon formation, and exposure to cells undergoing apoptosis. Dendritic cell immunizations have been used in a number of clinical studies ([457] , [462]). The experience with idiotype-pulsed dendritic cells in patients with follicular lymphoma ([419] ,

[420], [421] and [422]) and multiple myeloma ([204], [423], [424], [425] and [426]) have been discussed in the earlier section Active Immunization Against Idiotypes.

OUTLOOK FOR THE FUTURE

Although this chapter has historically, and once again, taken a T-cell–centric approach to tumor immunotherapy, the last 5 years can certainly be called the triumph of passive humoral immunity in the treatment of lymphoid malignancies (and solid tumors). The approval and widespread use of rituximab has changed the standard of care for lymphoma. Other therapeutic monoclonal antibodies alone and conjugated to cytotoxic payloads will surely be developed over the next few years. In some instances, these products will face competition from small molecule inhibitors of key components of malignant transformation [like gefitinib ([463]) and imatinib mesylate ([464])] ([465]). Harnessing the power of dendritic cells, while avoiding the difficulties of patient specific therapy, will be a major challenge for immunotherapy in the years to come. An increasing number of clinical triumphs have proven the potential of immunotherapy, but many challenges lie ahead if this form of treatment is to become widespread. Once again, the roller coaster history of immunotherapy investigation should provide a sobering perspective against which the next wave of clinical results will be judged. The next few years should be interesting for investigators in the field, and, more important, beneficial to patients.

Supportive Care in Hematologic Malignancies

Several advances have been made over the past few decades in the supportive care of patients undergoing therapy for hematologic malignancies. This has resulted in improved survival as well as better quality of life in such patients. Use of new treatment modalities, such as monoclonal antibodies, radioimmunotherapy, and reduced intensity stem cell transplants (SCT), has changed the infectious risk, the spectrum of infections, and, thereby, the complications in this patient population. Intensive treatment strategies, such as high-dose chemotherapy and hematopoietic SCT, are being increasingly used with curative intent in these diseases and are associated with significant morbidity. The challenges for the clinician who cares for these patients include management of infections in the immunocompromised host, toxic effects of chemoradiotherapy, nausea and vomiting, bleeding complications, and pain. In addition, the psychosocial impact on the patient of a cancer diagnosis, lengthy hospitalizations, the long-term sequelae of therapy, and treatment failure must not be overlooked. For patients who receive palliative treatment, quality-of-life issues assume paramount importance. Careful attention to supportive measures is therefore essential to achieve therapeutic goals.

This chapter provides an overview of current recommendations as well as recent advances in the management of common problems that are encountered during the treatment of patients with hematologic malignancies. Specific complications of the malignancies and their treatments are discussed elsewhere in the text.

APPROACH TO INFECTION IN THE IMMUNOCOMPROMISED HOST

Infection continues to be a significant cause of morbidity and mortality in patients who undergo antineoplastic chemotherapy. Despite improved diagnostic tools, better understanding of infectious etiologies, and the advent of several new antimicrobials, infections continue to be a major problem. An appreciation of the factors that predispose these patients to infection is the key to appropriate antimicrobial therapy, as well as the rational development of preventive strategies (Table 75.1) ([1]).

TABLE 75.1. Factors Predisposing to Infection

	Disease-Related and Other Host Factors	Therapy-Related Factors
Cellular	T- and B-lymphocyte dysfunction	Granulocytopenia
	Hodgkin disease, non-Hodgkin lymphoma, acquired immunodeficiency syndrome, hairy cell leukemia	Bactericidal and chemotactic defects
	Granulocytopenia (acute leukemia, myelodysplastic syndromes, myelofibrosis)	T- and B-cell dysfunction (cyclosporine A, steroids, total body irradiation)
		Deferoxamine therapy
Humoral	Hypogammaglobulinemia (multiple myeloma, chronic lymphocytic leukemia, acquired immunodeficiency syndrome)	Suppression of antibody, complement, and nonspecific humoral mediators (lactoferrin, tuftsin)
	Hyposplenism (hemoglobinopathies)	Splenectomy or autosplenectomy
Mechanical	Mass obstruction of a normally patent viscus	Disruption of integument by venous access devices or chemotherapy
	Ciliary dysfunction	Ciliary dysfunction
	Impaired micturition	Chemotherapy-induced nausea, vomiting, and mucositis
	Impaired cough or gag reflex	Suppression or inhibition of cough, gag reflex
	Alteration of microbial colonization	Alteration of normal flora by antimicrobial use
		Gastric acid neutralization
Multifactorial	Protein-calorie malnutrition	
	Zinc and vitamin B_6 deficiency	
	Uremia	
	Diabetes mellitus	
	Chronic hemolysis	
	Transfusion dependence	
	Chronic lung disease	
	Alcoholism	
	Impaired mobility	
	Reactivation of herpesviral infections (Epstein-Barr virus, herpes simplex viruses, varicella-zoster virus, cytomegalovirus)	

Adapted from Hathorn JW. Critical appraisal of antimicrobials for prevention of infection in immunocompromised hosts. Hematol Oncol Clin North Am 1993;7:1051–1099.

Patient Evaluation and Assessment of Risk

The immunocompromised state may occur due to one or several defects in the host defense mechanism. Factors that are responsible for compromise of the host defense system could be due to the underlying malignancy [myelodysplastic syndrome (MDS), aplastic anemia, chronic lymphocytic leukemia (CLL), and tumor infiltration of the marrow], the therapy of the hematologic malignancy (myelosuppressive agents, steroids, monoclonal antibodies) or a breach in the normal physical barriers (mucositis, indwelling intravenous catheters). Absolute neutropenia remains the single most important risk factor for infection in patients with hematologic diseases, which could be a result of myelosuppressive therapy, primary bone marrow failure, or marrow infiltration by tumor (Fig. 75.1) ([2], [3]). The definition of absolute neutropenia is variable, but an absolute neutrophil count (ANC) of less than 500/mm^3 is considered standard. The risk of infection correlates closely with the degree, as well as the duration of neutropenia; it is highest when neutropenia is prolonged (more than 10 to 14 days) and profound (ANC of less than 100/mm^3) and when the ANC falls sharply as the result of antecedent chemotherapy ([3], [4], [5] and [6]). Bodey, in 1966, demonstrated this phenomenon for the first time and reported that the risk of infection was 14% if the ANC fell to less than 500 to 1000/mm^3 but rose to 24 to 60% if the ANC fell to less than 100/mm^3 ([2]). The risk of infection is almost 100% if the host remains neutropenic for greater than 5 weeks.

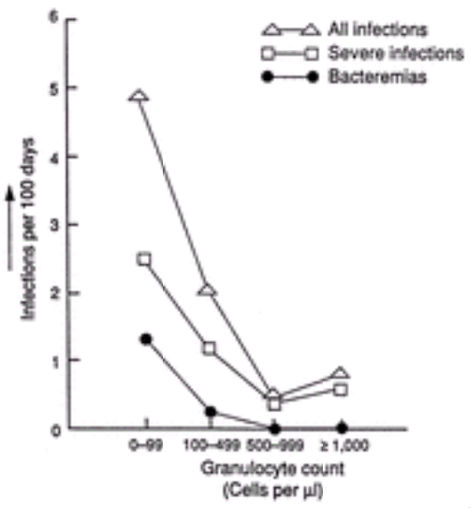

Figure 75.1. Relationship between neutrophil (granulocyte) count and risk of infection. (From Schimpff SC. Infections in the cancer patient: diagnosis, prevention and treatment. In: Mandell GL, Douglas RG, Bennett JE, eds. Principles and practice of infectious diseases, 4th ed. New York: Churchill Livingstone, 1995:2667–2675, with permission.)

All neutropenic patients are clearly not similar ([7]). Patients with aplastic anemia and hypoplastic MDS may remain free of bacterial infection, despite long periods of neutropenia, and may die principally of invasive aspergillosis ([8]). Several investigators have attempted to stratify neutropenic patients into low- and high-risk groups for the purpose of tailoring antibiotic therapy and assessing the need for hospitalization ([9], [10] and [11]). Although there are no strict criteria for risk-assessment, certain prediction rules help stratify these patients into high- and low-risk groups ([12]). Patients who receive chemotherapy for solid tumors, clinically stable patients, and those with a short duration of neutropenia (< 7 days) could be considered low-risk and are candidates for early discontinuation of parenteral antibiotics and discharge from the hospital before achieving complete neutrophil recovery ([13], [14], [15] and [16]).

More than 80% of infections in immunocompromised patients are acquired from colonizing microbial flora rather than from exogenous sources ([17]). Approximately 50% of these are hospital acquired. The virulence factors involved in the conversion of colonizing microorganisms into invasive pathogens are still incompletely characterized but are thought to include the alteration or exposure of mucosal attachment sites and changes in cell-surface fibronectin content in addition to the absence of functional granulocytes and damage to anatomic defenses ([18], [19] and [20]). The normal flora of chronically debilitated or hospitalized patients is rapidly dominated by gram-negative and antibiotic-resistant organisms ([21], [22]). It has been shown, for example, that less than 10% of patients who are newly diagnosed with acute leukemia are colonized with *Pseudomonas* before entering the hospital, in contrast to more than 50% of patients who are hospitalized for as long as 4 weeks ([23], [24]). The composition of the resident flora varies between institutions as a result of different patterns of microbial distribution and antibiotic usage ([3], [21]). The usual portals of entry for microbial pathogens are small breaks in the skin [increasingly via central venous catheters (CVCs)] and gastrointestinal (GI) (oropharyngeal and

perirectal) mucosa ([25], [26]).

The initial assessment of a febrile immunocompromised host is dependent on the underlying hematologic condition and other associated risk factors. Fever is defined as a single oral temperature of greater than or equal to 38.8°C (101°F) or a temperature of greater than or equal to 38.0°C (100.4°F) for more than 1 hour. Although fever remains the most important clue to an infectious process, it is necessary to remember that the characteristic signs and symptoms of infection may be absent in more than one-half of infected neutropenic patients, and routine cultures are often negative ([27], [28]). Because no known factors predict accurately which patients with fever and neutropenia are most likely to have bacteremia, a careful history and screening physical examination should be undertaken in every case, with special attention to the most common sites of infection: skin, oropharynx, nares, sinuses, lungs, GI tract (including perianal area), soft tissues, and indwelling catheter devices ([3]). Table 75.2 reviews important aspects of an initial evaluation of a febrile immunocompromised patient ([29]). Blood cultures, a urinalysis and urinary Gram's stain, and baseline chest radiograph should be obtained, as well as cultures of aspirated or biopsy material from accessible body sites that appear infected. In patients with an indwelling vascular catheter, blood cultures should be obtained from a peripheral vein and from each catheter port. Although some investigators believe that cultures from peripheral vein are not necessary, the current Infectious Disease Society of America (IDSA) guidelines recommend that blood samples be obtained from the vascular device and peripheral vein ([30]). Quantitative blood cultures are not routinely recommended. Aggressive diagnostic workup is warranted if any localizing signs or symptoms are elicited (e.g., biopsy and culture of a tender subcutaneous nodule). Patients who are unable to undergo invasive diagnostic procedures to determine an infectious etiology should be treated with antibiotics empirically until they can safely undergo diagnostic workup or until the neutropenia resolves. Additional tests, such as cerebrospinal fluid examination and computed tomography (CT) scans of the sinuses, chest, and abdomen, may be necessary based on individual patient evaluation. Speed is critical in the evaluation of the febrile neutropenic patient, and early administration of broad-spectrum antibiotics to cover gram-positive and gram-negative organisms is of utmost importance. Choice of antibiotics (combination therapy or monotherapy) varies between treating physicians. These guidelines are somewhat arbitrary and do not take into account individual risk factors, but their adoption has decreased infectious morbidity and mortality in neutropenic patients.

TABLE 75.2. General Management of the Febrile Neutropenic Patient

Instruct patients and families to seek medical help if they develop a fever when their neutrophil count is falling or low.
Initiate prompt broad-spectrum antibiotics when a neutropenic patient (polymorphonuclear leukocytes =500/mm ^{3}) becomes febrile (single oral-equivalent elevation =38.5°C or three elevations>38°C during a 24-hour period).
If the patient has an indwelling intravenous catheter, obtain cultures from each port and lumen, as well as peripherally. Also, rotate antibiotics so that they are delivered to each lumen of double- or triple-lumen catheters.
Monitor closely patients who are receiving antibiotics for breakthrough or superinfection that requires additions to or modifications of the primary empirical regimen.
Continue empirical antibiotics in neutropenic patients with protracted (i.e., =1 wk) periods of neutropenia, particularly those who remain persistently febrile.
Add empirical antifungal therapy in neutropenic patients who recrudesce after having initially become afebrile.
Discontinue antibiotics when the neutrophil count has risen to >500/mm ^{3} in high-risk patients or when it is recovering in low-risk patients.
Although most infections in neutropenic patients can be treated with conventional 10- to 14-d courses of therapy, more protracted therapy is necessary for neutropenic patients with a residual focus of infection or patients with invasive mycoses (such as hepatosplenic candidiasis).
Exercise careful hand washing in the care of hospitalized neutropenic patients.
From Pizzo PA. Management of fever in patients with cancer and treatment-induced neutropenia. N Engl J Med 1993;328:1323–1332, with permission.

An infectious cause is eventually identified in only one-third of febrile neutropenic episodes, partly because of early institution of empiric antibiotics. In patients with persistent fevers, reactions to drugs (including hematopoietic growth factors) or blood products, malignancy, graft-versus-host disease (GVHD), antilymphocyte serum therapy, and severe mucositis caused by chemotherapy should be considered to have noninfectious causes of fever. Of equal importance is the frequent reassessment of the patient's clinical status and physical findings, even when no obvious infectious source can be found, and empirical antibiotic therapy has been instituted; superinfection with fungi or resistant strains of bacteria may occur, requiring modifications in therapy. Severely immunocompromised patients are susceptible to infections by several different organisms, and this should be kept in mind when treating these patients for persistent fevers. The basic guidelines of neutropenic fever management, as outlined by Pizzo ([29]), are as shown in Table 75.3.

TABLE 75.3. Evaluation of Fever in Immunocompromised Patients

[a] An evaluation of cerebrospinal fluid is especially important in patients with persistent fever.

[b] Lung computed tomography to detect pulmonary aspergillosis should be performed in patients with persistent fever and neutropenia and who have had more than 1 week of empirical therapy with antibiotics.

[c] Special studies include computed tomography and magnetic resonance imaging.

[d] Abdominal computed tomography or magnetic resonance imaging to detect hepatosplenic candidiasis should be performed in patients who are recovering from neutropenia who have new or persistent fever.

From Pizzo PA. Fever in immunocompromised patients. N Engl J Med 1999;341:893–900, with permission.

The clinical benefit of routine surveillance cultures for bacteria from asymptomatic body sites in neutropenic patients and those who are already receiving antibiotic treatment is minimal. They do not appear to be cost-effective or helpful in guiding antimicrobial therapy because of delays in becoming positive in these patients and because multiple organisms are derived from any one body site ([31]). On the other hand, positive surveillance cultures (from urine, stool, and oropharynx) for *Candida tropicalis* are highly predictive of systemic infection but are not true for *Candida albicans*. Negative surveillance cultures for *C. tropicalis* and *C. albicans* have a high negative predictive value (95 to 99%) ([32] , [33]). It has been suggested that surveillance nasal swabs for *Aspergillus* may help identify high-risk patients in centers that have had an increased incidence of *Aspergillus* infection, but this has not been consistently confirmed ([34]). Stool cultures may aid in the prospective identification of drug-resistant organisms (vancomycin-resistant enterococci, methicillin-resistant staphylococci) in patients who are in protective isolation and who are receiving prophylactic antibiotics ([35] , [36]). Surveillance cultures may provide useful epidemiologic information regarding resistance patterns in specific patient populations and are used at some institutions solely for this purpose. In patients who are being treated for catheter-associated infection, bacterial or fungal surveillance blood cultures via a CVC are also performed frequently during therapy to assess the need for catheter removal. Surveillance cultures may be useful in monitoring microbial suppression in patients who are receiving selective intestinal decontamination. Surveillance for cytomegalovirus (CMV) has significantly reduced the incidence of CMV disease due to early use of preemptive therapy with ganciclovir or foscarnet. CMV surveillance using antigen detection assays or quantitative polymerase chain reaction (PCR) assays has become the standard of care in the management of allogeneic SCT patients.

Changing Epidemiology of Infections

The etiology of neutropenic fevers has changed constantly over the past few decades, and this change has been one of the challenges faced by the treating clinicians (Table 75.4) ([37] , [38]). In the late 1960s and early 1970s, aerobic gram-negative bacilli (particularly *Escherichia coli, Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*) emerged as predominant organisms causing infection in neutropenic patients, with *P. aeruginosa* being the leading organism in that era. In the middle 1980s, the trend of infections changed, and the incidence of gram-positive bacterial infections began to rise. An inexplicable decline in infections that were caused by *P. aeruginosa* [except in specific patient subgroups, such as children with human immunodeficiency virus (HIV) infection and indwelling catheters] and an increase in the number of non *aeruginosa Pseudomonas* isolates were noted. An increase in gram-positive infections could in part be explained due to the widespread use of intravascular Hickman and Broviac catheters over the past decade. Staphylococci (*Staphylococcus aureus* and *Staphylococcus epidermidis*) were the most common gram-positive organisms that were isolated. Along with the emergence of staphylococcal infections, several other “rare” gram-positive bacteria were found to be etiologically relevant. These include the a-hemolytic (viridans) streptococci (*Streptococcus mitis, Streptococcus oralis, Streptococcus salivarius*, and *Streptococcus milleri*) and group D enterococci. These streptococci have emerged as serious pathogens in patients with severe oral mucositis, in those who receive treatment with high-dose cytarabine and H_2-receptor antagonists, and in bone marrow transplant recipients ([38] , [39] and [40]). These organisms are capable of causing a fatal febrile illness that results in a toxic shocklike syndrome (fever, hypotension, and diffuse rash with subsequent desquamation) and the adult respiratory distress syndrome (ARDS) in the immunocompromised patients ([41] , [42] , [43] and [44]). Approximately 10% of patients who are infected with these bacteria develop this syndrome, but the mortality rate ranges from 6 to 30%. There has been an increasing incidence of resistance to penicillins, second and third generation cephalosporins ([45] , [46]). The enterococci are emerging as an important cause of nosocomial infections in the hospitalized patients, *Enterococcus faecium* being more predominant than *Enterococcus faecalis* in several health care facilities. There has been an increasing incidence of infections, as well as colonization with vancomycin-resistant enterococci ([47] , [48] and [49]). There has been an increase in resistance of gram-negative bacteria to the current antibiotics. Approximately 10% of *P. aeruginosa* isolates are noted to be resistant to the third generation cephalosporins, imipenem and ciprofloxacin. The incidence of resistance of gram-negative bacilli to ciprofloxacin may be as high as 25% at some centers ([50]). Some other less frequent gram-negative bacteria that have been responsible for infections in neutropenic patients are *Stenotrophomonas maltophilia, Legionella* species, *Burkholderia cepacia*, and *Alcaligenes xylosoxidans.* A recent study from Europe suggested that there might be an increase again in the rate of gram-negative bacteremias in neutropenic febrile patients, although the reasons are unclear (Fig. 75.2) ([51]).

TABLE 75.4. Changing Epidemiology of Opportunistic Infections

	Traditional	Increasingly Recognized
Bacteria (nh)	*Staphylococcus aureus*	Alpha-hemolytic (group D) streptococci
	Staphylococcus epidermidis	Enterococci
	Streptococcus pneumoniae (s)	
	Listeria monocytogenes (c)	
	Escherichia coli	*Propionibacterium acnes*
	Klebsiella pneumoniae	*Xanthomonas maltophilia*
	Pseudomonas aeruginosa	*Pseudomonas cepacia* and *Pseudomonas putida*
	Haemophilus influenzae (s)	Other Enterobacteriaceae (*Citrobacter, Serratia, Acinetobacter, Providencia, Morganella*, and *Enterobacter* species)
	Legionella species	
	Neisseria species	
	Salmonella species (s)	*Corynebacterium* JK.
		Bacillus species
		Capnocytophaga species and DF-2 (s)
		Clostridium tertium
	Clostridium perfringens	*Clostridium septicum*
	Bacteroides fragilis	*Clostridium difficile*
		Oral anaerobes (*Peptococcus, Peptostreptococcus, Veillonella, Fusobacterium, Eubacterium*, and *Bifidobacterium*)
Atypical (c)	*Mycobacterium tuberculosis*	*M. tuberculosis* (multidrug-resistant)
		Atypical mycobacteria (*Mycobacterium chelonei, Mycobacterium kansasii*, and *Mycobacterium fortuitum*)
	Nocardia species	
Fungi (cn)	*Candida albicans*	Other *Candida* species (*Candida neoformans, Candida krusei*)
	Candida tropicalis	*Torulopsis glabrata*
	Aspergillus flavus	Other *Aspergillus* species (*A. niger, A. terreus*)
	Aspergillus fumigatus	*Pseudoallescheria boydii*
	Pneumocystis carinii	*Drechslera* species
	Cryptococcus neoformans	*Trichosporon beigelii*
	Histoplasma capsulatum	*Scedosporium* species
	Coccidioides immitis	*Pityrosporum* species (*Malassezia furfur*)
	Zygomycetes *(Mucor, Rhizopus)*	*Fusarium* species
	Blastomyces hominis	
Viruses (ch)	Cytomegalovirus	Respiratory syncytial virus
	Epstein-Barr virus	Adenovirus

	Varicella-zoster virus	Human herpesvirus 6
	Herpes simplex virus	Human immunodeficiency virus
		Polyomaviruses (BK and JC viruses)
		Enteroviruses
		Influenza and parainfluenza
		Parvovirus
Other (ch)	*Toxoplasma gondii*	*Babesia* (s)
	Strongyloides stercoralis	
	Giardia lamblia	*Cryptosporidium*

NOTE: Associated immune defects are given in parentheses: c, T-cellular; h, humoral; s, asplenia; n, neutropenia.

Figure 75.2. *Fusarium* sepsis, manifesting as fever and a nodular, erythematous skin rash in an autologous bone marrow transplant recipient. See Color Plate. (Photograph courtesy of S. Antony.)

With the changing host immunity, the nature of nonbacterial infections has also changed in the past few decades. Atypical fungi that are relatively or absolutely resistant to amphotericin B therapy have also been isolated more often; these include *Fusarium, Drechslera*, and *Trichosporon* species, *Pseudallescheria boydii*, and some *Candida* species ([52], [53], [54] and [55]). Routine use of fluconazole has resulted in emergence of resistant *Candida* species, such as *Candida krusei* and *Candida glabrata*. Mycobacterial exit site or tunnel infections (*Mycobacterium chelonae* and *Mycobacterium fortuitum*) have been reported, as have multidrug-resistant strains of *Mycobacterium tuberculosis* ([47], [56]). Trends in viral infection are more difficult to trace. Infections with herpes viruses remain problematic in patients who undergo chemotherapy for leukemia and lymphoma, with herpes simplex virus (HSV), varicella-zoster virus (VZV), and CMV being the most common. Human herpesvirus 6 (HHV6) has recently emerged as an important etiologic agent in posttransplant pneumonitis ([57], [58]). Acyclovir- and ganciclovir-resistant herpesviral infections have been reported ([59], [60]). Many other common viruses have also been associated with serious illness in hematologic cancer patients: respiratory syncytial virus (RSV), adenovirus, rotavirus, echovirus, coxsackievirus, measles virus, influenza, and parainfluenza viruses ([1], [61]). Finally, protozoal and parasitic infections may reactivate in bone marrow transplant recipients and other abnormal hosts, especially in the setting of corticosteroid therapy. Well-described and emerging opportunistic pathogens in the immunocompromised patient population are listed in Table 75.4.

Diagnostic Techniques

Lysis centrifugation and constant-detection blood culture techniques for bacteria and fungi (such as BacT/Alert, Organon Teknika Corp., Durham, NC), shell vial cultures for viruses, immunofluorescent and enzyme-linked immunosorbent assays (ELISA) for antigen detection, and the PCR ([62], [63] and [64]) have all been added to the diagnostic armamentarium over the past 10 to 15 years. However, despite the clinician's best efforts, the source of fever in two-thirds of febrile neutropenic patients remains unknown or undiagnosed.

One of the problems with the management of fungal infections, especially aspergillosis, is late diagnosis. New diagnostic tools are now available that might help with the diagnosis of fungal infections early on in the disease process, especially in high-risk patients. Some of these tools, such as Galactomannan antigen testing of blood with ELISA methodology, help diagnose invasive aspergillosis before the appearance of clinical or radiologic signs. Other nonspecific fungal assays include the G-test, which is a specific test for ([1], [3])-ß-D-glucan, a component of the fungal cell wall. This test is sensitive but has low specificity and a high number of false positives. The most sensitive and specific test available for early diagnosis of fungal infections is PCR analysis. Although these tests are being routinely used in some centers in Europe, they are still considered experimental in the United States and are not a part of a routine diagnostic armamentarium ([65]). Cryptococcal antigen testing of serum, urine, or cerebrospinal fluid and *Histoplasma* antigen testing of urine are helpful in the diagnosis of these opportunistic infections. The cryptococcal latex agglutination test has been useful in the diagnosis of infections that are caused by *Trichosporon beigelii*, which shares antigens with *Cryptococcus* ([26]). Specific antigen tests (pp65) and PCR assays are available for diagnosis of CMV infection and direct preemptive therapy before development of CMV disease ([66]).

Imaging techniques to pinpoint the source of an occult infection, such as indium 111–labeled immunoglobulin (Ig) G tagging of leukocytes, CT scanning, and magnetic resonance imaging ([67]), have proved disappointing and might also be expected to have less usefulness in patients with neutropenia or diminished numbers of fully functional phagocytes. Spiral CT scanning of the chest has proved to be valuable in evaluating patients who are suspected to have fungal (especially *Aspergillus*) infections, as it can often detect pulmonary infiltrates that are not readily apparent on chest radiographs ([68]).

Bronchoalveolar lavage and protected brush specimens from the lung in conjunction with immunohistochemical staining methods have been particularly useful in establishing an infectious etiology of pulmonary infiltrates in immunocompromised hosts. The Gram's stain of an adequate (more than 25 neutrophils per high-power field) sputum specimen, although often discredited as nonspecific, is significant when more than ten organisms are noted per high-power field and is helpful in guiding initial therapy. The Gram's stain and cultures may be difficult to interpret in patients who are neutropenic or who are receiving antimicrobial therapy. Pathogens that do not normally inhabit the respiratory tract (*Legionella, Mycobacterium*, and *Histoplasma* species and RSV) may be identified by special stains of the sputum or by antigen tests, but most fungal organisms require invasive methods of detection ([69]). Although quantitative culture methods add sensitivity and specificity to the diagnosis of bacterial pneumonias, they are time consuming, costly, and often dependent on the growth rate of the organism. The optimal specimens and available diagnostic tests for many common opportunistic pulmonary pathogens are summarized in Table 75.5 ([70]). When bronchoalveolar lavage is nondiagnostic, open lung or percutaneous needle biopsy may be performed in selected patients who do not have a prohibitive risk of bleeding. However, the role of routine open lung biopsy in the evaluation of diffuse pulmonary infiltrates is controversial, as it is risky and is not better than empiric antimicrobial therapy ([71]). Several studies have demonstrated the feasibility of open lung biopsy in immunocompromised patients, but the results of the biopsy rarely resulted in a change in patient management ([72]).

TABLE 75.5. Detection of Common Opportunistic Pulmonary Pathogens

Organism	Specimen	Direct Stain	Antigen or Nucleic Acid	Culture/Incubation Time
Routine bacteria	**1, 4, 5**	Gram's stain	Not available	Routine methods, 3 to 4 d
Legionella species	1, 4, 5	Direct FAB	PCR, [a] urine antigen (radioimmunoassay)	Special *Legionella* media, 2 to 7 d (buffered charcoal yeast extract)
Fungi	1, 4, 5	Wet mount or calcofluor white	Serum cryptococcal antigen	Mycologic media, 6 to 8 wk (Sabouraud, brain–heart infusion agar)
Pneumocystis species	**2, 4, 5**	FAB, Giemsa stain, toluidine blue	PCR [b]	Nonculturable

Mycobacterium species	**1, 2, 4, 5**	Acid-fast stain	Chemiluminescent DNA probes, PCR [b]	Mycobacterial media, =8 wk (Middlebrook 7H 10/11)
Nocardia species	1, 2, 4, 5	Modified acid-fast stain	Not available	Blood agar, Sabouraud, 4 to 6 wk
Viruses	1, 3, 4, 5	FAB for respiratory syncytial virus, cytomegalovirus, herpes simplex virus, varicella-zoster virus	Enzyme immunoassay [b] for respiratory syncytial virus, influenza A	Traditional tissue, =2 wk
			FAB for cytomegalovirus, herpes simplex virus, varicella-zoster virus	Shell vial culture, [c] 2 to 5 d
Chlamydia species	3, 4, 5	None [d]	PCR [b]	HL or human laryngeal tumor cells, 3 to 5 d
Mycoplasma	1, 3, 4, 5	None	PCR [b]	Selective media, 7 to 10 d

NOTE: Bold indicates preferred.

1, expectorated sputum; 2, sodium chloride–induced sputum; 3, nasopharyngeal washings or swab; 4, bronchoalveolar lavage, brushings, biopsies; 5, percutaneous needle aspiration or open-lung biopsy; FAB, fluorescent antibody; PCR, polymerase chain reaction.

[a] The polymerase chain reaction assay is not widely available.

[b] Research technique.

[c] Influenza A and B; parainfluenza 1, 2, and 3; respiratory syncytial virus; cytomegalovirus; herpes simplex virus; and varicella-zoster virus are widely available.

[d] None for *Chlamydia pneumoniae*.

Empirical Antimicrobial Therapy: Current Guidelines and Regimens

Once the neutropenic febrile patient has been assessed, evaluated, and risk stratified, antimicrobial therapy should be promptly initiated. The use of empirical antibiotic therapy in febrile neutropenic patients before the culture documentation of an organism has resulted in decreased infectious morbidity and mortality. The rationale for early administration of broad-spectrum antibiotics has been the prevention of death from rapidly evolving gram-negative sepsis while providing coverage for gram-positive or mixed infections. The choice of antimicrobials (monotherapy or combination), the route of administration (oral or intravenous), and the need for inpatient admission depend on the assessment of the patient. The initial choice of the antibiotic regimen should also be based on the type, frequency, and antibiotic susceptibility patterns of the bacterial isolates in individual centers. Until recent years, all neutropenic patients were admitted to the hospital for broad-spectrum antimicrobials, which were continued until recovery of the neutrophil count (greater than 500/mm ^{3} in high-risk patients or greater than 100/mm ^{3} in low-risk patients), to prevent recrudescence of fever, septic complications, and breakthrough infections by resistant organisms ([73], [74]).

To date, no single empirical antimicrobial regimen has been proven to be superior to another. Just like the epidemiology of the infections in neutropenic patients has changed over the years, the initial empirical antimicrobial regimen of choice has changed too. Combination regimens incorporating two or three additive or synergistic drugs were used in the early 1970s; for example, a combination of an anti- *Pseudomonas* penicillin (such as piperacillin or ticarcillin) and an aminoglycoside (such as gentamicin, amikacin, tobramycin). Soon followed the ß-lactam and ß-lactamase inhibitor combinations, such as ticarcillin–clavulanic acid and piperacillin-tazobactam. With the advent of third generation cephalosporins and carbapenems in the 1980s, monotherapy became the regimen of choice (Fig. 75.3). The monobactam antibiotic aztreonam is most useful in patients with severe ß-lactam allergies. Owing to its lack of its efficacy against gram-positive organisms, it may be used in combination with vancomycin. Several prospective studies have now shown monotherapy with imipenem-cilastatin or ceftazidime to be an effective initial regimen, especially in patients with only mild to moderate neutropenia (an ANC of greater than 100/mm ^{3}) and with fever as the only manifestation of infection ([75], [76] and [77]). The use of fluoroquinolones (ciprofloxacin) as monotherapy in empiric regimens is controversial and is not recommended because of their poor activity against streptococci and anaerobes and the increasingly reported emergence of resistant organisms ([30], [78], [79]). These agents are also to be avoided in children younger than 18 years of age or in pregnant or nursing women because of potential adverse effects on cartilage and bone development ([76]). The newer fluoroquinolones, levofloxacin, moxifloxacin, and sparfloxacin, are superior to ciprofloxacin against *Streptococcus pneumoniae*, including strains that are highly resistant to penicillin. They are also moderately active against anaerobes ([80], [81]).

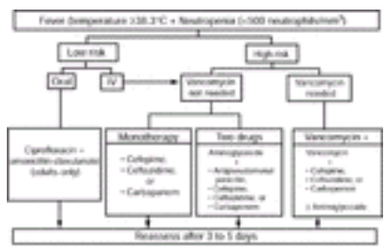

Figure 75.3. Empirical antibiotic regimens in febrile neutropenia. (Adapted from Hughes WT, Armstrong D, Bodey GP, et al. 2002 Guidelines for the use of antimicrobial agents in neutropenic patients with cancer. Clin Infect Dis 2002;34:730–751.)

The IDSA published new guidelines for the use of antimicrobial agents in neutropenic patients with cancers in 2002 ([30]). Patients who are determined to be low-risk (absent focus of bacterial infection and no other systemic signs like hypotension, rigors) should be considered for treatment with oral antibiotic regimens (combination ciprofloxacin and amoxicillin-clavulanate) ([12], [13], [30], [82]). If the clinician chooses to treat the patient with intravenous antibiotics, the guidelines offer three choices as follows: monotherapy, two-drug therapy without vancomycin, and two- or three-drug therapy with vancomycin. Monotherapy with a broad-spectrum antibiotic, such as cefepime or ceftazidime (third generation cephalosporins), or a carbapenem (imipenem-cilastatin or meropenem) has been found to be equally effective as multidrug combinations in several studies. Compared to the carbapenems and cefepime, ceftazidime has a restricted gram-positive activity, and the addition of vancomycin may become necessary when using ceftazidime. The addition of other antimicrobials to the monotherapy becomes necessary if the patient remains febrile or develops secondary infections. Aminoglycosides and fluoroquinolones are not currently recommended for monotherapy. Two-drug regimens that exclude vancomycin include an aminoglycoside in combination with a third generation cephalosporin (cefepime, ceftazidime) or carbapenem or an antipseudomonal penicillin (e.g., ticarcillin-clavulanic acid and piperacillin-tazobactam). The benefits of combination therapy include synergy and prevention of emergence of resistant bacteria. The disadvantages include increased renal toxicity and frequent drug administrations. A combination that uses quinolones is an option but needs to be further evaluated. Inclusion of vancomycin in the initial empirical regimen is controversial, as studies have failed to show a clear survival advantage with this approach ([83], [84]). At this time, initial empirical use of vancomycin is recommended for a subgroup of patients with the following findings: clinically suspected serious catheter-related infection (cellulitis, bacteremia), known colonization with penicillin- and cephalosporin-resistant pneumococci or methicillin-resistant *S. aureus*, positive blood cultures for gram-positive organisms before final identification, and hypotension or other cardiovascular compromise. Patients who are undergoing high-dose chemoradiotherapy, with or without stem cell rescue, who have severe mucositis may also benefit from early vancomycin therapy, although this remains unclear.

