All pregnant women should have their ABO/Rh type and antibody screen determined at the first visit to the obstetrician ([61]). These initial tests identify women as candidates for RhIG administration or for additional monitoring during pregnancy. After detection of clinically significant red cell alloantibodies, further testing may be required for evaluation of FMH, antenatal assessment of fetal anemia, and detection of neonatal anemia and hyperbilirubinemia. The principles of these laboratory tests and controversies surrounding their use are described below; specific practice recommendations for prevention and treatment of HDF/N are described in the subsequent sections Prevention of Maternal D Alloimmunization with Rh Immune Globulin , Management of Red Cell Alloimmunization in Pregnancy, and Treatment of the Newborn Infant.

Maternal ABO/Rh Type and Antibody Screen

The red cell ABO/Rh type is assigned in the forward group reaction by incubating the patient's red cells with IgM or IgG antibodies that cause their immediate and visible agglutination if they express the corresponding A, B, or D antigens. The reverse group identifies plasma reactivity due to ABO isoagglutinins and should confirm the forward, red cell typing reactions. The forward reaction for the D antigen may include an additional phase with antihuman globulin to enhance red cell agglutination and detect weak expression of the D antigen on the red cells.

Formerly known as *Du*, weak D phenotypes are due to quantitative or qualitative alterations in D antigen expression. Although weak D occurs in as much as 1 to 3% of the population, the risk of a weak D mother producing anti-D in pregnancy may be as low as 1 in 150,000 ([24] , [62]). In these rare cases of maternal alloimmunization, the infants demonstrated only mild HDN, although a single fatal case has been documented ([63]). Acknowledging the rarity of alloimmunization and the propensity for mild disease in this clinical setting, the American Association of Blood Banks has made testing pregnant women for weak D optional, and the American College of Obstetricians and Gynecologists (ACOG) recommends against administration of RhIG to weak D–positive women ([38] , [61]).

The antibody screen detects maternal antibody in plasma by hemagglutination in an indirect antiglobulin test, which is also referred to as the *indirect Coombs test*. The reaction conditions should allow detection of clinically significant IgG alloantibodies that are reactive at 37°C in the antiglobulin phase. Conditions that permit identification of IgM antibodies are not required in the setting of obstetric testing, because IgM antibodies cannot cross the placenta. If IgM antibodies cause interference in the antibody screen, reducing agents such as dithiothreitol can be used to eliminate their reactivity in the assay and allow for specific detection of IgG antibodies. If the initial antibody screen is negative, the need to repeat testing at 28 weeks' gestation is currently debatable. Arguments for eliminating this testing include the extremely low probability that anti-D or other antibodies are formed during pregnancy ([47] , [64]).

Serologic and Molecular Testing for Paternal/Fetal Blood Group Antigens

If a potentially significant red cell alloantibody is detected in a pregnant woman, the blood type of the biologic father may be investigated to assess the risk of HDF/N. Three possibilities exist: The father lacks the antigen, and the fetus is not at risk; the father is heterozygous for the antigen, and the fetus may be at risk; the father is homozygous for the antigen, and the fetus is definitely at risk. To distinguish between the latter two possibilities, paternal D antigen zygosity may be deduced by serologic determination of the extended Rhesus phenotype (D, Cc, Ee) based on the prevalence of Rh haplotypes in different populations and the Rh type of previous children ([65]). Another indirect approach to determine paternal zygosity involves parallel quantitative amplification of *RHD*- and *RHCE*-specific sequence ([66]). The development of direct, D allele–specific molecular assays is complicated by the genetic diversity of the D locus and the variety of insertions, deletions, and missense and nonsense mutations in the RHD gene that can produce the D-negative phenotype. Recently, a molecular test to specifically detect the most prevalent D-negative allele in white populations, the complete *RHD* deletion, was developed ([67]). This approach may be amenable to routine use in most laboratories, but its clinical application will be limited until modification allows for detection of other common D-negative alleles in ethnically and racially heterogeneous donor populations. Determining the paternal genotype of other blood group determinants is more straightforward with the currently available allele-specific assays for other Rh (C/c; E/e), Kell (K1/K2), Duffy (Fy [a]/Fy [b]), Kidd (Jk [a]/Jk [b]), and other red cell loci ([66]).

For definitive prenatal diagnosis, the fetus's red cell type may be determined by serologic or molecular methods. Standard immunohematologic assays for blood typing can be performed on fetal blood obtained by cordocentesis ([41]). Alternatively, polymerase chain reaction–based molecular assays for D and other blood group antigens use fetal DNA isolated from amniotic fluid or fetal blood ([66]). Because these invasive sampling procedures are associated with the risk of fetal morbidity or mortality, the feasibility of isolating fetal cells or genetic material from the mother's venous blood is an area of active investigation. RHD sequences can be detected in the circulation of many D-negative pregnant women, even in the first trimester, but a failure rate as high as 30% currently limits the clinical use of this approach ([68] , [69]).

Maternal Red Cell Alloantibody Titers

If molecular testing suggests the fetus is at risk for HDF/N, or if molecular testing cannot be performed, determination of the maternal red cell alloantibody concentration may be used as a screening test to guide further clinical management ([70] , [71] and [72]). The concept of a “critical titer” of maternal antibody has been criticized based on the poor predictive accuracy for severe HDN ([73] , [74]). However, critical titers are used not to predict the development of severe hemolytic disease after birth, but rather to predict its absence during gestation, because titers below “critical” thresholds are unlikely to require aggressive intervention *in utero*. In a classic study almost 50 years ago, Allen et al. followed 174 pregnancies with no history of affected fetuses or infants and with antibody titers of 1:32 or lower and reported 174 (96%) had live infants at 37 weeks' gestation ([70]). The observation that significant intrauterine disease is unlikely to occur when the antiglobulin titer remains low has been substantiated in recent studies ([71] , [72]). Recognizing that amniocentesis, cordocentesis, or both may cause fetal morbidity or mortality, most obstetricians and fetal-maternal specialists rely on maternal antibody titers as a screening test and do not perform these invasive procedures until the antibody level exceeds a critical titer or increases significantly in serial measurements ([33] , [61] , [71] , [72]).

Antibody titers are determined with the indirect antiglobulin (Coombs) test by making several dilutions of maternal serum in saline, adding reagent red cells and anti-IgG, and observing for macroscopic agglutination in the tubes. The titer is reported as the reciprocal of the highest dilution at which this endpoint is observed; for example, agglutination with a serum dilution of 1:16 but not 1:32 would be reported as an antibody titer of 16. Alternatively, a 12-point scoring system that takes into account the strength of agglutination as well as the dilution factor may be a more specific indication of severe fetal anemia but is used less commonly than simple tube-titration in current practice ([41] , [72]).

Because serial measurements of maternal antibody titer are necessary, an initial maternal sample should be frozen for comparison in subsequent titers determined with the same method, technique, and reagent red cells ([61]). A difference of greater than two dilutions or a score increase of more than ten should be considered a significant change in titer ([61] , [72]). For anti-D, the critical titer is often considered 16 (range, 8 to 32) ([61]). Critical titers for antibodies other than anti-D have been suggested, based on cumulative clinical experience at a center or historical published data. Because severe fetal disease may be caused by lower titers of anti-K than anti-D, a lower critical threshold of eight has been recommended for Kell-sensitized pregnancies ([33]). In contrast, other antibodies are less likely than anti-D or anti-K to cause hemolytic disease at low titers, and higher thresholds have been proposed for anti-Fy ^{a} (titer, 64), anti-M (titer, 32 to 64), and anti-U (titer, 128) ([33] , [72]). Anti-M often demonstrates IgG and IgM components that can be distinguished with the use of reducing agents in titration studies, and anti-M–sensitized pregnancies are managed on the basis of the titer of the IgG component ([33]).

Investigated as an alternative to maternal antibody titer, antibody functional assays, such as the monocyte monolayer assay, the antibody-dependent cellular cytotoxicity assay, and chemiluminescence test, examine the behavior of potentially significant red cell antibodies *in vitro* ([74] , [75]). These assays evaluate the ability of the maternal IgG antibody to interact with target red cells and effector cells expressing Fc receptors, such as lymphocytes or monocytes, to cause adherence, phagocytosis, or cytotoxic lysis. The antibody-dependent cell-mediated cytotoxicity assay showed a higher specificity than maternal antibody titer for prediction of fetal disease and may be more useful in guiding decisions about invasive testing for D alloimmunization in pregnancy ([75]). Antibody functional assays, however, have not been as widely used in the United States as in Europe, primarily due to the fact that prenatal testing is not centralized in highly specialized laboratories in the United States and the technical complexities of the tests precludes their use at most American centers ([61]).

Tests for Fetal-Maternal Hemorrhage

An assessment of the volume of fetal cells in the peripheral circulation of a D-negative woman must be performed to determine the adequacy of the dose of administered RhIG after delivery of a D-positive infant and in other obstetric situations ([38] , [39] and [40] , [76]). A common approach to evaluating FMH is the rosette test to screen for the presence of fetal cells followed by the Kleihauer-Betke acid elution method to quantify the magnitude of the bleed. The rosette test is a modified antiglobulin reaction, based on detection of the fetal (D-positive) red cells in a maternal (D-negative) blood sample. On reaction with reagent anti-D Ig, fetal (D-positive) red cells form small clumps or rosettes around indicator D-positive red cells (Fig. 36.2) ([41]). The presence of rosettes is a sensitive qualitative screen for FMH. A positive test is obtained in 75% of women with FMH of 2.5 ml of D-positive red cells (5 ml whole blood) and all women with FMH of 5 ml of D-positive red cells (10 ml whole blood) or more ([76] , [77]). If it is determined that an infant has the weak D phenotype, the rosette test is not reliable, and FMH should be evaluated with tests that do not rely on detection of the expression of the D antigen, such as the Kleihauer-Betke acid elution method ([61]). Rarely, maternal anti-D is present at such high concentration on the surface of fetal red cells that interaction with the reagent anti-D is blocked, and the rosette assay produces a false-negative result.

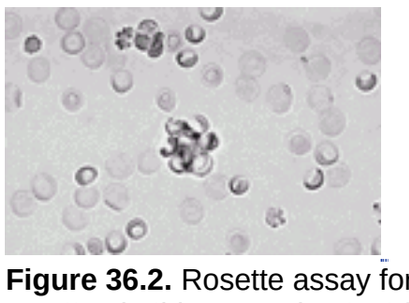

Figure 36.2. Rosette assay for fetal-maternal hemorrhage (FMH). D-positive red cells are identified in a background of D-negative red cells by the formation of rosettes in this screening test for FMH. There are two rosettes in this field—a large one in the center and a smaller one above it; unagglutinated red cells appear as refractile, biconcave (unstained) disks. See Color Plate.

The Kleihauer-Betke acid elution method provides a quantitative estimate of the volume of FMH based on the different solubility properties of fetal hemoglobin (HbF) and adult hemoglobin (HbA). On a peripheral blood smear treated with an acidic solution and counterstained, red cells containing acid-soluble HbA appear as pale ghosts compared to the deeply stained red cells containing acid-resistant HbF (Fig. 36.3). The Kleihauer-Betke test result is reported as the percentage of HbF-stained fetal cells present on the smear ([76]). The corresponding magnitude of FMH is calculated by multiplying the percentage of fetal cells, expressed as a fraction, by the maternal blood volume, which is 70 to 75 ml/kg or approximately 5000 ml for an average pregnant woman. For example, a Kleihauer-Betke result of 1.4% indicates the presence of 70 ml of fetal whole blood (0.014 × 5000 ml). The Kleihauer-Betke test is sensitive to bleeds between 0.01 and 0.06% or 0.2 to 1.0 ml, but samples containing at least 0.5% fetal cells are detected more reliably ([76] , [78]). Kleihauer-Betke results that exceed the total predicted fetal blood volume based on gestational age (i.e., 3 ml at 12 weeks; 30 ml at 20 weeks) may reflect the inherent technical imprecision of the method or may reveal precedent maternal conditions associated with increases in HbF-containing red cells such as hereditary persistence of HbF. Notably, the levels of HbF often increase during pregnancy in as many as 25% of women ([79]). In addition to these false-positives, the Kleihauer-Betke test tends to overestimate the quantity of hemorrhage, resulting in administration of more RhIG than is necessary ([78]). This inherent potential for “overdosing” RhIG is not a problem from a medical standpoint given the safety record of the drug, but it is a concern to countries coping with RhIG shortages or those striving for the most cost-effective use of RhIG ([40]).

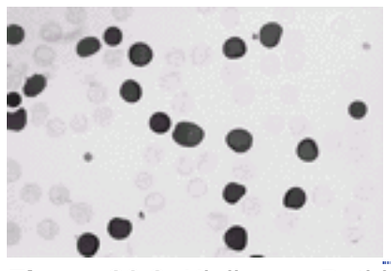

Figure 36.3. Kleihauer-Bethke acid elution for fetal hemoglobin (Hb). Cord blood was mixed with blood from a healthy adult to simulate fetal-maternal hemorrhage, and a Kleihauer-Bethke was performed. Red cells containing HbF are deeply stained red; red cells containing HbA appear as pale pink ghosts. See Color Plate.

Alternative methods to quantify FMH include flow cytometry and the enzyme-linked antiglobulin test ([80], [81]). Most flow cytometric assays for FMH are based on detection of the D antigen on fetal red cells, but detection of HbF-containing fetal red cells is also possible ([80]). Flow cytometric methods are sensitive to FMH of 0.1% or 1.8 ml and can be used to detect events as rare as 1 fetal cell in 10,000 maternal cells ([78]). The enzyme-linked antiglobulin test is a modified enzyme-linked immunosorbent assay and detects D-positive red cells in a maternal D-negative background by successive incubations with anti-D, anti-IgG conjugated with the enzyme alkaline phosphatase, and an enzyme substrate ([81]). This test is sensitive to 0.25% or 3 ml FMH ([41], [81]). Both the enzyme-linked antiglobulin test and flow cytometry are reproducible and reliable but are not as commonly used in practice as the Kleihauer-Betke test for quantifying FMH.

Noninvasive Fetal Monitoring

Fetal ultrasonography and Doppler studies of blood flow velocity in fetal vessels have been investigated as means to predict the severity of fetal anemia and guide the use of invasive methods in alloimmunized pregnancies. Images obtained with ultrasound are also used to guide needle placement during invasive procedures such as amniocentesis, cordocentesis, and intrauterine transfusion. Early sonographic signs of worsening fetal anemia include increases in the size of the fetal liver or spleen, an increase in placental thickness, the presence of effusions or polyhydramnios, visualization of both sides of the fetal bowel, and abnormalities of pulsed Doppler flow velocity waveforms in fetal vessels ([82]).

Variability in the use of ultrasound techniques and methodologic flaws in study design hamper systematic evaluation of the diagnostic accuracy of these tests in the clinical setting of HDF/N ([82]). Recent data support a role for measurement of the peak velocity of systolic blood flow in the middle cerebral artery of the fetus by Doppler velocimetry in cases of maternal red cell alloimmunization, but the strength of the conclusions has been challenged ([82], [83]). In a study of 111 fetuses at risk for anemia due to maternal red cell antibodies, Mari et al. demonstrated an increased peak velocity in the middle cerebral artery of all 35 fetuses with moderate to severe anemia; however, 9 of 76 fetuses (12%) were falsely identified as being as severely affected. The high sensitivity (100%) supports the use of Doppler velocimetry of the middle cerebral artery to screen for moderate to severe fetal anemia; the high negative predictive value (100%) suggests that normal Doppler studies are reassuring in alloimmunized pregnancies. In contrast, Divakaran et al. reexamined the diagnostic accuracy in Mari's study in terms of likelihood ratios and concluded that Doppler velocimetry was only moderately informative for including or excluding HDF, although the study ranked the highest among the noninvasive tests reviewed ([82]).

In practice, ultrasonographic evaluation for fetal assessment is widely and variably used as an adjunct to the invasive tests used to monitor red cell alloimmunized pregnancies. Serial Doppler assessments of the middle cerebral artery are specifically advocated for managing K1-sensitized pregnancies because maternal antibody titers and amniotic fluid studies may be misleading ([33]). Additional study with a more standardized approach to ultrasound and Doppler studies may further validate their clinical usefulness in monitoring fetal anemia.

Amniotic Fluid Analysis

Amniotic fluid analysis by spectrophotometry as introduced by Liley in 1961 is still a cornerstone of obstetric management of red cell alloimmunization in pregnancy ([8]). The principle of the test is based on the characteristic light absorbance by amniotic fluid between 365-nm and 535-nm wavelengths in unaffected pregnancies and the observed deviation from this linear baseline in alloimmunized pregnancies when bilirubin or other optically active compounds are present. An increase in optical density at 450 nm (?OD $_{450}$) relative to the normal baseline is proportional to the amount of bilirubin present in the amniotic fluid. Liley correlated the ?OD $_{450}$ values to clinical outcomes in 101 Rhesus-sensitized pregnancies from 27 weeks' gestation to term, generating what is commonly referred to as the *Liley curve* (Fig. 36.4) ([8]). Values in the lowest zone of the Liley curve, zone I, are reassuring because these infants have only a 10% chance of needing treatment after birth ([8]). In contrast, readings in zone III predict severe hemolytic disease with the risk of impending hydrops and imminent fetal death (within 7 to 10 days) with 98% accuracy ([8]). The presence of contaminating meconium, blood, or the porphyrin-containing breakdown products of red cells interferes with the analysis in approximately 10% of cases but can be remedied with chloroform extraction of the amniotic fluid, reducing this rate to 1% ([85], [86]). Amniotic fluid analysis may also be affected by fetal conditions other than hemolytic disease, such as congenital hepatitis, and maternal diseases, such as sickle cell anemia.

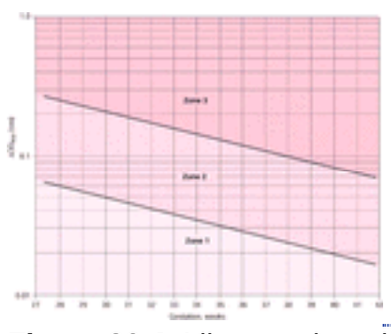

Figure 36.4. Liley graph and management zones for alloimmunized pregnancies, based on amniotic fluid increase in optical density at 450 nm (?OD $_{450}$) determination. (From Liley AW. Liquor amnii analysis in management of pregnancy complicated by rhesus sensitization. Am J Obstet Gynecol 1961;82:1359–1370, with permission.)

In most cases, Liley's method accurately reflects the severity of HDF due to anti-D after 27 weeks' gestation. Although some investigators claim that extrapolating the curves for early time points in gestation can be used to manage alloimmunized pregnancies in the second trimester, others maintain that these “modified” Liley curves are unreliable ([84], [85], [86] and [87]). Queenan et al. directly evaluated amniotic fluid in 520 unaffected pregnancies from 14 to 40 weeks' gestation and from 75 D-immunized pregnancies and developed four zones to guide management decisions in the second trimester (Fig. 36.5) ([88]). Analyzing the trends in the four zones was successfully used to manage pregnancies complicated by alloimmunization to the D antigen as well as the simultaneous presence of multiple blood group antibodies ([88], [89]). Spinnato et al., however, compared the Queenan curve to the modified Liley curve in 73 women sensitized to red blood cell antigens, using Liley data for treatment decisions ([85]). This group concluded that the Queenan approach overestimated risk and would have resulted in premature or unnecessary fetal blood sampling in nine cases ([85]). In contrast, Queenan and others have disputed the use of modified Liley curves in the second trimester, labeling this approach as an inappropriate or dangerous practice ([87], [90]). The controversy over appropriate management of second trimester alloimmunized pregnancies spurred development of management strategies that rely solely on fetal blood sampling that was, in turn, met with some controversy and still underlies considerable variation in current practice ([71], [91], [92]).

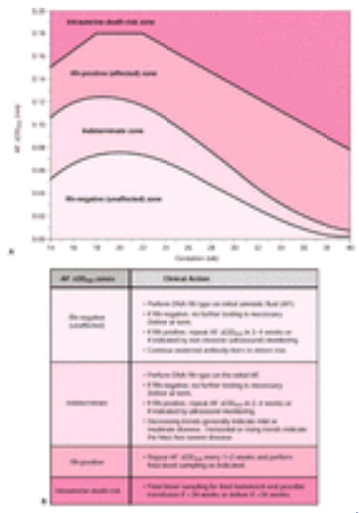

Figure 36.5. Queenan graph and clinical approach to D-alloimmunized pregnancies. **A:** Management zones proposed by Queenan et al. to monitor D alloimmunization in pregnancies, based on amniotic fluid (AF) increase in optical density at 450 nm (?OD $_{450}$) determination. (From Queenan JT, Tomai TP, Ural SH, et al. Deviation in amniotic fluid optical density at a wavelength of 450 nm in Rh-immunized pregnancies from 14 to 40 weeks' gestation: a proposal for clinical management. Am J Obstet Gynecol 1993;168:1370–1376; Mosby Inc., with permission.) **B:** Clinical action for ?OD $_{450}$ zones. (From Queenan JT. Management of Rh-immunized pregnancies. Prenatal Diagn 1999;19:852–855; John Wiley & Sons Limited, with permission.)

Fetal Blood Sampling

Fetal blood sampling (percutaneous umbilical blood sampling, cordocentesis) provides direct access to the fetal circulation for laboratory monitoring or blood transfusion ([93]). With ultrasound guidance, a needle (22- or 20-gauge spinal needle) can be introduced into an umbilical vessel as it enters the placenta or, rarely, at other points in its course. Fetal blood sampling permits direct measurement of HbF, hematocrit, reticulocyte count, and bilirubin, and normal values for these variables have been determined for fetuses from 15 weeks' gestational age onward. In addition, the fetal blood cells can be typed for the antigen in question, and, if positive, the presence of the corresponding maternal red cell antibody on the surface of fetal red cells can be assessed by the direct antiglobulin test.

The risk of fetal loss is generally greater with cordocentesis (1.0 to 2.7%) ([93] , [94] and [95]) than amniocentesis (<1%) ([88]), but their comparative risk has not been systematically evaluated. As experience with these invasive procedures increases at an institution, the risk of procedure-related morbidity and mortality decreases. Both amniocentesis and cordocentesis may cause FMH with consequent increases in maternal antibody titers that could potentially accelerate the course of HDF ([96] , [97]). Other complications of fetal blood sampling include fetal bradycardia, chorioamnionitis, placenta trauma, infection, cord hematoma, thrombosis, bleeding from the puncture site, and rupture of the membranes ([95]).

Laboratory Testing of Newborn Infants

Infants born to women with potentially significant red cell antibodies or those demonstrating clinical signs of hemolytic disease despite a negative maternal antibody screen should have their ABO and D blood type determined and a direct antiglobulin test (DAT; direct Coombs test) performed at birth ([61]). Anti-A and anti-B are not detected in the antibody screen because the reagent red cells are type O but can be detected in an indirect antiglobulin test using reagent group A or B red cells. The DAT involves mixing cord red cells directly with antihuman globulin (anti-IgG) and observing for visible agglutination, which reveals the presence of maternal antibodies on the surface of the newborn infant's red cells ([41]). A negative DAT does not rule out the possibility of immune-mediated hemolytic anemia and may reflect a low surface concentration on fetal red cells or low avidity of the offending antibody under the reaction conditions. In many cases, maternal antibody may be concentrated by elution from the surface of the fetal cells, facilitating its detection. If HDN is still suspected in the absence of both ABO incompatibility and detectable maternal antibody, the maternal serum or an eluate prepared from the infant's red cells can be tested against the biologic father's red cells ([41]). This procedure may detect a maternal antibody directed against a low-incidence red cell antigen that has been associated with severe HDN in rare cases, such as anti-Wr ^{a} (Wright), but is not represented on most red cell panels used for antibody identification ([41] , [61]).

The American Association of Blood Banks does not countenance routine immunohematologic testing of infants in the absence of clinically significant maternal antibodies or without a clinical suspicion of HDN ([61]). Despite these recommendations, some institutions continue to perform ABO/D typing and DATs on all newborn infants; others perform selective testing for infants born to group O mothers. The latter strategy is intended to identify infants at risk of ABO HDN, whose hospital discharge may be planned at less than 24 hours, but it has been criticized because all newborn infants should be monitored for jaundice during the first weeks of life ([61]).

Jaundice is the visible manifestation of increased serum bilirubin concentration, and it becomes apparent when levels exceed 5 mg/dl. Laboratory detection of total, direct (conjugated), and indirect (unconjugated) bilirubin provides important diagnostic information regarding the cause of the jaundice (Table 36.5). In immune-mediated hemolytic disease, the total serum bilirubin concentration may be routinely assayed to guide clinical management, because it is almost entirely unconjugated (indirect) bilirubin. Under investigation are transcutaneous bilirubin measurements as well as measurements of unbound bilirubin, such as the bilirubin to albumin ratio, serum-free bilirubin, bilirubin reserve binding capacity, and bilirubin saturation index, and other signs of elevated bilirubin production such as the carboxyhemoglobin level and exhaled carbon monoxide levels ([98]). Further study is needed to determine the reliability of these tests in managing infants with immune-mediated hemolytic anemia.

PREVENTION OF MATERNAL D ALLOIMMUNIZATION WITH RH IMMUNE GLOBULIN

RhIG prophylaxis is an international standard in obstetric care. Although the efficacy of RhIG in preventing alloimmunization to the D antigen is unequivocal, less clear are the mechanisms by which it inhibits the maternal immune response. Immune-mediated immunosuppression by passively transferred anti-D antibodies is not simply a matter of destruction of the D-positive red cells. This model was postulated initially because ABO-incompatible fetuses are partially protected from D alloimmunization, which suggests that ABO antibodies destroy fetal cells before the host reacts to them ([42]). RhIG, however, does not result in complete clearance of fetal red cells but is effective even though fetal red cells persist in the maternal circulation ([99]). Similarly, the theory that administered RhIG blocks the antigenic stimulus by coating D-positive red cells is not supported by the fact that immunosuppressive doses of RhIG bind only to a small fraction of the available antigen sites on red cells ([99]).

RhIG most likely prevents alloimmunization to the D antigen primarily through the activation of inhibitory intracellular signaling pathways, which ultimately blocks antibody production by the B cell ([99]). The pair of molecular interactions responsible for B-cell inhibition occur between the B-cell receptor (membrane IgG) and the D antigen on the red cell and between the B-cell Fc? receptor and the Fc portion of the bound anti-D on the red cell surface. In a primary immune response, naïve B cells are stimulated to produce antibody when B-cell receptors alone are activated by antigen (Fig.36.6A). In the presence of RhIG, this signal is overridden, and apoptosis occurs when Fc receptors are simultaneously aggregated in the complex by their association with the red cell–bound anti-D antibodies (Fig. 36.6B). Memory B cells differ from naïve B cells in that they can be activated to produce antibody even in the presence of preexisting antibodies. Consequently, RhIG is not effective for preventing a secondary or anamnestic immune response in a previously sensitized woman.

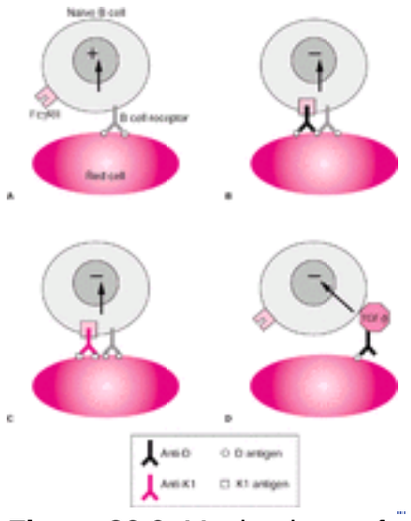

Figure 36.6. Mechanisms of anti-D immune globulin (RhIG) immune prophylaxis. **A:** Alloimmunization. Activation of naïve B cells in a D-negative individual occurs with exposure to D-positive red cells through interaction of the B-cell receptor (surface immunoglobulin) and D antigen. **B:** RhIG immune suppression. Inhibition of B cells is mediated by passively transferred anti-D (RhIG), which cross-links the B-cell receptor and Fc? receptor (Fc?RII). **C:** Specificity of immune suppression. Inhibition of B cells from a D-negative, K1-negative individual occurs despite exposure to D-positive, K1-positive red cells with the administration of anti-K1, in lieu of RhIG, through formation of the same receptor configuration as in **(B)** (i.e., cross-linking the Fc?RII receptor and B-cell receptor for the D antigen). **D:** Fc receptor–independent pathways for RhIG immune suppression. Inhibition or apoptosis of B cells may occur through interaction between the Fc portion of anti-D antibodies (RhIG) and immune complex formation on the surface of D-positive red cells. TGF, transforming growth factor.

Interestingly, immune suppression to the D antigen can be induced not only by anti-D but also by other passively transferred antibodies to a coexpressed blood group antigen, as long as the Fc? receptor is complexed with the B-cell receptor and the antigen (Fig. 36.6C). This phenomenon of coinhibition was supported by the observation that passively administered anti-K1 IgG antibodies suppressed anti-D antibody formation in D-negative/K1-negative human subjects given D-positive/K1-positive red cells ([100]). Finally, animal models of antibody-mediated immune suppression suggest the existence of Fc receptor–independent pathways ([99]). For example, RhIG may bind and localize factors to the B cell that inhibit antibody production and induce apoptosis, such as transforming growth factor-ß (Fig. 36.6D).

Viral Safety Record

All commercially available RhIG products approved for clinical use are polyclonal anti-D preparations derived from the plasma of immunized human donors (Table 36.6). Subsequent to the realization in the 1980s that human immunodeficiency virus (HIV) could be transmitted through blood product transfusion was the demonstration that the Cohn-Oncley fractionation process used for producing some of the RhIG formulations (e.g., RhoGAM) effectively partitioned and inactivated HIV. To further improve the safety of plasma derivatives, a serologic test to screen plasma donors for HIV was first implemented in 1985; a serologic test for hepatitis C virus (HCV) was introduced in 1991; and nucleic acid testing for both HIV and HCV was added to the repertoire in 2000. As a further precaution, specific viral removal steps, such as size-exclusion filtration (RhoGAM), or viral inactivation methods, such as solvent-detergent treatment (WinRho), have been added to the manufacturing process (Table 36.6). Despite these measures, every RhIG product derived from human plasma carries the warning that the potential for disease transmission has not been eliminated.

TABLE 36.6. Anti-D Immune Globulin Products Available in the United States in 2000

Route of Administration/ Brand Name	Manufacturer	Fractionation and Viral Inactivation	Dose	Coverage of D-Positive Red Cells (Whole Blood)	Labeled Indications
IM					
RhoGAM	Ortho-Clinical Diagnostics, Raritan, NJ	Cold alcohol fractionation; size-exclusion filtration [a]	300 µg (1500 IU)	15 ml (30 ml)	Pregnancy/obstetric; D-incompatible transfusion
MicRhoGAM			50 µg (250 IU)	2.5 ml (5 ml)	
BayRho-D full dose	Bayer Biological, Elkhart, IN	Cold ethanol fractionation; solvent-detergent and heat treatment [b]	300 µg (1500 IU)	15 ml (30 ml)	Pregnancy/obstetric; D-incompatible transfusion
BayRho-D mini dose			50 µg (250 IU)	2.5 ml (5 ml)	
IV or IM					
WinRho SDF	Cangene Corporation, Winnipeg, Canada; distributed by Nabi, Boca Raton, FL	Ion exchange chromatography; solvent-detergent and filtration [c]	120 µg (600 IU)	6 ml (12 ml)	Pregnancy/obstetric; D-incompatible transfusion; immune thrombocytopenic purpura
			300 µg (1500 IU)	15 ml (30 ml)	
			1000 µg (5000 IU)	Not for obstetric use	

[a] Filtration reduces levels of enveloped (e.g., hepatitis C, hepatitis B, human immunodeficiency virus) and non–lipid-enveloped viruses (e.g., parvovirus, hepatitis A).

[b] Solvent-detergent and heat treatment removes and inactivates enveloped and nonenveloped viruses.

[c] Solvent-detergent treatment inactivates enveloped viruses, and filtration removes some non–lipid-enveloped viruses.

More than 500,000 doses of RhIG are given to an estimated 350,000 women each year, and no cases of hepatitis or HIV transmission attributed to RhIG have been documented in the United States ([101], [102]). In Ireland and the former East Germany, however, hepatitis C was transmitted to several hundred women by different batches of contaminated intravenous RhIG in the late 1970s, before the introduction of routine donor screening for anti-HCV antibodies in 1991 ([103]). In 1994, HCV RNA was also detected in batches of RhIG manufactured in Ireland between 1991 and 1994, and a single donor was implicated in contributing the infectious plasma to the pool ([103]). A large-scale retrospective investigation screened more than 19,000 recipients of anti-D in this time frame and identified 19 women with the same strain of HCV as the implicated donor ([103]).

HCV transmission was linked in 1993 and 1994 to two brands of intravenous Ig (IVIg) (Gammagard and Polygam), and these infections were the impetus for introducing viral inactivation steps for all plasma derivatives, including RhIG. No cases of viral transmission have been documented in the United States to any plasma derivative since 1995 ([104]). Another precautionary step recently taken in the United Kingdom is the importation of all source plasma for anti-D products from the United States, in light of a theoretical risk of transmission of variant Creutzfeld-Jacob disease from plasma collected in Europe ([40]). No cases of human variant Creutzfeld-Jacob disease transmission have been attributed to blood component transfusion or plasma derivative administration in any country to date. To lessen the reliance on human source plasma, monoclonal antibodies directed against D antigen epitopes have been developed with recombinant technology and compare

favorably to RhIG in preventing D alloimmunization but are not commercially available ([105]).

Dosage and Administration

The effective dose of RhIG to prevent sensitization, 20 µg/ml D-positive red cells, was determined experimentally by challenging D-negative male volunteers with incompatible blood ([106]). Dosage formulations of different preparations of RhIG are based on this conversion, with the “standard” 300 µg (1500 IU) sufficient to protect against FMH of 15 ml D-positive red cells (30 ml fetal whole blood) (Table 36.6) ([76]). The intravenous preparation (WinRho) is used more often for treating immune thrombocytopenia purpura than for preventing D alloimmunization, but it is effective for both indications. Dosage adjustments must be made for FMH that exceeds the volume covered by a dose of RhIG ([41]):

- Multiply the percentage of fetal cells in maternal circulation (expressed as a fraction) by the maternal blood volume (approximately 5000 ml) to determine the volume (ml) fetal whole blood in the maternal circulation [Kleihauer-Betke result of 1.4%: (0.014) (5000 ml) = 70 ml fetal whole blood].
- Divide by the volume of D-positive whole blood covered and round off by standard convention to determine required number of 300-µg vials of RhIG [70 ml fetal whole blood ÷ 30 ml whole blood per 300-µg vial = 2.3 vials].

Given the inherent imprecision in calculating FMH with the Kleihauer-Betke test, some American authorities advocate administering one additional vial of RhIG than this calculated dose to ensure administration of sufficient RhIG ([41] , [76]). For example, if the number of vials is calculated to be 2.3, round off to 2.0 vials, but administer 3.0 vials. If the number of vials is calculated to be 2.5, round off to 3.0 vials, but administer 4.0 vials ([41]).

RhIG is indicated for antenatal and postnatal prophylaxis as well as any clinical situation in which FMH is demonstrated or suspected in D-negative pregnant women. RhIG may also be administered to D-negative women of childbearing potential who inadvertently or unavoidably receive incompatible D-positive red blood cells or cellular components (e.g., platelets) prepared from D-positive whole blood in an attempt to prevent D alloimmunization ([107]). RhIG should *not* be administered to infants or to the following pregnant women ([41] , [76]):

- A D-negative woman whose infant is D-negative
- Any D-positive woman, including women with weak/partial D phenotypes
- A D-negative woman known to be immunized to D

Although the appropriate dose of RhIG to administer was determined experimentally in red cell challenge experiments, the dosing interval of less than 72 hours after exposure was an arbitrary decision in early clinical trials but has been universally adopted. RhIG has been shown to be effective if administered 13 days, and possibly as late as 28 days, after exposure to D-positive red cells ([108]). Consequently, RhIG should be administered within 72 hours of potentially sensitizing events, but it should still be given if this interval is exceeded, as soon as the oversight is recognized. Depending on the administered dose and sensitivity of the laboratory tests, RhIG is detectable in maternal circulation for up to 6 months, with an average half-life of approximately 24 days. Cases of D alloimmunization in postdate pregnancies have been reported when delivery occurred more than 12 weeks after the antenatal dose of RhIG, although the residual circulating RhIG after the standard antenatal dose of 300 µg should still protect against 1 to 2 ml of D-positive fetal red cells at 40 weeks ([24]).

Serious adverse reactions to RhIG are extremely rare but include anaphylaxis in IgA-deficient individuals. More commonly, mild to moderate discomfort may occur at the site of intramuscular injection. Products labeled only for intramuscular injection must not be given intravenously, because they may contain immune complexes that could activate circulating complement proteins and subsequently cause a systemic inflammatory response. The anti-D antibodies in RhIG preparations can cross the placenta and bind to fetal cells but do not cause significant hemolysis ([109]). Although the possible effects on infants were not consistently examined in previous clinical trials of RhIG, no short-term or long-term detriment to infants whose mothers received RhIG during pregnancy has been demonstrated ([110]).

International Clinical Practice Guidelines

ACOG recommends an antenatal RhIG dose of 300 µg at 28 weeks of gestation for nonsensitized, D-negative women and another 300 µg after delivery of a D-positive infant, based primarily on data reviewed at the 1977 McMaster Conference revealing the high success rate associated with this regimen (Table 36.7) ([16] , [38]). Current recommendations from the Royal College of Obstetricians and Gynaecologists (United Kingdom) differ from those from ACOG in that antenatal prophylaxis is given as 100-µg (500-IU) doses at both 28 weeks and 34 weeks of gestation, and another 100 µg (500 IU) is given after delivery of a D-positive infant ([39]). Compared to the American strategy, the British approach achieves similar low rates of alloimmunization with less RhIG [300 µg (1500 IU) vs. 600 µg (3000 IU)] ([39] , [40]). This approach also avoids the risk of alloimmunization if delivery occurs more than 12 weeks after administration of the antenatal dose ([24]). A potential drawback, however, is the additional clinic visit required for the third injection at 34 weeks of gestation. Recommendations from Australian authorities diverge from current American and British guidelines in that antenatal prophylaxis is not currently recommended because of RhIG supply constraints in Australia ([40]).

TABLE 36.7. Recommendations for Prophylactic Anti-D Immune Globulin (RhIG) Administration to D-Negative Women without Anti-D within 72 Hours of Delivery, Abortion, or Event

Antenatal	300 µg RhIG at 28 weeks' gestation unless father of baby is known to be D negative.
Postpartum	300 µg RhIG after the delivery of a D-positive infant. American College of Obstetricians and Gynecologists acknowledges American Association of Blood Banks' recommendation for routine FMH screening in this situation to identify FMH >15 ml D-positive red cells requiring larger dose of RhIG.
Abortion	50 µg RhIG in the first trimester; 300 µg RhIG after the first trimester; for induced or spontaneous abortion, ectopic pregnancy
Potentially sensitizing events	50 µg RhIG in the first trimester; 300 µg RhIG after the first trimester. This includes chorionic villus sampling, amniocentesis, and fetal blood sampling. RhIG should be considered in cases of threatened abortion, second- or third-trimester antenatal bleeding, external cephalic version, and abdominal trauma.

FMH, fetal-maternal hemorrhage.

From American College of Obstetricians and Gynecologists. Prevention of RhD alloimmunization. Washington, DC: ACOG Practice Bulletin No. 4, May 1999.

All international medical authorities, however, emphasize the importance of recognizing potentially sensitizing events and appropriately administering RhIG after amniocentesis, chorionic villus sampling, percutaneous umbilical blood sampling, and obstetric complications, including abdominal trauma, manual removal of placenta, and antepartum vaginal bleeding (Table 36.2) ([38] , [39] and [40]). Smaller doses of anti-D immune globulin can be administered after first trimester events and procedures, because of the small total red cell mass of the fetus before 12 weeks' gestation. Consequently, ACOG recommends 50 µg to protect against sensitization by 2.5 ml of red cells in the first trimester and the standard 300-µg dose after 12 weeks.

Disconcertingly, the sensitization rate among D-negative women is higher than theoretically achievable rates, suggesting a failure to follow recommended prophylactic regimens ([29]). Although postpartum doses were almost always administered, anti-D immune globulin was less consistently administered after abortion (88 to 94%), antepartum hemorrhage (31%), and amniocentesis (14%) in a 1985 study ([111]). Deficiencies were noted as recently as 1994 in a series of more than 900 women in which RhIG administration followed only 60% of invasive procedures or other events associated with FMH ([112]). Ongoing vigilance in public health care is required to ensure effective use of RhIG given the potential severity of HDF/N due to D alloimmunization.

MANAGEMENT OF RED CELL ALLOIMMUNIZATION IN PREGNANCY

If the antibody screen at the initial obstetric visit detects the presence of anti-D or other potentially clinically significant red cell alloantibodies, additional monitoring is

necessary during the pregnancy, and prenatal intervention may be required. In general, the same principles of care provided for pregnant women with anti-D apply to those with other red cell alloantibodies reported to cause moderate to severe HDF, with some notable modifications for K1-sensitized pregnancies. Current American recommendations for the management of alloimmunization in pregnancy from ACOG and the American Association of Blood Banks are summarized in greater detail ([61], [113]). For matters not addressed in these guidelines because of a lack of data or controversial findings in available studies, the opinions of current experts in the field based on their published interpretation of the available evidence or their clinical experience are presented ([33], [71], [84], [91], [114]). Topics of debate have included the criteria used to identify the need for invasive fetal assessment, the timing of the first invasive procedure to assess the fetus's condition, the role of ultrasound, and the choice of invasive procedure and management protocol.

The obstetric history of an alloimmunized woman is extremely important in clinical management because the severity and onset of HDF/N are predictive of the course of disease in subsequent pregnancies. Antibody specificity is also taken into consideration; the presence of certain red cell antibodies are far more often implicated in cases of alloimmune fetal hydrops (e.g., anti-D, -c, -K, and -Fy ^{a}) than others (e.g., anti-E and anti-M) ([33], [58]). Other IgG red cell antibodies have demonstrated the potential in rare cases to cause severe fetal anemia or life-threatening HDN (Table 36.3), and still more IgG red cell antibodies have been reported to cause mild HDN. Although anecdotal reporting introduces bias toward the most severe cases, the previous behavior of non-D antibodies in sensitized pregnancies factors into monitoring and treatment decisions.

If paternal red cell typing reveals the fetus to be at risk for morbidity from these maternal red cell alloantibodies, prenatal diagnosis or further monitoring should be performed as necessary. The initial amniocentesis can be performed as early as 15 to 18 weeks' gestation for molecular diagnosis of blood group expression ([114]). Alternatively, fetal blood sampling may be performed as early as 20 weeks to determine fetal blood groups and monitor hematologic parameters ([33]). If the antigen is detected on fetal red cells or if testing is not performed, the maternal antibody titer should be determined at the first prenatal visit, at 18 to 20 weeks of gestation, and approximately every 2 to 4 weeks thereafter ([61], [113]). If the antibody titer equals or exceeds titer deemed “critical” for increased risk of HDF, amniocentesis or percutaneous umbilical cord blood sampling should be planned. Antibody titers are not used to follow women whose prior pregnancies were affected by sensitization, such as those with a history of intrauterine transfusion, early delivery, or neonatal exchange transfusion ([61], [113]). Similarly, once the decision has been made to use invasive measures to monitor a pregnancy, antibody titers are no longer indicated ([61]).

Serial ultrasounds in an immunized pregnancy may reveal early signs of worsening fetal anemia or abnormalities of pulsed Doppler flow velocity waveforms, especially in K1-sensitized pregnancies ([83]). Fetal evaluation in red cell alloimmunized pregnancies solely by ultrasound is currently not feasible, however, and ultrasound is usually used in conjunction with amniocentesis, fetal blood sampling, or both.

Amniocentesis versus Cordocentesis

A current pattern of practice in the United States is for the primary obstetrician to provide routine prenatal care to an alloimmunized pregnant woman and follow antibody titers, perform serial ultrasounds, and initiate amniotic fluid studies, if indicated, often in consultation with a fetal-maternal specialist. If the results suggest moderate or severe hemolytic disease in the fetus, the patient is usually referred to a specialty center for further management. Fetal blood sampling, although successfully used as a primary means of fetal surveillance in alloimmunized pregnancies, is often reserved for more aggressive management strategies for pregnant women at higher risk for severe hemolytic disease based on their previous obstetric history of affected infants.

In a first sensitized pregnancy, the initial invasive procedure is usually not necessary until 28 to 29 weeks if the titer is near the critical titer ([61], [113]). For women with prior affected pregnancies, the timing of the initial procedure is determined by clinical history, being performed at least 4 to 8 weeks earlier than the prior gestational age at which significant morbidity occurred ([113]). Amniocentesis can be performed at 18 to 20 weeks' gestation or earlier for patients with a history of a severely affected fetus.

Amniotic fluid ?OD $_{450}$ measurements can be plotted on a Liley curve for pregnancies of at least 27 weeks' gestation (Fig. 36.4) or on modified (extended) Liley curves for earlier time points in pregnancy, although the latter practice is controversial as previously discussed. The magnitude of the ?OD $_{450}$ value and, more important, the trend in ?OD $_{450}$ values with serial measurement guide treatment decisions ([113]):

- Patients in zone I or low zone II are allowed to proceed to term.
- Patients in the middle of zone II can progress to 36 to 38 weeks of gestation in most cases.
- Patients in zone III or with a rising value in the upper part of zone II should be delivered or the fetus should receive intrauterine blood transfusion, depending on gestational age.

Unresolved is the question of the optimal frequency for repeated amniotic fluid sampling. In general, amniocentesis is repeated every 1 to 4 weeks if the ?OD $_{450}$ reading falls in the middle of zone II and every 3 to 4 weeks if it has dropped into zone I. Declining values are reassuring but do not preclude hemolytic disease ([113]).

The reliability of modified Liley curves, generated by extrapolating the values for gestational ages earlier than 27 weeks, has been supported by some ([1], [86]) and contested by others ([87], [90]). The alternative to modified Liley curves for the second trimester is the method developed by Queenan and colleagues (Fig. 36.5) ([84], [90]). If the ?OD $_{450}$ values fall in the intermediate zones, the fetus's clinical condition may deteriorate, and intrauterine transfusion or delivery, depending on the gestational age, may be necessary ([84], [90]). ?OD $_{450}$ values or a trend into the uppermost zone put the fetus in jeopardy of dying *in utero*, prompting cordocentesis to evaluate the fetus. Although the zones predict fetal status, they do not correlate with the degree of fetal anemia; consequently, when cordocentesis is performed, the obstetric team must be prepared for the possibility of fetal transfusion.

Weiner and colleagues developed a management scheme based on fetal blood sampling instead of amniotic fluid analysis, which offered the advantage of direct assessment of fetal hematologic parameters between 24 and 26 weeks' gestation or as early as 20 weeks' gestation, if clinically indicated ([91], [92]). With this surveillance scheme, repeat cordocentesis to guide treatment decisions is then based on gestational age, hematocrit, reticulocyte count, and a DAT of fetal red cells. Fetal bradycardia was the major risk of cordocentesis in this trial; no procedure-related deaths occurred after 272 diagnostic cordocenteses performed in 128 pregnancies, and only one patient had a twofold rise in antibody titer after the procedure ([91], [92]). This approach, however, requires an experienced and multidisciplinary team and should be limited to regional specialty referral centers with sufficient experience to achieve the highest level of safety.

Intrauterine Fetal Transfusion

Intrauterine transfusion is performed to alleviate symptoms and extend gestation until the developing infant is mature enough to survive after delivery. Generally indicated if the fetal hematocrit falls below 25%, intrauterine transfusion can be given as early as 17 weeks' gestation by the intraperitoneal route and at approximately 20 weeks by the intravascular route ([115]). The only access before 17 weeks' gestation, the intracardiac route, is only an option in extreme circumstances, and most transfusions are given after 20 weeks by the intraperitoneal or intravascular routes ([115]).

Intraperitoneal transfusions are given by injecting blood into the abdominal cavity of the fetus, which is then absorbed into the fetal circulation by the subdiaphragmatic lymphatic system ([115]). The presence of ascites, however, interferes with absorption, limiting the benefit to the most severely affected infants. Intravascular transfusion directly into the fetus's circulation has largely supplanted the intraperitoneal method. The obvious advantage of the intravascular approach was the potential benefit offered to infants with hydrops and the ability to directly evaluate hematologic parameters after the transfusion ([115], [116] and [117]). A combined approach using both intravascular and intraperitoneal transfusion may produce more stable hematocrits and permit longer intervals between transfusions ([116], [117]).

The red cell volume to administer to a fetus during an intrauterine transfusion depends on the technique, the initial hematocrit, the target hematocrit, and the gestational age ([41]). For intraperitoneal transfusion, the volume of red cells is calculated by the following equation, which assumes the hematocrit of the donor red cell unit is approximately 75%: (gestational age in weeks - 20) × 10 ml ([114]). In a nonhydropic fetus, the rate of absorption is approximately 10 to 15% per 24 hours ([114]). Intravascular intrauterine transfusions are usually given as simple transfusions of small aliquots of red cells ranging in volume from 50 to 100 ml, and not as exchange transfusions, due to the technical complexity of the latter. Several equations have been developed to calculate the dose of red cells to transfuse for

intravascular transfusion, including the following method ([41], [118]):

1. Calculate the fetoplacental volume (ml): ultrasound estimated fetal weight (g) × 0.14
2. Calculate the volume to transfuse (ml): fetoplacental volume × [(desired hematocrit – pretransfusion hematocrit) ÷ donor unit hematocrit]

The red cells used for intrauterine transfusion should be type O, D-negative, and antigen-negative if other clinically significant maternal alloantibodies are present, and they should be crossmatched against maternal serum. If antigen-negative red cells are needed but cannot be located, maternal red cells can be transfused to the infant if ABO/Rh compatible and after reducing the amount of antibody-containing plasma ([119]). All red cell units for intrauterine transfusion should also be collected from cytomegalovirus (CMV)-seronegative donors or leukocyte-reduced to reduce the risk of CMV transmission, should lack hemoglobin S as a precaution against the potential for red cell sickling in hypoxic tissue beds, and should be gamma-irradiated to prevent transfusion-associated graft-versus-host disease ([41]).

Fetal blood is usually aspirated at the conclusion of intravascular transfusions to determine the final hematocrit and adequacy of the treatment. The goal of transfusions is usually to keep the fetal hematocrit around 27 to 30% ([41], [114]). Based on the association of increased umbilical cord venous pressure and mortality after transfusion, some authors recommend that in a severely anemic fetus, the final hematocrit after intravascular transfusion should not exceed a value of 25% or a fourfold increase from the pretransfusion value ([120]). Repeat transfusions are planned, based on an approximate 1% decline per day in hematocrit after intravascular transfusion ([41]). Brisk hemolysis of fetal cells with severe disease often necessitates a shorter interval between the first and second transfusion, usually 7 to 14 days, compared to subsequent transfusions, usually 21 to 28 days ([114]).

Complications of intrauterine transfusions in general include infection, premature rupture of membranes, premature labor, fetal hemorrhage, FMH resulting in increased maternal antibody titers and accelerated course of fetal hemolytic disease, and risks associated with allogeneic blood components including virus transmission and graft-versus-host disease ([115]). The risk of virus transmission with blood collected from repeat donors in the United States is currently estimated as 1 in 205,000 units for hepatitis B; 1 in 1,935,000 units for hepatitis C; and less than 1 in 2,135,000 units for HIV ([121]). The risk of physical injury during intrauterine transfusion, such as damage to fetal viscera with the intraperitoneal approach or umbilical cord damage with the intravascular approach, is minimized with the use of paralytic agents (i.e., vecuronium) to reduce fetal movement during intrauterine transfusions ([114], [115]). The procedure-related risk of fetal loss with intravascular transfusion is estimated as 4 to 9% ([114]). Complications of intravascular transfusion, not previously reported with intraperitoneal transfusion, include umbilical cord hematoma, fetal bradycardia, and porencephalic cysts ([114], [115]). The procedure-related risks of intrauterine transfusion must be weighed against the risks of preterm delivery and prematurity, and transfusions are rarely performed after completion of 34 gestational weeks ([114]).

Investigational Strategies

Investigational strategies to prenatal treatment of HDF aim to modulate the maternal immune response and delay or avert the need for intrauterine transfusion by administering prenatal IVIg or performing therapeutic plasma exchange. Results with therapeutic plasma exchange in red cell alloimmunized pregnancies are variable, and in many cases, the maternal anti-D titer was not affected or rebounded to even higher levels after treatment ([122]). Prenatal intravenous IVIg administration, to either the mother or fetus, is not efficacious and is not recommended for routine use for management of HDF ([123]). For an alloimmunized woman with multiple fetal losses facing her reproduction options with a man heterozygous for the implicated blood group antigen, preimplantation diagnosis after *in vitro* fertilization may provide a means to identify antigen-negative embryos ([124]). Another investigational approach proposes to immunize these high-risk women against paternal HLA antigens before conception, citing the apparent mitigating effect of HLA antibodies on HDF/N caused by anti-D ([51]). Finally, research to selectively suppress the maternal B cells that produce red cell alloantibodies is ongoing ([114]).

TREATMENT OF THE NEWBORN INFANT

The therapeutic approach to anemia and jaundice after birth due to HDF/N depends on the gestational age at delivery, severity of disease, and other factors ([98]). Treatment of each affected infant must be individualized after a detailed history, physical examination, and laboratory investigation. An infant born with hydrops requires intensive and immediate supportive care. A thorough physical examination may reveal findings of pallor, tachycardia, and tachypnea, which reflect neonatal anemia. The infant must be monitored for worsening jaundice and neurologic findings of bilirubin toxicity. In contrast to “physiologic” jaundice developing on the second or third day of life, early jaundice appearing in the first 24 hours of life is always pathologic and may signify hemolysis. Initial laboratory assessment should include ABO/D blood typing and a direct antiglobulin test, as well as bilirubin measurement and a complete blood count for assessment of hemoglobin/hematocrit, reticulocyte count, and red cell morphology (polychromasia, spherocytes, and nucleated red cells). Early erythrocyte precursors and nucleated red blood cells may be prominent in the peripheral blood smear with hemolytic disease due to anti-D, whereas spherocytes predominate in ABO HDN. Serial tests of bilirubin concentration obtained every 4 to 8 hours are recommended to follow the rate of the rise in bilirubin and to determine the most appropriate form of treatment ([98]). Active hemolysis increases the concentration of unconjugated bilirubin; the concentration of conjugated bilirubin is usually normal or not greater than 0.5 mg/dl and should not be subtracted from the total bilirubin for treatment decisions. Conjugated bilirubin above the upper limit of the normal range in HDN may indicate mild cholestasis or “inspissated” bile ([98]).

Infants with jaundice due to immune-mediated hemolysis are generally considered at greater risk for bilirubin encephalopathy than infants with jaundice due to other causes, at any given serum unconjugated bilirubin concentration ([98]). Acid-base disturbances, asphyxia, free heme groups, and other byproducts of hemolysis may potentiate the toxic effects of bilirubin in infants with alloimmune hemolysis. Consequently, the trend in pediatric practice toward less aggressive intervention for hyperbilirubinemia in the otherwise healthy term newborn does not apply to infants with alloimmune hemolysis ([98]). Recommendations offered for management of hemolytic disease due to anti-D, however, may be applied to infants with anti-K1 or other potentially significant red cell antibodies ([98]).

Phototherapy

Phototherapy is the first line of treatment for neonatal jaundice and often averts the need for an exchange transfusion in infants with HDN. Light exposure converts insoluble, unconjugated bilirubin into a water-soluble form, permitting more rapid excretion without conjugation through the bile or urine. Factors affecting optimal phototherapy include the dose of light, its spectral emission curve, the infant's exposed surface area, the depth of penetration of the light, and characteristics of the infant's skin and tissues. The effective wavelength of light for transcutaneous degradation of unconjugated bilirubin is in the 425- to 475-nm range, found at high irradiance in blue light ([125]). Conventional phototherapy uses banks of lights, whereas fiberoptic light systems contain optical fibers in a blanket or cummerbund-like band that is wrapped around the infant. The fiberoptic light systems expose greater surface area to light, are convenient to use, and are less disruptive to parent-child bonding than conventional phototherapy. Double phototherapy uses both fiberoptic and conventional phototherapy and lowers serum bilirubin faster than conventional phototherapy alone ([125]).

Treatment must be tailored individually to infants who develop unconjugated hyperbilirubinemia within the first 24 hours of life. In general, phototherapy should be initiated in term infants if bilirubin increases by 0.5 mg/dl/hour or more, or if total bilirubin exceeds 10 mg/dl within the first 12 hours of life; 12 mg/dl within the first 18 hours of life; or 14 mg/dl within the first 24 hours of life ([98]). After 24 hours of life, phototherapy should be initiated at bilirubin thresholds that take into account the infant's birthweight and clinical condition (Table 36.8). Premature infants are treated earlier in the course of disease at lower bilirubin concentrations than term infants. Earlier initiation of therapy, at lower bilirubin concentrations, may also be clinically indicated in other scenarios as well; for example, infants who required extensive prenatal treatment may be started on optimal phototherapy after birth.

TABLE 36.8. Treatment of Immune-Mediated Hemolytic Disease at 2 to 3 Days of Life [a]

Birth Weight (g)	Phototherapy Threshold (Bilirubin, mg/dl)	Exchange Threshold (Bilirubin, mg/dl)
=2500	15	18–20
2000–2499	10–13	15–17
1500–1999	7–8	13–15
1250–1499	Immediate or 5–6	12–13

<1250	Immediate or 4	9–12

[a] Jaundice on the first day of life is always pathologic and requires individualized treatment decisions.
Adapted from Peterec SM. Management of neonatal Rh Disease. Clin Perinat Hematol 1995;22:561–592.

Adverse effects of phototherapy include increased insensible water loss, diarrhea, photosensitization, overheating, and hyperpigmentation. Because of the potential for retinal damage with phototherapy, protective eye devices must be used ([125]).

Exchange Transfusion

Exchange transfusion is usually needed when phototherapy fails to adequately decrease bilirubin concentration or the initial serum bilirubin concentration places the infant at high risk for developing kernicterus. Current indications for exchange transfusion for HDN are debatable because recommendations often must be based on older studies before the development of effective phototherapy and prenatal interventions for fetal anemia. Historically, criteria for early exchange transfusion within 12 hours of birth are a cord bilirubin concentration exceeding 3 to 5 mg/dl for preterm infants and 5 to 7 mg/dl for term infants or a rate of rise of 0.5 mg/dl/hour or greater ([98]). A bilirubin level greater than 20 mg/dl despite phototherapy is generally cause for late exchange transfusion in term infants with hemolytic disease due to anti-D; the decision is triggered at lower bilirubin levels for preterm infants (Table 36.8).

If exchange transfusion is performed, a transfusion volume approximately twice the infant's total blood volume (85 ml/kg × 2 for a term infant; 100 ml/kg × 2 for a preterm infant) is administered incrementally while removing aliquots of the infant's blood over a period of 1 to 2 hours. The procedure either involves a push-pull method with a single vascular access or an isovolemic method that requires two catheters to allow for simultaneous withdrawal and infusion ([1], [98]). The umbilical artery is usually used for withdrawing blood, and the umbilical vein is usually used for infusion. The isovolemic method may be preferable because mean arterial pressure and cerebral blood volume may be more stable than during the single catheter push-pull method ([98]). An exchange of approximately two blood volumes removes approximately 85% of red cells but only approximately 45% of plasma bilirubin because the latter reequilibrates between intravascular and extravascular spaces. Consequently, infants with aggressive hemolytic disease may require more than one exchange transfusion before an acceptable bilirubin concentration is achieved.

Red cell units chosen for neonatal exchange transfusion should be O, Rh-negative, or ABO/Rh type–specific; should lack the blood group antigen implicated in hemolytic disease (e.g., ABO hemolytic disease requires the use of type O red cells); and should be compatible with maternal serum. Maternal serum or plasma is usually used in crossmatching red cells for infants because it contains the implicated antibody in high concentration and is available in large quantity. If a maternal sample is not available, the infant's plasma or serum can be used for compatibility testing; however, the concentration of circulating antibody may be low if most is bound to the infant's red cells. In this case, the bound antibody can be eluted from the surface of the infant's red cells, and the resulting eluate can be used for crossmatching. Rarely, HDN is due to an antibody to a high-incidence blood group antigen present in almost all persons, and no compatible units can be identified ([41]). In this case, maternal blood can be collected and washed to remove incompatible plasma for the infant.

Any blood component collected from biologic relatives must be irradiated as a precaution against transfusion-associated graft-versus-host disease, as well as blood components transfused to infants who received intrauterine transfusion or who are otherwise immunocompromised due to premature birth or severe primary immune deficiency. Because of the difficulty in identifying all high-risk newborn infants, many transfusion services provide gamma-irradiated blood for all infants until the age of 4, 6, or 12 months ([126]). Another common standard of practice is the use of either leukocyte-reduced cellular components or units selected from CMV-seronegative donors to reduce the risk of CMV transmission to newborn infants ([126]). Most blood banks also transfuse only units that lack hemoglobin S to infants to avoid the potential for hypoxia-induced sickling in a critically ill infant and fresh (<5 to 7 days old) or washed red cell units to avoid the risk of potassium-mediated cardiac toxicity with large transfusion volumes ([41], [126]). To prepare a two-blood volume exchange transfusion, red cells should be reconstituted with ABO-compatible plasma to the desired total volume and hematocrit. Albumin infusion before or during exchange in an effort to enhance bilirubin removal is controversial ([98]).

Morbidity and mortality among infants requiring exchange transfusion are usually due to the underlying disease and not the exchange transfusion procedure. In a study involving 331 exchanges given to 190 infants, there was only one death within 6 hours of an exchange transfusion—an infant who was critically ill before the procedure ([127]). Procedure-related reactions during exchange transfusion were noted in less than 10% of infants (22 of 328) and included transient, mild bradycardia ([127]). Other potential complications of neonatal exchange transfusion include hypervolemia and volume overload, cardiac toxicity due to citrate or hyperkalemia, air emboli or thrombosis in the umbilical vein, necrotizing enterocolitis, bleeding due to dilutional coagulopathy or thrombocytopenia, bacterial sepsis, or viral transmission, as previously described for fetal blood component transfusion ([1]).

Transfusion for Late-Onset Neonatal Anemia

Infants who respond to phototherapy alone or those who receive intrauterine transfusion may also require straight red cell transfusion between 2 to 10 weeks of life due to anemia developing as a result of low-grade hemolysis or erythropoietic suppression. Maternal antibody persists in the infant's circulation for approximately 6 weeks, and resultant hemolysis is usually associated with a marked reticulocytosis. In contrast, the late anemia associated with intrauterine transfusion is characterized by sustained suppression of erythropoiesis and decreased to absent reticulocytes and low erythropoietin concentrations ([128]). Erythropoietic suppression also occurs with anti-K1 and anti-D, irrespective of intrauterine transfusion ([98], [129]). To counter this late hypoproliferative anemia, erythropoietin treatment resulted in increased reticulocyte count and hemoglobin concentration and avoided the need for transfusion in some infants with HDN ([128], [129]).

Infants with circulating red cell antibodies should be closely monitored for at least 8 to 10 weeks to identify the development of late anemia. Hemoglobin concentrations below 7 to 10 g/dl have been proposed as transfusion “triggers.” In general, the transfusion decision should be guided not only by the hemoglobin concentration and reticulocyte count but also, and most importantly, by the infant's condition, signs of lethargy, poor feeding, or failure to thrive.

Adjunctive and Experimental Treatment

Whereas phototherapy and exchange transfusion effectively decrease bilirubin concentration in most infants with HDN, experimental strategies are aimed at blocking hemolysis and bilirubin production outright. High-dose IVIg may block binding of antibody-coated red cells to Fc receptors on cytotoxic cells, thereby preventing red cell destruction in the reticuloendothelial system ([123], [130]). Based on available data, IVIg is not recommended for routine use but may be a reasonable adjunct to phototherapy for infants with severe immune-mediated hemolytic disease and should probably be given as early as possible in the clinical course ([98]).

Metalloporphyrins are heme analogs that block the rate-limiting enzyme, heme oxygenase, in the heme metabolic pathway. Sn-mesoporphyrin (SnMP) was used to treat two infants with severe immune-mediated hyperbilirubinemia after their parents refused exchange transfusion because of their religious convictions as Jehovah's Witnesses ([131]). In both cases, phototherapy failed to achieve adequate control, but SnMP effectively halted the progression of hyperbilirubinemia. Without such extenuating circumstances, however, the use of SnMP is not recommended ([98]). Other agents investigated as means to decrease serum bilirubin include phenobarbital, clofibrate, cholestyramine, agar, and charcoal ([98]). The clinical effectiveness and the potential toxicity of these various treatments require further study before they can be recommended for treatment of immune-mediated hemolytic disease.

OUTCOME STUDIES

The survival rate among infants who required intrauterine transfusion varies with institution and experience, but infants without signs of hydrops have a relatively favorable prognosis. A survey of 16 institutions in the United States and Canada involving 1087 intrauterine intravascular transfusions given to 389 fetuses revealed a survival rate of 90% for nonhydropic fetuses and 82% in cases of hydrops ([114]). The degree of hydrops, and not merely its presence, is predictive of the outcome of alloimmunized pregnancies ([132]). In 2001, Van Kamp et al. reported that 41 of 42 fetuses with mild hydrops (98%) survived, compared to only 21 of 55 fetuses with severe hydrops (55%) ([132]). Hydrops can be reversed in 60 to 70% of fetuses after intrauterine transfusion, and almost all fetuses with resolved hydrops survived,

whereas persistent hydrops was more often associated with an unfavorable outcome ([114], [132]). The long-term neurodevelopmental outcome of infants successfully treated *in utero* with red cell transfusion compares favorably to other high-risk, very-low-birth-weight infants ([133]). The majority of surviving infants who received intrauterine transfusion demonstrate normal development and neurologic function; less than 10% exhibit mild to severe developmental delays or cerebral palsy (spastic tetraparesis or hemiplegia) ([133], [134] and [135]).

Recent outcome studies of infants with moderate and severe hemolytic disease in the neonatal period treated with current phototherapy modalities are not available, and uncertainties persist regarding the relationship between serum bilirubin levels and brain damage in both immune-mediated and nonimmune neonatal hyperbilirubinemia. In the early 1950s before effective treatment was available, approximately one-half of infants with bilirubin concentrations greater than 30 mg/dl developed kernicterus. An overall decrease in the incidence of kernicterus has been observed, but the neurologic or cognitive consequences of transient, severe hyperbilirubinemia due to alloimmune hemolysis have not been systematically studied ([98]). The National Institute of Child Health and Human Development clinical trial of phototherapy for neonatal hyperbilirubinemia failed to demonstrate an association between intelligence quotient and maximum bilirubin, mean bilirubin, or duration of exposure to elevated bilirubin, although patients with immune-mediated hemolysis were not analyzed separately ([136]).

CONCLUSION

Alloimmune HDF/N caused by anti-D continues to occur at a low rate despite the availability of RhIG. When other red cell incompatibility occurs in pregnancy, no measures are available to prevent alloimmunization, and severe fetal disease may be caused by anti-c, anti-K1, or, rarely, anti-Fy ^{a} or other red cell alloantibodies. With improved techniques for prenatal and peri-natal management, the mortality rate attributed to HDF/N has decreased over the past decades, and survival rates for nonhydropic fetuses with alloimmune hemolysis currently approach 90%. In 1999 in the United States, only 16 infant deaths were attributed to alloimmune HDN—a number too low to calculate a statistically reliable mortality rate, according to the National Center for Health Statistics ([137]). This estimate does not capture early intrauterine deaths, and some neonatal deaths may be attributed to other prevailing complications, but it is an accurate reflection of the current low burden of disease due to HDF/N because of the effectiveness of primary prevention and early treatment.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is closely associated with aplastic anemia. The syndrome arises as a consequence of expansion of a mutant hematopoietic stem cell that has a conditional growth or survival advantage in the setting of a specific type of bone marrow injury (putatively immune). It is a rare, acquired disorder that is insidious in onset and chronic in course. It is characterized, in the classic case, by attacks of intravascular hemolysis and hemoglobinuria that occur chiefly at night while the patient is asleep. Consequently, the patient becomes alarmed the following morning by the startling abnormal appearance of the first voided urine. In many patients, however, the classic pattern is absent at diagnosis. These patients manifest chronic, low-grade intravascular hemolysis punctuated by occasional episodes of hemoglobinuria, usually in association with infection or unusual stress. Thrombocytopenia, leukopenia, or both and recurrent venous thrombosis involving unusual sites (particularly abdominal) are other notable clinical characteristics of PNH.

The history of PNH has been recently reviewed ([1]). Strübing published a remarkable paper on PNH in 1882, clearly recognizing the uniqueness of the disease and providing laboratory support for his prescient hypothesis on the etiology of nocturnal hemoglobinuria. Marchiafava and Nazari (1911) and Micheli (1931) subsequently chronicled the clinical characteristics of the disease (in some older literature, PNH is called *Marchiafava-Micheli syndrome*). By 1953, at least 162 cases had been collected ([2]). Undoubtedly, many cases go undiagnosed because the classic signs and symptoms may be absent. Often, several years elapse between the onset of clinical symptoms and the correct diagnosis because this uncommon disease frequently presents without its most widely recognized symptom (i.e., hemoglobinuria that is most apparent in the morning) ([3]).

It can be argued that the term *paroxysmal nocturnal hemoglobinuria* is imprecise because it describes only one feature of the illness—a feature, moreover, that is found in only one-fourth of affected individuals at presentation. Nonetheless, the term has been established through long usage and, consequently, has become incorporated as a part of the essence of the disease.

ETIOLOGY AND PATHOGENESIS

Sensitivity to Complement-Mediated Lysis

The chronic intravascular hemolysis that is the clinical hallmark of PNH is due to the abnormal sensitivity of the erythrocytes to complement-mediated lysis. From 1937 to 1939, Ham and Ham and Dingle made the seminal observations that connected the hemolysis to complement ([4] , [5] and [6]). Those studies demonstrated that the abnormal cells are hemolyzed when incubated in acidified serum and that the hemolysis is complement dependent. The lysis of the defective cells in acidified serum (a process that activates the alternative pathway of complement) became the standard technique for the diagnosis of PNH, and appropriately, the assay is called the *Ham test*. Approximately 10 years after the studies of Ham and Dingle, cross-transfusion studies confirmed that hemolysis in PNH results from an intrinsic abnormality of the red cell ([7]). In those studies, Dacie reported that normal erythrocytes survive normally in patients with PNH, whereas the lifespan of PNH erythrocytes is shortened both in the patient and in a normal recipient. Not all PNH red cells are equally sensitive to complement-mediated lysis (see below), however, and cohorts of relatively long-lived and very short-lived cells can be distinguished in red cell survival studies ([8]). Moreover, the proportions of complement-sensitive and complement-insensitive cells vary greatly among patients. The percentage of abnormal cells remains remarkably stable in most patients although there are clearly exceptions to this rule. Generally, the percentage of markedly complement-sensitive cells correlates with the clinical course of each patient with respect to the hemolytic component of the disease (see below).

A defining feature of PNH is phenotypic mosaicism based on sensitivity of the erythrocytes to complement-mediated lysis. This remarkable characteristic was clearly elucidated by Rosse and Dacie in 1966 ([9]), and Rosse further refined the analysis in 1973 ([10]). Using an *in vitro* test that quantitates the sensitivity of erythrocytes to complement-mediated lysis (the complement lysis sensitivity assay), three phenotypes of PNH erythrocytes were identified (Table 37.1; Fig. 37.1 and Fig. 37.2). One of the phenotypes (designated PNH I) was characterized by normal or near-normal sensitivity to complement, whereas another phenotype (designated PNH III) was 15 to 25 times more susceptible to lysis. A third phenotype (PNH II) was of intermediate sensitivity, approximately 3 to 5 times more susceptible than normal cells. Most patients have a mixture of type I and type III cells, but mosaics of type I, type II, and type III, as well as type I and type II, are also observed.

TABLE 37.1. Paroxysmal Nocturnal Hemoglobinuria (PNH) Phenotypes

Phenotypic Designation	Complement Sensitivity [a]	GPI-AP Expression by Flow Cytometry [b]	Type of PIG-A Mutation
PNH I	Normal	Normal	None
PNH II	Moderately sensitive (3–5 times normal)	Dim positive	Missense (partial PIG-A inactivation)
PNH III	Markedly sensitive (15–25 times normal)	Negative	Nonsense, frameshifts, deletions, insertions (complete inactivation of PIG-A)

GPI-AP, glycosyl phosphatidylinositol–anchored protein.

[a] Based on the complement lysis sensitivity assay of Rosse and Dacie.

[b] Based on flow cytometric analysis of GPI-AP expression of erythrocytes.

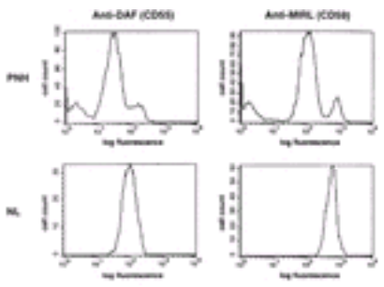

Figure 37.1. Phenotypic mosaicism in paroxysmal nocturnal hemoglobinuria (PNH). Erythrocytes from a patient with PNH and from a normal volunteer donor (NL) were analyzed by flow cytometry using anti–decay accelerating factor (anti-DAF) (CD55) and anti–membrane inhibitor of reactive lysis (anti-MIRL) (CD59) as primary antibodies. The histogram of the erythrocytes from the normal donor shows uniformly positive staining with both antibodies. In contrast, the patient's histogram (PNH) suggests three discrete populations of cells (a negative population, a population with partial expression, and a population with normal expression). Statistic analysis of the three groups of cells from the patient showed that the negative population contributed 14% to the total, the intermediate population contributed 75%, and the normal population contributed 11%. (From Parker CJ. Molecular basis of paroxysmal nocturnal hemoglobinuria. Stem Cells 1996;14:396–411, with permission.)

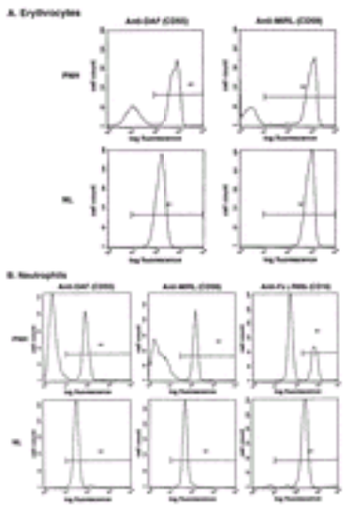

Figure 37.2. Analysis of glycosyl phosphatidylinositol–anchored proteins (GPI-APs) on erythrocytes **(A)** and neutrophils **(B)** from a patient with paroxysmal nocturnal hemoglobinuria (PNH). Erythrocytes and isolated neutrophils from a patient with PNH and from a normal volunteer donor (NL) were analyzed by flow cytometry using anti–decay accelerating factor (anti-DAF) (CD55), anti–membrane inhibitor of reactive lysis (anti-MIRL) (CD59), or anti-Fc?RIIIb (CD16b) (neutrophils only) as primary antibodies. The histograms of the cells from the normal donor show uniformly positive staining with both antibodies. In contrast, the patient's histograms (PNH) demonstrate two discrete populations of cells. In the case of the erythrocytes **(A)**, 30% of the cells are negative for DAF and MIRL expression, and 70% show normal expression. In the case of the neutrophils **(B)**, 65% are negative for DAF and MIRL expression. The same population of cells shows abnormal expression of Fc?RIIIb, but the deficiency is partial rather than absolute. Together, these results demonstrate three characteristic features of PNH: (a) The hematopoietic cells are a mosaic of normal and GPI-AP–deficient cells; (b) the proportion of abnormal neutrophils is greater than the proportion of abnormal erythrocytes; and (c) the deficiency of Fc?RIIIb is partial rather than absolute.

As noted above, the proportion of complement-sensitive and -insensitive cells varies greatly among patients. For example, the erythrocytes of one patient may be comprised of 10% PNH III cells and 90% PNH I cells, whereas another patient may have 75% PNH III cells and 25% PNH I cells. The intensity of the hemolytic component of the disease is related to the size of the PNH III population ([11]). As a rule, visibly apparent hemoglobinuria is absent or mild when PNH III erythrocytes (the most complement-sensitive cells) constitute less than 20% of the red cell population. Episodes of gross hemoglobinuria occur when the PNH III population ranges from 20 to 50% of the population, and constant hemoglobinuria is associated with greater than 50% PNH III cells. PNH II cells (the erythrocytes of intermediate sensitivity to complement), even when present in high proportions, are associated with minimal or no hemoglobinuria. The proportion of abnormal cells is greater in the marrow than in the blood and, among circulating cells, is greatest in young cell populations, especially in reticulocytes ([8], [9], [12], [13]). Erythrokinetic studies have shown that the complement-sensitive population does not gain recruits from the complement-insensitive population ([8]). The proportions of sensitive and insensitive cells usually remain stable for long periods, but population shifts may be observed during the course of the disease, and in some patients, the abnormal clone(s) remit spontaneously ([14], [15]).

PNH is not an immune-mediated hemolytic anemia that arises as a consequence of the development of autoantibodies. Rather, failure to regulate alternative pathway of complement activation on the erythrocyte surface underlies the hemolysis of PNH. Under physiologic conditions, the alternative pathway is in a state of continuous, low-grade activation. Normal erythrocytes are not hemolyzed as a result of this low-grade alternative pathway activation because specific cell-surface proteins have evolved that inhibit the activity of complement. In contrast, PNH erythrocytes are deficient in the two most important membrane regulators of complement; consequently, they are subject to chronic, spontaneous hemolysis *in vivo*. Failure to inhibit alternative pathway activation has a profound effect on red cell survival, as studies have shown that the half-life of complement-sensitive PNH cells is only 6 days ([8]).

Rosse and colleagues reported the first clear evidence of the nature of the aberrant interactions of PNH erythrocytes with complement in 1973 and 1974 ([16], [17]). Those investigators showed that when complement is activated *in vitro* by either the classic or the alternative pathway, PNH erythrocytes bind much greater amounts of activated C3 than normal erythrocytes. The difference in C3 deposition was particularly striking when acidified serum was used to activate the alternative pathway. Subsequent studies showed that PNH red cells lacked the capacity to regulate the formation and stability of the amplification C3 convertases of complement ([18], [19]), thus accounting for the greater binding of activated C3. A second defect was suggested by experiments demonstrating that PNH erythrocytes also failed to regulate the activity of the cytolytic membrane attack complex of complement ([20], [21] and [22]). Collectively, these observations indicated that PNH erythrocytes had two complement regulatory defects: one that affected regulation of the C3 convertases and a second that affected regulation of the membrane attack complex.

Erythrocyte Membrane Protein Deficiencies

ACETYLCHOLINESTERASE Although Beck and Valentine reported in 1951 that neutrophils from patients with PNH were deficient in leukocyte alkaline phosphatase ([23]), the first erythrocyte membrane protein that was found to be deficient in PNH was acetylcholinesterase ([24]). In 1959, Auditore and Hartmann ([24]) presented evidence that the extent of the acetylcholinesterase deficiency correlated with the severity of the hemolysis. More detailed studies by others ([25]) showed that PNH I red cells had a relatively normal amount of acetylcholinesterase, whereas PNH III erythrocytes were profoundly deficient. Although the deficiency of

acetylcholinesterase plays no role in the abnormal susceptibility of PNH red cells to complement-mediated lysis, the observations that the red cells lack acetylcholinesterase and that the neutrophils lack alkaline phosphatase ultimately provided important insights into the fundamental defect that underlies PNH.

DECAY ACCELERATING FACTOR (CD55) In 1983, two groups reported that PNH erythrocytes were deficient in decay accelerating factor (DAF, CD55) ([26], [27]). DAF, first identified by Hoffman ([28], [29]) in 1969 and subsequently purified by Nicholson-Weller and colleagues in 1982 ([30]), is a 70-kd protein that inhibits the formation and stability of the C3 convertases of complement ([31]). Thus, the absence of DAF provided a plausible explanation for the greater binding of activated C3 to PNH erythrocytes. Detailed studies, however, demonstrated that DAF does not regulate the activity of the membrane attack complex of complement ([32], [33]). Those results implied that PNH erythrocytes were deficient in a second complement regulatory protein that was functionally distinct from DAF.

MEMBRANE INHIBITOR OF REACTIVE LYSIS (CD59) In 1989, Holguin et al. ([34]) reported the isolation from normal erythrocytes of an 18-kd protein called *membrane inhibitor of reactive lysis* (MIRL, CD59) that protected PNH III red cells against complement-mediated lysis. As anticipated, PNH cells were found to be deficient in MIRL ([29]), and additional studies by those investigators and others demonstrated that MIRL inhibits complement-mediated lysis by blocking the assembly of the membrane attack complex ([29], [35], [36] and [37]). By comparing expression of DAF and MIRL on PNH I, PNH II, and PNH III erythrocytes, the functional basis of the different complement sensitivity phenotypes was defined ([34]). Those studies showed that PNH III cells are completely deficient in DAF and MIRL, whereas PNH II cells are partially deficient in the two complement regulatory proteins, and PNH I cells have normal expression. Thus, the variability in sensitivity to lysis among the different phenotypes is explained by quantitative differences in expression of DAF and MIRL ([38]). Additional experiments demonstrated that the combined deficiency of DAF and MIRL was sufficient to explain the enhanced susceptibility of PNH erythrocytes to hemolysis in acidified serum ([39]). Of the two complement regulatory proteins, MIRL is more important than DAF in protecting cells from complement-mediated lysis *in vivo*. Antigens of the Cromer-related blood group complex are located on DAF, and rare cases of a null phenotype called *Inab* have been reported ([40]). Like PNH cells, Inab erythrocytes are deficient in DAF, but unlike PNH erythrocytes, MIRL expression is normal on Inab red cells ([41]). Although Inab erythrocytes bind more activated C3 when exposed to acidified serum ([41]), they undergo little or no hemolysis ([41], [42] and [43]). Furthermore, subjects with the Inab phenotype have no known hematologic abnormalities, and in particular, they have no clinical evidence of hemolysis ([40], [42]). These observations show that isolated deficiency of DAF does not produce the PNH syndrome. In contrast, a patient with an inherited, isolated deficiency of MIRL (CD59) had a syndrome that was indistinguishable from PNH ([44], [45]). Clinically, the patient experienced recurrent episodes of hemoglobinuria, suggesting that MIRL is essential for protecting erythrocytes against complement-mediated lysis *in vivo*. Recurrent thromboembolic events were also observed in this patient. The patient had normal DAF expression ([45]), but *in vitro*, his cells were susceptible to hemolysis in acidified serum, implying that MIRL deficiency accounts primarily for the positive Ham test in PNH ([39]). Together, these observations indicate that the PNH phenotype is primarily a manifestation of MIRL deficiency although it is the *combined* deficiency of DAF and MIRL that results in the marked abnormal susceptibility of the red cells of PNH to complement-mediated lysis.

BASIS OF THE PROTEIN DEFICIENCIES IN PAROXYSMAL NOCTURNAL HEMOGLOBINURIA If only DAF or only MIRL were deficient in PNH, it would have been logical to hypothesize that the disease was due to mutations affecting the gene that encodes the particular protein. That PNH cells were deficient in multiple proteins (MIRL, DAF, and acetylcholinesterase on red cells and leukocyte alkaline phosphatase on neutrophils), however, eliminated the possibility that the gene for each protein was mutant. Rather, a more plausible hypothesis was that the PNH defect involved a posttranslational modification common to all of the proteins that are deficient in PNH. In 1984, Medof and colleagues ([46]) reported that isolated DAF spontaneously reincorporated into erythrocyte membranes. This property of DAF had actually been appreciated by Hoffman in 1969 ([28], [47]). Working with the butanol-saturated aqueous phase of a crude extract prepared from normal human erythrocyte stroma, he showed that the sample contained a factor capable of inhibiting complement-mediated lysis by accelerating the decay of the C3 convertase. He further showed that this substance (that he called *decay accelerating factor of stroma*) had the capacity to reincorporate into red cells and remain functionally active. In 1980, Low and Zilversmit ([48]) demonstrated that alkaline phosphatase that had been solubilized from cells by butanol extraction exhibited the capacity to bind to phospholipid vesicles. In this case, the incorporation was thought to be due to the attachment of a phosphatidylinositol moiety to the enzyme. Subsequent experiments demonstrated that isolated acetylcholinesterase also spontaneously reincorporated into cell membranes ([49], [50] and [51]). Previous studies ([48], [52]) had shown that alkaline phosphatase, acetylcholinesterase, and 5'-ectonucleotidase (another protein that is deficient in PNH) were released from the cell surface by treatment with phosphatidylinositol-specific phospholipase C. The cumulative work of a number of investigators showed that both the capacity to reincorporate into membranes and the susceptibility to cleavage by phosphatidylinositol-specific phospholipase C were characteristic of a group of amphipathic membrane proteins that shared the common structural feature of being anchored to the cell surface through a glycosyl phosphatidylinositol (GPI) moiety ([53], [54], [55], [56] and [57]). The structural link between DAF and acetylcholinesterase, alkaline phosphatase, and 5'-ectonucleotidase was made in 1986 by Davitz et al. ([58]) and Medof et al. ([59]) when those investigators presented evidence that DAF is a GPI-anchored protein (GPI-AP). Subsequent studies confirmed that MIRL is also a GPI-AP ([60]). The results of those studies suggested the following paradigm: *All proteins that are deficient in PNH are GPI anchored, and all GPI-APs that are expressed by hematopoietic cells are deficient in PNH.* All data to date are consistent with this postulate. GPI-APs are functionally diverse. In addition to the complement regulatory proteins [DAF (CD55) and MIRL (CD59)] and enzymes [acetylcholinesterase, alkaline phosphatase, and 5'-ectonucleotidase (CD73)] discussed above, proteins with receptor, adhesion, and immune modulatory function [e.g., Fc?RIIIb (CD16b), urokinase receptor (CD87), endotoxin binding protein receptor (CD14), and lymphocyte function-associated antigen-3 (CD58)] are also GPI anchored. Further, a number of proteins whose function is unknown are GPI anchored ([53], [54], [55], [56] and [57], [61]). To date, more than 80 eukaryotic proteins have been shown to be GPI anchored, and approximately 30 of these are found in humans. Currently, the list of proteins that are deficient in PNH numbers 18 (Table 37.2). This number is less than the total number of GPI-anchored human proteins because PNH is an acquired disease that affects only hematopoietic cells. Thus, GPI-APs that are present on somatic tissues other than hematopoietic cells are expressed normally in patients with PNH. Although PNH cells lack a number of functionally diverse membrane constituents, the only pathologic component of the disease that is unequivocally causally related to GPI-AP deficiency is the abnormal susceptibility of the erythrocytes to complement-mediated lysis.

TABLE 37.2. Glycosyl Phosphatidylinositol–Anchored Proteins Deficient in Paroxysmal Nocturnal Hemoglobinuria

Leukocyte alkaline phosphatase	5'-ectonucleotidase (CD73)
Acetylcholinesterase	Urokinase receptor (CDw52)
Decay accelerating factor (CD55)	JMH-bearing protein

Lymphocyte function-associated antigen 3 (CD58)	CD67
	Folate receptor
CD14	Cellular prion protein [a]

[a] Deficient on resting platelets, but putative transmembrane form expressed on activated platelets.

Molecular Basis of Paroxysmal Nocturnal Hemoglobinuria

The observation that, based on sensitivity to complement, the peripheral blood of PNH patients is a mosaic comprised of both normal and abnormal cells suggested that the abnormal cells were the progeny of a mutant clone and that they coexisted with the progeny of residual normal stem cells. Further, that PNH is an acquired rather than an inherited disease implied that the abnormal clone arises as a consequence of a somatic mutation. In 1970, Oni et al. ([62]) analyzed glucose-6-phosphate dehydrogenase isoforms in both the complement-sensitive and the complement-insensitive erythrocytes of a female PNH patient who was heterozygous at the glucose-6-phosphate dehydrogenase locus. The complement-insensitive cells expressed both glucose-6-phosphate dehydrogenase isoforms, indicating a polyclonal origin for this cohort. In contrast, the complement-sensitive cells expressed only one isoform, a finding consistent with monoclonality. These studies provided the first experimental evidence in support of the clonal hypothesis of PNH. In 1969, Aster and Enright ([63]) reported that a portion of both the platelet and granulocyte populations from patients with PNH was abnormally sensitive to complement-mediated cytolysis. This publication represented another watershed event in the understanding of the origins of PNH because it indicated that the mutation arose in a primitive hematopoietic stem cell that has the capacity to differentiate along myeloid lines. Subsequent studies showed that monocytes are also affected ([64]), and, in some patients, affected lymphocytes were demonstrated ([65]). Together with the observation that all proteins that are deficient in PNH are GPI anchored, these studies suggested that PNH arises as a result of a somatic mutation affecting a pluripotent hematopoietic stem cell and that the gene that is mutant is essential for the normal biosynthesis of the GPI anchor.

The GPI anchor is a complex structure ([61], [66]). Based on complementation analysis of GPI anchor–deficient mutant cell lines, at least eight proteins are essential for assembly of the GPI moiety ([61], [66]). Hypothetically, the PNH phenotype would result if any of these proteins were nonfunctional because if the GPI anchor is not

synthesized, GPI-APs are not expressed. Accordingly, it seemed probable that PNH would be found to be heterogeneous at the molecular level, as mutations affecting any one of several genes that encode elements critical for GPI anchor assembly would produce the disease phenotype. In 1992 ([67]) and 1993 ([68]), however, two groups published the surprising finding that GPI protein–deficient lymphocyte cell lines derived from different patients with PNH all belonged to the same complementation class. Additional experiments confirmed that the PNH cell lines had the same biochemical defect as the complementation class A mutants. Like the class A mutants, the PNH cell lines failed to synthesize *N*-acetylglucosaminyl-phosphatidylinositol (GlcNAc-PI), the first intermediate in the pathway of GPI anchor assembly ([61]) (Fig. 37.3).

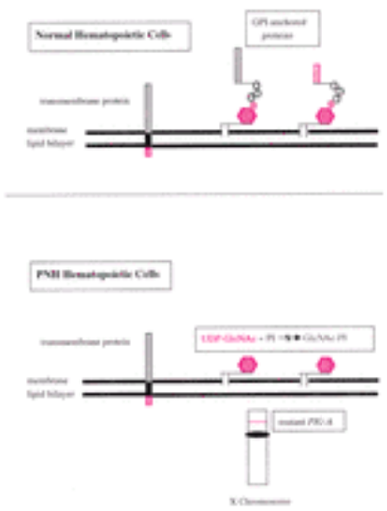

Figure 37.3. Paroxysmal nocturnal hemoglobinuria (PNH) defect. Transmembrane proteins have three domains: an ectoplasmic domain (rectangle with horizontal lines), a transmembrane domain (gray rectangle), and a cytoplasmic domain (red rectangle). In contrast, glycosyl phosphatidylinositol (GPI)–anchored proteins lack the cytoplasmic and transmembrane domains. This class of proteins is anchored to the cell by a GPI moiety consisting of phosphatidylinositol (red hexagon), glucosamine (light red circle), and three mannose (gray circles) molecules. The GPI moiety is linked to the COOH-terminus of the protein portion of the molecule by ethanolamine. The *PIG-A* gene product is essential for the transfer of the nucleotide sugar uridine diphosphate- *N*-acetylglucosamine (UDP-GlcNAc) to phosphatidylinositol (PI) to form GlcNAc-PI, the first intermediate in the synthesis of the GPI anchor. PIG-A is located on the X chromosome. Hematopoietic cells in PNH are deficient in all proteins that are GPI anchored because a somatic mutation in a hematopoietic stem cell partially or completely inactivates the PIG-A gene product. Consequently, the GPI moiety is not synthesized. (Modified from Parker CJ. Molecular basis of paroxysmal nocturnal hemoglobinuria. Stem Cells 1996;14:396–411.)

A gene that restores normal expression of GPI-APs in the complementation class A PNH cell lines was identified by Kinoshita and colleagues in 1993 ([69] , [70]). As predicted by the studies cited above, the gene, called *PIG-A* (for phosphatidylinositol glycan class A), encodes a protein that is essential for the normal synthesis of GlcNAc-PI ([69]). Subsequently, Takeda et al. ([70]) showed that *PIG-A* complements the deficient expression of GPI-APs in PNH lymphoblastoid cell lines and that those cell lines harbored somatic mutations in *PIG-A*. Together, those studies defined both the biochemical and the molecular bases of the deficiency of GPI-APs in PNH (Fig. 37.3).

Additionally, Takeda and colleagues observed that a heterozygous mutation was sufficient to produce the PNH phenotype ([70]). As presaged by the studies of Hyman et al. ([71]), the dominant expression of the somatic mutation was explained when *PIG-A* was mapped to chromosome Xp22.1 (i.e., the *PIG-A* gene is located on the short arm of the X chromosome in humans). As males have a single X chromosome, any functionally significant mutation affecting *PIG-A* is expressed. Females are functionally haploid due to X inactivation. Thus, somatic mutations in *PIG-A* appear dominant when they occur on the active X chromosome. To date, somatic mutations affecting *PIG-A* account for the PNH phenotype in all patients in whom the genetic basis has been identified ([61] , [72] , [73]). *PIG-A* mutations have not been identified in all patients studied, but this apparent discrepancy is probably a technical artifact rather than a true difference in etiology. The chromosomal location of *PIG-A* provides the most logical explanation for the uniformity of the molecular defect in PNH. This interpretation supposes that all other genes that are essential for synthesis of the GPI moiety are autosomal, a supposition supported by available data ([61] , [74]). However, until a case of PNH is shown to involve mutation of a gene required for GPI-AP synthesis other than *PIG-A*, this supposition remains unproved.

Analysis of *PIG-A* has revealed that the same mutation can be identified in isolated neutrophils, monocytes, and lymphocytes from individual patients with PNH ([70] , [75]), confirming that the disease involves the hematopoietic stem cell. Of 174 *PIG-A* mutations that have been identified in affected cells of 146 patients with PNH, only three large deletions have been observed ([72] , [76]) (Fig. 37.4). The remainder consists of nucleotide substitutions of the missense or nonsense types, or small deletions or insertions. The mutations are distributed randomly over the entire coding region and at splice junctions. At least 19 mutations have been observed to occur in more than one patient ([72]) (Fig. 37.4). Absence of repetitive mutations indicates that *PIG-A* lacks hot spots. That most of the mutations completely inactivate PIG-A function has suggested to some that complete deficiency of GPI-AP (the PNH III phenotype) may be advantageous relative to partial deficiency (the PNH II phenotype) ([77]). Arguing against this interpretation, however, is the observation that in some patients with both PNH II and PNH III cells, the PNH II cells dominate hematopoiesis ([75]). This finding is more consistent with the hypothesis that relative clonal dominance is determined not by the type of *PIG-A* mutation but by the intrinsic proliferative or survival properties of the affected stem cells ([78]). Further, in some PNH patients, two separate clones with distinct mutations that completely inactivate *PIG-A* can be identified, but the contribution to hematopoiesis of the two affected clones may be quantitatively very different ([14] , [75] , [79] , [80]). Thus, the *PIG-A* mutation may provide the conditional survival advantage, but other intrinsic factors may determine the proliferative properties of a particular clone. These proposed other factors may include stochastic epigenetic events or additional genetic abnormalities resulting from mutation affecting genes that regulate cellular proliferation or apoptosis ([81]).

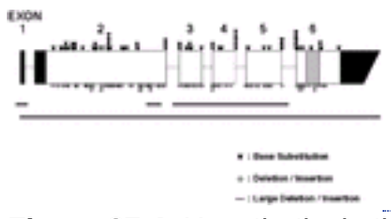

Figure 37.4. Hypothetical etiology of paroxysmal nocturnal hemoglobinuria. Diagram of the human PIG-A gene and the locations of somatic mutations reported in patients with paroxysmal nocturnal hemoglobinuria. The boxes represent exons within the *PIG-A* gene, and the blackened areas denote noncoding regions. Lines connecting the exons represent introns. The hatched region within exon 6 indicates the putative PIG-A transmembrane domain. Single nucleotide substitutions are indicated above the gene as inverted triangles, whereas small nucleotide deletions and insertions are identified beneath the gene by diamonds. Large DNA deletions and insertions are denoted by horizontal lines below the gene. ▾ base substitution; ?, deletion/insertion; ▬, large deletion/insertion.(From Nishimura J, Murakami Y, Kinoshita T. Paroxysmal nocturnal hemoglobinuria: an acquired genetic disease. Am J Hematol 1999;62:175–182, with permission of Wiley-Liss.)

An uncommon *PIG-A* sequence variant (C-55-T) has been identified in patients with PNH and in unaffected parents and normal volunteers ([72] , [77] , [82] , [83]). In some cases, inheritance has been demonstrated ([72] , [82]). This missense mutation results in replacement of tryptophan with arginine at amino acid position 19. This change in primary structure has no obvious effect on expression of GPI-AP ([82]). Thus, C-55-T appears to represent a silent polymorphism. Although unproved, finding C-55-T in 5 of approximately 100 PNH patients ([72]) suggests that this sequence variant may be in linkage disequilibrium with PNH. If so, it would suggest that PIG-A plays a direct role in the etiology of PNH.

Studies of *PIG-A* mutations have also provided insights into the molecular basis of the phenotypic mosaicism of PNH ([75]). Cloned lymphocyte cell lines were established from the peripheral blood of a patient whose erythrocytes were a mixture of PNH I, PNH II, and PNH III cells (Fig. 37.1). Based on expression of GPI-APs, lymphocyte clones with four different phenotypes were observed. Analysis of clones with normal expression of GPI-AP revealed no somatic *PIG-A* mutations. In

contrast, among the three phenotypically distinct lymphocyte clones with abnormal GPI-AP expression, four discrete *PIG-A* mutations were identified. In the lymphocyte clones with the PNH II phenotype, a missense mutation that changed a highly conserved amino acid was found. This finding suggests that cells with partial expression of GPI-APs (PNH II) are derived from stem cells with mutations that incompletely inactivate PIG-A. In the case of the lymphocyte clones with the PNH III phenotype, three separate mutations were identified, each of which was expected to inactivate completely the *PIG-A* gene product. Collectively, these experiments demonstrate that the phenotypic mosaicism that is characteristic of PNH is a consequence of genotypic mosaicism. Further, because any mutation that completely inactivates PIG-A results in PNH III cells, phenotypically identical cells can have different *PIG-A* genotypes (Fig. 37.5).

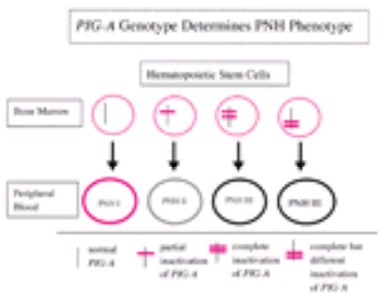

Figure 37.5. Schematic representation of the molecular basis of phenotypic mosaicism in paroxysmal nocturnal hemoglobinuria (PNH). Cells with normal expression of glycosyl phosphatidylinositol–anchored protein (the PNH I phenotype) are derived from stem cells with normal *PIG-A*. In patients with heterogeneous expression of glycosyl phosphatidylinositol–anchored protein, more than one abnormal clone is present, and the progeny of some of the abnormal clones are phenotypically different because the *PIG-A* genotype is different. For example, PNH II cells are the progeny of stem cells with mutations that incompletely inactivate the PIG-A protein, whereas PNH III cells are progeny of stem cells with mutations that completely inactivate PIG-A. Inasmuch as any mutation that completely inactivates PIG-A produces PNH III cells, phenotypically identical cells can have different genotypes. (Modified from Parker CJ. Molecular basis of paroxysmal nocturnal hemoglobinuria. Stem Cells 1996;14:396–411.)

Studies of the pattern of X chromosomal inactivation indicated that, in the female patient with four different *PIG-A* mutations, the abnormal clones were not derived from a common ancestor ([75]). Further, that each of the mutations was discrete demonstrated that the mutational events occurred independently rather than by clonal evolution. These results demonstrate that PNH is not strictly a clonal myelopathy and have important implications for the origins of the disease ([75], [78], [84], [85]).

Three studies ([86], [87] and [88]) have suggested that mutational frequency is increased in PNH, although the magnitude of the difference varied considerably among the three studies. Although abnormally high mutational frequency is a plausible explanation for the presence of multiple *PIG-A* mutant clones ([75], [84], [85]), it does not explain clonal dominance.

Clonal Dominance

Despite the progress that has been made in determining the basis of the abnormal sensitivity of the erythrocytes to complement-mediated lysis and the global absence of GPI-APs from hematopoietic cells, an issue that is fundamental to a more complete understanding of PNH remains unresolved. For PNH to become clinically evident, the hematopoietic stem cells bearing the mutant *PIG-A* must expand so that progeny sufficient to produce symptoms and signs of the disease are generated. In many instances, GPI-AP–deficient (GPI-AP $^-$) cells dominate hematopoiesis in patients with PNH, suggesting that the mutant stem cell has either a greater proliferative capacity or a survival advantage relative to GPI-AP–sufficient (GPI-AP $^+$) stem cells. That *PIG-A* mutations are necessary for the development of PNH is incontrovertible. At issue is whether *PIG-A* mutations are both necessary *and* sufficient to account for the PNH syndrome and whether the *PIG-A* mutation provides an absolute or a conditional growth/survival advantage.

That PNH is not strictly a monoclonal disease ([75], [84], [85]) suggests that the *PIG-A* mutation may not invest the mutant stem cells with an absolute growth advantage. Thus, PNH appears to differ from monoclonal hematopoietic stem cell disorders such as chronic myelogenous leukemia in which the t(9;21) that generates the fusion protein bcr-abl is sufficient to account for the proliferative advantage of the mutant cell. Further, the proportion of GPI-AP $^-$ to GPI-AP $^+$ cells varies greatly among patients, and the ratio tends to remain fixed over long periods of observations. Thus, PNH does not behave as a monoclonal disease with a malignant phenotype (e.g., acute leukemia) in which all normal hematopoiesis is progressively displaced as a consequence of the uncontrolled proliferation of a transformed clone.

An additional feature that suggests that the *PIG-A* mutation results in a conditional rather than an absolute growth advantage is the fact that the gene product is apparently a glycosyl transferase ([61], [72]). Thus, a role for PIG-A in the regulation of cell growth is not apparent. In contrast, the mutations that produce most hematopoietic malignancies affect expression of protooncogenes that have an obvious impact on signal transduction, regulation of transcription, or control of cellular proliferation or apoptosis. Further arguing against an intrinsic growth/survival advantage are the results of studies using gene targeting ([89]), in which evidence of outgrowth of *PIG-A* mutant hematopoietic cells has not been observed in transgenic mice (discussed in more detail below).

The oligoclonal nature of PNH ([75], [84], [85]) suggests that stem cells with mutant *PIG-A* dominate hematopoiesis because of a powerful selection process that is most likely based on phenotype. According to this hypothesis ([84], [90], [91] and [92]), stem cells with mutant *PIG-A* have an advantage because of some pathologic process (putatively immune) that involves a GPI-AP. For example, an autoimmune process could arise in which the target antigen is a GPI-AP expressed on hematopoietic stem cells. Under those circumstances, *PIG-A* mutant stem cells (lacking GPI-AP) would escape immune-mediated destruction because they lack the target antigen.

Support for the hypothesis that immune attack against a specific GPI-AP exerts selective pressure sufficient to cause the emergence of a population of GPI-AP $^-$ cells was provided by clinical observations in patients with chronic lymphocytic leukemia treated with anti-CD52 (the CAMPATH-1 antigen, a GPI-AP) ([93]). Some of those patients developed a population of GPI-AP $^-$ peripheral blood lymphocytes and monocytes. Analysis of *PIG-A* from cloned GPI-AP $^-$ T lymphocytes of one of these patients showed a nonsense mutation ([93]), demonstrating that a mutation involving *PIG-A* rather than the gene that encodes CD52 produced the population of cells with the selective advantage. This situation is not entirely analogous to PNH, however, because antibodies against a GPI-AP have not been demonstrated. Further, if immune selection underlies the pathophysiology of PNH, it is most likely a cellular rather than a humoral process.

Nonimmune mechanisms could also provide a basis for selection of *PIG-A* mutant stem cells—for example, if a GPI-AP functions as a receptor for a factor that functions as a negative regulator of hematopoiesis. Under these circumstances, GPI-AP $^-$ stem cells would have a growth advantage because they lack the receptor for the inhibitor.

Another important unresolved issue is the role of the GPI anchor in the development of PNH. Clearly, deficiency of GPI-AP accounts for most of the pathology associated with PNH. But is the clonal expansion of GPI-AP $^-$ stem cells the consequence of failure to synthesize the GPI moiety per se, or is it due to the absence of a particular protein that just happens to be GPI anchored? In addressing this question, one must attempt to separate the function of a particular protein from the function of the GPI moiety ([94], [95]). It is also important to consider that the GPI anchor may serve different functions on different proteins. Despite the progress that has been made in defining the structure of the GPI anchor, much less is known about its functional properties. Besides its most obvious role of providing a mechanism for membrane attachment of proteins, the GPI moiety may influence the release of proteins from the cell surface, the lateral mobility of the protein within the plane of the membrane, and the sorting of proteins in polarized epithelial cells ([94], [95]). Additionally, more than a dozen GPI-APs have been implicated in cellular activation and signaling through interactions with tyrosine kinases ([94], [95], [96] and [97]). GPI molecules that are not attached to protein (free GPIs) have been identified on the outer surface of cells ([98]). The significance of free GPIs is unknown, but they may have important biologic functions that influence cell proliferation. Thus, it is conceivable that the clonal expansion observed in PNH is due to the absence of a GPI-dependent signaling mechanism that regulates cell growth.

Although it is plausible to suggest that failure to synthesize the anchor per se underlies the development of PNH, it seems more likely that the global deficiency of GPI-AP is an epiphenomenon. Hematopoietic cells express a relatively large number of functionally diverse GPI-APs (Table 37.2). Thus, absence of all GPI-AP is probably not required for the clonal expansion of the mutant stem cells. Rather, the selective advantage may be dependent on the absence of a single protein that is GPI anchored, and the reason for the global deficiency of GPI-AP is that *PIG-A* is located on the X chromosome. According to this supposition, an autosomal gene encodes the GPI-AP that is conditionally detrimental (e.g., an antigen targeted for immune destruction or a receptor for a negative growth regulator). Inasmuch as two

alleles rather than one must be mutated, the probability of inactivating an autosomal gene through somatic mutagenesis is remote compared to the probability of inactivating an X-linked gene. Therefore, stem cells with a deficiency of the detrimental GPI-AP are most likely to arise as a consequence of *PIG-A* mutations (as was the case discussed above in which patients with chronic lymphocytic leukemia were treated with CAMPATH-1H). Assuming that the GPI-AP complement regulatory proteins are not the targets of the underlying pathologic process, the hemolytic anemia that is the clinical hallmark of PNH may represent an epiphenomenon related to the chromosomal location of *PIG-A*.

Although a compelling case can be made in support of the paradigm that the *PIG-A* mutation bestows a conditional growth advantage on the affected stem cell, the hypothesis that the mutant stem cells have an absolute growth or survival advantage must also be strongly considered. Data that both support and challenge this hypothesis can be found.

In support of the hypothesis are the studies of Iwamoto et al. ([99]). Using a model in which human bone marrow cells were transplanted into sublethally irradiated severe combined immunodeficiency mice, the investigators presented data suggesting that GPI-AP $^-$ stem cells have a growth advantage compared to GPI-AP $^+$ stem cells from either PNH patients or normal donors. Inasmuch as the only obvious variable in this model is whether the transplanted cells are GPI-AP $^+$ or GPI-AP $^-$, these results suggest that the growth advantage of the GPI-AP $^-$ stem cells relative to the GPI-AP $^+$ stem cells is an unconditional, intrinsic property of the mutant stem cells.

Brodsky and colleagues ([100]) presented data showing that *PIG-A* mutant cells are relatively resistant to apoptosis. Sensitivity to apoptosis was restored when the mutant cells were transfected with a *PIG-A*–containing expression vector. Others have also observed resistance to apoptosis in cells derived from patients with PNH ([101], [102]). Those authors, however, concluded that resistance to apoptosis was a property of cells isolated from patients with bone marrow failure syndromes (e.g., aplastic anemia and myelodysplasia) and was not specific for *PIG-A* mutant cells. More recently, Chen et al. ([103]) reported that GPI-AP $^-$ stem cells from patients with PNH have a growth advantage *in vitro* compared to their GPI-AP $^+$ counterparts. Interestingly, the proliferative properties of GPI-AP $^-$ cells were similar to those of stem cells isolated from normal volunteer donors. Interpretation of these studies is ambiguous, however. The findings could be explained by a difference in the intrinsic properties of the cells. Alternatively, the GPI-AP $^+$ cells could have been more severely damaged *in vivo* by the pathologic process that underlies PNH, resulting in diminished growth and survival in the *in vitro* studies.

The most compelling argument against an intrinsic growth or survival advantage for *PIG-A* mutant cells is made by the results of studies using transgenic mice ([89]). By using homologous recombination, Kawagoe et al. ([104]) disrupted *Pig-a* (the murine homolog of *PIG-A*). Only mice with a low degree of chimerism survived. Among those animals, the percentage of GPI-AP $^-$ erythrocytes ranged from approximately 1 to 5%. During 10 months of observation, the ratio of GPI-AP $^-$ to GPI-AP $^+$ peripheral blood cells did not increase. Studies by others using conditional knock-out technology have confirmed these observations ([89]).

In summary, the basis of the clonal dominance in PNH is enigmatic. Indirect evidence, however, supports the concept that *PIG-A* mutant, GPI-AP $^-$ stem cells emerge because they have a conditional growth or survival advantage. A cellular immune process most likely exerts the selective pressure. Thus, principles of darwinian evolution may apply to development of PNH. The extent of expansion of a particular mutant clone and the dominance of one *PIG-A* mutant clone in the presence of other *PIG-A* mutants may be mediated by secondary events (genetic or epigenetic) that influence cellular proliferation (Fig. 37.6).

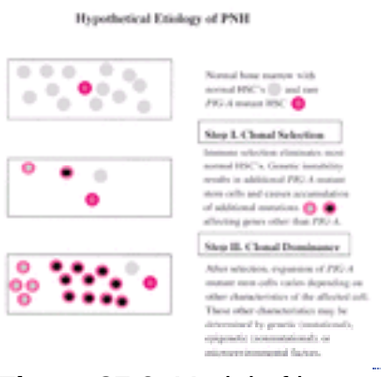

Figure 37.6. Model of how paroxysmal nocturnal hemoglobinuria (PNH) arises. Step I is clonal selection. According to this model, the *PIG-A* mutant, glycosyl phosphatidylinositol–anchored protein (GPI-AP)–deficient stem cells have a growth or survival advantage in the setting of a specific type of marrow injury. The close connection between PNH and aplastic anemia suggests that immune-mediated injury provides the selection pressure. Putatively, absence of one or more GPI-APs is advantageous in this setting. Step II is clonal dominance. Patients with PNH often have more than one mutant hematopoietic stem cell (HSC) that is active. The contribution of the *PIG-A* mutant clones to hematopoiesis varies greatly, however. This observation suggests that factors in addition to the *PIG-A* mutation influence the proliferative properties of stem cells that survive the injury-mediated selection process. Remarkably, a single clone can maintain normal (or near-normal) hematopoiesis for more than a decade without malignant transformation.

Aplastic Anemia and Paroxysmal Nocturnal Hemoglobinuria

Patients with PNH can be divided into the following two groups: those without a history of aplastic anemia (primary or hemolytic PNH) and those with a history of aplastic anemia who subsequently develop PNH (aplastic anemia/PNH). An association between aplastic anemia and PNH has been recognized at least since 1961 ([105]), and numerous subsequent studies have confirmed the association ([106], [107], [108], [109], [110], [111], [112], [113], [114], [115], [116], [117], [118] and [119]). The probability that two rare diseases could occur together so frequently by chance is negligible. Thus, there is a pathophysiologic link between PNH and aplastic anemia.

Recently, Hillmen et al. ([15]) reported that 23 of 80 PNH patients (29%) had a history of aplastic anemia, and in a series of 220 French patients with PNH, Socié and colleagues identified 65 (30%) in whom the diagnosis of aplastic anemia preceded that of PNH ([120]). The latter group of investigators also found that 10% of PNH patients with no history of aplastic anemia developed pancytopenia during the period of observation covered by the study (median follow-up of 2 years). The estimated cumulative incidence of pancytopenia was 8.2% [±2.4%, standard error (SE)] at 2 years and 14.2% (±3.3%, SE) at 4 years ([120]). This incidence appears to be somewhat higher than that observed in the study reported by Hillmen et al. in which 5 of 80 (6%) patients with PNH subsequently developed aplasia ([15]).

On the other hand, the proportion of patients with aplastic anemia who subsequently develop PNH varies widely among studies, in part, because the criteria for diagnosis of PNH are not uniform. In some cases, a positive Ham test or sucrose lysis test was required for diagnosis, and in other cases, identification by flow cytometry of a population of peripheral blood cells with GPI-AP deficiency was used to classify patients. A recent study reported that PNH cells were found in the bone marrow in 89% of 115 patients with aplastic anemia at some point during the course of their illness ([121]). Two other studies reported 38% (11 of 29 patients) ([115]) and 32% (12 of 37 patients) ([110]) for the portion of patients with aplastic anemia treated with immunosuppression who developed laboratory evidence of PNH during the course of their disease. In that study, 23% of patients had clinical signs and symptoms of PNH. Thus, in most patients with aplastic anemia, evidence of PNH is subclinical or transient. These results suggest that the selective pressure that favors *PIG-A* mutant cells occurs frequently in the setting of aplastic anemia but that the clinical syndrome occurs at a significantly lower frequency. The simplest interpretation of these observations is that factors in addition to *PIG-A* mutation contribute to the development of clinical signs and symptoms of PNH by determining the extent to which the *PIG-A* mutant stem cells expand. As discussed in the section Clonal Dominance, these factors could be genetic, epigenetic, or microenvironmental.

The time between the diagnosis of aplastic anemia and the development of PNH varies from a few months to several years. In the series reported by Socié et al. ([120]), the median time between diagnosis of aplastic anemia and laboratory evidence of PNH was 3.1 years (range, 0.17 to 15.0 years). Using an assay with the capacity to detect 0.004% GPI-AP $^-$ erythrocytes, Mukhina et al. reported that 61% of patients with aplastic anemia had detectable PNH cells before therapy ([112]). None of these patients, however, would have had GPI-AP– cells detected by conventional flow cytometry. Therefore, the selection of *PIG-A* mutant stem cells appears to occur early in the course of aplastic anemia. Expansion of the mutant clones occurs later and, thus, may be influenced directly or indirectly by therapy. Although many patients with aplastic anemia who develop PNH are treated with immunosuppressive therapy (e.g., antithymocyte globulin and cyclosporin) at the time the aplastic anemia is diagnosed, there is no direct evidence that immunosuppression causes PNH. Patients with aplastic anemia who respond to androgens appear equally likely

to develop PNH ([120]). Thus, marrow recovery per se may account for the expansion of progeny of the *PIG-A* mutant stem cell clones.

The basis of the relationship between PNH and aplastic anemia is speculative. Most patients with PNH have some evidence of bone marrow failure (e.g., thrombocytopenia, leukopenia, or both) during the course of their disease ([15] , [120]). Thus, bone marrow injury may be essential for the development of PNH. Currently, there is no evidence that the types of *PIG-A* mutations that occur in aplastic anemia/PNH are different from those observed in primary PNH ([83]). Further, a distinction between primary PNH and aplastic anemia/PNH may be artificial, as the underlying pathophysiologic process could be the same. According to this hypothesis, in primary or hemolytic PNH, the aplastic or hypoplastic component is subclinical with the recovery phase being spontaneous.

Leukocytes and Platelets

Deficiency of GPI-AP on neutrophils, monocytes, platelets, and lymphocytes has been demonstrated ([64] , [65] , [122] , [123] , [124] , [125] and [126]), and identical *PIG-A* mutations have been identified in neutrophils, monocytes, and lymphocytes from the same patient ([70] , [75]). Together, these studies indicate that the somatic mutation that gives rise to PNH affects a hematopoietic stem cell. Most PNH patients have pancytopenia or either neutropenia or thrombocytopenia in combination with anemia at some point during the course of their illness ([15] , [120] , [127]). The neutropenia and thrombocytopenia, however, are due to abnormal hematopoiesis rather than to increased peripheral, complement-mediated destruction, as *in vivo* studies have demonstrated normal survival of neutrophils and platelets in patients with PNH ([122] , [128]). That absence of GPI-anchored complement regulatory proteins from PNH neutrophils and platelets does not affect their survival implies that these cell types (unlike erythrocytes) have additional mechanisms that protect them from complement-mediated destruction *in vivo*.

In vitro studies have reportedly shown functional abnormalities of PNH leukocytes and platelets ([128] , [129] , [130] , [131] and [132]). Further, deficiency of some of the GPI-AP from PNH leukocytes and platelets would seem to have important functional consequences (e.g., deficiency of Fc?RIIIb from neutrophils, deficiency of urokinase-type plasminogen activator receptor from monocytes and neutrophils, deficiency of lymphocyte function-associated antigen-3 from lymphocytes, deficiency of the folate receptor from hematopoietic stem cells) (Table 37.2). However, evidence that deficiency of GPI-AP other than erythrocyte DAF and MIRL contributes to the pathophysiologic manifestations of PNH is largely conjectural. At least in some cases, functional redundancy appears to account for the lack of untoward consequences associated with GPI-AP deficiency ([133]).