Modifications of the initial drug regimen are made based on new physical findings, microbiologic data, or persistent fever that indicates a resistant organism (Fig. 75.4). It requires on an average 3 to 5 days to determine the efficacy of the initial antibiotic regimen. Low-risk patients may become afebrile as early as 2 days, and high-risk patients may take as long as 7 days to have a response to the antibiotics. The current guidelines suggest that if a patient becomes afebrile within 3 to 5 days of initiation of therapy, and no etiology is identified, low-risk patients can be switched to oral combination therapy, including ciprofloxacin and amoxicillin-clavulanate (cefixime in children), and high-risk patients can continue the same antibiotics. If a source of infection is found, adjust the antibiotics to the most appropriate treatment. Antibiotics should be continued for a minimum of 7 days or until the documented infection has been eradicated. It is preferable to have neutrophil recovery (ANC >500/mm ^{3}) before discontinuing therapy. If the patient continues to be febrile 3 to 5 days after the initiation of empiric antibiotics, one of the following three choices can be made: Continue the same antibiotics if patient is stable and no source of infection has been found; change or add antibiotics if the patient develops a new

complication or if the finding on evaluation or appears to worsen clinically; or add an antifungal drug. Amphotericin B had been the antifungal of choice for a long time, but, with the advent of several less toxic antifungals, such as caspofungin, voriconazole, and lipid formulations of amphotericin B (although more expensive). After 7 to 10 days of neutropenic fever that is associated with profound neutropenia, the risk of fungal infection (*Aspergillus* and *Candida*) rises precipitously, and the institution of empirical antifungal therapy is appropriate. Withholding antifungals until a fungal source is established by culture allows time for dissemination to occur and often proves catastrophic. Randomized clinical trials show that empirical antifungal therapy reduces infectious mortality in patients with new or persistent fever occuring after 1 week of antibiotic therapy ([85], [86] and [87]). Fluconazole is highly effective in the treatment of oropharyngeal and esophageal candidiasis and may be as effective as amphotericin B for systemic candidiasis ([88], [89]). However, it should not be used empirically in place of amphotericin B because of its absent or poor activity against *Aspergillus*, atypical fungi, and several clinically relevant *Candida* species (*C. krusei, C. tropicalis, Candida lusitaniae*, and *Torulopsis glabrata*) ([90], [91], [92] and [93]). The empirical use of antivirals in the treatment of neutropenic fevers is less defined. Antiviral drugs, such as acyclovir, valacyclovir, and famciclovir, are indicated in the treatment of neutropenic fevers only if there is clinical and laboratory evidence of a viral infection (herpetic lesions of the skin or mucous membranes) ([94]).

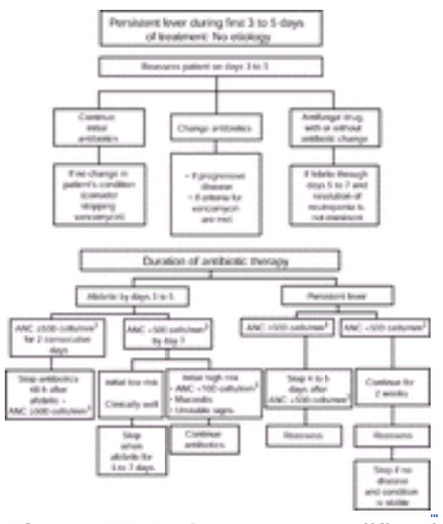

Figure 75.4. Common modifications of empirical antimicrobial therapy in the febrile neutropenic patient. ANC, absolute neutrophil count. (Adapted from Hughes WT, Armstrong D, Bodey GP, et al. 2002 Guidelines for the use of antimicrobial agents in neutropenic patients with cancer. Clin Infect Dis 2002;34:730–751.)

The next important decision is when to discontinue the antibiotics. The determining factors that help make that decision include neutrophil recovery, resolution of the fevers, and presence or absence of a source of infection. If a patient is afebrile for more than 48 hours, no source of infection is identified, and the ANC is more than 500/mm ^{3}, it is appropriate to discontinue the antibiotics. If the patient is still neutropenic but afebrile, the decision to discontinue antibiotics is less clear. If the patient is low risk at the initiation of treatment and is clinically stable, it may be appropriate to discontinue the antibiotics after 5 to 7 days of treatment, despite persistent neutropenia. If the patient continues to be febrile despite neutrophil recovery, reassess the patient for a source of infection that is not covered by the current antimicrobial regimen (e.g., fungal, viral, or protozoal infections) or other noninfectious sources of fever (e.g., drug fever, engraftment syndrome). The duration of antifungal therapy is determined by the type and extent of fungal infection.

Role of Granulocyte Transfusions and Growth Factors

The role of granulocyte transfusions in the management of neutropenic fevers is poorly defined. The published literature includes small nonrandomized studies that show the safety and feasibility of the procedure in the recipients and the donors. Although some studies have shown the benefit of granulocyte transfusions in profoundly neutropenic patients with documented severe bacterial and fungal infections, others have failed to show any benefit ([95], [96], [97] and [98]). Adverse reactions to granulocyte transfusions include febrile reactions, alloimmunization, pulmonary toxicity, and transmission of infection, particularly CMV ([99], [100] and [101]). Some investigators have administered a combination of granulocyte colony-stimulating factor (G-CSF) and steroids (dexamethasone, prednisolone) to the donor before harvesting the granulocytes, but there is no evidence to show that this approach is more efficacious ([102]). Transfusion of elutriated monocytes that are activated by macrophage colony-stimulating factor (M-CSF) is another strategy that is under investigation ([103]).

The 2001 American Society of Clinical Oncology (ASCO) guidelines recommend against routine use of hematopoietic growth factors [G-CSF, filgrastim or granulocyte-macrophage colony-stimulating factor (GM-CSF), and sargramostim] in patients with uncomplicated neutropenic fevers. Several randomized controlled trials have failed to show any beneficial impact of growth factors on the duration of fever, the use of antimicrobials, or infection-related mortality. On the other hand, use of these growth factors is indicated in a certain subgroup of neutropenic febrile patients: those with profound and protracted neutropenia with documented infections, sepsis, systemic fungal infections, and cardiovascular compromise ([104]).

Common Organ-Specific Febrile Syndromes

FEVER AND PULMONARY SYMPTOMS Pneumonia is the most common infectious cause of death in immunocompromised patients. Pulmonary infiltrates may occur as a primary focus of infection or as a complication of septicemia and the ARDS or systemic inflammatory response syndrome. The most important role of the clinician is in deciding when to initiate empirical antimicrobial therapy and how best to use invasive diagnostic modalities to establish a diagnosis without exposing the patient to undue risk ([105]). The differential diagnosis of pulmonary infiltrates in patients with hematologic malignancies is shown in Table 75.6 ([106]). Noninfectious causes of interstitial pneumonitis (IP) in the febrile patient are diagnosed by exclusion of an infectious etiology.

TABLE 75.6. Differential Diagnosis of Pulmonary Infiltrates in the Immunosuppressed Patient

Infectious causes
Conventional bacterial pneumonia
Legionella and *Legionella*-like infection
Nocardial infection
Tuberculosis
Fungal infection
Viral infection (cytomegalovirus, herpes simplex virus, adenovirus, human herpesvirus 6, and influenza or parainfluenza)
Protozoan infection (*Pneumocystis carinii*, *Toxoplasma gondii*)
Noninfectious causes
Tumor
Radiation pneumonitis
Drug-induced pneumonitis (bleomycin, busulfan, methotrexate, and cyclophosphamide)
Leukoagglutinin reaction
Pulmonary hemorrhage
Pulmonary emboli
Congestive heart failure
Postlymphangiography pulmonary embolization

Adapted from Rubin RH. Infection in the immunosuppressed host. In: Dale DC, Federman DD, eds. Scientific American Medicine, vol. 2. New York: Scientific American, 1997:1–23.

SEPSIS SYNDROME The clinical signs and symptoms of sepsis syndrome, which is typically associated with aerobic gram-negative infection, are well described,

although none are pathognomonic. Shock occurs in at least one-third of cases of gram-negative sepsis, but it is also being seen more commonly in gram-positive bacteremias ([107] , [108]). Common sequelae include ARDS and multisystem organ failure, which account for the high mortality of this syndrome. The source of bacteremia or fungemia is not apparent in 30% of cases, despite positive identification of an organism, and the prognosis is poor unless neutropenia resolves, and the underlying malignancy is controlled.

FEVER AND CUTANEOUS LESIONS Skin rash caused by infection must be distinguished from a nonspecific drug eruption, a reaction to radiation or chemotherapy (such as high-dose cytarabine), pyoderma gangrenosum, tumor, and GVHD. Biopsy of suspicious skin lesions may be the simplest or the only rapid means of diagnosing a disseminated bacterial or fungal process (such as *Neisseria meningitidis, Candida, Fusarium*) (Fig. 75.2). Sites of cutaneous necrosis may be clues to infectious endocarditis, catheter-related septic thromboembolism, *Pseudomonas* septicemia (ecthyma gangrenosum), or vascular invasion by *Aspergillus*.

OROPHARYNGEAL AND FACIAL SITES Severe mucositis, gingivostomatitis, and periodontal infection are common in patients during the course of therapy for hematologic malignancy. Mucositis may extend into the esophagus, causing retrosternal chest discomfort. Mucosal lesions are usually caused by HSV or *Candida* species, or both, but they are occasionally caused by CMV infection or fungal (*Histoplasma*) or bacterial pathogens, the most common of which are *Pseudomonas* species. Endoscopy with or without mucosal biopsy is often helpful in distinguishing these entities when there is no response to empiric antifungal or antiviral therapy or if clinical deterioration follows initial response to therapy. In acquired immunodeficiency syndrome and neutropenic cancer patients who are severely immunocompromised, and in patients with recurrent perineal candidiasis or refractory proven oropharyngeal candidiasis, systemic azole or amphotericin B therapy is preferred ([88] , [106]). Localized tenderness of the face, particularly when associated with periorbital inflammation or cranial nerve palsy, is a particularly ominous sign, as it often heralds invasive fungal sinusitis (such as rhinocerebral mucormycosis or *Aspergillus*). A black eschar in the nares or on the soft palate may be the first sign of such an infection. Aggressive surgical débridement, in addition to antifungal therapy, is usually mandatory to optimize the chances of recovery ([109]). Bacterial sinus infections are generally treated more successfully. Odontogenic abscess may occur rarely even in edentulous patients, if tooth fragments are retained in the gingiva.

FEVER AND LOWER GASTROINTESTINAL TRACT SYMPTOMS Perianal cellulitis with or without abscess formation, acute abdominal pain, and diarrheal syndromes may be associated with fever, especially in patients with acute monocytic or myelomonocytic leukemia. These complications have decreased in frequency because of improved antibacterial prophylaxis in neutropenic patients. Typhlitis should be suspected if right lower quadrant pain and bloody diarrhea are present. Surgical intervention may be required in the event of an intraabdominal catastrophe. Pseudomembranous enterocolitis that is caused by *Clostridium difficile* may occur as a complication of antibiotic therapy, and stool should be assayed for the *C. difficile* toxin ([110]). Empiric therapy for *C. difficile* enterocolitis should be instituted, despite a negative stool evaluation, if suspicion remains high, and other causes of diarrhea have been excluded. Focal hepatosplenic candidiasis has been reported to occur in patients who are recovering from myelosuppressive therapy ([111]). The characteristic presentation is one of fever that recrudescences as the neutrophil count recovers, nonspecific GI symptoms (such as diarrhea), an elevated alkaline phosphatase level, and hepatomegaly. Bull's-eye hepatosplenic lesions are the classic finding on imaging studies. Treatment is difficult, and eradication of candidal microabscesses requires prolonged, high-dose antifungal therapy. Hepatosplenic lesions may become transiently undetectable on CT scans during recurrent periods of chemotherapy-induced neutropenia. This has been accomplished with amphotericin B (with a total dose of 2 to 9 g). Lipid formulations of amphotericin B may permit treatment with reduced toxicity. Responses to fluconazole therapy have been reported after failure of amphotericin B therapy, thus suggesting a synergism between the two drugs ([112] , [113]). Amphotericin B remains the drug of choice for this condition, however. Other fungi (*Aspergillus*, *Fusarium*, and *Trichosporon*) may rarely cause a syndrome that is similar to hepatosplenic candidiasis.

FEVER AND ALTERED MENTAL STATUS Meningeal infections and cerebral abscesses present with fever, headache, or subtle behavioral changes, or a combination of these. Occasionally, seizures may be the first manifestation of a life- threatening infection of the central nervous system (CNS). Cerebrospinal fluid analysis may not be feasible if there is a bleeding propensity, and empirical therapy is based on the nature and duration of the immune dysfunction. Although immunosuppressed patients may develop conventional forms of meningitis, it is uncommon in the neutropenic setting, and more than 90% of cases in nonneutropenic patients are caused by *Cryptococcus neoformans* and *Listeria monocytogenes* ([106]). CNS infection by *Toxoplasma gondii* or *Aspergillus* may occur in patients who are heavily immunosuppressed for GVHD after hematopoietic SCT (Fig. 75.5). Rarely, viral pathogens have been reported to cause chronic meningoencephalitis (echovirus, coxsackievirus) ([1]). The prognosis of *Aspergillus* infection of the CNS in neutropenic patients is dismal; early detection, rapid institution of high-dose amphotericin B therapy with or without 5-FC, and reversal of immunosuppression are key to optimizing the chances of recovery.

INFECTIONS IN THE STEM CELL TRANSPLANT RECIPIENT

General Principles

Preparative regimens for autologous or allogeneic SCT consist of high-dose chemoradiotherapy, which causes short-term cytopenias as well as profound immunosuppression after engraftment. Reconstitution of cellular and humoral immunity in allogeneic transplant patients occurs gradually over a period of 12 to 24 months and may take much longer in those with chronic GVHD ([114]). GVHD, its prophylaxis and treatment, T-cell depletion of the graft, and CMV infection all contribute to delayed immune recovery in these patients, as compared to autologous transplant recipients ([115]). Evidence suggests that patients who receive autologous peripheral blood stem cell grafts undergo more rapid immune reconstitution than those who receive autologous marrow ([116]). The interplay of these factors results in characteristic periods of risk for infection with specific pathogens that form the basis for antimicrobial prophylaxis during the first year (Fig. 75.6). Before engraftment, the risk of bacterial infection, CVC infection, and reactivation of herpes simplex is highest. Prolonged neutropenia and antibiotic therapy leads to a steady rise in the risk of invasive fungal infection, which decreases after engraftment but remains significant if continued immunosuppression is required for GVHD. Reactivation of latent CMV infection is unusual before day 20 after transplant. Cellular immune dysfunction peaks at approximately day 40 after engraftment and the typical onset of GVHD. Varicella-zoster reactivation peaks at approximately day 120 but may occur any time within the first year. Long-term venous access catheters continue to give rise to infection as long as the access is maintained. Continuation of prophylactic antimicrobials beyond 1 year depends on the individual patient's infection history and the ability to wean immunosuppressive therapy ([147]).

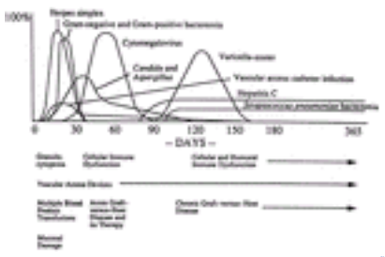

Figure 75.6. Periods of risk for infections after allogeneic transplantation. (From Schimpff SC. Infections in the cancer patient: diagnosis, prevention and treatment. In: Mandell GL, Douglas RG, Bennett JE, eds. Principles and practice of infectious diseases, 4th ed. New York: Churchill Livingstone, 1995:2667–2675, with permission.)

Early and Late Bacterial Infections

The management of bacterial infections in the early neutropenic phase of the transplant is similar to the management of febrile neutropenia in patients who do not undergo transplant. The source of infection is usually the gut and oral flora, although the increasing use of CVCs has increased the risk of gram-positive bacteremias from the skin flora. Streptococcal infections may be seen in patients with severe mucositis, and a comprehensive dental evaluation before transplant may reduce the incidence of such infections. The risk of late bacterial infections (those that occur after engraftment) depends on the immune status of the patient. It is extremely rare to see bacterial infections in patients who undergo autologous SCT after engraftment. On the other hand, patients who undergo allogeneic SCT are at risk for bacterial infections with encapsulated organisms (*S. pneumoniae*, *Haemophilus influenzae*, and *N. meningitidis*) if they develop chronic GVHD or develop profound hypogammaglobulinemia ([117]). Prophylactic fluoroquinolones have been used until marrow engraftment at most transplant centers, but the data are limited to suggest

routine use of these drugs for bacterial prophylaxis. An oral penicillin or trimethoprim-sulfamethoxazole (TMP-SMZ) is recommended until discontinuation of immunosuppressive therapy in allogeneic transplant recipients or until 6 months after transplant.

Cytomegalovirus

CMV infection causes a host of clinical syndromes and has been a major source of morbidity and mortality in stem cell and solid organ transplant recipients (Fig. 75.7). The virus may be acquired by primary infection via transfusion of blood products from a seropositive donor or by reactivation of the latent virus. With the increasing use of leukofiltered blood products, the incidence of primary infection has decreased. *CMV infection* is defined as the reactivation of the virus and the detection of the virus in the blood or other body fluids in the absence of organ-specific abnormalities (pneumonitis, hepatitis, colitis, and retinitis). *CMV disease* is defined as the isolation of the virus from body fluids or tissues in a symptomatic patient or the histopathologic evidence of CMV on tissue biopsy. Recent data also indicate that certain CMV serotypes may be more apt than others to cause myelosuppression ([118]). The incidence of CMV reactivation in allogeneic transplant recipients who are seropositive before transplant is approximately 70%, as compared to 15 to 20% in seronegative recipients with a seropositive donor ([119]). Although approximately 30% of seropositive recipients of autologous bone marrow transplants (ABMTs) also reactivate CMV, CMV disease occurs in fewer than 10%, and serious clinical consequences are rare ([115], [120]). The incidence of CMV disease is higher in patients who receive CD34 selected autografts (120a). CMV IP, the most imminently life-threatening form of CMV disease, occurred in approximately 17% of allogeneic bone marrow transplantation (BMT) patients, with ensuing mortality in 85%, before the use of ganciclovir. Mortality from CMV IP, when it occurs, remains at 30 to 50%, despite the combined use of ganciclovir and CMV-specific immune globulin ([121]). Risk factors for the development of CMV disease include older recipient age, pretransplant seropositivity of the recipient or donor, or both, and severe acute GVHD ([115], [122]). T-cell depletion of the stem cell graft or treatment of the recipient with antithymocyte globulin for GVHD also increases the likelihood of CMV reactivation, probably as a result of delayed reconstitution of CMV-immune T-cell clones ([123]).

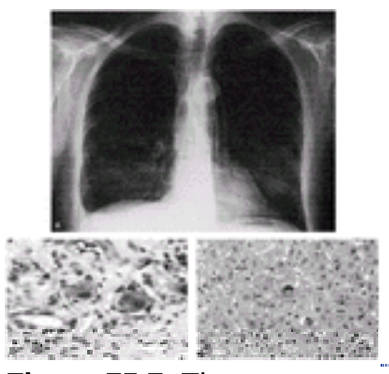

Figure 75.7. The spectrum of cytomegalovirus (CMV) disease in the abnormal human host. **A:** Chest radiograph demonstrating diffuse interstitial infiltrates in a patient 30 days after allogeneic bone marrow transplant. **B:** CMV inclusion disease of the colon. Typical infected cells show cellular ballooning with dense primary nuclear inclusions that are surrounded by a thin, cleared rim; secondary inclusions appear as cytoplasmic granules after the nucleus has filled with virions. **C:** CMV hepatitis demonstrated on liver biopsy. Viral cytopathic effect may be difficult to establish, but rare viral inclusions with surrounding parenchymal changes are diagnostic of CMV. Hematoxylin and eosin stain, ×400. See Color Plate. (Photo-micrographs courtesy of M. Scott.)

The prevention of CMV disease in allogeneic BMT is complex and is evolving. Administration of seronegative or leukofiltered blood products is recommended to all seronegative autologous and allogeneic SCT recipients to prevent primary CMV infection ([124], [125] and [126]). Also, CMV seronegative transplant recipients should use caution and protection during sexual intercourse and in caring for children, as these might be other mechanisms of transmission. In instances of recipient or donor CMV seropositivity, or both, CMV surveillance, starting at the time of engraftment, is recommended. Techniques of CMV surveillance include CMV pp65 antigenemia assay, DNA PCR detection methods or CMV blood cultures (shell vial culture) ([66], [127], [128] and [129]). Detection of CMV in the blood is the strongest predictor of CMV disease ([130]). However, 12 to 20% of patients with negative surveillance cultures still develop CMV disease.

There are two current recommended strategies for prevention of CMV disease. One strategy is prophylaxis with ganciclovir or valacyclovir, starting from engraftment until day 100, or even longer if the patient remains at risk for CMV reactivation (active GVHD, high-dose steroids, low CD4 count) ([115], [131], [132]). The other strategy is close surveillance and preemptive therapy with ganciclovir or foscarnet if ganciclovir is contraindicated when CMV reactivation is detected. In a few randomized and nonrandomized studies, high-dose intravenous acyclovir significantly reduced the incidence of all forms of CMV disease or delayed the onset of CMV infection, but it did not prevent CMV viremia ([133], [134]). Use of high-dose acyclovir has been abandoned by most centers with improved surveillance tools.

In several studies that evaluated preemptive therapy for patients with positive CMV surveillance cultures (blood, urine, throat, or bronchoalveolar lavage fluid), survival at 100 and 180 days was improved in ganciclovir recipients, as compared to placebo recipients, although 12% of patients with negative cultures developed CMV disease ([135]). CMV infection and disease were significantly reduced, if not prevented, by ganciclovir administration to all seropositive patients in three other studies ([136], [137] and [138]). There was no impact on survival because of infectious complications of ganciclovir-related neutropenia, but hematopoietic growth factors were not used. A study by Boeckh et al. also suggested a trade-off: A higher incidence of CMV disease before day 100 was noted in transplant recipients who were treated with ganciclovir only at the time of high-grade antigenemia, but more invasive fungal infections and late-onset CMV disease developed in those who received ganciclovir prophylaxis continuously through day 100 ([129]). Other problems with protracted ganciclovir prophylaxis are the emergence of resistant strains of the virus that were reported in some immunocompromised patients and the failure of natural immunity against CMV to develop, thus resulting in late recrudescences of the disease ([139], [140] and [141]). The selective transfer of CMV-immune donor T lymphocytes into the transplant recipient has been advocated as one solution to this problem ([142]). The optimal duration of preemptive therapy appears to be 1 to 2 weeks of twice-a-day induction followed by maintenance until PCR negativity.

Although ganciclovir is the drug of choice for CMV infection and disease, its major toxicity of cytopenias precludes its use in patients with significant pancytopenia. Foscarnet, an equally effective alternative against CMV can be used to treat ganciclovir-refractory CMV infections or those with significant cytopenias. Although not myelosuppressive, this drug is associated with renal toxicity and electrolyte imbalances ([143], [144]). Cidofovir is another nephrotoxic antiviral with efficacy against CMV, but there are few data on its use in the stem cell transplant patient population ([145]).

Other Viral Pathogens

Testing all transplant recipients for HSV exposure (HSV IgG) is recommended. Reactivation of HSV occurs in as much as 80% of seropositive allogeneic transplant recipients, causing mucocutaneous oral or genital lesions, esophagitis, and, occasionally, pneumonia or encephalitis. Prophylaxis with acyclovir or valacyclovir is recommended to all seropositive patients until the time of engraftment. Although its use is not recommended past 1 month after transplant, some patients with recurrent lesions might benefit from longer use of the prophylaxis ([146], [147]).

Current recommendations are to test every transplant patient for VZV serostatus (IgG). VZV reactivation may occur any time after engraftment in autologous and allogeneic transplant recipients, and the virus disseminates in as much as 30% of cases with ensuing high mortality. Many transplant centers administer oral acyclovir or valacyclovir for approximately 12 months after transplant to VZV-seropositive patients ([147]). Seronegative patients should be given varicella-zoster immune globulin within 96 hours of exposure to a VZV vaccine or on contact with active infection.

Infections with the Epstein-Barr virus (EBV), human herpesvirus 6, adenovirus, JC and BK viruses, RSV, parainfluenza, rotavirus, and other common viruses are also seen occasionally in transplant recipients ([57], [58], [61], [148], [149] and [150]), but effective prophylaxis has not yet been developed. High-risk patients (T-cell–depleted transplant recipients) for EBV may benefit from preemptive therapy if the quantitative PCR is rising, with rituximab (an anti-CD20 antibody) ([151]). Another strategy is prophylactic use of EBV-specific donor T lymphocytes in high-risk patients ([152]).

Fungal Infections

Fungal infections in the transplant patient continue to be a significant cause of mortality. Greater than 90% of the fungal infections in the SCT population are due to

Candida or *Aspergillus*. The etiologic agents in the remaining less than 10% of infections are uncommon fungi, such as *Fusarium, Scedosporium, Blastomyces*, and *Histoplasma.* Prevention of fungal infections in these patients is of utmost importance. One way that this can be achieved is by preventing exposure to invasive fungal species by protective isolation during the periods of neutropenia (i.e., high-efficiency particulate air filtration in patient rooms, avoidance of construction areas, and good hand washing) ([153], [154]). Effective control of GVHD can also reduce the incidence of fungal infections. As for prophylaxis, fluconazole at a dose of 400 mg/day, beginning at the time of transplant and until the time of engraftment, provides adequate protection against invasive yeast infections ([155], [156] and [157]). Failure of fluconazole prophylaxis against *Candida* is usually due to emergence of resistant yeast forms (*C. krusei, C. glabrata*). To date, no antifungal regimen has been shown to be clearly effective as prophylaxis against invasive mold infections in SCT patients. There are several studies that have studied intravenous amphotericin, inhaled ampho-tericin, and itraconazole ([158], [159] and [160]).

Preemptive therapy and empiric therapy for fungal infections are currently being practiced at several institutions. Empiric therapy in febrile neutropenic patients is considered the standard of care, and several studies are under way that are examining the preemptive approach ([161], [162] and [163]). Until recently, amphotericin B was the only broad-spectrum antifungal available for the treatment of invasive molds and resistant invasive yeast infections. The toxicity of intravenous amphotericin B is substantial and has been one of the reasons why its use has been abandoned for prophylaxis. The lipid formulations of the drug (Abelcet, Amphotec, AmBisome) have lesser renal and infusional toxicities. Two new antifungals have been approved by the U.S. Food and Drug Administration (FDA) in the past 2 years, which may change the practice of management of fungal infections in SCT patients. Caspofungin (Cancidis; Merck & Co., Inc., Whitehouse Station, NJ) is the first echinocandin available with a broad spectrum of activity against several species of *Candida* and *Aspergillus* ([164]). The other drug is a tria-zole, Voriconazole (Vfend; Pfizer Inc., New York, NY) with excellent activity against *Aspergillus* and a wide variety of yeasts and molds ([165]).

Protozoal Infections

Although *Pneumocystis carinii* pneumonia (PCP) in this section of protozoal infections, there is now evidence that this organism is not a protozoan but rather resembles the fungi, based on molecular studies, although it lacks ergosterol, the main fungal cell wall component ([106]). Prophylaxis against PCP is recommended in all allogeneic SCT recipients from the time of engraftment until 6 months after transplant or even longer if the patient is on high doses of immunosuppressive drugs for chronic GVHD. Oral TMP-SMZ is the preferred drug of choice, but aerosolized pentamidine, dapsone, dapsone in combination with trimethoprim or pyrimethamine, pyrimethamine and sulfadoxine, and atovaquone can be used as alternatives ([157], [166], [167], [168] and [169]). Patients who are prescribed dapsone should be tested for glucose-6-phosphate dehydrogenase deficiency before initiation of the drug. Guidelines for PCP prophylaxis in autologous SCT patients is less clear and should be considered in patients who are considered high risk, that is, those who receive fludarabine or cladribine, who have manipulated grafts, or who have had prolonged steroid use before transplant.

Toxoplasmosis reactivation or, less commonly, infection is rare but life threatening in the posttransplant period and usually occurs within the first 6 months (Fig. 75.8). Oral TMP-SMZ is the prophylactic agent of choice, but pyrimethamine-sulfadoxine (Fansidar) prophylaxis can been used ([170], [171]). Duration of prophylaxis is similar to that for PCP. It is worth noting, however, that pyrimethamine does not eradicate the cyst form of *T. gondii.* The organism can be acquired by ingestion of undercooked meat or through contact with cat feces.

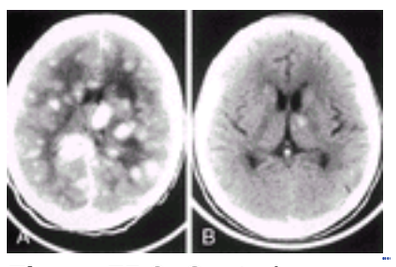

Figure 75.8. Central nervous system toxoplasmosis: magnetic resonance imaging study of the brain before therapy **(A)** and after therapy **(B)** with pyrimethamine and sulfadiazine.

STRATEGIES FOR THE PREVENTION OF INFECTION

The saying, “an ounce of prevention is worth a pound of cure,” holds true in the management of infections in immunocompromised patients.

Reduction of Nosocomial Pathogen Acquisition

- Avoid hospitalization when possible and if appropriate.
- Avoid overcrowding and unnecessary through-traffic on the hematology and transplant wards and intensive care units.
- Enforce strict hand washing among the hospital personnel who care for patients.
- Segregate patients with communicable diseases.
- Consider protective isolation for high-risk patients.
- Ensure proper construction and frequent upkeep of ventilation systems.
- Provide serial monitoring of hospital water supply and cooling and heating systems for microbial contamination.

PREVENTION OF PATHOGEN ACQUISITION The simplest and most effective means of preventing transmission of infection has proven to be meticulous hand washing by physicians, nurses, and others who are in close contact with patients ([172], [173]). A meticulous screening history, review of systems, and physical examination are important to identify any preexisting sites of infection before initiating myelosuppressive therapy. A cooked food diet that excludes fresh fruits and vegetables and nonprocessed dairy products during periods of neutropenia is advocated by some (these foods are often contaminated with gram-negative bacteria and fungal spores), but there is unclear evidence to support this practice. Some institutions practice low-bacteria diets for neutropenic patients, but, again, there is a lack of scientific basis for such food restrictions ([174], [175]). Interventional strategies to prevent acquisition of infectious agents by the immunocompromised host can be classified into two categories: isolation techniques and the use of prophylactic antimicrobial agents.
ISOLATION Reverse isolation has not been shown to significantly reduce the acquisition of nosocomial pathogens beyond what can be accomplished by strict hand washing practices. The value of a total protected environment (TPE) has also been studied extensively in patients undergoing aggressive chemotherapy ([1], [176], [177]). The TPE incorporates laminar airflow rooms that are equipped with high-efficiency particle air (HEPA) filters, aggressive decontamination of all surfaces and objects that enter the room, decontamination of the patient with topical antiseptics and oral nonabsorbable antibiotics (ONAs), and a nearly sterile diet. Enthusiasm for the TPE waned rapidly when it was found that maintaining the sterile environment was cumbersome and costly and that definite improvement in overall remission rates or long-term patient survival could not be demonstrated ([177]). Better management of infection, including the use of CSFs to shorten the duration of neutropenia, has largely supplanted the TPE in the support of neutropenic patients. Laminar airflow rooms and HEPA filtration are still considered important, if not essential, for certain high-risk patients, such as those undergoing BMT, as their use has decreased the incidence of *Aspergillus* infections at some institutions ([178], [179]).

Decreasing Microbial Colonization of the Patient

- Provide prompt treatment of prior active sites of infection.
- Use immunosuppressive drugs judiciously.
- Avoid invasive procedures, except when absolutely necessary, and remove such devices as soon as possible.
- Change intravenous needles and tubing at least daily.
- Monitor serologies and clinical course in patients with known history of tuberculosis or fungal disease, and consider prophylactic isoniazid for those with radiographic or skin test findings that are indicative of old tuberculosis.
- Consider prophylactic antimicrobials in high-risk patients.

ORAL NONABSORBABLE ANTIBIOTICS ONA regimens (such as vancomycin, neomycin, gentamicin, nystatin, and polymyxin B) were used in combination with total reverse isolation for prevention of infections in patients with high infection risk. This combination has been reported to reduce the incidence of infections by almost

75% ([180]). Regimens of nonabsorbable antibiotics are effective in eliminating the vast majority of bacteria from the stool, and, because the GI tract is one of the most common routes of acquisition of infectious organisms, elimination of bacterial from the gut reduces risk of infection. Decreased infectious morbidity and mortality with ONA regimens was reported by several investigators ([181] , [182]), but no consistent overall survival benefit was shown. Major problems with ONA regimens were the trend toward severe infections in patients who abruptly discontinued these antibiotics, their poor palatability, and the development of drug-resistant pathogens ([1]). Use of ONA was abandoned in neutropenic patients when the concept of *colonization resistance* was adapted. Antibiotics, such as TMP-SMZ, suppress the pathogenic bacteria but leave the anaerobic bacteria intact, which in turn prevent colonization by newly acquired organisms ([183]).

SELECTIVE GASTROINTESTINAL DECONTAMINATION AND SYSTEMIC PROPHYLAXIS The selective reduction of enteric aerobes while leaving anaerobic gut flora intact has been called *selective decontamination.* Clinical trials have used combinations of absorbable and nonabsorbable antibiotics ([184] , [185]) or, more commonly, TMP-SMZ alone. In pediatric and adult patients with acute leukemia, TMP-SMZ prophylaxis decreased the frequency of bacteremias and infections ([185] , [186] , [187] and [188]). However, follow-up studies failed to show improvement in remission rates and overall survival, and there was no clear decrease in empiric antibiotic use, the number of febrile episodes, or gram-negative infections. Other disadvantages of the prophylactic use of TMP-SMZ in patients with hematologic malignancies, including prolonged bone marrow suppression, allergic reactions, nephrotoxicity, the emergence of resistant organisms, and an increase in oropharyngeal candidiasis, were noted in some series ([187] , [188] , [189] and [190]).