Hematopoietic Stem Cells

The PNH defect can be demonstrated in erythroid and granulocytic precursors grown *in vitro* (i.e., colony-forming unit erythroid, burst-forming unit erythroid, and colony-forming unit granulocyte-macrophage) ([134]). Two populations of colonies can be identified in such studies, and they differ from one another in complement sensitivity and expression of acetylcholinesterase ([135]). These latter observations support the concept of a clonal process originating from a mutant hematopoietic stem cell.

Cytogenetic studies on hematopoietic cells of patients with PNH have yielded mixed results. The issue is complicated because patients with aplastic anemia can have karyotypic abnormalities ([136]). Recently, Araten and colleagues reported karyotypic abnormalities in 11 of 46 (24%) PNH patients examined in a retrospective study ([137]). In seven of these patients, there was evidence of clonal regression, and none of the patients developed excess of blasts or transformed into acute leukemia. These findings suggest that karyotypic abnormalities in PNH do not predict progression into a malignant phenotype. Nonrandom chromosomal abnormalities specific for PNH have not been identified, arguing against clonal evolution as a common process in PNH.

Uncommonly (~1%), patients with PNH develop acute leukemia ([15] , [120]). In some cases, the leukemic clone arises from the PNH clone because the blasts are GPI-AP deficient ([138]). Similar observations have been made in myelodysplasia arising in the setting of PNH ([139]). However, in other cases, PNH cells disappear after the onset of the leukemia ([140]) or myelodysplasia ([141]). Although transformation into acute leukemia or other clonal myelopathies is uncommon in PNH, the incidence is probably higher than in the general population. Thus, an element of genetic instability may be associated with PNH or the process that underlies PNH ([87]).

CLINICAL MANIFESTATIONS

PNH usually begins insidiously, with the abrupt onset of clinically apparent hemoglobinuria being the presenting symptom in approximately 25% of cases ([3]). The course is chronic with a generally stable clinical pattern in a given individual. The illness ranges in severity from a mild, clinically benign process to a chronically debilitating, potentially lethal disease. The diagnosis is made most frequently in the fourth to fifth decades of life ([15] , [120]), but PNH is also encountered in childhood ([13]) and in old age [age range, 16 to 75 years ([15]) and 6 to 82 years ([120]) in two large series]. Both genders are affected, with perhaps a slight female predominance ([120]), and PNH has been described in many racial groups but principally in whites and Asians ([80] , [106] , [142] , [143]). The disease has no familial tendency. Inherited cases due to global deficiency of GPI-AP have not been reported, suggesting that germline mutations of *PIG-A* are incompatible with life. This hypothesis is supported by the lack of success in producing a homozygous or hemizygous knock-out mouse using targeted mutation of *Pig-a* ([104]). A patient with an inherited deficiency of MIRL (CD59) had a syndrome that was clinically indistinguishable from PNH, but other GPI-APs were expressed normally by that patient ([45]).

Most commonly, patients initially report weakness, yellowish discoloration of the skin (jaundice), and other symptoms of chronic hemolysis, but (as noted earlier in this section) a history of hemoglobinuria is part of the initial presentation in only approximately 25% of patients (Table 37.3). Because PNH frequently is not considered in such patients, the correct diagnosis is often delayed by months to years.

TABLE 37.3. Presenting Features in 80 Patients with Paroxysmal Nocturnal Hemoglobinuria

Signs and Symptoms	Number of Patients (%)
Symptoms of anemia	20 (35)
Hemoglobinuria	21 (26)
Hemorrhagic signs and symptoms	14 (18)
Aplastic anemia	10 (13)
Gastrointestinal symptoms	8 (10)
Hemolytic anemia and jaundice	7 (9)
Iron deficiency anemia	5 (6)
Thrombosis or embolism	5 (6)
Infections	4 (5)
Neurologic signs and symptoms	3 (4)

From Dacie JV, Lewis SM. Paroxysmal nocturnal haemoglobinuria: clinical manifestations, haematology, and nature of the disease. Ser Haematol 1972;5:3–23, with permission.

Hemoglobinuria

Although most patients (80%) have episodes of hemoglobinuria some time during their illness ([15]), this classic symptom is reported as part of the initial evaluation in only one-fourth of all patients (Table 37.3). Nocturnal hemoglobinuria appears to result from an increase in the rate of hemolysis that occurs during sleep. It is not related to time of day, however, because the pattern can be reversed if the patient is kept awake at night and allowed to sleep during the day. In patients with nocturnal hemoglobinuria, the urine is usually darkly discolored in the morning and clears during the day. When hemolysis is intense, however, hemoglobinuria may

persist throughout the day.

The cause of the nocturnal exacerbation is poorly understood. Retention of CO_2 causing a slight fall in plasma pH that is sufficient to activate the alternative pathway of complement is a possible explanation ([4], [5]), but this hypothesis has been challenged ([2]).

Episodic Hemolysis

In addition to the sleep-related pattern, most patients experience irregular but recurrent exacerbations of hemolysis and hemoglobinuria. Paroxysms may be precipitated by a wide variety of events, including infections (even minor ones), surgery, transfusions, iron supplementation, vaccinations, and menstruation. Attacks of hemoglobinuria are unrelated to cold exposure, thus distinguishing PNH clinically from paroxysmal cold hemoglobinuria.

Mild hemolytic episodes often pass without significant symptoms, but more severe attacks may be associated with substernal, lumbar, or abdominal pain together with drowsiness, general malaise, fever, and headaches. The abdominal pain may be colicky and may last for 1 to 2 days. The abdomen may be tender, especially in the left upper quadrant, with guarding and rebound tenderness. The back pain resembles that noted in patients with other types of intravascular hemolysis and is most severe in the lumbar region. Headaches may be excruciating and sometimes last for days.

Marrow Hypoplasia

Because many patients with aplastic anemia/PNH have only a small proportion of complement-sensitive cells ([112]), few of the changes usually associated with hemolytic anemia are obvious. Thus, the aplastic anemia/PNH syndrome is probably underdiagnosed. Clinicians need to maintain a high degree of suspicion, and any evidence of hemolysis (e.g., elevated serum lactate dehydrogenase) in a patient with aplastic anemia warrants evaluation for PNH. In one series of 80 European patients with PNH, aplastic anemia was the first diagnosis in 23 cases (29%) ([3], [15]); the same was true for 26 of 85 patients (31%) from Thailand ([142]) and 65 of 220 French patients (30%) ([120]). In some instances, the diagnosis of hemolysis is made first, and pancytopenia develops subsequently ([3], [15], [120], [142]). Although speculative, the basis of the relationship between aplastic anemia and PNH is discussed in the section Aplastic Anemia and Paroxysmal Nocturnal Hemoglobinuria.

Thrombotic Disease

PNH is associated with a striking predisposition to intravascular thromboses, especially within the venous circulation ([15], [120], [144]). Intraabdominal veins are the most common sites of thrombosis in patients with PNH. Cerebral vein thrombosis and superficial dermal vein thrombosis also appear to be represented disproportionately. Thrombotic disease accounts for approximately 50% of all deaths in patients with PNH. Fatal thromboses usually involve the portal system or the brain.

Recurrent abdominal pain is the dominant clinical manifestation in some patients with PNH (Table 37.3). The cause of the pain is often obscure but may be severe enough to be confused with an acute abdomen warranting emergency surgery. The possibility that a thrombosis in the portal or mesenteric veins is the cause of the pain should be considered in this setting. Both transient intestinal ischemia and intestinal infarction are other possible causes.

Hepatic venous thrombosis (Budd-Chiari syndrome) is a serious, potentially fatal complication of PNH ([145], [146]). In various series, 15 to 30% of patients with PNH had hepatic venous thrombosis, and it might be even more common because affected individuals can be asymptomatic when the disease is in its early stage ([147]). The clinical manifestations include nausea, abdominal pain, variable degrees of ascites, variceal bleeding, and signs of liver failure. Often, the liver increases abruptly in size, but hepatomegaly is not always noted. Three pathophysiologic stages of hepatic venous thrombosis have been defined ([147]). In the early or mildest stage, only venules or small hepatic veins are involved. Patients may be asymptomatic; therefore, the condition may go unrecognized. Mild, easily controlled ascites is detected in some patients. In the second stage, larger hepatic veins are partially occluded. Ascites is noted in most patients with such abnormalities. Some individuals develop variceal bleeding, and a few become jaundiced. The third or advanced stage is characterized by complete occlusion of large hepatic veins. Ascites is almost always present, jaundice is common, and variceal bleeding occurs in a few patients. This stage is often fatal.

An increase in the level of serum lactate dehydrogenase, alanine aminotransferase, and aspartate aminotransferase may be an early clue to the presence of hepatic vein thrombosis. Plasma concentration of conjugated bilirubin also may increase, but other biochemical tests of liver function are of limited value. Ultrasonography probably is the most effective, noninvasive method for early detection of hepatic vein thrombosis ([148]). Serial computed tomography scans also are of value. Radioactive isotope scanning demonstrates patchy uptake in most of the liver, except for a normal-functioning, hypertrophied caudate lobe, which is spared because of its separate venous drainage ([146]). Hepatic venography can provide definitive information, but this procedure carries more risk than noninvasive techniques. Biopsy may demonstrate congestion and liver cell loss, but the procedure is hazardous and not always of diagnostic value.

Small-vessel thromboses may cause severe and refractory headaches, or they presage progressive cerebrovascular thrombosis ([149]). Isotopic brain scanning and electroencephalography usually are of little help in monitoring PNH patients with headaches.

The etiology of the thrombophilia associated with PNH is speculative ([144]). A link between thrombosis and GPI-AP deficiency has been suggested ([132], [150]). However, the lack of an association between thrombosis and the portion of GPI-AP deficiency implies that additional factors contribute to the thrombophilia of PNH. Risk factors for thrombosis in PNH have not been identified, and the frequency of mutations in factor V Leiden is not abnormally high among tested patients ([151]).

Renal Abnormalities

Both acute and chronic renal insufficiency occur in patients with PNH ([152]). Acute renal insufficiency is associated with hemoglobinuric crises and may resolve without residual damage. In one series of 19 patients with PNH, however, 12 individuals had reduced values for creatinine clearance, whereas their underlying disease was stable. Furthermore, at least three of these patients had progressive renal insufficiency. Patients with PNH may also have hematuria, proteinuria, hypertension, an inability to concentrate urine, or some combination of these abnormalities. The kidneys usually are enlarged when examined radiographically. The renal abnormalities probably result from repeated thrombotic episodes involving small venules.

Dysphagia

When closely questioned, many patients with PNH report painful or difficult swallowing. The symptom is often worse in the morning and appears to be exacerbated during hemolytic episodes. Studies of peristalsis have shown that the esophageal contractions that occur in this setting have nine to ten times the normal force. The pathogenesis of these esophageal symptoms is speculative. Inasmuch as hemoglobin binds nitric oxide, it has been proposed that the plasma free hemoglobin that is a consequence of the chronic intravascular hemolysis characteristic of PNH acts as a sump for nitric oxide. Esophageal (and intestinal spasm) may ensue due to consumption by plasma free hemoglobin of the smooth muscle–relaxing activity of nitric oxide.

Infections

Infectious diseases are common and may be attributable in part to leukopenia, to treatment with corticosteroids, or, possibly, to functional defects in leukocytes. Even mild infections may constitute a serious hazard because they may precipitate a hemolytic or an aplastic crisis.

Physical Examination

Findings may include pallor and jaundice. Moderate splenomegaly is usual, and mild to moderate hepatomegaly is sometimes found. The association of splenomegaly with “aplastic anemia” is often a clue to the real nature of the disease (i.e., PNH/aplastic anemia). Physical examination is otherwise unrevealing.

LABORATORY FINDINGS

Blood

Essentially all patients are anemic, and in many, the anemia is severe. The red cells are usually macrocytic, but size range varies considerably among patients. Occasionally, when urinary iron loss has been considerable, the red cells may appear hypochromic and microcytic. Spherocytes and other abnormal red cell shapes are not seen, but, occasionally, red cell fragments may be observed. When present, these fragments may indicate a complicating intravascular coagulopathy. In addition to polychromatophilia, normoblasts (nucleated red blood cells) may be found in the peripheral blood film. Relative reticulocytosis may be marked, but the absolute reticulocyte count is often lower than that found in association with other hemolytic disorders at comparable degrees of anemia. This discrepancy reflects underlying marrow dysfunction that is invariably a component of the disease. The osmotic and mechanical fragility of the erythrocytes is normal, and the reaction to the direct antiglobulin (Coombs) test is negative.

Leukopenia is often detected and may be marked ([120]). The leukopenia is a consequence of abnormal hematopoiesis, although a shift from the circulating to the marginated granulocyte pool may be a contributing factor ([128]). The neutrophil alkaline phosphatase (a GPI-AP) content is low or absent. Functional leukocyte defects have been demonstrated, but their clinical relevance is conjectural.

Thrombocytopenia of moderate to severe degree is common ([120]), but platelet lifespan and function generally are normal ([122]). Bleeding due to severe thrombocytopenia contributes significantly to the morbidity and mortality of the disease ([3], [120]).

Plasma

The plasma may be golden brown, reflecting the presence of increased levels of unconjugated bilirubin, hemoglobin, and methemalbumin. Predictably, serum haptoglobin levels are low, and lactate dehydrogenase concentration is usually markedly elevated, reflecting chronic intravascular hemolysis.

Urine

When the rate of blood destruction is increased, the urine contains increased amounts of urobilinogen. In addition, intravascular hemolysis leads to the depletion of serum haptoglobin, which results in the continuous presence of hemoglobin in the glomerular filtrate in the kidney. The cells of the proximal convoluted tubules that become heavily laden with iron reabsorb much of the hemoglobin. The excretion of this iron in the form of granules gives rise to hemosiderinuria. In addition, spectroscopic examination may reveal variable amounts of free hemoglobin. The continuous loss of relatively large amounts of iron in the urine may produce iron deficiency. Average daily losses of up to 15.9 mg have been observed, and as many as 3.6 mg of iron excreted in 24 hours have been demonstrated, even in the absence of hemoglobinuria. Albumin has been detected in the urine immediately before and after an episode of hemoglobinuria, and long-term study of PNH patients has shown an unexpected high incidence of functional renal abnormalities, such as hematuria, hyposthenuria, tubular malfunction, and declining creatinine clearance ([152]).

Bone Marrow

Normoblastic hyperplasia is the characteristic finding. As many as 50% of the nucleated cells may be normoblasts; megaloblastic changes are evident only occasionally. The absence of morphologic changes consistent with megaloblastic anemia suggests that deficiency of the GPI-anchored form of the folate receptor (Table 37.2) does not result in abnormalities in folate metabolism that are clinically significant. The number of megakaryocytes may be decreased. When pancytopenia is evident, hypoplastic marrow may be observed, although in many patients, pancytopenia is associated with cellular marrow, a feature that is more consistent with a myelodysplastic process.

Cytogenetic Studies

Although karyotypic abnormalities have been reported in PNH, nonrandom chromosomal aberrations specific for PNH have not been identified ([137]). Apparently, the presence of karyotypically abnormal bone marrow cells is not a negative prognostic factor in PNH as it is in myelodysplasia ([137]).

Diagnostic Tests

Until recently, the diagnosis of PNH was based on the results of special tests that exploited the abnormal sensitivity of PNH red cells to lysis by complement. Among the available assays, the Ham test (acidified serum lysis) and the sucrose lysis (sugar water) test ([153], [154]) were most commonly used for the clinical diagnosis of PNH. Although these tests are sensitive and specific when properly performed and relatively simple in both theory and practice, their accuracy is strongly operator dependent. Thus, in the hands of an inexperienced technician, results are not always reliable. This problem is compounded by the fact that the tests are usually performed on a sporadic basis in most clinical laboratories because the diagnosis of PNH is entertained relatively uncommonly.

The recognition that the deficiency of GPI-AP underlies PNH has resulted in the development of a simple, reliable method for diagnosing the disease ([113], [123], [124], [126], [155]). By analyzing the expression of GPI-AP on hematopoietic cells using monoclonal antibodies and flow cytometry, the abnormal cells can be readily identified (Fig. 37.1 and Fig. 37.2). The simplest method is to analyze the expression of MIRL (CD59) on erythrocytes. Because it is normally present in relatively high density, red cells with either complete or partial deficiency of MIRL are easily distinguished from normal (Fig. 37.1 and Fig. 37.2A). Thus, PNH I (normal expression), PNH II (partial expression), and PNH III (negative expression) erythrocytes can be identified by analyzing the flow cytometry histogram (Fig. 37.1 and Fig. 37.2A, Table 37.1). Analysis of erythrocyte DAF (CD55) expression is also informative. Because erythrocytes express approximately six- to eightfold less DAF than MIRL, however, separation into discrete populations may be less obvious when anti-DAF is used as the primary antibody. By using both antibodies, the diagnosis can be confirmed (Fig. 37.1 and Fig. 37.2A).

Expression of GPI-AP on other hematopoietic cells, such as granulocytes, can also be used to diagnose PNH, but, with rare exception ([113]), this approach offers no advantage over analysis of red cells. To the contrary, analysis of GPI-AP on granulocytes is technically more challenging than on erythrocytes ([123]). Further, granulocyte expression must be analyzed immediately after the blood sample is obtained, whereas erythrocytes can be analyzed 1 to 2 weeks after the blood is obtained if the sample is properly stored at 4°C.

GPI-AP– populations that comprise more than 1% of the red cells can be identified by standard flow cytometry ([123]). Concern that recent red cell transfusion might result in a false-negative result seems unfounded. Because the assay is so sensitive and because the proportion of GPI-AP $^{-}$ cells is greater in the reticulocyte population than in the peripheral blood as a whole ([12], [156]), massive transfusion that both replaces essentially all of the patient's blood volume and completely suppresses hematopoiesis would be required to produce a false-negative result. Transfusion has an impact on the percentage of GPI-AP $^{-}$ cells that are observed, but the possibility that the diagnosis would be obscured seems remote. Likewise, the possibility that a recent hemolytic episode would result in a false-negative result because all the abnormal cells are destroyed is negligible. Clearly, when documenting the proportion of affected cells and determining the precise phenotype, the analysis is best done when the patient has not been recently transfused, as well as when the patient is not experiencing a hemolytic crisis related to infection or some other cause.

Recently, Brodsky and colleagues developed a very sensitive assay for PNH by exploiting the properties of the bacterial toxin aerolysin ([112], [157], [158]). This channel-forming protein binds to the GPI anchor. Thus, PNH cells are selectively spared from the lytic effects of the toxin because they lack the GPI anchor. In samples containing a mixture of GPI-AP $^{+}$ and GPI-AP $^{-}$ cells, treating with the toxin can eliminate the GPI-AP $^{+}$ cells, and any residual GPI-AP $^{-}$ cells can be detected by flow cytometry. Using this method, as few as 0.004% GPI-AP $^{-}$ cells could be identified ([112]). This assay may be particularly valuable in identifying patients with aplastic anemia and myelodysplasia who have a very small portion of GPI-AP $^{-}$ cells, especially if finding such a population has prognostic or therapeutic significance.

Analysis of the expression of GPI-AP on erythrocytes is also a highly specific test for PNH. There is no other disease in which the erythrocytes are a mosaic of both GPI-AP $^{+}$ and GPI-AP $^{-}$ cells. Patients with isolated deficiency of either DAF [the Inab phenotype ([159])] or MIRL ([45]) are identified by this method (assuming that anti-DAF and anti-MIRL antibodies are used). Such patients are extremely rare, however, and their flow cytometry histograms are readily distinguishable from those of patients with PNH because 100% of the cells are abnormal and expression of only one GPI-AP is deficient.

DIFFERENTIAL DIAGNOSIS

The diagnosis of PNH must be considered in any patient who has the following: (a) signs of intravascular hemolysis of undefined cause, especially in the presence of hemoglobinuria, and a high serum lactate dehydrogenase; (b) pancytopenia in association with hemolysis, whether or not the marrow is cellular; (c) persistent, poorly explained iron deficiency, when accompanied by hemolysis; (d) evidence of recurrent venous thrombosis, especially intraabdominal events; and (e) unexplained recurrent bouts of abdominal pain, low backache, or headache in the presence of chronic hemolysis.

It is difficult to overemphasize the importance of documenting evidence of hemolysis before proceeding with tests more specific for PNH. As discussed in the section Hemoglobinuria, a history of hemoglobinuria (nocturnal or otherwise) is not part of the initial clinical presentation in approximately three-fourths of patients with PNH (Table 37.3). With rare exception, however, laboratory evidence of hemolysis is a constant feature of the disease. Quantitation of serum lactate dehydrogenase is particularly informative because intravascular hemolysis results in markedly elevated values. If lactate dehydrogenase levels are difficult to interpret because of other comorbid conditions (e.g., liver disease), alternative evidence for hemolysis should be sought (e.g., low serum haptoglobin, urine hemosiderin). Without evidence of hemolysis, more specific tests for PNH are generally unwarranted. PNH must be differentiated from antibody-mediated hemolytic anemias, especially paroxysmal cold hemoglobinuria and the cold agglutinin syndrome, and from HEMPAS (*h*ereditary *e*rythroblastic *m*ultinuclearity with *p*ositive *a*cidified *s*erum). The mechanism that underlies the abnormal susceptibility of HEMPAS erythrocytes to acidified serum lysis is different from that of PNH ([160]). By using flow cytometry, there is no difficulty distinguishing PNH from other hemolytic diseases because deficiency of GPI-AP affecting a portion of the erythrocytes is diagnostic of PNH.

TREATMENT

With the exception of marrow transplantation, no definitive therapy is available. Rigid guidelines for management are inappropriate because of the highly variable clinical course. Some patients have only a moderate degree of anemia with minimal hemoglobinuria, and in such patients, “he prescribes best who prescribes least.” Other patients have severe anemia punctuated by hemolytic crises, thromboses, and infection; in such patients, treatment is warranted, but response is often unsatisfactory.

Bone Marrow Transplantation

Allogeneic bone marrow transplantation (BMT) has been used in the treatment of severe PNH for more than 25 years ([161], [162], [163] and [164]). Presumably, the abnormal stem cells are destroyed by the conditioning regimen, and the marrow is repopulated with normal donor cells. The transplant process may also have immune modulatory activity that contributes to the efficacy of the treatment. Although allogeneic BMT is potentially curative, the benefits must be weighed against the significant morbidity and mortality associated with the procedure. The experience of the International Bone Marrow Transplant Registry was recently reviewed ([164]). A total of 57 patients were included in this study, with 48 receiving HLA-identical sibling transplants. The 2-year probability of survival for this group was 56%. Only one of seven patients who underwent unrelated donor transplant was alive after 5 years of follow-up. Recently, successful treatment of a patient with PNH using nonmyeloablative stem cell transplantation has been reported ([165]).

Although BMT has been used primarily to treat patients with PNH/aplastic anemia, consideration should be given to this form of therapy in patients with PNH who have thrombosis at presentation, as this group has only a 40% survival rate at 4 years ([120]). Progression to pancytopenia is also a risk factor that negatively affects survival ([120]), as do the development of myelodysplastic syndrome or acute leukemia, age older than 55 years at diagnosis, and thrombocytopenia at diagnosis (Table 37.4). Surprisingly, however, a history of aplastic anemia has been reported to favorably influence survival in a multivariate analysis (Table 37.4) ([120]). That some patients with PNH undergo spontaneous remission must also be taken into account when deciding on the appropriateness of allogeneic BMT as treatment for PNH ([15]).

TABLE 37.4. Risk Factors Affecting Survival

Factor	Relative Risk of Disease-Related Mortality (95% Confidence Interval)	*p* Value
Development of thrombosis	10.2 (6.0–17.0)	<.0001
Progression to pancytopenia	5.5 (2.8–11.0)	<.0001
Myelodysplastic disease or acute leukemia	19.1 (7.3–50.0)	<.001
Age >55 yr	4.0 (2.4–6.9)	<.0001
More than one treatment	2.1 (1.3–3.6)	<.003
Thrombocytopenia at diagnosis	2.2 (1.3–3.8)	<.003
Aplastic anemia antedating paroxysmal nocturnal hemoglobinuria	0.32 (0.14–0.72)	<.023

Modified from Socié G, Mary JY, de Gramont A, et al. Paroxysmal nocturnal haemoglobinuria: long-term follow-up and prognostic factors. Lancet 1996;348:573–577.

In the unusual circumstance in which the patient has a syngeneic twin, BMT is the most appropriate therapy for severe PNH because absence of graft-versus-host disease greatly reduces transplant-associated morbidity and mortality. Syngeneic transplantation without preconditioning has been unsuccessful generally because abnormal hematopoiesis usually returns, suggesting that the residual *PIG-A* mutant stem cells have a survival or proliferative advantage relative to the transplanted GPI-AP $^{+}$ cells ([79]). This same phenomenon may limit the efficacy of gene therapy ([166]), as transducing *PIG-A* mutant stem cells with normal *PIG-A* would hypothetically eliminate their conditional growth or survival advantage. An attractive alternative approach to gene therapy would take advantage of the fact that the hematopoietic stem cells of patients with PNH are a mosaic. Conceivably, the GPI-AP $^{+}$ cells can be selected and used for marrow rescue after myeloablation. The success of this approach depends on developing a method for separating uniformly and efficiently the GPI-AP $^{+}$ population from the GPI-AP $^{-}$ population and acquiring GPI-AP $^{+}$ stem cells sufficient to repopulate the ablated marrow. Fluorescence-activated cell sorting may be useful for this purpose, as CD34 $^{+}$, CD38 $^{-}$ hematopoietic stem cells express both CD55 and CD59 ([167]).

Hormones and Steroids and Immunosuppressive Therapy

Androgenic steroids and prednisone have been used in the treatment of PNH with some success. As a rule, androgens appear to be most effective in cases with prominent marrow hypoplasia, whereas prednisone is most useful in patients with overt hemolysis ([168]).

Approximately 50% of patients appear to respond to androgen therapy with an increase in their hemoglobin level or a reduction in transfusion requirement; however, attempting to identify the responders in advance is problematic. Furthermore, the side effects of androgen therapy can be substantial, ranging from virilizing effects in women and acne in both sexes to serious liver disease, including peliosis hepatitis and hepatocellular carcinoma. Although neither of the last two complications have been reported to occur in androgen-treated patients with PNH, some investigators suggest androgens might predispose patients to an insidious form of hepatic vein thrombosis ([168]). These considerations make prudent the institution of androgen therapy for 6 to 8 weeks with discontinuation if no clear response is observed. Oral preparations, such as fluoxymesterone (5 to 30 mg/day) or oxymetholone (10 to 50 mg/day), have been used most commonly. Because of fewer adverse effects, danazol is an attractive alternative to anabolic steroids. More recently, immunosuppressive therapy has been used to treat PNH patients with clinically significant bi- or trilineage cytopenias (discussed below). Initial results are encouraging, suggesting that this approach may represent an improvement over androgen therapy.

The value of using prednisone in treating the hemolysis of PNH is controversial. For prednisone to be effective in this setting, it must be given in relatively high doses (1 mg/kg), putting patients at risk for significant adverse effects. Toxicity seems to be least with an alternate day regimen, using doses of 15 to 40 mg every other day. In one series, 12 of 18 patients improved significantly with such therapy ([168]). Higher doses given daily can be administered for up to 7 days to treat hemolytic crises.

The response is usually rapid (often within 12 hours), but the mode of action of adrenal steroids in PNH is speculative.

Responses to immunosuppressive therapy with cyclosporin and antithymocyte globulin have been reported ([169], [170] and [171]). This approach to management has been used primarily for patients with the aplastic anemia/PNH syndrome. Use of high-dose cyclophosphamide (Cytoxan) for treatment of PNH and the aplastic anemia/PNH is under investigation ([172]).

Transfusions

Blood transfusions may be required for treatment of anemia. The recommendation that the blood is given in the form of saline-washed or frozen-thawed, deglycerolized red cells to avert a hemolytic episode has been questioned ([173], [174]). Transfused red cells survive normally in patients with PNH, and transfusion to near-normal hemoglobin levels can produce short-lived remissions. Such remissions may result from a temporary decrease in the production of abnormal cells with a consequent reduction of hemolysis and other disease-associated phenomena.

Iron

Iron deficiency eventually develops in most patients, sometimes even after repeated transfusion ([175]). The amount of iron lost should be replaced. Most patients tolerate oral iron therapy well, but hemolytic episodes have been precipitated by such treatment ([176]). This phenomenon probably results from the outpouring of a cohort of young erythrocytes of which a larger proportion is more complement-sensitive than those in the older, antecedent population ([168]). If hemoglobinuria after iron therapy is troublesome, hematopoiesis can be suppressed by a brief period of transfusion during which iron stores are replenished. Alternatively, a short course of high doses of prednisone given during the early phases of iron replacement therapy may ameliorate the hemolytic exacerbation.

Prevention and Treatment of Thrombosis

A recent review of 13 retrospective studies of PNH in nonpregnant patients revealed considerable variation in the reported rate of thromboembolic disease; however, overall 14.4% (95.0% confidence interval of 7.6 to 25.5) of the patients included in these studies were affected ([177]). Thromboembolic complications of PNH appear to be more common among patients from Western countries, with intraabdominal (hepatic and mesenteric veins) and cerebral veins being the most common involved sites. Nine of these studies described cause of death, with 22% of the mortality due to venous thrombosis (higher among Westerners).

Clinicians should be particularly alert for thrombotic disease in patients with indwelling catheters, after surgical procedures, during prolonged sedentary periods, and during the puerperium (see section Pregnancy and Paroxysmal Nocturnal Hemoglobinuria). Female patients should avoid the use of oral contraceptives because these agents increase the risk of serious thrombotic disease.

Anticoagulation is required for the treatment of venous thrombosis (including cerebral vein thrombosis) associated with PNH, with thrombolytic therapy being advocated for extensive acute or life-threatening hepatic vein thrombosis (see below). Mild to moderate thrombocytopenia (platelet count between 50,000 and 100,000 per µl) is not a contraindication to anticoagulation; however, platelet transfusion may be required for patients with counts less than 50,000 per µl. Occasional episodes of hemolysis coincident with the administration of heparin have been reported ([168]), and this phenomenon has been attributed to activation of the alternative pathway of complement by heparin. This complication is rare, however, and concern for exacerbation of hemolysis by heparin should not deter its use in standard pharmacologic doses in situations in which anticoagulation is warranted. Once adequately anticoagulated with heparin, warfarin (Coumadin) therapy should be initiated with a goal of maintaining the international normalized ratio between 2.0 and 3.0. Although data on recurrence rates have not been generated, patients with PNH who experience a thromboembolic episode probably warrant life-long anticoagulation.

For hepatic vein thrombosis, prompt treatment with heparin or thrombolytic agents is recommended ([146], [178]). Even with heparin therapy, extensive hepatic vein thrombosis is associated with a poor prognosis ([149], [178]). Experience with thrombolytic therapy in this setting is limited, but success has been reported with the use of streptokinase, urokinase, and tissue plasminogen activator ([178], [179]). A PNH patient with chronic hepatic vein thrombosis markedly improved after BMT ([180]).

In the study of Socié et al. ([120]), 30% of French patients experienced an episode of thrombosis within 8 years of the diagnosis of PNH, and based on Kaplan-Meier estimates, approximately 50% of patients were predicted to have this complication by 15 years. Because of the relatively high incidence of thrombosis (particularly among Westerners) and its associated morbidity and mortality, an argument can be made for prophylactic anticoagulation in patients without contraindications such as severe thrombocytopenia ([15], [181]). A nonrandomized study with a relatively short follow-up period suggested a significant reduction in thrombotic events when PNH patients with at least 50% GPI-AP ¯ granulocytes received prophylactic anticoagulation with warfarin (Coumadin) ([181]). The benefits of prophylactic anticoagulation, however, must be weighed against potential adverse effects of long-term anticoagulation. Patients at risk for cerebral vein thrombosis and portal/hepatic vein thrombosis would likely derive the greatest benefit from prophylactic anticoagulation. A method for identifying that small subgroup of patients, however, has not been developed.

Pregnancy and Paroxysmal Nocturnal Hemoglobinuria

It is clear that pregnancy is hazardous in PNH ([182], [183] and [184]). It is also clear that patients with PNH can have successful, uncomplicated pregnancies ([184], [185], [186] and [187]). De Gramont and colleagues ([184]) reported that approximately one-third of 38 pregnancies observed in 28 patients with PNH were uncomplicated and that life-threatening complications in mothers are uncommon. Complications experienced by mothers in that series were mainly hemorrhage and acute hemolysis. However, 45% of the pregnancies resulted in either spontaneous miscarriage or elective termination. Other studies ([182]) have reported a maternal mortality of approximately 6% with the major complications being related to thrombosis (particularly Budd-Chiari syndrome). Fetal wastage and prematurity were also reported to be relatively common. Based on a review of 20 published reports that described the outcome of 33 pregnant women with PNH, Ray and colleagues ([177]) calculated an all-cause maternal mortality rate of 20.8% (95.0% confidence intervals of 7.3 to 39.0). Approximately one-half of all infants were delivered preterm. Three deaths were reported among 34 live births (perinatal mortality of 8.8%, with 95% confidence intervals of 1.9 to 23.7).

When possible, patients with PNH who are contemplating pregnancy should be counseled about the potential for both maternal and fetal complications. The care of a pregnant patient with PNH requires the combined expertise of an experienced hematologist and an obstetrician who specializes in the management of high-risk pregnancies.

Unless there is an absolute contraindication, patients should receive therapeutic doses of subcutaneous heparin during pregnancy. Anticoagulation should be initiated during the first trimester and continued 4 to 6 weeks postpartum ([177]). As patients are often thrombocytopenic, platelet counts should be monitored regularly while on heparin. Patients should undergo hepatic ultrasound monthly to monitor the patency of hepatic veins.

Other Measures

As with other types of chronic hemolysis, supplemental folate (1 mg/day) is indicated for patients with PNH.

Splenectomy should be considered in patients with splenomegaly and clinically significant cytopenias with a cellular marrow, as such treatment may ameliorate the cytopenias. Anecdotal reports of amelioration of hemolysis after splenectomy have appeared, but evidence-based guidelines for splenectomy in the management of PNH are not available.

Currently available are a wide variety of reagents that are specific inhibitors of complement ([188]). For example, a recombinant, soluble form of complement receptor type 1 is currently undergoing clinical trials for treatment of a variety of complement-mediated diseases. This protein is a potent inhibitor of both the classic and the alternative pathways of complement, and a modified form that inhibits only the alternative pathway has been developed. Conceivably, soluble complement receptor type 1 could be used to treat acute hemolytic episodes. Clinical studies designed to test the efficacy of complement inhibitors in the treatment of PNH, however, have not been initiated.

Because they are GPI anchored, isolated DAF and MIRL have the capacity to reincorporate into cells. Thus, theoretically, expression of DAF and MIRL on PNH

erythrocytes could be supplemented by infusion of the recombinant proteins. The feasibility of this therapeutic approach appears limited, however, because plasma apolipoproteins bind the hydrophobic GPI anchor moiety of the proteins, preventing incorporation into cells ([46]). Molecular derivatization of soluble DAF and MIRL offers the potential of circumventing this problem.

Inasmuch as *PIG-A* mutations are necessary for the development of PNH, correction of the underlying defect by gene therapy is another hypothetical possibility. The results of BMT in the treatment of PNH suggest that for gene therapy to be successful, *PIG-A* mutant stem cells need to be ablated, as the GPI-AP $^{-}$ stem cells appear to have a relative proliferative or survival advantage ([79]).

DISEASE COURSE AND PROGNOSIS

PNH is a chronic disease with a median survival of 10 to 15 years ([15] , [120]). Approximately 25% of patients survive for 25 years or longer after diagnosis ([15]). The major causes of morbidity and mortality are thrombosis, bleeding, and infections. The latter two complications are due to thrombocytopenia and neutropenia, respectively, which are consequences of the abnormal hematopoiesis that underlies this stem cell disorder.

In some PNH patients, the severity of the illness lessens with time, and (in one series) approximately one-third of patients who survived 10 years experienced a spontaneous clinical remission ([15]). These cases suggest that, in time, the abnormal clone(s) can gradually lose its relative proliferative or survival advantage. That the disease spontaneously remits in a significant number of instances provides a basis for hope for both patient and physician. Additionally, this feature of the disease should enter into management decisions, particularly when the patient is a candidate for allogeneic BMT ([15]).

The development of other clonal myelopathies, including myelodysplastic disease and acute leukemia, adversely affects prognosis ([120]). The incidence of acute leukemia in association with PNH appears to be in the range of 1.0% ([120]), although higher [7.7% in a study of Japanese patients ([189])] and lower [0 of 80 patients in a study from England ([15])] incidences have been reported. The rate of myelodysplastic disease in association with PNH is in the range of 5% ([120]). Other clonal myelopathies that have been reported in association with PNH include myelofibrosis, chronic lymphocytic leukemia, chronic myelocytic leukemia, polycythemia vera, and erythroleukemia. In some instances, the clonal myelopathy arises in the PNH clone ([138] , [139]), whereas in other instances, it arises in a GPI-AP $^{+}$ clone ([140] , [141]). The association of PNH with other stem cell disorders, particularly myelodysplasia and acute leukemia, suggests that genetic instability is a component of the disease ([87]). This process may be a consequence of the as yet undefined bone marrow injury that underlies PNH.

Acquired Nonimmune Hemolytic Disorders

Hemolysis occurs when red blood cells (RBCs) are exposed to a variety of infectious agents, chemicals, or physical stresses. In some cases, these effects are antibody mediated (see Chapter 35 and Chapter 36). In others, such as in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency (see Chapter 33) or in those with unstable hemoglobins (see Chapter 41), there is an underlying propensity of the RBCs to be more susceptible to injury. In still other cases, such as paroxysmal nocturnal hemoglobinurea (PNH), hemolysis occurs as a consequence of an acquired clonal abnormality in the RBC membrane (see Chapter 37). Last, hemolytic anemia also occurs when otherwise normal RBCs are injured directly by infectious agents, chemicals, thermal injury, mechanical stresses, or altered metabolites. These disorders are the focus of this chapter.

HEMOLYSIS DUE TO INFECTION

A variety of infectious processes can lead to hemolytic destruction of normal RBCs. In some cases, such as in *Mycoplasma pneumoniae* infection or with infections related to paroxysmal cold hemoglobinuria, hemolysis is related to antibody-mediated cell destruction (see Chapter 35). With the infections described in this section, hemolysis is largely the result of direct nonimmune effects on erythrocytes. Some of the infections discussed here are not major problems in North America or Europe; however, to the extent that there is significant international travel to and from endemic areas, recognition of these infections is important for medical personnel worldwide.

Malaria

Malaria is an acute, chronic, or recurrent febrile disease caused in humans by four species of *Plasmodia*: *P. vivax*, *P. falciparum*, *P. malariae*, and *P. ovale*. Infections with *P. falciparum* are the major form of malaria in Africa and Southeast Asia, whereas *P. vivax* is most common in Central America and India. These protozoan microorganisms are capable of parasitizing erythrocytes and other body tissues. Malaria is spread by female mosquitoes of the genus *Anopheles* (Fig. 38.1). The sexual phase of the *Plasmodium* life cycle takes place within the mosquito. The semitropical and tropical endemic distribution of malaria corresponds to the distribution of the vector.

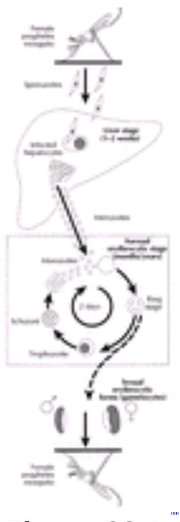

Figure 38.1. Life cycle of malarial parasite. (From Weatherall DJ, Kwiatkowski D. Hematologic manifestations of systemic diseases in children of the developing world. In: Nathan D, Orkin S, eds. Hematology of infancy and childhood. Philadelphia: W.B. Saunders, 1998:1893–1914.)

On a worldwide basis, malaria is the most prevalent of all serious diseases; 300 to 500 million people are affected at any given time, and 1.5 to 2.7 million die each year ([1]). Ninety percent of the deaths are in African children ([2]). Malaria has not been endemic in the United States since the 1940s, but approximately 1000 cases have been reported each year since 1985, and there has been a steady increase in the number of cases reported annually ([3]). Malaria can also be transmitted by blood transfusions ([4]) or by the sharing of needles among intravenous drug abusers ([5]).

CLINICAL MANIFESTATIONS After the initial exposure to malaria some patients are completely asymptomatic, while others have nonspecific flulike symptoms that mimic a viral illness ([6]). Classically, the most prominent clinical manifestations are recurrent paroxysms of chills and fever with temperatures as high as 105° to 106°F (40.5° to 41°C) associated with malaise, headache, vomiting, and other systemic symptoms. The paroxysms tend to recur regularly every 36 to 72 hours. They are most prominent with *P. malariae* infections and much less with *P. falciparum.* Splenomegaly is noted in approximately one-half of patients during early stages of disease ([6]) and becomes more common later. Jaundice and hepatomegaly may develop in later stages of the illness. Of the various malaria species, *P. falciparum* infection causes the most morbidity and mortality. In the acute stage it can be associated with increasing parasitemia, hypotension, malignant hyperthermia, and death. In addition, *P. falciparum* malaria is associated with cerebral, pulmonary, and renal complications ([7]). The overall mortality from a study of more than 1800 children with malaria in Kenya was 3.5%, and in 84% of cases death occurred within 24 hours of admission ([8]). The most important prognostic factors for death were impaired consciousness and respiratory distress (Fig. 38.2). Severe anemia alone did not affect prognosis ([2], [8]).

Figure 38.2. Prevalence, overlap, and mortality for major clinical subgroups of severe malaria in 1809 African children. In 1027 of these children, malaria was present without signs of impaired consciousness, respiratory distress, or severe anemia. In a subset of all children presenting with malaria (782 patients; approximately 40% of total) there was evidence of severe anemia (hemoglobin <5 g/dl), severe respiratory distress, impaired consciousness, and/or some combination of these clinical findings. Almost all deaths occurred in the children who presented with combinations of these clinical abnormalities. Total numbers of patients are given in parentheses. Mortality is given as a percentage. [Modified from Marsh K, Forster D, Waruiru C, et al. Indicators of life-threatening malaria in African children. N Engl J Med 1995;332(21):1399–1404.]

Anemia is common in malaria ([9], [10] and [11]). It is particularly characteristic of *P. falciparum* malaria because of the greater extent of RBC parasitization with this species. With uncomplicated *P. falciparum* malaria, moderately severe anemia is seen in approximately 20% of previously healthy patients during or after the first infection ([12]). Complete eradication of malaria parasites from the blood may take months to years, particularly in areas of high transmission, and immunity to malaria is slowly acquired. In tropical areas, anemia tends to be most prevalent and most severe in children from 1 to 5 years of age ([13]), whereas only moderate anemia is usually noted in adolescents and adults. Leukocyte numbers may be normal, but patients often have leukopenia. Thrombocytopenia has been observed in approximately two-thirds of patients with *P. falciparum* malaria ([7], [13]), frequently associated with splenomegaly ([14]). The most serious hematologic complication of malaria is acute intravascular hemolytic anemia (blackwater fever), which occurs as a rare event in the course of infection by *P. falciparum.* The clinical manifestations are fulminating, the intravascular hemolysis being associated with prostration, vomiting, chills, and fever. Hemoglobinemia, hemoglobinuria, and hyperbilirubinemia are consistent features, and in the most severe episodes, acute oliguric renal failure supervenes.

PATHOGENESIS After a bite from the female *Anopheles* mosquito, sporozoites introduced into the circulation go to the liver parenchyma where they proliferate into thousands of merozoites (Fig. 38.1). The duration of this liver development stage varies between species. The infected hepatocytes next release merozoites into the bloodstream, where they invade erythrocytes. The ability of various *Plasmodia* to infect RBCs is related to their attachment to specific membrane receptors. Of the species that infect humans, *P. vivax* and *P. ovale* invade only reticulocytes. *P. malariae* invades mature RBCs, and *P. falciparum* invades erythrocytes of all ages. As a result, the proportion of cells parasitized in *P. vivax* malaria rarely exceeds 1%, whereas as many as 50% of cells may be affected in *P. falciparum* malaria. It is of interest that *P. vivax* invades only Duffy blood group-positive RBCs ([15]); in West Africa, where the Duffy antigen is missing on RBCs, *P. vivax* malaria is nonexistent. *P. falciparum* apparently has two receptors: one that binds to sialic acid groups on the erythrocyte membrane protein glycophorin and another that binds to a trypsin-sensitive, nonsialated ligand ([16], [17] and [18]). Further development of the parasite within RBCs is along one of two pathways: asexual or sexual differentiation (Fig. 38.3). Sexual forms, or *gametocytes*, continue their development within mosquitoes. The asexual differentiation of parasites in RBCs proceeds from young ring forms through trophozoites to produce schizonts containing six to thirty-two merozoites (Fig. 38.3). In the process, parasites use 25 to 75% of the hemoglobin of the cell ([19]). The intraerythrocytic phase lasts 24 to 72 hours, depending on the species. The schizonts then lyse, the cell ruptures, and the merozoites are released to invade other cells, thereby continuing the erythrocyte cycle. The simultaneous rupture of billions of schizonts from RBCs is associated with the classic paroxysms of malarial fever.

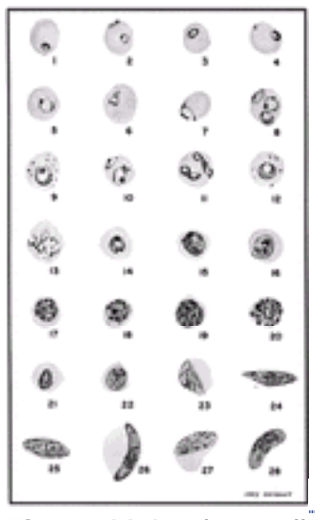

Figure 38.3. *Plasmodium falciparum*. **1:** Very young ring form trophozoite. **2:** Double infection of single cell with young trophozoites, one a marginal form, the other a signet-ring form. **3, 4:** Young trophozoites showing double chromatin dots. **5–7:** Developing trophozoites. **8:** Three medium trophozoites in one cell. **9:** Trophozoite showing pigment in a cell containing Maurer spots. **10, 11:** Two trophozoites in each of two cells, showing variation of forms that parasites may assume. **12:** Almost-mature trophozoite showing haze of pigment throughout cytoplasm. **14:** Mature trophozoite, showing clumped pigment. **15:** Parasite in the process of initial chromatin division. **16–19:** Various phases of the development of the schizont. **20:** Mature schizont. **21–24:** Successive forms in the development of the gametocyte, usually not found in the circulation. **25:** Immature macrogametocyte. **26:** Mature macrogametocyte. **27:** Immature microgametocyte. **28:** Mature microgametocyte. See Color Plate. (From Wilcox A. Manual for the microscopical diagnosis of malaria in man. National Institutes of Health Bulletin No. 180, with permission.)

Erythrocytes parasitized by certain strains of *P. falciparum* develop electron-dense knobs that mediate the attachment of the infected RBCs to venules ([20], [21]). Such sequestration of parasite-infected RBCs creates an obstruction to tissue perfusion. In addition, the sequestration in venules prevents parasitized cells from entering the splenic circulation, thereby evading destruction and allowing further merozoite development; this phenomenon may be a factor in the rapid development of anemia in severe infections ([22]). The anemia in malaria is due to a combination of factors that include parasite-mediated RBC destruction, splenic removal of infected RBCs, and decreased RBC production (Table 38.1). Hemoglobin digestion and cell disruption by the parasite is clearly the major cause of hemolysis ([9], [10], [23]).

TABLE 38.1. Factors Contributing to Anemia in Malaria

Accelerated RBC destruction
Direct parasite destruction of RBCs ([9], [10], [23])
Decreased deformability of parasitized RBC and destruction by splenic macrophages ([24], [25], [26] and [27])
Macrophage-mediated destruction of parasitized RBCs in marrow and liver sinusoids ([30])

Destruction of nonparasitized cells by immune mechanisms (33)
Destruction of nonparasitized cells by hypersplenism and hyperactive macrophages (27)
Hapten (quinine)-induced intravascular hemolysis (blackwater fever) (42, 43 and 44)
Decreased RBC production
Bone marrow suppression due to inflammatory cytokines (10, 32, 35, 36, 37 and 38)
Inadequate erythropoietin production (39, 40)
Dyserythropoiesis (11, 34, 35)
Modified from Menendez C, Fleming AF, et al. Malaria-related anaemia. Parasitol Today 2000;16(11):469–476.

The role of the spleen in RBC destruction is related to the decreased deformability of RBCs infected with plasmodia (24, 25 and 26), erythrocyte retention in the red pulp, prolonged exposure to splenic macrophages, and removal of parasitized cells or "pitting" of the parasite, with consequent damage to the cell (27, 28 and 29). A similar process of macrophage-mediated destruction of parasitized RBCs occurs in the marrow sinusoids (30). Moreover, normal nonparasitized RBCs have a shorter survival in malaria, presumably a consequence of hypersplenism and hyperactive macrophages (31). Even after complete clearance of the parasites, hemolysis may persist for 4 to 5 weeks (32). A complement-mediated process may be responsible in part, and often the direct antiglobulin test is positive (33). Dyserythropoiesis with characteristic morphologic findings in red cell precursors also occurs in malaria. It is thought that this contributes to the slow recovery seen after a single malarial attack, and also to the persistence of anemia in individuals with chronic parasitemia (11, 34, 35). Anemia often persists for weeks after treatment of malaria and results in part from relative marrow failure, as occurs in association with other forms of infection (see Chapter 47) (10, 32). Tumor necrosis factor and other cytokine mediators of the anemia of chronic disorders are increased in patients with severe *P. falciparum* malaria (36, 37 and 38). Serum erythropoietin levels also are inadequate (39, 40). The percentage of reticulocytes tends to be low during active infection and increases transiently after effective treatment. In *P. vivax* malaria, however, the low reticulocyte count may be explained in part by the increased affinity of the organism for reticulocytes (41). The pathogenesis of acute intravascular hemolysis (blackwater fever) remains uncertain, and currently this complication is less commonly seen, although it still occurs (42). Blackwater fever does not reflect an unusual degree of parasitemia. Often, the acute intravascular hemolysis appears to be precipitated by quinine ingestion (43, 44), and quinine may act as a hapten, becoming antigenic after interacting with the RBC. Cases involving untreated individuals also have been reported, however (7). Some episodes thought to represent blackwater fever may have resulted from the use of primaquine-like drugs in G6PD-deficient people. Certain inherited RBC disorders appear to confer resistance to malaria, by inhibiting parasitic invasion or by slowing intracellular growth. It is thought that these phenomena may contribute to increased prevalence of such inherited diseases because of their effects on survival (i.e., balanced polymorphism). These disorders include sickle cell trait (45, 46 and 47), G6PD deficiency (48, 49, 50 and 51), thalassemia (52, 53), hemoglobin E variants (54), hemoglobin C variants (55), ovalocytosis of the Melanesian (Malayan) type (56), and lack of the Duffy blood group antigen (15).

DIAGNOSIS Diagnosis of malaria in the United States is often delayed because it is not suspected (6, 57). Such delays are dangerous because the early mortality rate from *P. falciparum* malaria approaches 10%, and these deaths can be prevented with adequate treatment. Malaria should be considered in the differential diagnosis of any febrile patient returning from an endemic zone. Diagnosis traditionally has required identification of parasites on the blood smear (Fig. 38.3). The parasites can be recognized on ordinary Wright-stained smears, but the chances for detection and identification of species are enhanced by the use of thick smears. Single negative smears do not exclude the disease with certainty in patients with low-grade infections. Parasites may be detected in blood during any phase of the illness, but the chances of detection are greatest during afebrile periods. *P. falciparum* disease is distinguished from that caused by other strains by heavy parasitemia involving all ages of erythrocytes and by the lack of trophozoites and schizonts; usually, only ring forms and the distinctive, banana-shaped gametocytes are apparent (Fig. 38.3). Simple test strips that take 10 to 15 minutes are available for diagnosis of malaria from a drop of finger-stick blood. The sensitivity of these tests is probably as good as microscopy (58, 59 and 60). Test strips are available to detect *P. falciparum* only or *P. falciparum* as well as other P. species. It is important to distinguish *P. falciparum* malaria from other malaria species because of therapeutic considerations, and only *P. falciparum* infection has the potential for being rapidly fatal (7).

MANAGEMENT Therapeutic considerations for malaria include supportive medical care for anemia and other complications. Chemoprophylaxis should be recommended to all people traveling to an endemic area (61, 62). Because of the spread of drug-resistant strains of *P. falciparum*, however, no single regimen is completely effective. Knowledge of the characteristics of the malaria strains in the sites to be visited is essential. Because of changes in drug resistance and the development of new agents, before recommending a regimen to a prospective traveler, physicians should become familiar with current guidelines from the U.S. Centers for Disease Control and Prevention (http://www.cdc.gov/travel/malinfo.htm).

Babesiosis

Infection by tick-borne protozoans of the genus *Babesia* is rare in humans (63, 64, 65 and 66). The infection has been reported in Nantucket and other islands off the northeastern U.S. shore, as well as in neighboring coastal areas of New England. It also is found in north central states, Washington, and California (63). Recently, cases of babesiosis have been described in Europe, and almost all have occurred in asplenic individuals (65). In the United States, *Babesia microti* is the causative agent, whereas *B. divergens* is the species identified in Europe, and the later cases are usually more severe (66). Babesiosis also can be transmitted by blood transfusion (65, 67).

Babesiosis is characterized by an acute febrile illness and hemolytic anemia, very similar to malaria. In most cases it is a mild self-limited disorder that goes undiagnosed, and thus not reported. It is likely the true incidence of babesiosis in healthy hosts is under-recognized. However, in asplenic individuals it can produce serious, often fatal illness with hemolytic anemia, renal failure, or pulmonary edema (65, 66, 68).

Laboratory features include hemoglobinuria, hyperbilirubinemia, normocytic anemia, thrombocytopenia, and sometimes leukopenia (66). *B. microti* and *B. divergens* can be seen in RBCs on the peripheral blood smear, and this can be confused with malaria (66). Serologic antibody tests and polymerase chain reaction–based assays are available to aid in diagnosis (66).

In most mild cases of babesiosis no treatment is necessary. In some more severe cases, clindamycin and quinine are useful (66), and, rarely, RBC exchange transfusions have successfully been used (66, 69).

Trypanosomiasis

Moderate to severe hemolytic anemia is a regular feature of African trypanosomiasis (sleeping sickness) (70, 71 and 72). This often-fatal illness is caused by *Trypanosoma brucei gambiense* or *T. brucei rhodesiense.* The diseases induced by the two subspecies are similar, except that *T. brucei gambiense* infection follows a more chronic course. The organisms are transmitted to humans and domestic animals by the bite of the tsetse fly.

Normocytic anemia with reticulocytosis is prominent. RBC survival is shortened, and autoagglutination of erythrocytes with accelerated erythrocyte sedimentation characteristically is observed. The results of the direct antiglobulin (Coombs) test may be positive. Erythrophagocytosis by macrophages is seen throughout the reticuloendothelial system (73).

The toxic effects of the parasite and immunologic mechanisms are implicated in the destruction of RBCs. The intensity of the hemolytic anemia may fluctuate with the degree of parasitemia. Transient hepatosplenomegaly and decreased serum complement levels accompany the episodes. Marrow failure often supervenes during the terminal phases of the illness. Diagnosis depends on serologic tests or demonstration of the parasite in the blood.

Visceral Leishmaniasis (Kala Azar)

Leishmaniasis is an infection caused by intracellular protozoan parasites transmitted by sand flies. There are three main forms of leishmania infections in humans: cutaneous, mucocutaneous, and visceral. The major hematologic problems occur with the visceral infection (kala azar) and involve the lymph nodes, liver, spleen, and bone marrow. The disorder is caused by *Leishmania donovani*, and is found throughout Asia and Africa, affecting individuals of all ages. A variant parasite, *L. donovani infantum*, is the form that causes kala azar in southern Europe and North Africa, and primarily affects young children and infants. Visceral leishmaniasis mainly occurs in local endemic areas; however, it may be contracted on short-term visits, and it is being recognized in the United Kingdom after return from

Mediterranean holidays ([74]).

After an incubation period of 1 to 3 months, there is the insidious onset of fever, sweating, malaise, and anorexia, but these acute symptoms gradually abate. Next, hepatosplenomegaly gradually evolves, and this stage of illness is associated with anemia, neutropenia, and thrombocytopenia. In young children with acute visceral leishmaniasis, particularly in Mediterranean populations, the clinical and hematologic features may be more aggressive with a rapid onset of severe hemolytic anemia ([75]).

The bone marrow is hyperplastic with dyserythropoietic changes, and diagnosis can usually be made by finding macrophages containing intracellular parasites (Leishman-Donovan bodies). The overall hematologic picture is typical of hypersplenism. RBC survival studies indicate that hemolysis is the major cause of anemia in leishmaniasis ([75], [76]).

In most cases, there is no evidence of immune hemolysis, although immunoglobulin (Ig) G and complement occasionally are found on the RBCs. Similar to what is seen in malaria, nonsensitized RBCs are destroyed by macrophages recruited to the spleen and liver as part of the inflammatory response to the parasite.

Bartonellosis

A severe, acute hemolytic anemia is produced in humans by *Bartonella bacilliforms*, a flagellated bacillus ([77]). The infection is limited to South America, particularly in the Andean valleys of Peru, Ecuador, and Colombia, at elevations of 500 to 3000 m ([78], [79], [80] and [81]). The bacillus is transmitted by the sand fly (Phlebotomus) and probably by other arthropods. After a 2- to 3-week incubation period, the acute phase of the illness, known as *Oroya fever*, begins. It is marked by malaise, headache, muscle pains, remittent fever, chills, and rapid onset of severe anemia. The disease has existed in Peru since pre-Inca times ([82]). The highest rates of infection are in children ([78], [81]).

The findings in the blood are characteristic of acute extravascular blood destruction ([83], [84]). As viewed in Wright- or Giemsa-stained blood smears, numerous *Bartonella* organisms are apparent in the erythrocyte ([83]). The organisms are rod-shaped (1 to 2 µm in length and 0.2 to 0.5 µm in width) or round (0.3 to 1.0 µm in diameter).

Bartonella infection can be controlled with chloramphenicol and other antibiotics. Depending on the reported study, up to 35% of affected patients are transfused with RBCs ([78]), and in cases that do not receive treatment, the fatality rate may be 60 to 80% ([78]).