ANTIBACTERIAL PROPHYLAXIS The key to antimicrobial prophylaxis is to know the spectrum of infection-causing pathogens at the individual clinical center. TMP-SMZ has been used for many years for prophylaxis against bacterial infections. Initial studies using this drug showed its efficacy in preventing PCP ([191]). Later studies demonstrated its benefit in reducing the incidence of bacterial infections in patients with hematologic malignancies ([192] , [193]). Since the advent of fluoroquinolones, TMP-SMZ for antibacterial prophylaxis has fallen out of favor. The fluoroquinolones are broad-spectrum derivatives of nalidixic acid that are orally bioavailable with a broader spectrum of activity, preserve colonization resistance ([1]), and are extremely well tolerated. Quinolone-based prophylaxis has been successful in reducing the risk of aerobic gram-negative infections in neutropenic patients who undergo cytotoxic chemotherapy for acute leukemia and BMT ([194] , [195] , [196] and [197]). However, an increased frequency of breakthrough gram-positive bacteremias, which are caused predominantly by viridans streptococci (*S. mitis, Streptococcus sanguis*) and coagulase-negative staphylococci, was noted by several investigators, particularly with the older quinolones ([198]). The newer fluoroquinolones (ciprofloxacin, levofloxacin) have broader gram-positive activity, and the coadministration of roxithromycin, amoxicillin-clavulanate, vancomycin, or rifampin has been variably effective in preventing infection with a-hemolytic streptococci ([199] , [200]). As with other prophylactic antibiotics, however, emergence of secondary resistance remains a problem with these augmented regimens. Gram-negative bacteremias in patients who receive fluoroquinolone prophylaxis are often caused by resistant *P. aeruginosa*, but infections that are caused by non- *aeruginosa Pseudomonas* species, especially *E. coli*, and *Enterobacter* species, are being increasingly reported ([201] , [202]). Levofloxacin has somewhat greater *in vitro* activity than ciprofloxacin against *S. pneumoniae, Enterococcus*, and *S. aureus* ([203]) but may be inferior to ciprofloxacin against *P. aeruginosa*, although studies are suggestive of equal efficacy against *P. aeruginosa* ([204] , [205]). Studies using prophylaxis with fluoroquinolones alone or in combination with other antibiotics have failed to demonstrate any significant improvement in survival or remission rates but have shown a definite reduction in the incidence of gram-negative infections ([206] , [207] , [208] and [209]). Most prophylactic trials have also failed to show decreased empiric parenteral antibiotic use. In fact, the recently published IDSA guidelines do not recommend routine prophylaxis with antimicrobials in neutropenic patients due to concerns about development of antimicrobial resistance ([30] , [210]).

ANTIFUNGAL PROPHYLAXIS Risk factors for fungal infections in patients with hematologic malignancies include prolonged and profound neutropenia, immunosuppressive therapy, use of broad-spectrum antibiotics, use of parenteral nutrition, and use of indwelling vascular devices. Preventive efforts toward the reduction of fungal infections in this patient population have focused primarily on *Candida* and *Aspergillus* species, as they have traditionally been the most common causes of fungal disease in immunocompromised patients ([211]). Nosocomial aspergillosis had been an uncommon problem at most institutions but may be increasing in frequency because of changes in drug usage patterns; it remains a serious threat to patients who require prolonged immunosuppressive (especially corticosteroid) therapy, such as recipients of bone marrow transplants (Fig. 75.5). Hospital outbreaks of *Aspergillus* are more likely to occur during periods of construction or renovation. HEPA filtration, regular maintenance of ventilation systems, and floor-to-ceiling barriers around construction sites are important measures in reducing the risk of invasive aspergillosis. When possible, patients should be counseled to avoid dust or soil exposure when traveling to areas that are endemic for organisms such as *Blastomyces dermatitidis, Coccidioides immitis*, and *Histoplasma capsulatum*, but most other pathogens, such as *Aspergillus* species, *C. neoformans*, and the Mucorales order (Phycomycetes class), are ubiquitous in the environment. Before the development of the imidazole class of drugs, few effective antifungal agents other than amphotericin B were available. Randomized trials using oral polyenes (nystatin and oral amphotericin B) have failed to demonstrate a reduced incidence of systemic fungal infections, primarily because they are poorly tolerated at effective doses and are not orally bioavailable ([1] , [212]). Nystatin and clotrimazole prevent oropharyngeal candidiasis, but it is not well tolerated in patients with severe mucositis. Miconazole and ketoconazole are seldom clinically useful because of their toxicity profiles and erratic absorption. Inhaled amphotericin B has shown promise in preventing colonization and infection with *Aspergillus* in uncontrolled trials but may be poorly tolerated in some patients with cancer ([213] , [214]). Low-dosage prophylactic intravenous amphotericin B (0.15 to 0.25 mg/kg/day) has been demonstrated in one historically controlled study to significantly reduce mortality from invasive *Aspergillus* in allogeneic transplant recipients and may be indicated in patients who have a history of fungal infection ([158]). The newer lipid formulations of amphotericin B are less nephrotoxic and have been therapeutically effective in some cases of amphotericin B–resistant *Aspergillus* ([215] , [216]). Fluconazole prophylaxis at a dosage of 400 mg/day in several randomized trials in patients with leukemia and patients who were undergoing allogeneic SCT reduced the incidence of superficial and invasive candidal infections, except those caused by *C. krusei* ([155] , [217]). There was no difference in the incidence of infections with *Aspergillus* in these studies, because fluconazole is ineffective against the molds. Low-dosage fluconazole is also effective, but studies in the acquired immunodeficiency syndrome population indicate increased risk of fluconazole resistance at lower dosages of 50 to 100 mg/day ([218]). Itraconazole has also been evaluated, but its efficacy in preventing colonization or invasive infection with *Aspergillus* has been shown in small studies ([219]). It has known activity against *Aspergillus* and has been effective in treating *Aspergillus* infections in patients who have failed with or are intolerant to amphotericin B ([220] , [221]). It is available in parenteral and oral forms. It is recommended that the parenteral form should not be administered for more than 14 days owing to toxicity. The oral form is available as liquid and capsules. The capsules are poorly absorbed in the presence of chemotherapy-induced mucositis and gastric achlorhydria, but the absorption of the liquid formulation appears to be better. Histamine blockers and proton pump inhibitors, such as omeprazole, should be avoided, and serum itraconazole levels must be monitored during therapy to ensure bioavailability. Several newly developed antifungal agents with *in vitro* activity against *Aspergillus* are in clinical trials for prevention and treatment of fungal infections. These include the new class of drugs that are called *echinocandins*, with caspofungin being the only approved agent at this time. The other echinocandins that are being tested are micafungin and anidulafungin. The newer triazoles with activity against *Aspergillus* include voriconazole, posaconazole, and ravuconazole; of these drugs, only voriconazole is FDA approved ([222] , [223]).

ANTIVIRAL PROPHYLAXIS Acquisition of opportunistic viral disease may occur by primary infection or by reactivation of latent infection. Herpesviruses, including CMV, VZV, and HSV-1 and -2, are by far the most common infection-causing viruses. Administration of oral or intravenous acyclovir prevents HSV reactivation (gingivo-stomatitis, esophagitis) in patients who are receiving intensive chemotherapy for acute leukemia or BMT ([224] , [225]). Prophylaxis of HSV in these patients is prudent, because morbidity from infection is high, toxicity from acyclovir is low, and the development of resistance is unlikely ([226]). There is evidence of development of acyclovir resistance in HIV and transplant patients. Treatment with foscarnet or cidofovir is recommended for resistant infections. Foscarnet-resistant HSV strains have been recently reported in allogeneic stem cell transplant patients; such patients have been treated with cidofovir ([227]). The incidence of acyclovir-resistant HSV has remained stable between 4 to 7% over the past few decades. Data to support the prophylaxis of VZV are limited, as the natural history of varicella-zoster infections in patients who are treated with conventional chemotherapy is poorly defined. Newer nucleoside analogs (such as BV-ara U, Brovavir) and acyclovir-related prodrugs (valacyclovir, famciclovir) are as effective as acyclovir for HSV and VZV prophylaxis ([228] , [229] , [230] and [231]). Avoidance of close contact with infected or exposed individuals, especially small children in daycare, is advisable for severely immunocompromised seronegative patients.

Augmentation of Host Defenses

Despite several advances in antimicrobial prophylaxis, efforts to prevent infections in immunocompromised patients with cancer have been disappointing. One of the possible ways to reduce infection risk may be to bolster the immune status of the host. There are several ways of boosting the immune status of the host and a few such strategies are outlined in this section.

ACTIVE IMMUNIZATION Patients with hematologic neoplasms often manifest impaired T-cell, granulocyte, and reticuloendothelial cell function and defective antibody responses that put them at increased risk of infection with polysaccharide-encapsulated bacteria, viruses, and fungi. This susceptibility may persist for several months after antineoplastic therapy has been completed, because preexisting protective antibody titers often decline below protective levels after therapy ([232]). Patients with Hodgkin disease, depending on the nature of prior therapy and spleen status, may have a greatly increased susceptibility to infections that are caused by encapsulated bacteria ([233] , [234] and [235]). Immunization as a means of preventing infectious morbidity has been best studied in children with acute lymphocytic leukemia (ALL) or solid tumors, patients with Hodgkin disease with or without splenectomy, and marrow transplant recipients. Although the optimal timing of immunizations in these patients and specific recommendations for each type of cancer are still unclear, general guidelines have been established (Table 75.7) ([236] , [237]).

TABLE 75.7. Recommendations for Active Immunization of Adults with Malignancies

Vaccine	Persons Who Should Receive Vaccine	Timing with Relation to Chemotherapy	Regimen [a]
Haemophilus influenzae type b	Lymphoma patients	Before staging splenectomy, >10 d before initiation of chemotherapy, or 3 mo after completion of chemotherapy.	Single dose
Hepatitis B [b]	Cancer patients with hepatitis B surface antigen (+) household contacts	Not during immunosuppressive therapy.	3 doses: second dose 1–2 mo after the first, third dose 4–6 mo after the first
Influenza	All cancer patients	>2 wk before initiation or between cycles of intermittent chemotherapy.	Annually each fall/winter
Measles, mumps, rubella	Nonimmune leukemic patients in remission and household contacts of all immunosuppressed individuals	For leukemic patients in remission, >3 mo after completion of therapy otherwise contraindicated in patients with leukemia, lymphoma, or those undergoing immunosuppressive therapy.	Once
Meningococcal (*Neisseria meningitides*)	Lymphoma patients	Before staging splenectomy.	2 doses; second dose 3–5 yr after the first
Poliomyelitis (inactived poliovirus vaccine only) [c]	Adults at increased risk of infection; all susceptible household contacts of cancer patients	No data available; recommend each dose >10 d before initiating chemotherapy.	3 doses; second dose 4–8 wk after the first, third dose 6–12 mo after the second
23-Valent polysaccharide pneumococcal (*Streptococcus pneumoniae*)	Any nonimmune cancer patient, especially lymphoma and multiple myeloma patients	Before staging splenectomy, >10 d before initiation of chemotherapy, or 3 mo after completion of chemotherapy.	2 doses; second dose at least 5 yr after the first
Tetanus and diphtheria toxoids combined	All cancer patients	No data available; recommend administration >10 d before initiating chemotherapy.	Primary 3-dose series if not previously immunized; second dose 4–8 wk after the first, third dose 6–12 mo after the second; booster doses at 10-yr intervals throughout life or with dirty wound if >5 yr since last dose.
Varicella	Nonimmune household contacts of cancer patients	Not applicable—contraindicated in patients with leukemia, lymphoma, or those undergoing immunosuppressive therapy.	For persons >13 yr of age, 2 doses separated by 4–8 wk.

[a] Adapted from the Centers for Disease Control and Prevention.

[b] May be used in conjunction with hepatitis B immunoglobulin prophylaxis.

[c] Live oral polio vaccine is no longer available for general use in the United States and is contraindicated in immunosuppressed persons or their household contacts.

The risk of *Haemophilus influenzae* type B (Hib) infection is probably highest in asplenic patients. Owing to the current Centers for Disease Control and Prevention (CDC) recommendations that require all infants to be vaccinated for Hib, almost all adults have adequate immunity against this organism. Siber et al. (238) reported immune response to Hib vaccine in patients with Hodgkin disease who were undergoing chemotherapy. The study showed that patients who received antineoplastic therapy had significantly greater decrease in Hib titer at a 6- to 12-month period after the primary vaccination (given before starting chemotherapy) as compared to normal controls (239). Most children who receive maintenance chemotherapy for leukemia or lymphoma are able to generate protective antibody responses to a single dose of conjugate polysaccharide Hib vaccine, although responses are less than those that are seen in healthy children (240 , 241). Recommendations for children are therefore to continue the primary series of Hib-conjugate vaccinations during chemotherapy treatment and to administer a booster immunization 1 year after completion of chemotherapy (236). As for adults with cancer, it is recommended that a dose of Hib vaccine be given before initiation of chemotherapy or before splenectomy, if one is planned. The need for a booster in adults is yet to be determined, and further studies are warranted. The Advisory Committee on Immunization Practices of the CDC recommends that the 23-valent polysaccharide pneumococcal vaccine be given to all severely immunocompromised children and adults (i.e., patients with lymphoma, leukemia, multiple myeloma, aplastic anemia, or disseminated malignancy and patients who are being treated with cytotoxic chemotherapy, high-dose steroids, or radiation) (237). Complete protection might not be achieved if the vaccine is given within 3 years after antineoplastic therapy, although some immunity is seen (242 , 243 and 244). A newer, more immunogenic pneumococcal-conjugate vaccine is likely to have superior efficacy but remains investigational at this time (245). Attempts to develop an antipseudomonal vaccine are also under way (246). Immunization for *N. meningitidis* by using a polysaccharide vaccine is recommended in some cancer patients before splenectomy, as splenectomized patients are at increased risk of infection, which can result in significant morbidity (247). This vaccine offers no protection from serogroup B (which is responsible for one-third of the cases). Children who undergo chemotherapy and who have not completed all of the diphtheria-tetanus (DT) (or diphtheria, pertussis, and tetanus; pertussis is included if the child is less than 7 years of age) and polio immunization series should complete the boosters as scheduled, although aggressive and prolonged chemotherapy may blunt the response. Only the inactivated polio vaccine (IPV) should be given to immunocompromised patients because of the risk of acquiring polio from the live-attenuated oral polio vaccine. Booster doses of DT or diphtheria, pertussis, and tetanus and the IPV should then be administered 1 year after chemotherapy completion. There are some data that suggest that patients with lymphoid malignancies are more likely to loose their immunity to DT after chemotherapy, as compared to patients with myeloid disorders (248). The current recommendations for adult patients with cancer is to administer DT immunization boosters in the same dose and schedule as for healthy individuals, as most immunocompromised patients have some response to this vaccine (236). The influenza vaccine is generally recommended in immunocompromised patients on a yearly basis. There are several studies that have evaluated the efficacy of this vaccine in cancer patients; there is definite efficacy of this vaccine in patients with solid tumors, and the response is somewhat blunted in the patients with hematologic malignancies (249). Despite a lack of a clear-cut benefit in immunocompromised patients, the likelihood of some protection against the infection has urged physicians to vaccinate all cancer patients with the influenza vaccine. The live-attenuated measles, mumps, and rubella (MMR) vaccine may be considered in previously unimmunized children with leukemia who are in remission, who have been off chemotherapy, and who will not receive chemotherapy for at least 3 months; it is otherwise contraindicated in immunocompromised individuals (236 , 237). The recently developed live-attenuated varicella vaccine has been used safely in children with ALL and has had approximately 90% efficacy in leukemic children in the Japanese experience (250). It is not recommended for use in immunocompromised patients, except in seronegative children with HIV (251 , 252 and 253). The response of asplenic patients to polysaccharide vaccines is controversial. Most healthy asplenic adults have antibody responses to polysaccharides that are normal or close to normal; splenectomized children also respond (254 , 255). Patients should be immunized before planned splenectomy, when possible, but postsplenectomy immunization is still effective in otherwise healthy patients. The situation in patients with lymphoproliferative disorders, such as CLL, is less clear; studies in small numbers of patients with CLL show poor antibody responses to polysaccharide vaccines that are given before splenectomy (256). Immune-reconstitution after bone marrow and peripheral blood SCT is dependent on several factors: type of transplant, graft manipulation, intensity of the conditioning regimen, the severity of GVHD, donor immune status, graft function, and ongoing immunosuppressive therapy. Recently, the CDC and the European Group for Bone Marrow Transplantation issued specific immunization recommendations for patients undergoing SCT (257 , 258). Patients who undergo autologous transplants recover their immunity faster than patients who undergo allogeneic transplants; in the allogeneic setting, mismatched and haploidentical transplant recipients have extreme delays in immune recovery. Graft manipulation techniques, such as T-cell depletion and CD34 selection, result in impaired immune recovery, as does the presence of chronic GVHD (259). Protective antibodies to the common childhood diseases (polio, tetanus, diphtheria, mumps, measles) wane after ablative therapy and autologous or allogeneic transplantation, thus necessitating revaccination. Increased susceptibility to polysaccharide-encapsulated organisms (pneumococcus, meningococci, *H. influenzae*) also results from a combination of splenic hypofunction, loss of protective antibody, and defective B- and T-cell responses after transplant. All BMT patients should be vaccinated with combined tetanus-diphtheria toxoids at 12, 14, and 24 months after transplant (260 , 261 , 262 and 263). Vaccinating adults against pertussis is not recommended, as it is an unusual infection in adults. Antibody levels against *H. influenzae* gradually decline after transplant, and revaccination by using the Hib conjugate vaccine is recommended at 12, 14, and 24 months after transplant to regain immunity. The oral polio vaccine is contraindicated in all immunocompromised individuals. IPV and hepatitis B vaccines are recommended at 12, 14, and 24 months after transplant owing to the loss of immunity against the virus by 1 year after transplant in the majority of transplant recipients (264 , 265). Routine vaccination against *Meningococci*, rabies, and hepatitis A is not recommended. Annual seasonal administration of influenza vaccine is recommended, starting 6 months after transplant (266). The MMR vaccine, a live-attenuated vaccine, may be given approximately 2 years after

transplant to BMT patients and may be administered to household contacts before then. Patients with GVHD who are continuing to receive immunosuppressive therapy should not be given the MMR vaccine ([267]). The CDC recommends the use of the 23-valent polysaccharide pneumococcal vaccine at 12 and 24 months after transplant. The varicella vaccine, another live-attenuated vaccine, is contraindicated in all transplant recipients. Use of the bacille Calmette-Guérin vaccine is contraindicated before 2 years posttransplant. There is evidence that donor immunization with conjugate vaccines before bone marrow harvest significantly enhances antibody responses to vaccination in the recipient after transplant ([268]). This is true for Hib immunity. Transfer of antigen-specific B cells and memory B and T cells from the donor is believed to confer this booster effect. A similar benefit is not seen after donor immunization with the unconjugated pneumococcal vaccine, but different results may be obtained with the investigational conjugated vaccine that is currently in trials. A significant, but smaller, benefit is noted in autologous BMT patients to whom the Hib-conjugate vaccine was given before bone marrow harvest ([269]). Pretransplant donor immunization against CMV and VZV or adoptive transfer of immune cells from the donor to the recipient may be effective in preventing viral disease in allogeneic transplant recipients in the future ([142] , [270] , [271]). Immunocompromised patients should be discouraged from traveling to areas that are endemic for typhoid, cholera, or yellow fever. The currently available live-attenuated vaccines for typhoid and yellow fever are contraindicated, and the inactivated typhoid vaccine has unknown efficacy in these patients ([257] , [258] , [272]). The newer oral recombinant cholera vaccine is potentially useful for immunocompromised patients ([273]). Patients must be particularly careful to avoid local water exposure and insect bites, particularly mosquitoes, in areas that are endemic for malaria. Asplenic patients are also at risk for babesiosis and should avoid tick exposure when traveling to the New England states ([274]).

PASSIVE IMMUNIZATION IVIG therapy for prevention of infection has been evaluated primarily in patients with lymphoproliferative disorders and multiple myeloma and stem cell transplant recipients. Currently available IVIG preparations are safe and well tolerated and consist primarily of IgG, although small amounts of IgA and IgM are present. They differ with respect to the various IgG subclasses and titers to several infectious organisms ([275]). IgA-poor preparations must be used in patients with known or suspected congenital IgA deficiency or those with high anti-IgA titers to prevent anaphylaxis. Polyvalent IgM-enriched preparations have been available for some time, but a role for them has not been defined. IVIG (400 mg/kg given every 3 weeks) has been shown in a double-blinded, randomized trial to reduce the frequency of moderately severe bacterial infections in patients with CLL and Ig levels that are less than 50% of normal or with a history of recurrent infections ([276] , [277]). However, a cost-benefit analysis in the same multicenter trial failed to prove that such therapy was cost-effective, as it neither prolonged survival nor demonstrably improved the quality of life of patients with CLL ([278] , [279]). Several subsequent studies have confirmed the benefit of IVIG infusions in reducing infection rates in hypogammaglobulinemic patients with CLL who have had recurrent infections ([280] and [281]). Reduction in the number of symptomatic and life-threatening infections has also been reported in patients with multiple myeloma who are given monthly infusions of IVIG, despite accelerated Ig metabolism in these patients ([282] , [283] , [284] and [285]). The optimal dosage and schedule of administration of IVIG and the patient subgroups that are most apt to benefit from such prophylaxis are less clearly defined. Several small studies in allogeneic bone marrow transplant patients have reported fewer episodes of gram-negative septicemia or local infections in those receiving weekly IVIG followed by monthly IVIG to day 360 ([286] , [287]). A metaanalysis of all these studies that was published in 1993 showed that transplant recipients who received IVIG had fewer episodes of CMV pneumonia, fatal CMV infections, non-CMV interstitial pneumonia and reduced transplant-related mortality ([288]). A randomized multicenter trial, which compared different doses of IVIG (100 mg/kg, 250 mg/kg, and 500 mg/kg) that were given weekly until day 90 or later and then monthly until 1 year, failed to show any difference in the infection rates in the three groups ([289]). Owing to the high costs of IVIG and the availability of better antimicrobials, use of IVIG should be considered in selected patients who undergo allogeneic transplants. Autologous transplant recipients do not appear to benefit from prophylactic globulin therapy, and at least one study has linked its use in these patients to a higher incidence of fatal hepatic venoocclusive disease (VOD) ([290] , [291]). Although IVIG and CMV hyperimmune globulin confer some passive immunity against CMV infection, CMV disease, or IP, other, more cost-effective methods of CMV prophylaxis, such as leukofiltration of blood products and avoidance of granulocyte transfusions, may be more cost-effective ([292] , [293]). The best-established indication for prophylactic IVIG in allogeneic transplantation is prevention of acute GVHD (grades II through IV) ([294] , [295] and [296]). Passive immunization with varicella-zoster immune globulin, if it can be given within 72 to 96 hours of the exposure, is indicated in seronegative patients who are immunosuppressed ([297]). Patients who are exposed to measles, mumps, or rubella may benefit from passive Ig prophylaxis if it is given within 6 days of exposure ([298]). Intramuscular Ig is recommended for patients who travel to areas that are endemic for hepatitis A or for postexposure prophylaxis ([299]). Two doses of hepatitis B Ig, given 1 month apart, are recommended for postexposure prophylaxis. Other biologic agents that have been studied include polyclonal and monoclonal antibodies, cytokines, growth factors, interferons, interleukins (ILs), and interleukin-receptor or tumor necrosis factor (TNF)-a antagonists ([300]). Polyclonal antibodies against the core glycolipid of the family Enterobacteriaceae (J5 antiserum), although shown to reduce mortality in some patients with sepsis syndrome caused by gram-negative infection, have not been observed to benefit neutropenic patients ([301]). Similarly, human monoclonal antiendotoxin (HA-IA) antibodies have not proven beneficial in neutropenic patients with or without gram-negative infection and may cause serious toxicity ([302]). The role of interferon-? in combination with cytokines, such as macrophage CSF, and traditional modalities in bolstering host defenses against certain types of infections (especially fungal) appears promising ([303]). Despite promising initial results in animal models of sepsis by using anti-TNF-a and anti–IL-1 receptor, clinical trials have not demonstrated any benefit ([304]).

PREVENTION AND TREATMENT OF CHEMOTHERAPY-RELATED CYTOPENIAS

Use of Hematopoietic Growth Factors

The most common dose-limiting toxicity of several systemic chemotherapeutic regimens remains myelosuppression. Myelosuppression has long been a major obstacle to the delivery of effective doses of chemotherapy. Since the 1980s, tremendous progress in the understanding of hematopoiesis and its regulation has led to the identification, cloning, and large-scale production of numerous cytokines, several with clinical applications. Several distinct growth-stimulating and inhibitory cytokines (individually known as *growth* or *CSFs*, *ILs*, or *interferons*) are known, each of which acts through a specific cell-surface receptor ([305]). A wide array of early- and late-acting CSFs and ILs regulate the differentiation of pluripotent stem cells into committed progenitors and their subsequent lineage-specific growth and differentiation ([306] , [307]). In the past decade, several recombinant hematopoietic growth factors have been approved for clinical use ([308] , [309] , [310] and [311]). These are G-CSF [filgrastim (Neupogen)], GM-CSF [sargramostim (Leukine)], erythropoietin (EPO) (Procrit), IL-11 [oprelvekin (Neumega)], pegylated G-CSF [pegfilgrastim (Neulasta)], and darbepoetin alfa (Aranesp). The approved clinical indications for their use include shortening the duration of cytopenias that result from standard or high-dose chemoradiotherapy, treating congenital or acquired bone marrow failure states, mobilizing peripheral blood progenitor cells (PBPCs), treating the anemia of chronic disease, and facilitating autologous blood donation (Table 75.8).

TABLE 75.8. Potential Uses of Hematopoietic Growth Factors in Supportive Care

Clinical Indication for Hematopoietic Growth Factor	Evidence of Benefit	Evidence of Harm	Cost-Effectiveness
Supporting dose intensity in standard dose regimens for solid tumors	Limited	No	Unknown
Primary prevention of febrile neutropenia in solid tumors	Yes	No	Yes, if risk of febrile neutropenia is high (=40%)
Secondary prevention of febrile neutropenia in solid tumors	Limited	No	Unknown
Treatment of established febrile neutropenia in solid tumors	Limited	No	No
Mobilization of progenitor cells	Yes	No	Yes
Postrescue in high-dose therapy: bone marrow or peripheral blood stem cell transplantation	Yes	No	Likely
Cell cycling in leukemias	No	Unclear	Unknown
Promotion of myeloid recovery in acute leukemia	Yes	Unclear	Unknown

Anemia

Anemia is a frequent hematologic manifestation in patients with cancer that is due to the underlying malignancy or as a result of its treatment. Anemia in turn manifests as fatigue in such patients, causing worsening in quality of life as well as other physiologic impairments owing to reduced oxygen carrying capacity. Until the advent of erythropoietic agent, epoetin alfa, blood transfusions and iron replacement were the primary treatments for symptomatic anemia. Epoetin alfa (Epogen,

Procrit) is a glycoprotein hormone with multilineage activity that promotes the survival and proliferation of committed erythroid progenitors and their terminal differentiation into mature red blood cells ([312]). Recombinant human EPO is effective in the treatment of anemia that is caused by hematologic malignancy or chemotherapy, although the origin of the anemia in most such patients is multifactorial ([313] , [314] , [315] and [316]). Recently published evidence-based clinical practice guidelines by ASCO and American Society of Hematology help clear some of the uncertainty regarding dosing and patient selection ([317]). In several randomized, double-blind, placebo-controlled trials, EPO increased the mean weekly hematocrit in cancer patients, irrespective of their chemotherapy status ([316] , [318]). The current guidelines recommend the use of EPO in all patients with chemotherapy-associated anemia with a hemoglobin level of less than 10 g/dl. There is less clear evidence to support its use in patients with hemoglobin greater than 10 g/dl but less than 12 g/dl, and use should be based on clinical situation. The current recommended dosage of EPO is 150 U/kg three times a week or 40,000 U once a week, with the later dosing regimen being based on common clinical practice ([319]). In the absence of a response despite dose escalation at 6 to 8 weeks after therapy, use of EPO should be discontinued. In the absence of response, iron deficiency should be ruled out. More recent data suggest that the use of EPO significantly decreases overall transfusion requirements and delays the onset of anemia in patients with cancer who are undergoing chemotherapy ([320]). Significant improvement in quality of life has also been reported by responding patients ([320] , [321]). The administration of EPO after ABMT has been evaluated in randomized prospective trials, but no trial to date has shown reduced time to transfusion independence or a decreased total red blood cell transfusion requirement between patients with ABMT who receive EPO and those who receive placebo ([322] , [323] and [324]). In contrast, erythroid reconstitution is accelerated by the use of EPO in allogeneic transplant recipients ([325] , [326]). Median time to red blood cell transfusion independence was reduced by 8 days in allogeneic transplant recipients who were randomized to receive EPO after transplant at 150 U/kg/day versus placebo in a study by Lin et al. ([327]). The use of EPO to boost the hematocrit before or during courses of chemotherapy has been helpful in managing patients whose religious or other beliefs preclude the transfusion of blood products ([327] , [328]).

Although EPO levels are generally increased in MDS, the degree of increase may not be proportionate to the degree of anemia ([329]). Erythroid responses to EPO alone, which are defined as a greater than 50% decrease in transfusion requirement or a greater than 1 g/dl rise in hemoglobin, are seen in only 10 to 28% of patients with MDS, even when EPO is used at doses that are considerably higher than those used in chronic renal failure (100 to 200 U/kg three times per week, with dose escalation as needed to achieve response) ([330] , [331]). Baseline EPO levels do not appear to predict response to EPO alone ([332]). High-dosage EPO alone (more than 1000 U/kg/week) or dosages exceeding 150 U/kg daily in combination with a myeloid growth factor, such as G-CSF, result in durable responses in 35% and 48% of patients, respectively ([330] , [331] and [332]). In the study by Negrin et al. ([330]), a response to combined therapy was significantly more likely in patients with EPO levels less than 500 U/L and in those with higher basal reticulocyte counts and normal cytogenetics. Approximately 50% of responders require G-CSF and EPO to maintain the erythroid response, suggesting an *in vivo* synergy between these cytokines in myelodysplastic erythropoiesis. There is no demonstrable effect by EPO on granulocyte counts or platelet production. A trend toward greater responses to EPO in low-risk MDS subtypes (refractory anemia and refractory anemia with ringed sideroblasts) has been noted by some investigators ([333]). Cost constraints preclude the routine use of EPO or combination EPO–G-CSF therapy in support of MDS patients.

Darbepoetin alfa, a newer erythropoietic molecule, stimulates erythropoiesis by the same mechanism as EPO. The biochemical structure of darbepoetin alfa differs from that of EPO (darbepoetin alfa contains two additional *N*-linked carbohydrate chains, conferring more sialic acid, which prolongs its serum half life). Darbepoetin alfa, at a dosage of 3 µg/kg subcutaneously every 2 weeks, when compared to a placebo in a randomized clinical trial, was statistically more effective in reducing the number of blood transfusions as well as increasing the total hemoglobin. There was also improvement in quality of life in patients who received darbepoetin alfa ([334] , [335]).

Myelosuppression and Colony-Stimulating Factors

Neutropenia continues to be the most significant dose-limiting toxicity of systemic chemotherapy. Discovery of the recombinant human growth factors has been revolutionary in the management of chemotherapy-induced neutropenia. Recombinant human G-CSF is a nonglycosylated protein that is derived from *E. coli* and regulates neutrophil production and function. In contrast, glycosylated (Chinese hamster ovary or yeast-derived) and nonglycosylated (*E. coli*–derived) forms of recombinant GM-CSF are available. In conjunction with other cytokines, such as G-CSF and EPO, GM-CSF stimulates the production, growth, and activity of several hematopoietic cell lineages. It acts on granulocyte-macrophage colony-forming unit and on colonies that are made up of committed granulocytic, erythroid, and monomegakaryocytic progenitors and enhances various aspects of phagocyte and cytotoxic cell function ([308]).

Several large randomized clinical trials have shown that the prophylactic administration of G-CSF or GM-CSF after conventional-dose chemotherapy reduces the incidence of febrile neutropenia by 50% in patients with a 40% or greater incidence of febrile neutropenia than the control group ([307] , [308] , [336]). No trials have demonstrated any significant impact of growth factors on infectious mortality, response rates, or overall survival ([104]). Economic analyses suggest that prophylactic cytokines are cost-effective only in chemotherapy regimens that are associated with a greater than 40% incidence of febrile neutropenia or when febrile neutropenia has occurred with previous cycles of chemotherapy ([104]). Comprehensive, evidence-based practice guidelines that are set forth by the ASCO ([104]). The use of myeloid growth factors in addition to antibiotics to treat episodes of febrile neutropenia is less well substantiated in the literature and is not recommended by the ASCO guidelines unless certain clinical features are present. Febrile neutropenic patients who are at risk for clinical deterioration and who should receive growth factors include those with fungal infections, pneumonia, cardiovascular compromise, or multiorgan dysfunction. Collective results of eight randomized trials indicate a lack of evidence to support the use of growth factors in febrile neutropenic patients with none of the previously stated risk factors ([104] , [337] , [338]). The ASCO guidelines do not recommend that hematopoietic cytokines be used in patients who become neutropenic but remain afebrile after chemotherapy, and this has been substantiated by a more recently published study ([339]). Use of growth factors is currently recommended in patients older than 50 years of age with acute myeloid leukemias who are receiving induction chemotherapy. There are randomized clinical trials that show the safety and benefit of use of CSFs in this setting when started a few days after completion of the chemotherapy ([104] , [340] , [341] and [342]). Current ASCO guidelines recommend the use of CSFs to reduce the duration of neutropenia in patients with ALLs who are receiving chemotherapy ([343] , [344] and [345]). Few studies that directly compare G-CSF and GM-CSF have been performed ([346] , [347]), but the limited data suggest that these growth factors have equal efficacy in chemotherapy-induced neutropenia at currently recommended doses (5 µg/kg/day or 250 µg/m ^{2}/day, respectively). GM-CSF and G-CSF have been evaluated (GM-CSF more extensively) in the setting of high-dose therapy and hematopoietic SCT. Significant reductions in hospitalization and neutrophil engraftment times and in the incidence of infection have been demonstrated in autologous, as well as allogeneic, transplant recipients. There appears to be no increase in the incidence of graft rejection or acute GVHD in allogeneic transplant recipients who receive G-CSF or GM-CSF ([348] , [349] , [350] , [351] and [352]). An overall reduction in the cost of transplantation has also been demonstrated ([353]).

The administration of G-CSF or GM-CSF to patients with MDS and neutropenia results in significantly increased neutrophil counts in most patients ([354]). Some patients have also shown improvements in platelet count and hematocrit in trials of GM-CSF or maintenance therapy with G-CSF, but these effects are unpredictable ([331] , [355]). As in the case of EPO, response to myeloid growth factors persists only as long as therapy is maintained ([356]). Dosage-ranging studies for GM-CSF suggest that an initial dosage of 10 to 40 µg/m ^{2} daily is reasonable, and responses to G-CSF have been noted at dosages of 0.1 to 3.0 µg/kg daily. Limited evidence from follow-up cytogenetic studies suggests the possibility that the granulocyte response is caused by the activity of the abnormal clone rather than by normal granulopoiesis ([331]). Even though there is a theoretical likelihood of transformation of MDS to leukemia with the use of CSFs, randomized trials have shown that the incidence of transformation in patients with MDS who received G-CSF was no greater than that of untreated controls ([356]). A phase III trial that compared G-CSF versus observation in neutropenic MDS patients showed a benefit toward the use of G-CSF with clinical improvement in infections ([355]). The current ASCO guidelines do not support the continuous use of CSFs in patients with MDS, but a subset of patients with neutropenia and infections does benefit from intermittent use of CSFs.