In patients who recover from the acute phase, a quiescent period ensues during which the organisms disappear from the blood. A chronic, eruptive stage follows, *verruca peruviana*, a benign condition characterized by hemangioma-like lesions of the skin but without hematologic manifestations ([84]). Oroya fever and verruca peruviana constitute the two phases of Carrion disease, named after Daniel Carrion, the medical student who lost his life while investigating its cause ([85]).

Clostridial Sepsis

Clostridium perfringens septicemia occurs after septic abortion ([77], [86]) or in association with a diseased biliary tree, traumatic wound infections, cancer, leukemia, endocarditis, gastrointestinal arteriovenous malformations, or necrotizing enterocolitis of newborns ([87], [88], [89] and [90]). Sometimes no underlying disease is identified ([91], [92]). Profound, often-fatal hemolytic anemia is a regular feature of clostridial sepsis ([93]). Signs of intravascular RBC destruction are prominent, and many microspherocytes are found in the blood. The hemolysis can be rapid and massive, with hematocrit values falling to very low levels in a matter of hours ([91], [92], [94]). Hemolysis is thought to result from the elaboration of a clostridial toxin, a phospholipase that attacks erythrocyte membrane lipids to form highly lytic lysolecithins ([95], [96]). The diagnosis should be suspected when fever, jaundice, and intravascular hemolysis occur together in a patient with a history of previous gastrointestinal or genitourinary surgery, a recent wound, cancer, or other disease. Clostridial infections respond to antibiotic therapy, but to affect outcome, treatment must be started quickly, usually before culture results are available ([97]).

Other Bacterial Infections

Acute hemolytic anemia with bacterial infection is common, especially in childhood, and has been reported with streptococcal, staphylococcal, or pneumococcal septicemia or endocarditis ([98], [99], [100], [101] and [102]). Intravascular hemolysis with hemoglobinuria has been observed in patients with cholera ([103]) and with typhoid fever ([104]). *Escherichia coli* O157 gastroenteritis can cause the hemolytic-uremic syndrome (HUS) (see below), but can also bring about hemolytic anemia with no renal involvement or RBC fragmentation ([105]). Severe hemolytic anemia is observed occasionally in patients with military tuberculosis ([100], [106]). Certain spirochetal infections are occasionally associated with hemolytic anemia, including relapsing fever caused by *Borrelia recurrentis* ([107]), and leptospirosis (Weil syndrome) ([108]).

The pathogenesis of hemolysis in most cases cited previously is uncertain. In some it is thought that anemia is due to direct action of the infectious agent or its products on erythrocytes. Adsorption of microbial antigens to RBCs has been detected by immunofluorescent techniques ([109]), and this phenomenon may lead to phagocytosis or complement-mediated erythrocyte destruction. The capsular polysaccharide of *Haemophilus influenzae* type b, polyribosyl ribitol phosphate, is released from growing organisms during human infection and can be found in body fluids including RBCs. It has been proposed that the hemolytic anemia that occurs during *H. influenzae* type b infection may owe to absorption of polyribosyl ribitol phosphate to RBCs and immune destruction of sensitized erythrocytes ([110]).

In other cases, serious bacterial infections are associated with disseminated intravascular coagulation (DIC) and a microangiopathic hemolytic anemia. Also, as discussed previously, *C. perfringens* may release phospholipases that can lead to RBC membrane injury and cell destruction. Other bacteria release neuraminidase, an enzyme that cleaves RBC sialic acid residues, thereby exposing a cryptic “T-antigen” ([111]). These “T-activated” RBCs can react with anti-T IgM antibodies present in most human adult plasma, thereby resulting in RBC agglutination and possible hemolysis *in vivo* ([111]). The main bacteria that release neuraminidase are *C. perfringens* and *Streptococcus pneumoniae*; however, *Bacteroides, E. coli, Actinomyces*, and *Vibrio cholera* also have been implicated.

HEMOLYSIS DUE TO DRUGS AND CHEMICALS

Many drugs and chemicals injure normal RBCs to cause hemolytic anemia. Some of the more common occurrences are summarized in this section.

Oxidant Drugs and Chemicals

Certain chemical agents can bring about the oxidative denaturation of hemoglobin, leading to the sequential formation of methemoglobin, sulfhemoglobin, and Heinz bodies (see Chapter 8). In some cases, the chemical itself acts as an oxidizing agent; more often, however, it interacts with oxygen to form free radicals or peroxides. These free radicals or peroxides, if produced in quantities too great to be detoxified by the glutathione-dependent reduction system, denature hemoglobin and damage other cellular structures. Individuals deficient in RBC G6PD or other components of glutathione-dependent detoxification processes (see Chapter 33) are particularly sensitive to the hemolytic effects of oxidant compounds (Table 38.2). However, some of these agents are powerful enough to overcome the defense mechanisms of normal erythrocytes, and can cause hemolysis when given to healthy subjects in higher than usual doses or if renal failure leads to unusually high blood levels.

TABLE 38.2. Drugs and Chemicals That Cause Hemolytic Anemia in Patients with Normal Erythrocytes

Sulfonamides (112, 460, 461 and 462)	Aniline (476)
Sulfones (460, 463, 464, 465 and 466)	Phenylsemicarbazide (477)
Phenazopyridine (Pyridium) (112, 113, 467)	Phenylhydrazine (478, 479)
	Chlorates (480, 481)
Nitrofurantoin (Furadantin) (460)	Nitrates (482, 483 and 484)

Phenacetin (468, 469)	Oxygen (485, 486)
Phenol (108)	Hydroxylamine (487)
Cresol (Lysol, penetrating oil) (114, 470, 471)	Methylene blue (in infants) (488)
	Hematin (489)
Naphthalene (mothballs) (460, 472, 473 and 474)	Pentachlorophenol (490)
	Cisplatin (491)
Nitrobenzene (475)	

Some of the agents that can induce hemolytic anemia in apparently normal subjects are listed in Table 38.2. Many of these are derivatives of aromatic organic compounds.

Hemolytic anemia caused by oxidant drugs varies considerably in severity. Usually, the anemia is noted within 1 to 2 weeks after drug therapy is initiated, with laboratory findings of low hemoglobin, reticulocytosis, hyperbilirubinemia, low serum haptoglobin, and erythroid hyperplasia of the bone marrow. In some cases, hemoglobinemia and hemoglobinuria may be apparent. Cyanosis with methemoglobinemia or sulfhemoglobinemia is sometimes noted. The hemolytic process usually disappears within 1 to 3 weeks after use of the offending drug has been discontinued.

Morphologic findings characteristic of hemolytic anemia caused by oxidant drugs and chemicals include the following: Heinz bodies (seen with brilliant cresyl blue supravital stains of blood during hemolytic episodes) (Fig. 38.4A); “bite cells” (seen in routine Wright-stained blood smear) as erythrocytes that look as if a semicircular bite has been taken from one edge (Fig. 38.4B) (112, 113); and hemighosts (114) or eccentrocytes (115), erythrocytes that look as if the hemoglobin has shifted to one side of the cell, leaving the other side clear (Fig. 38.4C). These hemighosts also are referred to as *blister cells* and may appear to contain a large vacuole. These RBCs contain a coagulum of hemoglobin that has separated from the membrane, often leaving an unstained non–hemoglobin-containing cell membrane (116). Hemighosts appear only when hemolysis is brisk (112, 114), and probably indicate a particularly severe degree of oxidant damage. All of these morphologic alterations are a consequence of the oxidative assault on hemoglobin.

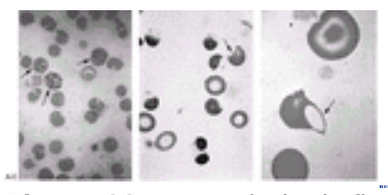

Figure 38.4. Morphologic findings characteristic of hemolytic anemia caused by oxidant drugs and chemicals. **A:** Heinz bodies (arrows) (seen with brilliant cresyl blue supravital stains of blood during hemolytic episodes). **B:** “Bite cells” (seen in routine Wright-stained blood smear) as erythrocytes that look as if a semicircular bite has been taken from one edge (arrow). **C:** “Blister cells” or hemighosts (seen in routine Wright-stained blood smear) appear as if hemoglobin has shifted to one side of the cell, leaving the other side clear. These blister RBCs contain a coagulum of hemoglobin that has separated from the membrane, leaving an unstained non–hemoglobin-containing cell membrane (arrow) (116). Arsine Exposure

Arsine (AsH_3) is the most acutely toxic form of arsenic. It is a colorless, nonirritating, highly toxic gas that is produced by the action of water on a metallic arsenide. Arsine poisoning is associated most often with the use of acids in refining, extracting, or otherwise processing crude metals that contain arsenic as an impurity (117, 118). Such industrial processes as galvanizing, soldering, etching, and lead plating can expose workers to this noxious gas (119). Arsine is also used in the transistor industry to stabilize silicon, and leakage from cylinders in which the gas is transported can lead to accidental poisoning (120).

Manifestations of poisoning appear 2 to 24 hours after exposure and include abdominal pain, nausea, and vomiting, the passage of dark-red urine, jaundice, anemia, reticulocytosis, leukocytosis, and other signs of acute hemolytic anemia. Hemoglobinemia and hemoglobinuria are found, and acute, oliguric renal failure often ensues. The antiglobulin test result is negative. The mortality rate can approach 20% (121). The mechanism of RBC injury is not known for certain. Interactions between arsine and oxyhemoglobin may be involved (122). Also, arsine-induced membrane injury with altered ion transport has been proposed (123, 124).

The treatment of choice for acute toxicity is exchange transfusion to remove the arsenic-containing erythrocytes and to restore the blood hemoglobin levels (119).

Copper Toxicity

Hemolytic episodes due to copper toxicity have been noted in humans after accidental exposure to toxic amounts of copper sulfate (125, 126 and 127). Moreover, copper has been implicated in hemolytic episodes after hemodialysis due to faulty copper tubing and increased levels of the metal in dialysis fluid (128, 129).

When inorganic copper enters the blood in large amounts, much of it accumulates in RBCs (130, 131). Within RBCs it may damage the cell membrane, accelerate oxidation of hemoglobin, and inactivate enzymes of the pentose–phosphate and glycolytic pathways. Which of these abnormalities is responsible for shortened RBC survival is not known.

The release of inorganic copper into the circulation accounts for the occurrence of hemolytic anemia in Wilson disease (hepatolenticular degeneration) (132, 133, 134, 135, 136, 137, 138 and 139). This inherited illness, characterized by a lifelong tendency to accumulate copper, is due to a deficiency of ceruloplasmin the copper transport protein (140). It usually becomes symptomatic in the teens or early twenties, when copper concentration in the liver or nervous system reaches toxic levels (141). Hemolytic anemia can be associated with the early stages of Wilson disease (142) and occasionally may be the first manifestation of the disorder (138, 139, 143, 144 and 145), or it may be associated with hepatic decompensation (135). However, it may appear late in the course of the disease if therapy with penicillamine is discontinued (132, 133). The hemolytic episodes in Wilson disease usually are transient and self-limited, but they may be severe and recurrent. When they occur with hepatic decompensation, death from liver failure often follows (135).

The true incidence of this copper-induced hemolysis in Wilson disease is not known, and there are estimates of 2 to 50% (144, 145 and 146). Laboratory test findings include the usual signs of hemolytic anemia. Treatment of this complication may require plasma exchange transfusion (147).

Lead Toxicity

Risk factors for lead toxicity are related to occupational hazards in adults and environmental exposure in children (148). Occupational hazards include the manufacturing of batteries, paint or pigments, mining, and smelting; the primary route of assimilation is by inhalation. Environmental exposures in children occur by ingestion of lead from ceramics, paint, gasoline, water from lead pipes, or having a parent who works in a high-lead environment. Recently, there have been reports of herbal-associated lead poisoning from Asia (149).

Acute toxicity occurs when lead accidentally gets into a food or water source. Such acute poisoning leads to lead encephalopathy (headache, confusion, stupor, coma, and seizures), and in addition there is abdominal colic, hypertension, and hemolytic anemia. Chronic exposure over time also is associated with a variety of neurologic, gastrointestinal, reproductive, and hematologic complications.

The peripheral smear shows extensive coarse basophilic stippling and reticulocytosis. RBC morphology is not otherwise characteristic. The diagnosis of lead-related

hemolysis can be made from the history of lead exposure, the physical finding of the gingival lead sulfide line, and from the coarse basophilic stippling of RBCs. The diagnosis is confirmed by measuring of blood and urine lead levels.

Lead inhibits two steps in heme synthesis: delta-aminolev-ulinic acid dehydratase and heme synthetase (or ferrochelatase). The latter enzyme catalyzes the insertion of iron into protoporphyrin IX to form heme. The lead-induced inhibition of ferrochelatase is responsible for the increase in free erythrocyte protoporphyrin seen in this disorder, and also the basis of a simple screening test for lead toxicity.

The explanation for hemolysis in acute lead toxicity is not known for sure, but it is intriguing that the basophilic stippling seen in acute lead poisoning is similar to that found in hereditary deficiency of the enzyme pyrimidine 5'-nucleotidase (P5'N) (see Chapter 33). In the enzyme-deficient cells, intracellular aggregates form as a consequence of impaired ribosomal degradation; these aggregates appear as basophilic stippling on Wright-stained peripheral blood smears. Of interest, the P5'N enzyme is readily inactivated by heavy metals such as lead, and it has been proposed that the basophilic stippling in lead poisoning is secondary to acquired P5'N deficiency ([150] , [151] and [152]). As blood lead levels approach 200 µg/dl packed RBCs, P5'N activity decreases to levels comparable to those associated with the homozygous deficiency state, intracellular pyrimidine nucleotides accumulate, and basophilic stippling can be demonstrated ([151] , [153]).

Water

There are anecdotal reports of hemolysis after inadvertent injection of water and other hypotonic fluids. Hemoglobinuria, renal failure, and death were observed in association with transurethral resection of the prostate when distilled water was used for irrigation. Apparently, the water entered the bloodstream by way of the lymphatic and venous channels opened during the operation ([154]). Hemolysis also has been noted in survivors of near-drowning in fresh water ([155]). The entry of more than 0.6 L of water into the circulation produces hemoglobinemia and hemoglobinuria as a result of osmotic hemolysis.

HEMOLYSIS DUE TO VENOMS

Spider Bites

Certain spider bites produce severe, necrotic, gangrenous lesions (“necrotic arachnidism”) that are sometimes associated with hemolytic anemia or DIC, and occasionally renal failure ([156] , [157] , [158] , [159] and [160]). In South America and the southwestern part of the United States, the spiders implicated are the brown recluse spider (*Loxosceles reclusa*) and other *Loxosceles* species ([160] , [161]). In the northwestern United States, a similar picture follows the bite of the hobo spider, *Tegenaria agrestis* ([162] , [163] and [164]).

The initially painless *Loxosceles* bite develops into a painful, edematous, necrotic lesion that may progress to an extensive, slowly healing, gangrenous process, necrotic arachnidism ([161] , [165] , [166]). In a few patients, systemic manifestations, including intravascular hemolytic anemia, develop within several hours to 5 days later. Hemoglobinuria and severe anemia are characteristic findings; spherocytes, basophilic stippling, and leukocytosis are found in the blood. Thrombocytopenia also has been observed, sometimes associated with diffuse intravascular coagulation ([167]). In some cases, RBCs are coated with complement and the results of the direct antiglobulin test are positive ([166] , [168]). Most often, the hemolytic episode subsides spontaneously in approximately 1 week, but occasionally severe reactions occur with renal failure and death.

Pathogenesis of this syndrome is beginning to be understood. The venom primarily attacks endothelium and secondarily activates granulocytes with adhesion and discharge of their granular contents ([169]). Granulocytes are required for the necrotic process to ensue. The spider venom also causes complement-dependent intravascular hemolysis associated with cleavage of glycophorin from the RBC membrane ([165] , [168] , [170]). These events occur because *Loxosceles* venom contains sphingomyelinase activity that activates a membrane-bound metalloproteinase ([171] , [172] and [173]).

Treatment is largely supportive. An antivenom to *Loxosceles* toxin has been produced, but is not commercially available ([166]).

Snakebites

Snakebites are a significant health problem worldwide, especially in parts of Asia where thousands of people die annually ([174]). The composition of snake venom varies considerably between species, between the same species living in different geographic locations, and in the same snake at different times of the year. Most venoms contain a mixture of active ingredients ([175] , [176]). The problems resulting from snake venoms include neurotoxicity, myotoxicity, renal failure, edema, bleeding due to activation of clotting proteins, and intravascular hemolysis. Hemolysis is seen after envenomation with most poisonous snakes including cobras ([177] , [178]), Australian king brown snakes ([179]), the Tunisian saw-scaled (carpet) viper ([180]), U.S. rattlesnakes ([181]), habu snakes ([182]), and most significantly in the several species of Russell viper (*Daboia russelli*) found throughout India and the rest of Asia ([174] , [175] and [176] , [183]). Much of the information regarding the pathophysiology of envenomation comes from studies of the Russell viper in Asia ([176]).

The clinical presentation of intravascular hemolysis from snakebites can be acute and fulminant, associated with few clinical or laboratory findings, or the effects can be delayed for a few hours to days. Hemoglobinemia and hemoglobinuria are present, the severity of which varies with the degree of envenomation and species of snake. The main venom component responsible for hemolysis is thought to be phospholipase A_2, which has direct toxicity for many tissues including the RBC membrane ([176] , [184]). Venom from the habu snake has additional actions in that it activates complement and cleaves CD55 and CD59 from the RBC membrane, thus leaving the RBC susceptible to complement-induced lysis ([182]).

Bee Stings

Africanized honeybees (*Apis mellifera*) are a problem in Brazil ([185]), where these bees were accidentally released 40 years ago. However, they also are now appearing as far north as the southwestern United States ([186]). These bees are aggressive, and their attacks are usually massive ([187]).

The effects of bee stings can be immediate or delayed. “Immediate” reactions are related to anaphylaxis. “Delayed” reactions refer to patients who are asymptomatic after massive bee envenomation, but 12 to 24 hours later, have evidence of hemolysis, DIC, thrombocytopenia, rhabdomyolysis, liver dysfunction, or renal failure ([186] , [188]). The delayed effects are related to the degree of envenomation, and it is thought that problems in an adult occur after 100 to 500 stings, whereas as few as 30 to 50 stings can be problematic in a child ([189]). In one instance, a 3-year-old child stung 200 to 300 times by honeybees died after the development of intravascular hemolysis and oli-guric renal failure ([190]). The venom contains melittin and phospholipase A_2, which together disrupt the RBC membrane and cause hemolysis ([187]). Hemolytic reactions to bee stings appear to be rare. Renal failure is a much more significant problem than hemolytic anemia.

HEMOLYSIS DUE TO THERMAL INJURY

Burns

Acute hemolytic anemia has been observed after extensive thermal burns ([191] , [192] and [193]). Signs of intravascular hemolysis are associated with schistocytes, spherocytes, and echinocytes in the blood, along with increased osmotic and mechanical fragility of the erythrocytes ([192] , [194]). The severity of the reaction is related to the area of body surface affected. In one series, hemoglobinuria was found in 11 of 14 patients who were moderately to severely burned, with more than 15% of the body surface involved in most cases ([192]). In another series, hemolysis was apparent in patients with third-degree burns affecting more than 20% of the body surface ([195]).

Hemolysis occurs during the first 24 to 48 hours after the burn ([194]), and as much as 30% of the circulating RBC mass may be destroyed in this 2-day period ([196]). After the acute hemolytic episode, anemia develops and may last for many weeks ([191]), although signs of hemolysis disappear. This later stage of the anemia of

thermal injury is probably a form of the anemia of chronic disease (see Chapter 47) ([197], [198] and [199]).

The acute hemolytic reaction in burned patients results from the direct effects of heat on erythrocytes. When RBCs are heated to temperatures greater than 47°C, irreversible morphologic and functional abnormalities occur, the severity of which is related to the temperature and the duration of exposure ([200], [201]). The major alterations are fragmentation of the cells and the development of spherocytes, accompanied by an increase in osmotic and mechanical fragility. These changes result from irreversible denaturation of the cytoskeletal protein spectrin ([202], [203] and [204]). Mildly heat-damaged erythrocytes are removed predominantly by the spleen, and with greater degrees of damage, the RBCs also are destroyed in the liver ([201], [205]).

Heated Fluids and Blood

Overheating of biologic fluids is another clinical circumstance resulting in thermal RBC damage. One reported example of this was the overheating of dialysis solution due to failure of thermostatic controls on the hemodialysis equipment ([206]). It also is recognized that direct microwave warming of blood before transfusion can damage RBCs and cause hemolytic anemia after infusion ([207], [208], [209] and [210]). Similarly, the heating of intravenous tubing has resulted in hemolysis ([211]). In one interesting report, intravascular hemolysis was noted in a child after two separate RBC transfusions. In both cases, the hemolysis occurred after the patient's mother had warmed a wet towel in a microwave oven for the purpose of decreasing the painful cold sensation of the blood transfusion ([212]).

It is noteworthy that the current use of U.S. Food and Drug Administration–approved inline blood warmers equipped with thermometers and alarms, and close adherence to the manufacturer's specific directions, should provide a safety level that prevents the accidental overheating of blood.

FRAGMENTATION HEMOLYSIS

When RBCs are subjected to excessive physical trauma, they may undergo premature fragmentation and intravascular hemolysis, thereby resulting in hemoglobinemia, hemoglobinuria, and hemosiderinuria. The hallmark of this type of hemolysis is the fragmented RBC or schistocyte, and these cells take the form of crescents, helmets, triangles, and/or microspherocytes (Fig. 38.5). Hemolytic anemias resulting from RBC fragmentation are associated with abnormalities of the heart and great vessels, diseases of small vessels, DIC, and hypertension (Table 38.3). In most of these conditions hemolysis is one of many clinical findings, although not usually the major problem.

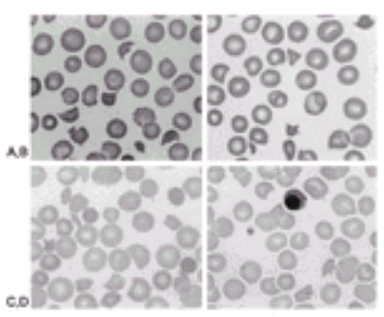

Figure 38.5. Schistocytes in patients with thrombotic thrombocytopenic purpura **(A)**, disseminated intravascular coagulation **(B)**, aortic valve replacement **(C)**, and hemolytic uremic syndrome **(D)**. See Color Plate.

TABLE 38.3. Causes of Red Cell Fragmentation

Associated with abnormalities of the heart and great vessels
Synthetic valvular prostheses
Valve homografts
Valve xenografts and xenobioprostheses
Autograft valvoplasties
Ruptured chordae tendineae
Intracardiac patch repairs
Unoperated valve disease (especially aortic stenosis)
Coarctation of the aorta
Associated with small vessel disease: microangiopathic hemolytic anemia
TTP
HUS
HUS- /TTP-related disorders
Disseminated carcinoma
Chemotherapy/drugs
Transplant-associated microangiopathy
Pregnancy and postpartum period
HELLP syndrome
TTP/HUS
Malignant hypertension
Disseminated intravascular coagulation
Immune mechanisms
Lupus erythematosus
Acute glomerulonephritis
Scleroderma
Wegener granulomatosis
Hemangiomas
Giant hemangioma (Kasabach-Merritt syndrome)
Hemangioendothelioma of the liver
Plexiform lesions in pulmonary hypertension
March hemoglobinuria

HELLP, hemolysis *(H)*, elevated liver *(EL)* enzymes, and low platelet *(LP)* counts; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

Cardiac and Large Vessel Abnormalities

ETIOLOGY Soon after the advent of open-heart surgery it became apparent that the postoperative course of some patients was complicated by the development of anemia of varying severity. The discovery of fragmented RBCs as a characteristic feature of this type of anemia was made in 1961, when Sayed et al. described these morphologic alterations in a patient who developed severe and persistent intravascular hemolysis after repair of an ostium primum defect with Teflon ([213]). It now is well recognized that fragmented erythrocytes with intravascular hemolysis are commonly associated with a wide variety of structural defects of the heart or great

vessels (Table 38.3). Surgically inserted prosthetic devices furnish the most striking examples of RBC fragmentation. These devices include valves of the ball-and-basket variety ([214], [215], [216] and [217]), disk-type prostheses ([218]), Teflon leaflets, and synthetic valves made of Dacron cloth impregnated with rubber ([219]), as well as valve homografts ([215]) and autograft valvoplasties ([220], [221]). Most of the valve prostheses associated with hemolytic disease are of the aortic variety ([214], [219], [220], [222]), but cases of hemolysis caused by mitral valve replacement ([216], [217], [223], [224], [225], [226] and [227]), unsuccessful mitral valvoplasties ([228], [229]), and repair of ruptured chordae tendineae ([230]) also have been reported. The use of bioprosthesis has reduced the risk of hemolysis greatly, although RBC fragmentation still occurs after the insertion of porcine xenografts or bioprosthesis constructed from bovine tissues ([224], [231], [232], [233], [234], [235] and [236]). In these patients, hemolysis usually is associated with a paravalvular leak ([232]), a torn cusp ([233]), or other manifestations of valvular dysfunction ([231]), including infective endocarditis or calcification ([237]). Intracardiac patch repairs of various types also may lead to intravascular hemolysis ([213], [238], [239]); typical cases involve patients with Teflon patches used in the repair of ostium primum defects. Last, although RBC fragmentation is associated most strikingly with intracardiac surgical procedures, intravascular hemolysis occurs in many patients with valvular heart disease who have not had surgery ([240], [241], [242] and [243]). Most often, this RBC fragmentation is noted in patients suffering from severe aortic valve disease, especially aortic stenosis; occasionally, however, patients with mitral valve involvement are affected. Intravascular hemolysis also has been reported in patients with a ruptured aneurysm of the sinus of Valsalva ([244]), coarctation of the aorta ([245], [246]), coarctation with a bicuspid aortic valve ([246]), and a ventricular septal defect in conjunction with a patent ductus arteriosus ([247]). The hemolysis accompanying valvular heart disease that has not been treated surgically is usually minor and rarely severe.

INCIDENCE Clinically significant hemolytic disease is reported in 5 to 25% of patients with various types of valvular prostheses ([214], [221], [248]), usually involving replacement of defective aortic valves, and in approximately 5% of patients with Teflon repairs of ostium primum defects ([190]). The incidence of clinically detectable hemolysis in patients with mitral valve prostheses is considerably lower. When more sensitive techniques are used to detect RBC destruction, such as RBC survival studies ([240], [242], [249]), or haptoglobin levels ([243], [250], [251] and [252]), most patients with aortic valvular prostheses have evidence of mild intravascular hemolysis ([221], [240], [242], [249], [252]). The incidence of intravascular hemolysis in patients with aortic valve disease who have not undergone surgical treatment ranges from 5% to more than 60% when patients are studied with erythrocyte ^{51}Cr survival techniques ([221], [240], [242], [249], [252], [253]) or by assessing haptoglobin levels ([243], [252]). Undoubtedly, the severity of the valvular disease is an important variable.

PATHOGENESIS Several mechanisms may account for the intravascular nature of the hemolysis and the appearance of the characteristic fragmented cells. Direct mechanical trauma, for instance by the closure of prosthetic valves, has been postulated; it is known also to occur in other conditions, such as march hemoglobinuria ([254]). However, it is unlikely that valve closure itself is responsible for RBC fragmentation because many patients with prosthetic valves do not have clinically significant hemolysis. It also is unlikely that the presence of prosthetic materials per se contributes to RBC fragmentation ([214], [255]), although Teflon that is not covered by endothelium ([213], [239]) has been found at reoperation in some patients. In all likelihood, therefore, hemolysis and the lack of endothelialization depend on the presence of a third factor, such as turbulence. The most common feature in recorded cases of hemolysis occurring after the insertion of prosthetic devices is the existence of some form of hemodynamic defect, such as regurgitation through or around valvular prostheses ([214], [226], [232]) or mitral insufficiency after Teflon patch repair of atrioventricular canal defects ([238]). Extreme turbulence is a common factor in all of these patients, and can easily generate shearing stress greater than 3000 dynes/cm ^{2} ([217], [256], [257]), leading to mechanical hemolysis *in vitro* ([258]) and *in vivo*, such as in the presence of regurgitant defects between the aorta and the left ventricle, when the lumen of the aortic prosthesis is small relative to the stroke volume or when the ball of a ball valve is large relative to the diameter of the aorta. A positive direct antiglobulin test is observed occasionally in patients with prosthetic valves ([259], [260] and [261]) and also in patients with severe aortic valve disease in the absence of surgical intervention ([262]). It is possible that mechanical damage may expose subsurface antigens, which then elicit the production of autoantibodies.

CLINICAL MANIFESTATIONS No distinctive clinical features are noted, with the exception of those related to preexistent heart disease or cardiac surgery. The development of hemolysis sometimes coincides with severe deterioration of cardiac function because of the tear of a valve cusp or the loosening of valve attachments. When the hemolysis is clinically significant, jaundice often is obvious, but hemoglobinuria may not be detectable by the naked eye.

LABORATORY FINDINGS The blood findings of these patients vary widely, depending on the severity of hemolytic process. The hemoglobin level may be normal if hemolysis is compensated, or it may be extremely low. Most cells are normocytic and normochromic, but there also are variable numbers of fragmented erythrocytes, and these are identical to the schistocytes seen in patients with microangiopathic hemolytic anemia (Fig. 38.5). The number of fragmented cells apparent in the blood smear directly reflects the severity of the hemolytic process ([263]). In patients with long-standing hemolysis iron stores may be depleted because of hemoglobinuria and hemosiderinuria, and the RBCs may appear hypochromic due to iron deficiency. Hemosiderinuria is present in many patients when hemoglobinuria is not detectable. The serum bilirubin level is slightly or moderately raised. Serum haptoglobin is reduced or absent. Lactate dehydrogenase levels, especially isoenzyme LDH1, usually are elevated. The reaction to the antiglobulin test is usually, but not always, negative.

TREATMENT A marked degree of anemia and elevation of lactate dehydrogenase isoenzymes often indicate wear or malfunction of a valvular prosthesis ([216], [263]), and under these circumstances, prompt surgical intervention and valve replacement are usually indicated. Only occasionally does the condition causing hemolysis improve spontaneously ([220]). Because the severity of the hemolytic process increases with physical activity ([264]), bed rest is mandatory during acute exacerbations. When iron deficiency has developed because of prolonged hemosiderinuria, iron therapy is indicated. Erythropoietin has been used as a substitute for blood transfusion ([265]).

Small Vessel Disease (Microangiopathic Hemolytic Anemia)

In 1952, Symmers introduced the term *microangiopathic hemolytic anemia* to describe a clinical syndrome now commonly called *thrombotic thrombocytopenic purpura* (TTP) ([266]). Brain, Dacie, and Hourihane subsequently popularized the term ([267]), and it is now used to designate any hemolytic anemia related to RBC fragmentation occurring in association with small vessel disease (Table 38.2). The term *thrombotic microangiopathy* also is used to describe syndromes characterized by hemolytic anemia with RBC fragmentation, thrombocytopenia, and thrombotic lesions in small blood vessels ([268]).

TTP and HUS are similar disorders included in this category. They share many laboratory and clinical features, and the clinical distinction between TTP and HUS is not always clear. In addition, there are also TTP-/HUS-related conditions seen with pregnancy, cancer, drug therapy, tissue transplantation, and other disorders (Table 38.3).

Thrombotic Thrombocytopenic Purpura

TTP, also known as *Moschcowitz disease*, is an uncommon but serious disorder of young adults characterized by hemolytic anemia secondary to RBC fragmentation; thrombocytopenia; and evidence of central nervous system dysfunction, renal failure, and fever. This disorder is discussed in detail elsewhere in this text (see Chapter 54). Most laboratory and clinical manifestations are attributable directly to microvascular thrombotic lesions that characterize this disease.

The pathophysiology of TTP is related to the interaction of von Willebrand factor (vWF), platelets and endothelial cells. vWF multimers are produced within megakaryocytes and endothelial cells and stored within the a-granules of platelets and the Weibel-Palade bodies of endothelial cells (see Chapter 19 and Chapter 22). The intracellular forms of vWF are much larger than the normal vWF multimers in plasma, and they are referred to as *ultra-large vWF* (ULvWF) *multimers*. These ULvWF multimers in endothelial cells are secreted to the subendothelium and to the vascular lumen. The ULvWF forms that reach the subendo-thelium become part of a matrix that can cause aggregation of platelets when the endothelial barrier is disrupted and the matrix is exposed to flowing blood. In contrast, the ULvWF multimers secreted into the lumen are cleaved into smaller forms before release into the plasma. This is accomplished on the endothelial cell surface by a metalloproteinase enzyme known as ADAMTS 13 (*A d*isintegrin *a*nd *m*etalloproteinase with *t*hrombospondin-1-like domains) ([269], [270]). ADAMTS 13 is made in hepatocytes, and its regulatory gene is located on chromosome 9q34 ([271], [272]).

An important physical property of ULvWF multimers is a high binding affinity for platelet gpIb-IX and gpIIb-IIIa complexes ([273]). Under conditions in which ULvWF multimers are exposed to blood, this affinity for platelets can lead to platelet activation and formation of platelet thrombi. In TTP, there is decreased metalloproteinase activity with impaired cleavage of ULvWF multimers as they are secreted by endothelial cells ([272], [274], [275]). As a consequence of this, the uncleaved ULvWF multimers on the endothelial surface cause adhesion of platelets, further platelet aggregation, and formation of microvascular thrombi in many organs. Characteristically these thrombi contain platelet aggregates and vWF antigen, with little or no fibrin or evidence of endothelial cell damage ([276]). The reduced metalloproteinase activity can occur as an acquired abnormality due to inhibitors or autoantibodies against the enzyme ([277]). Alternatively, it can occur as an inherited disease due to mutations of the ADAMTS gene ([278]). (See Chapter 54 for a more extensive discussion.)

The microangiopathic hemolytic anemia in TTP presumably is a consequence of RBCs flowing in turbulent parts of the microcirculation that are partially occluded by platelet-rich thrombi. The serum lactic dehydrogenase level is markedly elevated, a consequence of tissue necrosis, not necessarily RBC destruction ([279]).

Hemolytic Uremic Syndrome

The term *hemolytic uremic syndrome* (HUS) was first used by Gasser et al. in 1955 to describe the association of acute intravascular hemolytic anemia and renal failure in infants and young children ([280]). Since then, several thousand patients have been reported, and the clinical features of the disease and its pathogenesis are now well established ([275] , [281] , [282] , [283] , [284] , [285] , [286] and [287]). The defining features of HUS are renal microangiopathy involving small arterioles and glomerular capillaries, microangiopathic hemolytic anemia, and platelet destruction leading to variable degrees of thrombocytopenia. HUS has been classified as epidemic (prodromal) or sporadic (nonprodromal, also called *atypical HUS*). The epidemic form of HUS is most common and is associated by an enteritis prodrome, whereas the sporadic form of HUS is not preceded by enteritis ([288] , [289]). The sporadic form of HUS is not common in children. It has a worse prognosis, is more likely to relapse, and may be associated with a family history of HUS. It has been associated with a variety of drugs, cancer, and transplantation (see later).

Epidemic HUS occurs predominantly in otherwise healthy children younger than 5 years. It is preceded by bloody diarrhea caused by various *E. coli* serotypes or *Shigella dysenteriae* serotype I ([288] , [289]). The offending organisms share the capacity to produce similar forms of powerful exotoxins, the prototype of which is the Shiga toxin (Stx) produced by *S. dysenteriae* and encoded in its DNA ([285] , [290]). Because of the effect of these toxins on kidney Vero cell lines, these toxins are also called *verotoxins* and the pathogenic O157:H7 coliforms are called verotoxin-producing *E. coli* (VTEC) ([284]).

Enterohemorrhagic *E. coli* has a bovine reservoir and generally is transmitted by undercooked meat, unpasteurized milk, or food and water contaminated by bovine feces ([286] , [291] , [292]). Epidemic HUS occurs predominantly in the first 2 years of life ([293] , [294]), with a marked decline thereafter; only occasionally does the disease affect older teenagers or young adults. Infections caused by *S. dysenteriae* and other organisms presumably account for the epidemics of HUS described in Argentina ([295]) and elsewhere ([282] , [296]).

PATHOGENESIS The central feature of HUS is vascular endothelial damage in the glomerular capillaries, renal arterioles, and, to a lesser extent, other vessels ([285] , [297]). This injury is known to be a direct consequence of Stx ([298]). Stx and Shiga-like toxins consist of a single 32-kd catalytic A subunit and five 7.7-kd B binding subunits ([284] , [285] , [299]). The B subunit binds with high affinity to a glycosphingolipid on cell membranes, globotriosyl ceramide (Gb3), which functions as the predominant membrane receptor for Stx on endothelial and other target cells ([285] , [299]). Once Stx is bound to the cell, the A subunit is internalized by endocytosis and, after proteolysis, a smaller fragment binds to 60S ribosomal subunits ([284] , [285]) and inhibits protein synthesis, and cell death ensues ([285] , [296] , [299]). In epidemic HUS, enteropathogenic bacteria enter intestinal mucosa cells and the Stx damage the underlying tissue and vasculature, thereby causing bloody diarrhea. Stx next enter the bloodstream, where they directly bind and activate platelets ([300]). They also bind to neutrophils, monocytes, and the RBC P_1 antigen ([301]), and travel to targets in the glomerular endothelial cells, mesangial cells, and glomerular and tubular epithelial cells ([285] , [296] , [299]). In conjunction with various cytokines Stx injure and kill renal glomerular and tubular epithelial cells ([275]). Stx-induced endothelial cell injury leads to increased expression of ULvWF multimers on the luminal surface. As a result, platelets are activated and thrombi form on the endothelial surface ([275]). In contrast to TTP, ADAMTS 13 activity is not decreased in HUS ([302] , [303] and [304]). The Stx–induced death of endothelial cells also exposes subendothelial matrix, leading to further platelet aggregation. Moreover, in HUS there is activation of clotting and fibrinolysis as evidenced by increased levels of thrombin activation markers (e.g., thrombin-antithrombin complexes, prothrombin fragment 1+2) and increased D-dimer levels ([305] , [306] and [307]). In contrast to TTP, the thrombi in HUS contain mainly platelets and fibrin with much less vWF ([304]). Capillary and arteriolar lumina are narrowed by swollen endothelial cells, thrombi, and the effect of vasoactive substances released by platelets and endothelial cells ([299]). All of the aforementioned factors contribute to impaired renal function ([299]). The anemia in HUS is mainly attributed to RBC damage by fibrin and platelets deposited on the damaged endothelium, with the subsequent sequestration of damaged cells within the spleen and the liver ([308] , [309] and [310]).

CLINICAL MANIFESTATIONS The most common antecedent symptoms include vomiting and bloody diarrhea. The onset of hemolysis and renal failure may be dramatic, with sudden pallor, abdominal pain, vomiting, and the appearance of dark-red or nearly black urine. These manifestations quickly give way to oliguria and, in many patients, total anuria. Neurologic manifestations may include drowsiness, convulsions, and transient pareses ([311] , [312] and [313]). The presence of these neurologic signs is what sometimes confuses the clinical presentations of TTP and HUS. Sporadic forms of HUS may occur in children and adults and account for 5 to 10% of all cases ([314]). In contrast to the classic epidemic form, sporadically affected children tend not to have VTEC infections, and their family contacts have no concurrent illness ([314]). A majority of these patients need dialysis, and the morbidity and mortality rate at 1 year is very high ([314] , [315] , [316] and [317]). Sporadic forms of HUS in adults are also associated with a poor prognosis unless the disease trigger is transient, as occurs in enterohemorrhagic *E. coli* infections ([318]).

LABORATORY FINDINGS The anemia often is severe and may be accompanied by moderate polymorphonuclear leukocytosis. The blood smear findings are distinctive: many fragmented erythrocytes, burr cells, some microspherocytes, and a number of polychromatophilic cells representing reticulocytes. The direct and indirect antiglobulin tests usually are negative. Thrombocytopenia may be severe, but is not a constant finding. Hemoglobinemia may be marked and correlates with the degree of anemia and the severity of the morphologic changes. Serum haptoglobin levels are low or absent. The bilirubin levels usually are mildly elevated, but rarely exceed 2 to 3 mg/dl. The blood urea nitrogen and serum creatinine levels may be high. The urine usually contains hemoglobin and hemosiderin in addition to large quantities of other proteins, especially albumin. Microscopically, RBCs, white cells, and casts are seen. The prothrombin time and partial thromboplastin time usually are normal or minimally prolonged; fibrin breakdown products may be elevated and D-dimers present ([319] , [320] and [321]). Overall, both coagulation and fibrinolysis are activated in HUS ([305] , [306] and [307]). It is estimated that approximately 90% of North American and European children with HUS have some evidence of VTEC infection, and that the serotype O157:H7 can be demonstrated in many cases by culture and/or the detection of free verotoxin in the feces ([284] , [322] , [323]). In addition, IgM antibodies against the O157 lipopolysaccharide sometimes are present ([322]).

TREATMENT AND PROGNOSIS Children with anuria of less than 24 hours' duration usually require only careful monitoring of fluid and electrolyte balance, control of blood pressure, and correction of acidosis ([282] , [324]). Unless anemia is severe, transfusion of packed RBCs should be given sparingly to prevent volume overload. When children are more severely affected, peritoneal dialysis or hemodialysis may be required; the usual indications include fluid overload unresponsive to diuretics, a rapidly rising creatinine value, anuria for more than 24 hours, severe electrolyte imbalance, and serious clinical signs of uremia, such as seizures ([324]). Early and careful management of the acute renal failure, control of hypertension, and the judicious use of packed RBC transfusions appears to constitute the safest and most effective approach to the management of HUS in children ([297]). Platelet transfusions rarely are needed because bleeding manifestations are uncommon, and theoretically platelet transfusions could make the disease worse by accelerating thrombus formation. There are no good data to support the use of heparin, antiplatelet drugs, corticosteroids, or intravenous immunoglobulin. Currently, the overall mortality in children with epidemic HUS is 3 to 5% ([283] , [325] , [326] and [327]). It is the most common cause of acute renal failure in U.S. children ([327]). Approximately 50% of children require dialysis, and 5% of surviving children have long-term renal impairment ([328]). In adults, the management plan is similar to that proposed for children. However, because of the excellent results achieved in the treatment of TTP, therapy with fresh frozen plasma or plasmapheresis is recommended by some ([329] , [330] , [331] and [332]). Platelet transfusions, on the other hand, may have an adverse effect on the patient's clinical course ([333]). Renal impairment often is more severe in adults than in children.

Thrombotic Microangiopathy Due to Other Disorders

Patients with thrombotic microangiopathy (i.e., sporadic or atypical HUS) caused by other diseases such as cancer, the use of cytotoxic agents, autoimmune disorders, or immune deficiency disorders, and patients who have had bone marrow transplantation (BMT) tend to do poorly ([318] , [334]).

DISSEMINATED CARCINOMA A microangiopathic hemolytic anemia occasionally is observed in patients with disseminated malignant disease ([335] , [336]). The onset of hemolysis may be abrupt and severe, often requiring several units of transfused blood daily to maintain a safe hemoglobin level ([335]). Reticulocytosis is almost always present, but may be less than expected because of associated marrow suppression from myelophthisis or chronic disease ([337]). Thrombocytopenia is usually present ([335] , [338]), and in many cases, patients also have documented laboratory evidence of DIC. Most, but not all, tumors are adenocarcinomas, with gastric cancer being the most common ([309] , [336] , [339] , [340]). A most striking finding is the extensive involvement of blood vessels, especially within the pulmonary bed ([309] , [335] , [337]). It has been proposed that the intimal proliferation in these vessels elevates pulmonary arterial pressure sufficiently to magnify the shearing force on RBCs and platelets passing through these abnormal pulmonary vessels, thereby producing fragmentation ([335]). The RBC fragmentation in cancer patients often is attributed to RBC shearing on fibrin strands produced by intravascular coagulation ([309] , [335]); however, microangiopathic hemolysis can occur in the absence of DIC ([335] , [337]). In some patients with microangiopathic hemolysis and cancer there is evidence of ULvWF multimers in plasma, along with decreased metalloproteinase activity ([341]). However, in other similar patients with microangiopathic hemolysis and cancer there is no evidence of ADAMTS 13 deficiency ([209]). Once microangiopathic hemolysis is seen, the overall prognosis is poor, with observed survival periods of only a few weeks ([335] , [342]).

CHEMOTHERAPY-INDUCED DISEASE An HUS/TTP syndrome less commonly may follow treatment with certain antineoplastic agents and other drugs. In one review, most were attributed to mitomycin C use, often given in combination with other drugs such as doxorubicin and 5-fluorouracil ([338] , [343] , [344] and [345]). Tamoxifen,

given in conjunction with mitomycin, also has been shown to increase significantly the risk of developing thrombotic microangiopathy ([346]). Less commonly, the syndrome is observed with other drugs: carboplatin ([347] , [348]), occasionally after daunorubicin in combination with cytosine arabinoside ([348]), and 1-(2-chlorethyl)-3-(4-methylcyclohexyl)-1-nitrosourea ([349]). Immunosuppressive drugs such as tacrolimus (FK506) ([350] , [351]) and cyclosporine A (CsA) ([352] , [353] and [354]) have been associated with microangiopathic hemolysis. A similar clinical picture also was noted in two people with chronic myelogenous leukemia receiving interferon-a ([355]). The syndrome described here is characterized by microangiopathic hemolytic anemia, thrombocytopenia, renal failure, and hypertension ([338]). Severe dyspnea and hypoxemia caused by noncardiogenic pulmonary edema is considered characteristic of chemotherapy-related HUS ([342]). These complications, as well as the hypertension, can be aggravated by administered blood transfusions. Most patients with cancer who develop this syndrome are in clinical remission ([338]) or have recently experienced significant regression of their tumors in response to chemotherapy ([356]). It is postulated that the primary pathogenetic mechanism involves direct drug-induced damage to the renal endothelium, with subsequent activation of the clotting system at sites of injury and the ultimate deposition of fibrin ([338] , [357]). The onset of microangiopathy usually occurs a few weeks after the last dose of chemotherapy, the median time being 12 months from the beginning of therapy. The laboratory findings are typical of moderate microangiopathic hemolytic anemia, with evidence of intravascular hemolysis, schistocytes on the peripheral blood smear, moderate reticulocytosis, and decreased plasma haptoglobin levels. Generally, there is no evidence of DIC; the serum creatinine level is usually elevated; and urinalysis reveals hematuria, proteinuria, and occasional hyaline or granular casts ([338]). The prognosis in patients with chemotherapy-related HUS is poor; approximately 70% of patients succumb to the complications of the syndrome within a few weeks of onset ([358]). Deaths that occur early in the disease course usually are related to renal or pulmonary failure ([338]). Among patients who survive for a longer period, the hemolytic process and thrombocytopenia may abate, but the renal failure usually persists ([355]). A few patients experience complete recovery without relapse ([338] , [355] , [359] , [360]). Plasmapheresis reportedly improves the hematologic abnormalities, but has little if any effect on renal failure in most cases ([361]).

TRANSPLANT-ASSOCIATED MICROANGIOPATHY A thrombotic microangiopathy syndrome similar to that associated with HUS/TTP has been shown to occur in recipients of solid organ ([268] , [362]) and bone marrow transplants ([363] , [364] and [365]), both autologous and allogeneic. Analysis of 96 patients who developed HUS or TTP after BMT identified a number of factors that appeared to be associated with the appearance of thrombotic microangiopathy: 91% of patients had received total body irradiation, and nearly all had received cyclophosphamide ([363]), although the latter is common to most transplant programs and the significance of its contribution to the development of the syndrome is therefore unclear. CsA appeared to have an exacerbating effect, and a reduction in the dose of this drug often led to the resolution of the syndrome ([363]). Clinically, a fulminant, rapidly fatal disease, severe renal impairment, seizures, and significant microangiopathic hemolytic anemia and thrombocytopenia may develop ([365]). Graft-versus-host disease, infection, and intensive pretransplant conditioning may be aggravating factors. In some patients, CsA may precipitate microangiopathic hemolytic anemia with nephrotoxicity ([366] , [367]) or microangiopathic hemolytic anemia with neurotoxicity similar to that described in association with TTP ([365]). Microthrombi are found, especially in the kidney. The fulminant, multifactorial form of the transplant-associated disease is difficult to treat with measures usually applied to patients with TTP, including plasma exchange ([365] , [368]). Antiplatelet drugs and heparin are of no benefit ([365]). Plasma exchange may be of benefit in some patients with conditioning-associated HUS. Cyclosporin-associated nephrotoxicity and neurotoxicity usually respond to a reduction or cessation of CsA therapy ([365]).

Hemolysis and Thrombotic Microangiopathy Associated with Pregnancy

Three major microangiopathic disorders associated with pregnancy are the HELLP syndrome [hemolysis *(H)*, elevated liver *(EL)* enzymes, and low platelet *(LP)* counts], TTP of pregnancy, and postpartum HUS (Table 38.4). It is necessary to distinguish these disorders because they have different prognoses and treatments. TTP and HUS occur much less frequently than HELLP.

TABLE 38.4. Major Clinical Characteristics of HELLP Syndrome, TTP, and HUS

Clinical Features	HELLP Syndrome	TTP	HUS
Target organ/system involved	Liver	Neurologic	Renal
Gestational age	2nd to 3rd trimester	2nd trimester	Postpartum
Platelets	Decreased	Decreased	Decreased
PT/PTT	Normal	Normal	Normal
Hemolysis	Present	Present	Present
Fibrinogen	Normal	Normal	Normal
Creatinine	Normal/increased	Increased	Increased
Liver enzymes	Increased	Normal	Normal

HELLP, hemolysis *(H)*, elevated liver *(EL)* enzymes, and low platelet *(LP)* counts; HUS, hemolytic uremic syndrome; PT, prothrombin time; PTT, partial thromboplastin time; TTP, thrombotic thrombocytopenic purpura.

Modified from Saphier CJ, Repke JT. Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome: a review of diagnosis and management. Semin Peri-natol 1998;22(2):118–133.

HELLP SYNDROME Preeclampsia is characterized by gestational hypertension and proteinuria or pathologic edema; eclampsia is complicated by the additional occurrence of seizures ([369] , [370]). Preeclampsia and eclampsia are systemic diseases involving the kidney, liver, heart, and central nervous system ([370]). Hematologic complications have been recognized for some time and include microangiopathic hemolytic anemia with characteristic fragmented RBCs in the peripheral blood, thrombocytopenia, and well-defined abnormalities of the coagulation system ([370]). This subset of patients with severe preeclampsia/eclampsia are considered to have HELLP syndrome, characterized by hemolysis *(H)*, elevated liver *(EL)* enzymes, and low platelet *(LP)* counts ([300] , [369] , [371] , [372] , [373] , [374] , [375] , [376] and [377]). It is thought that RBC fragmentation and thrombocytopenia associated with HELLP are a result of a number of interrelated, largely mechanical factors, including endothelial damage, vasoconstriction coupled with hypertension, and the deposition of fibrin in injured vessels. Women with preeclampsia can have evidence of chronic intravascular coagulation syndrome ([378]) with a shortened platelet lifespan ([379] , [380]), an increased rate of factor VIII consumption ([381]), a decline in plasma antithrombin III activity ([382] , [383]), and fibrin deposition within the kidney ([384]) and the liver ([385]). Women with preeclampsia also have higher circulating levels of endothelin, one of the most potent vasoconstrictors produced by the vascular endothelium ([386] , [387]); when endothelin is injected into rabbits, they develop vasospasm and HELLP ([388]). Preeclampsia also has an imbalance of placental prostacyclin and thromboxane production ([389]), with a decrease in the production of the vasodilator prostacyclin in comparison to the vasoconstrictor thromboxane A_2 ([373] , [389]). HELLP syndrome reportedly occurs in 20% of women with severe preeclampsia and 10% of women with eclampsia ([374]). The median gestational age at presentation is 32 to 34 weeks, with a range of 24 to 39 weeks ([372] , [375]). Clinical findings at presentation include malaise, right upper quadrant tenderness, hypertension, and edema. Most women with HELLP syndrome are not anemic at presentation, although they may drop their hemoglobin out of proportion to the volume of blood lost at delivery ([372]). Laboratory features include elevated liver enzymes (i.e., ALT and AST), thrombocytopenia with less than 100,000/µl in most patients, and evidence of compensated hemolysis. The latter is probably the most specific abnormality associated with HELLP syndrome, but sometimes difficult to detect. The peripheral blood smear usually reveals schistocytes and there also may be burr cells and polychromatophilia ([372]). In one study, however, schistocytes were seen in only a small fraction of patients and it was proposed that the fragmented cells may have been removed by the spleen ([390]). Hemoglobinemia and hemoglobinuria occur in less than 10% of cases. The one consistent abnormality noted in women with HELLP syndrome is a decreased serum haptoglobin in virtually all patients, and this is considered to be the most sensitive test to detect this RBC abnormality when only a few schistocytes are present on smear ([390]). The management of preeclampsia with HELLP syndrome is a matter of some obstetric debate, and is beyond the scope of this chapter. In general, the issues relate to immediate delivery or close observation, and these in turn are governed by maternal clinical status and fetal gestational age ([375] , [377]). The most common approach is to deliver the fetus as soon as possible or, if it is likely that there is fetal lung immaturity because of gestational age, steroids are administered to the mother for 2 to 3 days, and then the infant is delivered. It is intriguing that a small, but significant fraction of women (30% in one study) spontaneously improves without more aggressive intervention ([391]). In contrast to TTP, there currently are no data indicating a role for plasmapheresis. One of the most serious complications is hepatic rupture, with 50% maternal and 60 to 70% fetal mortality. Other complications include DIC, renal failure, pulmonary edema, and placental abruption ([376]). Overall, maternal mortality ranges from 0 to 4% in different series ([375]). Hematologic and chemical abnormalities resolve within a few days of delivery. Neonatal mortality ranges from 5 to 20% ([375] , [376]), and this is more a reflection more of fetal age rather than any specific complication of maternal HELLP issues.

PREGNANCY-ASSOCIATED THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC UREMIC SYNDROME In most reported studies of thrombotic

microangiopathy with pregnancy, TTP and HUS have been distinguished on the basis of the predominant symptomatology, neurologic or renal. TTP most commonly occurs antepartum, with a significant majority of cases presenting before 24 weeks' gestation. Postpartum TTP is very rare ([392]). HUS, on the other hand, typically occurs after a normal delivery and a symptom-free interval, and is characterized by acute-onset renal failure and microangiopathic hemolytic anemia ([377], [378]). Hypertension is almost always found. A small fraction (10 to 15%) of HUS and TTP patients have signs of preeclampsia. Sometimes TTP/HUS is not correctly diagnosed until the patient, thought to have preeclampsia, has an atypical prolonged recovery in the postpartum period ([393]). Laboratory results show the expected hemolytic anemia with many RBC fragments. Severe thrombocytopenia usually is present. Fibrin breakdown products are often increased, but the findings of other coagulation studies usually are normal ([378]). In postpartum HUS azotemia is the rule, but is rare in TTP. In an extensive case review, the overall maternal mortality was 44%. The rate was reduced to 0% with plasma therapy, but was 68% if plasma therapy was not instituted ([378], [394], [395]). The pregnancy should not be terminated because this does not cure the disease, and the fetus may survive with successful therapy.

HEMOLYSIS DUE TO MALIGNANT HYPERTENSION

An association between RBC fragmentation and malignant hypertension was first recorded in 1954, and has since been confirmed in many other studies ([396], [397]). The pathogenesis of microangiopathic hemolytic anemia in malignant hypertension is attributed to the presence of fibrinoid necrosis within the arterioles ([267]), which in turn appears to depend on the presence of hypertension.

Experimental animal models have been useful in studying the role of hypertension in producing RBC fragmentation. Rats given desoxycorticosterone and having a high salt intake develop malignant hypertension with widespread degenerative vascular lesions and, coincidentally, hemolytic anemia characterized by RBC fragmentation ([398]). Closely analogous to the human counterpart of this syndrome, the most anemic animals are those with the most severe vascular lesions. Fibrin and platelet deposits may be apparent within the lumen of some blood vessels, but they do not play a predominant role in RBC fragmentation. The striking finding on electron microscopic analysis of arterioles is the close juxtaposition of erythrocytes to endothelial cells, the apparent molding of projections of endothelial cells around the erythrocytes, and the partial penetration of the endothelium by erythrocytes. RBC fragmentation is the result of shearing stress from the force of arterial blood as it moves past RBCs that are attached to endothelial projections or that have partially penetrated the endothelium.

HEMOLYSIS DUE TO DISSEMINATED INTRAVASCULAR COAGULATION

Microangiopathic hemolytic anemia is associated with a variety of disorders characterized by DIC, including sepsis ([399], [400]), purpura fulminans ([401]), heat stroke ([402]), and abruptio placentae ([403]) (see Chapter 60). In all of these clinical conditions, RBC fragmentation is thought to result from the deposition of fibrin within the microvasculature. Hemolysis often is not severe, however, and may not contribute significantly to the morbidity of the disease. As the underlying disease comes under control with appropriate therapy, RBC fragmentation also ceases.

The generation of RBC fragmentation with DIC is supported by classical experimental animal data. When intravascular coagulation is induced in rabbits by the infusion of endotoxin ([267]) or thrombin ([404]), the onset of RBC fragmentation and hemoglobinemia is closely linked to the development of renal glomerular thrombosis. These findings indicate a link between the deposition of platelet and fibrin thrombi and RBC fragmentation; this is supported by histologic studies that associate hemolysis with a loose fibrin network to which RBCs adhere ([310]). From *in vitro* experiments it has been observed that when RBCs are forced through a loose fibrin clot within a slide chamber, they attach to fine fibrin threads and fold around these razor-sharp strands (Fig. 38.6) ([405]). As other cells flow past the attached RBCs, they cause their release or their fragmentation, often with resealing of the membrane, and thus the formation of RBC fragments. Similar results are obtained when nylon or glass fibers are used in artificial circuits ([405]).

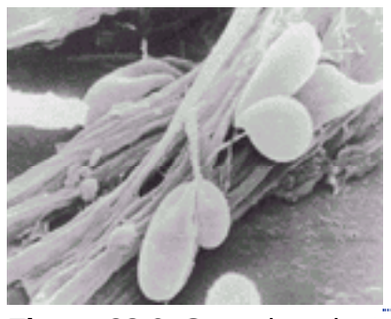

Figure 38.6. Scanning electron micrograph. Red blood cells are “clotheslined” over fine fibrin strands (*in vitro* model). Other cells, moving past these trapped erythrocytes, may cause their fragmentation. Thicker fibrin strands in background do not cause this injury. (From Bull BS, Kuhn IH. The production of schistocytes by fibrin strands. Blood 1970;35:104, with permission.)

HEMOLYSIS DUE TO IMMUNE DISORDERS

Microangiopathic hemolytic anemia may be a feature of diseases in which the microvasculature is damaged by immune mechanisms. Connective tissue diseases characterized by vasculitis, which occasionally leads to RBC fragmentation, include lupus erythematosus ([406]) and perhaps rheumatoid arthritis, Sjögren syndrome, and polyarteritis nodosa ([268]). RBC fragmentation also has been observed in association with polymyositis ([268]), scleroderma ([407]), Wegener granulomatosis ([408], [409]), and giant-cell arteritis ([410]).

Circulating immune complexes trigger the coagulation cascade ([308]), leading to fibrin deposition, which in turn stimulates the proliferation of endothelial cells. Fibrin deposition and endothelial changes, including immune complex–mediated damage of endothelial cells, are probably responsible for the RBC fragmentation that occurs in disorders characterized by the presence of circulating immune complexes. Such complexes, together with RBC fragmentation, have been found in patients with a variety of disorders, including TTP, subacute bacterial endocarditis ([411]), and glomerulonephritis ([412], [413]). The significance of this association is unclear, however, because immune complexes are found commonly in patients with some of these conditions ([414]), whereas RBC fragmentation and other manifestations of thrombotic microangiopathy are much less common.

Giant Hemangiomas and Hemangioendotheliomas

Microangiopathic hemolytic anemia has been identified in patients with giant hemangiomas ([415], [416] and [417]) and in patients with hemangioendotheliomas of the liver ([418], [419]). Microangiopathic hemolytic anemia also has been described in the blue rubber–bleb nevus syndrome, a rare disorder characterized by subcutaneous and gastrointestinal hemangiomas ([420]). It is thought that local coagulation in the abnormal blood vessels plays a role in RBC fragmentation ([415]). Therapeutic resolution of the hemangioma cures the microangiopathic hemolytic anemia and consumption coagulopathy ([416]). Antifibrinolytic therapy with e-aminocaproic acid has caused several hemangiomas to thrombose and to stabilize the hematocrit in one reported case ([421]).

March Hemoglobinuria

March hemoglobinuria is an unusual hemolytic disorder in which transient hemoglobinemia and hemoglobinuria develop in susceptible individuals after strenuous exercise that involves forceful contact of the body with a hard surface. Although RBC fragmentation is not always evident, the condition carries all the hallmarks of acute intravascular hemolysis, which presumably results from the mechanical disruption of circulating RBCs. Few cases have been reported since Fleischer described the first case in 1881 ([254]). Clinically inapparent hemoglobinemia may be more common.

With rare exception ([422]), march hemoglobinuria primarily affects young males ([254]). Hemoglobinuria is precipitated by prolonged marches or competitive running, but the syndrome has also been noted in conga drum players ([423], [424]) and people participating in karate exercises ([425]). Passage of red or dark urine after physical exertion is often the only complaint. Occasionally, symptoms include nausea; vague abdominal, back, or thigh pain; and a burning feeling in the soles of the feet.

Hemoglobinuria characteristically occurs immediately after exercise and lasts for only a few hours. March hemoglobinuria most commonly affects athletes at the beginning of a running career or on resumption of road training ([254]).

Laboratory studies reveal the hallmarks of intravascular hemolysis: hemoglobinemia and a decreased value of serum haptoglobin. Significant anemia is uncommon. The bilirubin concentration rarely exceeds 2 mg/dl. Serum lactic dehydrogenase levels may be elevated ([422] , [426]). The urine contains hemoglobin; after recurrences, it also may contain hemosiderin. Long-distance runners may develop iron deficiency attributable to hemosiderinuria ([426]).

Hemoglobinuria can be prevented by the use of shoes with thicker and more resilient soles than those usually worn. Thus, one postulation was that susceptible individuals destroy RBCs in the soles of their feet while running ([254]). Confirmation came from the ingenious experiments of Davidson, who inserted polyvinyl tubes containing blood into the running shoes of susceptible individuals and showed that these runners destroyed their own and the control blood at approximately the same rate, and to a greater degree than control subjects running on the same surface.

Whether hemolysis is entirely attributable to the type of exercise and the style of running or whether other factors make the RBCs of some people particularly susceptible to hemolysis is not clear. In three patients with march hemoglobinuria, a well-defined and similar membrane protein abnormality was identified by means of sodium dodecyl sulfate–polyacrylamide gel electrophoresis ([427]). In each case, differences from the normal pattern were readily apparent in the low-molecular-weight regions, and these changes were not evident in patients with other hemolytic anemias. In another unique report, intravascular hemolysis was noted in an individual while swimming, generally not considered to be a contact sport ([428]). Of interest, this individual also had an intrinsic RBC membrane disorder, hereditary xerocytosis, characterized by dehydrated RBCs (see Chapter 33). The RBCs of this patient manifested increased sensitivity to shear stress *in vitro*; this was most pronounced in the dehydrated cells, and partially corrected when the cells were rehydrated. The significance of the aforementioned observations is unknown. It is possible that hemolysis occurring with shear stress in some cases may be associated with underlying RBC abnormalities.

No specific therapy is usually needed for individuals with march hemoglobinuria. Attacks may be prevented by wearing shoes with more resilient soles and by changing to a less traumatic running style.

OTHER ACQUIRED CAUSES OF HEMOLYSIS

Hemolytic anemia also is seen in association with a number of nonhematologic systemic disorders, and in most cases there are several etiologies to the anemia.

Hypersplenism

Normal functions of the spleen include the monitoring and processing of “old” and “damaged” RBCs. These culling and pitting functions are executed by macrophages that line reticuloendothelial sinuses of the spleen, and also the liver and bone marrow (see Chapter 70). Macrophages have receptors that recognize immunoglobulin and complement molecules on the RBC surface, and possibly receptors that detect alterations in the outer portion of the phospholipid bilayer. The spleen is considered to be the most stringent of the reticuloendothelial filters, and this is aided by the slow rate of blood flow through the splenic red pulp.

Broadly defined, the term *hypersplenism* refers to sequestration and/or destruction of blood cells occurring in an enlarged spleen, associated with peripheral anemia and/or neutropenia and/or thrombocytopenia. In experimental animals with splenomegaly induced by methylcellulose injections, there is accelerated destruction of normal erythrocytes ([429]). Also, in humans, it is generally held that splenomegaly from any cause can be associated with increased filtering, extended macrophage attack, and increased erythrocyte destruction ([430]). Rarely does hypersplenism cause significant hemolysis. However, under conditions in which macrophages are activated there may be increased RBC destruction, and this may explain the accelerated hemolysis commonly seen with infections, in particular with malaria ([27]).

Massive splenomegaly often is associated with an increased plasma volume, and in these cases the low hemoglobin or hematocrit gives a falsely low estimate of the true RBC mass.

Liver Disease

Anemia in liver disease has many causes, including hemolysis (see Chapter 47). One component of this shortened RBC survival relates to portal hypertension and associated splenomegaly. However, the hemolysis occurring under these conditions is usually mild, with varying degrees of a compensatory increase in RBC production.

Another cause of hemolysis in liver disease is associated with the formation of “spur cells,” a variant form of acanthocytes. In patients with liver disease, abnormalities in lipid metabolism result in RBCs becoming selectively loaded with excess cholesterol. The cholesterol-loaded RBCs have impaired ability to repair peroxidized membrane lipids ([431]), and thus they undergo oxidative damage. As a consequence, they become rigid, nondeformable, and are rapidly cleared by the reticuloendothelial system, in particular the spleen ([432] , [433]) (see Chapter 47).

Attempts to correct portal hypertension have used angiographic techniques to create a communication between the intrahepatic portal vein and the hepatic vein. The placement of these transjugular intrahepatic portosystemic shunts avoids the anesthetic and surgical risks of other shunting procedures; however, some 10% of patients develop mild intravascular hemolysis ([434]). The hemolysis usually is self-limited and rarely requires intervention.

Renal Disease

Hemolytic anemia and renal failure occur together as discussed in the section on thrombotic microangiopathy. Anemia also is a frequent complication of primary renal disease, the most common cause being impaired erythropoietin production (see Chapter 47). However, in some cases there also is a hemolytic component ([435] , [436]), thought to be a consequence of uremia. Classic cross-transfusion studies from several years ago demonstrated that normal erythrocytes have a shortened survival in uremic patients while RBCs from uremic patients survive normally when transfused into healthy control individuals ([437] , [438]). RBC survival is decreased in proportion to the blood urea nitrogen concentration ([439]), and it improves significantly after intensive hemodialysis ([440]). The exact uremic metabolite responsible for RBC injury is not known.

The specific uremia-induced RBC injury that causes shortened RBC survival also is not defined. It has been suggested that oxidative stresses and impaired membrane fluidity may be involved ([441]). Of interest, it also has been observed that uremic RBCs have increased expression of phosphatidylserine on the outer membrane surface, and incubation of normal RBC in uremic plasma also induces increased expression of phosphatidylserine on the outer cell surface ([442] , [443]). These observations are important because it is now thought that one mechanism for macrophage recognition of damaged RBC may be the loss of phospholipid asymmetry across the membrane, particularly the appearance of phosphatidylserine on the external side of the membrane ([444] , [445]).

Nowadays, with aggressive dialysis programs and the regular use of erythropoietin, hemolytic anemia associated with uremia is uncommon. However, there are reports that complications of hemodialysis itself can cause hemolytic anemia. This has been attributed to the presence of chloramines (i.e., oxidant compounds used as bactericidal agents in urban water supplies) ([446]), formaldehyde in a water filtration system ([447]), overheated dialysate ([206]), and contaminants in the dialysates such as nitrates ([448]) or copper ([128] , [129]). In addition, mechanical-induced hemolysis due to kinking in the arterial blood line has been reported ([449]).

Hypophosphatemia

Severe hypophosphatemia can occur in patients undergoing prolonged antacid therapy, in those receiving intravenous hyperalimentation without phosphorus supplementation, in debilitated and starved people, and in alcoholics. In addition to confusion, weakness, anorexia, malaise, paresthesias, and electroencephalographic and electromyographic changes, hypophosphatemia also has been noted to cause hemolytic anemia ([450] , [451] , [452] , [453] , [454] , [455] and [456]). The anemia is characterized by reticulocytosis and microspherocytosis seen on the peripheral smear ([451]). In affected individuals, the serum phosphorus concentration invariably is very low. When measured, the concentrations of intracellular phosphorylated compounds also are reduced and glycolysis is thought to be inhibited. In particular, RBC adenosine triphosphate is decreased, cell deformability is reduced, and RBC survival is shortened ([451]). Therapy with parenterally administered

phosphate corrects the hypophosphatemia and all RBC abnormalities.

Postperfusion Syndrome

Cardiopulmonary bypass sometimes is associated with several adverse reactions, including acute intravascular hemolysis, leukopenia, a hemostatic deficit, and nonspecific systemic inflammatory reactions, collectively referred to as the *postperfusion syndrome*. This systemic dysfunction may result in acute respiratory distress syndrome and shock.

After cardiopulmonary bypass intravascular hemolysis can occur with hemoglobinemia, and, at the same time, lysed RBC ghosts can be found in the plasma. The mechanism of hemolysis associated with this syndrome was thought to be due to mechanical factors during surgery ([457]). However, it now is recognized that complement is activated during the procedure ([458]) and the terminal C5b-9 complement complexes are deposited on erythrocytes and polymorphonuclear neutrophilic leukocytes ([459]). In one interesting study using lysed erythrocyte membranes recovered from blood of patients at the end of bypass surgery, C5b-9 components were identified on the RBC ghosts but not on intact erythrocytes. Moreover, the appearance of ghosts carrying C5b-9 neoantigens always coincided with hemolysis ([459]). Thus, it now is thought that complement activation occurs as blood flows through the oxygenator, and the resultant deposition of C5b-9 on RBCs leads to immediate intravascular hemolysis. The same reactions presumably lead to granulocyte activation and sequestration in the lungs ([458]).

The hemolytic process is transient. Hematologic treatment is directed toward RBC support as needed until spontaneous resolution occurs.

ACKNOWLEDGMENTS

The authors wish to acknowledge G. Richard Lee, M.D., and John Foerster, M.D., for the excellent previous chapters on acquired hemolytic anemias and fragmentation syndromes in the Tenth Edition of Wintrobe's *Clinical Hematology*. These earlier contributions provided a template for the current chapter in this, the Eleventh Edition.

Abnormal Hemoglobins: General Principles

Inherited abnormalities of hemoglobin synthesis may be divided into two groups: those characterized by structurally abnormal hemoglobin variants and those in which one or more of the normal polypeptide chains of hemoglobin are synthesized at a reduced rate. The term *hemoglobinopathy* is used to designate the former disorders, and the term *thalassemia* is associated with the latter. The hemoglobinopathies may be divided further into functionally distinctive groups. Many are functionally normal and, therefore, clinically silent. Some form polymers [hemoglobin (Hb) S] or crystals (Hb C), giving rise to hemolytic disease (see Chapter 40). Others are unstable, producing either intermittent or chronic hemolysis (see Chapter 41). Structural changes that increase the affinity of hemoglobin for oxygen are characterized by erythrocytosis (see Chapter 50), whereas those with decreased oxygen affinity are associated with cyanosis (see Chapter 49). Mutations that maintain hemoglobin iron in the ferric state are responsible for methemoglobinemia (see Chapter 49). A few structural variants remain that are characterized by a thalassemic phenotype rather than by one of the syndromes associated with hemoglobinopathies. Most of the latter variants are thought to arise from a single mutation that simultaneously produces a structural and a quantitative defect in globin chain synthesis. Some may involve two mutations within a single gene—one responsible for a structural defect and the other for a biosynthetic defect. These thalassemic hemoglobinopathies are discussed in Chapter 42, the focus of which is on thalassemias. This chapter provides a broad introduction to the abnormal hemoglobins, with an emphasis on population genetics, molecular pathology, and pathophysiology. In addition, the clinical consequences of some of the more prevalent hemoglobin disorders are discussed (those involving Hb C, Hb D, and Hb E). Hb S and the sickling disorders are discussed in Chapter 40.

HISTORY

The story of the events leading to an understanding of the hemoglobinopathies and thalassemia provides a fascinating picture that illustrates the value of the pursuit of knowledge for its own sake. It reveals the fruits that can be gained if curiosity is aroused and an answer sought to questions that may at the time seem to be of no practical importance, as well as the progress that can be made when the right question is put to a “prepared mind.”

In 1910, James B. Herrick reported “peculiar, elongated, sickle-shaped red corpuscles” in “a case of severe anemia” in a black student ([1]). He described the clinical manifestations in his patient in considerable detail. The sickle cells, he thought, were freakish poikilocytes, and, with considerable prescience, he suggested that they were a manifestation of a peculiar chemical or physical condition. Emmel, in 1917, observed the transformation of the biconcave red cell to the sickle form *in vitro* ([2]). He also noted that sickling occurred both in persons with severe anemia and in others who were apparently healthy, thus recognizing both sickle cell anemia and sickle cell trait.

The comprehensive studies of Hahn and Gillespie in 1927 delineated the conditions affecting sickle cell formation *in vitro*, including pH, temperature, fixatives, tonicity, and others ([3]). Perhaps their most important observations were the observation that exclusion of oxygen was a prerequisite for sickling and the recognition that sickling was reversed on reexposure to the gas. They postulated that similar effects of oxygen could occur *in vivo*, with hypoxia leading to cellular distortion and consequent hemolysis. Later, Hahn applied the term *sickle cell trait* to the asymptomatic condition associated with *in vitro* sickling. He performed studies in families and concluded that the trait was inherited as a dominant character.

Paralleling these events was the report of Cooley and Lee, in 1925, who separated from the complex of disorders of infancy and childhood that had been known as *Von Jaksch anemia* a syndrome characterized by chronic, progressive anemia beginning early in life, with pronounced peripheral blood erythroblastosis, characteristic facies, splenomegaly, and a familial incidence ([4]). The observation that these patients were of Mediterranean background led to the introduction of the name *thalassemia*, derived from the Greek word for *sea*. The parents of these children, however, were not examined. At this time and in the following years, descriptions appeared in the Italian literature of a milder disorder, encountered in adults as well as in children, that was marked by morphologic abnormalities in the red cells and decreased red cell osmotic fragility (microelliptopoikilocytic anemia, *malattia di Rietti-Greppi-Micheli*). In 1938, Caminopetros noted that the parents of a child suffering from severe thalassemia had diminished red cell osmotic fragility ([5]), but the relationship between Cooley anemia and the Rietti-Greppi-Micheli syndrome remained obscure.

Curiosity regarding the significance of basophilic stippling of the red cells of several adult patients with minor ailments led to the description in 1940 by Wintrobe and his associates of what they considered to be a mild form of Cooley anemia ([6]). These investigators also showed that the manifestations of this disorder were present in both parents of a child with classic Cooley anemia. Subsequent genetic studies established that Cooley anemia is the homozygous or doubly heterozygous state for an autosomal gene; the patients described by Rietti and by Wintrobe and their co-workers represented the heterozygous state ([7]).

In 1940, the sickling phenomenon was reinvestigated by Sherman ([8]), who confirmed the observations of Hahn and Gillespie regarding reversibility and the importance of oxygen. Sherman also found that the cells in sickle cell disease were birefringent, an observation that aroused curiosity but remained unexplained for nearly a decade. Then, in a casual conversation, the birefringence was called to the attention of the physical chemist Linus Pauling ([9]), who immediately deduced that the phenomenon was the manifestation of an abnormal hemoglobin molecule. With Itano, he demonstrated an electrophoretically abnormal hemoglobin in sickle cell anemia ([10]), thus introducing the concept of molecular disease.

In the same year that Pauling made his discovery, Neel established that sickle cell trait was the heterozygous and sickle cell anemia the homozygous state for the same gene ([11]). With the demonstration by Ingram of a difference in the amino acid sequence in one small part of the polypeptide chains of sickle cell hemoglobin ([12]), the science of molecular biology took root. The contributions of Perutz, Lehmann, and many others have resulted in an expansion of knowledge to a degree unforeseen even in the 1950s, let alone when Herrick wrote about his patient with a peculiar anemia.

NOMENCLATURE

When newly discovered hemoglobins were first reported, they were designated by letters of the alphabet. Normal adult hemoglobin and fetal hemoglobin were called *Hb A* and *Hb F*, respectively. When sickle cell hemoglobin was discovered, some individuals called it *Hb B*, but soon the letter *S* was assigned to it, and, to avoid confusion, no other hemoglobin was designated *B*. Hemoglobins associated with methemoglobinemia were given the letter *M*. Other hemoglobins were assigned letters in alphabetic order. By the time the letter *Q* was reached, the inability of this system to provide sufficient designations was apparent. Furthermore, structurally different hemoglobins occasionally had been given the same letter. In 1960, a new system of nomenclature was adopted, and the letters *R* and *T* through *Z* were unassigned ([13]). Solitary letter designations are used only for the normal hemoglobins A and F and for the abnormal hemoglobins C, E, S, and H. Letters, however, may be used as part of a more complete common name.

Abnormal hemoglobins are now assigned both a common name and a scientific designation. The common name is selected by the discoverer. It usually represents a geographic area, such as a city, district, province, or hospital, and may be the native region of the propositus or the place of discovery. Capital letters are sometimes retained to indicate a special property of the hemoglobin variant. Thus, the designation *Hb G Copenhagen* indicates a hemoglobin discovered in Copenhagen with the same electrophoretic mobility as that of other hemoglobins G. Similarly, *Hb M Boston* indicates a variant that, like other M hemoglobins, tends to form methemoglobin.

Recommended scientific designations indicate the variant chain, both the sequential and helical number of the aberrant amino acid, and the nature of the substitution. Thus, ß6(A3)Glu?Val, the scientific designation for Hb S, indicates that the substitution of valine (Val) for glutamic acid (Glu) has occurred at amino acid number 6, the third amino acid in the A helix, in the ß-chain. In the case of hemoglobins with two substitutions, both are indicated; thus, Hb C Harlem is designated ß(A3)Glu?Val; 73(E17)Asp?Asn.

Amino acid deletions are indicated by the symbol 0; thus, ß23(B5)Val?0, the designation for Hb Freiburg, indicates the deletion of valine at position 23 in the ß-chain. Less commonly, the word *missing* is used to indicate deletions; thus, ß56-59(D7-E3) missing, the designation for Hb Tochigi, indicates the deletion of four amino acids in the ß-chain.

Various designations have been used for fusion hemoglobins. The current convention identifies the portions of the chains that are fused insofar as they are known. Hemoglobin Lepore-Boston is shown as d(1-87) ß(116-146). The fusion occurs somewhere between amino acids 88 and 115. The first 87 amino acids come from the d-chain, and the last 32 come from the ß-chain.

Variants with elongated chains are indicated by the use of a plus sign followed by the number of added amino acids. For example, Hb Tak can be designated ß+ 11C, indicating that 11 amino acids have been added to the *C*-terminal of the normal ß-chain. When the elongation is accompanied by altered amino acids, they are shown in parentheses, as in Hb Constant Spring, which is designated a+ 31C (142 Gln), or Hb Wayne, which is designated a (139-141 Asn Thr Val) + 5C.

CLASSIFICATION

A catalog of human hemoglobin variants was maintained until 1998 by Dr. Titus H.J. Huisman ([14]). After his death, this syllabus was converted to an electronic database, which is expanded and revised on an ongoing basis ([15]). It is accessible on the World Wide Web at http://globin.cse.psu.edu. As of 2002, the database included no fewer than 850 unique hemoglobin variants. Of these, 44 were associated with a thalassemic phenotype (thalassemic hemoglobinopathies). These are discussed in Chapter 42.

The hemoglobin variants can be classified on the basis of functional characteristics or structural abnormalities. The functional properties of hemoglobin variants are discussed in the section Pathophysiology. Structural alterations include single and double amino acid substitutions; amino acid deletions, insertions, and both deletions and insertions; additions; and fusion chains formed from two different polypeptide chains (Table 39.1).

TABLE 39.1. Summary of the Molecular Abnormalities of Hemoglobin Variants

	Number of Variants				
	a-Chain	ß-Chain	d-Chain	?-Chain	Total
Single amino acid substitution	253	405	34	67	759
Two amino acid substitutions	1	23	0	5	29
Deletions	9	12	0	0	21
Insertions	5	2	0	0	7
Deletions and insertions	0	11	0	0	11
Extended chains	9	9	0	0	18
Fusions	0	9	8	1	18
Totals [a]	277	471	42	73	863

[a] The total number of hemoglobin variants (854) is 9 less than the sum of the first four columns because each of the nine fusion hemoglobins is recorded in two columns.

Most abnormal hemoglobins differ from normal hemoglobin in the substitution of a single amino acid for another. In Hb S, for example, valine replaces glutamic acid in the sixth position from the *N*-terminal of the ß-globin chain. Many other examples of this kind have been discovered. More than 600 hemoglobin variants characterized by a single amino acid substitution have been recognized and characterized ([14], [15]). Of these variants, more than 200 involve the a-chain, nearly 400 involve the ß-chain, more than 30 involve the d-chain, and more than 70 involve the ?-chain (Table 39.1). The paucity of a-chain variants as compared with ß-chain defects is explained by duplication of the a-globin genes. Individuals homozygous for a-chain variants have two normally functioning a genes and are therefore likely to be protected from clinical expression of the abnormal hemoglobin, whereas homozygotes for ß-chain variants are unable to synthesize Hb A. Thus, mutations affecting the ß gene are detected during the investigation of disease, whereas most of those involving the a gene escape recognition, except in the course of population surveys. Likewise, structural alterations of the d- and ?-chains are unlikely to produce signs or symptoms that would warrant diagnostic evaluation. Two exceptions are the ?-chain substitutions in Hb F Poole and Hb FM Osaka. The former renders the hemoglobin molecule sufficiently unstable to produce hemolytic disease in fetal and early postnatal life ([16]), and the latter is responsible for neonatal cyanosis ([17]).

Other abnormal hemoglobins are characterized by more complex structural alterations. Two amino acid substitutions have been detected in 24 hemoglobin variants (Table 39.2). Many of the ß-globin variants with two amino acid substitutions are unstable and therefore associated with hemolytic anemia of varying severity. Of particular interest are six variants in which one of the two point substitutions is identical to that in Hb S (ß6 Glu?Val). Not surprisingly, these variants possess sickling properties. Two variants include the substitution found in Hb C (ß6 Glu?Lys), and another two variants include the substitution found in Hb E (ß26 Glu?Lys).

TABLE 39.2. Hemoglobins Characterized by Two Amino Acid Substitutions in the Same Globin Chain

Common Name	Scientific Designation
J-Singapore	a78(EF7) Asn?Asp; a79(EF8) Ala?Gly
S-Antilles	ß6(A3) Glu?Val; ß23(B5) Val?Ile

C-Ziguinchor	ß6(A3) Glu?Val; ß58(E2) Pro?Arg
C-Harlem	ß6(A3) Glu?Val; ß73(E17) Asp?Asu
S-Providence	ß6(A3) Glu?Val; ß82(EF6) Lys?Asp
S-Oman	ß6(A3) Glu?Val; ß121(GH4) Glu?Lys
S-Travis	ß6(A3) Glu?Val; ß142(H20) Ala?Val
C-Rothchild	ß6(A3) Glu?Lys; ß37(C3) Trp?Arg
Arlington Park	ß6(A3) Glu?Lys; ß95(FG2) Lys?Glu
D-Agri	ß9(A6) Ser?Tyr; ß121 (GH4) Glu?Gln
O-Tibesti	ß11(A8) Val?Ile; ß121(GH4) Glu?Lys
Corbeil	ß26(B8) Glu?Lys; ß104(G6) Arg?Thr
T-Cambodia	ß26(B8) Glu?Lys; ß121(GH4) Glu?Gln
Medicine Lake	ß32(B14) Leu?Glu; ß98(FG5) Val?Met
Grenoble	ß51(D2) Pro?Ser; ß52(D3) Asp?Asn
Poissy	ß56(D7) Gly?Arg; ß86(F2) Ala?Pro
Casablanca	ß65 (E9) Lys?Met; ß122(GH5) Phe?Leu
Atlanta-Coventry	ß75(E19) Leu?Pro; ß141(H19) Leu?0
Villeparisis	ß77(EF1) His?Tyr; ß80(EF4) Asn?Ser
Duino	ß92(F8) His?Pro; ß104(G6) Arg?Ser
Cleveland	ß93(F9) Cys?Arg; ß121(GH4) Gln?Glu
Fannin-Lubbock	ß111(G13) Val?Leu; ß119(GH2) Gly?Asp
Masuda	ß114(G16) Leu?Met; ß119(GH2) Gly?Asp
Nijkerk	ß138(H16) Ala?0; ß139(H17) Asn?Tyr

Shortened polypeptide chains result from the loss of one or more amino acid residues. Most involve the ß-globin chain. The clinical phenotype is that of mild anemia when no more than one or two amino acids are deleted, whereas more extensive deletions are responsible for unstable hemoglobin disease (Chapter 41). Hb Higashitochigi (ß24 or 25 Gly?0) is characterized by both hemolytic anemia and methemoglobinemia ([18]). Hemoglobin variants characterized by the loss of one or more amino acids are listed in Table 39.3. In all but nine, the deletions involve the ß-chain. The loss of one to five amino acids renders these variants unstable. Other variants are characterized by the insertion of one or more amino acids (Table 39.4). These hemoglobins, also, are unstable.

TABLE 39.3. Hemoglobins Characterized by Simple Amino Acid Deletions

Common Name	Scientific Designation
Boyle Heights	a6 (A4) Asp?0
Heraklion	a37 (C2) Pro?0

TABLE 39.4. Hemoglobins Characterized by Amino Acid Insertions

Common Name	Scientific Designation
Catonsville	a+ Glu between codons 37 and 38
Neuilly-sur-Marne	a+ Ser-Asp-Leu between codons 86 and 87
Phnom Penh	a+ Ile between codons 117 and 118
Zaire	a+ His-Leu-Pro-Ala-Glu between codons 116 and 117
Grady (Dakar)	a+ Glu-Phe-Thr between codons 118 and 119
Fairfax	ß+ Glu-Leu-His-Cys-Asp between codons 94 and 95
Koriyama	ß+ Leu-His-Cys-Asp-Lys between codons 95 and 96

Elongation of a-globin chains beyond the expected 141 amino acids and of ß-globin chains beyond 146 amino acids occurs with mutations affecting the initiator or terminator codons of the a- and ß-globin genes (Table 39.5). Hb Thionville, Hb Doha, Hb South Florida, and Hb Marseille (also designated *Hb Long Island*) are characterized by point mutations involving the NH_2 terminal valine of the a- or ß-globin chain or the histidine residue in the second position of the ß-chain. These substitutions prevent the initiator methionyl residue from being cleaved from the polypeptide chain, elongating the chain by one amino acid. In Hb Constant Spring, Hb Icaria, Hb Koya Dora, Hb Seal Rock, and Hb Paské, 31 additional amino acids are added to the C-terminus of the a-globin chain. The a-globin gene frameshift mutation in Hb Wayne replaces lysine at position 139 with asparagine and extends the a-chain by five amino acid residues to an inphase terminator codon. Base mutations extend the ß-globin chain 11 additional amino acids in Hb Cranston, and 10 additional amino acids in Hb Saverne. Insertions in the midportions of the a- and ß-globin genes are responsible for extending the corresponding polypeptide chains by one to five amino acid residues in Hb Catonsville, Hb Neuilly-sur-Marne,

Hb Phnom Penh, Hb Zaire, Hb Grady (also designated *Hb Dakar*), Hb Fairfax, and Hb Koriyama (Table 39.4).

Fusion hemoglobins are those containing a globin chain formed from parts of two different polypeptide chains (Table 39.6). Thus, the non–a-chains in Hbs Lepore-Hollandia, Lepore-Baltimore, and Lepore-Boston (also known as *Hb Lepore-Washington*) are formed from the *N*-terminal portion of the d-chain and the *C*-terminal portion of the ß-chain. “Anti-Lepore” hemoglobins (see Chapter 42) (i.e., those with a ß- *N*-terminal and a d- *C*-terminal) have also been described: Hbs Miyada, P Nilotic, P Congo, and P India. Hb Lincoln Park is identical to Hb P Nilotic except for the deletion of a single amino acid in the d portion of the hybrid chain. The non–a-chain in Hb Kenya is composed of ?-chain sequences in the *N*-terminal portion and ß-chain sequences in the *C*-terminal portion ([19]). In Hb Parchman, the non–a-chain is a hybrid of three different portions of the d- and ß-chains: d sequences in the *N*-terminal portion, ß sequences in the midportion, and d sequences in the *C*-terminal portion ([20]).

TABLE 39.6. Fusion Hemoglobins

Common Name	Scientific Designation
Lepore-Hollandia	d(1-22) ß(50-146)

Lepore-Boston (or -Washington)	d(1-87) ß(116-146)
Miyada	ß(1-12) d(22-146)
P Nilotic	ß(1-22) d(50-146)
P Congo	ß(1-22) d(116-146)
P India	ß(1-87) d(116-147)
Parchman	d(1-12) ß(22-50) d(86-146)
Kenya	^{A}?(1-80) ß(87-146)

Some structural changes in globin chains result from posttranslational modifications. Deamination of asparagine to aspartic acid occurs when asparagine is substituted for another amino acid that is adjacent to a histidine residue or when histidine is introduced adjacent to a normally present asparagine ([21]). When this occurs, two abnormal hemoglobins may be detected by electrophoresis or high-performance liquid chromatography—one containing the encoded asparagine and the other containing aspartic acid. In Hb Wayne, for example, a reading frameshift causes the substitution of asparagine for lysine at position 139 of the a-globin chain, leading to the retention of an additional five amino acids until a new terminator codon is encountered (Table 39.5). Partial deamination of the substituted asparagine produces two Hb Wayne peptides, one containing asparagine and the other containing aspartic acid at position 139 ([22], [23]). Posttranslation oxidation was shown to modify the apparent structure of Hb Coventry. This variant was initially thought to involve two amino acid substitutions in the ß-globin chain, a substitution of proline for leucine at ß75, and the deletion of leucine at ß141. Subsequent sequencing of the gene identified the expected mutation in the codon for ß75 but, surprisingly, found an intact codon for ß141 ([24]). This apparent paradox was explained by the oxidation of ß141 leucine to hydroxyleucine, which is not detected by amino acid analysis ([25]). It is postulated that the ß75 mutation, lying within the heme pocket, predisposes to the generation of activated oxygen species that then oxidize some of the ß141 leucine residues. Hb Bristol, also, undergoes posttranslational modification. Methionine, which is substituted for valine at ß67, is converted to aspartate after transcription ([26]).

PREVALENCE AND GEOGRAPHIC DISTRIBUTION

The frequency of the abnormal hemoglobins varies considerably with geographic location and racial group. Four hemoglobin variants, Hb S, Hb C, Hb E, and Hb D Punjab, each affects millions worldwide.

Hemoglobin S is found in equatorial Africa in a broad zone extending from coast to coast (Fig. 39.1) ([27]). The highest incidence occurs in the eastern part of the continent, where 40 to 50% of the members of some tribes are affected. A prevalence rate of 10 to 20% is common throughout other parts of the zone, but considerable variation exists from one tribe to another.

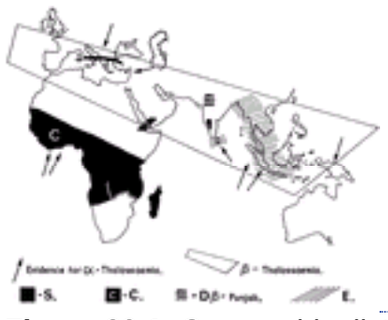

Figure 39.1. Geographic distribution of hemoglobin (Hb) S, Hb C, Hb E, Hb D Punjab, and a- and ß-thalassemia. (Specially prepared by Dr. Hermann Lehmann.)

The Hb S gene is found also in non-African populations. A prevalence as high as 25% has been reported in southern Turkey, in Saudi Arabia, especially in the oasis areas of Qatif and Al Hasa, in Israeli Arabs, and in southern India. Hemoglobin S is also found along the northern Mediterranean shore, especially in Sicily, Cyprus, and Greece, where as many as 32% of the inhabitants of certain villages are affected. Isolated cases of sickle cell disease in white Americans also have been reported ([28], [29]).

Results of studies of DNA polymorphisms linked to the ß ^{S} gene suggest that Hb S arose from three independent mutations in tropical Africa ([30]). All three haplotypes are associated with the ß ^{S} gene in black Americans and Jamaicans ([31], [32]), whereas only the haplotypes encountered in West Africa are prevalent among North Africans, Greeks, and Italians ([31], [33]). A different pattern of polymorphisms associated with the ß ^{S} gene in Saudi Arabia and India suggests that the Asian gene may have arisen from an independent mutation ([34], [35]).

In the United States, the prevalence of sickle cell trait among blacks is approximately 8% (Table 39.7), although the rate varies in different parts of the country. A lower incidence is found in the north, possibly because of greater racial mixture, whereas in such isolated populations as the Gullahs of South Carolina, the prevalence of Hb S approaches 20%. The frequency of the gene among blacks in Central and South America and in the West Indies is similar to that in North America.

TABLE 39.7. Prevalence of Hemoglobinopathies and Thalassemia among Blacks

Disorder	Prevalence (Subjects/100,000 Population)
Heterozygous states	
a-Thalassemia $^{+}$ (silent)	24,000
Sickle cell trait	8600
Hb C trait	2400
ß-Thalassemia minor	1400
HPFH trait	100
Others	300 [a]
Homozygous disorders	
a-Thalassemia minor	5700
Sickle cell anemia	141
ß-Thalassemia major	20
Hb C disease	21
Doubly heterozygous disorders	
Hb SC disease	132
Hb S/ß-thalassemia disease	60
Hb C/ß-thalassemia disease	13
Hb S/HPFH	29
Hb C/HPFH	7
Hb S/other Hb variants	4
Hb C/other Hb variants	2
All variant Hbs	12,000
All Hb S syndromes	9000
All Hb C syndromes	2500

Hb, hemoglobin; HPFH, hereditary persistence of fetal hemoglobin.

NOTE: Prevalence figures are based on data culled from population surveys reported in references [42], [43] adn [44].

[a] Figure is approximate. Of the 249,000 persons screened for variant hemoglobins, 164 kindreds were detected. However, the existence of kindreds biases the numbers because family members have an incentive to participate in screening. The most common were Hb G Philadelphia (47 kindreds), Hb N Baltimore (12), Hb D Punjab (9), and Hb O Arab (9).

Compared with Hb S, Hb C is found in a smaller and more sharply demarcated geographic zone in western Africa (Fig. 39.1). The greatest prevalence is in northern Ghana, where 28% of the population harbors the gene. The frequency declines sharply to the south, east, and west. Within Nigeria, the River Niger seems to have been a barrier to eastward spread. Nearly 3% of blacks have the Hb C gene (Table 39.6).

Hemoglobin E is most prevalent in Southeast Asia, affecting more than 50% of the population in eastern Thailand (Surin Province) and from 20 to 45% in other parts of Thailand and in Cambodia, Laos, and Burma. A somewhat lower prevalence, 3 to 8%, is found in Vietnam. Altogether, an estimated 30 million people may carry hemoglobin E ([36]). From the mainland, the gene spreads southward to parts of Indonesia, but the incidence is low in India to the west and in China to the northeast. With the resettlement of many Southeast Asians in the United States, the Hb E syndromes assumed significance in North America as well.

Hemoglobin D Punjab is found in greatest frequency (2%) among the Sikhs of the Punjab in India (Fig. 39.1) as well as in nearby Gujerat (1%) and in Iran. It has also been found in blacks (0.4% in North Carolina) ([37]), sporadically in whites throughout the world, and in American Indians.

The high rates of occurrence of the more prevalent hemoglobin variants as well as thalassemia and glucose-6-phosphate dehydrogenase deficiency suggest that the deleterious effects of the homozygous states of these disorders are counterbalanced by the selective advantage they provide to heterozygous individuals (“balanced polymorphism”). By this mechanism, the gene frequency increases in the population despite the adverse effects on survival of homozygous individuals, because the heterozygote is more “fit” than a normal subject. Most of the studies of this phenomenon have focused on the role of malaria, especially *Plasmodium falciparum* malaria, as the selecting agent and on the possible resistance to malaria offered by subjects heterozygous for the aforementioned disorders.

The “malaria hypothesis” is best established with respect to Hb S. The geographic distribution of *P. falciparum* malaria and of Hb S coincides remarkably. Furthermore, subjects with sickle cell trait have a lower rate of parasitization of the blood, even when they are deliberately inoculated with the parasite, and the mortality rate from cerebral malaria is lower in children with the trait than in those without Hb S ([38]). The mechanism of malarial resistance has not been established, but the most likely hypothesis holds that parasitization of cells induces sickling, which is followed by destruction of sickled cells and their parasites by macrophages (

[39]). Indeed, the sickling phenomenon itself can kill and lyse parasites within the cells ([40]).

Most other hemoglobin variants are rare. Many have been reported in a single individual or in a single family. Occasionally, in isolated populations, a minor variant may attain considerable prevalence; for example, Hb J Tongariki was found to affect nearly 10% of the population on an island in the Pacific. In a survey of 8000 Europeans (5000 Danish, 3000 British), only 11 were found to have an electrophoretically identifiable abnormal hemoglobin ([41]).

As might be expected, the prevalence of hemoglobin variants in the United States is a function of the ethnicity of the population sampled. Approximately 12% of blacks have a hemoglobin variant (Table 39.7). Hb S is found alone or in combination with other hemoglobins in 8.5%, and Hb C is found alone or in combination with other hemoglobins in 2.5%. Hb G Philadelphia is the third most common hemoglobin variant among blacks. At least 19 other variants, affecting 117 kindreds, were found in a survey of 249,000 blacks in Alabama ([42]).

Both a-thalassemia and ß-thalassemia also are prevalent among blacks. In gene mapping studies, approximately 27% of blacks lack a single a-globin gene (silent carrier state) and approximately 2% lack two of the four a-globin genes (a-thalassemia minor). ß-Thalassemia minor affects approximately 1.4% of this population ([43]).

GENETIC MECHANISMS AND MOLECULAR PATHOLOGY

Organization and Structure of Globin Genes

A discussion of the molecular pathology of abnormal hemoglobins assumes an understanding of the organization and structure of the globin genes ([44], [45] and [46]). These genes occur in clusters, the a- and a-like genes on the short arm of chromosome 16, and the ß- and ß-like genes on the short arm of chromosome 11 (Fig. 39.2). The a-like cluster extends over a 40-kilobase (kb) range, and the ß-like cluster extends over a 60-kb range. In the a gene cluster, two a-globin structural genes a1 and a2 are located at the 3' end of the complex. The nucleotide sequences of the coding portions of these two genes are identical. Minor differences in sequences in the second intron have been detected. Upstream, or 5' from the expressed a genes, is a pseudo–a gene (?), a DNA sequence closely resembling the a genes but having a mutation that renders it nonfunctional. Further upstream are two embryonic a-like genes (? genes), one of which is not expressed.

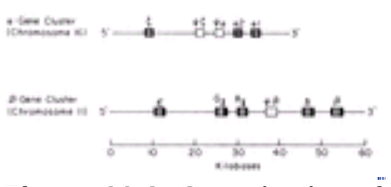

Figure 39.2. Organization of the human globin gene clusters on chromosomes 16 and 11. Solid areas within genes indicate coding sequences; open areas indicate intervening sequences. Each cluster includes pseudogenes (?,?, and ?) that have sequence homology to functional genes but include mutations that prevent their expression.

The ß gene complex comprises six genes arranged in the following 5' to 3' order: a single embryonic gene (e), two fetal genes (^{G}? and ^{A}?), a pseudo–ß gene (?), the d gene, and the ß gene. The polypeptide chains produced by the two ? genes differ only in the amino acid at position 136: glycine in ^{G}? and alanine in ^{A}?. Because of extensive homology between them, the d and ß genes are thought to have arisen from duplication of a single gene. Subsequent mutations in the regulatory region of the d gene have rendered it functionally insignificant. In both gene clusters, genes are arranged on the chromosome in the order in which they are expressed during embryonic, fetal, and postnatal development. The nucleotide sequences of each of these genes and of intragenic DNA have been determined ([47]).

All of the functional globin genes share a common general structure, consisting of three exons and two introns. A schematic representation of globin gene structure is provided in Figure 39.3. Although not translated, DNA sequences that are 5' as well as those that are 3' to the gene are important for gene expression. The promotor region consists of approximately 100 base pairs immediately preceding the point at which transcription begins (cap site). Three short sequences within this region bind RNA polymerase, which catalyzes messenger RNA (mRNA) synthesis. Two sequences (referred to as the *TATA box* and the *CAT box*) are particularly important for the initiation of gene transcription. Mutations involving these sequences reduce enzyme binding, thereby limiting mRNA transcription. The region downstream from the third exon contains a sequence (AATAAA) that signals the termination of gene transcription. This region is thought to trigger an enzymatic process that cuts mRNA at the appropriate point and releases it for further processing.

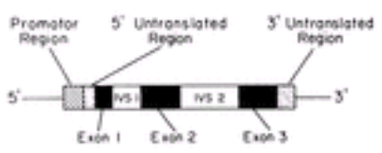

Figure 39.3. Structure of the globin genes. Each of the human globin genes contains three coding blocks (exons) that are separated by two introns, or intervening sequences. In the ß-globin gene, exon 1 encodes for amino acids 1 through 30, exon 2 encodes for amino acids 31 through 104, and exon 3 encodes for amino acids 105 through 146. Shaded regions indicate 5' and 3' transcribed but untranslated regions. The promotor region contains approximately 100 base pairs, some of which are necessary for the initiation of transcription.

The primary mRNA transcript includes copies of the entire genomic DNA sequence, including both exons and introns. Before this pre-mRNA is transported to the cytoplasm, it is processed by capping of the 5' end, splicing to remove sequences transcribed from introns, and polyadenylation of the 3' end. The last step appears to be important for the nuclear-to-cytoplasmic transport of the finished product as well as for stability of mRNA in the cytoplasm. Splicing involves the formation of loops in pre-mRNA, such that the downstream ends of exons (donor sites) approximate the upstream ends of the next exons (receptor sites). The intron sequences are then enzymatically excised, and the donor and acceptor sites of exons are sealed. Donor sites are identified by the nucleotides GT at the 5' end of introns, and acceptor sites are identified by AG at the 3' end. In addition to these dinucleotides, certain preferred nucleotide sequences adjacent to them are required for accurate and efficient splicing. These sequences are referred to as *consensus sites*. Mutations involving splice junctions and consensus sites result in abnormal splicing and therefore in abnormal mRNAs.

Genetic Basis of Abnormal Hemoglobins

POINT MUTATIONS Approximately 90% of hemoglobin variants are due to point mutations (i.e., the substitution of a single DNA nucleotide base for another). This mutation alters the genetic code, often in such a way that an amino acid change occurs in the resulting globin. When the amino acid substitutions in the reported human hemoglobin variants have been examined in relation to the genetic code, almost all such variants have been explainable by a change in only one of the three bases coding for each amino acid. The mutation responsible for the Glu?Val substitution in Hb S, for example, is GUG?GAG. As a rule, substitutions that require a change in more than one base have not been observed. For example, the substitution Asp?Lys does not occur because neither of the codons for aspartic acid (GAC, GAU) can change to a codon for lysine (AAA, AAG) without altering two bases. Only one possible exception to the one-base change rule has been noted. In Hb M Milwaukee, the change at ß67 is Val?Glu; in Hb Bristol, it is ß67 Val?Asp. None of the known valine codons (GUU, GUC, GUA, and GUG) can change to both a glutamic acid codon (GAA, GAG) and an aspartic acid codon (GAU, GAC) by means of one-base changes. Sequence analysis has shown that the usual Val codon at ß67 is GUG. Thus, either Hb Bristol represents a two-base change or the ß67 codon has normal variants. DNA nucleotide substitutions have been described for 113 of the 141 codons that determine the sequence of amino acids in the a-globin chain and for 143 of the 146 codons for the ß-globin chain. As many as 13 different mutations involving the same codon have been documented. Most codons with multiple substitutions encode contact sites between the a- and ß-globin chains or between globin and the heme moiety. The mutation rate of single bases in the globin genes is estimated to be 1 in 104 individuals per generation. The *de novo* mutation rate for all ß-chain variants is calculated to be 7.4 × 10 ± 9 per ß gene nucleotide per generation ([48]). Two types of point mutations have been defined. A *transition* is a substitution of a pyrimidine for another pyrimidine or a purine for another purine. A *transversion* is a substitution of a purine for a pyrimidine or vice versa. The amino acid changes produced by transversions tend to result in more radical alterations in protein structure than those occurring with transitions. If

mutations occurred at random, twice as many transversions as transitions would be observed. The number of human hemoglobin variants resulting from transitions, however, is approximately equal to that resulting from transversions. If only substitutions affecting the molecular surface are tabulated, the expected 2:1 ratio is found, but changes in the molecular core are produced only rarely by transversion. Purine transitions are more common than pyrimidine transitions, and the most common of all point substitutions is adenine?guanine in DNA (guanine?adenine in RNA). The reasons for the nonrandom nature of these genetic defects are not entirely clear.

Hemoglobins with elongated globin chains also arose from point mutations ([49]). Termination of polypeptide chain synthesis during translation occurs when a stop codon is reached. In the a-chain, this codon, UAA, is in position 142 (i.e., after the codon for the amino acid normally in the *C*-terminal position). Five hemoglobins have been detected with 31 amino acids added to the *C*-terminal of the a-chain (Table 39.5). In all of these hemoglobins, an amino acid that probably arose from the stop codon by means of a one-base mutation (UAA?CAA, Gln; UAA?AAA, Lys; UAA?GAA, Gln; and UAA?UCA, Ser) appears at position 142. A different mechanism is responsible for ß-chain elongation in Hb Marseille (also designated *Hb Long Island*), Hb South Florida ([50]), and Hb Doha ([51]). The latter two are characterized by point substitutions at the first position of the ß-chain; Hb Marseille is characterized by a point substitution at the second position. In each case, the substitution prevents the removal of the initiator methionine during translation, thus extending the N-terminus by one residue.

NUCLEOTIDE DELETIONS AND INSERTIONS Deletion or insertion of one or two nucleotide bases changes the grouping and therefore the meaning of codons downstream from the mutation. The result is a frameshift error, so called because of a shift in the reading frame produced by the mutation. Most frameshift mutations result in the thalassemia phenotype, because the globin chains they produce are nonfunctional. Frameshift mutations occurring at the end of the coding portion of globin genes permit the synthesis of viable globin chains, however, and result in structurally abnormal hemoglobins. Such is the case with Hb Wayne, in which a nucleotide deletion in codon 139 changes the termination signal, permitting the translation of an additional five amino acids ([49]). Similarly, Hb Cranston and Hb Tak have elongated chains, probably resulting from the insertion of two bases (AG in codon 145 in Hb Cranston and AC in codon 147 in Hb Tak). The frameshift mutation responsible for Hb Saverne results from deletion of the second base in the codon at position 143. Hb Grady results from an internal frameshift mutation ([52]). Because only three residues are inserted in tandem, a viable globin chain is produced. The nucleotide deletions in Hb Birmingham and Hb Galicia result in the loss of four and two amino acids, respectively, from the ß-chain ([53]). In addition, one amino acid residue is inserted, encoded by a hybrid codon created by the nucleotide deletions.

CROSSOVERS Crossing-over between homologous chromosomes also has the potential for generating abnormal hemoglobins. Normal crossovers that occur at identical loci on the chromosome pairs are called *homologous* or *equal crossovers*. Such a crossover in an individual carrying genes for Hb S (ß6 Val) and Hb Korle-Bu (ß73 Asn) on separate chromosomes is a way to form the gene for Hb C Harlem, carrying both substitutions on the same chromosome ([54]). Other hemoglobins with two abnormal amino acids may have developed in this way. In addition to Hb C Harlem, three others, Hb C Ziguinchor, Hb Arlington Park, and Hb S Travis, are formed from the combination of the common ß6 Glu?Val mutation found in Hb S with another mutation elsewhere in the ß-chain. An alternative hypothesis for the development of such hemoglobins is that they simply represent a second point mutation in a subject already carrying the gene for Hb S. Unequal homologous crossing-over (chromosomal mutation) has the potential for producing more extensive changes in structural genes, such as deletion of a portion of the gene, as well as an addition to it or a fusion of genes at the crossover sites. The hemoglobins with single or multiple deletions probably arose in this way because a minimum of three nucleotide bases must have been deleted. In Hb Lyon, for example, an unequal crossover resulted in deletion of amino acids 17 and 18 (Fig. 39.4) ([55]). Presumably, sufficient homology between nucleotide bases exists in certain regions of the chromosome to allow a slight misalignment during crossover. For example, if the DNA segments of two chromosomes are misaligned in the manner necessary to produce the deletion in Hb Lyon, as many as 12 of 18 nucleotide bases in the crossover region can be identical as compared with the random chance identity of only 25% ([55]). Similarly, correspondence of nine bases has been identified in the crossover producing Hb Gun Hill. The fact that Hb Gun Hill and Hb Leiden appear to have arisen by spontaneous mutation more than once lends support to the idea that such areas of near identity exist and make unequal crossing-over possible.

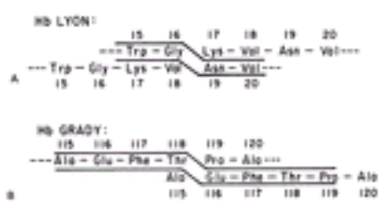

Figure 39.4. Unequal crossovers producing deletions or elongations of globin chains. **A**: Slight misalignment of codons for amino acids 15 through 20 in the ß-chain allows a crossover that eliminates amino acids 17 and 18, forming Hb Lyon. **B**: A similar misalignment, allowing a crossover, in which amino acids a 116, 117, and 118 are duplicated to form Hb Grady. The crossover, of course, occurs in the DNA coding for the amino acids shown rather than in the globin chains themselves.

Unequal crossovers may also add amino acids to the chain, as in the case of Hb Grady (Fig. 39.4) ([49]). In this hemoglobin, the sequence of three amino acids at a116-118, Glu-Phe-Thr, is repeated, resulting in an a-chain elongated by three amino acids. A greater degree of misalignment allows crossing-over between different genes, which results in fusion genes. The Lepore and anti-Lepore hemoglobins must have arisen from unequal crossovers in which the ß and d genes were in alignment (see Chapter 42). Similarly, Hb Kenya results from a crossover between the ß and ? genes. Other genetic mechanisms resulting in thalassemias and the formation of the tetrameric hemoglobins are discussed in Chapter 42.

Patterns of Inheritance

All genes for abnormal ß-chain variants are alleles (i.e., genes that occupy the same genetic locus). Furthermore, the genes producing ß-thalassemias and hereditary persistence of hemoglobin F are allelic with those producing the ß-chain structural variants. Similarly, the genes producing a-chain structural abnormalities and the a-thalassemias are alleles. As would be expected from the different chromosomal location, however, a- and ß-chain abnormalities are not alleles, nor are they linked ([56]).

The abnormal hemoglobin diseases are inherited in a fashion sometimes referred to as *autosomal codominant*. If the properties of the hemoglobin are such that symptoms are produced in the heterozygous state, as in unstable hemoglobin disease, then the pattern of inheritance of the “disease” is that of an autosomal-dominant trait. If, on the other hand, only the homozygous condition is symptomatic, as in sickle cell anemia, a recessive inheritance pattern is observed, and the heterozygous state is called the “trait.” Whether symptomatic or not, the heterozygous state is detectable by means of hemoglobin analysis.

A patient carrying two different abnormal hemoglobin genes is referred to as *doubly heterozygous*. The inheritance pattern in such situations may take one of two forms, depending on whether the two genes are alleles or nonalleles (i.e., whether they affect the same or different polypeptide chains) (Table 39.8). For example, children of a man doubly heterozygous for Hbs S and C, both of which are ß-chain defects and therefore allelic, can inherit only one of these genes. All children, therefore, will be heterozygous for either Hb S or Hb C, but none will be normal, and none will be doubly heterozygous. Nonallelic inheritance, when one gene affects the a-chain and one affects the ß-chain, is quite different. In such pedigrees, children of the doubly heterozygous patient may be normal, or they may inherit either or both abnormal genes.

TABLE 39.8. Allelic and Nonallelic Inheritance Patterns in Doubly Heterozygous Individuals

Patient	Spouse	Expected Proportion of Children		
		Normal	Heterozygous	Doubly Heterozygous
Two genes affecting the same chain (allelic) (e.g., Hbs S and C)	Normal	0	100% (50% S, 50% C)	0
Two genes affecting different chains (nonallelic) (e.g., Hb S, Hopkins II)	Normal	25%	50% (25% S, 25% Hopkins II)	25%

Hb, hemoglobin.

Because of their close linkage, d-chain abnormalities tend to be inherited with a ß-chain abnormality on the same chromosome (cis), but if on opposite chromosomes (trans), they are not inherited together.

Hemoglobin Patterns Associated with Various Genetic Combinations

ß-CHAIN VARIANTS The homozygous state has been described for Hbs S, C, D Punjab, D Iran, E, and O Arab, as well as for several variants not associated with

any clinical or hematologic abnormality. The variant hemoglobin comprises the major hemoglobin fraction, Hb A is absent, and the proportion of Hbs A_2 and F may be increased slightly. In the heterozygous state for ß-chain variants, Hb A predominates, and the abnormal hemoglobin constitutes less than one-half of the total. On average, 38% of the hemoglobin is abnormal, but values range from 35 to 50%. To some extent, variability in the relative amount of the variant hemoglobin can be attributed to the multiplicity of techniques used in the quantitation of hemoglobin fractions. That more fundamental differences are involved is apparent from failure noted when using consistent techniques in a single laboratory to provide more uniform results ([57]). A few variants, such as Hbs Lepore, Vicksburg, and North Shore, are synthesized at a slower rate than Hb A and, as a result, produce a thalassemia phenotype. Other variants are preferentially degraded because of instability. More commonly, the relative amount of the variant hemoglobin is decreased by iron or folate deficiency or by a-thalassemia ([58] , [59]). Because ß ^{A}-chains appear to have a greater affinity for a-chains than variant ß-chains, relatively more Hb A is synthesized when the availability of a-chains is limited ([59]). For this reason, a trimodal distribution of the relative amount of Hb S is observed in sickle cell trait, corresponding with the presence of four, three, or two a-globin genes ([60]). Finally, variability in the rate of subunit assembly related to differences in electrostatic interactions may also contribute to differences in the relative proportion of variant hemoglobins ([61]).

a-CHAIN VARIANTS The expected hemoglobin pattern in subjects with a-chain abnormalities is complicated by the reduplication of the a gene. In theory, one, two, three, or four genes may be affected, corresponding to abnormal hemoglobin proportions of approximately 25%, 50%, 75%, and 100%, respectively. Furthermore, interaction with a-thalassemia is frequent enough to make the interpretation even more complex. A state similar to the “homozygous” state described for ß-chain variants has been reported for Hb J Tongariki ([62]), Hb G Philadelphia ([63]), and Hb Q ([64]); in each, the variant hemoglobin comprises the major hemoglobin fraction, and Hb A is absent. This hemoglobin pattern is explained by the fact that the a gene mutation has occurred on a chromosome with only a single a-globin gene. Affected individuals are, in fact, doubly heterozygous for a-thalassemia and an a-chain structural variant (see Chapter 42). The clinical phenotype is similar to that of Hb H disease ([64]). In most instances, a-chain variants probably have occurred in patients with only one of the four a genes affected. As a result, the proportion of abnormal hemoglobin averages only 23%. Wide variation in the relative concentration of a-chain mutants results from differences in expression of the a_1- and a_2-globin genes. Mutations affecting the a_2 gene are expressed at two- to threefold higher levels than those involving the a_1-globin gene. Because Hb F and A_2 contain a-chains, these minor hemoglobin fractions are also affected when there is a mutant a-chain. Thus, in infants, as many as six hemoglobins may be detected: Hb A, Hb A_2, and Hb F, along with three corresponding abnormal hemoglobins containing the mutant a-chain ([65]).

DOUBLE HETEROZYGOTES The hemoglobin pattern in doubly heterozygous individuals depends on whether the two abnormal genes are alleles. When they are allelic, as in Hb SC disease, no hemoglobin A is produced. The two abnormal hemoglobins are found in the circulation in approximately equal amounts, and in addition, some compensatory increase in Hb F may be noted. In nonallelic double heterozygotes, four variants of adult hemoglobin circulate. Such individuals can synthesize a ^{A}-, a ^{X}-, ß ^{A}-, and ß ^{Y}-chains (X and Y superscripts indicate the mutant chains) to form four hemoglobins: Hb A, Hb X, Hb Y, and Hb XY.