The use of G-CSF and GM-CSF has permitted intensification of chemoradiotherapy, although nonmyeloid toxicities are still limiting. Retrospective studies suggest increased response rates with the use of high-dose chemotherapy to minimize the development of tumor resistance in leukemias and lymphomas ([357]). Evidence from prospective trials now also suggests that dose intensification and SCT can improve response rates and treatment outcomes in selected patients with hematologic malignancies ([358] , [359] , [360] and [361]). Phase I dose escalation trials using growth factor support with intensified standard chemotherapy regimens for lymphoma, such as the combination of cyclophosphamide, hydroxydaunomycin, Oncovin (vincristine), and prednisone, suggest improved response and survival rates without the need for stem cell rescue ([362]). Nevertheless, the use of growth factors to maximize dose intensity within standard-dose chemotherapy regimens has not translated into improved overall or disease-free survival. Because of the way in which some of these studies were conducted and their occasionally conflicting results, the impact of dose intensity on survival in lymphoid malignancies remains in question. Intermittent administration of G-CSF or GM-CSF has also permitted maintenance of dose intensity in patients who undergo chemotherapy for Hodgkin disease. The current body of literature does not support the routine use of CSFs for dose intensification, and such use should be done in the context of clinical trials.

In vitro studies show that myeloid growth factors can render leukemic cell lines more susceptible to cell cycle specific cytotoxic agents, such as cytarabine, by

recruitment of blasts into S phase, and the potential clinical benefit of this phenomenon has been investigated in patients with acute leukemia ([363], [364] and [365]). However, there is no evidence to date that growth factor priming to recruit leukemic cells into a cycling state before antileukemic therapy results in improved remission rates or prolonged remission duration and is not recommended per ASCO guidelines. In general, CSFs should not be administered simultaneously with chemoradiotherapy because of the potential for increased thrombocytopenia, as has been evidenced in a randomized trial in small cell lung cancer patients ([366]); however, one recent study in patients with ALL indicated that treatment-related morbidity, and thus treatment delays, could be prevented by the use of G-CSF in patients who are undergoing multimodality therapy. Current ASCO guidelines suggest avoiding the use of CSFs when patients are treated with concomitant chemotherapy and radiation.

Mobilization of hematopoietic PBPCs into the peripheral blood has become the standard of care at most transplant centers for stem cell collection for autologous transplantation. Treatment with G-CSF or GM-CSF effectively increases the number of circulating progenitors available for transplantation; indeed, graft priming may be as important as the source of the graft ([367], [368]). Other potential advantages to the use of PBPC over bone marrow include ease of collection, immunomodulatory antitumor effects, decreased tumor contamination ([369], [370]), and more rapid hematopoietic and immunologic recovery ([371], [372]). G-CSF and GM-CSF are effective in increasing the yield of PBPC during leukapheresis, and, when used in combination, they are more effective than either growth factor alone, but increased cost becomes the inhibitory factor. Allogeneic peripheral blood stem cell transplants are being increasingly done and are being studied in the unrelated setting too ([373]). The current trend towards use of peripheral blood stem cells in the allogeneic setting has raised concern about potential long-term toxicity of use of CSFs in normal donors. Studies have failed to show any long-term risk for the use of CSFs in normal donors ([374]).

Thrombocytopenia

Thrombocytopenia remains a challenge in the treatment of patients who undergo aggressive chemotherapy. Several cytokines have been developed and tested for treatment and prevention of chemotherapy-induced thrombocytopenia ([375], [376], [377] and [378]). The most promising results are from recombinant human IL-11 (Neumega), which, when tested in a randomized placebo-controlled study in breast cancer patients receiving chemotherapy, reduced the number of platelet transfusions required, and a smaller proportion of patients who received the drug needed platelet transfusions ([379]). In this study, recombinant human IL-11 also reduced the time to platelet recovery. This is the only current FDA-approved drug for chemotherapy-induced thrombocytopenia at a dosage of 50 µg/kg subcutaneously daily, starting a day after completion of chemotherapy until a platelet count of greater than 50,000/µl is reached.

Risks and Toxicities of Growth Factors

In general, the later-acting hematopoietic cytokines have been associated with fewer side effects than those that act earlier and on multiple cell lineages. EPO causes little or no toxicity when used in patients with normal renal function and intravascular volume regulation. Toxicity with G-CSF is usually mild, bone pain being the most common symptom 1 to 2 days before neutrophil recovery. Recombinant yeast-derived GM-CSF has been reported to have a better side-effect profile than *E. coli*–derived GM-CSF (less fever, rash, and myalgias), although a randomized trial that compared them revealed no statistically significant differences ([380]). GM-CSF also has diverse toxicities involving many organ systems that are poorly understood, but elevated levels of TNF-a and IL-6 may be partly responsible. GM-CSF at high doses has been associated with hepatic transaminase elevation, serositis, fluid retention, venous thrombosis, and reactivation of autoimmune disease. A syndrome of hypoxemia, flushing, cardiovascular instability, musculoskeletal pain, nausea, and vomiting has also been described with intravenous GM-CSF at doses greater than 1 µg/kg ([381]). Recombinant human IL-11, when used for prevention of chemotherapy-induced thrombocytopenia, has been associated with increased fluid retention, capillary leak syndrome, and occasional pulmonary edema and should be used with caution in patients with cardiac disease. IL-11 use is also associated with hypersensitivity and anaphylactic reactions in some patients, as are anemia and tachycardia ([375], [379]).

It is likely that broader-acting cytokines, such as IL-1, IL-3, PIXY-321, IL-6, and stem cell factor (SCF), more often cause systemic toxicity (fever, chills, rash, hypotension) than the growth factors that have already been discussed. SCF may cause symptoms similar to those of mast cell activation in some patients ([382]). M-CSF causes a dose-dependent thrombocytopenia ([383]).

COMMON COMPLICATIONS OF CHEMOTHERAPY

Dermatologic Toxicity

Alopecia and pigmentary skin changes (usually hyperpigmentation) occur with a number of chemotherapeutic drugs ([391]). Resolution of alopecia may take several weeks or months, and patients should be referred to a reliable source for wigs, such as the American Cancer Society or the Alopecia Areata Foundation, before commencing treatment. Skin hyperpigmentation also resolves in most cases but can occasionally be permanent and of considerable cosmetic significance to the patient.

Certain chemotherapeutic agents, such as bleomycin, doxorubicin, and methotrexate, are associated with enhancement of radiation effects that can increase toxicity to target tissues, areas of exposed skin, and other mitotically active organs. This effect is dependent on drug dose and has the greatest potential to occur if chemotherapy is given within 1 week of radiation therapy. Skin changes include edema, erythema with or without bullae, or necrotic ulceration. Treatment consists of cool, wet compresses; débridement, if necessary; the use of topical occlusive dressings; and monitoring for infection ([392], [393]).

Radiation recall reactions, in contrast, are characterized by recurrent inflammation in previously irradiated tissue (skin, lung, heart, and GI tract), usually within a few weeks of radiation therapy. A number of drugs (bleomycin, doxorubicin, etoposide, vinca alkaloids, and hydroxyurea), most notably anthracyclines, are associated with radiation recall ([391]). Photosensitivity and sunburn are infrequent side effects of chemotherapy and may be prevented by avoidance of skin exposure ultraviolet light and by withholding methotrexate for at least 1 week after sunburn, respectively ([394]). Sunscreens are not helpful in preventing photosensitivity but are recommended in transplant recipients who receive total body irradiation (TBI) to prevent flares of GVHD. Specific types of skin eruptions are noted with individual chemotherapeutic drugs. Tender erythematous plaques in acral areas (palms and soles) may be seen with cytarabine and 5-fluorouracil ([395], [396] and [397]). More generalized erythematous macules suggest neutrophilic eccrine hidradenitis, which was first described in association with cytarabine in acute leukemia patients but may also occur with other drugs ([398], [399]). Dermatologic side effects are increasingly being reported in patients who receive thalidomide, with most being minor skin eruptions and dermatitis, but few cases of erythema multiforme and toxic epidermal necrolysis have been reported ([400]).

Mucositis

The rapid proliferation of mucosal epithelial cells makes the oropharyngeal and GI mucosa particularly vulnerable to cytotoxic chemotherapy and local radiotherapy effects. Incidence of mucositis varies from 40% in patients who receive standard chemotherapy to as high as 75% in stem cell transplant patients ([401]). Combined-modality chemoradiotherapy increases the potential for serious gut toxicity that is caused by concomitant myelosuppression and local mucosal damage. The use of methotrexate further potentiates mucositis, despite folinic acid rescue. Mucositis usually begins as erythema of the soft palate, of the buccal mucosa, on the ventral surface of the tongue, and in the floor of the mouth. Buccal edema, desquamation, and frank ulceration follow in severe cases, and superficial bleeding may occur. Edema and scalloping of the lateral borders of the tongue may be noted if teeth are present. The severity of mucositis is dependent on therapy-related and host factors. The type of chemotherapy that is used, dose and field of radiation, cumulative dose, and treatment schedules of therapy are important determining factors. The presence of poor oral hygiene has been associated with a higher incidence of mucositis in transplant patients ([402]). Routine assessment of dental and oral soft tissue health before initiation of high-dose chemotherapy or radiotherapy to this region is therefore an important part of prevention of mucositis and secondary infection.

If handling of oral secretions due to pharyngeal mucositis is significantly impaired, the patient should be provided with a stiff catheter for suctioning, and evaluation of the airway by an otolaryngologist or even elective intubation may be prudent in severe cases. In addition to causing acute mucositis, radiation to the head or neck may lead to salivary gland dysfunction, bony and soft tissue changes, dental caries, and periodontal disease ([403]). Meticulous oral hygiene must continue once therapy begins, but, because of lack of patient motivation, nausea, mucositis pain, and general debility, this may be a difficult task. Multiple daily oral rinses with chlorhexidine, a salt and soda solution, or a topical antifungal are believed to reduce the risk of mucosal and systemic infection. Simultaneous pain control is also essential, and the use of topical anesthetics (viscous lidocaine) has limited success. Systemic analgesia with narcotics, which are delivered via patient-controlled analgesia pump, is often necessary. When natural teeth are present, the use of a soft toothbrush or chlorhexidine-saturated foam brush assists in maintaining oral

hygiene.

Several agents have been studied to reduce the incidence and degree of mucositis. A randomized, placebo-controlled study using prophylactic oral rinses with sucralfate did not prevent oral ulcerative mucositis that was caused by radiation ([404]). Similarly, studies of the protective effects of the drug azelastine in combination with other antioxidants, such as vitamins C and E, in patients with solid tumors have failed to show any clear benefit ([405]). Vitamin E in topical form has been reported to be effective in treating chemotherapy-induced oral mucositis as compared with placebo in one randomized study ([406]). Prechemotherapy topical administration of transforming growth factor-ß, which has been shown to reduce the turnover of basal epithelial cells *in vitro* and *in vivo*, significantly decreased the incidence, severity, and duration of oral mucositis in one study and may be a promising avenue to prevention ([407]). The cytoprotectant amifostine has been reported in small, randomized, clinical trials to significantly reduce mucositis in patients who undergo chemoradiotherapy for head and neck cancers and also in patients who undergo stem cell transplant using melphalan as a conditioning regimen ([408]). Prostaglandin E_2 has been reported in healing mucositis in bone marrow transplant patients ([409]). In patients receiving 5-fluorouracil and high-dose melphalan, cryotherapy using ice-cold mouthwashes or ice pops immediately before and at least 30 minutes after melphalan administration may be helpful in reducing the incidence of mucositis, even when melphalan is not used as a single agent ([410]). The mechanism is thought to be local vasoconstriction and a decrease in temperature-dependent melphalan cytotoxicity. Keratinocyte growth factor, an epithelial-specific tissue growth factor, has been shown in preclinical and phase I and II studies to have cytoprotective properties ([411]). There are several ongoing clinical trials in patients who receive chemoradiotherapy as well as SCT.

Radiation-related mucositis occurs 10 to 14 days after the initiation of radiation therapy and heals within 2 to 3 weeks. It may be patchy or confluent. Topical anesthetic suspensions, topical antifungals, and frequent daily saline or sodium bicarbonate lavages are helpful in maintaining hygiene and reducing microbial colonization; topical vancomycin may be of benefit prophylactically in patients who receive TBI ([412] , [413]). Acute sialadenitis, a common and often painful complication of TBI and of localized irradiation, is usually transient; stimulation of salivation with hard candy often provides relief in the interim. Chronic hyposalivation and xerostomia are more difficult to treat, as artificial saliva substitutes are unsatisfactory; systemic sialogogues (such as pilocarpine and bethanechol) have been efficacious in preliminary trials ([403] , [414]).

Diarrhea is a common occurrence after TBI or bowel irradiation; it can also result from chemotherapy with several chemotherapy agents. Noninfectious mild diarrhea can be controlled with opioid drugs, such as loperamide and diphenoxylate and atropine, and by lowering the fiber content of food. Loperamide may be superior to diphenoxylate and atropine for acute nonspecific diarrhea ([415]). Bile acid-binding resins (such as cholestyramine) may be effective in preventing and controlling diarrhea but at dosages that are unpalatable to most patients. Anecdotal reports have shown salicylates to be successful in refractory cases ([416]). There are preliminary reports of success with sucralfate ([417]) and glutathione ([418]) in prevention of radiation-induced diarrhea. Octreotide (0.1 mg subcutaneously) is an effective antidiarrheal against chemotherapy-induced diarrhea ([419] , [420]). This agent has been used extensively in GVHD of the gut after BMT and may lead to adynamic ileus, although immunosuppressive therapy remains the mainstay of treatment of GVHD ([421] , [422] and [423]). In immunocompromised patients, infectious causes, such as *Shigella, E. coli*, and *C. difficile*, must be ruled out as cause of diarrhea.

Urinary Tract Toxicity

Acute and chronic nephrotoxicity is a common and dose-limiting complication of cancer chemotherapy. The most well-known nephrotoxic agents are ifosfamide and platinum drugs, which are used often in childhood and adult hematologic malignancies. Risk factors for ifosfamide renal toxicity that emerge from the pediatric literature include high cumulative dose, young patient age, prior nephrectomy, concomitant therapy with a platinum agent, and preexisting renal abnormalities ([424]). Continuous infusion may be less toxic than bolus infusion Mesna is effective in protecting against bladder toxicity that is caused by the 4-hydroxy metabolites of cyclophosphamide, acrolein, and 4-hydroxy cyclophosphamide; it is widely used to reduce the risk of hemorrhagic cystitis that is caused by high-dose or daily low-dose cyclophosphamide ([425]). The efficacy of mesna in blocking the action of toxic ifosfamide metabolites appears to be considerably less ([424] , [426] , [427]), although it may exert some protective effect. In the event of bladder hemorrhage, support with blood products and continuous irrigation of the bladder with saline or hydrocortisone are needed. More extreme measures, such as intravesical formalin instillation, urinary diversion, or cystectomy, may be performed for refractory cases, but with generally disappointing results.

Cisplatin nephrotoxicity is well described but poorly understood. An autopsy study found significant correlation between tissue levels of the drug and the dose of cisplatin per course, the concomitant use of metoclopramide and phenytoin, and the renal cortical platinum level. The investigators suggest that the protective effect that is observed with hydration may not be caused by reduced cortical platinum concentrations ([428]). There is some evidence that prospective determinations of urinary tubular enzyme and retinol-binding protein excretion may be useful in predicting later decline in creatinine clearance in adults who receive cisplatin ([429]). Several other strategies, most of which entail the use of certain drugs before cisplatin administration, remain investigational at this time: chelation or inactivation of platinum metabolites (amifostine, sodium thiosulfate, mesna, glutathione, and selenium), inhibition of tubular cisplatin secretion and accumulation (probenecid), renal vasodilation (captopril and verapamil), and removal of cisplatin from DNA adducts (diethyldithiocarbamate) ([430] , [431]). The primary means of minimizing cisplatin toxicity is aggressive saline diuresis (2 to 3 L over 8 to 12 hours on the day of chemotherapy), with or without mannitol.

Dosage modification for renal or hepatic insufficiency is required for many chemotherapeutic agents (see Chapter 73).

Cardiotoxicity

Several chemotherapeutic drugs can cause cardiac toxicity, some reversible and some irreversible. Anthracycline antibiotics (doxorubicin and daunomycin) may lead to acute supraventricular tachyarrhythmias within hours of bolus administration in as much as 40% of patients who receive bolus doxorubicin, but this is usually transient and asymptomatic. Chronic dose- and schedule-related toxicity is of more concern, as it is usually irreversible. Cumulative doses of greater than 400 mg/m^2 are associated with a significant increase in risk, and the incidence of clinical congestive heart failure is probably higher than was previously reported. Additional risk factors that have been identified are exposure to ionizing radiation to the chest, an age of older than 70 years, prior exposure to anthracyclines, and preexisting cardiac disease or coronary risk factors, but the relative importance of these risk factors has not been established ([432] , [434]). Prolongation of the QTc interval may correlate with cumulative anthracycline dose and risk for long-term cardiac sequelae ([433]).

The major advance in prevention of anthracycline-induced cardiac toxicity is the development of the cardioprotectant dexrazoxane, which protects against free radical myocardial damage that is induced by anthracyclines. Randomized, placebo-controlled trials of this compound in patients with breast cancer and sarcomas show conclusively that dexrazoxane at a dose ratio of 10:1 or 20:1 dramatically reduces doxorubicin cardiotoxicity without diminished antitumor activity ([435] , [436]). Patients in a New York University Medical Center study were able to tolerate significantly more cycles of anthracycline-based therapy for breast cancer (fluorouracil, doxorubicin, and cyclophosphamide at doses of 500, 50, and 500 mg/m^2, respectively) and higher cumulative doxorubicin doses (with a median cumulative dose of 500 mg/m^2 versus 441 mg/m^2, with a range to as high as 1000 mg/m^2) with a decreased incidence of cardiac toxicity ([437]). The median fall in left ventricular ejection fraction was 1 to 3% in the dexrazoxane group versus 15 to 16% in the control group. ASCO published guidelines for use of dexrazoxane for patients who receive anthracyclines in 1999 ([438]).

High-dose cyclophosphamide, especially in the transplant setting, has also been associated with transient congestive heart failure, hemorrhagic myocarditis and pericarditis, and death, but these are uncommon complications ([439]). Finally, the infusion of autologous stem cells or marrow that is cryopreserved with dimethyl sulfoxide causes transient arrhythmias that are usually asymptomatic; slowing the rate of infusion and administering a diuretic immediately after infusion decreases the likelihood of this problem ([440]).

Pulmonary Toxicity

Many chemotherapeutic agents may result in pulmonary toxicity (Table 75.9). Careful attention to risk factors when designing therapeutic regimens and monitoring lung function is key to preventing such toxicity. Risk factors for toxicity that is caused by bleomycin, the most notable offender, are a total dose of greater than 400 U; older patient age; concomitant therapy with anthracyclines, cyclophosphamide, vincristine, dexamethasone, or methotrexate; radiotherapy; preexisting pulmonary function abnormalities; and high-dose oxygen exposure. Bleomycin should be discontinued for a greater than 10 to 15% decline in the measured parameters of pulmonary function ([441]). Another common offender that is seen often in the stem cell transplant setting is carmustine, which can cause pulmonary toxicity as late as 8

weeks after transplant. If diagnosed early, carmustine toxicity of the lung can be reversible with systemic steroid therapy.

TABLE 75.9. Pulmonary Toxicity of Chemotherapeutic Agents

Drug	Toxic Dose Range [a]	Toxicity
Bleomycin	Total dose =400 U	Interstitial pneumonitis and fibrosis Dyspnea and cough (early symptoms) Fine rales (early signs) Decreased vital capacity and lung volumes; toxicity is dose and age related
Busulfan	Conventional dose	Bronchopulmonary dysplasia and fibrosis Onset delayed for months or years
Carmustine	Total dose =1 g/m ^{2}	Interstitial pneumonitis; delayed pulmonary fibrosis
Chlorambucil	Conventional dose	Interstitial pneumonitis and fibrosis
Cyclophosphamide	High dose	Pulmonary edema
Cytarabine	Conventional dose	Interstitial pneumonitis and fibrosis
Melphalan	High dose	Interstitial pneumonitis
Methotrexate	Conventional dose	Interstitial pneumonitis
Mitomycin	Conventional dose	Interstitial pneumonitis
Thiotepa	High dose	Interstitial pneumonitis

[a] Route of administration is intravenous, unless otherwise indicated. The conventional dose is the commonly accepted therapeutic range.

NONINFECTIOUS ISSUES IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

Conditioning Regimen Toxicity

Regimen-related toxicity (RRT) is a major cause of early mortality after myeloablative SCT for hematologic malignancies. Hepatic VOD and acute lung injury are the two principal components of RRT. The specific risk factors, proposed pathophysiology, and management of these disorders are discussed fully in Chapter 25. The source of stem cells for transplantation may significantly affect the risk of RRT ([442]).

Venoocclusive Disease

VOD of the liver is the most common regimen-related toxicity that is seen after SCT when high-dose chemoradiotherapy is used as the conditioning regimen. Differentiation of VOD from other liver abnormalities, such as GVHD, drug-induced liver toxicity, or infectious hepatitis, may be difficult (Fig. 75.9) ([443] , [444] and [445]). Imaging studies, such as CT scanning or ultrasound of the right upper quadrant, are nonspecific but are occasionally useful for documenting ascites and for excluding extrahepatic biliary obstruction. In selected patients, transvenous liver biopsy and measurement of the hepatic venous pressure gradient may be considered, but these procedures require a skilled and experienced operator. Noninvasive tests, such as magnetic resonance imaging and color Doppler ultrasound, have been found to be useful in the diagnosis of VOD, with the later test being exceptionally specific and sensitive ([446] , [447]). One study suggests that an elevated plasminogen activator inhibitor-1 level in hyperbilirubinemic transplant recipients is a sensitive and specific marker for distinguishing VOD from GVHD and other causes of hepatic injury, but the plasminogen activator inhibitor-1 assay is not available to clinicians ([448]).

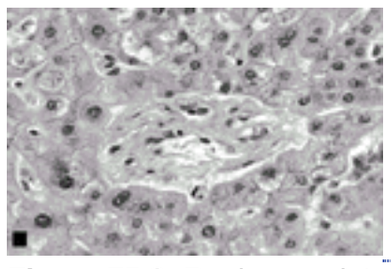

Figure 75.9. Regimen-related organ toxicity. Vasoocclusive disease of the liver with nonthrombotic fibrous occlusion of central veins and small venules. Hematoxylin and eosin stain, ×400. See Color Plate. (Photomicrograph courtesy of M. Scott.)

The pathogenesis of VOD is unclear and appears to be multifactorial. Recent studies have implicated low levels of von Wil-lebrand factor cleaving-protease activity that lead to high levels of large von Willebrand factor multimers as a possible factor in development of VOD ([449]). At present, no consistent effective options exist for preventing fatal VOD. Several agents, including heparin, ursodiol, *N*-acetyl glucosamine, and L-glutamine, have been studied for prevention of VOD. Heparin and ursodiol were found in randomized studies to reduce the incidence of VOD but not the incidence of fatal VOD nor was there any survival benefit ([450]). Similarly, several treatment approaches toward VOD have been reported, but all have been in small studies. The drugs that have been found to be effective for the treatment of VOD are tissue plasminogen activator, antithrombin III, defibrotide, and high-dose corticosteroids ([451] , [452]). Some investigators believe that there is no significant benefit with thrombolytic therapy over standard supportive care ([452]), and large prospective randomized trials are needed to properly evaluate this strategy.

Trans-jugular intrahepatic portosystemic shunt has been tried in some patients with significant portal hypertension as a result of VOD, but it is associated with long-term sequelae, such as encephalopathy ([453]). Fluid overload requires cautious diuresis with a loop diuretic or spironolactone because of frequent intravascular volume depletion and the risk of precipitation of the hepatorenal syndrome. Albumin and fresh frozen plasma are rarely of benefit and may ultimately worsen fluid overload. Hemodialysis and mechanical ventilation are mainstays of supportive care in patients with renal failure, pulmonary edema, and hypoxemia, but the need for hemodialysis portends a poor prognosis ([454]). Patients with VOD are also at high risk for developing subsequent pulmonary complications, possibly as a result of toxic lung injury ([455]). Although a combination of clinical and laboratory parameters may aid in the assessment of severity, predicting the course and reversibility of VOD in the individual patient remains a challenge ([456]).

Acute Lung Injury and Alveolar Hemorrhage

Idiopathic IP occurs in as much as 35% of marrow transplant recipients, most commonly between 30 and 100 days after transplantation. The development of diffuse, patchy pulmonary infiltrates, with fever, dyspnea, and nonproductive cough, necessitates bronchoalveolar lavage to exclude an infectious etiology, such as CMV. The risk of true idiopathic pneumonitis is clearly greater in allogeneic than in autologous transplant recipients for reasons that are not entirely obvious, although acute GVHD and the use of methotrexate for GVHD prophylaxis are among the known risk factors for IP ([365] , [366]). There is evidence that supports the hypothesis that dysregulated cytokine effects that are akin to those seen in the systemic inflammatory response syndrome and acute GVHD may play an important role in the pathogenesis of IP in these patients ([367] , [368] , [369] and [370]). Therapy is primarily supportive, but mortality remains extremely high in patients with this complication who require mechanical ventilation. A trial of corticosteroids is indicated early in the course of IP, once infection has been excluded, as some patients respond to this therapy. Combination cytokine (IL-10) and anticytokine (anti-TNF and IL-1R antagonist) therapy may prove useful in ameliorating the inflammatory response ([371]).

Diffuse alveolar hemorrhage occasionally occurs in the early posttransplant period in patients with severe mucositis, infection, and thrombocytopenia ([365], [372], [373]). It also tends to occur at the time of engraftment for reasons that are not entirely clear, but neutrophilic influx into the lung has been demonstrated, and proinflammatory cytokines may play a role. This entity usually presents as patchy consolidation on chest radiograph in association with hemoptysis, dyspnea, and evolving hypoxemia. If the diagnosis is established or suspected, immediate treatment with high-dose corticosteroids is indicated to reverse lung inflammation ([374]), and any bleeding tendency should be aggressively treated with platelet transfusions or plasma. Improvement is often noted within 24 to 48 hours.

MANAGEMENT OF NAUSEA AND VOMITING

Two of the most common and most dreaded side effects of chemotherapy are nausea and vomiting. Nausea and vomiting, which occur in as much as 80% of patients with cancer, profoundly affect quality of life and, if poorly controlled, may lead to patient noncompliance ([466], [467]). An improved understanding of the neural pathways and neurotransmitter receptors that are involved in chemotherapy-induced emesis has led to the development of better drugs for treatment and prophylaxis. The availability of these drugs in a variety of formulations has also broadened their clinical usefulness and has reduced the need for prolonged hospitalizations for chemotherapy.

Emesis Response

Since the initial neuronal ablation and electrical stimulation studies that were performed by Borison and Wang in the 1950s, several pathways have been proposed for the emetic reflex ([468], [469] and [470]). According to the current model (Fig. 75.10), cellular injury that is induced by chemotherapy leads to the local or systemic release of neurotransmitters that generate a vomiting signal. The major excitatory neurotransmitters that are involved in emesis are 5-hydroxytryptamine (5-HT_3, also known as *serotonin*) and dopamine, although corticosteroids, acetylcholine, substance P, endorphins, and histamine also appear to play a role ([471], [472] and [473]). The role of opiates is unclear, as they may block or stimulate emesis ([475]). Receptors for 5-HT_3 and dopamine D2 are present in the chemoreceptor trigger zone (CTZ), which lies outside the blood–brain barrier in the *area postrema* of the fourth ventricle and in the GI mucosa; serotonin receptors are also located in the vomiting center in the medulla ([471], [476], [477]). Transmission of the signal to the vomiting center occurs via three principal routes: the CTZ, the cerebral cortex, and the visceral afferent nerve fibers from the pharynx and GI tract. The vomiting center also receives emetogenic input from the vestibular apparatus, thalamus and hypothalamus (limbic system), and midbrain receptors of intracranial pressure ([468], [478]). Limbic input may be especially important in evoking anticipatory emesis. Cranial nerve nuclei and other medullary centers in control of vasomotor responses, salivation, and respiration are in turn stimulated by the vomiting center to initiate the motor events of emesis. Most of the available antiemetic drugs act on a single pathway, and, hence, a combination of antiemetic drugs is required to get the best antiemetic response.

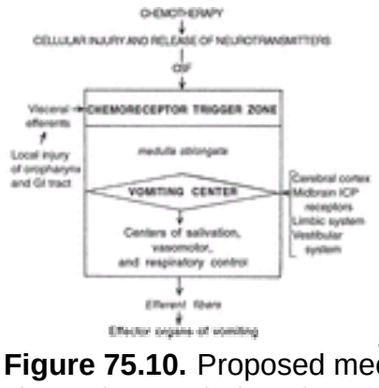

Figure 75.10. Proposed mechanisms of emesis. CSF, cerebrospinal fluid; GI, gastrointestinal; ICP, intracranial pressure. (Adapted from Ettinger D. Preventing chemotherapy-induced nausea and vomiting: an update and a review of emesis. Semin Oncol 1995;22:6–18; and Grunberg SM, Hesketh PJ. Control of chemotherapy-induced emesis. N Engl J Med 1993;329:1790–1796.)

Characteristics of Emesis That Is Induced by Chemoradiotherapy

Nausea and vomiting in patients with hematologic malignancies is multifactorial. All factors that are potentially responsible for causing nausea and vomiting should be considered when treating such patients. Other than chemotherapy-induced nausea and vomiting (CINV), reasons for emesis could be constipation that is caused by prolonged inactivity and narcotic analgesic use, bowel obstruction or CNS metastasis, metabolic derangements (such as hypercalcemia), peptic ulcer disease, and other nonchemotherapeutic medications. Radiation therapy to the GI tract (especially the small bowel) or the brain has the highest potential for inducing nausea, with the risk increasing with increases in total dose and the amount of tissue that is irradiated ([479]). Patients who receive TBI as conditioning for SCT are especially prone to severe nausea.

Several patterns of nausea are recognized in cancer patients who are receiving chemotherapy. *Acute-onset CINV* is defined as nausea and vomiting that occur within the first 24 hours after chemotherapy administration and within a few minutes to several hours after administration of the drug, reaching peak intensity by 5 to 6 hours. This pattern of nausea is generally seen with moderately or highly emetogenic agents, such as doxorubicin and cisplatin. Younger patients, female patients, and patients with history of motion sickness are at greatest risk for acute emesis. Previous history of nausea, the environment in which the chemotherapy is given, the dose and method of administration of the drug (bolus vs. continuous infusion), and the type of antiemetic premedication that is given are also determining factors for acute CINV ([471], [480], [481]). Chronic heavy alcohol consumption has been reported to reduce the risk ([482]). *Delayed-onset CINV*, by definition, occurs more than 24 hours after administration of chemotherapy, with a peak at 48 to 72 hours, and may last for weeks. Morbidity is greatest with this type of nausea, because it is particularly hard to control, tends to prolong hospitalization, and can lead to anxiety and depression if it is not promptly addressed ([483]). Female gender, a history of motion sickness, high-dose intensity of chemotherapy, and prior severe acute emesis are risk factors ([483], [484]). Delayed-onset nausea probably involves mechanisms that are different from those that are involved in acute nausea. It is not uncommon after the administration of cyclophosphamide, ifosfamide, doxorubicin, and cisplatin. *Anticipatory CINV* is usually a result of a conditioned response from previous chemotherapy experience and more often affects younger patients, although this may be more a reflection of the aggressive chemotherapy that is given to these patients. Motion sickness is a predisposing factor ([483], [485]). Compliance with subsequent courses of therapy may be seriously hindered by such negative experiences, and early prevention of chemotherapy-induced nausea and emesis is therefore essential ([486]).

The intrinsic emetogenicity, dose, and method of administration of the chemotherapeutic agent are the most consistent predictors of nausea and vomiting. Antineoplastic drugs have been categorized according to their emetogenic potential ([471]); many of these drugs exhibit a dose-dependent increase in emetogenicity. In general, bolus injections of drug are less well tolerated than extended intravenous infusions ([480]). Nausea that is caused by continuous infusions peaks in the first 24 hours and then gradually diminishes. The duration of chemotherapy-induced emesis is also a function of the chemotherapeutic agent. Most antineoplastic drugs are emetogenic for a 12- to 24-hour period after administration. Cyclophosphamide may cause emesis after 24 hours, and mitomycin may still be emetogenic 48 to 72 hours after administration.

Control and Prevention of Nausea

When designing an effective antiemetic regimen, the schedule of administration, duration, and site of action of the antiemetic are as important to consider as the pattern of emesis that is caused by the chemotherapy agent. Maximal efficacy is achieved if antiemet-ics are initiated before chemotherapy administration and scheduled throughout the period of emetic activity of the chemotherapeutic agent. Other important considerations in the selection of an antiemetic regimen are the route, the ease of administration, the potential adverse effects, and the patient's preference. An intravenous route is preferable in hospitalized patients who receive continuous or intensive chemotherapy or radiation and who have severe mucositis. Oral or rectal formulations are appropriate for patients in the outpatient setting and for those with mild to moderate, intermittent nausea.

Antiemetics that have been found to be effective in patients with hematologic malignancies include the dopamine (D2)–receptor antagonists (phenothiazines, substituted benzamides, and butyrophenones), the serotonin (5-HT_3) antagonists (ondansetron, granisetron, and dolasetron), and miscellaneous agents (corticosteroids, antihistamines, benzodiazepines, anticholinergic drugs, and cannabinoids). Agents that act directly on the CTZ and on peripheral receptors are the

most effective in preventing chemotherapy-induced emesis. Combinations of synergistic drugs are generally used for optimum efficacy and reduction of adverse effects (Table 75.10). Drugs that are useful for enhancing the efficacy and tolerability of other antiemetics in combination include benzodiazepines, antihistamines, corticosteroids, and anticholinergic drugs, such as scopolamine (transdermal). The early antiemetic agents that were studied formally in clinical trials included the dopamine receptor antagonists, which at standard doses were found to be ineffective against highly emetogenic cisplatin. The use of higher doses of metoclopramide in combination with corticosteroids increased the antiemetic response ([487]). The development of the specific serotonin receptor antagonist (SSRA) class of antiemetics revolutionized the management of acute CINV ([488], [489]). Ondansetron, dolasetron, and granisetron are the SSRAs that are approved for use in the United States. Clinical trials have demonstrated superior antiemetic efficacy with oral or intravenous ondansetron over metoclopramide in the control of acute-onset nausea and emesis ([490]). The efficacy of ondansetron is further enhanced by the addition of dexamethasone (20 mg orally) to the regimen ([491]). Single-dose oral (32 mg) or every-8-hour intravenous doses (0.15 mg/kg) of ondansetron were also effective in preventing and controlling emesis that was caused by high- or moderate-dose cisplatin in 68% and 78% of patients, respectively ([492]). Similarly, granisetron at a dosage of 0.01 mg/kg intravenously once within 30 minutes before chemotherapy, or 2 mg orally within 1 hour before and 12 hours after chemotherapy administration is effective for cisplatin-induced emesis ([493]). The combination of oral granisetron and intravenous dexamethasone significantly delays the onset of nausea and vomiting and achieves complete prevention of emesis in 65 to 90% of patients ([494]). Dosage recommendations for delayed nausea are 100 mg by mouth (PO) twice a day (BID) of dolasetron, 1 mg PO BID of granisetron, and 8 mg PO BID of ondansetron in combination with oral dexamethasone. Side effects that are associated with SSRAs are usually mild and transient; headache is the most common. Other side effects that are reported infrequently are diarrhea, constipation, asthenia, and abdominal discomfort. Dysphoria, dystonia, and akathisia, which are seen with some traditional antiemetics, are not problematic with the SSRAs. Single-dose granisetron is more cost-effective in emesis control than multiple, round-the-clock doses of ondansetron, and a statistically significant difference in patient preference in favor of granisetron has been shown in one randomized study ([495]). The most recently FDA-approved class of antiemetics is the neurokinin-1 receptor antagonists. These drugs have a unique mechanism of action by inhibition of substance P. In several randomized trials, addition of these drugs to standard antiemetic regimens was found to result in moderate reduction in acute CINV and a significant prevention of delayed emesis ([496]). The current available drug in this class is aprepitant (MK-869, Emend) and is available for oral dosing.

TABLE 75.10. Rationale of Combination Antiemetic Therapy

Primary Agent	Effective Secondary Agent
Specific serotonin receptor antagonist	Corticosteroid (E), phenothiazine (E), and butyrophenone (E)
Substituted benzamide	Corticosteroid (E, T), anticholinergic (E), and antihistamine (T)
Phenothiazine	Corticosteroid (E) and antihistamine (T)
Butyrophenone	Corticosteroid (E) and antihistamine (T)
Cannabinoid	Phenothiazine (T)
Corticosteroid	Benzodiazepine (E)

E, improves the efficacy of the primary drug; T, reduces the adverse effects of the primary drug.
Adapted from Grunberg SM, Hesketh PJ. Control of chemotherapy-induced emesis. N Engl J Med 1993;329:1790–1796.

Modification of the antiemetic regimen is necessary when there is a determination of *treatment failure*, which is generally defined as the occurrence of three or more vomiting episodes within 24 hours of chemotherapy administration or continued nausea that is bothersome to the patient. If delayed CINV is anticipated, prophylaxis with lower-dose SSRAs in combination with 4 to 8 mg of dexamethasone daily orally or intravenously for 2 to 4 days, with the addition of metoclopramide (20 mg orally) and diphenhydramine to prevent dystonia, if the patient is younger than 35 years of age, is often successful (Table 75.11). These medications should be administered at the expected time of onset of nausea (e.g., 12 hours after cyclophosphamide or 18 to 20 hours after cisplatin infusion). Chemotherapy of low emetogenicity usually requires only the administration of a phenothiazine antiemetic orally or intravenously before drug infusion and on an as-needed basis every 6 to 8 hours thereafter. Satisfactory control and prevention of nausea and emesis ultimately depend on good communication with the patient and serial evaluation of the efficacy of the antiemetic regimen being used. The ASCO has published evidence-based guidelines for the use of antiemetics ([497]).

TABLE 75.11. General Guidelines for Selection of Antiemetic Agents

Low	Moderate to Severe (Cisplatin-Containing)	Moderate to Severe (Non–Cisplatin-Containing)
Acute emesis		
Phenothiazine or butyrophenone ± benzodiazepine ± substituted benzamide ± antihistamine	Specific serotonin receptor antagonist ± corticosteroids ± benzodiazepine (failure) Substituted benzamide ± antihistamine ± corticosteroid ± benzodiazepine (failure) Phenothiazine ± benzodiazepine ± substituted benzamide ± corticosteroid ± antihistamine or cannabinoid	Specific serotonin receptor antagonist ± corticosteroids ± benzodiazepine Butyrophenone ± antihistamine ± corticosteroid ± benzodiazepine
Delayed emesis Corticosteroid ± benzamide/antihistamine ± benzodiazepine

SELECTION AND CARE OF VASCULAR ACCESS DEVICES

General Considerations

Intravascular devices (IVDs) have become one of the most essential features in the current care of patients with hematologic malignancies. Reliable long-term venous access is often necessary in these patients for safe delivery of vesicant chemotherapy agents, multiple incompatible intravenous drugs, blood products, and hyperalimentation. Central access also promotes patient comfort when frequent phlebotomy is required and helps infusion of large volumes over shorter periods, when required. However, the IVDs are associated with increased risk of infections with bacteria and fungi.

Types of Access Devices

CVCs can be short term or long term, depending on the duration for which they can remain in the patient. The typical short-term catheters are noncuffed, single or multiple lumen and are usually inserted into a subclavian, intrajugular, and, occasionally, femoral vein. These catheters need to be changed frequently, as often as every 3 to 5 days. Long-term CVCs are of two general types: those that have external access (Hickman, Broviac, Groshong, and Quinton catheters) and those that are

accessed through one or more subcutaneous ports (LifePort, Port-A-Cath). Hickman- and Broviac-style catheters are anchored with a subcutaneous Dacron cuff, which becomes ingrown by host tissue, creating a mechanical barrier and tunnel subcutaneously into the central venous system, most commonly via the subclavian or internal jugular vein. The number and diameter of the lumens that are available with these catheters are variable. Subcutaneous and externalized catheters are placed surgically, but only the latter may be removed at the bedside or in the office setting. Peripherally inserted central catheters (P.A.S. peripheral access system) have recently gained popularity, because they may be placed at the bedside by trained personnel; however, peripherally inserted central catheters may not provide a sufficient number of lumens for patients who receive complex chemotherapy regimens. Finally, dual-purpose vascular catheters that can be used for leukapheresis or dialysis as well as chemotherapy are also available (Neostar catheter). They are of shorter length, have larger lumens, and are noncollapsible at high flow rates but have an increased tendency to kink near the exit site.

Selection of Catheters

Several factors should be kept in mind while making a choice of IVD for a certain patient. Factors to be considered include the type of therapy that is planned (multiagent vs. single-agent chemotherapy) and whether vesicating agents are to be given; the frequency and duration of therapy; the frequency of blood draws; the need for blood transfusions, total parenteral nutrition (TPN), and other supportive infusions; whether the catheter may be used for hemodialysis, plasmapheresis, stem cell collection, or bone marrow reinfusion; and, last but not the least, patient preference and ability to care for the catheter ([497], [498]).

The risk of infection increases with lumen number. A recent prospective observational study that compared Hickman catheters to central ports in cancer patients showed that the risk of infections might be lower with ports in patients who need intermittent access ([499], [500]).

Catheter Care

To reduce the incidence of bloodstream infections that arise from IVDs, guidelines have been issued regarding the care of such devices. These guidelines were issued by the Hospital Infection Control Practices Advisory Committee in 1996 and were recently updated in 2001 ([501]). General measures include use of aseptic techniques while inserting, manipulating, or removing IVDs. Dedicated intravenous teams are strongly recommended to care for the IVDs. Daily cutaneous antisepsis is recommended with chlorhexidine, iodophor, or alcohol, followed by a sterile gauze or semipermeable polyurethane film dressing. The use of prophylactic systemic antibiotics without the presence of infection is strongly discouraged. Hickman-Broviac catheters must be flushed with 2 to 3 ml of heparin solution (100 U/ml) through all ports daily or after each use. The protective caps on each port should be replaced twice per week. Groshong catheters require flushing only once per week with 5 ml of sterile saline. Subcutaneous ports should be flushed with 2 to 3 ml of heparin solution (100 U/ml) monthly and after each use. Percutaneous access is achieved by using a noncoring (Huber) needle, and the needle should be replaced every 3 to 5 days during continuous access.

Any difficulty in withdrawing blood or flushing the ports of a CVC should be investigated to see if there is potential for extravasation of a vesicant drug or suspicion of catheter malposition. Patients and their caregivers should be instructed in advance of hospital discharge in heparin flushing, dressing changes, and changing the Luer Lok cap. Damage to the external portion of the catheter should be addressed immediately; repair kits may be used to replace the damaged portion in many cases.

Complications

INFECTION Complications that are related to insertion of the catheter itself are rare (approximately 1%) and are not covered here. After placement, CVCs constitute a nidus for thrombus formation and infection. Systemic prophylactic antibiotics have not been consistently effective in averting infectious complications ([497]). Use of “antibiotic lock” solutions is a technique in which an antibiotic solution (ciprofloxacin or vancomycin, or both, at dose of 25 µg/ml) is instilled into the catheter lumen for 6 to 12 hours after which it is removed. Recently published randomized studies that use this technique for prevention of infections of CVCs show a reduction in risk of bacteremia with long-term IVDs ([502]). Neutropenic and nonneutropenic patients with indwelling venous catheters are at increased risk of bacteremia ([503]). Coagulase-negative staphylococci are the most common etiologic agents that are isolated, but *S. aureus*, gram-negative bacteria, corynebacteria, bacillus species, and mycobacterial and fungal organisms are also reported. Simultaneous cultures from peripheral sites and through all catheter ports are helpful in distinguishing infection of the catheter itself from infection arising from another source. Successful treatment of catheter-associated bacteremias that are caused by coagulase-negative staphylococcal or even gram-negative organisms does not always require catheter removal, even in the presence of neutropenia. Infections of the skin pocket of an implanted port also resolve in approximately 70% of patients without removal of the device ([504]). Intravenous antibiotics should be administered for 1 to 3 weeks and should be rotated through all lumens; if clinical improvement is noted, and surveillance cultures from all lumens remain negative after 3 days of antibiotic therapy, the catheter can probably be sterilized. This is also true of uncomplicated exit-site infections, which usually resolve with aggressive local care and systemic antibiotic therapy. It may not be possible to treat some bacterial infections successfully, even when the organism is sensitive (e.g., *S. aureus*, some *Bacillus* species, corynebacterium group JK, and *Stenotrophomonas* species), and the catheter must then be removed. Other indications for immediate removal of the catheter are evidence of complicating endocarditis, septic thrombosis, and septic pulmonary embolism. Certain organisms, such as *Candida* and fungi, are extremely difficult to eradicate because of their attachment properties and necessitate prompt catheter removal to avoid the complications of disseminated infection. Fungemia that is caused by *Malassezia furfur* (*Pityrosporum orbiculare*) tends to occur in patients who receive parenteral lipids and may be resistant to amphotericin B. This infection often manifests as fever, pulmonary infiltrates, and thrombocytopenia; discontinuation of the lipid, as well as removal of the catheter, is needed ([505]).

OCCLUSION AND VENOUS THROMBOSIS Occlusion due to a fibrous sheath or a thrombus should be suspected if difficulty withdrawing from or infusing through a catheter happens. Fibrin blockage is common, and simple repositioning of the patient and a Valsalva maneuver may allow blood to be withdrawn. If this strategy fails, catheter position should be confirmed by chest radiograph after injection of contrast dye through the catheter. Patients in whom there is no contraindication to thrombolytic therapy may be given an infusion of urokinase at 200 U/kg/hour for as long as 12 hours to reopen the catheter. Otherwise, 5000 units of urokinase (in 2 ml of sterile water) may be injected into the catheter, and a blood draw may be attempted again in 30 minutes; this procedure may be repeated twice in 24 hours if necessary. Recombinant tissue plasminogen activator (alteplase) at a dose of 2 mg/2 ml, which is instilled for 30 minutes, results in restoration of function in occluded venous catheters ([506]). The incidence of catheter-related venous thrombosis is probably underestimated, because many cases are asymptomatic; however, pain, ipsilateral extremity edema, and superficial venous dilation require evaluation with venography or noninvasive contrasted imaging techniques. In one prospective, randomized placebo-controlled study, low-dosage warfarin (1 mg/day) was shown to reduce significantly the incidence of catheter-associated venous thrombosis without prolongation of the clotting times or an increase in bleeding complications ([507]). The catheter should be removed if it is no longer needed or if treatment with systemic anticoagulation fails. Prophylactic use of urokinase (5000 IU/ml) every 1 to 2 weeks into long-term IVDs has shown reduced incidence of thrombosis and also catheter-related infections ([508]).

DRUG EXTRAVASATION Incorrect needle placement in an implanted port, catheter tip migration, or forcible flushing of an occluded catheter may result in extravasation of vesicant chemicals into the skin. A burning sensation, pain, or swelling at the site suggests this complication, and cellulitis, ulceration, necrosis, and sloughing of soft tissue may result. Conservative therapy, which includes following specific measures for individual drugs, stopping the infusion, and withdrawing the needle, is usually effective ([509]). Anthracycline extravasations may progress to ulceration more often, and one uncontrolled study suggests that topical application of dimethyl sulfoxide can prevent this complication ([510], [511]).

PHARMACOLOGIC MANAGEMENT OF CANCER PAIN

Control of cancer-related pain is one of the most important aspects of supportive care for patients who receive antineoplastic therapy or for those with an advanced stage of cancer. Other coexistent conditions, such as depression, malaise, fatigue, anorexia or cachexia, dyspnea, and weakness, also influence the perception of pain by the patient and must be addressed simultaneously. Knowledge of the pathogenesis of cancer pain, pain assessment techniques, and various analgesics is important for appropriate pain management. Satisfactory pain relief depends on the ability to treat the primary source of the pain, to alter the central perception of pain, or to block the transmission of pain to the CNS. Ideally, this is done while preserving performance and cognition. Invasive procedures are rarely necessary, and pain control is achieved in 85 to 95% of patients through integrated pharmacologic, nonpharmacologic, and anticancer therapy ([512], [513] and [514]).

Types of Cancer Pain

Several types of cancer-related pain are recognized. The manner in which pain is described often gives a clue to the source and etiology of the pain. Pain may result from tumor pressure on adjacent structures (70%), from anticancer therapy (approximately 20%), or from cancer-induced syndromes, such as paraneoplastic syndromes (<10%), or it may be unrelated to the cancer (3 to 5%) ([515], [516]). The concept of a pain threshold is highly subjective and is dependent on the complex interplay between emotional, spiritual, and cultural factors, in addition to the physical effects of malignancy. Pain is often classified as nociceptive, neuropathic, or sympathetically maintained. *Nociceptive pain*, as the name describes, is due to the activation of somatic or visceral nociceptors, with the common example being pain due to bony metastasis. *Neuropathic pain* is typically due to injury to the nervous system structure and is described by patients as a burning type of pain.

Sympathetically maintained pain is less commonly seen in cancer patients and is associated with brawny edema, burning discomfort, allodynia, and hyperpathia.

Obstacles to Pain Management

Studies show that approximately 50% of patients with cancer receive inadequate analgesia ([515]). Several factors lead to pain undertreatment; a discrepancy between patients and physicians in judging the severity of pain, ignorance about types of pain and lack of pain assessment skills in the health care providers, and an unfounded fear of opioid addiction and tolerance among health care professionals and patients. The perception that opioid analgesia is to be used only in the advanced or terminal stages of malignancy, fear of scrutiny by regulatory agencies, and cost and drug procurement considerations are among the other reasons ([515] , [517] , [518] and [519]). True psychological addiction rarely occurs in patients with hematologic and other malignancies, and there is no reason for hesitation in prescribing narcotic analgesics at effective doses for patients with cancer pain ([520]). When given for long periods, physical dependence on opioids may occur, but this should not be taken to imply drug dependence in a global sense and can be managed by gradual tapering of narcotic analgesics, if the source of the pain has been eliminated, or pain transmission has been blocked.

Pain Assessment

A detailed history of pain is an essential component of pain assessment. Many instruments have been developed to assess pain, because pain is subjective, and the patient can best guide therapy. When possible, using one of a number of simple pain rating scales (verbal or numeric), such as the Wisconsin Brief Pain Inventory or the Memorial Pain Assessment Card, which have been shown to be remarkably reliable indicators of pain intensity ([521] , [522] and [523]). A modified pictorial version of the Wisconsin Brief Pain Inventory has been used in patients who cannot read or comprehend the written scale. Responses are then interpreted according to a three-step analgesic ladder (Fig. 75.11), which was developed by the World Health Organization, to decide the level of analgesic therapy that is required. Mild pain is given a rating of 1 to 4, moderate pain is given a rating of 5 to 6, and severe pain is given a rating 7 to 10. Pain that is rated as 5 or greater is considered substantial and interferes with the quality of life ([524]). Other available tools for pain assessment include the Hopkins pain rating instrument, which is a modification of the visual analog scale, and the Edmonton staging system for cancer pain, which uses several patient characteristics to assess the likelihood of response to therapy ([519] , [525]). After a thorough history and physical, laboratory testing and noninvasive radiographic techniques might help determine the etiology of pain and better direct therapy.

Analgesic Agents

The inflammatory and mechanical effects of tumor growth in surrounding tissues can lead to the release of several cytokines, such as bradykinin, prostaglandins, and serotonin, which can trigger pain in patients with cancer. Nonsteroidal antiinflammatory drugs (NSAIDs) exert their analgesic and antiinflammatory effects by blocking prostaglandin synthesis. According to World Health Organization guidelines, the treatment of patients with mild to moderate pain should begin with a nonopioid (step 1) analgesic drug, and, as long as pain persists, the dose should be titrated upward until the maximal dose has been reached. Step 1 agents include NSAIDs, such as aspirin, naproxen, ibuprofen, and acetaminophen. A step 2 opioid analgesic may also then be added to the regimen, and the dose is titrated accordingly. Only one drug from each of the groups should be used at the same time, and doses should be given on a regular schedule, so as to maintain continuous pain relief. Included in the step 2 group of drugs are codeine, dihydrocodeine, hydrocodone and oxycodone (in combination with acetaminophen), and propoxyphene. If pain of level 5 or greater persists, and further increase in the dose of the step 2 agent is impractical, change to a step 3 opioid is indicated. The dose of the step 3 opioid is increased if mild to moderate pain persists. Single-agent oxycodone, hydromorphone, fentanyl, and morphine are step 3 opioids ([526] , [527]). These guidelines have demonstrated efficacy in improving pain control in cancer patients ([528] , [529]) (Table 75.12). The toxicities and dosage threshold of nonopioid analgesics limit their role in cancer analgesia. For example, the total dosage of acetaminophen, for example, should not exceed 6 g/day, and dosages between 4 and 6 g/day may be hepatotoxic in patients with underlying liver dysfunction. NSAIDs carry the risk of GI distress, bleeding, and renal toxicity. Availability of the selective COX-2 inhibitors with reduced GI toxicity and antiplatelet effects may help override this problem with the NSAIDs. However, reports of some degree of GI toxicity with the COX-2 inhibitors demand caution when using these drugs in cancer patients ([530]).

TABLE 75.12. Guidelines for Adjuvant Drug Use in Cancer-Related Pain

Drugs	Oral Dose (mg/day)	Indication/Type of Cancer Pain
Nonsteroidal antiinflammatory drugs		
Choline magnesium trisalicylate	3000	Bony metastases, soft-tissue infiltration, serositis, arthritis
Ibuprofen	2400	—
Naproxen sodium	1100 to 1650	—
Sulindac	300 to 400	—
Indomethacin	150 to 200	Postoperative pain
Ketorolac	60 to 120 IV (give for no more than 5 days)	—
Corticosteroids		
Prednisone	40 to 120	Perineuronal edema, lymphedema, soft-tissue infiltration, nerve compression, visceral distention, [b] and intracranial pressure
Dexamethasone	8 to 24	—
Methylprednisolone (=40 to 80 mg dexa-methasone equivalent IV for severe acute [b] ICP or spinal cord compression)	32 to 96	—
Tricyclic antidepressants [a], [b]		
Amytriptyline	50 to 150	Neuropathic (dysesthetic pain)
Nortriptyline	50 to 150	Rectal tenesmus
Desipramine	50 to 200	—
Chlorimipramine	25 to 100	Postherpetic pain
Trazodone	150	—
Fluvoxamine	100 to 300	Depression

Fluoxetine	20	Depression, diabetic neuropathy
Neuroleptics		
Chlorpromazine	10 to 25	Rectal tenesmus, vomiting
Haloperidol	2.5 to 5.0	Vomiting
Prochlorperazine	5 to 10	Vomiting
Anticonvulsants [a], [b]		
Carbamazepine	400 to 1600	Neuropathic pain (including nerve compression and infiltration)
Sodium valproate	400 to 600	—
Phenytoin	300	—
Benzodiazepines		
Diazepam	10	Anxiety
Clonazepam [b]	0.5 to 3.0	Muscle spasm
Triazolam	0.25	Insomnia
Oxazepam	20	Insomnia
Local anesthetics		
Mexiletine	10/kg	Diabetic neuropathy
Tocainide	20/kg	Cranial neuralgia, neuropathic pain
Miscellaneous		
Disodium pamidronate	60 to 90 IV every 2 to 4 wk	Bony metastases
Calcitonin	200 IU IV or intranasally BID	Bony metastases
Octreotide	50 to 100 µg SQ BID to TID	Bowel spasm
Bupivacaine	4 to 18 ml (0.125 to 0.25%) per h epidurally	Neuropathic pain
Clonidine	30 µg/h epidurally	Neuropathic pain
Baclofen	5 to 30 µg BID to TID	Neuropathic pain

[a] Serum drug levels should be monitored.

[b] Start at 50% of lowest dose, titrate up every few days.

Adapted from Ripamonti C, Bruera E. Pain and symptom management in palliative care. Cancer Control 1996;3:204–213 and Levy MH. Pharmacologic treatment of cancer pain. N Engl J Med 1996;335:1224–1232.

Opioid drugs are the mainstay of cancer pain therapy. Many of the step 2 opioids are problematic because of undesirable dose-limiting side effects or a long half-life, or because their combination with nonopioid analgesics precludes adequate dose titration. Hydrocodone and oxycodone, when combined with acetaminophen, cannot be given at dosages greater than 15 mg every 4 hours, or the acetaminophen dosage exceeds 6 g/day. The side effects of codeine limit its use at higher doses, and it may also be ineffective in patients who are taking drugs that inhibit its hepatic conversion to morphine (such as fluoxetine). The partial opioid agonists (such as buprenorphine) and mixed opioid agonists (such as pentazocine) are not effective analgesics and may be toxic at higher dose ranges. These drugs may also paradoxically aggravate pain in patients who are receiving full opioid agonists, such as morphine, and are therefore not recommended for routine treatment of cancer pain ([521], [531]). Patients who are given NSAIDs and opioids should be observed carefully for increased central opioid toxicity because of NSAID-induced renal and hepatic effects that may lead to the accumulation of opioid metabolites. The drug tramadol, a new centrally acting analgesic, has been recently approved in the United States for patients with moderate or moderately severe pain. A 50-mg dose of tramadol is as effective as 60 mg of codeine in patients with cancer ([532]), but tramadol may cause nausea, dizziness, constipation, sedation, or headache. It acts by binding to U-opioid receptors and by inhibiting serotonin and norepinephrine reuptake. It may be considered in patients with mild to moderate pain who are intolerant of NSAIDs and who wish to avoid opioid analgesics.

The opioid analgesic of choice in chronic cancer pain is morphine, because it is available in immediate- and sustained-release formulations and is easily titrated and consistently effective. Patients with chronic, stable pain do well on a regimen of twice-daily sustained-release morphine, with immediate-release morphine as needed for breakthrough pain. A small number of patients may require long-acting morphine every 8 hours. Oxycodone is also available in sustained-release form. In general, when switching to a different opioid, the equianalgesic dose of the new drug should be reduced by one-third to one-half to account for incomplete cross-tolerance between drugs, unless the reason for the switch is poor pain control. An exception to this rule is methadone, which should be reduced in dose by eight- to tenfold during the titration phase, as stated by clinicians who are experienced in its use ([512]). For moderate to severe pain in patients who are simply intolerant to morphine, a trial of an alternative opioid, such as methadone, hydromorphone, oxycodone, fentanyl, or levorphanol, is now recommended ([522]). Optimal methadone dosing is controversial, because it shows considerable interindividual variability in pharmacokinetics. Although methadone and morphine have similar potency, methadone must be given at lower doses and longer intervals and requires closer monitoring for redistribution from the tissues, accumulation, and toxicity; hence, the reluctance of most clinicians to use it routinely. Hydromorphone given orally exerts its peak effect more rapidly than morphine but has a shorter duration of action, often necessitating frequent administration every 2 or 3 hours. Fentanyl citrate is a highly potent synthetic opioid analgesic that has considerable epidermal absorption. Transdermal fentanyl is contraindicated in small children, in patients with generalized edema, and in the treatment of acute or postoperative pain.

There is no ceiling on the dose of an opioid analgesic; the appropriate dose is that which completely relieves pain over the entire dosing interval. Pain can usually be controlled with 240 mg or less per day of oral morphine, but those with severe cancer pain may need as much as 1800 mg/day, and, rarely, 4.5 g of parenteral morphine per hour may be required ([512]). Variation in the required dose is to be expected between individuals. However, accumulation of active metabolites of these drugs may be responsible for the late toxicity that is seen when using high doses for prolonged periods. Opioid rotation may be useful in combating adverse effects while ensuring adequate long-term pain control in these instances ([533]). Preterminal patients are often unable to communicate, but this does not necessarily imply adequate pain relief; grimacing or moaning should prompt an increase in the dose of opioid medication.

Routes of Administration and Dosing Considerations

The oral route of administration is the most optimal and least expensive, but patients who are unable to swallow tablets or liquids require other modes of administration. Subcutaneous or intravenous morphine or hydromorphone via patient-controlled analgesia pumps allows for continuous pain relief, smooth dose titration, and rapid relief of breakthrough pain in patients who require a parenteral route. Routine rectal administration of pain medication is inconvenient and unappealing to patients, but rectal morphine or hydromorphone suppositories may be used for short-term pain control in patients with advanced cancer who cannot take oral medication; buccal and sublingual formulations of morphine are also available for this purpose. Transdermal fentanyl citrate acts for 72 hours and is effective in controlling chronic, stable cancer pain; however, dose titration is difficult. Buccal fentanyl can be used for episodic breakthrough pain. The short dosing intervals that are required for buccal and sublingual opioids preclude their use for long-term pain control ([534], [535]). It is important to note that the bioavailability of most opioids is different by enteral and parenteral routes, thus necessitating a change in dosage when switching from one route to the other.

Acute pain or pain exacerbations that last less than 24 hours are best managed with medication on an as-needed basis. Sustained analgesia for persistent cancer pain is provided with round-the-clock or delayed-release medication. The primary goal is to prevent pain recurrence. Supplemental doses of opioid analgesics should always be made available to prevent and to treat pain that is apt to vary in intensity because of progressive disease, stress, or activity. The total dose of this rescue medication over a specific time interval should be equal to the regular dose that is given during that interval. For example, a patient on a regimen of 90 mg of delayed-release morphine every 12 hours should be given roughly 30 mg of immediate-release morphine to take every 4 hours as needed for breakthrough pain ([521], [529], [536]). The optimal dosing interval for analgesic drugs is determined by the type of drug that is used and the route of administration. Pain relief from controlled-release opioid formulations should last throughout the dosing interval, and, if many rescue doses are needed, the long-acting dose should be increased.

The exception to this rule occurs when an increased number of rescue doses is needed, only in special instances, and when raising the standing dose would cause undesirable side effects. The opioid dose should be increased by 50 to 100% every 24 hours in patients with severe unrelenting pain or by 25 to 50% in those with moderate unrelieved pain. Similarly, a decrease in dose titration by 25 to 50% each day is indicated in patients whose pain is resolving ([512]).

Prevention and Management of Side Effects

Opioid analgesics have many adverse side effects, and adjuvant therapies should be used whenever possible to minimize them. Neuropsychiatric effects of opioids include myoclonus, grand mal seizures, delirium, hyperalgesia or hyperexcitability, and cognitive impairment. Others include nausea, constipation, sedation, and respiratory depression. Respiratory depression, myoclonus, and seizures are rarely seen, unless the dose is inappropriately high, especially in opioid-naive patients. Other causes of these symptoms must be sought, as well. The clearance of morphine is decreased in patients who are older than 50 years of age, and dose reductions are often required. Centrally acting antiemetics, such as phenothiazines, haloperidol or droperidol, and metoclopramide, are useful in preventing and treating opioid-related nausea ([537]). Relief of constipation, which is required in all patients on chronic opioid therapy, may also help nausea in these patients. A prophylactic laxative regimen is essential in patients who receive these drugs. Urinary retention is not uncommon in older men, and Foley catheterization may be needed. Problems with sedation and cognitive impairment may be handled by allowing tolerance to take place, by using opioid-sparing analgesic drugs along with the opioid, by rotating opioids, and by treating the patient with psychostimulants (caffeine or methylphenidate). Dose reduction by 50 to 75% after withholding one or two doses is sometimes necessary. Circadian rhythms in the dose requirement may also allow for dose reductions at certain times of day. Although sedation is generally an unwelcome side effect of analgesic therapy in patients, it may be used intentionally to promote comfort in preterminal cancer pain as an adjunct to other measures. Naloxone may be given by intravenous bolus (20 to 40 µg) or by continuous infusion ([538]) to reverse severe respiratory depression that is caused by opioids if supportive measures are unsuccessful, but careful titration is necessary to avoid severe rebound pain. Delirium and confusion often respond to a low-dose neuroleptic agent, such as haloperidol (0.5 to 1 mg two to three times a day). Finally, preliminary evidence indicates that several other agents, such as baclofen, valproic acid, midazolam, and lorazepam, may be helpful in reducing hyperexcitability effects, but little of this evidence comes from controlled studies. Other strategies for overcoming opioid neurotoxicity include hydration, opioid rotation, dose reduction, and the use of adjuvant therapies ([512], [539], [540] and [541]).

For the minority of patients who fail standard pharmacologic management, formal consultation with an anesthesia or neurosurgical pain specialist may be necessary. Inability to tolerate oral or parenteral opioid analgesics at adequate doses may be an indication for spinal or epidural catheterization to reduce opioid dose requirements, but this costly and function-limiting method of analgesic delivery clearly must not be overused. In such cases, pain control may be achieved with minimally invasive procedures, such as anesthetic nerve blocks for well-localized pain and implantable epidural catheters to administer opioid analgesia via an external or subcutaneous pump for more diffuse pain ([542]). Although most useful in patients with metastatic solid tumors, it has been suggested that early use of an anesthetic approach may be considered in patients with refractory abdominal, pelvic, or rectal pain, localized severe chest wall pain, perineal pain with urinary diversions, and unilateral lower body pain.

Adjuvant Therapy

Opioid therapy alone may be inadequate for some types of malignancy-associated pain syndromes, and the use of adjuvant drugs has the advantage of reducing opioid requirements in specific circumstances (Table 75.12). Corticosteroids are helpful in pain that is caused by increased intracranial pressure, epidural metastasis, nerve compression, and soft-tissue and visceral infiltration, and they may be administered in pulses to minimize adverse side effects. A few controlled studies have documented their efficacy in cancer patients ([512], [521], [543], [544]). The NSAIDs are effective in treatment of the inflammatory component of soft-tissue infiltration, bony metastases, arthritis, and serositis. Pain that is caused by malignant bone involvement may also respond to therapy with agents that inhibit osteoclast activity, such as bisphosphonates (pamidronate) or calcitonin. Neuropathic pain that is caused by chemotherapy (vinca alkaloids, paclitaxel) is a challenging problem and can be especially distressing to patients; treatment with tricyclic antidepressants relieves pain in some but not all patients in 2 to 4 weeks. Nortriptyline and desipramine are the preferred drugs in this class, because they have fewer side effects than amitriptyline at higher doses. They are initially begun at a low dose (10 to 25 mg) and are titrated upward to 100 to 150 mg for effect. Antidepressant effects are seen in the higher dose range, may boost pain tolerance at the same time, and also help with insomnia in some patients. Other drugs that are effective in neuropathic pain include mexiletine, baclofen, and certain anticonvulsants (carbamazepine and clonazepam), which may be used alone or in combination with full-dose antidepressants. Careful monitoring for myelosuppression and other side effects is necessary ([512]).

MISCELLANEOUS ISSUES

Infertility and Sexual Dysfunction

Sexual dysfunction after treatment of cancer may be seen in a large number of patients and may be underreported. A recent review reported an incidence of sexual dysfunction that ranged from 40% to almost 100% ([545]). More patients are surviving aggressive therapy for hematologic malignancies that develop during childhood or the early reproductive years. Long-term chemotherapy and radiation effects on fertility and sexual function are therefore major quality-of-life considerations for many patients and their families. These issues should be discussed with patients during initial counseling sessions when deciding on the timing and nature of the treatment regimen. The chemotherapeutic agents that are most apt to affect fertility are alkylating agents (such as nitrogen mustard and cyclophosphamide) and cisplatin. Single-agent melphalan may be more fertility sparing in women of reproductive age ([546]). The patients that are best studied are those that undergo BMT ([547], [548]) or therapy for Hodgkin disease ([549], [550]).

Patient age, sex, the total dose and schedule of drugs administered, and the inclusion of radiotherapy are the most important factors that determine the long-term effects of therapy on sexual development and fertility ([551]). The addition of high-dosage busulfan (16 mg/kg) to cyclophosphamide as a preparative regimen may impair pubertal development and gonadal function in adolescents, thus necessitating sex hormone replacement. Adolescent girls who undergo radiation therapy as conditioning for BMT often experience delayed menarche or primary amenorrhea and require sex hormone replacement. In contrast, boys usually recover Leydig cell function, unless they receive radiation to the testicles, and rarely need testosterone replacement. Prophylactic cranial irradiation for ALL may also retard pubertal development ([552]). Among adults, conditioning with chemotherapy results in infertility only in some patients, the reversibility of which is age and dose dependent. Sterility is to be anticipated after TBI-based preparative regimens. Spontaneous recovery of ovarian function and spermatogenesis is uncommon but has been reported in patients after TBI ([553]).

Potency and libido are usually unaffected by chemotherapy in men ([554]), whereas secondary amenorrhea is often associated with menopausal symptoms, decreased libido, and dyspareunia in women ([555]). Clearly, the systemic effects of chemoradiotherapy; other medications, such as narcotics; and the alterations in body image that occur in cancer patients can profoundly affect the expression of sexuality ([556], [557]).

There is considerable controversy among health professionals regarding the usefulness of sperm banking for male patients before initiating antineoplastic therapy. Physicians may be reluctant to recommend sperm banking for a variety of reasons, including concern about delaying chemotherapy to accommodate semen collection, discomfort in discussing issues of a sexual nature, and the perception that the quality of cryopreserved semen that is obtained from patients with cancer is generally poor ([557], [558], [559] and [560]). Significant treatment delays may result if specimen volume and quality are low, and as many as eight collections that are obtained 2 to 3 days apart are needed ([561]). Although cryopreservation and some malignancies, such as Hodgkin disease, decrease sperm viability, several studies report a reasonable success rate in inducing pregnancy by using cryopreserved semen ([554], [562]). Banking is feasible if the sperm count is at least 20 million/ml, and motility is 60%, but these numbers are not known before a collection attempt ([563]). Sperm banking should therefore be offered to most patients before initiation of therapy if the required delay is not deemed harmful.

A satisfactory method of oocyte preservation has not yet been developed. Implantation of embryos that are generated from *in vitro*–fertilized autologous ova has resulted in at least one successful pregnancy after allogeneic BMT ([564]). This technique is feasible in women whose disease permits time for ovarian hyperstimulation pretransplant and whose risk of subsequent infertility is high.

Pregnancy

Fortunately, the diagnosis of a hematologic malignancy in pregnancy is rare. Whereas pregnancy itself is not known to alter the prognosis of leukemia, it greatly complicates treatment of the mother and the pregnancy. Fetal anomalies are unlikely, provided that teratogenic chemotherapy is begun after the first trimester of

gestation ([565]). The risk of preterm delivery, perinatal complications, and birth defects is increased whenever alkylating agents or folic acid antagonists are used, however, and the patient should be so advised. Most physicians recommend termination of a first-trimester pregnancy if treatment of the mother's disease cannot be postponed. If a leukemic patient still wishes to continue the pregnancy, leukapheresis may be a helpful temporizing measure, but definitive therapy may be unavoidable ([566]). In patients with non-Hodgkin lymphoma (NHL) or Hodgkin disease, therapy is delayed, unless there is rapid disease progression ([567]). Radiation therapy should be avoided altogether in the first trimester and to fields below the diaphragm thereafter. The anticipated fetal dose can be calculated before therapy; doses greater than 10 rads require termination of the fetus ([568]). Modified radiation fields and doses and abdominal shielding can be used if radiation is to be given to fields above the diaphragm ([569]).