PATHOPHYSIOLOGY

The construction by Perutz and co-workers of a three-dimensional model of the hemoglobin molecule made it possible to visualize the effects of amino acid substitution on molecular function ([66]). The Perutz model demonstrates that the water-free, molecular core is stabilized by nonpolar interactions of the van der Waals type. Amino acids with polar side chains are completely excluded from the interior and are found only on the molecular surface, where they interact with water, rendering the molecule soluble. The heme group is covalently bound at the F8 histidine but also forms approximately 60 contacts with nonpolar amino acids in the heme crevice, thereby contributing to the stability of the tertiary structure. This nonpolar environment makes possible the association of heme iron with oxygen without significant methemoglobin formation. The contacts between the four polypeptide chains in each molecule were also evaluated from the model; two kinds were identified. The larger contact, called a $_1ß_1$, is formed from nonpolar interactions among 34 amino acids; the smaller contact, a $_1ß_2$, involves only 19 amino acids. With oxygenation, the a $_1ß_2$ contact undergoes significant alteration, a movement of approximately 0.7 nm (7.0 Å) taking place, producing so-called heme–heme or subunit interaction.

The *C*-terminal portions of the globin chains are also important in oxygen binding. When oxygen is added to the molecule, the spin state of iron is altered, and the subsequent molecular changes result in the expulsion of the penultimate tyrosine residue from its pocket between the F and H helices ([67]).

On the basis of this general background, one can understand the effects of substitution at certain molecular sites, and one can make a functional classification of the abnormal hemoglobins (Table 39.9). Substitutions at the molecular surface usually are innocuous because they are not likely to affect tertiary structure, heme function, or subunit interaction. Indeed, most of the functionally normal hemoglobin variants are characterized by substitutions at surface positions. Many of them have been discovered by hemoglobin electrophoresis in population screening studies and result, therefore, from substitutions that change the net charge of the molecule. Some surface substitutions result in hemoglobin molecules that tend to polymerize or aggregate. Such mutations likely create a site on the molecular surface that can interact with a complementary site on an adjacent molecule. The aggregating hemoglobins, of which Hb S is the prototype, tend to crystallize or polymerize intracellularly with consequent distortion of cell shape, reduced cell deformability, hemolysis, and impaired microvascular circulation.

TABLE 39.9. Functional Classification of Abnormal Hemoglobins

Functional Abnormality	Location of Substitution	Clinical Abnormality	Example
None	Surface	None	Hb G Philadelphia
Aggregation with reduced solubility	Surface	Hemolytic anemia (homozygous)	Hb S (Chapter 40)
Unstable	Internal, nonpolar residues	Hemolytic anemia (heterozygous)	Hb Köln (Chapter 41)
Increased oxygen affinity	a ^{1}ß ^{2} Contact or ß *C*-terminal	Erythrocytosis	Hb Chesapeake (Chapter 50)
Decreased oxygen affinity	Near heme and a ^{1}ß ^{2} contact	Cyanosis	Hb Kansas (Chapter 49)
Methemoglobinemia	Proximal (F8) or distal (E7) histidine	Cyanosis	Hb M (Chapter 49)
a-Thalassemia phenotype	Variable	Hemolytic anemia (doubly heterozygous)	Hb Constant Spring (Chapter 42)
ß-Thalassemia phenotype	Variable	Hemolytic anemia (doubly heterozygous)	Hb Lepore (Chapter 42)

Hb, hemoglobin.

Several hemoglobin variants exhibit structural instability (see Chapter 41). These hemoglobins have a tendency to precipitate intracellularly, forming inclusion bodies and causing shortened cell survival. Most unstable hemoglobins result from neutral (unchanged) substitutions, affecting internal, nonpolar residues. Many of these substitutions affect residues that contact the heme group; thus, heme-globin bonding is reduced, water may gain access to the heme pocket, and heme may drop out of the molecule. Heme-free normal globin and partially heme-free hemoglobin are, themselves, unstable. Some unstable hemoglobins are characterized by a marked change in conformation of the entire molecule, especially those hemoglobins with deletions (e.g., Hb Gun Hill) and those in which proline has been inserted into a helical segment, a change that disrupts or bends the helix [e.g., Hb Bibba, a136 (H19) Leu?Pro]. The van der Waals forces on which structural stability depends are greatly affected by molecular dimensions; therefore, the altered dimensions of the substituted amino acid can have far-reaching consequences. The insertion of a charged amino acid into the nonpolar core is likely to have devastating effects on stability unless the charge can be stabilized by internal salt formation, as in Hb Wien, or the charged group can be accommodated on the molecular surface, as in hemoglobins Sögn, Riverdale-Bronx, Shepherds Bush, and Ann Arbor.

Many hemoglobins exhibit increased oxygen affinity, which may be of sufficient magnitude to cause erythrocytosis (see Chapter 50). Most of the substitutions producing this abnormality occupy an $_1ß_2$ contact point, where they impair subunit (heme–heme) interaction. Some have been near the C-terminus of the ß-chain, where they interfere with the alkaline Bohr effect, with 2,3-diphosphoglycerate binding, or with the formation of salt bridges that tend to stabilize hemoglobin in the low oxygen affinity (T) state.

Decreased oxygen affinity has been described in many variants, some of which also are unstable (see Chapter 49). In some of these variants, of which Hb Kansas is the best-studied example, the abnormality is severe enough to produce cyanosis. In many others, the abnormality is detected only in the laboratory. The substitution in Hb Kansas [ß102 (G4) Asn?Thr] occurs at a residue that forms part of the $_1ß_2$ contact and that also contacts the heme group. The ß102 Asn residue normally forms a hydrogen bond with a94 Asp when hemoglobin is oxygenated. This bond tends to stabilize the high-affinity (R) form of hemoglobin. Another hemoglobin with a

substitution at the same site, Hb Beth Israel (ß102 Asn?Ser), shares many of the properties of Hb Kansas.

A proclivity to methemoglobin formation is created by substitution of a tyrosine for either the proximal (F8:a87, ß92) or distal (E7:a58, ß63) histidine residue (see Chapter 49). These substitutions allow an ionic bond to form between heme iron and the phenolic oxygen of tyrosine, thereby stabilizing iron in the nonfunctional, ferric state. In Hb M Milwaukee [ß67 (E11) Val?Glu], a similar ionic bond forms with the glutamic carboxyl group. Such heme groups cannot bind oxygen, and affected patients have methemoglobinemia and cyanosis.

Some unstable hemoglobins also have a tendency to form methemoglobin, but they lack some of the clinical, electrophoretic, and spectral properties characteristic of the other hemoglobins M; these hemoglobins include Hbs St. Louis, Freiburg, and I Toulouse.

Several different mechanisms limit the synthesis of structurally abnormal globin chains, thereby producing a thalassemia phenotype (see Chapter 42). The synthesis of hybrid globin chains is roughly intermediate between that of normal ß- and d-chains (in the case of the Lepore hemoglobins) or that of normal ß- and ?-chains (for Hb Kenya). The mRNA generated by chain terminator mutations is less stable than normal mRNA, again upsetting the balance between a- and ß-globin synthesis. Thus, some of the hemoglobins containing elongated a-chains (Hb Constant Spring, Hb Icaria, Hb Seal Rock, and Hb Koya Dora) are characterized by the a-thalassemia clinical phenotype, and Hb Tak, containing an elongated ß-chain, is characterized by the ß-thalassemia phenotype. Mutations activating cryptic splice sites limit normal mRNA synthesis by competing with normal splice sites. The ß-thalassemia phenotype associated with Hb E and Hb Knossos is explained by such mutations. Finally, the thalassemia phenotype may result from instability of the variant globin chain. Such is the case for the ß-chains of Hb Indianapolis and the a-chains of Hb Quong Sze, Hb Suan-Dok, and Hb Petah Tikva.

HEMOGLOBIN C DISORDERS

In Hb C, lysine replaces glutamic acid in the sixth position of the ß-chain. The positive charge resulting from this substitution gives the variant a slow electrophoretic mobility at both an acid and an alkaline pH. Although Hb C cannot be separated from Hb A_2 by electrophoretic techniques, separation is possible with the use of column chromatography. This variant appears to have originated on the west coast of Africa ([68]) where the carrier rate is as high as 25%. Although less convincing than for Hb S, the distribution of Hb C in Africa suggests that it also may have conferred a survival advantage in areas endemic for malaria. Among the Dogon of West Africa, where the gene frequency of Hb C is high and that of Hb S is low, cerebral malaria and other forms of severe malaria are uncommon in those having Hb C ([69]). Although not providing full protection against malaria, Hb C appears to minimize the risk of severe infection. These clinical observations are supported by *in vitro* studies that demonstrate the inability of Hb CC red cells to release merozo-ites by cell lysis at the appropriate stage of parasite development ([70]). The heterozygous state is noted in 2 to 3% of blacks, and homozygous Hb C disease affects approximately 1 in 5000 (Table 39.7) ([42], [45]). As with Hb S, Hb C has been identified in individuals with no known African ancestry ([71]). The $ß^C$ gene can be identified in fetal DNA by using restriction fragment length polymorphisms ([72]) and by sequence-specific oligonucleotide probes ([73]).

Hemoglobin C Trait

The heterozygous state for Hb C (Hb AC) is clinically silent. Although the hemoglobin concentration is within the broad range of normal, the mean for groups of subjects is clearly low. The red cell mass and red cell survival also may be decreased ([74]). Reticulocyte numbers, however, are not increased. The physiologic basis for the apparent failure of appropriate erythropoietic response to shortened cell survival is probably similar to that operative in Hb CC disease. The peripheral blood smear contains moderate numbers (5 to 30%) of target cells. By electrophoretic analysis, 30 to 40% of the hemoglobin is Hb C, and 50 to 60% is Hb A; Hb A_2 (separated chromatographically) is increased slightly. The relative amount of Hb C with coexistent a-thalassemia is less, reflecting the higher affinity of $ß^A$- compared with $ß^C$-globin for limited amounts of a-globin during hemoglobin assembly ([75]). Hb C trait has no adverse consequences for individuals with pernicious anemia, glucose-6-phosphate dehydrogenase deficiency, or hereditary elliptocytosis.

Hemoglobin C Disease

Hemoglobin C disease (Hb CC) is a mild disorder that characteristically is detected through newborn hemoglobinopathy screening programs or during the investigation of an unrelated medical problem ([76]). Growth and development are appropriate, and pregnancy and surgery are well tolerated. Mild intermittent abdominal discomfort, arthralgia, and headaches are noted in some reports, but their relationship to the hemoglobinopathy, if any, is far from clear. The spleen is enlarged in many affected individuals, and spontaneous rupture of the organ has been reported ([77]). Spleen function is unaffected, however, and unusual infectious problems are not observed. As with other hemolytic disorders, cholelithiasis occurs with increased frequency.

Anemia is mild to moderate in severity ([78]). The mean packed cell volume is 33%; individual values often fall within the normal range. Reticulocyte counts are elevated only slightly (2 to 6%). Erythrocyte morphology is strikingly abnormal, with microcytosis, target cells (=90%), occasional spherocytes, and cells distorted by what appear to be crystals of hemoglobin (Fig. 39.5) ([79], [80]). The intracellular crystallization of Hb C is potentiated by the overnight incubation of red cells in 3% sodium chloride. Target cells appear more plump and smaller in diameter than those seen in individuals with liver disease, although their resistance to osmotic lysis is similar to that of other target cells ([79]). A smaller population of osmotically fragile cells (spherocytes) is also present. Red blood cell survival is shortened with evidence of splenic sequestration. Plasma iron turnover and incorporation of iron into red cells are increased. Considering the relative indolence of the hemolytic process, it is surprising that anemia is not fully compensated by a greater erythropoietic effort. This apparent inconsistency is explained by an increase in the oxygen half-saturation pressure of hemoglobin of Hb CC erythrocytes, which, in turn, is explained by an intracellular pH lower than that of normal cells ([81]). The right-shifted oxygen dissociation curve of whole blood permits normal tissue oxygenation in spite of a smaller-than-normal red blood cell mass. The mechanism responsible for the decrease in intraerythrocytic pH is not known.

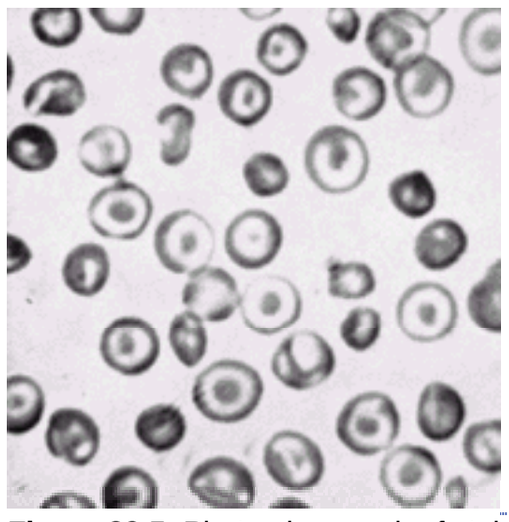

Figure 39.5. Photomicrograph of stained smear from a patient with homozygous hemoglobin C disease. Note the prominence of target cells.

Shortened red cell survival probably is related to the decreased solubility of deoxy-Hb C, a consequence of electrostatic interactions between positively charged ß-6 amino groups and negatively charged groups on adjacent molecules ([79]). When suspended in hypertonic medium, Hb CC cells form intracellular crystals, a process that begins along the membrane ([82]) and is enhanced by deoxygenation ([79]). Intracellular aggregates of hemoglobin limit cell deformability by increasing internal viscosity ([83]), thereby predisposing to fragmentation, spherocyte formation, and splenic sequestration. Although calcium flux and cytosolic calcium levels are normal, the total calcium content of Hb CC red cells is increased ([84]).

Diagnosis rests on the electrophoretic or chromatographic analysis of hemoglobin. The major fraction is Hb C, Hb A is absent, and Hb F is slightly increased.

Relatively more Hb F (to 22%) is present in individuals having coexistent Hb CC disease and a-thalassemia ([85]). Therapy is neither available nor needed.

Hemoglobin SC Disease

The sickling disorder known as *hemoglobin SC disease* results from the inheritance of an Hb S gene from one parent and an Hb C gene from the other. Red cells contain approximately equal amounts of the two hemoglobins. Hb A is absent, and Hb F is normal or slightly increased. The disorder occurs with an approximate frequency of 1 in 833 births among blacks and 1 in 1400 births in Jamaica. In Ghana, Hb SC disease is as prevalent as sickle cell anemia, and in some regions, it affects as many as 25% of the population.

The clinical and laboratory features of Hb SC disease cannot be explained by copolymerization of Hb C with Hb S ([86]). The solubility of mixtures of deoxy-Hb S and Hb C is no different from that of mixtures of Hb S and Hb A ([87]). Differences in the sickling properties of sickle trait cells and Hb SC cells are related to two factors: a higher proportion of Hb S and a higher concentration of hemoglobin in Hb SC cells compared with Hb AS cells ([86], [88]). The 10 to 15% greater proportion of Hb S in Hb SC cells is the result of differences in rates of subunit assembly, which, in turn, are determined by the net surface charges of $ß^{A}$, $ß^{S}$, and $ß^{C}$ ([88]). The higher mean corpuscular hemoglobin concentration of Hb SC cells relates to the opening of normally dormant membrane channels that allow the loss of potassium and water ([89]). The shrunken, dehydrated cells of Hb SC disease may be classified morphologically as xerocytes ([90]).

CLINICAL FEATURES The clinical manifestations of Hb SC disease are similar to, but less severe than, those of sickle cell anemia. Growth, development, and sexual maturation are normal. Symptoms in the first year are rare, and one-fourth of affected individuals remain asymptomatic throughout the first decade of life ([91]). The most common symptom is episodic abdominal or skeletal pain, qualitatively similar to that caused by vasoocclusive events in sickle cell anemia. Moderate enlargement of the spleen is present in approximately two-thirds of children and often persists into adult life. Spleen perfusion is intact, however, and as a result, symptomatic splenic infarction ([92], [93] and [94]) and acute splenic sequestration ([95]) may occur in adults as well as in children. Despite preservation of splenic perfusion, spleen function as assessed by quantitation of intraerythrocytic inclusions (“pits”) is compromised. “Pit counts” are intermediate between normal and those associated with sickle cell anemia. Loss of spleen function is more gradual and occurs at a later age than in sickle cell anemia. Probably because of altered spleen function, the frequency of infections is increased. Fatal pneumococcal septicemia, although well documented ([96]), is less of a risk than is noted in sickle cell anemia ([97]). In contrast to the infectious complications of sickle cell anemia, those of Hb SC disease are characteristically associated with a primary focus, tend not to recur, and respond promptly to therapy ([98], [99]). *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most frequent bacterial isolates, and the respiratory tract is the most common focus. The incidence of bacteremia drops abruptly after 2 years of age, a contrasting pattern to sickle cell anemia, in which incidence rates decline gradually between 2 and 6 years of age. Central nervous system deficits ([100]), proptosis resulting from infarction of the orbital bones ([101]), asymptomatic hematuria, ankle ulceration, priapism, and other complications of sickling are reported but infrequent events. Because of the frequency with which they occur, three complications of Hb SC disease deserve special comment. Proliferative retinopathy is more common and more severe than in sickle cell anemia. Retinal vascular disease has been noted in most Jamaicans with Hb SC disease, and retinitis proliferans affects one-third of this population. Progressive loss of vision may have its onset early in the second decade. Aseptic necrosis of the femoral heads is also seen with greater frequency than in association with sickle cell anemia. An acute chest syndrome, attributed to fat emboli after bone marrow infarction, occurs most commonly during the final months of pregnancy ([102], [103]). The exaggerated vulnerability of individuals with Hb SC disease to these complications is thought to be a function of the higher viscosity of the blood relative to that in sickle cell anemia. The primary determinant of blood viscosity is the concentration of erythrocytes with sickling properties. Moderately severe complications of *in vivo* sickling occur in Hb SC Harlem disease ([104]) and in the Hb SC/a-thalassemia syndrome ([105]). Combined Hb SC disease and hereditary spherocytosis were documented as the cause of recurrent splenic sequestration crises ([106]).

LABORATORY FEATURES Anemia is mild or nonexistent, with only 10% of individuals with Hb SC disease having a hemoglobin concentration less than 10 g per dl ([107], [108]). The mean corpuscular volume may be decreased, and the mean corpuscular hemoglobin concentration may be increased owing to cellular dehydration ([90]). Reticulocytes are modestly increased in number. Blood films contain as many as 50% target cells. Although sickled cells are seen rarely, cells containing hemoglobin “crystals” are noted regularly ([80]). These hyperchromic, shrunken cells are distorted into pyramidal or elongated contours by condensed aggregates of hemoglobin (Fig. 39.6).

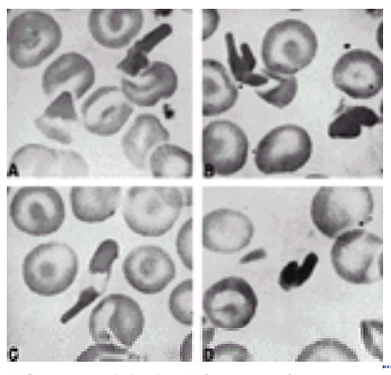

Figure 39.6. Photomicrographs of stained blood smears of patients with hemoglobin (Hb) SC disease. Dark, blunt protuberances and other distortions are produced by condensation of Hb crystals. In frame **C**, the red cell is elongated, and the Hb is concentrated at each end, leaving an Hb-free central area. (From Diggs LW, Bell A. Intraerythrocytic crystals in sickle cell-hemoglobin C disease. Blood 1965;25:218–223. Copyright American Society of Hematology, with permission.)

Hemoglobin C Korle-Bu Disease

The doubly heterozygous state for Hb C and Hb Korle-Bu also has been described ([109]). At 6 months of age, the propositus' hemolysate contained 55% Hb Korle-Bu, 39% Hb C, and 6% Hb F. The moderately severe hemolytic anemia was characterized morphologically by microcytosis and target cells. Anemia was attributed to the acceleration of Hb C crystal formation by Hb Korle-Bu.

HEMOGLOBIN D DISORDERS

Hemoglobin D has an electrophoretic mobility identical to that of Hb S at pH 8.6. It is distinguished from Hb S by its normal solubility, an electrophoretic mobility on agar gel at an acid pH that differs from that of Hb S, and its failure to produce sickling ([110]). The electrophoretic and solubility properties of Hb G are so similar to those of Hb D that the two generally are not differentiated. At least 11 ß-chain variants and 6 a-chain variants have the electrophoretic and solubility characteristics of Hb D and Hb G. Hb D Punjab (also known as *Hb D Los Angeles*) is by far the most common of the Hb D variants, occurring in 1 to 3% of western Indian populations and in small numbers in European communities having colonial ties with India. In North America, the most prevalent variant is Hb G Philadelphia, an a-chain abnormality seen primarily in blacks.

Hemoglobin D Trait

The heterozygous state (Hb AD) is associated with no clinical, hematologic, or physiologic abnormality. Persons with Hb AD usually are identified in screening programs for Hb S. Unless a test for sickling is performed, the condition is mistaken for sickle cell trait.

Hemoglobin D Disease

Homozygous Hb D disease (Hb DD) is characterized by a mild microcytic anemia, poikilocytosis, minimal hemolysis, and mild to moderate splenomegaly ([110], [111]). Hemoglobin electrophoresis shows 95% Hb D and normal amounts of Hb F and Hb A_2. This disorder is easily confused with the doubly heterozygous state for Hb D and $ß^{0}$-thalassemia, in which microcytes and target cells also are prominent ([112]). The two disorders may be differentiated on the basis of red cell indices, levels of Hb A_2 and F, and family studies.

Hemoglobin SD Disease

Of the 16 variants fulfilling the electrophoretic and solubility criteria for Hb D or Hb G, at least 9 have been recognized in association with Hb S ([113], [114]). With but one

exception, the doubly heterozygous states for Hb S and Hb D or Hb G are clinically silent. Hemoglobin D Punjab interacts with Hb S to produce mild hemolytic anemia and symptoms that mimic those of mild sickle cell anemia. The Hb SD Punjab syndrome was first detected in a white man whose case had been previously reported as one of sickle cell anemia. Subsequently, Hb SD Punjab disease was recognized in a number of subjects, with most of African origin ([115]). In each of these subjects, the clinical and hematologic features were those of mild sickle cell anemia.

HEMOGLOBIN E DISORDERS

Hemoglobin E (ß26 Glu?Lys) is the most common hemoglobin variant in Southeast Asia and the second most prevalent hemoglobin variant worldwide ([116]). Of the estimated 30 million persons with Hb E, more than 80% live on the Southeast Asian mainland. Hb E is particularly prevalent at the borders shared by Thailand, Laos, and Cambodia. Its high frequency is attributed to its mild thalassemia phenotype, which may impart positive selection in areas where malaria is endemic. Three chromosome backgrounds containing the $ß^{E}$ gene have been detected, suggesting multiple origins of the $ß^{E}$ mutation ([117]). This theory is supported by the rare occurrence of Hb E in Europeans ([118]). Spread of the variant to North America resulted from the Indochinese resettlement program in the late 1970s ([119]). The incidence of Hb E in refugee children settling in the United States is approximately 19% for those from Cambodia and Laos and 1% for those from Vietnam ([120]). The electrophoretic mobility of Hb E is similar to, although slightly faster than, Hb C at pH 8.6. It can be differentiated from Hb C by performing agar gel electrophoresis at an acid pH and by its instability on exposure to oxidants ([121]).

The Hb E syndromes are associated with red cell microcytosis and hypochromia. The doubly heterozygous state for Hb E and ß-thalassemia is characterized clinically by thalassemia major (see Chapter 42), a situation different from other compound heterozygous states for structural ß-chain variants and ß-thalassemia. The thalassemic phenotype of the $ß^{E}$ gene is the result of the activation of a cryptic donor splice site by the codon 26 nucleotide mutation ([122]). The new splice site competes with the normal donor site at the beginning of the first intron, thereby reducing $ß^{E}$-mRNA generation ([123] , [124]). Decreased synthesis may be compounded by $ß^{E}$-mRNA instability ([125] , [126]).

Hemoglobin E Trait

The heterozygous state (Hb AE), although clinically silent, is associated with microcytosis (mean corpuscular volume, 65 fl), slight erythrocytosis, and target erythrocytes ([120]). No anemia or reticulocytosis is noted. Hemoglobin electrophoresis reveals 20 to 35% Hb E, less than the relative amount of Hbs S, C, and D usually found in individuals heterozygous for these variants. The relative proportion of Hb E is reduced further by coexistent a-thalassemia and iron deficiency ([126]).

Hemoglobin E Disease

Homozygosity for Hb E (Hb EE) is characterized by prominent microcytosis (mean corpuscular volume, 55 to 65 fl) and significant morphologic alterations (target cells, leptocytosis) but little or no anemia or reticulocytosis. No physical abnormalities are noted other than possible slight splenomegaly ([120] , [127]). Hb E accounts for 85 to 95% of the hemoglobin; Hb F is normal or is increased only slightly. Red cell hypochromia is due to defective $ß^{E}$-globin synthesis resulting from $ß^{E}$-mRNA instability ([128]). Red cell survival is reduced slightly, and osmotic fragility is decreased. Shortened cell survival may result, in part, from instability of Hb E, a property attributed to the tendency for $ß^{E}$-dimers to dissociate into monomers, thereby exposing reactive SH groups ([121]).

Sickle Cell Anemia and Other Sickling Syndromes

This chapter discusses hemoglobin (Hb) variants that cause alterations in erythrocyte morphology and rheology. Three recent texts offer extensive information and indicate the rapid expansion of information about sickle cell disease ([1], [2] and [3]). Because of their prevalence and worldwide distribution, the disorders resulting from sickle Hb (Hb S) are of enormous clinical importance. Sickle cell anemia alone is the most common heritable hematologic disease affecting humans.

Long before they were recognized in the Western hemisphere, sickling disorders were known in Africa by onomatopoeic names denoting the recurrent, unrelenting, and painful nature of the crises ([4], [5]). Although in one Ghanaian family, symptoms of sickle cell anemia could be traced to the year 1670 ([6]), disorders of Hb synthesis went unrecognized by the scientific community until 1910, when Herrick, a Chicago cardiologist, recorded observations made during investigation of anemia in a 20-year-old West Indian student ([7]). The fascinating account of the events that followed and of the individuals who contributed to the still unfolding story of sickle cell anemia is presented in detail by Conley ([8]). Herrick's report led not only to the recognition of hundreds of abnormalities of Hb synthesis, but also to a series of remarkable scientific advances involving protein chemistry, cell biology, physiology, and genetics. In 1949, Linus Pauling and collaborators demonstrated for the first time that an abnormal protein could be causally linked to a disease ([9]). A historical review of all of the major developments in the current understanding of sickle cell disease has recently been published by Sergeant ([10]).

The genetic basis for Hb synthesis is discussed in Chapter 5 and Chapter 39. Each major hemoglobinopathy occurs in both a heterozygous and a homozygous form. In the heterozygous state, red cells contain both normal adult Hb (Hb A) and the variant Hb. Because they rarely have phenotypic expressions of clinical significance, heterozygotes are said to have the trait for that abnormality, for example, sickle cell trait. In the homozygous state, Hb A is totally lacking, and clinical manifestations are of variable severity; individuals so affected have sickle cell anemia. In addition, disease may result from the combination of two variant hemoglobins or from a variant Hb and an interacting thalassemia gene. These doubly heterozygous states are designated by both aberrant gene products, such as Hb SC disease, Hb S/ß-thalassemia. The term *sickle cell disease* is used in a generic sense to refer to all of the sickling syndromes.

HEMOGLOBIN S: PREVALENCE AND GEOGRAPHIC DISTRIBUTION

Hb S, so called because of the sickle shape it imparts to deoxygenated red cells, is responsible for a wide spectrum of disorders that vary with respect to degree of anemia, frequency of crises, extent of organ injury, and duration of survival. Some of the sickling syndromes lack significant pathologic potential, but they are easily confused with clinically aggressive disorders on the basis of laboratory evaluation; consequently, precision in diagnosis is essential both to proper clinical management and to meaningful genetic counseling.

The highest prevalence of Hb S is in tropical Africa and among blacks in countries that participated in the slave trade. It occurs with lower frequency in the Mediterranean basin, Saudi Arabia, and parts of India. Results of studies of DNA polymorphisms linked to the $ß^S$ gene suggest that it arose from three independent mutations in tropical Africa (Fig. 40.1) ([11], [12]). The most common $ß^S$ chromosome is found in Benin (neighboring Nigeria) and central West Africa. A second haplotype is prevalent in Senegal and the African West Coast, and a third haplotype is seen in the Central African Republic (Bantu-speaking Africa). The same three haplotypes are associated with the $ß^S$ gene in black Americans and Jamaicans ([13]). The Hb S gene in the Eastern Province of Saudi Arabia and in Central India is associated with a different DNA structure not encountered in Africa and probably represents a fourth independent occurrence of the sickle cell mutation ([12]). Only the Benin and Senegal haplotypes are prevalent among North Africans, Greeks, and Italians, suggesting that the $ß^S$ mutation spread to the Mediterranean basin from West Africa ([13], [14]). In some parts of Africa, as much as 45% of the population has sickle cell trait. In the United States ([15], [16] and [17]), Latin America, and the Caribbean ([2], [18]), approximately 8% of blacks carry the sickle gene. In the United States, the expected incidence of sickle cell anemia (Hb SS) at birth is 1 in 625. The validity of this estimate is borne out by prospective studies of the Hb phenotypes of black infants at birth ([19], [20]). Taking into account increased mortality, approximately 70,000 cases of sickle cell disease would be expected among black Americans in the United States.

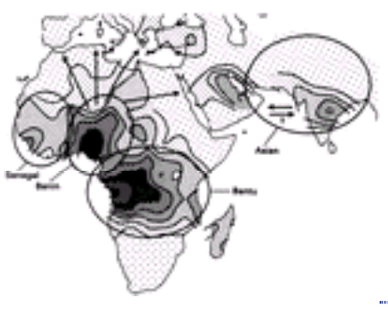

Figure 40.1. Geographic dispersion of $ß^S$-globin gene haplotypes. (From Ragusa A, Lombardo M, Sortino G, et al. Beta S gene in Sicily is in linkage disequilibrium with the Benin haplotype: implications for gene flow. Am J Hematol 1988;27:139–141, with permission.)

Before this century, most individuals with sickle cell anemia died before the age of reproduction. Without selective advantage to Hb S trait, the sickle gene would have been eliminated. The most widely accepted theory to account for the remarkable stability of the sickle gene in Africa is that of balanced polymorphism ([21], [22]). Recognition that sickle cell trait has its highest prevalence in areas hyperendemic for malaria suggested that Hb S afforded selective protection against lethal forms of

malaria. Although there is a great deal of clinical evidence to support this concept ([21]), the mechanism affording selective advantage remains conjectural. Preferential sickling of parasitized cells has been observed in the blood of children with sickle cell trait and malaria ([23], [24]). Selective removal of sickled cells from the circulation probably reduces the degree of parasitemia and substantially limits the infectious process.

PATHOPHYSIOLOGY

The sickle mutation substitutes thymine for adenine in the sixth codon of the ß gene (GAG?GTG), thereby encoding valine instead of glutamine in the sixth position of the ß-chain. This ostensibly minor change in structure is responsible for profound changes in molecular stability and solubility. The tendency of deoxygenated Hb S to undergo polymerization underlies the innumerable expressions of the sickling syndromes ([25]).

Molecular Basis of Sickling

An abundance of information indicates that the distortion of cells containing Hb S is the result of Hb polymerization ([26]). Cell-free solutions of Hb S undergo a pronounced decrease in solubility and an increase in viscosity when deoxygenated ([27]). Deoxy Hb S polymers in the cell exist in a spectrum of forms from scattered individual fibers to highly ordered fiber aggregates that essentially fill the cell and distort it into the classic sickle shape or other elongated forms. It is the presence of polymer that causes the reversible, oxygen-linked changes in the rheologic properties of the sickle erythrocyte that characterizes the disease. On oxygenation, these polymers dissolve or “melt,” and the sickle erythrocyte loses most of those pathologic properties caused by the presence of polymer ([25]). If the concentration of Hb S in such solutions or in the red cell approaches 30 g/dl, a semisolid gel forms.

STRUCTURE OF HEMOGLOBIN S POLYMER The structure of the deoxygenated Hb S polymer has been deduced from studies involving the use of electron microscopy (Fig. 40.2) ([28], [29]) and x-ray diffraction ([29], [30]). The polymerized Hb fiber is a helical structure with 14 Hb tetramers in each layer; these form a central core of four strands and an outer sheath of ten additional strands with a diameter of approximately 21 nm ([29], [31], [32]). The points of contact between molecules along the longitudinal axis of the chains and laterally between chains have been determined by x-ray diffraction ([33]) and by the gelling characteristics of mixtures of deoxy Hb S and variant ([27], [34], [35]) or hybrid ([36]) hemoglobins. Only one of the two ß6 Val residues appears to participate in the intermolecular contact; it fits into a hydrophobic pocket formed by a ß ^{85} Phe and a ß ^{88} Leu residue on a ß-chain of a nearby Hb S tetramer ([37]). Bonds between contact points include both hydrophobic ([38]) and electrostatic ([27]) forces.

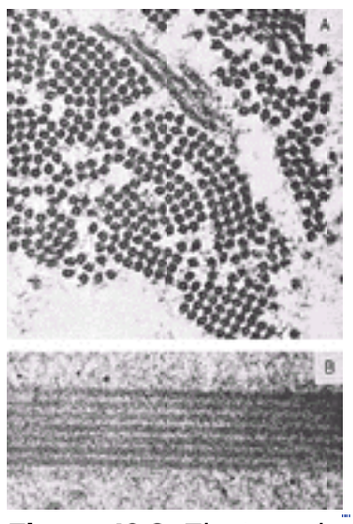

Figure 40.2. Electron photomicrographs of cell-free pellets of deoxy hemoglobin (Hb) S. **A:** Transverse section through fibers of polymerized Hb S (×97,000). **B:** Longitudinal section through same (×102,000). PHYSIOLOGIC DETERMINANTS OF POLYMERIZATION The equilibrium of Hb S between its liquid and solid phases is determined by four variables: oxygen tension, Hb S concentration, temperature, and hemoglobins other than Hb S.

Oxygen The most important physiologic determinant of Hb S gelation is oxygen. Polymerization occurs only with deoxygenation. Liganded states of the molecule (oxy, met, and carbonmonoxy Hb S) do not aggregate and, in fact, are excluded from the polymer ([37], [39]). With deoxygenation, the oxygen affinity of Hb S falls ([40]), thereby stabilizing the deoxy state. The effects of 2,3-diphosphoglycerate and pH on gelation are mediated primarily through their influence on the oxygen affinity of Hb. An increase in 2,3-diphosphoglycerate decreases the affinity of Hb S for oxygen and enhances gelation ([41]). Likewise, a decrease in pH decreases oxygen affinity via the Bohr effect, thereby increasing the amount of deoxy Hb S at any given oxygen tension.

Hemoglobin S Concentration There is a positive correlation between Hb S concentration and gelation ([39]). Under standard laboratory conditions, gelation occurs as the concentration of deoxy Hb S is raised above 20.8 g/dl ([42]). Because the mean Hb concentration of the red cell is normally greater than 30 g/dl, intracellular gelation of Hb S is a predictable consequence of deoxygenation. The concentration dependence of sickling provides the basis for both the minimum gelling concentration assay ([39]) and equilibrium solubility assays ([43]).

Temperature Gels of deoxy Hb S dissolve when cooled below a critical temperature. Because the temperatures required for melting are well below the physiologic range, the significance of this phenomenon is limited to the laboratory study of gelation. The gradual heating of cold, concentrated solutions of deoxy Hb S permits study of the kinetics of polymerization ([44], [45]).

Other Hemoglobins The influence of other hemoglobins on Hb S polymerization is variable. Both Hb A and Hb F have an inhibitory effect on gelation ([46]). When deoxygenated, these hemoglobins enter the sickle polymer less readily than does deoxy Hb S, thereby retarding gelation by a dilutional effect ([27]). Because there are 20 surface amino acid differences between ß ^{S}- and ?-chains and only a single residue difference between ß ^{S}- and ß ^{A}-chains, it is not surprising that Hb F is excluded from Hb S polymers to a greater extent than Hb A. Differences in the relative amounts of the G? and A? fractions of Hb F do not affect the polymerization of mixtures of Hb F and Hb S ([46]). Other hemoglobins interfere with polymer formation less well. By measuring the minimum gelling concentration of various mixtures of hemoglobins, the extent of interaction can be quantitated. Deoxy Hb S molecules copolymerize most effectively with other Hb S molecules and, in decreasing order, with Hb C, D, O Arab, A, J, and F ([34], [39], [47]). These *in vitro* observations predict the clinical severity of disorders involving these variants ([48]). In contrast, the doubly heterozygous state for Hb S and hereditary persistence of fetal Hb (HPFH), in which red cells contain approximately 70% Hb S and 30% Hb F, is not associated with clinical disease ([49], [50], [51] and [52]). It is now possible to correlate the estimated level of polymerization with clinical severity in untreated patients ([53]). It is also possible to estimate how much inhibition of polymerization would result from therapeutic interventions such as altering Hb S solubility, which might be accomplished by modifying polymer structure, lowering mean corpuscular Hb concentration (MCHC), or elevating the fraction of Hb F ([54]). Analysis of Hb S polymerization allows the design of new therapies and enhances interpretation of the pathophysiology of the various sickle cell syndromes ([25]).

KINETICS OF SICKLING Sickling is not an instantaneous phenomenon. Analysis of the kinetics of sickling suggests that molecular polymerization occurs in stages. The delay period between deoxygenation and polymerization is attributed to nucleation processes, in which Hb S tetramers form small aggregates without modification of internal viscosity. When these aggregates reach a critical mass, a rapid addition of free Hb units occurs to form fibers that then undergo alignment to form a tactoid ([55], [56]). A red cell spends approximately 1 to 2 seconds in the arterial circulation and 1 second in the microcirculation; it then requires approximately 15 seconds to return to the lungs ([57]). Thus, if the delay time is longer than 15 seconds, the cell can return to the lungs and be reoxygenated before any significant polymerization has begun. If the delay time is between 1 and 15 seconds, gelation occurs while the cell is in the venous circulation. Sickling in the large veins does not produce vasoocclusion, but the cell membrane may be damaged, resulting in a loss of water and a shorter delay time in subsequent trips through the circulation. If the delay time is less than approximately 1 second, gelation can occur while the cell is in one of the narrow vessels of the microcirculation. Because the cell is much less deformable, it may not be able to “squeeze” through and may become transiently or permanently stuck ([57]). Under physiologic conditions, the delay between complete deoxygenation and erythrocyte sickling is approximately 2 seconds, but it is strongly influenced by changes in Hb concentration, the presence of hemoglobins other than Hb S, temperature, pH, and 2,3-diphosphoglycerate ([44], [58]). Of particular clinical significance is the MCHC. Small increments in deoxyhemoglobin concentration (e.g., those that occur with loss of cell water) profoundly shorten the delay time ([55], [59]), thereby potentiating sickling.

Cellular Pathology

Red cells containing Hb S acquire the sickle-shape deformity on deoxygenation because of the intracellular polymerization of Hb. This phenomenon may be

monitored directly with light or scanning electron microscopy (Fig. 40.3) ([26] , [60]) and indirectly by measuring changes in viscosity or filterability ([61]). Electron micrographs demonstrate filaments in parallel array, some of which extend into the protuberances of sickled cells ([62] , [63]). The membrane is secondarily involved by repeated or prolonged sickling. Irreparable damage to membrane structures obviates resumption of the normal disc shape despite solubilization of intracellular polymers and thus produces the irreversibly sickled cell (ISC) ([64]). Both Hb polymerization and membrane injury contribute to the pathophysiology of the sickling syndromes.

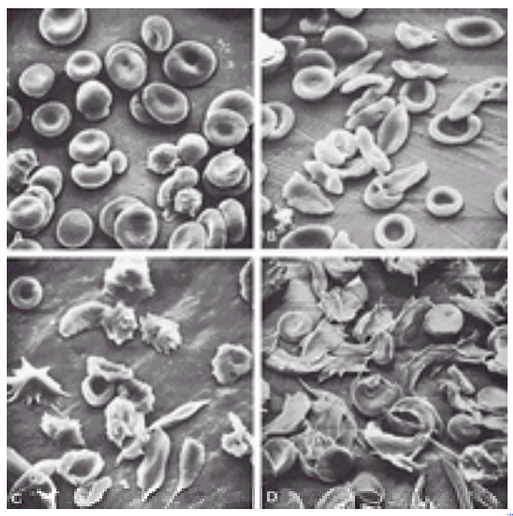

Figure 40.3. Erythrocytes from a patient with sickle cell anemia examined with scanning electron microscopy. **A:** Oxygenated blood. Red cells appear normal except for one microspherocyte. Three leukocytes are evident in the field. **B:** Oxygenated irreversibly sickled cells are smooth in texture and outline but are ovoid or boatlike in shape. **C:** Partial deoxygenation causes the cells to assume bizarre shapes with spikes, spicules, and filaments that protrude from the cells. **D:** More complete deoxygenation causes the cells to assume sickled shapes with longitudinal surface striations.

RED CELL SICKLING Deoxygenation is associated with a continuum of cellular changes. Hb polymers rapidly expand to command large domains that distort cells into elongated crescents. Long, thin filaments extend from the body of cells exposed to prolonged deoxygenation. When quantitated by ^{13}C nuclear magnetic resonance spectroscopy, polymerized Hb S can be detected in significant amounts, even in morphologically normal cells maintained at oxygen saturations in excess of 95%. This observation is attributed to the nonideal nature of Hb solutions, in which a high concentration of oxy Hb S crowds deoxy Hb S molecules out of solution ([65]). Only with deoxygenation is the growth of polymers sufficient to cause cellular distortion ([66]). The presence of polymerized Hb at arterial oxygen saturations suggests that abnormal rheology is not restricted to the capillary and venous side of the circulation. Because cellular flexibility is governed by the amount and alignment of intracellular polymer, some cells with polymer but no deformation may have difficulty in traversing the constriction of precapillary arterioles ([65]). The sickling of erythrocytes containing Hb S is induced by the same physicochemical perturbations as those responsible for the gelation of Hb S solutions. Arterial blood, having a high oxygen saturation, contains fewer sickle cells than blood collected from various sites in the venous circulation ([67]). The oxygen affinity of blood from subjects with sickle cell anemia is abnormally sensitive to pH fluctuations in the physiologic range. A decrease in pH from 7.4 to 7.2 is attended by twice the normal decrement in oxygen affinity and a corresponding excess of deoxygenated Hb ([68] , [69]). The pathophysiologic significance of the increased Bohr effect is underscored by the observation that the intracellular pH of fresh blood from subjects with sickle cell anemia is approximately 0.15 pH unit lower than that of normal blood ([70]). Predictably, sickling is potentiated by increasing the intracellular concentration of Hb S ([68]). Red cells containing relatively more Hb F sickle less readily ([47] , [71]) and survive longer than cells containing little Hb F. Some of these predisposing factors are interrelated. In contrast to normal red cells, cells containing Hb S become more dense when deoxygenated, particularly at reduced pH ([72]).

MEMBRANE ALTERATIONS Red cell sickling is associated with reversible membrane changes. With repeated cycles of sickling and unsickling, aberrations in membrane function and structure become increasingly pronounced, culminating in fixation of the membrane in the sickled configuration ([73]).

Reversibly and Irreversibly Sickled Cells When sickled, red cells leak K^+ and gain Na^+, a phenomenon previously ascribed to partial failure of the Na^+, K^+-adenosine triphosphatase (ATPase) pump ([74] , [75]). Because the net flux of Na^+ and K^+ is approximately equal in reversibly sickled cells, no change occurs in intracellular hydration or Hb concentration ([76] , [77]). The intracellular concentration of Ca^{2+} is increased during sickling, owing in part to increased membrane permeability for Ca^{2+} and possibly in part to impairment of the ATPase-dependent Ca^{2+} pump ([78] , [79]). From 5 to 50% of cells from individuals with sickle cell anemia are ISCs, permanently stabilized in their abnormal crescent or oval shape ([80] , [81]). These cells fail to assume a normal shape even with vigorous reoxygenation. Their low mean cell volume (MCV) and high MCHC reflect a shrunken, dehydrated state. They may be quantitated morphologically or indirectly by measurements of deformability or density ([82]). The number of ISCs is relatively constant for a given individual, but it varies considerably from person to person ([83]). Results of cohort labeling studies of reticulocytes suggest that ISCs are formed shortly after release from the marrow and thereafter are rapidly removed from the circulation ([80]). ISCs contain substantially less Hb F than reversibly sickled cells ([80] , [84]), and their endowment of Hb F appears to be the primary determinant of irreversible sickling. The physicochemical basis for irreversible membrane alterations has been the focus of intense research ([79] , [85] , [86]). The importance of membrane protein alterations is apparent from the demonstration that Hb-free ISC ghosts and membrane skeletons prepared from ISC ghosts retain the sickled shape ([87]). Fixation of membrane skeletons in a sickled form is thought to result from abnormal interactions between cytoskeletal proteins rather than from cross-linking phenomena. A functional abnormality in ankyrin is suggested by inefficient binding of normal spectrin by the ankyrin of inside-out vesicles prepared from sickle red cells; a reduced ability of protein 3 to bind ankyrin has also been found ([88]). Oxidation of membrane protein thiol has been proposed to explain increased microvesiculation of sickle red cells during thermal stress ([89]). In the ISC, the quantity of membrane lipids is decreased consistent with membrane loss, probably as a result of vesiculation ([90] , [91]). The normal phospholipid organization of the red cell membrane is asymmetric and involves a dynamic equilibrium: Phosphatidyl choline and sphingomyelin predominate in the outer monolayer, and phosphatidyl ethanolamine and phosphatidyl serine (PS) are primary in the inner monolayer. On deoxygenation of Hb S, polymerization leads to mechanical stress on the membrane as well as uncoupling of the bilayer from the membrane skeleton. Ultimately, membrane lipid organization is altered, resulting in negatively charged PS on the red cell surface. This phospholipid may initiate blood clotting by enhancing the conversion by prothrombinase of prothrombin to thrombin as suggested by the findings of increased plasma levels of fragment 1.2 in the circulation ([92] , [93]). Vesicles that are lost from the red cell membrane may also contribute significant exposure of PS on their surfaces ([91]). Sickle red cells contain and spontaneously generate increased amounts of malonyldialdehyde ([94] , [95]). This by-product of lipid peroxidation is of particular interest in that it has the potential to form cross-links between proteins, aminophospholipids, or both ([94] , [96]).

Dehydration The ISC exhibits several perturbations in cation homeostasis, related at least in part to physical distortion of the cation permeability barriers by bundles of Hb S polymers ([97]). The amount of intracellular Ca^{2+} is increased as much as fourfold ([98] , [99] and [100]). Two pathways play a major role in formation of dense cells: the Ca^{2+}-activated K^+ channel (Gardos pathway) and the K-Cl cotransport channel. The transient increase in free Ca^{2+} induced by red cell deoxygenation leads to activation of the Gardos pathway and subsequent activation of K-Cl cotransport with further K^+ loss. In ISCs, unlike reversibly sickled cells, K^+ loss exceeds Na^+ gain, and there is overall loss of cell water and increased concentration of intracellular Hb. These changes cannot be attributed to metabolic exhaustion because the level of adenosine triphosphate (ATP) is normal or increased ([101]), and Na-K and Ca-ATPase activities also are increased ([100]). Although total cellular Ca^{2+} is increased, it is compartmentalized in cytoplasmic vesicles, resulting in normal levels of free cytoplasmic Ca^{2+} and prevention of dysfunction of the inner membrane ([102] , [103] and [104]). The mechanisms of sickle red cell dehydration and potential therapeutic strategies for its prevention have been reviewed in three recent articles ([105] , [106] and [107]). The rate of dehydration of sickle cells is uneven, and those destined to become ISCs dehydrate by a fast-track process ([108] , [109]). Reversible permeability pathways for Na^+, K^+, Mg^{2+}, and Ca^{2+}, sometimes referred to as the *sickling-induced pathway*, are the result of ionic shifts affecting cell hydration; the direct effect on Ca^{2+} permeabilization activates the Gardos channel, which triggers the loss of KCl and water and is associated with red cell acidification ([106]). In reticulocytes and young red cells with high expression of K-Cl cotransporter, acidification results in further KCl loss, further acidification, and K-Cl cotransport stimulation. The combined activity of the Gardos channel and K-Cl cotransport leads to rapid dehydration of a relatively young subpopulation of sickle cells, many with the characteristics of ISCs ([106]). The antimycotic agent clotrimazole is an inhibitor of the Ca^{2+}-activated K^+ channel and prevents dehydration of sickle cells *in vitro* and *in vivo* ([110]). Red cell magnesium is abnormally reduced in sickle erythrocytes, and increasing cell magnesium produces a marked decrease in the activity of K-Cl cotransport ([107]). A study carried out in ten adult patients with Hb SS demonstrated that a 4-week course of oral magnesium supplementation (using magnesium pidolate) resulted in increased red cell Mg^{2+} and K^+ concentrations, a reduction in K-Cl cotransport activity, and a decrease in the number of dense SS erythrocytes ([111]). A subsequent study on 20 patients with Hb SS disease involved the administration of magnesium pidolate for 6 months ([112]). In this unblinded study, a reduction in the number of pain crises was noted during the period of magnesium supplementation. In both of the above studies, a significant decrease in red cell

density was noted. This inhibition of the Gardos channel is mediated by metabolites without the imidazole ring ([107]). Recently, an analog of clotrimazole with greater potency and fewer side effects has been shown to prevent dehydration of red cells in a transgenic sickle mouse model ([113]). Still another approach to prevention of red cell dehydration has been to inhibit chloride conductance with a reversible anion conductance inhibitor ([114]). The sickling-induced permeability pathway may be affected by transport inhibitors, including dipyridamole at pharmacologic levels ([115]). Regulation of the K-Cl cotransport activity involves phosphorylation and dephosphorylation reactions in membrane-bound serine/threonine kinases and phosphatases ([107]). Transferrin receptor-positive reticulocytes, which have a very low content of Hb F, have much greater K-Cl cotransport activity and may reach a state of intermediate dehydration. Subsequent dehydration is mediated by Hb S polymerization, sickling, and activation of the Gardos channel ([116], [117]).

Adhesion Sickle red cells demonstrate abnormal adherence to vascular endothelium ([118], [119]), monocytes ([120]), macrophages ([95]), and model lipid membranes ([121]). Compared with normal red cells, sickle cells are two to ten times more adherent to bovine ([121], [122]) and human ([118], [123]) endothelial cells. This property of sickle blood is imparted by deformable sickle cells rather than by ISCs ([119], [122], [124]), perhaps because rigid cells are unable to form multiple surface contacts with endothelial cells. The importance of this observation in regard to the pathophysiology of vasoocclusive events is suggested by the demonstration that red cell deformability has a strong positive correlation with the frequency and severity of pain crises ([125], [126]). Individuals who generate a relatively greater number of ISCs have decreased red cell deformability and milder disease compared with those whose red cells are more deformable. Presumably, rigid ISCs are unable to enter capillaries or to adhere tenaciously to capillary endothelium, whereas deformable sickle cells enter capillaries readily, adhere to the endothelium, and compromise blood flow. When examined under dynamic conditions, red cell adherence is noted primarily at sites of turbulence rather than where flow is laminar ([127]). Several mechanisms for increased adherence have been proposed ([128]). The repellent force of the red cell is thought to reside in negatively charged sialic acid residues that are homogeneously distributed over the surface of the membrane. The distribution of negative charges on membranes of sickle red cells is patchy and interrupted ([118]), creating surface areas that may have an electrostatic attraction for other cells. Alternatively, abnormal adherence may be a derivative of cellular dehydration. Dehydration of normal red cells induces an abnormality of negative charge distribution similar to that of sickle red cells ([129]). Excessive autooxidation of sickle red cells is yet another possible mechanism for increased adherence. Induction of excessive free radical generation in normal red cells is associated with increased adherence under conditions that allow the influx of calcium ([130]). Conditions and factors that promote the expression of adhesion receptors by endothelial cells include hypoxia, thrombin, tissue necrosis factor, platelet-activated factor, and interleukin-1 ([131]). These conditions/factors also cause increased adhesion of sickle cells to endothelium *in vitro*. Thrombospondin may be an important plasma adhesogen because of its ability to bridge CD36 expressed on sickle stress reticulocytes ([132], [133]). Thrombospondin-mediated adherence occurs under flow conditions with both microvascular and large-vessel endothelial cell assays. Thrombospondin levels are elevated in sickle cell patients during crisis ([134], [135]), perhaps as a result of platelet activation. Fibronectin may link endothelial receptors with the fibronectin receptor $a_4ß_1$ (very late antigen-4) expressed on sickle reticulocytes ([136], [137]). Ultralarge forms of von Willebrand factor are postulated to promote adherence through nonreceptor mechanisms such as by binding with co-clustered hemichrome–band 3 aggregates on sickle membranes ([132], [138], [139]). It is possible that different mechanisms predominate under various circumstances or in different parts of the circulation. Coagulopathy might cause thrombospondin release and precipitate vasoocclusion in microvessels, and dehydration-induced vasopressin elevation might stimulate von Willebrand factor release and precipitate vasoocclusion in large postcapillary venules. The increased sickle cell adherence to injured endothelium, the role of platelet and leukocyte receptors, and the possible stimulation of nitric oxide (NO) production by adherent red cells all require further evaluation. Recently, circulating activated endothelial cells have been assayed using immunohistochemical examination of buffy coat smears with anti–endothelial cell antibodies ([140]). Patients with sickle cell anemia who had acute painful episodes had higher levels of circulating endothelial cells than patients with no recent events, who, in turn, had higher levels than controls. Circulating endothelial cells were predominantly microvascular ($CD36^+$) and expressed markers of endothelial cell activation [intercellular adhesion molecule-1, vascular cell adhesion molecule (VCAM)-1, E-selectin, and P-selectin]. This study suggested that vascular endothelium is activated in patients with sickle cell anemia and that adhesion proteins on the cells may have a role in the vascular pathology. Using an animal model that uses the *ex vivo* rat mesocecum venules and human sickle cells, two monoclonal antibodies were demonstrated to inhibit interactions between sickle cells and endothelial cells by blocking ligand binding to integrin $a_vß_3$, a molecule that binds to several adhesion proteins, including von Willebrand factor and thrombospondin ([131]). P-selectin may also mediate SS red cell adhesion to endothelial cells *in vitro* ([141]). Macrophages have an increased affinity for sickle red cells. Excess immunoglobulin (Ig) G is found on the surface of sickle red cells, which are ingested by macrophages as readily as are red cells giving a positive antiglobulin test ([95], [142]). Increased phagocytosis is inhibited partially by blockade of macrophage Fc receptors with human IgG or its Fc fragment. A possible recognition signal is co-clustering of denatured Hb with band 3, which is followed by accumulation of IgG and complement, leading to recognition by macrophage receptors ([143], [144]). Both erythrophagocytosis and increased cell-associated IgG are more evident with ISCs than with less dense sickle cells. A common mechanism likely underlies many of the membrane lesions. Because of the multiplicity of effects that calcium accumulation may have on cellular properties, several pathways have been suggested for the putative influence of calcium on ISC formation ([77], [145], [146]). Hemichromes (ferric derivatives resulting from oxidative Hb denaturation) co-cluster with band 3 and Ig on the membranes of sickle cells ([147]). Free heme and nonheme iron such as free iron are also on the membrane surface. The pathologic deposition of iron on the membrane catalyzes the formation of highly reactive hydroxyl radicals and promotes oxidative reactions ([148]). A particularly comprehensive hypothesis argues that excessive red cell autooxidation initiates a cascade of interrelated events causing cytoskeletal dysfunction, perturbation of the lipid bilayer, and disruption of normal mechanisms for cation hemostasis ([96], [149], [150] and [151]). The hypothesis is based in part on the observation that sickle cells spontaneously generate twice as much superoxide, peroxide, and hydroxyl radicals as normal cells ([151]). Excessive free radical generation is explained in part by membrane-bound heme ([149], [152]), nonheme iron ([153]), and the release of hemin from denatured Hb S ([150], [154]). It may be potentiated by impaired *in vitro* antioxidant defense, as manifested by decreased levels of vitamin E in both plasma and red cells ([155], [156]). Although exposure of normal red cells to oxidants produces many of the membrane lesions responsible for ISC formation, it is not clear that free radical generation by sickle cells exceeds the capacity of their protective mechanisms.

RHEOLOGY OF SICKLE CELLS The clinical features of sickle cell anemia are directly or indirectly related to increased blood viscosity. The viscosity of plasma in sickle cell anemia is slightly higher than that of plasma from normal subjects as a result of higher total protein concentration in plasma ([157]). However, the viscosity of oxygenated sickle blood is lower than that of normal blood at all shear rates, mainly as a result of lower hematocrit values ([157], [158]). The viscosity of a sickle blood sample increases with decreased oxygen saturation, primarily because of reduced cellular deformability ([157], [159]). When the cell concentration of sickle blood is raised *in vitro* to 45%, viscosity becomes higher than that of normal blood. The extent to which membrane rigidity ([61], [160], [161]), Hb polymerization ([162]), and increased intracellular Hb concentration ([80], [158]) contributes to altered blood flow depends in part on the method used to study the rheologic and mechanical properties of sickle red cells. Reduction in the cellular deformability of oxygenated sickle red cells has been demonstrated by increased viscosity of sickle blood (viscometry) ([158]), decreased filtration of dilute cell suspensions through narrow pores ([61], [163]), decreased ability of cells to undergo deformation in shear fields (ektacytometry) ([145], [164]), and increased aspiration pressures needed to induce entry of cells into micropipettes ([160], [165], [166]). Cellular dehydration, as well as the resulting increase in cytoplasmic viscosity, is a major determinant of abnormal rheologic behavior of oxygenated sickled red cells ([145]). Sickled red cell membranes demonstrate extensional rigidity and persistent deformation as documented by videomicrographs of micropipette aspiration ([160], [165]). The rheologic properties of oxygenated sickle cells are strongly influenced by the state of cell hydration and the increased propensity for oxidative damage to the membrane ([145], [165], [167], [168]). The already compromised deformability of oxygenated sickle cells is dramatically reduced further after deoxygenation. Both static extensional rigidity and dynamic (time-dependent) rigidity increase by orders of magnitude after deoxygenation ([169], [170] and [171]). Under conditions of high shear stress, increased internal viscosity appears to determine the rheologic behavior of ISCs, whereas at low shear rates, membrane rigidity assumes greater significance ([172]). Under physiologic conditions, increased viscosity results primarily from cellular dehydration. The poor deformability of ISCs, as measured by ektacytometry, can be rectified by osmotically hydrating them to a normal MCHC ([73], [145]). The membrane rigidity of oxygenated sickle cells also can be returned to a normal level by replacing Hb S with Hb A, suggesting that the interaction of Hb S with the cell membrane is an important determinant of cellular rigidity ([173]). Peripheral vascular resistance is increased in proportion to ISC numbers, the extent of ISC deoxygenation, and ISC density ([174]). The microvascular response to rheologically abnormal cells has been studied by measuring cutaneous blood flow with a laser Doppler velocimeter ([175]). This technique demonstrates local, large-amplitude rhythmic variations in resting blood flow, suggesting that microvascular flow is somehow synchronized at the precapillary level in large domains of small vessels. One may infer that the terminal arteriole or precapillary sphincter is the initial site of blood flow impedance rather than the capillary or vein, where deoxygenation is greatest. This concept is supported by the demonstration that red cells are entrapped on the arterial side of capillaries in the retina ([176]) and nail folds ([177]) of patients with sickle cell disease and in the microcirculation of laboratory animals given human sickle red cells ([178]). This concept is also consistent with the view that the rheologic properties of red cells containing Hb S polymers at arterial oxygen saturation are sufficient to influence microvascular perfusion before any change in red cell morphology is apparent ([65]). Laser Doppler velocimetry has been used to examine microcirculatory cutaneous blood flow in Hb SS patients ([179]). Impairments of microcirculatory fluxes resulting from a vasodilated state combined with abnormal vasoreactivity resembled those in patients with chronic venous insufficiency and may contribute to the pathogenesis of chronic leg ulcers. The functional significance of the impaired flow properties of sickle red cells was convincingly demonstrated by measuring exercise tolerance before and after partial exchange transfusion. By increasing the relative number of cells containing Hb A without increasing the total Hb concentration, exercise capacity improved significantly ([180]).