Psychosocial Support

Initial discussions with patients who are diagnosed with a hematologic malignancy necessarily focus on prognosis and therapeutic options. However, a diagnosis of cancer has huge personal, social, and economic ramifications for patients and their families ([570] , [571]). The coping skills of individual patients and families vary widely. Anxiety disorders, clinical depression, and cognitive impairment are among the most common psychological complications in patients with cancer, the recognition and treatment of which can also alleviate suffering considerably ([572] , [573] , [574] , [575] and [576]). It is therefore important to anticipate these problems, when possible, and to marshall the help of a dedicated social worker, counselors, nursing staff, and, when indicated, a psychiatrist who is knowledgeable about cancer therapy. Preexisting psychiatric problems should be explored before embarking on major therapeutic maneuvers. Patients who undergo BMT experience considerable psychological stress and need special support ([577]). Assessments of how the patient and his or her family are dealing with the disease should be made at regular intervals from the time therapy is initiated through its completion and particularly when therapy fails ([578]). Unrelieved pain, depression, delirium, a family history of suicide, lack of psychosocial support, and substance abuse are risk factors for suicide in patients with cancer ([579] , [580]). Prognostic information should be imparted in a consistent manner by members of the health care team who are directly responsible for management decisions and who have rapport with the patient and family. Furthermore, spouses, relatives, and patients alike should be strongly encouraged to be as open as possible about the illness. Efforts to protect a person by withholding unpleasant information generally fail; they also deprive patients of the opportunity to participate in their care and discuss their fears. However, direct patient involvement in discussions about disease and death is alien to some cultures, and these differences should also be respected ([581] , [582]). Some patients ask pointed questions about how and when death occurs and should receive a candid answer; others may not wish to discuss these issues at all ([583]). It is therefore necessary to tailor one's approach to the individual patient ([584]). Such an approach clearly requires a significant commitment of time to detailed and, above all, unhurried discussion with the patient and family, often with repetition of facts that may seem obvious. Facilitating the practice of religious and cultural beliefs can also be therapeutic. Existential concerns that transcend religious faith are common in terminally ill patients and may be handled by consultation with a chaplain who is experienced in this area ([585] , [586]).

One must be alert to the special needs of family members and spouses in caring for ill patients, so that substantive help in the form of a home health or hospice nurse may be arranged. Special counseling should be offered to young children when a parent is critically ill or dying and to pediatric patients with hematologic malignancies, as serious behavioral problems and learning disabilities may be averted ([587] , [588]). Encouraging self-care and limited work or exercise, as tolerated, can contribute greatly to the sense of well-being ([589]).

Palliative and Terminal Care

ADVANCE DIRECTIVES, ESCALATION OF CARE, AND WITHDRAWAL OF LIFE SUPPORT Quality of life is an uncommon endpoint in supportive care trials, in part because it is hard to measure ([590]). Ongoing discussion of the goals of treatment and quality-of-life issues is particularly important in palliative care and reaffirms the ethic of patient self-determination and autonomy in decision making ([591] , [592] , [593] and [594]). It includes discussion of advance directives, living wills; assignment of a health care proxy or durable power of attorney; or documentation of the circumstances under which a “do not resuscitate” order should prevail. Preferences regarding resuscitation should be investigated (and documented) after the patient has had ample time to assimilate information about the disease and prognosis but before the development of complications that impair competence ([595] , [596]). Physicians often hesitate to discuss the possibility of treatment failure, serious complications, or death, even in patients whose deterioration is predictable ([597]), but these physician attitudes appear to be changing ([598] , [599]). Clarification of the patient's wishes and expectations at the outset relieves the burden on family members, who may be called on to act as surrogates without knowledge of the patient's wishes. Greater emphasis on communication should obviate legalization of physician-assisted suicide or euthanasia ([600]). The decision to escalate care in patients with hematologic malignancies may be straightforward, as in the case of a patient with single-organ dysfunction who is being treated with curative intent. It is not so clear-cut in elderly patients with multiple medical problems and in patients who have recurrent or persistent disease after therapy. In such instances, factors that contribute to the acute decline and the overall potential for meaningful recovery must be weighed carefully and discussed with the patient (if possible) or a surrogate before deciding how to proceed ([601]). Treatment of depression, nausea and vomiting, and pain may significantly alter patient choices ([602] , [603]). When the patient is incompetent, and the efficacy of further treatments is uncertain or controversial, prior directives should be exercised fully ([604] , [605]). If the reversibility of the problem is unclear, or the patient's wishes regarding resuscitation are uncertain, it is prudent to provide maximal support for 24 to 72 hours, allowing time for clarification of the prognosis before withdrawal of support ([606]). The statistical likelihood of recovery, which is extremely small when there is failure of more than two organ systems, may be estimated by using the multiorgan dysfunction score. The multiorgan dysfunction score is a useful objective parameter to consider in conferences between the health care team and the family ([607]). Involvement of an impartial medical ethics committee is rarely necessary. Life-prolonging measures, including mechanical ventilation, the use of pressor medications, chest compressions, and cardiac defibrillation should not be allowed to delay death when death is deemed inevitable. Withdrawal of life-sustaining measures that have already been instituted requires education of the family in what to expect and, when properly performed, causes no discomfort ([608]). The practice of medicine is founded on the principle of preserving all human life, but patient comfort and quality of life become paramount when medical therapy has little to offer. The physician's primary role then is to assist the patient, family, and other caregivers in specific interventions that provide comfort and as much control over their lives as possible. The pace of hematologic malignancies may not afford patients time to plan their final days, but the patient should make choices whenever possible. Those patients who wish to die in the hospital should be allowed to do so. Most studies do not show that terminal care that is performed in the home with skilled nursing is more cost-effective than in-hospital care. The optimal arrangement for outpatient care depends on the nature and extent of further therapy to be provided. The feasibility of home care must be assessed in each case. Enrollment in a hospice program is only one of several options for the terminally ill ([609]). Other alternatives include using family support systems that are already in place, often with added training and assistance by a home health nurse in the initial phase of home care. Patients should be informed that no decision is irrevocable and that hospitalization for comfort remains an option if attempts to care for the patient at home are unsuccessful. Most patients are much more fearful of the conditions that lead up to death—the symptoms of advancing disease—than of death itself. They need to be given some idea of what to expect (death from infection being the most common) but should be reassured that pain, nausea, dyspnea, and other discomfort can be relieved effectively. Overt hemorrhage is a rare occurrence in end-stage hematologic disease.

NUTRITIONAL SUPPORT

Patients with hematologic malignancies are extremely heterogeneous with respect to their nutritional status and requirements. Malnutrition appears to be multifactorial in these patients and could be due to a combination of several factors, such as underlying disease, complications of treatment of the disease (e.g., nausea and vomiting, anorexia, mucositis, diarrhea, esophagitis, and gastritis) and altered metabolism. In few situations, multiorgan toxicity (skin, lungs, liver, and kidneys) may be an important contributing factor. Patients who receive intensive combination therapy for aggressive leukemias and lymphomas are at particularly high risk of becoming malnourished ([610] , [611] and [612]). Serial evaluations of the nutritional status by a multidisciplinary team, which includes a physician, a nurse, pharmacist, dietitian, and, sometimes, a speech therapist, is therefore essential in all patients with a hematologic malignancy.

Hypermetabolism

Children and adults with leukemia exhibit greatly accelerated resting energy consumption and protein turnover and reduced resting energy expenditure during the first few days of chemotherapy, which then becomes stable. Such an effect has been shown in some lymphoma patients too, not during their initial chemotherapy cycle (first cycle), but more so in the subsequent cycle (third cycle) ([613] , [614] and [615]). Fever, opportunistic infection, and other stresses once again increase metabolic rate and protein loss during the neutropenic period ([615] , [616]). Moreover, the cytokine mediators of tumor cachexia and sepsis (TNF-a, IL-1, IL-2, IL-6, and interferons) promote anorexia and weight loss due to hypocaloric intake ([617] , [618]).

Protein-Calorie Malnutrition

Protein-calorie malnutrition is uncommon at presentation; weight loss of more than 10% occurs in only a minority of patients in the 6 months preceding diagnosis ([619]). It is most likely to occur in bone marrow transplant recipients, patients with high-risk acute nonlymphoblastic leukemia (ANLL) and ALL, and patients who are undergoing chemotherapy for NHL that involves the GI tract. The resulting impaired cell-mediated and humoral immunity leads to alterations in the normal flora, diminished levels of secretory IgA antibody, and reduced resistance to all types of infection ([620], [621] and [622]). Gram-negative bacteremias that arise because of invasion of microorganisms across a damaged enteric mucosa are also potentiated by mucositis. Preexisting malnutrition has been known to adversely affect survival in patients with NHL ([623]). The impact of nutritional deficits on growth and psychomotor development in children is well recognized. Overly aggressive nutritional supplementation should be avoided in severely malnourished patients, because it may lead to refeeding edema, possibly as a result of carbohydrate effects on renal sodium handling when protein stores are low ([618]).

Nutritional Assessment

The assessment of nutritional status and needs during chemotherapy must take into account the extent and duration of prior weight loss and dietary deficiency. The serum albumin, prealbumin, and transferrin levels may be unreliable measures of true nutritional status in patients who are undergoing aggressive chemotherapy ([624]). Energy expenditure may be estimated in patients who are not severely ill or may be calculated in severely ill patients by using the Harris-Benedict equations, with adjustments for periods of stress, such as sepsis (Table 75.13) ([625]). Free water needs are modified by the presence of cardiac, respiratory, or renal dysfunction and GI or insensible losses. Care must be taken to avoid negative nitrogen balance, especially in critically ill patients who experience protein catabolism to meet increased energy requirements. Nitrogen needs are estimated from urinary nitrogen excretion and usable dietary protein content. No more than 60% of calories should come from carbohydrates in patients with respiratory failure, because carbohydrates increase carbon dioxide production and ventilatory demand. A daily record of caloric intake that is obtained by a dietitian is useful in serial evaluation, especially in critically ill patients whose weight may not accurately reflect nutritional adequacy because of organ dysfunction or hypervolemia. Indirect calorimetry, when available, may be extremely helpful in ensuring adequate nutritional therapy in severely ill and mechanically ventilated patients while preventing the metabolic complications of overfeeding ([625]). In pediatric patients, the use of growth charts and serial weight to height ratios yields valuable information regarding early or chronic malnutrition and the need for urgent intervention. Children who fall below the tenth percentile in weight to height ratio and adults with more than a 10% weight loss over 10 months usually require nutritional supplements in conjunction with the treatment of symptoms that interfere with intake. Pediatric or adolescent patients who are receiving TBI, cranial irradiation, or transplant conditioning chemotherapy also exhibit slowed height velocity, and a fall below the fifth percentile for height according to a standardized chart signals the need for further evaluation ([626], [627] and [628]).

TABLE 75.13. Effect of Critical Illness on Resting Energy Expenditure

Patient's Condition	Stress Factor	Estimated Daily Energy Expenditure (kcal/kg)
Minimal illness or minor surgery	1.2	25
Moderate stress or trauma	1.35	35
Sepsis or severe trauma	1.6	45
Severe burns	2.1	80

Adapted from Zakko W, Van Dam J. Techniques for nutritional assessment. Tips for designing an effective enteral feeding regimen. J Crit Illness 1996;11:405–412.

Enteral Nutrition

Use of the oral route for nutritional support prevents mucosal atrophy and is clearly the most physiologic way to nourish patients. Vigorous treatment of nausea and emesis, diarrhea, metabolic disturbances, and other compromising conditions facilitates oral intake. However, most patients who receive aggressive chemotherapy regimens experience dysgeusia and varying degrees of mucositis that necessitate nutritional supplementation by other routes. Consultation and follow-up by a trained dietitian facilitate nutritional supplementation that is palatable and best meets the needs of the individual patient. Use of continuous drip, in contrast to intermittent or bolus feedings, and enteral formulas that are lower in fat, lactose, and tonicity may be appropriate if malabsorption is a problem ([625], [629]). If persistent anorexia, gastric dysfunction, or severe dysphagia is present, the use of alternative enteral routes may be justified. These options include the placement of a percutaneous gastrostomy or jejunostomy tube (if more than 6 weeks of enteral supplementation is anticipated). Nasoenteric tube feeding is favored over gastrostomy if significant gastric dysfunction or aspiration is present.

Several legitimate concerns regarding tube feeding have discouraged its use in patients with hematologic neoplasms. Delivery of tube feeding in a volume that is sufficient to meet caloric needs is difficult in patients with diarrhea, nausea and vomiting, and mucositis. Bleeding and discomfort that are caused by irritation by the tube and aspiration may occur. Second, increased rates of bacterial and yeast colonization of the gut and bacteremias have been reported in patients who are immunosuppressed and who are receiving peptic ulcer prophylaxis ([630], [631] and [632]). The use of a closed, sterile feeding system, sterile formulations, and restricted infusion times (less than 8 hours at room temperature) are important safeguards against infection ([632], [633]). Tube feedings should be withheld and cultured if diarrhea or fever develops.

Parenteral Nutrition

Patients who are unable to eat are usually given TPN with follow-up by a hospital nutrition service. Malnutrition in children with acute leukemia and advanced NHL has been reversed by the use of TPN ([634]). Significantly improved long-term survival with TPN in bone marrow transplant recipients has been demonstrated in one large-scale, randomized study, although no impact on engraftment times, bacteremias, or incidence of GVHD was noted, and smaller studies have had conflicting results ([635]). Hematopoietic recovery after chemotherapy of ANLL and in transplant recipients may be accelerated by TPN administration ([636], [637]), but improved survival in ANLL or lymphoma patients has not been documented.

Various TPN solutions are available. Whether modulating the content of micronutrients or the composition of protein in TPN is helpful in reducing muscle catabolism or hepatic encephalopathy is controversial ([638], [639] and [640]). Certainly, requirements for specific electrolytes, vitamins, and minerals vary considerably among patients. Adjustments must often be made to account for impending tumor lysis, insensible losses, and medication effects on the kidney, liver, and gut. The addition to TPN of certain nonessential amino acids that are normally absent from adult parenteral formulations (such as taurine and glutamine) may be of benefit in ameliorating liver dysfunction or mucositis in marrow or blood stem cell transplant recipients ([641], [642]). Insulin is added to TPN in patients with diabetes mellitus or steroid-induced glucose intolerance. Finally, patients with significant sloughing of skin or hemolysis should receive folate supplementation.

Lipid requirements are generally 25 to 30% of total calories. Intravenous lipid emulsions should be infused over at least 12 hours to minimize potential adverse effects on reticuloendothelial cell function and inflammatory responses that have been reported with bolus administration ([643]). Marrow transplant recipients who receive standard versus low daily doses of lipid have not been found to differ with respect to the incidence of bacterial or fungal infections ([644]).

Nutrition in Transplant Hematology

The factors that affect nutrition in marrow transplant recipients are extremely complex. Failure to thrive and chronic malnutrition are not uncommon in allogeneic transplant recipients, who are usually catabolic because of prolonged corticosteroid therapy. In the early posttransplant period, a capillary leak syndrome that results from hepatic VOD or sepsis may lead to third-space edema, intravascular volume depletion, and renal hypoperfusion. If urinary output is normal in VOD, restriction of total sodium and fluid intake (as with concentrated TPN) and spironolactone may be beneficial ([645]). When renal failure necessitates hemodialysis, the levels of

fat-soluble vitamins and serum triglycerides must be monitored to avert toxicity that is caused by decreased clearance of these nutrients ([646] , [647]).

Protein and electrolyte losses are particularly high in acute GVHD that involves the lower GI tract, which manifests as a secretory diarrhea that contains varying amounts of mucus, blood, and sloughed epithelium. The diarrhea is exacerbated in hepatic GVHD by steatorrhea that is caused by derangements in bile salt synthesis and enterohepatic circulation ([648] , [649]). Magnesium supplementation, which is needed to replace renal losses that are caused by cyclosporine, should be given via the intravenous route because of bloating and diarrhea that is associated with oral forms. Complete bowel rest and TPN support are necessary, with close monitoring of stool volumes until the diarrhea responds to immunosuppressive therapy. When abdominal cramping, distention, and diarrhea subside, oral intake is gradually resumed. Initially, isoosmolar liquids are introduced, followed by foods that are low in fat, lactose, fiber, and acidity ([650]). Even after overt healing of the intestinal mucosa, however, mucosal absorptive capacity may remain abnormal ([651] , [652]). Severe acute GVHD that involves the skin leads to large fluid and protein losses that must be replaced, depending on the percentage of skin surface that is involved. Significant cholestasis that is caused by acute GVHD of the liver or other causes requires elimination of copper and manganese from TPN, because these substances are normally excreted in bile. Pretransplant protein restriction may help to prevent azotemia but is inadvisable in most transplant recipients, whose protein needs are high, and it does not reduce the risk of acute GVHD through limitation of antigenic exposure, as was once proposed ([653]). Chronic GVHD has profound effects on all aspects of nutrition ([654]).

CONCLUSION

Supportive care is clearly an essential component in the management of patients with hematologic malignancies. There have been several advances in this field that have resulted in improved quality of life in these patients. It is hoped that more studies in this rapidly evolving area will include quality of life as an endpoint and cost-benefit analyses to aid the clinician in choosing the appropriate prophylactic and therapeutic interventions.

ACKNOWLEDGMENT

I wish to thank Dr. Asha Khallianpur, who created the format of this chapter in the previous edition; the same format was used with some modifications in the current edition.

Molecular Genetics of Acute Leukemia

Molecular genetic analysis of acute leukemia has been at the forefront of research into the pathogenesis of cancer because the presence of recurring chromosomal translocations provides immediate clues to the genetic events leading to leukemia and the means to clone and identify the dysregulated oncogenes. On the other hand, the classification of acute leukemia has until recently been on the basis of morphology (FAB classification) and immunophenotype [acute myelogenous leukemia (AML) vs. acute lymphoblastic leukemia (ALL)]. The recognition of distinctive morphologies that correlate with specific translocations and the development of treatments that are based on specific genetic defects has led to acknowledgment of the importance of these recurring translocations in the classification of acute leukemia. A subset of the new World Health Organization classification of AML is entitled “acute myeloid leukemia with recurrent genetic abnormalities”([1]), as is described in detail in Chapter 77.

In this chapter, the focus is on a description of the more common genetic abnormalities found in acute leukemias, with special emphasis on what these genetic defects indicate about the pathogenesis of acute leukemias. Specific examples are given when this basic science information has led or is leading to development of molecular inhibitors as specific therapies with far fewer side effects than traditional chemotherapy. This is truly an exciting time for hematologic oncology when the bench and the bedside have finally met.

In the majority of childhood acute leukemia and 54 to 78% of adult AML, cytogenetic abnormalities are detected on karyotype analysis of peripheral blood or bone marrow ([2]). Large clinical studies of both AML and ALL have demonstrated that the pretreatment diagnostic cytogenetics is one of the most valuable prognostic indicators for acute leukemia. Results from these studies are routinely used to classify a leukemia as favorable or unfavorable, as listed in Table 76.1 and Table 76.2 for adult AML and pediatric B-ALL, respectively.

A theme in the translocations found in acute leukemia is that the majority of these translocation events produce a fusion gene that encodes an aberrant protein in which the 5' end of one translocation partner encodes the N-terminal protein sequence of the fusion protein, and the 3' end of the other translocation partner encodes the C-terminal protein sequence of the fusion protein. This is in contrast to many of the balanced translocations found in non-Hodgkin lymphoma, in which the intact coding sequence of an oncogene is translocated into a region where it is under the abnormal regulation of enhancer sequences highly active in lymphoid cells.

The fusion genes produced by the translocation event in leukemia encode aberrant proteins that have altered functional properties. Presumably, these altered properties are the pathogenetic basis of the leukemia. A large percentage of these aberrant proteins are transcriptional regulatory proteins that often preserve the original DNA binding specificity of one of the fusion partners but have altered properties of transcriptional activation or repression. The search to understand these altered properties has led investigators to basic discoveries of how transcriptional regulatory proteins modify chromatin structure to open up or inhibit the transcription of target genes. The search for the sets of genes targeted by these altered transcriptional regulators that are most directly involved in leukemogenesis has proven difficult. The majority of this chapter describes recurrent translocations that encode aberrant transcription factors. Additional functional categories of fusion proteins produced by recurrent translocations include kinases, inhibitors of apoptosis, and nuclear pore proteins.

Another theme that emerges from the study of leukemia with recurring translocations is that usually more than one genetic hit is necessary for the development of leukemia ([3]). This principle has been repeatedly demonstrated by animal models in which introduction of the fusion gene found in acute leukemia into mice via transgenic technology or retroviral transduction results in mice with a predisposition to acute leukemia with long latency, unless the accumulation of additional genetic hits is facilitated by treatment with a mutagenic agent. The discovery of frequent FLT3 mutations in leukemias with recurring translocations supports the hypothesis that multiple genetic defects are involved in leukemogenesis.

Finally, the breakthroughs in understanding of the molecular genetics of leukemia in the 1990s have had a direct and major impact on clinical treatment. The paradigm for the translation of basic research knowledge to clinical treatment has been chronic myelogenous leukemia (CML). The first leukemia to be associated with a recurrent translocation, the Philadelphia chromosome ([4]), CML was also the first leukemia in which the product of the translocation, BCR-ABL, was characterized ([5]). That BCR-ABL is directly involved in the pathogenesis of CML has been shown in mouse models in which efficient retroviral transduction of murine bone marrow stem cells results in induction of a CML-like disease in 100% of recipient mice ([6]). The constitutive tyrosine kinase activity of BCR-ABL is necessary for transformation as demonstrated by mutational analysis ([7]). This knowledge provided the basis for designing a specific inhibitor of the active site of the ABL kinase, STI571 [also called *imatinib* or *Gleevec* ([8])]. STI571 blocks access of adenosine triphosphate (ATP) to the kinase pocket, inhibiting the ability of the kinase to phosphorylate substrates (Fig. 76.1). Current results of phase 2 trials demonstrate a complete hematologic remission in 95% of patients in chronic phase of CML and a major cytogenetic response in 60% of patients using a drug with many fewer side effects than conventional treatment ([9]). In the following discussion of the recurring translocations in acute leukemia, the pathogenesis of leukemia and the possibilities for development of molecular therapies are emphasized.

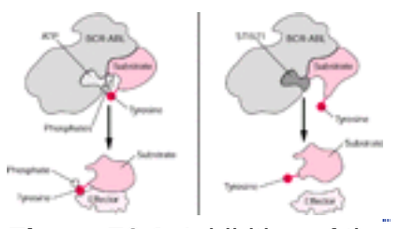

Figure 76.1. Inhibition of the active site of BCR-ABL by STI571. The BCR-ABL oncoprotein is shown **(A)** with a molecule of adenosine triphosphate (ATP) in the kinase pocket. The substrate is phosphorylated on a tyrosine residue using the phosphate group donated by the ATP. The phosphorylated substrate then interacts with downstream effector molecules. When STI571 occupies the kinase pocket **(B)**, ATP cannot enter, and the substrate is not phosphorylated. (From Goldman JM, Melo JV. Targeting the BCR-ABL tyrosine kinase in chronic myeloid leukemia N Engl J Med 2001;344:1084–1086, with permission.)

TRANSLOCATIONS INVOLVING TRANSCRIPTIONAL REGULATORS

Transcriptional Regulation

In the majority of recurring translocations in acute leukemia, at least one of the genes involved encodes a transcription factor so that the fusion protein product is an aberrant transcriptional regulatory protein. In this section, the major classes of transcription factors involved in translocations are discussed. Structure-function studies of the properties of aberrant fusion proteins have elucidated fundamental mechanisms of transcriptional regulation. These are briefly summarized before the description of individual models of transcriptional deregulation.

DNA is packaged into chromatin as nucleosomes, consisting of 146 bp of DNA wrapped around a histone core comprised of two molecules each of histones H2A, H2B, H3, and H4 ([10]). Interaction of the histones and DNA is such that histone tails reach to the exterior of the nucleosome and contact DNA to add to the stability of the complex. One way in which transcription factors can act as activators and repressors of transcription is to regulate the tightness of the DNA-histone interaction ([11]). If the available lysine residues in the histone tails are acetylated, the negatively charged acetyl group is repelled from the negatively charged DNA backbone, and the histone-DNA interaction is destabilized (Fig. 76.2A) ([12]). This results in more access of the gene promoter DNA to transcription factors and the transcriptional machinery. Conversely, if the lysines of the histone tails are deacetylated, then the histone-DNA interaction is stabilized, and the promoter is less accessible (Fig. 76.2B). Therefore, transcriptional activators generally are associated with coactivator proteins, such as p300/CBP and pCAF, which have histone acetylase activity themselves or recruit histone acetyltransferases ([13], [14]). Conversely, transcriptional repressors generally are associated with co-repressor proteins, such as N-CoR (nuclear receptor co-repressor), SMRT (silencing mediator of retinoid and thyroid receptor), and mSin3, which bind to histone deacetylases (HDACs) ([15], [16]).

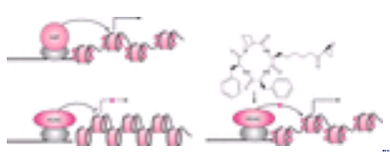

Figure 76.2. The effect of histone-modifying enzymes on chromatin structure. **A:** The oval represents an intact transcription factor contacting a coactivator with histone acetyltransferase (HAT) activity. Histone acetylation (*small sphere*) leads to a relaxed chromatin structure, allowing transcription of target genes (*straight arrow*). **B:** The altered transcription factor is a repressor, binding a co-repressor complex containing histone deacetylases (HDACs). Histone deacetylation results in condensation of the chromatin and transcriptional repression of the target gene (X). **C:** HDAC inhibitors, such as trapoxin, block HDAC activity and thereby allow acetylation of histones to occur. Therefore, the relaxed chromatin structure permits transcription of the target gene (*straight arrow*). (From Kramer OH, Gottlicher M, Heinzel T. Histone deacetylase as a therapeutic target. Trends Endocrinol Metab 2001;12:294–300, with permission.)

There are three classes of HDACs: class I (HDACs 1, 2, 3, and 8), class II (HDACs 4 to 7, 9, and 10), and class III (sirtuins 1 to 7). These are based on homology to three yeast deacetylases, rpd3, hda1, and sir2a, respectively ([17]). Class I deacetylases are more ubiquitously expressed than class II deacetylases ([18]). The role of class III sirtuins in leukemia is least understood. The above-mentioned co-repressors are associated with specific HDACs: N-CoR/SMRTs associate with HDACs 3, 4, 5, and 7 ([19]), whereas mSin3 associates with HDACs 1 and 2 ([20]).

Recently, additional complexities of the “histone code” have been decoded. First, DNA methyltransferases 1 and 3a (DNMT1 and DNMT3a) may interact with HDACs, conferring a more permanent mark of repression, DNA methylation, to the promoter targeted by the transcriptional repressor ([21]). Second, it appears that modification of histone lysines by methylation is also important in transcriptional regulation. Whether histone methylation results in transcriptional repression or activation depends on the specific lysine residues methylated and the specific transcriptional regulatory protein interaction ([22], [23]).

Retinoic Acid Receptor Translocations

One of the most elegant examples of the interaction between clinical and molecular advances in the treatment of acute leukemia is acute promyelocytic leukemia (APL). The association between the t(15;17)(q22;q21) translocation and the characteristic morphology of APL (hypergranular blasts with frequent Auer rods or microgranular variant with dumbbell shaped nuclei) has been known for a long time. The ability to treat APL with retinoic acid (RA) and the understanding of the molecular basis for this treatment is a stunning example of the power of molecular medicine. The initial report from China ([24]) that all *trans*-RA (ATRA) could induce

complete remission in APL patients actually preceded the discovery that the t(15;17) translocation involved the RA receptor a gene (*RARa*) on chromosome 17 ([25], [26] and [27]).

Of four translocations associated with APL, the most common is t(15;17)(q22;q21), in which the 5' portion of the fusion protein is encoded by the *PML* (promyelocytic leukemia) gene from 15q22, and the 3' portion is encoded by the *RARa* gene from 17q21. The *RARa* gene is a ligand-dependent steroid receptor that mediates the effects of the ligand, RA, on the cell. The breakpoint is invariant in intron 2, yielding the C-terminal portion of the fusion protein that includes the DNA-binding, ligand-binding, dimerization, and repression domains of RARa. There are three major breakpoints in the *PML* gene. The most common generates PML(L)-RARa, which includes the first six exons of *PML* encoding 554 amino acids of PML ([28]).

The wild-type RARa is a nuclear receptor that acts as a tran-scription factor and binds to RA response elements (RAREs) in the promoters of many genes, including genes important in myeloid differentiation. RARa binds as a heterodimer with retinoid X receptor protein (RXR) and acts as a transcriptional repressor until ligand (RA) binding occurs, changing the conformation of the protein and resulting in transcriptional activation ([29]). Target genes important for myeloid differentiation include granulocyte colony-stimulating factors (G-CSFs), G-CSF receptors (G-CSFRs), neutrophil granule proteins (leukocyte alkaline phosphatase and lactoferrin), cell surface adhesion molecules (CD11b and CD18), regulators of the cell cycle, regulators of apoptosis (Bcl-2), and transcription factors (RARs, STATs, HOX genes) (reviewed in reference 30). Expression of a dominant negative RARa in either a murine hematopoietic cell line or primary murine bone marrow cells, followed by stimulation with granulocyte-macrophage CSF (GM-CSF), results in arrest of granulocytic differentiation at the promyelocyte stage ([31]).

In the absence of RA, the wild-type RARa, present as a heterodimer with RXR on the RARE, binds to the co-repressor proteins SMRT, N-CoR, mSin3, and HDACs. Deacetylation of the histones at the target gene promoter results in transcriptional repression. Ligand binding at physiologic concentrations of ATRA causes a conformational change that results in release of co-repressors and recruitment of a coactivator complex (SRC-1) that associates with histone acetyltransferases (Fig. 76.3A) ([32]). Acetylation of the histones at the target gene promoter is associated with transcriptional activation (reviewed in reference 30).

Figure 76.3. Model for the role of nuclear co-repressors and retinoic acid receptor a (RARa) fusion proteins in the pathogenesis and treatment of acute promyelocytic leukemia. **A:** In the absence of all *trans*-retinoic acid (ATRA), RARa, PML-RARa, and promyelocytic leukemia zinc finger (PLZF)-RARa associate with N-CoR/sin3A/HDAC1 co-repressor complex, which deacetylates histone tails, resulting in a compressed chromatin and transcriptional repression. Binding of ATRA at a physiologic concentration induces a conformational change in RARa, causing release of the co-repressor complex and binding of coactivator (SRC-1) with histone acetyltransferase activity. Acetylation (Ac) of histone tails opens up the chromatin, facilitating transcriptional activation. **B:** In the case of PML-RARa protein, pharmacologic doses of ATRA are required to achieve dissociation of the N-CoR repressor complex. **C:** Because of additional interactions of the PLZF moiety of PLZF-RARa fusion protein with co-repressors, they do not dissociate even in the presence of pharmacologic doses of ATRA. Therefore, the chromatin still remains in the repressed state. RXR, retinoid X receptor protein. (From Guidez F, Ivins S, Jhu J, et al. Reduced retinoic acid-sensitivities of nuclear receptor corepressor binding to PML- and PLZF-RARa underlie molecular pathogenesis and treatment of acute promyelocytic leukemia. Blood 1998;91:2634–2642, with permission.)

Wild-type PML protein is normally localized in subnuclear PML oncogenic domains, also called *nuclear bodies* (NBs) in which other nuclear factors co-localize ([33]). PML may act as a tumor suppressor protein and is involved in growth suppression as well as in induction of apoptosis (reviewed in reference 30). Although it does not bind DNA directly, it influences transcription by interacting with both CBP ([34]), a transcriptional activator, and HDACs, transcriptional repressors, possibly within the NBs. The protein encoded by the PML-RARa fusion transcript resulting from the t(15;17) translocation is delocalized from the NBs to a microspeckled nuclear pattern ([35]).

In APL, the PML-RARa protein binds to RAREs with similar affinity to the RARa protein and is able to heterodimerize with RXR. It acts in a dominant negative manner, competing with wild-type RARa for binding to the RAREs. It binds co-repressor proteins in the absence of ligand (via the RARa portion of the protein). However, physiologic levels of ATRA [10^{-8} Molar (M)] are not able to convert PML-RARa into a transcriptional activator; pharmacologic concentrations are required (10^{-6} M; Fig. 76.3B) ([32], [36]). This provides the mechanistic basis for the efficacy of treatment of APL patients with ATRA to induce differentiation of the promyelocytes.

Understanding of the mechanism of the response of APL to ATRA was furthered by studies on an alternative translocation, t(11;17)(q23;q21), documented in only eight patients with APL ([37]). Patients with this translocation are resistant to treatment with pharmacologic doses of ATRA. The fusion partner gene on chromosome 11q23 encodes promyelocytic zinc finger (PLZF), a transcriptional repressor. The N-terminal portion of the fusion protein encoded by PLZF includes the N-terminal POZ-BTB protein-interaction domain, transcriptional activation and repression domains, and a various number of zinc fingers important for protein and DNA interactions (reviewed in references 30 and 32). PLZF interacts with NCoR, SMRT, mSin3A, and HDAC1 via the POZ/BTB domain ([38], [39]) and therefore contributes a second binding site for co-repressor proteins. Therefore, although pharmacologic doses of ATRA induce release of co-repressors from the RARa portion of the fusion protein, the co-repressors binding to PLZF are unaffected (Fig. 76.3C) ([30], [40]). Significantly, concomitant treatment of cells with HDAC inhibitors, such as Trichostatin A (TSA), restores ATRA sensitivity, as TSA inhibits the deacetylase activity of the co-repressors on the PLZF moiety ([36], [38]).

Comparison of the ATRA-sensitive and ATRA-resistant PML-RARa and PLZF-RARa fusion proteins has demonstrated the pivotal role of HDACs in transcriptional repression and has triggered interest in the use of HDAC inhibitors as therapeutic agents in acute leukemia. In addition, recent experiments demonstrate that PML-RARa may recruit DNA methyltransferases to the RARE. Binding of PML-RARa to the target promoter of the *RARß2* gene induced hypermethylation of the promoter ([41]). Chromatin immunoprecipitation analysis demonstrated the presence of the DNA methyltransferases Dnmt1 and Dnmt3a at the promoter, along with PML-RARa. Treatment with RA reduced methylation of the promoter, but concomitant treatment with RA, TSA, and 5-azacytidine (a drug that causes demethylation) relieved repression more completely than RA alone. This is the first example of recruitment of DNA methylases as well as HDACs to a promoter by a leukemic transcription factor, and it raises the possibility of using demethylating agents in conjunction with HDAC inhibitors as therapeutic agents.

A further insight into the pathogenesis of leukemia has come from study of transgenic mice expressing the PLZF-RARa variant. Although transgenic mice expressing PML-RARa develop a leukemia with similar features to APL, transgenic mice expressing PLZF-RARa develop a chronic leukemia similar to CML, which lacks the promyelocytic block of APL. Likewise, transgenic mice expressing the reciprocal translocation RARa-PLZF develop a myeloproliferative disorder. However, mutants produced by crossing of these mice (*PLZF-RARa* $^{+}$*/RARa-PLZF* $^{+}$) develop acute leukemia with a block in promyelocytic differentiation ([42]). Therefore, in APL there may be a synergistic role of the reciprocal product of translocation in leukemogenesis.

Finally, two additional alternative translocations are associated with APL, both of which are ATRA responsive. In the t(5;17)(q35;q21) translocation, nucleophosmin is fused with RARa, contributing an oligomerization domain ([43]). In the t(11;17)(q13;q21) translocation, the nuclear mitotic apparatus (NuMA) gene is fused to *RARa*. The NuMA protein is involved in the mitotic process and also contributes a coiled-coil dimerization domain ([44]). Therefore, all of the translocation partners of RARa encode proteins with multimerization domains.

Core Binding Factor Translocations

The t(8;21) translocation is present in approximately 15% of patients with AML ([45], [46]), and the *AML-1* gene, cloned from the t(8;21)(q22;q22) breakpoint ([47], [48]), is mutated in another 3% of AML. In addition, the t(12;21) translocation implicates disruption of AML-1 in the pathogenesis of B-ALL ([49], [50]). The activity of the murine

counterpart of AML-1 was first described as part of the core binding factor (CBF), which binds to a core enhancer sequence of the Molony leukemia virus long terminal repeat ([51]). Another component of CBF, the non-DNA binding CBFß was found to be associated with inversion 16 in M4 AML ([52]). Finally, the fusion partner of *AML-1* in t(8;21), named *eight-twenty-one* (*ETO*), also is a transcriptional regulator ([53]). A gene related to *ETO*, *MTG16*, is involved in yet another translocation involving *AML-1*, t(16;21) ([54]). The structure of the fusion proteins resulting from these CBF translocations is shown in Figure 76.4.

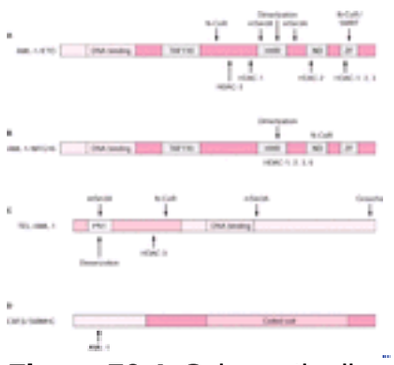

Figure 76.4. Schematic diagram of the t(8;21), t(16;21), t(12;21), and inv(16) with known co-repressor contacts. **A:** t(8;21) AML-1/ETO. The AML-1 portion is shown in light red, with the DNA binding domain indicated. The ETO portion is the dark red box with domains conserved between ETO and its *Drosophila* homolog in light grey boxes. Known contacts with co-repressors and histone deacetylases are shown. **B:** t(16;21) AML-1-MTG16. AML-1 is shown as a red box, and MTG16 is shown in a similar manner to ETO in **A. C:** t(12;21) TEL-AML-1. TEL is in the dark red box, with the conserved pointed (PNT) domain indicated. The AML-1 portion is in the light red box. Interactions with co-repressors and HDACs are shown. **D:** inv(16) CBFß-SMMHC The CBFß portion, which interacts with AML-1, is light red, and the SMMHC is dark red, with the coiled-coil domain indicated and the C-terminal portion, which is necessary for interaction with mSin3A and HDAC8 ([82]). HHR, hydrophobic heptad repeat; ND, nervy domain; TAF110, a domain with homology to the TAF110 coactivator; ZF, zinc finger domain. [From Hiebert SW, Lutterbach B, Amann J. Role of co-repressors in transcriptional repression mediated by the t(8;21), t(16;21), t(12;21), and inv(16) fusion proteins. Curr Opin Hematol 2001;8:197–200, with permission.]

AML-1 is located on chromosome 21q22.3 and is encoded by 12 exons over 260 kilobases (kb) of DNA. Alternative splicing yields four different transcripts ([55]). In the N-terminal portion of the protein is the runt homology domain (RHD), which is homologous to the *Drosophila* runt protein ([56]) and is responsible for the official HUGO name for AML-1, RUNX1. This is the DNA-binding domain, and it is mutated in familial platelet disorder (FPD) and in AML associated with *AML-1* mutations ([57], [58]). CBFß interacts via this domain and changes the conformation of AML-1 to increase DNA-binding affinity ([59]). C-terminal to the RDH are potential MAP kinase phosphorylation sites, followed by three weak activation domains, a nuclear matrix target signal, a dimerization domain, and sequences that are recognized by co-repressor proteins (reviewed in reference 60).

The CBFs are essential for hematopoietic development. Gene deletion of either *AML-1* ([61]) or *CBFß*([62]) in mice results in fetal death at E11.5-12.5. These embryos lack all fetal hematopoiesis. Further transgenic experiments have demonstrated that AML-1 is essential for development of hematopoietic stem cells in the aorta/gonadal/mesodermal region, source of definitive hematopoiesis ([63]). The essential role of AML-1 in hematopoietic development appears to be through its function as a transcriptional activator. It regulates lymphoid genes such as B-cell tyrosine kinase ([64]) and T-cell receptor a and ß ([65]), cytokines (interleukin-3) ([66]), GM-CSF ([67]), and granulocyte-specific genes [MPO and neutrophil elastase ([68])], to name a few. In addition, AML-1 acts as a transcriptional repressor of genes such as *p21* $^{Waf1/Cip1}$ via interactions with the mSin3a co-repressor ([69]). AML-1 also influences T-cell development by repressing CD4 expression in double negative CD4 $^{-}$CD8 $^{-}$ thymocytes ([70]).

The *ETO* gene, cloned from the t(8;21) fusion ([48]), is the mammalian homologue of the *Drosophila nervy* gene ([71]). The four homology domains shared with the *Drosophila* protein include a region of similarity to TAF110, a hydrophobic heptad repeat (HHR), an ND domain of undetermined function, and two zinc finger motifs that may be a protein-protein interaction domain (Fig. 76.4A) ([60]). ETO does not appear to bind DNA specifically on its own. However, it may act as a co-repressor protein ([72]). It associates with N-CoR and mSin3A and directly binds to the class I HDACs, HDAC-1, HDAC-2, and HDAC-3 (Fig. 76.4A) ([73]).

In the t(8;21) translocation, the *AML-1* gene is fused to the *ETO* gene on chromosome 8. The breakpoint in the *AML-1* locus is between exons 5 and 6 ([74]), yielding a fusion protein with the N-terminal 177aa of AML-1 ([48]). In this fusion protein, the DNA-binding domain is present, but the C-terminal activation domains, co-repressor interaction sites, and nuclear localization signals of the wild-type AML-1 are not present (Fig. 76.4A) ([60]). The breakpoint in the *ETO* gene occurs in the introns between the first two alternative exons of *ETO*, resulting in the inclusion of almost all of the coding region for *ETO* in the fusion transcript ([48]). Unlike APL, a transcript of the reciprocal *ETO*/ *AML-1* fusion is not usually present ([60]).

The AML-1/ETO protein specifically binds to the same DNA binding site as AML-1 and can heterodimerize with CBFß ([75]). Therefore, the AML-1/ETO protein can act as a dominant negative inhibitor of wild-type AML-1. However, co-transfection experiments demonstrated that AML-1/ETO can also function as an active transcriptional repressor, not only inhibiting activation of a reporter gene containing the GM-CSF promoter by co-transfected AML-1, but also reducing the expression of the reporter gene below baseline ([76]). The ability of AML-1/ETO to act as a transcriptional repressor depends on its association with HDACs (via ETO; Fig. 76.4A), as the HDAC inhibitor TSA can abrogate effects of AML-1/ETO on the cell cycle ([73]). Targets of AML-1/ETO repression are presumed to include genes important for granulocyte differentiation. In addition, AML-1/ETO represses p14 ^{ARF} ([77]). p14 ^{ARF} stabilizes p53 by antagonizing MDM2, an inhibitor of p53 ([78]). Therefore, repression of p14 ^{ARF} reduces the checkpoint control path of p53 and may be a key event in t(8;21) leukemogenesis. The promoter of p14 ^{ARF} has eight AML-1 DNA binding sites, and wild-type AML-1 can activate p14 ^{ARF}. However, transfection of AML-1/ETO into cells that have only low levels of AML-1 and high endogenous levels of p14 ^{ARF} results in repression of p14 ^{ARF}. Samples of bone marrow from patients with t(8;21) leukemia have low levels of p14 ^{ARF} transcript by quantitative polymerase chain reaction analysis.

Surprisingly, expression of AML-1/ETO in myeloid progenitor cells inhibits cell cycle progression. However, this may contribute to leukemogenesis by allowing time for accumulation of mutations in a cell immune from p53-induced apoptosis due to inactivation of p14 ^{ARF} ([77]).

AML-1 is also involved in a translocation that is present in 25% of pediatric B-acute lymphoblastic leukemia, t(12;21)(p13;q22). This translocation is associated with a good prognosis, although it is often missed by standard karyotype analysis. In this translocation, the N-terminus of *TEL* (translocation-ETS-leukemia) is fused to most of the coding region of *AML-1* ([49]). TEL contains a DNA-binding ETS domain and a “pointed” domain homologous to the *Drosophila* development protein, pointed ([79]). TEL is a transcriptional repressor, and as such it contains a DNA-binding ETS domain and domains that interact with mSin3A (pointed domain), NCoR, and HDAC-3 (Fig. 76.4C) ([80]). The functional significance of these interactions with HDACs was demonstrated by the ability of TSA to inhibit two properties of 3T3 fibroblast cells transformed with TEL and Ras: expression of the stromelysin-1 gene and aggregation ([80]).

Finally, inversion 16, present in approximately 8% of AML cases, involves the CBF complex member *CBFß* and is associated with a morphologically distinct subset of AML, M4Eo, a myelomonocytic leukemia with abnormal eosinophils that have dark purple as well as orange granules. This cytogenetic abnormality in which the *CBFß* gene is fused to the smooth muscle myosin heavy chain gene, *MYH11*, results in fusion of the first 165aa of CBFß to the C-terminal coiled-coil region of smooth-muscle myosin heavy chain protein (SMMHC; Fig. 76.4D) ([81]). A C-terminal region of SMMHC is necessary for the activity of CBFß/SMMHC as a transcriptional co-repressor, and this region also associates with mSin3a and HDAC8. Presumably, CBFß/SMMHC, which cannot bind DNA on its own, interacts with AML-1 to form a transcriptional repressor complex ([82]).

A number of experiments demonstrate that the CBF translocations are necessary but not sufficient for induction of leukemia. To determine whether expression of AML-1/ETO is sufficient to produce leukemia, mice were generated with a conditional AML-1/ETO knock-in allele using the Lox-Cre system. This obviates the embryonic lethality that results when AML-1/ETO is introduced into transgenic mice (recapitulating the phenotype of the AML-1 null mouse). No leukemia developed in 20 *AML-1/ETO*+ mice in 11 months, and no hematologic abnormality was detected except for a slight increase in the number of hematopoietic colony forming cells. Expression of AML-1/ETO did not cause a significant block in differentiation of hematopoietic precursors. When the mice were mutagenized with the DNA alkylating

agent, ENU, 31% of the mice developed granulocytic sarcoma or AML ([83]) This supports the hypothesis that several genetic “hits” are necessary for the development of leukemia. Similarly, chimeric mice created with *Cbfb* $^{+/Cbfb\text{-}MYH11}$ embryonic stem cells fail to have a high rate of acute leukemia unless they are treated with ENU ([84]).

Another study used retroviral transduction of CD34 $^{+}$ human hematopoietic progenitor cells to investigate the effect of AML-1/ETO on proliferation and differentiation ([85]). Expression of AML-1/ETO in primitive CD34 $^{+}$ cells slows differentiation and promotes progenitor cell self-renewal. Expression of AML-1/ETO in more mature progenitor cells results in growth arrest. Similar *in vivo* results were obtained with mice reconstituted with AML-1/ETO expressing hematopoietic stem cells. In these mice, there was an expansion of the hematopoietic stem cell population and immature myeloid cell populations, although the mice did not develop acute leukemia ([86]). Therefore, the expression of AML-1/ETO promotes accumulation of immature cells and prolongs the period during which progenitor cells may accumulate additional mutations.

Further support for the hypothesis that genetic mutations besides a mutant *AML-1* locus are necessary for development of acute leukemia comes from the study of patients with FPD with propensity to develop AML (FPD/AML). These patients have mutations in one allele of *AML-1* ([87]). They have defective platelets, progressive pancytopenia, and develop myelodysplasia and a high incidence of AML with age. However, second mutations appear to be necessary before progression to AML occurs. Similarly, syngeneic twins who have identical *TEL/AML-1* t(12;21) translocations at birth may develop ALL at different times later in life ([88], [89]). This implies that acquisition of additional mutations is necessary for development of leukemia.

Transcription Therapy with Histone Deacetylase Inhibitors

Each CBF translocation results in fusion of AML-1 (AML-1/ETO, TEL-AML-1) or CBFß with a protein that efficiently recruits HDACs either directly or via co-repressor complexes. The presence of these HDACs appears to be important in repression of target genes and therefore in leukemogenesis. Likewise, the function of the RA-responsive and RA-insensitive RARa translocations depends on how tightly they bind to HDACs and co-repressors. These data have triggered much discussion of the possibility of treatment of acute leukemia with HDAC inhibitors. The rationale is that if the aberrant transcription factors involved in leukemia repress target promoters via deacetylation of histones, then treatment with HDAC inhibitors will overcome this repression by keeping the target promoter DNA in the open acetylated configuration (Fig. 76.2C). This relief of repression of target genes, therefore, should slow proliferation and induce differentiation of the leukemic cells.

Several HDAC inhibitors are available that vary in specificity, potency, and ease of administration (reviewed in reference 17). The oldest of these is butyrate; however, butyrates have low specificity, low potency, and fairly high toxicity at the dose necessary for treatment. Valproic acid is less toxic and is already used in medicine for neuropsychiatric illnesses. It is more active on class I HDACs than class II HDACs. Other newer HDAC inhibitors are suberoylanilide hydroxamic acid (SAHA), MS-275, and depsipeptide. An HDAC inhibitor used in laboratory experiments but not yet in clinical trials is TSA.

Cell culture results are promising as far as the ability of HDAC inhibitors to reverse transcriptional repression brought about by the CBF translocations or RARa translocations. In transient transfection assays, TSA blocks repression of the stromelysin-1 promoter by TEL ([80]). In experiments in which either INV-16 or ETO are fused to the GAL4 DNA-binding protein and cotransfected with a reporter plasmid containing GAL4 binding sites, repression is abrogated by treatment with TSA ([82]). In addition, TSA and butyrate block repression of reporter genes by PLZF-RARa ([38]). In cell culture experiments, HDAC inhibitors induce partial differentiation or apoptosis in leukemic cell lines ([90], [91]).

Phase 1 and phase 2 trials are ongoing investigating the use of butyrates, valproic acid, MS-275, depsipeptide, and SAHA in hematologic malignancies (reviewed in reference 17). The first successful treatment with HDAC inhibitors (HDIs) occurred with the use of phenyl butyrate on a patient with APL with the PML-RARa fusion in her third relapse, having failed ATRA and chemotherapy, allogeneic bone marrow transplant, and arsenic trioxide. Phenylbutyrate was added to ATRA, and the patient achieved a molecular remission that has lasted longer than 6 months ([92]). However, most early results from trials report stabilization of disease or partial remissions but not complete remissions (reviewed in reference 17).

A theoretical concern about treatment of patients with HDAC inhibitors is that global derepression of genes might occur, leading to untoward expression of oncogenes. In differential display analysis of the global effects of HDI treatment on gene expression, only 2 to 5% of genes were induced ([93]). The “histone code” is complex enough that global hyperacetylation of DNA does not directly translate to global gene overexpression ([22]). The complexity of effects that HDAC inhibitors may produce is compounded by the fact that important transcription factor and regulatory proteins are acetylated as well as histones ([94]). In addition, up-regulation of genes besides those that are targeted by the aberrant transcription factors may occur and be responsible for the effect of HDIs. For example, experiments demonstrate that up-regulation of a protease may be the cause of HDI-mediated apoptosis ([95]). Therefore, many of the effects of treatment with HDIs may be unrelated to de-repression of the genes targeted by the specific leukemic transcription factor. Therefore, *in vitro* studies on leukemic cell lines or analysis of bone marrow from patients treated with HDIs should include analysis of the acetylation state of promoters targeted by the leukemic transcription factor using chromatin immunoprecipitation assays ([17]). Finally, an additional layer of complexity is emerging with the discovery of the importance of histone methylation ([22]) and the influence of modified histones on DNA methylation ([21]). Therefore, demethylation agents, such as 5-azacitidine, and histone methyltransferase inhibitors may emerge as important adjuncts in “transcription therapy.”

Mixed Lineage Leukemia: 11q23 Translocations

A transcriptional activator that is characteristically rearranged in infant leukemia, therapy-related leukemia, and mixed lineage leukemia is mixed lineage leukemia gene (*MLL*), which maps to chromosome 11q23 (reviewed in references 96 and 97). Other names for this locus are *HRX* or *ALL-1*. The *MLL* gene consists of 34 exons over 100 kb encoding a 3969 aa protein ([98]) (Fig. 76.5). *MLL* bears homology regions with *trithorax*, a *Drosophila* transcriptional regulator that positively regulates homeobox (*HOX*) genes ([99]). *HOX* genes are a large family of genes named for a shared homeobox sequence motif, which are developmental regulators essential for growth and differentiation. They were first identified in *Drosophila* during the study of genes whose mutations led to developmental abnormalities involving misassignment of body segment identity ([100]). The mammalian homologs consist of 39 *HOX* genes, which are important in mammalian development and cell fate determination ([101]). Wild-type MLL appears to be responsible for the maintenance of *HOX* gene expression during development ([102], [103]). Recent evidence suggests that it may perform this transcriptional regulation via histone methyltransferase activity conferred by the SET domain in its carboxyl terminus ([104]). The SET domain is a protein domain shared by a number of transcriptional regulators that have histone methyltransferase activity ([22]). However, the SET domain is truncated in most of the fusion proteins resulting from translocations involving MLL ([98]).

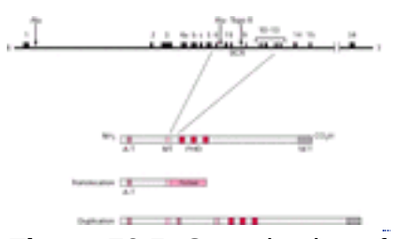

Figure 76.5. Organization of the mixed lineage leukemia (MLL) gene, protein, and products of MLL rearrangements. **Top:** Exon/intron structure of the *MLL* locus at 11q23. Topo II sites shown with arrows correspond to the BCR (breakpoint cluster region). **Middle:** The full length protein is shown, with the A-T hook domain (A-T), a second DNA binding domain (MT), a zinc finger domain used for protein interaction (PHD), and the SET domain that has histone methyltransferase activity. **Bottom:** The schematic of translocations and duplications demonstrate conservation of the A-T and MT domains but loss of the SET domain in the fusion protein. (From DiMartino J, Cleary M. MLL rearrangements in haematological malignancies: lessons from clinical and biological studies. Br J Haematol 1999;106:614–626.)

MLL rearrangements involve 5 to 10% of chromosomal rearrangements overall in patients with ALL, AML, and myelodysplastic syndrome (MDS), and are associated with poor prognosis ([105]). In a study of 550 cases of acute leukemia and MDS with acquired 11q23 rearrangements, 16% involved additions, duplications, and inversions at the *MLL* locus ([106]). Of the remaining reciprocal translocations, 30 different partner loci were identified ([107]). The three most common partners are the *AF4* gene at 4q21 in t(4;11), the *AF9* gene at 9p21-22 in t(9;11), and the *ENL* or *ELL* genes at 19p13.3 and 19p13.1, respectively, in t(11;19). t(4;11) is associated

with ALL, whereas t(9;11) is associated with AML ([108]). As the name implies, MLL is associated with mixed lineage leukemias, in which blasts express both myeloid and lymphoid markers. This association and the presence of MLL rearrangements in both ALL and AML cases suggest that the recombination event may take place in an uncommitted hematopoietic stem cell. The most common leukemia associated with MLL is M4/M5 AML ([106]).

The breakpoints of 11q23 usually occur between exons 5 and 11 (Fig. 76.5) ([109]), leaving approximately the N-terminal 1400 amino acids of the MLL protein ([97]). The retained protein contains AT-hook sequences thought to bind DNA at the minor groove ([110]), two regions mediating subnuclear localization, and a conserved DNA methyl-transferase region; the SET domain is routinely lost (Fig. 76.5) ([98]). Domain-swapping experiments have been performed to determine the properties of the 3' fusion partner necessary for the hybrid protein to immortalize cells. These experiments demonstrate that two transcriptional activating domains are necessary for immortalization ([98] , [111]). This suggests that as a result of the translocation, the *MLL* fusion gene becomes a stronger or constitutive transcriptional activator. A possible result of this activity would be abnormally sustained *HOX* gene expression. If *MLL-ENL* is transduced into bone marrow of mice lacking *HOXA9* or *HOXA7*, no immortalization of hematopoietic precursors occurs ([97]). This suggests that overexpression of these genes is necessary for leukemogenesis. Microarray analysis of MLL supports this hypothesis, as high levels of HOXA9, HOXA5, and HOXA4 are found in the group of leukemias with MLL translocations ([112]).

MLL rearrangements are associated with several unique types of leukemia. First, in infant acute leukemia (birth to 1 year) there is a 60 to 80% incidence of 11q23 rearrangement ([113]). Second, in acute leukemias related to treatment with DNA topoisomerase II inhibitors, there is a 70 to 90% incidence of *MLL* rearrangements, particularly t(4;11)(q21;q23) and t(9;11)(p21-22;q23) ([107] , [114]). Topoisomerase II is an enzyme involved in unwinding of DNA during replication and transcription. It does so by producing double-stranded nicks in the DNA after which the ends are rejoined by a ligase activity of topoisomerase II. Topoisomerase II inhibitors, such as epidophyllotoxins, inhibit this ligase function so DNA-free ends accumulate, triggering apoptotic events. In *MLL*, there are 11 sites similar to topoisomerase II consensus–binding sites in the breakpoint cluster areas ([115]). Therefore, if DNA-free ends created by the topoisomerase II are incorrectly relegated, translocations in *MLL* are likely to occur. Infant leukemia with *MLL* translocations has a similar distribution of breakpoints, whereas sporadic cases of acute leukemia have more random breakpoints ([116]). This observation has triggered speculation that *in utero* exposure to environmental topoisomerase II inhibitors, such as flavonoids, may have a role in the etiology of infant leukemia ([117]).

The latency of development of leukemia appears to be shorter for *MLL* rearrangements than for other leukemogenic rearrangements. In studies of twins who develop infant leukemia, those bearing a shared *MLL* rearrangement have a concordance of nearly 100% in the first year of life, whereas in twins sharing another rearrangement, the concordance is 25%, and the time to development may be years instead of months ([118] , [119]). Similarly, therapy-related leukemias based on *MLL* rearrangement occur sooner after therapy than those occurring after alkylating agents or radiation, usually 7q- or 5q- ([114] , [120]). This suggests that the oncogenic fusion protein produced by the MLL rearrangement can deregulate the cell without the accumulation of many secondary mutations. However, in genetic experiments in mice in which the *MLL-AF9* fusion gene is knocked-in, there is still a latency of 6 months before development of acute leukemia, suggesting that some secondary mutations are necessary ([121]). An additional reflection of the potency of *MLL* rearrangements is that they are a poor prognostic indicator in infant leukemia, ALL, and most AML cases ([113]).

E2A Translocations

In acute lymphoblastic leukemia, most of the common translocations involve transcription factors that are members of common classes of transcription factors known to be involved in regulation of tissue-specific gene expression during development. A common translocation in childhood B-ALL, present in 5% of pre B-ALL cases ([122]), is the t(1;19)(q23;p13.3) translocation, which fuses the *E2A* gene on chromosome 19p13.3 with the *PBX1* gene on chromosome 1q23 (Fig. 76.6) ([123] , [124]). Presence of this translocation usually indicates a poor prognosis ([125]). The *E2A* locus encodes three transcripts, E12, E47, and E2-5, which are generated by alternative splicing ([126]). They belong to class I of the basic helix-loop-helix (bHLH) family of transcription factors. bHLH transcription factors bind to specific E-box (CANNTG) sequences in promoters and enhancers, the first of which were identified in the enhancer regions of the immunoglobulin heavy-chain and kappa-chain genes ([126]). Usually, the ubiquitous E2A proteins heterodimerize through the HLH domain with members of the class II bHLH proteins, most of which are tissue specific in expression. These heterodimers are crucial in transcriptional regulation of tissue-specific genes during development. Although E2A proteins are ubiquitous, they are preferentially expressed in B lymphocytes ([127]), and E47 forms homodimers exclusively in B cells ([128]). The requirement for E2A proteins in B-cell development is demonstrated by *E2A* $^{-/-}$ null mice, which exhibit a complete block in B-cell differentiation at the pro–B-cell stage before immunoglobulin gene rearrangement, as well as defective thymocyte differentiation ([129] , [130]). These mice have an increased frequency of T-lymphoblastic lymphoma ([130]).

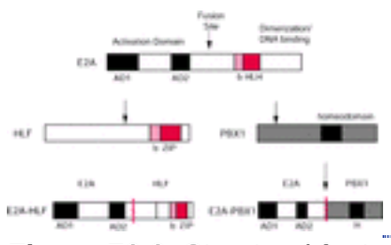

Figure 76.6. Structural features of E2A fusion proteins. The N-terminus of the E2A gene encodes a transcriptional activation domain that is translocated to hepatic leukemia factor (HLF) or pre–B-cell leukemic homeoboX1 (PBX1) by chromosome translocations in acute lymphocytic leukemia. In the case of E2A-HLF, the DNA binding and dimerization domains of E2A are replaced by similar domains in HLF. For E2A-PBX1, the same DNA binding and dimerization domains of E2A are replaced with the DNA-binding homeodomain of PBX1. AD, activation domain; bHLH, basic helix-loop-helix; b ZIP, basic leucine zipper domain; H, homeodomain.

PBX1 (pre–B-cell leukemic homeoboX1), identified as the fusion partner of *E2A* in t(1;19) ([131]), encodes another transcription factor that is a member of the homeodomain family of transcription factors encoded by *HOX* genes. The *PBX* gene is the mammalian homologue of the *Drosophila* gene *Extradenticle* whose protein product cooperates with other homeodomain proteins during development ([132]). Likewise, PBX1 forms heterodimers with other homeodomain proteins via the homeo-domain and the C-terminal HOX cooperativity motif (HCM) ([133]). Co-transfection experiments with reporter genes containing DNA binding sites for PBX1 have demonstrated that PBX1 is not a strong transcriptional activator ([134]). The *PBX1* $^{-/-}$ mice have late embryonic lethality associated with multiple organ abnormalities ([135]), supporting the hypothesis that PBX1 interactions regulate homeodomain protein function. PBX1 is not normally expressed in lymphocytes.

In the t(1;19) translocation, the breakpoint on chromosome 19 occurs within the intron between exons 13 and 14 of *E2A*, so that the N-terminal two-thirds of E2A, aa1-483, are included in the fusion protein ([124]). This includes both of the transcriptional activation domains (AD1 and AD2), but excludes the bHLH DNA-binding and dimerization domains (Fig. 76.6). Therefore, the E2A-PBX1 fusion protein depends on the homeo-domain of PBX1 for DNA-binding specificity. Two alternatively spliced forms of PBX1 result in two possible fusion proteins, E2A-PBX1a and E2A-PBX1b, which differ in the C-terminal end. Both forms join E2A at aa89 of PBX1 and contain the DNA-binding homeodomain and the HCM protein-interaction domain ([124]). The translocation is usually imbalanced, so that the reciprocal PBX1-E2A is not expressed ([136]).

Several hypotheses exist for how expression of the E2A-PBX fusion protein results in the development of leukemia. The most straightforward model is that fusion of the E2A activation domains onto PBX1 sequence results in abnormally strong *trans*-activation of target genes recognized by the PBX1 homeo-domain ([137]). These target genes would be activated in lymphocytes, in which PBX1 is usually not expressed. Evidence for this model comes from the study of the ability of deletion mutants of E2A-PBX1 to transform fibroblasts and lymphocytes and to *trans*-activate reporter genes. Mapping experiments demonstrate that the activation domains AD1 and AD2 of E2A are necessary for *trans*-activation of reporter genes containing PBX1 binding sites, and they are also necessary for transformation of NIH 3T3 cells ([138]). In primary murine bone marrow, the homeodomain and HCM are both required for immortalization and differentiation blockade ([139]). However, using a fibroblast transformation assay, the only part of PBX1 that is necessary is the HCM ([133]). Based on these results, an alternative model of oncogenicity is that interaction between the E2A-PBX1 and homeodomain proteins via the HCM alters homeodomain protein function in development ([133]). Finally, E2A-PBX may alter wild-type E2A function in cells by a dominant negative effect or by sequestering coactivator proteins from E2A in cells that already are haploinsufficient for E2A due to the translocation event ([137] , [140]).

Another translocation involving E2A occurs in approximately 1% of pediatric ALL, t(17;19)(q22;p13), which fuses *E2A* to hepatic leukemia factor (*HLF*) ([141] , [142]).

Clinically, these patients are adolescents and may present with disseminated intravascular coagulation and hypercalcemia. *HLF* encodes a transcription factor of the basic leucine zipper (bZIP) family, in which the basic region is the DNA-binding region and the leucine zipper refers to an amphipathic alpha helical domain through which HLF can homodimerize or heterodimerize with other bZIP proteins. HLF is usually expressed in liver, kidneys, and CNS neurons, but not in hematopoietic cells ([143]).

The E2A-HLF fusion protein is homologous to the E2A-PBX1 fusion protein in that the N-terminal 483 amino acids of E2A, contributing the activation domains AD1 and AD2, are fused to the C-terminal portion of HLF, which contains the bZIP DNA-binding and dimerization domains (Fig. 76.6) ([144]). Unlike PBX1, wild-type HLF is a strong *trans*-activator, but the alteration in cell-type expression and alterations in DNA-binding affinity and protein interactions by virtue of fusion to E2A may contribute to the transforming properties of E2A-HLF ([145]). In addition, as with the t(1;19) translocation, loss of one *E2A* allele and sequestration of coactivators from the wild-type E2A protein may be contributory factors ([137]).

The possibility that a mechanism of E2A-HLF–induced leukemogenesis is inhibition of apoptosis was raised by experiments in which expression of a dominant negative mutant of E2A-HLF in cells harboring t(17;19) resulted in apoptotic cell death ([146]). Representational difference analysis experiments to identify transcriptional targets of t(17;19) have strengthened this hypothesis. Pools of RNA were obtained before and after induction from a t(17;19) leukemic cell line that had been stably transfected with an inducible dominant negative E2A-HLF. One of the genes identified in the representational difference analysis screen was *SLUG*, the human homolog of the *Caenorhabditis elegans* gene *ces-1* involved in programmed cell death during neuronal development ([147]). *Ces-1* is regulated by *Ces-2* in *C. elegans*, and *Ces-2* has homology with *E2A-HLF* ([147]). SLUG may inhibit the cytochrome c/Apaf-1/caspase-9 apoptotic pathway by transcriptionally repressing members of the Bax family. Therefore, induction of SLUG by E2A-HLF inhibits apoptosis and promotes cell survival ([148]).

TAL1/SCL Translocations

Alterations in expression of another member of the HLH family of transcription factors, *TAL1/SCL* (T-cell acute lymphoblastic leukemia 1/stem cell leukemia) are the most common molecular abnormalities in childhood T-cell ALL (T-ALL). The *TAL1/SCL* gene was originally cloned from a translocation, t(1;14)(p34;q11) present in 3% of patients with T-ALL ([149]). In the translocation, the breakpoint is 5' to the coding region of *TAL1/SCL* on chromosome 1, and the translocation places *TAL1/SCL* under the regulation of the T-cell receptor a/ß gene on chromosome 14 ([150] , [151]). A second series of rearrangements that occurs in 12 to 26% of patients with T-ALL results in deletion of 90 to 100 kb of DNA from the 5' upstream region of *TAL1/SCL*, placing the gene under the control of the upstream *SIL* promoter, which is constitutively active ([152]). In both cases, the coding region of *TAL1/SCL* is usually intact, unlike the fusion proteins that are usually expressed in acute leukemia. In addition, in some cases of T-ALL, overexpression occurs when there is no evident gene rearrangement by Southern blot analysis, suggesting a mutation in regulatory sequence ([153]).

During development, TAL1/SCL is expressed in early hematopoietic elements, in both the yolk sac blood islands and the definitive blood cells of the aorta/gonadal/mesodermal and fetal liver ([154]). Postnatally, it is expressed in erythroid, megakaryocyte, and mast cell lineages, but not in T cells. In nonerythroid cells, TAL1/SCL is expressed in stem cells but is not expressed as the cells differentiate; however, in erythroid cells, TAL1 expression increases with early erythroid differentiation but decreases with terminal differentiation ([155]). The essential role of TAL1/SCL in hematopoietic development is demonstrated by mice made null for *TAL1/SCL*; embryonic lethality occurs due to a total deficiency in hematopoietic progenitors ([156] , [157]). Conditional gene-targeting experiments using the Lox-Cre system to delete *TAL1/SCL* in adult mice demonstrates that continued expression of TAL1/SCL is not necessary for maintenance of hematopoietic stem cells, but it is necessary for erythrocyte and megakaryocyte differentiation ([158]).

TAL1/SCL is a bHLH transcription factor and as a heterodimer with E2A proteins can bind to E-box DNA sequences. It also participates in multi-protein complexes with E2A, LMO2, GATA-1, and Ldb-1 ([159] , [160]). LMO-2 can be co-precipitated with TAL1 from T-ALL cell lines ([161]), and mice overexpressing both TAL1 and LMO2 develop a T-ALL–like illness faster than transgenic mice overexpressing either gene alone ([162]). TAL1-BCL also associates with transcriptional activators p300 and pCAF ([163]), but also can interact with transcriptional co-repressors mSin3A and HDAC1 ([164]). The transcriptional targets of activation or repression that are important for generating T-ALL are not known. However, recently it has been shown that a multiprotein complex involving TAL1/SCL regulates c-kit receptor expression ([165]). TAL1/SCL is expressed in early hematopoietic cells along with c-kit, and co-transfection experiments demonstrated a role for TAL1/SCL in transcriptionally inducing expression of a reporter gene containing the c-kit promoter. Interestingly, c-kit is expressed in a subset of T-ALL cases ([166]). Inappropriate expression of c-kit or another growth-promoting gene that TAL1 usually regulates in early hematopoiesis may contribute to development of T-ALL when expressed in immature T-cells. Another hypothesis is that TAL1/SCL acts as a dominant negative inhibitor of the E2A transcription factors with which it can heterodimerize.