Pathogenesis of Hemolysis

Intravascular hemolysis results from the lysis of complement-sensitive red cells ([181]) and Hb lost during sickling- or shear-induced membrane fragmentation ([26], [182], [183]). Extravascular hemolysis may occur by two mechanisms: monocyte and macrophage recognition and phagocytosis of red cells that have undergone sickling- or oxidation-induced membrane changes ([95], [184], [185]) and physical entrapment of rheologically compromised red cells ([174], [186]). Sickling- and oxidation-induced membrane changes promote cell dehydration and clustering of membrane protein band 3. This leads to accumulation of IgG and complement on the sickle cell surface ([187], [188]). In addition, sickle cells have an impaired ability to inactivate surface complement ([189]). Monocyte and macrophage phagocytosis of these dense cells is the dominant mechanism for extravascular hemolysis. However, these cells are also abnormally sensitive to complement lysis causing intravascular hemolysis ([189]). Increased susceptibility to mechanically induced cell fragmentation has been documented *in vitro* and in sickle cell patients undergoing vigorous exercise ([183]), another component of intravascular hemolysis.

Several factors bear a strong relationship to the rate of hemolysis. Of greatest significance is the relative number of ISCs ([83]). The extent of Hb polymer formation, calculated from the MCHC and the relative proportion of Hb fractions, also correlates closely with the severity of hemolysis ([190], [191]). Of particular interest is the relationship between hemolytic rate and adherence of sickle cells to macrophages ([95], [192]).

Pathogenesis of Vasoocclusion

Possible risk factors for the development of sickle cell vasoocclusion include Hb S polymerization, sickle cell deformability, sickle blood viscosity, the fraction of dense cells, sickle cell–endothelial cell adherence, endothelial cell activation, hemostatic activation, vascular tone, contributions from white blood cells and platelets, local and regional environmental factors, and psychosocial factors ([193]). A hypothetical interrelationship with the risk factors for vasoocclusion is shown in Figure 40.4. It is possible that the mechanism of vasoocclusion varies over time and anatomic site and among patients. For example, there is functional heterogeneity of endothelial cells from large vessel and microvessel sources, and there are organ-to-organ differences in microvascular architecture ([194], [195]). It is possible that different mechanisms are likely to prevail as primary precipitants under different circumstances ([193]). For example, during inflammation, increased white blood cell interactions with endothelium could be a triggering event. Under other circumstances, platelet activation might result in an elevation in thrombospondin level. Clinical dehydration might lead to an increased release of von Willebrand factor. Any of these events might trigger red cell adherence to endothelium, precipitating vascular obstruction.

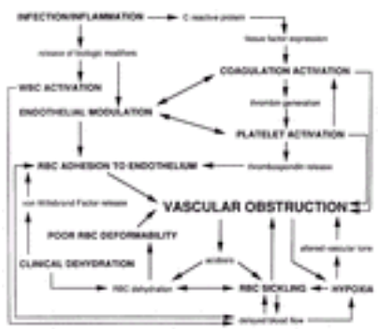

Figure 40.4. Interrelationships of risk factors for vasoocclusion. RBC, red blood cell; WBC, white blood cell. (From Embury SH, et al. Pathogenesis of vasoocclusion. In: Embury SH, Hebbel RP, Mohandas N, et al., eds. Sickle cell disease: basic principles and clinical practice. New York: Raven Press, 1994, with permission.)

Because of their higher Hb S concentration, the most dense cells are least deformable and are at greatest risk for intracellular polymerization ([145]). Obstruction by these cells develops at the arteriolar-capillary junctions in model systems ([194], [196], [197]). The role of dense cells may be to create a logjam behind an obstruction rather than to initiate the vascular plug. The proportion of dense cells increases immediately before an acute pain crisis and falls during the first few days afterwards ([198], [199] and [200]). Initiation of vasoocclusion by adherent cells may explain the fractional reduction in the least dense, most adherent cells during the initial stages of a vasoocclusive pain crisis. This is consistent with the frequency of painful events correlating with better red cell deformability ([125], [171]) rather than poorer deformability as might be expected.

The abnormal interaction between sickle cells and vascular endothelium may be of greater relevance for vasoocclusive events than are alterations in red cell morphology or viscosity. Although endothelial adherence does not correlate with standard hematologic measurements, it correlates significantly with the severity of pain crises ([201]). Likewise, patients with clinically less severe sickling disorders, such as Hb SC disease, tend to have less adherent red cells ([202]). When red cells from patients with sickle cell anemia are suspended in autologous plasma, however, dramatic increases in adherence are noted at the onset of vasoocclusive events ([202], [203]). Both plasma fibrinogen ([202], [204]) and fibronectin ([204]) have been implicated as factors modulating adherence. These findings from *in vitro* studies complement the clinical observation of a temporal relationship between infections and pain crises ([205]) and the demonstration of increased plasma fibrinogen levels during vasoocclusive crises ([202], [206]). Red cell adherence is also augmented by hyperosmolar conditions and by endothelial injury ([202]). Together, these observations suggest that alterations in the environment of the red cell predispose to vasoocclusion by amplifying the abnormal attraction of sickle red cells to vascular endothelium.

Sickled red cells may adversely affect local regulation of vascular tone. Normal endothelial cell–derived vasoactive factors include prostacyclins and NO (vasodilators) and endothelin-1 and platelet-derived growth factor-ß (vasoconstrictors). These agents act on vascular smooth muscle cells and inhibit or stimulate platelet aggregation and adhesion. Vascular tone is also modulated by local oxygen tension and shear forces. Free radicals, especially superoxide, may cause vasoconstriction, possibly by interfering with NO-induced vasodilation ([207]). An abnormal state of vasodilation and low vascular resistance in subjects with sickle cell disease occurs during steady-state periods, but during crisis states, there is a decrease in the levels of vasodilator substances like the prostacyclins and an increase in vasoconstrictor substances including endothelin and prostaglandins (PGs). This shift in the balance of vascular tone toward vasoconstriction results in slowing of vascular flow, further obstruction, and more profound deoxygenation of sickled red cells ([208]). NO is the major endothelium-derived relaxing factor in normal physiology. It plays a central role in vascular homeostasis by maintaining vasomotor tone, limiting ischemia-reperfusion injury, and modulating endothelial proliferation ([209]). Plasma levels of the NO metabolites nitrite and nitrate and plasma arginine levels are depressed in sickle cell patients during vasoocclusive crisis and the acute chest syndrome (ACS) ([210], [211]). Basal and stimulated NO production and responses to exogenous NO may be significantly reduced in adult men (but not women) with sickle cell disease, consistent with a protective effect of ovarian-produced estrogen on endothelial function in sickle cell disease ([209]). NO has been linked to transcriptional control of fetal Hb, suggesting that it may contribute to the increased fetal Hb level seen in women ([212]). In patients with sickle cell disease, elevated levels of plasma Hb cause destruction of NO and limit its bioavailability ([213]) and its ability to cause vasodilatation ([214]). Increased plasma Hb concentrations during vasoocclusive crisis and ACS ([215]) lead to increased scavenging of NO. Basal endothelial NO production and pharmacologic NO treatment reduce VCAM-1 gene transcription ([216]); conversely, diminished endothelial NO bioavailability and increased NO destruction are associated with increased plasma VCAM-1 levels ([217]). Thus, NO appears to play a critical compensatory role in maintaining endothelial homeostasis ([209]). L-arginine is an orally available dietary supplement that produces NO-dependent increased blood flow and reduced pulmonary artery pressure in patients with pulmonary hypertension. Arginine levels are low in sickle cell patients with vasoocclusive crisis and ACS, providing a rationale for argi-nine therapy in these conditions ([210], [218]). Several potentially beneficial effects of NO require further investigation in sickle cell disease including prevention of red cell dehydration by inhibition of the Gardos channel ([219]) and a function in hydroxyurea or arginine-butyrate–induced expression of fetal Hb ([212], [220]).

Adhesion of red cells to endothelial cells alters vascular flow as described above. Specific ligands that may mediate adhesion of sickled red cells to endothelium include von Willebrand factor, thrombospondin, fibrinogen, fibronectin, laminin, and vitronectin ([221], [222], [223] and [224]). Factors that act as vasoconstrictors, such as free radicals, PGs (PGI_2 and PGD_2), and endothelin-1, may enhance adhesion of sickled red cells to the endothelium. Infection or tissue inflammation may exacerbate erythrocyte adhesion through inflammatory cytokines such as tumor necrosis factor ([225]).

Alterations in the number and function of white blood cells may contribute to vasoocclusive events ([226], [227]). Alterations in chemotaxis and adhesion and increased

stickiness of neutrophil membranes also have been observed in crisis states ([228], [229]). Leukocytes may interfere with microvascular flow by lodging in the capillary entrance or adhering to venous or capillary endothelium ([230], [231]). Increased white blood cell counts in patients with sickle cell disease have been associated with increased mortality ([232]) and silent infarcts in the brain ([233]). The beneficial effect of hydroxyurea in the Multi-Center Study of Hydroxyurea has been associated with its effect in reducing leukocyte counts ([234]). Data from the Cooperative Study of Sickle Cell Disease (CSSCD) show that increased baseline white blood cell counts in infants are a predictive factor for severe manifestations of sickle cell disease in later childhood ([235]). Furthermore, acute infection, possibly because of the attendant leukocytosis, is thought to be a triggering mechanism for vasoocclusive pain events in many cases. In addition, four separate reports have linked the administration of a myeloid colony-stimulating factor (granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor) to the initiation of severe or even fatal sickle cell crisis ([236], [237], [238] and [239]). Recently, an experimental *in vivo* model using blood flow in the cremasteric muscle of sickle cell mice has indicated that leukocytes that are adherent to the vessel wall can directly contribute to vascular occlusion by means of their interaction with sickle red cells; inhibition of leukocyte adhesion by targeted disruption of P- and E-selectin expression can prevent vasoocclusion ([240]). A multistep pathogenesis of vasoocclusion based on white cell involvement has been proposed in which the following take place: (a) endothelial activation in postcapillary venules; (b) recruitment of adherent leukocytes to the endothelium; (c) interactions of sickle erythrocytes with adherent leukocytes; and (d) vascular clogging by white blood cell/sickle red blood cell aggregates resulting in ischemia, further activation of the endothelium, and so forth ([241]). It is also possible that platelets participate in the process through the formation of platelet–Hb SS red cell aggregates ([242]). However, a recent study in which thrombin generation was correlated with exposure of either erythrocyte or platelet PS on the cell surface noted a correlation of markers of thrombin generation (prothrombin fragment F1.2) and fibrin dissolution (D-dimers and plasmin complexes) only with red cell PS ([243]). Leukocytes may cause further tissue damage by release of inflammatory mediators and oxygen radicals. Endothelium adhesion molecules such as E-selectin, VCAM-1, and intercellular adhesion molecule-1 mediate leukocyte recruitment and promote an inflammatory response, as may the release of heme from red cell lysis ([244]). In sickle cell transgenic mice, induction of hypoxia followed by reoxygenation enhances peroxide production and increases leukocyte recruitment ([245]). Elevation of multiple circulating cytokines, including tumor necrosis factor-a, interleukin-1, granulocyte-macrophage colony-stimulating factor, and endothelin-1, occurs in sickle disease ([246], [247], [248] and [249]). The inhibitor nuclear factor-?B was shown in the sickle cell mouse model to reduce the expression of intercellular adhesion molecule-1 and VCAM-1 and on circulating endothelial cells of patients with sickle cell disease ([250]). It has been postulated that sickle cell disease leads to a proinflammatory state and that the inflammatory response is enhanced in both the sickle cell mouse model and patients ([241]).

Consistent alterations in platelet numbers and function have invited speculation regarding the possible involvement of platelets in vasoocclusive events. Abnormalities include increased platelet counts, increased platelet volume ([251]), decreased platelet survival ([252]), and decreased platelet aggregation ([253]). The latter has been attributed to a refractory state resulting from *in vivo* platelet activation. In support of this interpretation is the demonstration that plasma ß-thromboglobulin, a measure of release activity from platelet a-granules, is elevated in the steady state and increases further during vasoocclusive crises ([254]). Elevated urinary levels of thromboxane metabolites and depressed platelet thrombospondin content provide evidence for platelet activation in steady-state sickle cell patients ([255], [256]). The levels of the contact factors (factor XII, prekallikrein, and high-molecular-weight kininogen) are low and decrease further during crises ([257]). The coagulation inhibitors protein C and free protein S are reduced in steady-state sickle cell disease ([258], [259]); antithrombin III activity levels have been variable, but increased thrombin–antithrombin III complexes and plasma factor VII levels indicate increased tissue factor activity during the steady state ([260]). Plasma prostacyclin activity, thought to be generated from vessel wall PG, is increased ([261]). The level of fibrin D-dimer, a breakdown fragment of cross-linked fibrin, increases during vasoocclusive crises and returns to normal after crisis resolution ([262]). Whether these alterations in hemostasis and fibrinolysis are of pathogenic significance or are simply epiphenomena remains to be determined.

SICKLE CELL ANEMIA (HEMOGLOBIN SS)

Clinical Features

Although disease attributed to Hb S has been observed in early infancy ([263]), affected individuals characteristically are without symptoms until the second half of the first year of life ([264]). The lack of clinical expression of the Hb SS genotype during fetal and early postnatal life is explained by the production of a sufficient quantity of Hb F to limit clinically important sickling. Because erythrocytes contain increasing amounts of Hb S and proportionally decreasing amounts of Hb F, the conditions for sickling under physiologic conditions gradually are met. Prospective studies of affected infants followed from birth indicate a close temporal relationship between the postnatal decline in Hb F and evolution of anemia ([265], [266], [267], [268] and [269]). Mild hemolytic anemia is apparent by 10 to 12 weeks of age ([266], [270]) (Fig. 40.5). Splenomegaly is first noted after 6 months of age. The first vasoocclusive episode is experienced between 6 and 12 months of age by approximately one-half the subjects ([266]), before 6 years of age by the majority ([265]), but not until late childhood or adult life by a few. Dactylitis and ACS have the highest incidence during the first year of life ([269]); dactylitis is a common presenting symptom ([268]). Loss of function of the spleen has been documented as early as 5 months of age ([266], [271]), and death from overwhelming infection is clearly an increased risk before 12 months of age ([265], [268]).

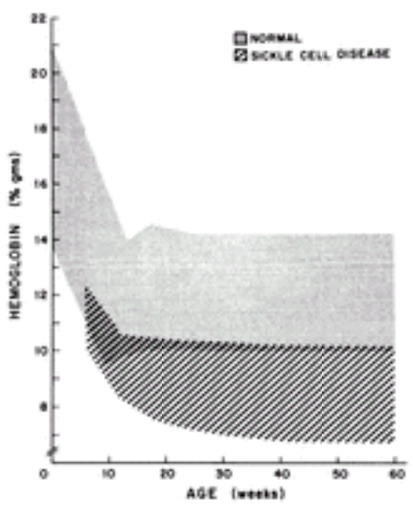

Figure 40.5. Hemoglobin concentration as a function of age in infants with sickle cell anemia. (From O'Brien RT, McIntosh S, Aspnes GT, et al. Prospective study of sickle cell anemia in infancy. J Pediatr 1976;89:205, with permission.)

The clinical features of sickle cell anemia result more from the vasoocclusive consequences of sickle cells than from the anemia itself. These features may be divided into those that characteristically are acute and episodic and those that are chronic and often progressive. The multiinstitutional CSSCD generated prospective information regarding the “natural history” of sickle cell disease in a group of more than 3500 patients, some of whom were followed for almost two decades.

ACUTE EVENTS: CHARACTERISTICS, MANAGEMENT, PREVENTION

Vasoocclusive Events The term *sickle cell crisis* was introduced to describe a recurring attack of pain involving the skeleton, chest, abdomen, or all three ([205]). Using the term in a broader sense, vasoocclusive “crises” comprise a variety of syndromes that are typically recurrent and potentially catastrophic. Clinical manifestations are sudden in onset and are directly attributable to obstruction of the microcirculation by intravascular sickling. Modest exacerbation of anemia and increased leukocytosis are common. Infections often precede vasoocclusive episodes in children, suggesting that fever, dehydration, and acidosis may be contributing factors. In adults, a triggering event is not often identified, but in a Jamaican series, painful crises developed most often between 3:00 p.m. and midnight. Perceived precipitating factors included skin cooling, emotional stress, physical exertion, and pregnancy ([272]). No seasonal variation in the frequency of crises has been noted ([273]).

Hand-Foot Syndrome The initial episode in young children often involves the small bones of the hands and feet (the hand-foot syndrome). By 2 years of age, nearly 50% of Jamaican children and 25% of American children with sickle cell anemia have experienced at least one episode of dactylitis ([269], [274]). Typically, the dorsa of the hands and feet are swollen, nonerythematous, and exquisitely painful. Fever and leukocytosis are common. Radiographic changes are limited initially to soft-tissue swelling; cortical thinning and destruction of metacarpals, metatarsals, and phalanges appear 2 to 3 weeks after the onset of symptoms. Dactylitis is sudden in onset and usually lasts 1 or 2 weeks. It may recur on one or more occasions until the patient is approximately 3 years of age ([274], [275]).

Painful Crises Typically, after the first few years of age, interruption of blood flow occurs in the larger bones of the extremities, spine, rib cage, and periarticular

structures, producing painful crises of the bones and joints ([4], [205], [276], [277]). The sinusoidal circulation of the bone marrow provides an ideal vascular bed for the sickling phenomenon. In the CSSCD, epidemiologic features of pain crises were analyzed in a large group of patients with sickle cell disease ([278]). The average rate of pain was 0.8 episode/patient-year in Hb SS, 1.0 episode/patient-year in Hb Sß ^{0}-thalassemia, and 0.4 episode/patient-year in Hb SC disease and Hb Sß $^{+}$-thalassemia. However, the rate varied widely from patient to patient: 39% of patients with sickle cell anemia had no episodes of pain, but 1% had more than six episodes/year. Five percent of Hb SS patients accounted for almost one-third of all the episodes. The pain rate increased moderately from childhood to the third decade of life. Recently, a higher rate of pain crises has been associated with low nocturnal oxygen saturation detected by continuous monitoring during sleep ([279]). Pain resulting from ischemia of the bone marrow is gnawing and progressive in severity. The most frequent sites of involvement are the humerus, tibia, and femur ([276]). Involvement of facial bones is less common but is well documented. The swelling associated with infarction of the orbital bone may be sufficient to produce proptosis and ophthalmoplegia ([280]). Swelling of the elbows or knees may mimic rheumatic fever or septic arthritis ([281]). Infarcts involving deep bones and joints are not associated with detectable swelling, erythema, or surface temperature change. Laboratory findings, too, are inconstant and nonspecific. The radiographic features of bone infarction and periostitis usually do not appear until after the resolution of symptoms. Increased signal with T2-weighted images are seen by magnetic resonance imaging (MRI) in approximately one-third of pain crises ([282]). Discrete areas of decreased localization of ^{99}Tc-sulfur colloid identify areas of decreased marrow blood flow, and ^{85}Sr or ^{99}Tc-phosphate localizes the increased osteoblastic activity that occurs with healing ([283], [284] and [285]). Although radionuclide bone and bone marrow scans theoretically enable differentiation of bone infarcts from osteomyelitis, in practice they are of limited value ([276]). Unlike osteomyelitis, bone infarcts are associated with no more than a low-grade fever and little or no left shift in the leukocyte differential. As a cause of bone pain, infarction is more than 50 times as common as osteomyelitis ([276]). Abdominal pain crises are attributed to small infarcts of the mesentery and abdominal viscera and are characterized by severe abdominal pain and signs of peritoneal irritation. Persistence of bowel sounds differentiates pain crises from acute intraabdominal disorders requiring surgical intervention. Diagnosis is facilitated by prior experience with the patient, because the pattern of pain tends to repeat itself from crisis to crisis. Atypical clinical or laboratory features should suggest one of several complications to which patients with sickle cell anemia are especially susceptible such as ACS, urinary tract infection, or cholecystitis. On average, painful crises persist for 4 or 5 days, although protracted episodes may last for weeks. Data from the CSSCD indicate that an increased frequency of painful events is associated with a high hematocrit and a low fetal Hb level ([278]). No additional influence on pain rate results from concurrent a-thalassemia among patients with sickle cell anemia who are older than 20 years of age. Adults with high rates of pain episodes tend to die earlier than those with low rates ([278]). Of potential therapeutic significance, it was noted in the CSSCD that even when the level of Hb F is low, a small increase is associated with an ameliorating effect on the pain rate and may ultimately improve survival. No specific form of therapy has proven effective for vasoocclusive crises. None of the many medications and manipulations that have been touted as beneficial have withstood critical scrutiny. Low-molecular-weight dextran, phenothiazines, antifibrinogenolytic agents, bicarbonate and other alkalis, and urea solutions, when evaluated in controlled clinical studies, were found to be without apparent effect on vasoocclusive crises ([286], [287], [288], [289], [290], [291] and [292]). Other therapeutic strategies, although not subjected to randomized clinical trials, have enjoyed only fleeting popularity. These strategies include carbonic anhydrase inhibitors ([293]), vasodilators ([294]), anticoagulants, progesterone ([295]), testosterone ([296]), papaverine ([297]), antithyroid drugs ([298]), and hyperbaric oxygen ([299], [300]). Pentoxifylline, an agent that increases red blood cell deformability and inhibits platelet aggregation, may be beneficial for treatment of a pain crisis; clinical studies have been poor methodologically ([301]). Similarly, early reports on the use of cetiedil, a smooth muscle relaxant that inhibits sickling and cell dehydration through inhibition of the Gardos channel, suggested a reduction in duration of painful crises ([302], [303]), but they have not been substantiated by further trials. Poloxamer-188, a monionic surfactant compound, reduced total analgesic use, but a phase III trial demonstrated only a slight shortening of the duration of pain crises ([304]). The duration and severity of pain crises are notoriously variable, and the natural course is one of spontaneous improvement. Consequently, uncontrolled reports of effective therapies must be viewed with skepticism, especially if the proposed treatment entails an element of risk. The cornerstones of present day therapy are fluids and analgesics. The volume of fluids administered should be sufficient to abolish any deficit, correct hypertonicity, and fully compensate for ongoing losses imposed by fever, hyposthenuria, vomiting, or diarrhea. Because urinary sodium losses are increased during crises, maintenance sodium requirements also are exaggerated ([305]). Precipitants of the crisis should be sought and eliminated. Infection, a common precipitating cause in children, may require antibiotic therapy. Acidosis is corrected readily with intravenous administration of sodium bicarbonate. Oxygen therapy in the absence of documented hypoxemia is without benefit and triggers an increase in the number of ISCs when discontinued ([306]). Control of pain requires the liberal use of analgesics ([307], [308]), but narcotic addiction is unlikely as long as the use of analgesics is closely monitored. Recently, benefit from adjunctive therapy with a short course of high-dose corticosteroid (methylprednisolone) ([309]) or a long-acting nonsteroidal antiinflammatory drug (e.g., ketorolac) ([310]) has been reported. The use of patient-controlled analgesia, which enables patients to inject themselves with limited boluses of intravenous morphine or meperidine, has been beneficial for some and provides an element of self-control in pain management ([311], [312]). Patient-controlled analgesia also allows individualization of narcotic dosing, which may be valuable in view of the wide variability in morphine pharmacokinet-ics ([313]) and the rare fatality from narcotic overdose ([314]). Self-hypnosis has been used successfully for pain control in selected subjects ([315]). Blood transfusions do not modify the course of an established crisis and are not without risk. Because fever and back pain are common features of pain crises, transfusion reactions may escape early recognition ([316]).

Central Nervous System Events Stroke is a catastrophic complication of sickle cell anemia that affects 6 to 17% of children and young adults ([317], [318], [319] and [320]). Two major syndromes are observed: One results from occlusion of major cerebral vessels and primarily affects children from 2 to 15 years of age (mean, 6 to 7 years) ([318], [319]); the other results from intracerebral or subarachnoid hemorrhage and affects older children and adults ([318], [320], [321]). The risk of stroke appears to be increased in patients with Hb F levels less than 8% ([322], [323]) and in patients with siblings who have had strokes ([322]). Data from the CSSCD, in which approximately 4000 patients were followed for an average of 5 years, indicated that infarctive stroke was most frequent in children and older adults with Hb SS, whereas hemorrhagic stroke had the highest incidence in patients 20 to 29 years of age ([325]). The mortality rate was 26% after hemorrhagic stroke and 0% after infarctive stroke. Risk factors for infarctive stroke included prior transient ischemic attack, low steady-state Hb concentration, frequent or recent episodes of ACS, and elevated systolic blood pressure. The pathogenesis of cerebral vascular disease is incompletely understood (Fig. 40.6). In approximately 80% of cases, cerebral arteriograms performed on children who have had strokes demonstrate occlusion or stenosis of one or more of the major cerebral arteries ([318], [324], [326]), sometimes with a telangiectatic network of collateral vessels producing a moyamoya (“puff of smoke”) pattern ([327]). Pathologically, vascular narrowing results from segmental proliferation and fragmentation of the intima. The internal elastic lamina may show degenerative changes, and the media may be disrupted by fibrosis and hemorrhage. Occlusion is the result of progressive proliferation of vascular smooth muscle, superimposed thrombosis, or an embolus ([328], [329]). Adherence of sickle red cells to the endothelium of vessel walls may be an additional mechanism ([322]). Aneurysms can be demonstrated in some patients who have sustained intracranial hemorrhage ([318]) and may be observed as an incidental finding in children with cerebral vasoocclusive disease ([322]). Presumably, these aneurysms result from progressive damage to the intima at sites of weakened vessel walls.

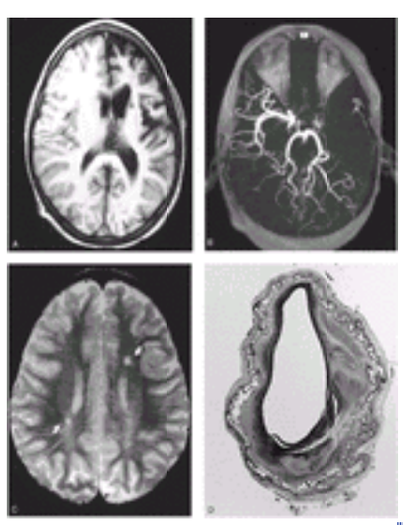

Figure 40.6. Vasoocclusive effects in the central nervous system. **A:** T1-weighted magnetic resonance imaging (MRI) in a 6-year-old girl with hemoglobin (Hb) SS and a history of stroke. There is extensive atrophy involving the distributions of the left anterior and middle cerebral arteries with compensatory enlargement of the left lateral ventricle. **B:** Magnetic resonance angiography in same patient showing occlusion of left middle cerebral artery and diminished flow through both anterior cerebral arteries. **C:** T2-weighted sagittal MRI in a 4-year-old boy with “silent infarcts.” Small areas of leukomalacia are seen in deep white matter in frontal and parietal areas (*arrows*). **D:** Pathologic section of internal carotid artery showing fibrinous thrombus with parallel layers of fibrin deposited on intimal surfaces and atrophic media. (Courtesy of Dr. JJ Jenkins, St. Jude Children's Research Hospital.)

Clinically, strokes are characterized by the abrupt onset of hemiparesis, aphasia, seizures, sensory deficits, and altered consciousness, occurring singly or together. The patient may make a full recovery, but incomplete resolution of neurologic deficits is the rule. Although the findings may be negative early in the course of infarction, MRI permits noninvasive visualization of focal damage. Individuals with cerebral vessels that appear normal on magnetic resonance angiography and who have no evidence of brain infarction on MRI are rarely encountered after symptoms and signs indicative of a cerebrovascular accident. It is not certain if these patients also require transfusion therapy. A recent study indicated that patients with moyamoya were more than twice as likely to incur subsequent stroke or transient

ischemic attack despite treatment with chronic transfusions ([330]). Strokes tend to be repetitive because of the progressive nature of cerebral vascular disease. Unless patients begin a long-term transfusion program, they are at risk for recurrent cerebral infarctions with progressive neurologic deterioration. Chronic transfusion therapy designed to maintain the level of Hb S below 30% slows or arrests the progression of arterial abnormalities and reduces the risk of recurrent strokes (within 36 months) from approximately 70 to 90% to 10 to 20% ([318] , [322]). Interruption or termination of treatment, even after 8 years of chronic transfusion, is associated with a stroke recurrence rate similar to that of untransfused patients ([331] , [332] and [333]), suggesting that transfusion therapy for secondary stroke prophylaxis should be continued indefinitely. However, reduction of the intensity of chronic transfusion to allow pretransfusion Hb S levels to reach 50% appears safe after the first few years of prophylaxis ([334] , [335]). Recently, the risk of recurrent stroke in patients who received blood transfusion therapy for at least 5 years was analyzed in relationship to antecedent medical events (e.g., hypertension, ACS, fever) that may have led to the cerebrovascular accident ([336]). Although 22% had a second stroke despite long-term transfusion, patients who had a possible etiology for their initial stroke had much less risk of recurrence. Many chronically transfused children have transfusions discontinued when they reach adulthood. None of the nine adult patients who stopped transfusion after a median of 6 years suffered recurrent stroke ([337]). Hydroxyurea may be an alternative to blood transfusion for the prevention of recurrent stroke in patients who cannot tolerate continued chronic transfusion (or the need for chronic iron chelation), and associated phlebotomy may be of additional benefit ([338] , [339]). Transcranial Doppler ultrasonography (TCD) is a noninvasive technique in which cerebral artery blood flow velocity is measured in the distal internal carotid and proximal middle and anterior cerebral arteries. Markedly increased flow velocity is often an indicator of vascular stenosis and has been associated with a greatly increased risk of cerebral infarction within a 3-year period ([340]). In a recent multicenter phase III trial, patients with confirmed abnormally elevated TCD velocity were randomized to receive chronic transfusion versus standard care ([341]). Subsequent stroke occurred in 1/63 patients randomized to transfusion and in 11/67 randomized to standard therapy, a significant difference that has prompted routine TCD screening in many pediatric sickle cell centers. Rare neurologic complications include infarction of the spinal cord ([319]) and brain stem ([342]) as well as cord compression by extramedullary masses of erythropoietic tissue ([343]).

Acute Chest Syndrome Characterized by fever, tachypnea, chest pain, increased leukocytosis, and pulmonary infiltrates, pulmonary events are a frequent cause of morbidity and mortality in patients with sickle cell anemia. Because it may be impossible to determine the relative importance of vascular occlusion and infection in the process in any given patient, the term *acute chest syndrome* has been applied. Infection tends to predominate in children and infarction in adults, but the two processes are often interrelated and concurrent ([344]). Impaired access of oxygen to infected segments of the lung likely enhances local sickling with resulting focal microvascular thrombotic disease. Data from the CSSCD indicate that patients with Hb SS have an incidence of ACS of approximately 13/100 patient-years; the rate is highest in children 2 to 4 years of age (25/100 patient-years) and decreases gradually with increasing age to that seen in adults (9/100 patient-years) ([345]). A higher ACS rate is associated with a higher rate of mortality from all causes ([349]). The risk of ACS is associated with a lower fetal Hb level and a higher steady-state hematocrit and leukocyte count. Before the availability of pneumococcal vaccines and the widespread use of penicillin prophylaxis, pulmonary events in children typically were the result of bacterial infection ([346] , [347]). *Streptococcus pneumoniae* was the most common causative organism. Infiltrates often affected multiple lobes, and resolution was slower than in the general population ([346] , [348]). Identified infectious agents have included *Mycoplasma pneumoniae* ([349]), *Chlamydia* ([350]), parvovirus B19 ([351]), and respiratory viruses. The National Acute Chest Syndrome Study Group reported causes and outcomes based on analysis of 671 episodes of ACS ([352]). Nearly one-half the patients were initially admitted for another reason, mainly pain. The mean length of hospitalization was 10.5 days; 13% required mechanical ventilation, and 3% died. Patients who were 20 years of age or older had a more severe course. A specific cause of ACS was identified in 38% of all episodes and 70% in episodes with complete data (Table 40.1 and Table 40.2) ([353]). The most common specific causes were pulmonary fat embolism, chlamydia, mycoplasma, miscellaneous viruses, and bacterial infections due to coagulase-positive *Staphylococcus aureus* and *S. pneumoniae*. Treatment with transfusion and bronchodilators improved oxygenation, although older patients often progressed to respiratory failure. In adults, an infectious basis for lobar consolidation is established less often than in children, and antibiotic therapy is without apparent effect on the duration or severity of symptoms ([354] , [355]). *In situ* vasoocclusion owing to erythrocyte stasis appears to be the more common primary event.

TABLE 40.1. Causes of Acute Chest Syndrome

Cause	Number of Episodes (N = 670)	Percentage	Age at Episode of Acute Chest Syndrome		
			0–9 yr (N = 329)	10–19 yr (N = 188)	=20 yr (N = 153)
Fat embolism, with or without infection	59	8.8	24	16	19
Chlamydia	48	7.2	19	15	14
Mycoplasma	44	6.6	29	7	8

TABLE 40.2. Most Common Pathogens Isolated in 671 Episodes of Acute Chest Syndrome

Pathogen	Number of Episodes
Chlamydia pneumoniae	71
Mycoplasma pneumoniae	51
Respiratory syncytial virus	26
Coagulase-positive *Staphylococcus aureus*	12
Streptococcus pneumoniae	11
Mycoplasma hominis	10
Parvovirus	10
Rhinovirus	8
Parainfluenza virus	6
Haemophilus influenzae	5

Modified from Vichinsky EP, Neumayr LD, Earles AN, et al. Causes and outcomes of the acute chest syndrome in sickle cell disease. National Acute Chest Syndrome Study Group. New Engl J Med 2000;342:1855–1865.

Hematologically, ACS is characterized by a sudden drop in Hb concentration and an increase in the number of platelets and leukocytes ([356]). Rib infarcts are a primary cause of ACS when bone pain is followed by soft-tissue reaction, pleuritis, splinting, hypoventilation, atelectasis, and the typical radiologic picture ([357]). Lung crises may result from embolization of fat from infarcted bone marrow (pulmonary fat emboli) ([358] , [359] and [360]) or deep vein thrombi ([361]). Occlusion of major pulmonary vessels is a recognized cause of sudden death ([362]). Pulmonary fat emboli are found more commonly than previously appreciated when a diagnosis is sought by fat staining of pulmonary macrophages obtained by bronchoalveolar lavage ([360]). Fat emboli are associated with bone pain, chest pain, neurologic symptoms, acute decreases in Hb level and platelet count, and prolonged hospitalization. Recently, secretory phospholipase A_2, an inflammatory mediator that liberates free fatty acids and may be responsible for acute lung injury, was found to be dramatically elevated in sickle cell patients before the diagnosis of ACS ([363]). Incentive spirometry with the use of maximal inspirations every 2 hours has been shown to prevent ACS in patients with sickle cell disease who were hospitalized with chest or back pain ([364]). Because the relative importance of infection and infarction is difficult to ascertain, broad-spectrum parenteral antibiotics should be provided for children with fever, chest pain, and pulmonary infiltrates. If mycoplasma infection is an endemic problem, coverage should include a macrolide antibiotic. Of utmost

importance is the correction of hypoxemia. If the arterial PO_2 value is less than 75 mm Hg or the O_2 saturation by pulse oximetry is significantly below baseline, the clinician should consider prompt simple ([365]) or partial exchange transfusion ([307] , [355]). Recently, intravenous dexamethasone was shown to result in a shorter hospital stay and reduced need for blood transfusion and oxygen when compared to placebo in children with ACS ([366]). However, there appeared to be a high risk of readmission to the hospital after dexamethasone was discontinued. The role of NO and Hb in the regulation of hypoxic pulmonary vasoconstriction and possible treatment with NO inhalation or arginine (a precursor to NO) are currently being explored ([367]).

Priapism The incidence of priapism in patients with sickle cell disease has been reported to be between 5% and 45% ([368]); it has a bimodal distribution of age of onset with peaks at 5 to 13 years of age and 21 to 29 years of age ([369]). It may be initiated during the normal erections of rapid eye movement sleep and may be associated with physiologic dehydration and hypoventilation, which results in metabolic acidosis followed by increases in sickling and stagnation of blood within the penile sinusoids or the corpora cavernosum. Although usually self-limited and of relatively short duration, priapism is often recurrent and may become chronic. "Stuttering" priapism refers to multiple episodes, each less than 3 hours in duration, which occur several times a week. Usually, these do not require medical intervention. Typically, priapism results from engorgement of the paired cavernosal bodies with sparing of the glands and corpus spongiosum (bicorporal). However, tricorporal priapism may occur, especially in postpubertal patients, and is associated with a poor prognosis ([370]). Although it occurs with approximately equal frequency in prepubertal and postpubertal males, priapism is more difficult to manage in the latter group ([371] , [372] and [373]). Numerous ISCs and clots are found in the distended sinuses when needle aspiration or incisional drainage is performed ([374]). The repetitive trapping of cells in the corpora cavernosa, with or without surgical intervention, may lead to fibrosis of the septa and impotence ([375]). Penile blood gas measurements and technetium-99 penile scintigraphy scans ([373]) have been used to define intracorporeal hemodynamics and to guide therapy. However, these modalities are not readily available, and a more conventional approach to treatment is necessary. Of particular concern is an increased rate of impotence reported in sickle cell patients whose attacks lasted more than 24 hours ([376] , [377]). As with other complications resulting from the sludging of sickled erythrocytes, aggressive hydration and adequate analgesia are of primary importance and should be pursued within the first few hours of symptoms. If no response is seen within 12 to 24 hours, partial exchange transfusion to lower the Hb S level to less than 30% should be performed; this is occasionally sufficient ([378]). If no resolution occurs within another 12 to 24 hours, corporal aspiration and irrigation with saline are indicated through such means as a Winter procedure ([379]), in which a fistula between the glans penis and the corpora cavernosa is created using a biopsy needle. If this is unsuccessful, creation of a cavernosa spongiosum shunt ([380]) or a venous bypass may be considered. Prevention of recurrent priapism has been accomplished in some patients with chronic transfusion, particularly through exchange transfusion ([368]). a-Adrenergic agonists are thought to increase the contractile state of the trabecular/arterial meshwork and facilitate venous outflow from the corpora ([368]). Agents including etilefrine pseudoephedrine and phenylephrine may be administered either orally or by intracavernous injection ([381] , [382]). Another approach has been the administration of diethylstilbestrol ([383]), the gonadotropin-releasing hormone analog leuprolide acetate ([384]), and low-dose antiandrogens ([385]). Despite either conservative or aggressive treatment, more than 25% of patients have some degree of impotence ([372] , [373] , [386]) and may be candidates for a penile prosthesis after 6 to 12 months ([387]). A recently described association of sickle cell disease, priapism, exchange transfusion, and neurologic events, including seizures and obtundation, is also of concern ([388] , [389]).

Hematologic Crises Hematologic crises, characterized by sudden exaggeration of anemia, are pathogenetically and temporally unrelated to vasoocclusive crises. If unrecognized or untreated, the decrease in Hb concentration may be so precipitous and severe as to cause heart failure and death within hours.

Aplastic Crises These events are the most common of the hematologic complications. The pathogenesis and course of aplastic crises in sickle cell anemia are similar to those of other chronic hemolytic states. Several characteristics are indicative of an infectious basis: The crises are characteristically preceded by or associated with febrile illnesses; several members of families with congenital hemolytic anemia may have concurrent aplasia ([390]); recurrence of crisis within the same individual is not observed ([391]); and most aplastic episodes occur during childhood ([392] , [393]). Results of recent epidemiologic studies clearly implicate human parvovirus B19 as the cause for almost all aplastic crises ([391] , [392] , [394] , [395] , [396] and [397]). Aplasia is the result of direct cytotoxicity of the parvovirus to erythroid precursors, especially colony-forming units, erythroid ([398] , [399]). Susceptible hospital workers exposed to patients with aplastic crises are at high risk of contracting nosocomial erythema infectiosum ([400]). Because infection during the midtrimester of pregnancy may result in hydrops fetalis and stillbirth, isolation precautions are a necessity if an aplastic crisis is suspected ([401]). In the early phase of an aplastic crisis, peripheral blood reticulocytes and bone marrow normoblasts disappear or are greatly reduced in number. Because red cell survival in Hb SS is no more than 10 to 20 days ([402]), cessation of erythropoiesis is followed by a rapid decrease in Hb concentration. The process is self-limited, however; within 10 days, red cell production resumes spontaneously, and large numbers of reticulocytes and nucleated erythrocytes appear in the peripheral blood. Thereafter, the Hb concentration returns to its precrisis level. Often, the patient is first seen early in the recovery phase, when differentiation from a hemolytic crisis may be difficult. Although leukocytes and platelets are usually normal, all marrow elements may be affected ([403]). Treatment consists of supportive care with red cell transfusion when necessary.

Splenic Sequestration This event is characterized by sudden trapping of blood in the spleen. A splenic sequestration crisis is defined by a decrease in the steady-state Hb concentration of at least 2 g/dl, evidence of compensatory marrow erythropoiesis, and an acutely enlarging spleen ([404]). This complication occurs in infants and young children whose spleens are chronically enlarged before autoinfarction and fibrosis. Although splenic sequestration has been documented in infants as young as 3 and 4 months of age ([405] , [406]), it is observed most commonly during the second 6 months of life and is a less frequent finding after 2 years of age ([404]). Children experiencing splenic sequestration may have an earlier onset of splenomegaly and a lower level of Hb F at 6 months of age ([267] , [406]). Crises often are associated with respiratory tract infections ([404] , [406]) or, rarely, with parvovirus B19 in conjunction with an aplastic crisis ([407]). The already enlarged spleen rapidly increases in size at the expense of blood volume; hypovolemic shock and death may occur within hours ([408] , [409]). The sole pertinent postmortem finding is engorgement of splenic sinusoids with sickled cells ([374]). Individuals who survive have a tendency for recurrent episodes until 5 or 6 years of age, by which time sufficient fibrosis of the spleen has occurred to limit its expansion. The long-term management of patients with splenic sequestration has not been well defined. Chronic transfusion is of limited benefit in preventing reoccurrence of splenic sequestration ([410]). In a large series of Jamaican Hb SS patients with recurrent splenic sequestration or chronic hypersplenism, splenectomy did not increase the risk of death or bacteremic illness ([411]). Although encountered less frequently, sudden trapping of blood in the liver (hepatic sequestration crisis) also occurs ([412] , [413] and [414]).

Hemolytic Crises (Hyperhemolytic Crises) Such crises result from a sudden acceleration of the hemolytic process. They have been described in association with hereditary spherocytosis ([415]) and mycoplasma infection ([349]). Although approximately 10% of black male patients with sickle cell anemia have the unstable A variant of glucose-6-phosphate dehydrogenase ([416] , [417]); they have no more severe anemia and no greater frequency of acute hemolytic episodes than those with normal levels of glucose-6-phosphate dehydrogenase, even when challenged with oxidant drugs and infections ([418]). This finding is explained by the young mean age of sickle red blood cells. Increased lipid peroxidation of sickle red cells by reactive oxygen species derived from activated neutrophils is another possible mechanism for infection-associated hemolytic crises ([419]).

Megaloblastic Crises These crises result from the sudden arrest of erythropoiesis by folate depletion ([420] , [421]). Chronic erythroid hyperplasia imposes a drain on folate reserves, and biochemical evidence of mild folate deficiency can be demonstrated with high frequency in subjects with sickle cell anemia ([422]). Megaloblastic crises likely occur when food consumption is interrupted by illness or alcoholism or when the folate requirement is augmented by rapid growth or pregnancy. The inverse relationship between plasma homocysteine concentration and folate status has led to a series of recent reports describing homocysteine levels and the possible need for folate supplementation. However, both elevated homocysteine levels ([423] , [424]) and normal homocysteine levels have been reported ([425] , [426]). Currently, folic acid deficiency, as a cause of exaggerated anemia in sickle cell disease, appears to be extremely rare in the United States. Nevertheless, it is common practice to prescribe prophylactic folic acid (1 mg/day) to patients with sickle cell disease.

Infections Overwhelming infection may be the presenting manifestation of sickle cell anemia in early childhood. Acute infection is one of the most common causes of hospitalization and previously was the most frequent cause of death, particularly during the first 3 years of life. *S. pneumoniae* is the usual infecting organism; the blood and spinal fluid are the major sites of infection ([427] , [428] and [429]). The incidence of invasive infection with *S. pneumoniae* previously was approximately 7/100 patient-years in children with sickle cell anemia younger than 5 years of age; this rate was 30 to 100 times that which would be expected in a healthy population of this age ([429] , [430]). More than 70% of meningitis in children with sickle cell anemia resulted from *S. pneumoniae* ([431]). The mortality rate of pneumococcal sepsis was as high as 35%, but the widespread improvement in parental education and aggressive management of the febrile child have greatly improved the likelihood of surviving a septic event ([432]). Furthermore, penicillin prophylaxis and pneumococcal vaccines have substantially lowered the risk of invasive pneumococcal infection. A major threat to continued success in prevention and management of *S. pneumoniae* invasive infection is the emergence of antibiotic-resistant pneumococcal organisms over the past 15 years. A recent report cited 16 cases of intermediate or high resistance to penicillin among *S. pneumoniae* causing sepsis in children with sickle cell anemia in the United States ([433]); many of the organisms were also resistant to extended-spectrum cephalosporins and other antibiotics. After 5 years of age, the incidence of life-threatening infections decreases substantially. Gram-negative bacteria replace *S. pneumoniae* as the major offenders ([347] , [429] , [434] , [435]). In contrast to infections in young children, those in older children and adults generally have an identifiable source or focus (e.g., *Escherichia coli* associated with urinary tract infection) ([347] , [429] , [431]). Osteomyelitis, often involving multiple sites, occurs with increased frequency at all ages. The increased risk of osteomyelitis may stem from tissue ischemia and infarction associated with pain crises; these provide a potential nidus for infection in the long bones (Fig. 40.7). Although more than 80% of hematogenous osteomyelitis in the general population is caused by staphylococcus, most cases of osteomyelitis occurring in individuals with sickle cell anemia are caused by *Salmonella* ([436] , [437] , [438] and [439]). Serum antibody levels against *Salmonella* antigens are normal, but microinfarcts of the intestinal mucosa may predispose to invasive infections ([440] , [441]). Documentation of *Salmonella* in a patient with sickle cell anemia strongly suggests the diagnosis of osteomyelitis. Staphylococcal bone infection, clinically indistinguishable from *Salmonella* infection, also occurs with increased frequency in sickle cell disease ([347] , [442] , [443]).

Figure 40.7. Pathogenesis of infection in sickle cell disease. Ig, immunoglobulin. (Modified from Wang WC. Sickle cell disease. In: Patrick C, ed. Infections in immunocompromised infants and children. New York: Churchill Livingstone, 1992.)

Human parvovirus B19 has been noted to produce sequelae other than aplastic crises in patients with sickle cell disease. In a series from Jamaica, seven patients developed glomerulonephritis with proteinuria and symptoms of nephrotic syndrome within 7 days after an aplastic crisis ([444]). Renal failure appears to be a common consequence of this complication. Parvovirus may also result in severe pulmonary problems ([444]) and in cerebrovascular complications, including hemiplegia, encephalitis, and seizures ([445]). The pathophysiologic basis for increased susceptibility to aggressive infection relates in large part to the loss of spleen function (Fig. 40.7) ([446] , [447]). During the first few years of life, recurrent perivascular hemorrhage and infarction reduce the spleen to a small siderofibrotic vestige ([448]). Despite the frequent occurrence of splenomegaly in the first few years, spleen function often is impaired by 6 to 12 months of age ([266]). Howell-Jolly bodies and “pits” (depressions in the red blood cell membrane) are seen in peripheral blood erythrocytes ([271] , [449] , [450] and [451]), and radiolabeled sulfur colloid is not cleared by the spleen ([452]). Spleen function is temporarily restored by transfusion therapy in early life, suggesting that functional asplenia is a consequence of altered perfusion imposed by intrasplenic sickling ([453]). In the absence of spleen function, bloodborne particulate antigens fail to elicit an expected antigenic response ([454]), and challenge with *S. pneumoniae* is not followed by an appropriate generation of pneumococcal opsonins ([455]). Spleen function is necessary for effective host response to *S. pneumoniae* in the absence of preformed antibodies; in the presence of antibody, organisms are trapped effectively at extrasplenic sites. Because the acquisition of pneumococcal antibodies occurs with advancing age, young children without spleen function fare less well than older children and adults. However, responses to conjugated *Haemophilus influenzae* vaccine in young infants with sickle cell anemia ([456]) and an experimental conjugated pneumococcal vaccine in 2- to 5-year-olds have been appropriate ([456] , [457]). Other mechanisms may contribute to the vulnerability of children with sickle cell disease to infectious crises. Serum IgM levels are decreased ([458]). The alternative pathway for complement activation has been described as defective ([459] , [460]) or normal ([461]). Alterations of B- and T-lymphocyte number and function and of the function of neutrophils and monocytes are of uncertain significance ([462] , [463] , [464] and [465]).

Prevention of Infection Over the past 15 years, penicillin prophylaxis has emerged as a success story in the management of sickle cell disease. Two controlled trials, one in Jamaica and the other organized by the National Institutes of Health, led to the widespread acceptance of penicillin prophylaxis as standard therapy ([466] , [467]). In the latter trial, twice-daily oral penicillin V resulted in an 84% reduction in the incidence of pneumococcal bacteremia in infants younger than 36 months of age. Current recommendations are to initiate penicillin prophylaxis by 3 months of age and to continue it at least until 5 years of age in children with Hb SS or Hb Sß ^{0}-thalassemia. A multiinstitutional controlled trial found no further advantage of penicillin in the prevention of invasive pneumococcal infection in children older than 5 years of age ([468]). The use of prophylaxis in young children with Hb SC disease or sickle ß $^{+}$-thalassemia is controversial ([469]), but many centers maintain all children with sickle cell disease on penicillin until 5 years of age. Of concern has been the question of whether prophylaxis might increase the risk of penicillin-resistant pneumococcal organisms. Its usage reduces nasopharyngeal colonization with *S. pneumoniae*, but an unequivocal effect on the development of antibiotic resistance has not been described ([470] , [471] and [472]). However, the pneumococcal serotypes that are most prevalent in the community and most highly virulent (types 6A, 14, 19, and 23F) are least immunogenic ([466] , [473] , [474] and [475]). Although the immunologic response of children 2 years of age and older to polysaccharide-conjugated pneumococcal vaccine is comparable to that of the general population ([476] , [477]), antibody titers fall more rapidly than in adults. It is recommended that all children with sickle cell anemia receive a primary immunization with the 23-valent polysaccharide vaccine at 2 years of age and a booster immunization 3 to 5 years later ([478]). However, the vaccine is ineffective in children younger than 2 years of age, and at all ages, it fails to establish reliable protection against some of the serotypes included in the vaccine (e.g., types 6A, 19F) ([466] , [479]). The seven-valent protein-conjugated pneumococcal vaccine, which is immunogenic in the first few months of life, became available for general pediatric use in 2000. Protein-conjugated pneumococcal vaccine (which includes serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F) administered at 2, 4, and 6 months of age produced adequate antibody concentrations in the same range as those achieved among infants without sickle cell disease ([480] , [481]). In addition, significant rises were seen in antibody concentration to all seven protein-conjugated pneumococcal vaccine serotypes after the administration of polysaccharide-conjugated pneumococcal vaccine at 24 months of age. The conjugated *H. influenzae* type B vaccine induces protective antibody levels in young infants with sickle cell anemia ([456] , [482]) and has virtually eliminated invasive *H. influenzae* infection in this population. The influenza virus vaccine ([483]) and hepatitis B vaccine ([484]) offer further protection.

Management of Fever Any fever greater than 38.5°C in a child with sickle cell anemia must be considered a medical emergency because of the potential risk of overwhelming pneumococcal sepsis, especially during the high-risk period between 6 months and 3 years of age ([432]). This risk remains significant despite the efficacy of penicillin prophylaxis. Previously, routine hospitalization of every febrile patient with sickle cell anemia was standard management to deliver intravenous antibiotic coverage until blood cultures were demonstrated to be negative. More recently, in certain centers, the majority of febrile patients have been managed in the emergency department and the outpatient setting if they do not have high-risk characteristics (e.g., toxic appearance, very high fever, serious localized infection, exceptionally high or low white blood cell count, a history of invasive infection, or inadequate capacity for close follow-up) ([485] , [486] and [487]). These children may be managed with prompt assessment in the emergency department, rapid administration of ceftriaxone, observation for several hours, and close outpatient follow-up.

CHRONIC ORGAN DAMAGE

Growth and Development The sickling syndromes profoundly affect growth and development. Growth curves for the height, weight, and sexual development of children with sickle cell anemia have been constructed to permit the identification of individuals whose growth delay is greater than what can be accounted for by the hemoglobinopathy (Fig. 40.8) ([488] , [489]). Although normal at birth, the heights and weights of children with sickle cell anemia are significantly delayed by 2 years of age ([488] , [489] , [490] , [491] and [492]). The growth curves maintain a relatively normal configuration but deviate progressively from the normal curves. Increases in velocity of adolescent height and weight growth occur later, and the magnitude of the growth spurt is substantially less than in healthy children. Puberty also is delayed. Menarche occurs 2 to 3 years later than in the general population (median age, 14.0 to 15.5 years) ([493] , [494]), and Tanner stage V is not achieved until the median ages of 17.3 and 17.6 years for girls and boys, respectively ([488]). As in normal subjects, progression through Tanner stages is orderly and appropriate for bone age ([494]), and the age of menarche correlates closely with age and weight ([488]). By adulthood, both men and women with sickle cell disease appear to acquire normal or near-normal heights, but their mean weights are still lower than those of controls ([488]). Investigations in small numbers of subjects show that growth hormone, thyroid hormone, adrenocorticotropic hormone and cortisol levels, and pituitary responses to growth hormone–releasing factor are normal ([495]). Transient hypogonadism may occur in adolescence. The normal relationship of puberty and growth pattern seen in most patients suggests that the delay in skeletal maturation represents constitutional delay rather than gonadal or pituitary failure ([488]). Former descriptions of the adult with sickle cell anemia as thin, asthenic, long-limbed, short-trunked, and sexually immature are now recognized as misleading.

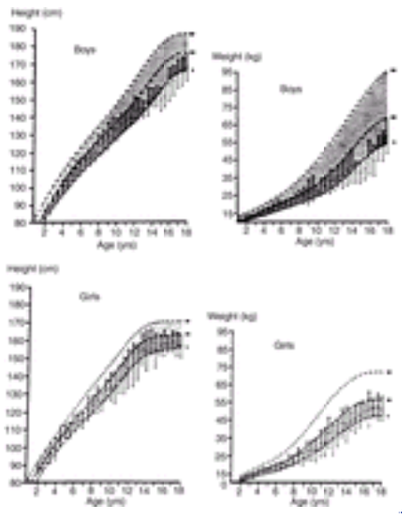

Figure 40.8. Height and weight (mean, ±1 standard deviation) of American boys and girls with sickle cell anemia compared with National Center for Health Statistics growth percentiles. (From Phebus CK, Gloninger MF, Maciak BJ. Growth patterns by age and sex in children with sickle cell disease. J Pediatr 1984;105:28, with permission.)

Low weight appears to be the most critical variable influencing differences in physical maturation among the sickling syndromes ([488]). The basis for delay in weight gain is not fully understood, although it has been hypothesized that chronic hemolysis leads to a state of high protein turnover and increased basal metabolic requirements ([496]). Several recent reports have confirmed that resting energy expenditure measured by indirect calorimetry is 15 to 20% greater in Hb SS patients ([497] , [498] and [499]). Increased whole body protein breakdown and protein synthesis ([497]) may be related to increased bone turnover ([500]). Prepubertal children with sickle cell disease do not compensate for their higher resting energy expenditure by increasing their energy intake, measured by weighing all food consumed during a 3-day period ([501]). Furthermore, caloric intake is significantly decreased at the time of an admission for acute illness, contributing to an overall energy deficit ([502]). When body composition of children and adolescents with sickle cell disease was measured by bioelectrical impedance analysis, male subjects had significantly lower fat-free mass and body fat compared with controls ([503]). Response to nasogastric dietary supplementation has been reported ([504]). Other studies have suggested increased requirements for zinc, folate, riboflavin, vitamin B_6, ascorbate, and the fat-soluble vitamins A and E, but consistent correlations between deficiencies and growth retardation have not been established ([498] , [505] , [506] and [507]). A relationship between zinc deficiency and hypogonadism in adults with sickle cell anemia has been suggested ([508]), and zinc supplements may promote adolescent growth ([509]). Recently, defective growth hormone secretion, decreased insulinlike growth factor-1, and partial resistance to growth hormone in short children with sickle cell disease were reported ([510]). Hematocrit and fetal Hb levels are related to total insulinlike growth factor-1 and insulinlike growth factor binding protein in patients with sickle cell anemia, suggesting that delayed growth may be linked to intrinsic factors of the disease ([511]).