HOX Gene Dysregulation

As discussed in the section Mixed Lineage Leukemia: 11q23 Translocations , homeobox genes, or *HOX* genes, encode homeodomain proteins, homeodomain-containing transcription factors that are involved in cell fate determination during development ([100]). They are involved in several of the less frequent recurring translocations, and microarray analysis of T-ALL ([167]) and AML ([168]) have demonstrated overexpression of *HOX* genes in additional cases of leukemia that do not have a recurring translocation. *HOX11*, on chromosome 10q24, is involved in two translocations found in T-ALL: t(10;14)(q24;q11) and t(7;10)(q34;q24); in each of these translocations an intact *HOX11* gene is placed under the control of a T-cell receptor gene (T-cell receptor d on 14q11 or T-cell receptor ß on 7q34) ([169]). The abnormal recombination events involving the T-cell receptor gene loci may occur early in T-cell development as a result of faulty attempts at rearrangement of the T-cell receptor locus ([170]). By cytogenetic analysis, 4 to 7% of pediatric T-ALL cases have a rearrangement involving *HOX11*; in addition, by reverse-transcriptase polymerase chain reaction, 4 of 12 T-ALL and 0 of 56 B-ALL samples overexpressed HOX11 messenger RNA ([171]). Yet another *HOX* gene, *Hox11L2*, is involved in the recently described t(5;14)(q35;q32) translocation that occurs in up to 25% of T-ALL cases ([172]).

Finally, a series of translocations associated with AML, MDS, and blast crisis of CML produce fusions of the *NUP98* gene on chromosome 11p15, with *HOXA9* [t(11;7)(p15;p15)], *PMX1* [t(1;11)(q24;p15)], or *HOXD13* [t(2;11)(q31;p15)] ([173] , [174]). In each of these cases, the N-terminal portion of NUP98, a nucleoporin protein, is fused to the C-terminal portion of the homeodomain protein. Nucleoporins participate in the nuclear side of the nuclear pore complex necessary for transport of proteins in and out of the nucleus. Presumably, the nucleoporin portion of the fusion protein ensures nuclear expression of the NUP98-HOX fusion protein. Transduction of NUP98-HOXA9 into murine bone marrow cells induces AML after a shorter latency than transduction of HOXA9 alone ([175]). Expression of NUP98-HOXA9 in marrow progenitor cells in culture immortalizes the cells, preventing differentiation in response to GM-CSF and promoting proliferation in response to stem cell factor ([176]). The transcriptional targets of the NUP98-HOXA9 fusion protein that are involved in leukemogenesis are not known; however, in cells overexpressing NUP98-HOXA9, expression of several other *HOX* genes is induced ([176]).

TRANSLOCATIONS AND MUTATIONS INVOLVING TYROSINE KINASES

BCR-ABL: Philadelphia Chromosome+ Acute Lymphoblastic Leukemia

The Philadelphia chromosome is the result of the t(9;22)(q34;q11) translocation in which the 5' domains of the breakpoint cluster region (BCR) gene from chromosome 22 are fused with the 3' tyrosine kinase domain of the ABL gene from chromosome 9 ([177] , [178]). The Philadelphia chromosome is the resultant shortened chromosome 22. It is the most frequent recurring translocation in adult ALL, occurring in 15 to 30% of patients ([179]), and also is present in 5% of pediatric B-ALL ([180]). It is an adverse prognostic factor in children and adults.

The *BCR-ABL* fusion gene is associated most commonly with CML. The pathogenesis of CML is discussed in Chapter 84. A lymphoid blast crisis arising from CML may be difficult to distinguish from a Philadelphia chromosome–positive (Ph+) ALL. The size of the BCR-ABL fusion protein and whether it is restricted in expression to lymphoid cells may be helpful in making this distinction. The most common breakpoint region, the major breakpoint cluster region (M-bcr) spans almost 6 kb between exons 12 and 16 of *BCR* and results in a fusion protein of 210 kd, referred to as p210 $^{bcr\text{-}abl}$ ([5]). A minor breakpoint, the m-bcr, is farther 5', after exon 2 of *BCR*, resulting in a truncated fusion protein of 190 kd, which contains only the first two exons of *BCR* (p190 $^{bcr\text{-}abl}$) ([181]). p210 $^{bcr\text{-}abl}$ is much more common in CML and CML with lymphoid blast crisis, whereas p190 $^{bcr\text{-}abl}$ is much more commonly expressed in Ph+ ALL. p190 $^{bcr\text{-}abl}$ is present in 80-90% of pediatric Ph+ ALL and 50% of adult Ph+ ALL ([179]). However, some cases of Ph+ ALL contain both p190 $^{bcr\text{-}abl}$ and p210 $^{bcr\text{-}abl}$. Transgenic mice expressing p190 $^{bcr\text{-}abl}$ develop an aggressive leukemia restricted to pre-B cells, whereas transgenic mice expressing p210 $^{bcr\text{-}abl}$ develop a more chronic disease involving B and T cells and myeloid

lineages ([182]). In some cases of Ph+ ALL, the aberrant fusion gene is present in lymphoid and myeloid marrow cells, whereas in other cases the aberrant fusion gene, usually p190 $^{bcr\text{-}abl}$, is restricted to lymphoid cells. Those cases in which p210 $^{bcr\text{-}abl}$ is present in both lymphoid and myeloid cells are most likely to represent a CML lymphoid blast crisis ([183]).

Studies of BCR-ABL expression in CML have demonstrated the leukemogenic properties of BCR-ABL as a constitutive tyrosine kinase ([184]). This constitutive kinase activates by phosphorylation multiple downstream signal transduction intermediates, including ras (via grb2), PLC?, and PI3 kinase ([185]). Activation of these pathways results in proliferation and resistance to apoptosis ([186]). Presumably, similar mechanisms are at work in Ph+ ALL. Restriction of expression of BCR-ABL to the lymphoid lineage would explain the development of ALL. However, in those cases of Ph+ ALL in which BCR-ABL is expressed in the stem cell compartment, it is unclear why ALL has resulted instead of CML.

Treatment of Ph+ ALL remains problematic. Initial response to chemotherapy is similar in Ph+ ALL and Ph–ALL, but remissions tend to be short-lived. Transplantation appears to be the best means of attaining a lasting remission. In a phase 2 trial of imatinib in relapsed or refractory Ph+ ALL, 60% of patients achieved a hematologic response, but it was usually short-lived ([187]). Development of resistance to imatinib occurs due to acquisition of mutations in the ATP-binding pocket of BCR-ABL that is targeted by imatinib ([188]).

FLT3 Mutations

FLT3 may be the single most commonly mutated gene in AML (reviewed in reference 189). Originally cloned from CD34 $^{+}$ hematopoietic stem cells, it encodes a type III receptor tyrosine kinase. FLT3 ligand (FL) is a type I *trans*-membrane protein that is expressed on the surface of support and hematopoietic cells in the bone marrow, and it normally stimulates growth of immature myeloid cells and stem cells ([190]). When FL ligand binds to the FLT3 receptor, FLT3 dimerizes and autophosphorylates intracytoplasmic tyrosine residues. The phosphorylated, activated FLT3 then activates downstream signal transduction pathways. Two types of mutations in *FLT3* have been cloned from leukemic cells. The most common are internal tandem repeat (ITD) mutations, in which head-to-tail duplications of various lengths and positions occur in the juxtamembrane (JM) portion of the molecule (Fig. 76.7) ([191]). These elongation mutations may occur due to DNA replication errors as a result of a potential palindromic intermediate that may form at that site ([192]). The JM domain is an autoinhibitory domain whose inhibitory function is usually relieved by autophosphorylation after ligand binding ([189]). The in-frame insertions in the JM domain produce mutant proteins that are constitutively activated; they are able to dimerize and autophosphorylate in the absence of ligand ([192]). The second type of mutations are activation loop mutations, usually an Asp825Tyr substitution resulting from a point mutation. Usually, the activation loop inhibits access of ATP and substrate to the kinase domain until phosphorylation occurs as a result of ligand binding. The activation loop mutations again produce a constitutively active FLT3 ([189]). Not only is the kinase constitutively active, but its effect on downstream signal transduction intermediates is altered. Ligand-activated, wild-type FLT3 stimulates proliferation via activation of the Ras/Raf/MAP kinase pathway (Fig. 76.8). In contrast, FLT3-ITD only weakly activates MAP kinase and Akt, but strongly activates STAT5 via phosphorylation ([193]).

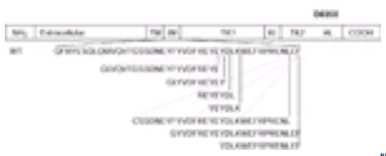

Figure 76.7. Schematic of the internal tandem repeat (ITD) and activation loop FLT3 mutations in acute myelogenous leukemia (AML). The structure of the FLT3 receptor tyrosine kinase is shown, with the position of the transmembrane domain (TM), the juxtamembrane domain (JM), the kinase domains (TK1 and TK2), kinase insert (KI), and activation loop (AL). The amino acid sequence of the wild-type JM domain is listed, and underneath are the tandem duplication sequences found in individual patients with AML. These are always in-frame insertions. The position of the amino acid that is commonly substituted in activation loop mutations is indicated above the schematic of the protein domains. (Adapted from Mizuki M, Fenski R, Halfter H, et al. FLT3 mutations from patients with acute myeloid leukemia induce transformation of 32d cells mediated by the ras and stat5 pathways. Blood 2000;96:3907–3914; and Kelly LM, Liu Q, Kutok JL, et al. FLT3 internal tandem duplication mutations associated with human acute myeloid leukemias induce myeloproliferative disease in a murine bone marrow transplant model. Blood 2002;99:310–318.)

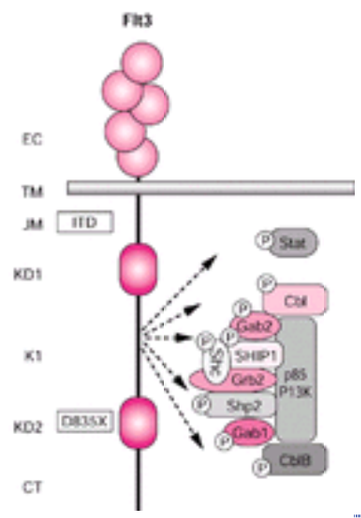

Figure 76.8. Hypothetical interactions of signaling molecules with FLT3. The model of FLT3 protein demonstrates the five immunoglobulin-like domains in the extracellular (EC) region of the receptor, followed by a transmembrane (TM) and juxtamembrane (JM) domain, a split kinase domain (KD1 and KD2) containing a kinase insert (K1) region, and a C-terminal tail (CT). The internal tandem repeat (ITD) in the JM domain and the site of activation loop mutations at D835 are indicated. The dashed arrows indicate phosphorylation of substrates at phosphotyrosine sites, and the potential adaptor and effector substrate proteins are portrayed. (From Scheijen B, Griffin JD. Tyrosine kinase oncogenes in normal hematopoiesis and hematological disease. Oncogene 2002;21:3314–3333, with permission.)

The overall frequency of FLT3-ITD in adult AML is 24% of patients, whereas in pediatric AML the frequency is somewhat lower at 10 to 15% (reviewed in reference 189). The frequency is very low in MDS and ALL. In contrast, the FLT3 activation loop mutation is reported in 7% of AML, 3% of MDS, and 3% of ALL patients ([194]). FLT3-ITD is detected most frequently in the M3 FAB subtype of AML, but has been detected in all FAB subtypes ([189]). The role of the FLT3-ITD in leukemogenesis has been investigated by retroviral transduction of murine bone marrow stem cells followed by transplantation into mice. These mice develop a myeloproliferative disease with predominantly maturing myeloid elements, but they do not develop acute leukemia ([195]). Therefore, the FLT3 mutations may confer the proliferative signal in patients with acute leukemia, whereas a concomitant balanced translocation or other genetic defect confers the block in differentiation necessary for development of acute leukemia ([189]).

The expression of FLT3 may be the most significant independent prognostic factor for poor outcome in patients younger than 60 years old. In a study of 91 pediatric AML patients on Children's Cancer Group protocol, the remission induction rate was 40% in patients with FLT3-ITD, compared to 74% with wild-type FLT3. The difference in event-free survival at 8 years was even more striking, at 7% for patients with FLT3-ITD compared to 44% for patients with wild-type FLT3 ([196]). In a study of patients with AML in the age range of 16 to 60 years with otherwise normal cytogenetics, the presence of the FLT3-ITD mutation also significantly decreased the length of remission and overall survival ([197]).

As with BCR-ABL for CML, the implication of a mutant constitutively active tyrosine kinase receptor in the pathogenesis of AML opens up the possibility of identifying a selective kinase inhibitor as a specific treatment for AML patients with a mutant FLT3. At this time, several kinase inhibitors have been identified by inhibition of interleukin-3–independent growth of cell lines expressing FLT3-ITD in culture ([198] , [199]). These inhibitors bind to the ATP recognition domain of the enzyme and have differing degrees of specificity for the mutant FLT3 versus other kinases. They also prevent development of leukemia in mice transplanted with marrow transduced

with a FLT3-ITD–expressing retrovirus. Clinical trials will soon indicate whether these inhibitors will be effective clinically ([200]).

MICROARRAY ANALYSIS OF ACUTE LEUKEMIA

This chapter focuses on analysis of translocations present in acute leukemia, the majority of which produce a fusion protein encoding an abnormal transcriptional regulator. It is assumed that the aberrant regulation of the targets of this protein is directly relevant to leukemogenesis, but in only a few cases have a handful of putative targets been identified. Development of the technology of microarray analysis has made it possible to examine the global changes in gene expression that occur in leukemic cells. Microarray analysis of leukemic blasts from patients bearing recurring mutations, as well as controlled experiments in which gene expression profiles of hematopoietic stem cells transduced with a retrovirus encoding the aberrant fusion product are compared to profiles of hematopoietic stem cells transduced with retroviral vector only, will lead to a better understanding of the transcriptional targets involved in leukemogenesis.

Gene expression profiling, or microarray analysis, is a technique that has emerged as a powerful way to glimpse a large proportion of the genes being transcribed in a tissue at any one time. This provides a more global and unbiased view of gene expression than the traditional Northern blot, which assays for the expression of a handful of candidate genes. The potential goals of this approach to study acute leukemia are several-fold: (a) discovery of previously unidentified subsets of ALL or AML that may have prognostic significance; (b) discovery of novel markers or groups of genes that allow class prediction, and thus aid in diagnosis of a case that is indeterminate by traditional morphologic and flow cytometric grounds; and (c) discovery of sets of genes that are instructive as to the pathogenesis of acute leukemia. These goals have been met to some degree by several recently published studies.

Microarray analysis involves preparing RNA from tumor samples that is then reverse transcribed to complementary DNA (cDNA), labeled with a fluorochrome, and hybridized to oligonucleotide arrays (Affymetrix) containing sequence from greater than 5000 genes. cDNA arrays can also be used, in which case the cDNA from the test sample is hybridized along with reference cDNA labeled with a different fluorochrome onto cDNA spotted on a micro-grid. However, most of the published studies on leukemia have been performed on Affymetrix oligonucleotide arrays. The normalized expression value for each gene is expressed as a number and visualized as a color representing expression higher or lower than the mean of all the samples.

In the first microarray experiment performed using leukemia samples, 38 bone marrow samples, 27 ALL and 11 AML, were analyzed using an oligonucleotide grid containing probes for 6817 genes ([168]). Neighborhood analysis was performed to determine a subset of genes that would be “class predictors,” assigning a given specimen to ALL or AML. The validity of this set was tested by cross-validation on the initial data set and then by the use of the predictive genes to categorize a new test set of samples. In 29 of 34 new samples, strong predictions were made with 100% accuracy. Among the genes identified in this group of predictors were membrane markers such as CD33 and CD11c. However, other genes involved in cell cycle progression, chromatin remodeling, adhesion, transcription, and oncogenesis were defined. Among cases from patients with treatment failure, the homeobox gene *HOXA9* was the single most highly correlated gene.

Further validation of the efficacy of microarray analysis in the subtyping of acute leukemia was demonstrated in a study of 367 bone marrow samples from pediatric patients with ALL ([201]). These samples were initially analyzed using Affymetrix-oligonucleotide microarray containing 12,600 probe sets. Analysis of the data using an unsupervised, two-dimensional, hierarchical clustering algorithm to group the leukemic samples having the most similar patterns of gene expression identified six major subtypes that corresponded to known subtypes of ALL: T-ALL and B-ALL with the following cytogenic abnormalities: E2A-PBX1, MLL, hyperdiploid >50, BCR-ABL, and TEL-AML-1 (Fig. 76.9). That clustering of cases based on gene expression patterns corresponds to known cytogenetically defined subsets of ALL validates the significance of the gene expression patterns. A seventh group consisting of a somewhat more heterogeneous gene expression pattern corresponded to cases with a mixture of normal and abnormal cytogenetics (14 of 327 cases). However, the manner in which this study extended the understanding of ALL was in its ability to predict prognosis in a limited manner. Using supervised learning algorithms within the T-ALL and hyperdiploid >50 subgroups, gene expression profiles identified cases that went on to relapse with an accuracy of 97% and 100%, respectively, by cross-validation methods. In addition, in the TEL-AML-1 subtype, a distinct profile of 20 genes characterized those patients who developed therapy-related AML. The goal of this diagnostic approach would be to predict those patients likely to relapse to tailor the strength of the chemotherapy regimen appropriately.

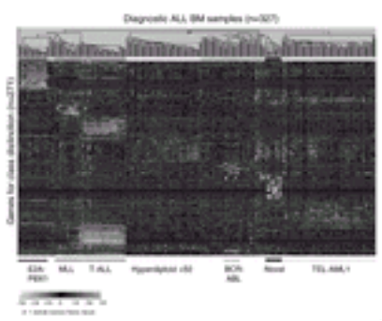

Figure 76.9. Microarray analysis of pediatric acute lymphoblastic leukemia (ALL). Hierarchical clustering of 327 diagnostic ALL samples (columns) versus 271 genes (rows). The genes used in this analysis are the top 40 genes chosen by a chi-square statistic that are most highly correlated with the seven specific class distinctions. The normalized expression value for each gene is indicated by a color, with red representing high expression and green representing low expression, with the scale shown at the bottom. See Color Plate. (From Yeoh E-J, Ross ME, Shurtleff SA, et al. Classification, subtype discovery, and prediction of outcome in pediatric acute lymphoblastic leukemia by gene expression profiling. Cancer Cell 2002;1:133–143, with permission.)

An additional aspect of microarray analysis of acute leukemias is the identification of new subcategories of leukemias based on pathogenesis. Identification of genes whose expression is uniformly altered in these subcategories advances the understanding of pathogenesis and may suggest novel therapeutic targets. For instance, subsets of T-ALL and B-ALL that harbor an MLL translocation also overexpress several *HOX* genes, *HOXA9*, *HOXA10*, and *HOXC6*, as well as the *MEIS1 HOX* co-regulator ([112]). Because *MLL* appears to be a *HOX* gene regulator, ([103], [104]) these genes may be aberrantly regulated by the mutant MLL. In another study, microarray analysis was used to subdivide 59 pediatric T-ALL cases into five groups that correspond to overexpression of different T-cell oncogenes (*HOX11, TAL1/SCL, LYL1, LM01*, and *LM02*) ([167]). The gene expression pattern associated with three of these categories appears to correlate with stages of thymocyte differentiation. High levels of Lyl1 expression were associated with a gene expression pattern characteristic of an undifferentiated thymocyte ($CD34^+$, L-selectin+, BCL-2+, and LSP1). Similarly, high levels of HOX11 correlated with a gene expression pattern of early cortical thymocytes, whereas TAL1/SCL expression correlated with a gene expression pattern of late cortical thymocytes. This supports the long-standing notion that stage-specific developmental arrest of leukocytes occurs in leukemia. These studies demonstrate that microarray analysis may allow subclassification of leukemia into meaningful groups with unique prognosis and pathogenesis.

SUMMARY

This chapter has reviewed the major translocations found in acute leukemia with a focus on understanding the function of the fusion protein encoded by the translocated genes. A major theme has been alteration of transcriptional regulation. Study of the aberrant transcription factors resulting from translocations has increased the understanding of the importance of histone acetylation and deacetylation in transcriptional regulation. This in turn has led to trials of HDAC inhibitors as potential transcription therapy agents. Study of mutated tyrosine kinases present in leukemia led to the first specifically engineered kinase inhibitor for the therapy of CML and Ph+ ALL. Kinase inhibitors are being developed for the relatively common mutant FLT3 proteins present in AML. This is a truly exciting time for hematologic oncology, in which increased understanding of the pathogenesis of acute leukemia is leading to development of new therapeutic agents. However, mouse models demonstrating that several genetic events are necessary for the development of acute leukemia underscore the complexity of the process.

ACKNOWLEDGMENTS

I thank Drs. Stephen Brandt, Scott Hiebert, and Katherine Hamilton for critical review of the manuscript and Ms. Brenda Miller for assistance with the manuscript.

Classification and Differentiation of the Acute Leukemias

The acute leukemias are a heterogeneous group of neoplasms arising from transformation of uncommitted or partially committed hematopoietic stem cells ([1]). The retained partial capacity of differentiation was the basis for phenotypic classification that evolved throughout the twentieth century. Acute leukemias are divided into myeloid (or nonlymphocytic) and lymphoid. These differ somewhat in clinical presentation and differ substantially in response to therapy and course. Therefore, differentiation of acute lymphoblastic leukemia (ALL) from acute myeloid leukemia (AML) is fundamental to therapeutic decisions. Further subclassification of each group has become essential, as treatment is evolving for specific genetic and pathogenetic groups of disease. The initial diagnostic workup of acute leukemia is critical, and requires a variety of sophisticated laboratory techniques, some of which are currently available only in specialized centers.

Acute leukemias are currently classified pragmatically by a combination of differentiation (AML vs. ALL, precursor B vs. precursor T-lymphoblastic leukemia/lymphoma), pathogenesis (myelodysplasia-related vs. *de novo* AML), and genetic abnormalities [e.g., acute promyelocytic leukemia (APL) with t(15;17)]. Lineage assignment is based on morphologic features, cytochemistry, and immunophenotyping. Correlation between experienced observers in classification increases from approximately 70% to greater than 95% when morphologic criteria alone are supplemented with cytochemistry and immunophenotyping ([4]). Obtaining accurate morphologic, cytochemical, immunophenotypic, and genetic data are critical for guiding treatment decisions. The clinical features of ALL and AML are considered in Chapter 78, Chapter 79, Chapter 80, Chapter 81 and Chapter 82, respectively.

DIAGNOSTIC EVALUATION

An adequate sample is critical for accurate diagnosis and classification of acute leukemia. Obtaining a proper sample for complete evaluation (i.e., microscopy, immunophenotyping, cytogenetics, and molecular genetics) must be emphasized before initiation of definitive therapy. Initiation of any definitive therapy before this, including corticosteroids, compromises accurate diagnosis, and hence proper treatment, of the patient.

Clinical Features

Clinical features are not definitive for differentiation of ALL and AML. The age profiles of the acute leukemias differ, but overlap completely. ALL is predominant in childhood and AML in adults (Fig. 77.1) ([2], [3]). Massive lymph node enlargement (diameter exceeding 2 or 3 cm) is suggestive of ALL. Widening of the mediastinum as a result of thymic enlargement is encountered most often in ALL of the T-cell type. Solid masses of leukemic cells (i.e., myeloid sarcoma, also known as *chloroma* or *granulocytic sarcoma*), often involving facial or intracranial structures, may occur in AML. Extensive involvement of the gums is common in acute monocytic leukemia ([2]).

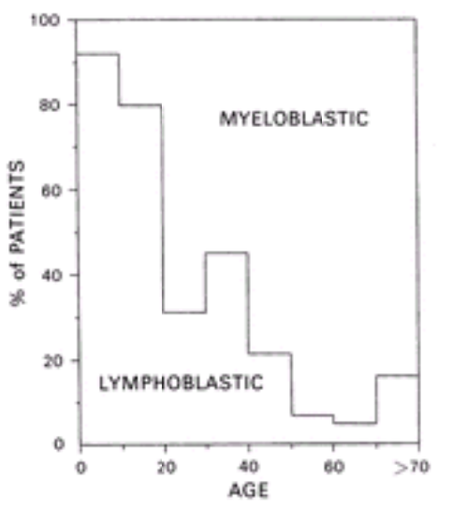

Figure 77.1. Relative frequencies of acute lymphoblastic leukemia and acute myeloid leukemia at different ages (based on data compiled from two series). (Adapted from Boggs DR, Wintrobe MM, Cartwright GE. The acute leukemias. Analysis of 322 cases and review of the literature. Medicine 1962;41:163–225; and Freireich EJ, Gehan EA, Sulman, et al. The effect of chemotherapy on acute leukemia in the human. J Chronic Dis 1962;14:593–608.)

Morphology

The morphologic and cytochemical features of the acute leukemias are illustrated in Figure 77.2, Figure 77.3, Figure 77.4, Figure 77.5, Figure 77.6, Figure 77.7, Figure 77.8 and Figure 77.9, and in texts ([5], [6] and [7]). Even experienced morphologists can accurately classify only 70 to 80% of acute leukemias as ALL or AML on Romanovsky-stained smears. Helpful features are chromatin (fine in myeloblasts, often clumped in lymphoblasts), nucleoli (distinct in myeloblasts, variable in lymphoblasts), and cytoplasm (moderate or abundant, often with granules in myeloblasts; scant to moderate, granules uncommon in lymphoblasts) (Fig. 77.2 and Fig. 77.4). The granules of standard APL are large and reddish violet; in the microgranular variant of APL, they are indistinct (Fig. 77.5). ALL demonstrates cytoplasmic granules in approximately 10% of cases; the granules are usually larger and less abundant than those seen in AML ([8], [9] and [10]) (Fig. 77.2D). Auer rods, refractile needlelike crystalline inclusions in azurophilic granules, are diagnostic of myeloid blasts (Fig. 77.4B). Auer rods may be single or multiple (faggots) and are seen in 60 to 70% of AML cases. The appearance of more differentiated myeloid cells in the marrow may provide a clue to myeloid lineage, particularly if the marrow is arising out of myelodysplasia. Erythroid and maturing myeloid precursors may be megaloblastoid in AML, but normal in ALL. Ring sideroblasts may be present.

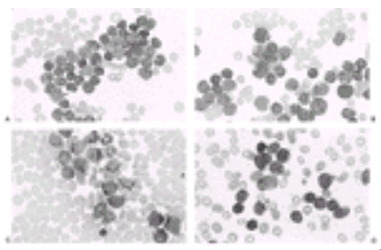

Figure 77.2. Acute lymphoblastic leukemia (ALL) cytologic appearance, Wright stain. **A:** French/American/British (FAB) L1 lymphoblasts, marrow. The blasts are small with folded or clefted nuclei, fine to condensed chromatin, and scant cytoplasm. Nucleoli are inconspicuous. **B:** FAB L2 lymphoblasts, marrow. The blasts are larger with more cytoplasm. Most nuclei are irregular or folded and chromatin is dispersed. Nucleoli are prominent. **C:** FAB L3 lymphoblasts, marrow. The blasts are medium to large with abundant vacuolated basophilic cytoplasm. The nuclei are round with dispersed chromatin and prominent nucleoli. **D:** ALL with cytoplasmic granules, marrow. These granules were Sudan black negative with this stain and had a typical ALL immunophenotype (CD19 $^{+}$, CD10 $^{+}$, CD34 $^{+}$, TdT $^{+}$). See Color Plate.

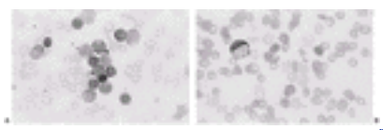

Figure 77.3. Acute lymphoblastic leukemia (ALL) cytochemical studies. **A:** Precursor B ALL. Blasts have coarse granular and block periodic acid-Schiff positivity. **B:** Precursor B ALL. Blasts are Sudan black negative. A residual normal myeloid cell is positive. See Color Plate.

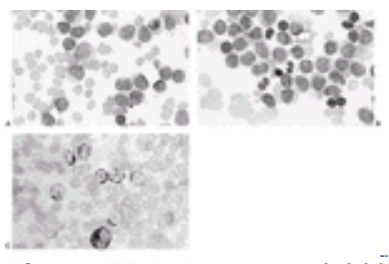

Figure 77.4. Acute myeloid leukemia, minimally differentiated [French/American/British (FAB) M1] and differentiated (FAB M2), marrow. Wright stain and cytochemical studies. **A:** FAB M1. Myeloblasts predominate with few maturing myeloid elements. **B:** FAB M2. Blasts show maturation beyond the blast stage. Numerous Auer rods are present. **C:** FAB M2. Blasts are Sudan black positive. See Color Plate.

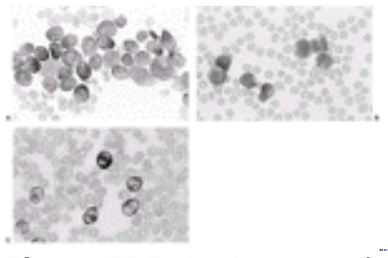

Figure 77.5. Acute promyelocytic leukemia (APL), French/American/British (FAB) M3, M3v. Wright stain and cytochemical studies (**A**, marrow; **B** and **C**, blood). **A:** Typical hypergranular APL (FAB M3h) has hypergranulated promyelocytes. **B:** The microgranular variant, FAB M3v, has promyelocytes with folded, indented, or U-shaped nuclei and abundant cytoplasm with scant, fine, pink granules. These may be confused with myelomonoblasts. **C:** FAB M3v. The promyelocytes are strongly Sudan black positive. See Color Plate.

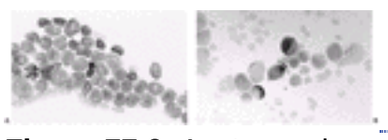

Figure 77.6. Acute myelomonocytic leukemia, French/American/British (FAB) M4, marrow. Wright stain and cytochemical studies. **A:** The blasts have myeloid and monocytic differentiation. **B:** Combined esterase stains show chloroacetate esterase reactivity (*red*) in myeloblasts and nonspecific esterase reactivity (*black*) in monoblasts. See Color Plate.

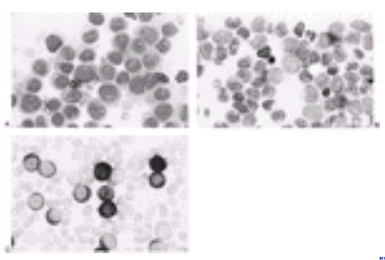

Figure 77.7. Acute monocytic leukemia, French/American/British (FAB) M5, marrow. Wright stain and cytochemical studies. **A:** FAB M5a. Predominant cell is a monoblast. **B:** FAB M5b. Blasts show differentiation to promonocytes and monocytes. **C:** FAB M5a. Nonspecific esterase is strongly positive. The reaction is inhibitable with fluoride treatment (not shown). See Color Plate.

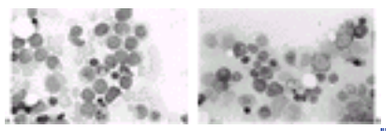

Figure 77.8. Erythroleukemia, French/American/British (FAB) M6, marrow. Wright stain and cytochemical studies. **A:** FAB M6 has a mixture of myeloblasts and erythroid precursors. Auer rods are present. Erythroid cells have dysplastic features, including megaloblastic change, lobated nuclei, and cytoplasmic vacuolization. **B:** The pronormoblasts have strong, coarse, blocklike periodic acid-Schiff staining, and later stage erythroids are diffusely positive. See Color Plate.

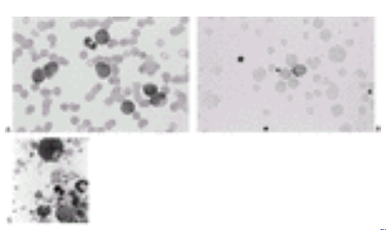

Figure 77.9. Megakaryocytic leukemic French/American/British (FAB) M7, marrow. Wright stain and immunoalkaline phosphatase staining. **A:** Megakaryoblasts often

have dense chromatin and little cytoplasm, as shown here. **B:** Some megakaryoblasts have cytoplasmic blebs. **C:** The megakaryoblastic origin is confirmed by demonstrating CD41 expression using immunoalkaline phosphatase staining. See Color Plate.

Cytochemistry

Cytochemical stains may be used to demonstrate myeloid differentiation in leukemic blasts. Useful stains are myeloperoxidase (MPO), Sudan black B (SBB), and nonspecific esterase (NSE) (Fig. 77.3, Fig. 77.4, Fig. 77.5, Fig. 77.6, Fig. 77.7 and Fig. 77.8). Periodic acid-Schiff (PAS) and specific esterase (SE) stains are less helpful. The cytochemistry of the acute leukemias has been reviewed extensively ([10], [11], [12], [13], [14] and [15]).

The MPO reaction is positive in cells of the granulocytic series and may be weakly positive in monocytes. MPO is located in the azurophilic granules of neutrophils and monocytes and specific granules of eosinophils. The reaction may be positive in poorly differentiated myeloblasts that lack azurophilic granules on Wright stain. Staining may be most pronounced in the Golgi region. Lymphocytes and erythroid precursors are negative. MPO is useful for distinguishing AML from ALL; demonstration of MPO activity in leukemic blasts establishes a diagnosis of AML ([16], [17]). In cases of ALL, residual normal MPO-positive immature myeloid precursors are present in small numbers. A threshold of 3% positivity is frequently used to separate these from lymphoblasts, but regardless of threshold, lymphoblasts themselves are MPO negative.

SBB stains granule membranes (Fig. 77.4C). The pattern of staining closely parallels MPO, but SBB positivity is usually stronger than MPO. Monocytes may contain sudanophilic granules, and monocytic leukemias may be SBB positive. Erythroid precursors are negative, and lymphoblasts are negative for myeloid-type intense positivity. SBB is useful for distinguishing AML from ALL, but ALL (especially granular ALL) may have weak SBB positivity ([18], [19]), so it is important to compare reactivity to residual normal differentiating myeloid precursors. Auer rods are both MPO and SBB positive. As with MPO, a threshold of 3% positivity is frequently used to accommodate normal residual myeloid precursors in ALL, but regardless of threshold, lymphoblasts are negative for MPO-type SBB positivity.

NSE activity is found in monocytes (Fig. 77.6B and Fig. 77.7C). Several substrates are available, but the most commonly used are alpha naphthyl butyrate (ANB) and alpha naphthyl acetate (ANA). Reactivity in monocytes is granular or diffuse, dependent on the color developer used. Monocytic NSE is inhibited by sodium fluoride (NaF). This is generally unnecessary with the ANB stain, but the ANA stain also reacts with megakaryoblasts with a coarse granular pattern. In megakaryoblasts, the NSE activity is partially resistant to NaF inhibition. Megakaryoblasts are negative with ANB staining. These features may be used to identify megakaryoblasts, although if possible this should be corroborated with immunophenotyping. Twenty-five percent of APL cases are NSE positive ([20]). Lymphoblasts may be positive for NSE, with variable inhibition by NaF.

The substrate for SE staining is naphthol AS-D chloroacetate. SE is present in neutrophils and their precursors, but may also be present in monoblasts and monocytes. In the neutrophil series, it is only found in specific granules; hence, the reaction is typically negative in poorly differentiated AML, and the stain is not very useful for leukemia classification. SE has been used to demonstrate myeloid precursors in tissue sections (Leder stain). Monoblasts may have diffuse cytoplasmic staining, and lymphoblasts (especially granular lymphoblasts) may be positive with a granular pattern.