Bones and Joints In addition to the acute episodes of skeletal pain described previously, chronic and progressive destruction of the bones and joints may take place in the absence of clearly defined episodes of pain. The most prominent changes evolve slowly from the cumulative effect of recurrent, small episodes of ischemia or infarction within the spongiosa of bone. Radiographs of the long bones of adults show a mottled, strandlike increase in density randomly distributed within the medullary region (Fig. 40.9). These irregular areas of increased density are produced by new bone laid down on devitalized trabeculae ([512] , [513]). Increased signal is seen with T2-weighted MRI images of infarcted areas ([282]). Because the bone is weakened during the early stages of repair, weight-bearing may collapse the femoral head, producing osteonecrosis with the clinical and radiologic features of Legg-Calvé-Perthes disease ([514]). Osteonecrosis of the femoral and humoral heads affects patients with all the genotypes of sickle cell disease but occurs most often in those with Hb SS and a-thalassemia (4.5 cases/100 patient-years) ([515]). The overall prevalence of osteonecrosis of the hip in persons with sickle cell disease older than 5 years of age is approximately 10% ([515]); the prevalence of osteonecrosis of the humoral head is approximately one-half as much ([516]). Typically, the pain from osteonecrosis of the hip begins insidiously, is brought on by walking or quick movements, and is localized to the groin or buttock. After several months, radiographs may show areas of increased density mixed with areas of increased lucency, followed by the appearance of a “crescent sign,” segmental collapse, molding of the femoral head, loss of joint space, involvement of the acetabulum, and complete degeneration of the joint. When osteonecrosis occurs in the femoral capital epiphysis before closure, healing with minimal destruction may occur. However, long-term follow-up shows that in the majority of cases, the hip is painful and permanently damaged ([517]). Because weight-bearing is not required of the shoulder joint, the prognosis of osteonecrosis of the humeral head is substantially better. Only approximately 20% of patients have pain or limited range of movement at the time of diagnosis ([516]), but functional abnormalities of the shoulder may be a long-term consequence in adults ([518]).

Figure 40.9. Sickle cell anemia. **A:** Femur. The cortex is thinned, and the normal bony architecture is disturbed. Adjoining small areas of translucency are areas of sclerosis. **B:** Tibia and fibula. Marked thinning of the cortex of the bones as well as periosteal reaction and disarrangement of the trabeculae. The latter changes and the extensive coarseness of the cortical layers suggest the bone is involved from within.

Avoidance of weight-bearing in the early phases of bone necrosis may permit sufficient repair to preserve reasonable joint function. More often, however, the deformity is progressively crippling. Total hip replacement is usually recommended for the painful hip in stages III or IV or for restoration of joint movement, if this is desired. However, the prognosis for hip replacement has been suboptimal with a 30% chance that arthroplasty will require revision within 4 to 5 years ([519] , [520]). For stage I and II osteonecrosis, core decompression, in which a core of cancellous bone approximately 8 mm in diameter is removed from the neck and head of the femur through an incision in the lateral cortex, has been of benefit ([521]), but this approach has not yet been proven superior to avoidance of weight-bearing. In a multicenter study, the perioperative complication rate of orthopedic surgery was 67%, including excessive intraoperative blood loss, postoperative ACS, and transfusion reactions ([522]). Another characteristic bone change develops in the vertebral column of some individuals during the second decade of life. Recurrent infarcts of the main vertebral arteries lead to ischemic damage of the central portion of the vertebral body growth plates. Because the outer portion of the plates is supplied by numerous apophyseal arteries, vertebral growth is irregular, producing a “fish-mouth” deformity in which symmetric cuplike depressions are confined to the central three-fifths of the vertebral plates ([437] , [523]). Other skeletal changes result from expansion of medullary cavities owing to long-standing erythroid hyperplasia. Radiographs of the skull show a thickening of the diplöe and thinning of the outer table of the calvaria in the frontal and parietal regions. Gnathopathy (prominent maxillary overbite) may result from overgrowth of maxillary bone ([4]) and frequently leads to significant malocclusion ([524]). Joints may be affected by avascular necrosis of adjacent bone ([525]). The joint effusion, pain, fever, and leukocytosis accompanying such infarcts make differentiation from septic arthritis difficult. Numerous neutrophils and sickled erythrocytes are found in the joint fluid ([281] , [526]). Less commonly, joint disease is related to infection ([527] , [528]), gout ([529]), or synovial hemosiderosis. Adults may have deformities of the hands and feet with shortening of the digits, apparently the remote sequelae of dactylitis during early childhood ([530]).

Central Nervous System As expected, children with a history of overt stroke have significant cognitive impairment, reduced language function, and problems in adjustment ([531]). Several reports in the past two decades have identified deficits in global and specific neuropsychological functioning in school-aged children with sickle cell disease when compared with their siblings or healthy children ([532] , [533] , [534] and [535]). Diminished performance has been noted in the areas of visual-motor integration, attention and concentration, arithmetic, memory, and reading. Routine MRI of the central nervous system performed prospectively in children between the ages of 6 and 14 years as part of the CSSCD disclosed a 17% prevalence of “silent infarcts” (areas of increased signal intensity primarily in deep white matter or watershed areas of the cerebral cortex) in children with Hb SS and no history of stroke ([536]). Data from the CSSCD gathered over a 10-year period of follow-up of school-aged children with Hb SS indicated that those with silent infarct had significantly lower scores for math and reading achievement, full-scale intelligence quotient (IQ), verbal IQ, and performance IQ, when compared with normal MRI findings ([537]). However, even in children with normal MRI findings, the scores for verbal IQ and math achievement declined with increasing age ([537]). A metaanalysis of 17 reports of cognitive functioning in children concluded that sickle cell disease is associated with detrimental effects even in the absence of cerebral infarction. Direct effects of sickle cell disease on brain function or the indirect effects of a chronic illness may be important ([538]). A multiinstitutional study from France in which children with sickle cell disease were compared to sibling controls reported impaired cognitive function in patients both with a history of stroke and with silent infarcts. In addition, hematocrits less than 20% and platelet count greater than 500×10^9/L were independent risk factors for cognitive deficiency ([539]). Patients with frontal lobe infarction differed from their peers in measures of attention, executive function, and memory ([540] , [541]). In another recent study, children with silent infarcts had twice the rate of school difficulties as those without infarcts, including poor *educational attainment*, defined as repeating a grade in school because of lack of educational progress, a requirement for special educational services, or both ([542]). Recent data from the CSSCD have shown that children with silent infarcts had an increased incidence of new stroke and new or more extensive silent infarcts ([543]) and that silent infarcts were the strongest independent predictor of stroke ([544]). Data from the Stroke Prevention Trial in Sickle Cell Anemia (STOP) of transfusion therapy in patients with abnormal TCD velocities indicated that those who had silent infarcts as well as abnormal velocities were at higher risk for developing a new silent infarct or stroke than those whose MRI showed no abnormality ([544]). However, a comparison of patients who were on both the CSSCD and STOP studies indicated that those who had abnormal TCDs did not have an unusually high frequency of MRI abnormality; conversely, those who had silent infarcts did not have an unusually high frequency of abnormal TCD velocities, suggesting that those findings represent different aspects of the pathophysiology of the brain in children with sickle cell disease ([545]). The role of magnetic resonance angiography and diffusion- and perfusion-weighted MRI requires further evaluation at this time. However, diffusion-weighted imaging may be particularly sensitive to identify newly occurring stroke, and perfusion-weighted imaging abnormalities appear to be highly associated with neurologic symptoms ([546]). In general, increased stroke risk may be related to both environmental factors (e.g., hypoxia and inflammation) and

genetic factors (e.g., mutations resulting in thrombogenesis) ([547]).

Cardiovascular System The cardiovascular system is stressed by chronic anemia, recurrent small pulmonary artery occlusions, and myocardial hemosiderosis ([548]). Autopsies have revealed that right and left ventricular dilation is common in both children and adults ([549]). Left ventricular hypertrophy may result from systemic hypertension secondary to chronic renal failure; right ventricular hypertrophy is associated with pulmonary thromboses and cor pulmonale. Echocardiography, performed on adult sickle cell patients from the CSSCD in their baseline state, has shown striking left atrial and biventricular enlargement, normal shortening fraction, prolonged ejection time, and increased stroke volume ([550]). In general, there is an absence of atherosclerotic heart disease, although one study reported myocardial infarction and fibrosis in 17% ([551]). Adults with sickle cell disease may present with clinical signs of acute myocardial infarction in the absence of atherosclerosis or coronary occlusion, but this is uncommon ([552] , [553] and [554]). In children, rare cases of myocardial infarction and transient ventricular dysfunction have been reported ([555] , [556]), and myocardial perfusion abnormality measured by thallium-201 single-photon emission computed tomography may be relatively frequent ([557] , [558]). Congestive heart failure generally does not occur in the absence of extracardiac complications of sickle cell disease ([550]). However, physical performance is severely compromised; adults are usually unable to exceed 50% of expected work capacity ([559] , [560]), and children and adolescents have 60 to 70% work capacities ([561] , [562] and [563]). This is the result of a high cardiac output at rest and an inability to increase output adequately under stress as demonstrated by abnormalities of systolic (ejection) and diastolic (filling) function. Cardiac enlargement, particularly an increase in left ventricular dimensions and mass, results from an increase in cardiac output imposed by chronic anemia and has its onset in early childhood ([564]). The typical physical examination in sickle cell disease reveals cardiomegaly, a hyperdynamic precordium, and a grade II-III systolic ejection murmur with wide radiation. An ejection click from pulmonary artery dilatation and an S3 or apical diastolic rumble also may be heard. Other factors may compound the cardiac embarrassment resulting from anemia. The shunting of blood through infarcted, nonaerated segments of the lung compromises arterial oxygen saturation, and sludging of sickled erythrocytes in small pulmonary arteries may result in pulmonary hypertension. Myocardial hemosiderosis, the consequence of long-standing transfusion therapy, may be responsible for intractable heart failure.

Pulmonary System Chronic pulmonary disease, presumably related to recurring episodes of infarction and infection, is characterized by a decrease in the radiolucency of the lungs and by moderate to severe impairment of pulmonary function. Typically, the vital capacity and total lung capacity are reduced ([565] , [566]), and gas mixing and exchange are compromised. Less often, obstructive lung disease is noted. Blood is shunted through poorly aerated or collapsed segments of the lung, creating a disparity between ventilation and perfusion. The resulting reduction in the functional pulmonary vascular tree is responsible for a decrease in arterial oxygen tension (70 to 90 mm Hg) and desaturation of arterial blood ([567]). The availability of noninvasive monitoring of arterial oxygen saturation through transcutaneous pulse oximetry has led to more careful assessment of oxygenation in sickle cell patients hospitalized for ACS and painful crises ([568]). Hb oxygen saturation is lower in children with Hb SS compared with those with Hb SC and in those with a history of ACS ([568]). Children with acute pulmonary illness have an oxygen saturation level that is below their baseline state and generally less than 96% ([568]). Oxygen saturation measured by pulse oximetry has been compared with arterial cooximeter blood gas measurements. Pulse oximetry may underestimate true arterial saturation, but pulse oximetry values correlate positively with Hb and fetal Hb levels in patients with Hb SS ([569] , [570] , [571] , [572] and [573]). Evidence of pulmonary hypertension has been increasingly recognized in the echocardiograms of patients with sickle cell disease and is now considered to be a major cause of morbidity and mortality ([574] , [575] and [576]). In one study, the median survival for patients with pulmonary hypertension was only 26 months, and pulmonary artery pressure had a significant inverse relationship with survival ([575]). The role of NO in the pathophysiology and treatment of pulmonary hypertension is currently being explored. The use of hydroxyurea for these patients also has been recommended ([577]). In children with sickle cell disease, obstructive restrictive defects and airway hyperreactivity are particular problems and have been associated with responsiveness to bronchodilators ([578] , [579]).

Hepatobiliary and Gastrointestinal Systems Liver enlargement is present by 1 year of age and persists to a moderate degree throughout life. Analysis of histologic sections reveals distention of sinusoids with sickled cells, Kupffer cell erythrophagocytosis, and varying degrees of periportal fibrosis and hemosiderin pigment ([580] , [581]). Sickle cell disease may be associated with disturbances in hepatic function ([581] , [582]). In adult life, diffuse nodular cirrhosis may occur ([583]). Acute enlargement of the liver, such as may occur with sequestration of sickle cells, subcapsular infarction, or hepatic vein thrombosis ([584]), is associated with tenderness or right upper quadrant pain. Intrahepatic infarcts may be complicated by abscess formation. In addition, hepatic function as assessed by lidocaine metabolism is impaired in patients with sickle cell disease, suggesting caution when using hepatically metabolized medication in these patients ([585]). It is not unusual for hyperbilirubinemia to punctuate the course of sickle cell anemia. These episodes may result from intercurrent infectious hepatitis, intrahepatic sickling (hepatic crisis, “sickle hepatopathy”), or choledocholithiasis. It has been suggested that coexistent glucose-6-phosphate dehydrogenase deficiency may be a contributing factor ([586]). The clinical picture of acute viral hepatitis is similar to that seen in non–sickle cell patients except for the remarkable elevation of serum bilirubin concentration (which may reach 100 mg/dl) ([587] , [588]). Hepatitis A virus may be a frequent cause of acute icteric hepatitis in endemic areas and may result in fulminant hepatic failure and death ([589]). Hepatitis B surface antigen has been found in 6 to 14% of patients in limited studies ([590] , [591]). However, most sickle cell patients respond normally to hepatitis B vaccine ([484]), although surface antibody titers after immunization should be measured to identify those who do not convert and require booster injections ([592]). Evidence of prior hepatitis C virus infection has been found in 21% of sickle cell anemia patients in Philadelphia ([593]), 10% in Brooklyn ([594]), 2% of previously transfused sickle cell patients in Jamaica ([595]), and 18% in Saudi Arabia ([591]). Liver biopsies may show progression to chronic active hepatitis and cirrhosis. Since the advent of screening of transfused blood for hepatitis C, new cases of this infection have become extremely rare. Orthotopic liver transplantation has been used in a patient with liver failure due to cirrhosis ([596]). The histologic consequences of intrahepatic sickling include impaction of hepatic sinusoids with sickled erythrocytes, patchy areas of hepatocellular necrosis, engorgement of Kupffer cells, and bile stasis ([580] , [597] , [598]). In children, manifestations of sickle hepatopathy are mild and transient. These include right upper quadrant pain, hepatomegaly, fever and leukocytosis, mild elevation of serum transaminase levels, and moderate to marked elevation of serum bilirubin and alkaline phosphatase levels ([599]). Although the course in children is benign and symptoms usually resolve in 1 to 3 weeks, progression to fulminant hepatic failure, generalized bleeding, and death are much more frequent in adults ([590]) and are occasionally seen in adolescents ([600] , [601] and [602]). Prompt exchange transfusion and, occasionally, chronic transfusion have been the only effective therapies in these patients ([600] , [601] , [602] and [603]). Liver transplantation has been attempted in at least one patient ([604]). Because of a sustained increase in heme catabolism, the frequency of pigmentary gallstones in sickle cell disease is high. These stones, which may be either radiolucent or radiopaque, have been documented in children younger than 5 years of age ([605] , [606] and [607]). The incidence of gallstones increases with age, from 12% in the 2- to 4-year-old age group to 42% in the 15- to 18-year-old age group and 60% in adults ([608]). In Jamaica, the prevalence of gallstones was 53% at 23 years of age in Hb SS and 20% in Hb SC ([609]). When ultrasonography is used routinely, the finding of gallbladder sludge with or without concurrent stones is common ([610]); even if not present initially, patients with sludge eventually develop stones. Genetic variations in the uridine diphosphate–glucuronosyltransferase 1a promoter significantly influence serum bilirubin levels and the development of symptomatic cholelithiasis in children with sickle cell anemia ([611]). Not more than 10 to 15% of patients have symptoms that can be attributed to the biliary tract ([605] , [612]). Occasionally, they are able to distinguish the pain of choledocholithiasis from that of abdominal vasoocclusive crises. Elective cholecystectomy may be followed by a dramatic decrease in the frequency of abdominal crises ([605] , [606]). Laparoscopic cholecystectomy has replaced open cholecystectomy in many centers because it results in shorter hospitalization and decreased postoperative pain and other complications ([613] , [614] , [615] and [616]). Although duodenal ulcer disease has been reported in patients with sickle cell anemia ([617] , [618]), there is no clear evidence that it is more common than in the general population. Gastric acid output is not increased in patients with duodenal ulcers ([617] , [619]). Severe ischemic colitis has been reported in two patients ([620] , [621]), and pancreatitis has been a rare problem in sickle cell disease ([622]).

Kidneys A variety of defects in renal function have been described ([623]), and a number of histologic alterations have been noted ([624] , [625]). Even in the absence of clinically apparent renal disease, small cortical infarcts of varying ages are evident ([626]), hemosiderin is deposited in the epithelium of proximal convoluted tubules, glomerular arterioles are dilated and congested, glomerular surface area relative to kidney size is increased ([625]), and varying degrees of juxtamedullary glomerular hypertrophy and sclerosis are seen ([624]). Symmetric enlargement of the kidneys is a regular feature, and distortion of the collecting system has been a common finding on intravenous pyelograms ([627]). Frank papillary necrosis may occur. Hyposthenuria ([628] , [629]) and a limited capacity for hydrogen ion excretion ([630] , [631] and [632]) are present after 6 or 12 months of age. Hyposthenuria is corrected temporarily with red cell transfusions until up to 15 years, but not thereafter ([628] , [633]). Disruption of the countercurrent multiplication system owing to sludging of sickle cells in the more hypertonic portions of the renal medulla has been proposed as the mechanism responsible for the concentrating defect ([628]). The demonstrated obliteration of a portion of the vasa rectae is in keeping with this hypothesis ([627]). An alternative mechanism involving decreased perfusion and progressive destruction of structures in the renal papillae has been proposed ([623]). Presumably, because of the large fluid consumption necessitated by the renal concentrating defect, most patients experience enuresis ([634]). Enuretic sickle cell patients have nocturnal urine osmolality equivalent to that of nonenuretic patients but may respond to desmopressin ([635] , [636]). Urinary acidification is abnormal in sickle cell patients probably resulting from an incomplete form of distal tubular acidosis attributable to diminished ability of the collecting duct to maintain hydrogen ion gradient ([631] , [632]). Impaired potassium excretion by the kidney and subsequent hyperkalemia, increased phosphate reabsorption, and increased uric acid clearance have also been described ([637] , [638] and [639]). Hematuria is common and may be both brisk and prolonged. Bleeding may originate in one kidney or both, or it may take place in an alternating fashion. The most common lesion is an ulcer in the renal pelvis at the site of a papillary infarct ([640] , [641] and [642]). The possibility that painless hematuria may be the result of poststreptococcal glomerulonephritis ([643]), renal medullary carcinoma ([644]), or other disorders unrelated to the hemoglobinopathy should not be overlooked. Idiopathic hematuria rarely requires more than symptomatic treatment. The risk of clotting within the collecting system is best minimized with a high fluid intake. Rarely, protracted blood loss necessitates iron supplementation. Although there is no controlled study of its use, e-aminocaproic acid is said to shorten the duration of hematuria in both sickle cell anemia and sickle trait patients ([645] , [646] and [647]). Its use, however, is attended by a risk of ureteral obstruction resulting from blood clots.

Unrelenting, brisk hematuria is best managed with a course of transfusion therapy designed to maintain the Hb S concentration below 40%. The nephrotic syndrome is an infrequent but well-documented complication of sickle cell anemia that occurs in adolescents and adults. The syndrome may be associated with hypertension, hematuria, and progressive renal insufficiency culminating in renal failure ([648], [649]). Pathologic lesions include glomerular enlargement and focal segmental glomerulosclerosis ([624], [625], [648], [650], [651]). In more advanced disease, a lesion that resembles membranoproliferative glomerulopathy has been described ([652]); immune complex nephropathy has also been reported ([653]). Glomerular enlargement is probably secondary to the increased glomerular filtration rate and effective renal plasma flow that are found in children but that decline to subnormal levels with increasing age or from adverse effects of nonsteroidal antiinflammatory agents ([654], [655]). In adults with glomerulopathy and end-stage renal disease, the mortality rate was 40% ([655]). Microalbuminuria occurs in 46% of children between the ages of 10 to 18 years ([656]) and is directly related to age and degree of anemia ([652]). Approximately one-fourth of adult sickle cell patients have at least 1+ proteinuria, and 7% have serum creatinine concentrations above the normal range ([651]). Administration of enalapril, an angiotensin-converting enzyme inhibitor, reduces proteinuria, suggesting that glomerular capillary hypertension may be a pathogenic factor in sickle cell nephropathy ([657]). The overall incidence of hypertension in patients with Hb SS is 2 to 6%, compared with a published incidence of 28% for the black population in the United States ([658]). Recent data from the CSSCD confirmed that individuals with sickle cell disease have a significantly lower blood pressure than the general population, but hypertension is still a risk factor for stroke and increased mortality ([659]). Intermittent hypertension occurring during sickle cell crises and associated with transient elevation of plasma renin activity has been attributed to the reversible sludging of red cells in the small vessels of the kidney ([660]). Renal failure, which occurs in approximately 4% of patients with sickle cell anemia at a median age of onset of 23 years ([661]), is a significant cause of mortality in adults ([232]). The preazotemic manifestations of hypertension, proteinuria, and increasingly severe anemia predict end-stage renal failure with an average survival (despite dialysis) of 4 years after diagnosis ([661]). Management of renal failure is the same as that for renal insufficiency owing to other causes. Both hemodialysis ([649]) and peritoneal dialysis, when used in conjunction with a transfusion program, are efficacious in transiently correcting uremic complications. Erythropoietin is of value in correcting the worsened anemia associated with renal failure ([662]). The role of renal transplantation has not been well established because of limited numbers of patients and posttransplant problems of increased pain crises, graft thrombosis, and recurrence of sickle nephropathy ([663]). A report from the North American Pediatric Transplant Cooperative Society described nine patients with end-stage sickle cell nephropathy for whom graft survival was 71% at 2 years after transplant ([664]). In another recent report, 82 patients with end-stage sickle cell nephropathy received renal allografts ([665]). The short-term result was similar to that seen with other causes of end-stage renal disease, but the long-term outcome was diminished. Pharmacologic doses of exogenous erythropoietin have been effective in correcting anemia, but higher hematocrits have been associated with increased pain crises ([666]). Recently, a patient with intrahepatic cholestasis and renal failure was successfully transplanted with a combination of liver and kidney ([667]), but a combined bone marrow/renal transplant, which would be theoretically advantageous, has not been reported.

Eyes A variety of ocular lesions result from occlusion of the small vessels of the eye by sickled erythrocytes (Fig. 40.10). The prominence of end arterioles within the retina renders this tissue especially vulnerable to irreversible injury after vascular occlusion.

Figure 40.10. Ocular abnormalities in sickle cell anemia. **A:** “Comma” vascular sign: superficial conjunctival vessel that contains densely packed sickled cells (*arrow*). **B:** Widened veins and tortuous large vessels of the retina. **C:** Large preretinal hemorrhage of approximately 2 weeks' duration. There is partial resorption and exposure of a darkened area that was the probable site of intraretinal hemorrhage. **D:** Old pigmented chorioretinal scar. See Color Plate. (Photographs by Professor Mansour Armaly, The George Washington University Medical Center.)

Sludging of blood in conjunctival vessels is responsible for the so-called conjunctival sign ([668], [669]), which consists of dark red, comma-shaped or corkscrew-shaped vascular fragments that appear to be isolated from other vessels. The anomalous segments are seen most often in that part of the temporal bulbar conjunctiva covered by the lower lid. A direct relationship between the prominence of these saccular segments and the number of ISCs on blood smears has been noted ([176], [670]). Vasoocclusive disease of the retina is responsible for both nonproliferative and proliferative (neovascular) changes ([671], [672] and [673]). The former consist of “salmon patches,” produced by small intraretinal hemorrhages; iridescent spots, representing collections of iron-loaded retinal macrophages; and schisis cavities, left after resorption of blood. Hemorrhages that break into the potential space between the sensory retina and pigment epithelium stimulate pigment production and migration, giving rise to black, disc-shaped scars known as *black sunbursts*. Proliferative changes begin with the formation of arteriovenous anastomoses, followed by the development of vascular fronds resembling sea fans ([674]). Immunohistochemical techniques have been used to demonstrate the association of vascular endothelial growth factor and fibroblast growth factor with sea fan formation ([675]). Vessels grow anteriorly toward the preequatorial, ischemic portion of the retina. Inspection of sea fans with ultraviolet light after the intravenous injection of fluorescein usually reveals small leaks into the vitreous. Major hemorrhages from sea fans that extend into the visual axis can generate visual symptoms. More often, however, they are confined to the peripheral portions of the retina and go undetected except by ophthalmoscopy. With time, repeated vitreous hemorrhages cause vitreous degeneration and vitreoretinal traction, which in turn produces retinal holes, tears, and detachment. Although these changes may culminate in loss of vision, they do so less often in association with Hb SS than in association with Hb SC disease ([674], [676], [677] and [678]). No correlation has been found between retinopathy and age, sex, systemic complications, and various hematologic parameters except Hb F level, which is higher in less affected patients ([677]). Proliferative retinal disease may be arrested satisfactorily by using xenon arc or argon laser photocoagulation or cryocoagulation ([176]). These procedures not only seal off the feeder vessels of neovascular patches and coagulate vascular leaks, but also promote the absorption of intraretinal and subretinal fluid by producing chorioretinal adhesions. Vitreous hemorrhages can be removed by pars plana vitrectomy followed by photocoagulation. Retinal detachment is treated by using standard surgical techniques, taking special precaution to avoid anterior segment ischemia. An additional ocular complication of sickle cell disease is hyphema. Bleeding into the anterior chamber leads to trapping of sickled red cells, mechanical obstruction of the outflow apparatus, compromised circulation of the aqueous humor, and increased intraocular pressure, which may result in sudden blindness ([678], [679]). This complication, which also can occur with sickle cell trait red cells, may be effectively managed by lowering intraocular pressure through anterior chamber paracentesis. Mild edema of the eyelids is frequently seen in association with vasoocclusive pain crises, but more significant sickle “orbitopathy” has been described in approximately 20 patients ([281], [680], [681]). A vasoocclusive process in the marrow space around the orbit may result in frontal headache, fever, eyelid edema, and orbital compression. Subperiosteal hematomas are common and appear to result from bone marrow infarction. Although supportive care is usually adequate, the presence of optic nerve dysfunction or unusually large hematomas may require surgical evacuation to prevent loss of vision ([680]).

Leg Ulcers Breakdown of the skin over the malleoli and distal portions of the legs is a recurring problem during adult life (Fig. 40.11). Stasis of blood in the small vessels supplying these areas may interfere with the healing of minor traumatic abrasions. Venous incompetence detected by Doppler ultrasonography was more frequent in Jamaican patients with Hb SS than in controls and was highly associated with leg ulcers ([682]). These were observed in 2.5% of sickle cell patients over 10 years of age in North America ([683]), but they affect as many as 75% of adults with sickle cell anemia who live in tropical areas ([684]). A number of other risk factors have been identified. Ulcers are common in patients with Hb SS but quite rare in those with Hb SC disease or Hb S ß $^{+}$-thalassemia ([683]). The presence of a-thalassemia with either three or two a-globin genes reduces the incidence of ulcers. They are more common in men than in women and in those older than 20 years of age. There is a positive correlation with a low steady-state Hb concentration and with a low level of Hb F ([683]).

Figure 40.11. Chronic leg ulcers in a patient with sickle cell anemia. (Courtesy of AF Jonas, Jr.)

The ulcers typically form a shallow depression with a smooth and slightly elevated margin; often, they have a surrounding area of edema ([374]). There may be

exudation, crusting, and granulation at the base. Secondary infection of the ulcer with undermining of the edges and progressive extension are common. Single or multiple bacterial organisms may be cultured from the lesions and may contribute to their refractoriness. Healing leaves a thinned, depigmented epithelium often surrounded by areas of hyperpigmentation and hyperkeratosis. This fragile epithelium is likely to break down with minimal trauma or edema, leading to recurrence rates greater than 70% ([685]). Healing of leg and ankle ulcerations is facilitated by bed rest, elevation of the affected extremities, wet-to-dry dressings, and eradication of documented wound infections with systemically administered antibiotics. When acute inflammation has subsided, occlusive zinc oxide–impregnated gel boots (Unna boots) are applied, and partial ambulation is permitted. In refractory or progressive cases, the healing process may be enhanced if the level of Hb S is maintained below 40% with transfusions. Split-thickness skin grafting may be necessary ([686]). Zinc deficiency has been invoked to explain slow tissue healing ([687]), and oral zinc therapy may hasten healing in some patients ([688]). A number of alternative approaches have also been described in recent years. Topical oxygen using a local tent to envelop an ulcer can be used on an outpatient basis ([689]). Erythropoietin and hydroxyurea may improve healing by increasing fetal or total (or both) Hb levels ([690] , [691]). The use of collagen matrix dressings (RGD peptide matrix) in a controlled collaborative trial resulted in greater ulcer closure ([692]). Antithrombin III in combination with subcutaneous heparin ([693]) and pentoxifylline ([694]) have also yielded anecdotal benefit.

Pregnancy Pregnancy ([695]) poses potentially serious problems for the woman with sickle cell anemia, as well as for the fetus and neonate. In the absence of medical supervision, the mortality for mother and infant is as high as 20% and 50%, respectively ([696]). With optimal care, mortality and morbidity are reduced substantially ([697] , [698]), even in difficult settings in Africa ([699]). The jeopardy imposed by pregnancy is explained in part by marginal health status before conception and in part by the sinusoidal circulation of the placenta, whereby a high degree of oxygen extraction provides an excellent milieu for sickling, stasis, and infarction ([374]). Although life-threatening complications generally are not encountered until the third trimester, an increased incidence of pyelonephritis, hematuria, and thrombophlebitis is noted throughout pregnancy ([698]). Anemia is more severe and may be compounded by folate deficiency. During late pregnancy and the postpartum period, major infarctions may involve the lungs, kidneys, or brain. Toxemia, heart failure, and postpartum puerperal endometritis occur with greater frequency in women with sickle cell anemia than in the general population ([697] , [698] , [700] , [701] and [702]). The risk to the fetus is no less serious, with an overall survival rate of only approximately 58% compared with 87% in the general population. Fetal wastage results from a combination of abortion and stillbirth ([698] , [700]). The incidence of congenital malformations or susceptibility to complications is comparable to that shared by all preterm infants ([697]). Striking hyperbilirubinemia of cord blood owing to a reversal of the usual maternal-fetal bilirubin gradient has been observed ([696]). Infants born to women with sickle cell anemia are at greater risk of preterm birth, low birth weight, being small for gestational age, and neonatal jaundice ([701]). Infants small for their gestational age are two and one-half times more likely than in the general population ([701]); 21% of infants in a recent CSSCD report were small for their gestational age ([702]). Possible etiologic factors are severe maternal anemia; frequent episodes of vasoocclusion leading to hypoperfusion and hypoxia of the placenta; increased risks of abruptio placentae, placenta previa, and toxemia of pregnancy; diminished maternal nutrition; and increased narcotic use in the mother. Preeclampsia and acute anemic events were risk factors identified by the CSSCD ([702]). The increased risk of preterm labor and prematurity may be caused by similar factors including anemia, abruptio placentae, placenta previa, toxemia, and narcotic use, as well as increased urinary tract infection and chorioamnionitis. A high maternal Hb F level may have an ameliorating effect on perinatal mortality ([703]). The efficacy and safety of various methods of contraception have not been investigated systematically in women with sickle cell disease. Despite a theoretical possibility of enhancing thrombotic risk, low-estrogen-dose birth control pills are sometimes recommended. Recent studies in Nigeria and Brazil found no adverse effects from the progestational contraceptive implant and a possible improvement in fetal Hb level ([704] , [705]). An association of pain crises and menstrual periods seen in 37% of women suggests the use of a continuous combined contraceptive pill regimen or Depo-Provera to induce amenorrhea in severe cases ([706]).

Prognosis

Prognostic expectations for persons with sickle cell anemia have undergone dramatic change as a result of early diagnosis, patient education, and therapeutic intervention. In a retrospective review of autopsy cases from the United States in 1972, 20 to 30% were younger than 5 years of age at the time of death ([374]). The median age at death was 14 years, and survival beyond 40 years of age was unusual. In a 1976 report of a screening program involving the use of cord blood, 31% of children diagnosed at birth died before 15 years of age at a mean age of 2 years ([707]). The disproportionate number of reported deaths occurring in early childhood was the result of overwhelming bacterial infections and splenic sequestration crises ([265] , [708]).

Newborn screening for sickle cell disease and greater awareness of the unique needs of affected infants and children are effecting a change in prognosis ([709] , [710]). The simple adoption of a standardized protocol for the management of febrile illnesses reduced the mortality in children with sickle cell anemia 0 to 5 years of age from 3.2/100 patient-years to 1.4/100 patient-years ([432]). In 1989, the CSSCD documented an 85% survival rate at 20 years of age ([711]). In that study, peak incidence of death (mostly resulting from infections) occurred between 1 and 3 years of age. Cerebrovascular accidents and traumatic events exceeded infections as a cause of death in the second decade of life. Mortality data for young children with Hb SS born in the early 1990s in three large states with newborn hemoglobinopathy screening indicated that 1% died as a result of sickle cell disease–related causes during the first 3 years of life ([712]). In another retrospective review, mortality rates of black children with sickle cell disease decreased by 40 to 50% between 1968 and 1992 ([713]).

In a report from the CSSCD ([232]), causes of death for 209 adult patients who died during the study were analyzed. Among adults with Hb SS, the median age at death was 42 years for males and 48 years for females. However, among those with Hb SC disease, the median age at death was 60 years for males and 68 years for females. Only 18% of deaths occurred in patients with chronic organ failure; of these, 58% had chronic renal failure, 29% had chronic congestive failure, and 23% had chronic debilitating stroke. One-third of the deaths occurred in the context of hospitalization for an acute painful episode, ACS, or stroke, which was predominantly hemorrhagic. Six percent died with infection, 6% had perioperative deaths, and 6% died from trauma. Miscellaneous causes included cancer, gastrointestinal bleeding, and fulminant hepatic failure. In approximately 23%, the exact cause of death was unknown. Statistical modeling revealed that in patients with sickle cell anemia, ACS, renal failure, seizures, baseline white cell count above 15,000/mm ^{3}, and a low level of fetal Hb were associated with an increased risk of early death. Early mortality was highest among patients whose disease was symptomatic. It was concluded that a high level of fetal Hb is probably a reliable childhood forecaster of improved adult life expectancy.

DETERMINANTS OF SEVERITY Extensive data from the CSSCD highlighting frequency/incidence and risk factors for various complications of sickle cell disease have been published. Because of the large number of patients involved and the efforts to avoid patient selection bias, these data represent the most ambitious attempt to describe the natural history of sickle cell disease to date. A large, carefully followed cohort of sickle cell patients from Jamaica described in numerous publications and a textbook provides another major source of data for prognostic analysis ([2]). Sickle cell anemia is remarkably variable in its clinical expression, even among affected members of the same family. Whereas many individuals have recurrent, severe complications, others enjoy a relatively benign, virtually symptom-free course ([714]). The calculated extent of polymer formation is purported to correlate with the clinical severity of different sickling syndromes ([194]). Occasionally, patients with apparently mild sickle cell anemia are found on further study to be doubly heterozygous for Hb S and another Hb variant having the same electrophoretic mobility as Hb S or to be heterozygous for both Hb S and HPFH. That clinical heterogeneity is related to genetic variables is suggested by the tendency for differences in disease severity to follow selected geographic and ethnic lines. In the eastern oases of Saudi Arabia, for example, sickle cell anemia is clinically benign ([715] , [716] , [717] and [718]), whereas in western Saudi Arabia, it is comparable in severity to that seen in black Americans ([719]). At least four important modulators of hematologic and clinical severity have been identified: Hb F level, the presence of a-thalassemia, the ß-globin gene cluster haplotype, and gender ([720] , [721] , [722] , [723] and [724]). Because Hb F is excluded from the Hb S polymer, individuals with relatively greater amounts of Hb F should have less severe disease than those with less Hb F. The level of Hb F in patients with sickle cell anemia is determined by the number of red cells containing Hb F (F cells), the Hb F concentration within F cells, and the survival of F cells ([725]). The proportion of reticulocytes containing Hb F is relatively constant over time, but it varies greatly among affected individuals (2 to 50%). Other confounding factors in studies to determine the prognostic significance of Hb F include the variability in techniques used to measure fetal Hb and the fact that Hb F levels in sickle cell patients gradually decline over a long period of childhood and do not reach equilibrium until 12 years of age ([726]). The expression of high levels of Hb F and F reticulocytes may be inherited as an autosomal-dominant characteristic ([727] , [728]). Five factors have been shown to influence the 20-fold variation of fetal Hb in sickle cell anemia: age, sex, a-globin gene number, ß-globin haplotype, and the F-cell production locus. In the eastern province of Saudi Arabia ([715] , [729]) and in Kuwait ([730]), Iran ([731]), India ([718]), and the West Indies ([732]), mild disease is associated with Hb F levels of 15 to 30%. Levels of Hb F influence the age at which symptoms develop ([268]) and partially determine the risk of splenic sequestration crisis ([267] , [406]), stroke ([322] , [324]), ACS ([345]), leg ulcers ([683]), pain crises ([278]), loss of spleen function ([271]), and mortality ([662]). Among patients of West African ancestry, higher levels of Hb F are associated with an improvement in hematologic features ([274] , [733]), but an improvement in measures of clinical severity related to increased Hb F has been difficult to establish. One study concluded that Hb F levels substantially lower than 20% conferred minimal benefit on disease severity, indicating a threshold effect ([734]). However, evidence from the CSSCD indicates that even when the fetal Hb level is low, small increments in the level may have an ameliorating effect on the pain rate and may ultimately improve survival ([278]). The limited capacity of Hb F levels to predict disease severity, however, does not negate the importance of Hb F production. Hb F levels are determined not only by synthetic rates but also by the extent to which F cells are enriched by differential cell survival. Thus, high levels of Hb F may reflect increased synthesis, resulting in mild disease, or greater amplification through accelerated destruction of cells containing no Hb F, a manifestation of more severe disease ([725]). Co-inheritance of

sickle cell anemia and a-thalassemia is not an unusual event. Nearly 30% of black Americans have a single a gene deletion, and in approximately 2%, deletion of two of the four a-globin genes has been found. Hematologic studies provide support for the clinical relevance of a-thalassemia. Subjects with sickle cell anemia and a-thalassemia have a higher Hb concentration, lower MCV and MCHC, fewer ISCs, a lower reticulocyte count, lower serum bilirubin concentration, and relatively more Hb A2 than subjects without concurrent a-thalassemia ([125], [735], [736], [737], [738] and [739]). The a gene deletion also is associated with improved cell deformability ([740]), a decreased fraction of dense cells ([740], [741]), protection against cation leak ([742]), and improved red cell survival ([743]). There is relatively little effect of a-thalassemia on Hb F levels ([736], [737]), although in patients with the Senegal haplotype, Hb F levels are higher ([716]). The mechanism responsible for these differences in hematologic status is probably mediated by a decrease in the MCHC, because the extent and the rate of Hb S polymerization are highly dependent on the cellular concentration of Hb S. Early reports indicated that the frequency of a-thalassemia increases progressively with the age of patients with sickle cell anemia ([744], [745]). However, a subsequent larger study demonstrated that coexistent a-thalassemia is associated with a diminished mortality risk in patients older than 20 years of age ([232]). The rheologic benefits of more deformable a-thalassemic sickle cells are offset by rheologic impairment associated with the greater viscosity of a higher hematocrit induced by a-thalassemia ([746]). Thus, a-thalassemia is associated with more frequent vasoocclusive pain crises by virtue of its effect on hematocrit ([278]). Osteonecrosis and perhaps sickle retinopathy occur more often in sickle cell subjects with coexistent a-thalassemia ([515], [516], [739], [747], [748] and [749]). On the other hand, the incidence of stroke is lower in subjects with sickle cell anemia and a-thalassemia ([750]). Sickle cell trait is also influenced by a-thalassemia. Subjects with lower fractional content of Hb S associated with a-thalassemia have less severely impaired urinary-concentrating ability ([751], [752]). Genetic factors that modulate the phenotype of sickle cell disease are now known to be associated with polymorphic sites within the ß-globin–like gene cluster. These are identifiable by restriction fragment length polymorphisms and are referred to as ß *-globin gene haplotypes* ([753]). The haplotypes are characteristic of different populations; most patients with sickle cell anemia in the United States have the Benin haplotype, with fewer having the Bantu (Central African Republic) and Senegal types. The origin of these genes in malarial regions of Africa is shown in Figure 40.1 ([11], [754], [755]). In Mediterranean populations, the $ß^S$ gene is usually associated with a Benin haplotype, whereas the haplotype found in Eastern Saudi Arabia and parts of India resembles but is distinct from that of Senegal. The Senegal haplotype is associated with higher levels of Hb F ([716], [755], [756] and [757]) and with fewer hospitalizations and painful episodes ([758], [759]). By contrast, the Bantu haplotype has been associated with the highest incidence of organ damage, particularly renal failure ([661]). More recently, fetal Hb levels in sickle cell patients and normal individuals have been found to be partially controlled by an X-linked gene located at Xp22.2 called the *F-cell production locus* ([723]). Female gender increases the expression of Hb F both in patients with sickle cell anemia and in normal individuals ([723]). Multiple regression analysis in one study showed that the F-cell production locus was the strongest predictor of Hb F level, although approximately one-half of the variation was not accounted for ([724]). When ß-globin haplotype and gender were considered together, the Hb F level in female patients of all haplotype groupings was higher than that in male patients, with the highest level occurring in female patients with one Senegal haplotype chromosome (Hb F, 12.8%) ([760]). Thus, gender and ß-globin gene cluster haplotype interact in the modulation of Hb F and Hb level in sickle cell anemia. In Jamaica, high levels of Hb F (and a normal a-globin gene complement) have been associated with a benign disease, which occurred in 15% of patients ([761]). A recent report from the CSSCD involved a cohort of 392 infants with Hb SS or Hb $Sß^0$-thalassemia who were followed for an average of 10 years beginning at younger than 6 months of age. Eighteen percent had an adverse outcome, defined as death, stroke, frequent pain, or recurrent ACS ([234]). Three statistically significant predictors of an adverse outcome could be identified at 2 years of age: Hb level less than 7 g/dl, leukocytosis in the absence of infection, and an episode of dactylitis before 1 year of age. Although these are easily identifiable manifestations of sickle cell disease, other investigators did not confirm this finding ([762]). Sickle cell disease should no longer be considered a single gene disorder ([763]) because a number of epistatic and pleiotropic genes have been defined ([764], [765]). Microchip array technology and high throughput sequencing may be used in the future to identify expressed genes that predict clinical outcome, and recently, single nucleotide polymorphisms have been used to identify alleles of VCAM-1 associated with protection from stroke ([766]).

Laboratory Features

RED BLOOD CELLS In sickle cell anemia, a moderately severe normocytic, normochromic anemia manifests by 3 months of age ([270]) and persists throughout life ([266]). The average Hb concentration is 8.0 g/dl, with a range from approximately 6.0 to 10.0 g/dl. Mean Hb levels vary with gender and with age; they are higher in adult men compared with women and higher in males between the ages of 20 and 39 years ([767]). In adults with Hb SS, the mean MCV is approximately 90 fl, and the mean MCHC is approximately 34.0 g/dl ([767]). The MCV and MCHC are substantially lower (mean, 72 fl and 32.5 g/dl, respectively) in patients with concurrent a-thalassemia minor (-*a*/-a genotype) ([735], [736], [737] and [738]) and in children with incidental iron deficiency ([768]). The MCV in males with sickle cell anemia is below that for females in almost all age groups ([769]); this may reflect the higher Hb F concentration seen in female patients. Modern automated blood cell counters (based on aperture and impedance or light scatter techniques) may result in overestimation of the MCV and underestimation of the MCHC ([756], [770]) because of the inability of dehydrated, dense sickled red cells to deform like normal cells as they pass through the narrow counter aperture. However, the use of two-angle light scattering technology permits accurate measurement of MCV and MCHC and generation of histograms of these properties ([771]). This allows routine quantitation of the percentage of dense, dehydrated red cells, which enhances the monitoring of therapeutic interventions. Blood smears contain variable numbers of sickled forms, target cells, cigar-shaped cells, and ovalocytes (Fig. 40.12). The great variety of sickle cells is best appreciated by scanning electron microscopy (Fig. 40.2). The morphologic features of accelerated erythropoiesis, which include polychromatophilia, basophilic stippling, and normoblastosis, are prominent. The mean reticulocyte count is approximately 10%, with a range of 4 to 24% ([767]). Howell-Jolly bodies and Pappenheimer bodies reflect functional asplenia. Numerous pits in red cell membranes, also a feature of the asplenic state, require phase interference contrast microscopy for visualization ([271], [450]). With transmission electron microscopy, dense aggregates of Hb can be seen adjacent to red cell membranes ([772]).

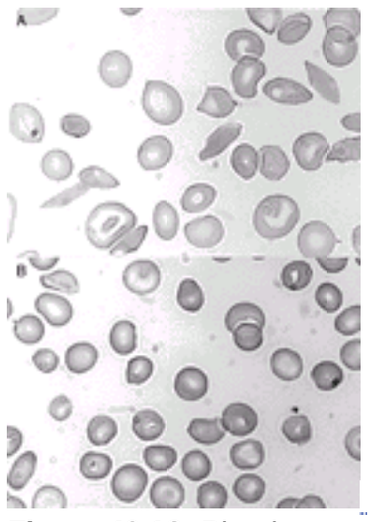

Figure 40.12. Blood smears of patients with hemoglobin (Hb) SS and Hb SC disease. **A:** Red blood cell morphology in sickle cell anemia is characterized by sickled forms (dense elongated cells with pointed ends), target cells, ovalocytes, and polychromatophilia. **B:** Hb SC disease is characterized by target cells, relatively few sickled forms, and a small proportion of cells that contain dark, blunt protuberances (hemoglobin “crystals”). See Color Plate.

Erythrokinetic studies performed in the steady state indicate a four- to fivefold increase in red cell production and erythron iron turnover and a comparable shortening of red cell survival. The curves of cell survival obtained with ^3H- or ^{32}P-labeled diisopropylfluorophosphate indicate a random rather than a senescent mode of cell destruction ([402], [773], [774]). This pattern of cell loss is explained by the lack of dependence of ISC formation on cell age ([83]). Chronic hemolysis, some of which is intravascular, is responsible for an increase in endogenous carbon monoxide generation and for elevated serum levels of unconjugated bilirubin and heme proteins ([215]). The serum haptoglobin level is decreased. Serum immunoreactive erythropoietin levels are lower than those noted in association with other anemias of comparable severity ([775]).

WHITE BLOOD CELLS The white blood cell count is consistently elevated owing to an increase in the number of mature granulocytes. The mean leukocyte count under steady-state conditions is 12 to 15 × 10^9/L, with a range of 6 to 20 × 10^9/L ([769]). This increase is explained to a large extent by a shift of granulocytes from the marginated to the circulating compartments (see Chapter 10) ([226]). Both total and segmented leukocyte numbers increase during vasoocclusive crises and infections, but only with bacterial infections does a consistent increase occur in nonsegmented neutrophils, often to levels above 1 × 10^9/L ([227]).

PLATELETS AND COAGULATION The platelet count is increased (mean, approximately 440 × 10^9/L), reflecting reduced or absent splenic sequestration ([251], [769], [776]). Totals of both platelets and megathrombocytes decrease during vasoocclusive crises ([251], [252]). Platelet aggregation is decreased, the likely result of *in vivo* platelet activation ([253], [777]). The plasma ß-thromboglobulin level is elevated ([254]). The contact factors are decreased ([257]), whereas factor VIII activity, fibrinogen concentration, and fibrinolytic activity are increased ([778], [779] and [780]). Some of these alterations likely reflect vascular endothelial damage inflicted by the sickling process and not primary perturbations responsible for crises.

OTHER LABORATORY TESTS The sedimentation rate is consistently low, even in the presence of anemia, hyperfibrinogenemia, and active inflammation, because of the failure of sickle cells to undergo rouleaux formation. The serum lactate dehydrogenase level, which is increased in the steady state because of hemolysis, increases further during vasoocclusive episodes ([781]). The level of serum alkaline phosphatase also increases during symptomatic crises ([782]).

Diagnosis

The diagnosis of sickle cell anemia rests on the electrophoretic or chromatographic separation of hemoglobins in hemolysates prepared from peripheral blood. The predominant Hb is S; Hb F is present in varying concentrations; and Hb A2 is normal. There is no Hb A. Electrophoresis using cellulose acetate and an alkaline buffer is rapid, inexpensive, and effective in the separation of normal hemoglobins from common variants. Whole blood, blood specimens dried on filter paper, or Hb solutions may be used ([783]). However, several relatively rare Hb variants have an electrophoretic mobility identical to that of Hb S on cellulose acetate. Because most of these variants do not copolymerize with Hb S on deoxygenation, the doubly heterozygous states are seldom associated with the clinical and hematologic features of sickling. The interaction of Hb S with ß ^{0}-thalassemia also gives an electrophoretic pattern that is indistinguishable from that of homozygous sickle cell anemia. In general, the appropriate diagnosis can be made by taking into consideration associated hematologic data (Table 40.3). However, detailed family studies, Hb separation by isoelectric focusing or high-performance liquid chromatography (HPLC), globin-chain electrophoresis or structural analysis of Hb (by protein chemistry, mass spectrometry or sequencing of polymerase chain reaction (PCR)–amplified DNA) may be required to characterize accurately the genotypic basis for a sickling disorder.

TABLE 40.3. Differential Diagnosis of Electrophoretic Pattern of Hemoglobin (Hb) SS at pH 8.6

Diagnosis	Symptoms	Anemia	Red Blood Cell Morphology	Distinguishing Features
Sickle cell anemia (Hb SS)	Present	Moderate or severe	ISCs, target cells	—
Hb S/ß ^{0}-thalassemia disease	Present	Moderate or severe	ISCs, target cells, hypochromia, microcytosis	Hb A $_{2}$ increased; mean cell volume and mean corpuscular Hb concentration decreased
Hb S/hereditary persistence of fetal Hb	Absent	Absent	Target cells	Hb F evenly distributed in erythrocytes
Hb S/D-Punjab disease	Present	Moderate	ISCs, target cells	Hb S and D separable on citrate agar at acid pH

ISC, irreversibly sickled cell.

A variety of simple tests permit detection of Hb S. The sickling phenomenon can be induced by sealing a drop of blood under a coverslip to exclude oxygen or by adding agents that induce chemical deoxygenation, such as 2% sodium meta-bisulfite or sodium dithionite ([784]). The decreased solubility of deoxy Hb S forms the basis for tests in which blood is added to a buffered solution of a reducing agent such as sodium dithionite. Hb S is insoluble and precipitates in solution, rendering it turbid, whereas solutions containing hemoglobins other than Hb S remain clear ([785]). Hyperglobulinemia and other sickling hemoglobins may cause false-positive results ([786] , [787]); false-negatives may result from the addition of an inadequate number of red cells. Neither the sickle cell preparation nor solubility tests differentiate sickle cell anemia from sickle cell trait or detect Hb variants that interact with Hb S. Thus, they should never be used as a primary screening test. Their principal value has been as an adjunct to electrophoretic identification of Hb S.

Quantitation of Hb A $_{2}$ is performed by minicolumn chromatography or HPLC. Quantitation of Hb F can be carried out by alkali denaturation, HPLC, or radioimmunodiffusion ([788] , [789] and [790]). The distribution of Hb F in red cells may be analyzed by its resistance to acid elution ([791]) or, more precisely, by Hb F–specific antibodies that measure the number of “F cells” ([792]).

Although the diagnosis of Hb SC disease is straightforward, that of Hb Sß-thalassemia may sometimes be problematic. In Hb Sß $^{+}$-thalassemia, there is a preponderance of Hb S, with Hb A comprising 5 to 30% of the total. This must be distinguished from sickle cell trait in which Hb A exceeds Hb S and from the presence of Hb A resulting from red blood cell transfusions within the previous 3 to 4 months. Hb Sß ^{0}-thalassemia produces an electrophoretic pattern that is visually indistinguishable from that of sickle cell anemia, but a diagnosis can often be made by the presence of an elevated Hb A $_{2}$ level and a decreased MCV. However, because sickle cell anemia with coincident a-thalassemia also has a phenotype with reduced MCV and elevated Hb A $_{2}$, family or DNA-based studies may be necessary to make this distinction.

NEONATAL DIAGNOSIS The first statewide newborn hemoglobinopathy screening program was initiated in New York in 1975 ([793]), but the impetus for universal screening came from the demonstration that early diagnosis and comprehensive care could reduce morbidity and mortality in infants with sickle cell anemia, particularly through the prevention of pneumococcal sepsis with penicillin prophylaxis ([467]). A National Institutes of Health Consensus Conference concluded that every child should be screened early for sickle cell disease ([794]), leading to statewide newborn screening programs in at least 41 states ([795]). Universal rather than targeted screening is necessary to insure that all with disease are identified and none are discriminated against or stigmatized ([794]). In California, it was shown that 58 nonblack infants with sickle cell disease would not have been diagnosed over a 4-year period if screening were confined to blacks ([796]). In 1990, more than 3.4 million newborns were tested, and approximately 2800 with clinically significant Hb variants were detected ([795]). Most programs use dried blood spots on filter paper because Hb testing can easily be integrated into existing metabolic programs with established methods of sample collection, specimen processing, data management, and quality control ([797]). A comparison of liquid cord blood and heel puncture blood on filter paper showed that both systems were subject to a small error rate, primarily involving carrier phenotypes, but that cord blood testing was more prone to lead to inconclusive results and noncompliance in sample collection ([798]). Isoelectric focusing and HPLC have replaced cellulose acetate electrophoresis in most screening programs ([798] , [799]). The primary goal of newborn screening for sickle syndromes is reduction of morbidity and mortality by identifying affected infants at birth, initiating prophylactic penicillin early, and providing ongoing care by knowledgeable health professionals ([797]). The number of early deaths avoided has been estimated at 0.6 to 1.2/100 births ([800]). All cases of suspected disease still must be confirmed with a separate sample from the infant because clerical errors may be encountered ([798]). A common problem is the need to establish a mechanism for educating and counseling parents of carriers detected by testing at birth ([794]). Using public health and state genetic program resources, it is possible to provide parents with individual counseling, education, and extended family testing ([801]). Prenatal education for expectant mothers, which includes information about newborn sickle cell screening, significantly increases the follow-up rate for infants with sickle cell trait and contributes to a greater retention of information ([802]). Each of the above techniques allows the detection of minor Hb components in the presence of large amounts of Hb F. The pattern in infants destined to develop sickle cell anemia comprises Hb F, a relatively small amount of Hb S, and no Hb A. Neonates doubly heterozygous for Hb S and ß ^{0}-thalassemia and for Hb S and HPFH have a Hb separation pattern indistinguishable from that for Hb SS. They may be differentiated by hemoglobinopathy testing of the parents or by repeat testing of the infant at a later age. Another potential pitfall is misdiagnosis of Hb Sß $^{+}$-thalassemia by incorrect identification of an FS or FAS (sickle cell trait) pattern rather than the correct FSA pattern ([803]). Molecular genetic analysis using PCR-based techniques may provide reliable confirmatory testing (e.g., for distinguishing Hb Sß ^{0}-thalassemia from Hb SS) ([804] , [805]). The combination of isoelectric focusing and HPLC also is an effective strategy for dramatically reducing the risk of errors ([806]).

PRENATAL DIAGNOSIS The clinical application of recombinant DNA techniques to the prenatal diagnosis of sickle cell anemia permits a high level of diagnostic accuracy with relatively little risk to the fetus ([807] , [808] and [809]). Guidelines for the ethical application of prenatal diagnosis have been developed ([810] , [811]), and the use of routinely incorporating screening and counseling into the early prenatal care of populations at risk has been demonstrated ([812]). Initially, prenatal diagnosis required fetal blood sampling. More recently developed assays permit the use of DNA prepared from amniotic fluid cells obtained at 15 to 20 weeks' gestation or from a biopsy of chorionic villi obtained at 10 to 12 weeks' gestation. The latter technique is an outpatient procedure that involves passing a catheter through the cervix with ultrasonographic guidance ([813] , [814]). It provides earlier diagnostic information, thereby permitting termination of pregnancy in the first trimester, when it is simpler, safe, and less psychologically stressful. The least invasive method of prenatal diagnosis uses fetal cells from the maternal circulation isolated by a variety of techniques such as multiparameter flow cytometry ([815]). A recent experimental technique uses preimplantation diagnosis ([816] , [817]): *In vitro* fertilization is performed, and an unaffected embryo is implanted into the uterus. Recently, the first unaffected pregnancy resulting from identification of an unaffected embryo using *in vitro* fertilization and preimplantation genetic diagnosis was reported ([818]). Although prenatal diagnosis of fetuses conceived by couples at risk of having children with

sickle cell disease is widely accepted in some countries ([819]), use of this technology has been infrequently requested by couples at risk in the United States. Several strategies have been successfully used for the analysis of fetal DNA. Methods that involve the use of restriction fragment length polymorphisms are indirect and suitable only for those cases in which the parents at risk can be shown to carry the appropriate linked polymorphism ([820]). The most widely used approach is based on the fact that the DNA mutation in the ß ^{S} gene is itself a cleavage site for the restriction enzyme Mst II ([821] , [822]), which cleaves DNA at the normal sixth codon and, therefore, generates abnormally long DNA fragments with base mutations involving this codon. Synthetic oligonucleotides that are specific for the ß ^{S} nucleotide substitution also permit direct, rapid, and sensitive detection of the ß ^{S} gene ([823] , [824]). The use of the PCR to amplify ß-globin sequences enzymatically before restriction enzyme or oligonucleotide analysis greatly increases the sensitivity and speed of the procedure, making it possible to provide genetic diagnoses within a few hours ([824] , [825]). The dot-blot method of allele-specific hybridization uses fixation of PCR-amplified target ß-globin DNA to filters and hybridization of the filters with labeled probes complementary to ß ^{A} and ß ^{S} sequences ([826]); the reverse dot-blot method allows screening for multiple mutations simultaneously with a single hybridization ([827]). Prenatal screening of single-gene disorders from maternal blood is possible using cell-free fetal DNA obtained from maternal plasma ([828]).

Treatment

Several recent review articles reflect the rapid pace of development of feasible and effective treatment options for patients with sickle cell disease ([829] , [830] , [831] , [832] , [833] , [834] and [835]). In addition to prophylactic measures aimed at preventing specific complications of sickle cell disease, three treatment options have been increasingly used for overall management: chronic transfusion, hydroxyurea, and stem cell transplantation. Gene therapy remains a future goal.

PREVENTIVE MEASURES Until a safe and widely applicable mechanism for the prevention of intravascular sickling is found, a high priority must be placed on the prevention of complications. Because vasoocclusive crises are precipitated by infection, fever, dehydration, acidosis ([269]), hypoxemia, and cold exposure ([598]), measures to prevent or remedy these conditions assume importance. Optimal hydration is essential, especially during febrile illnesses. In estimating fluid requirements, the hyposthenuria of sickle cell anemia, as well as increased insensible losses, must be considered. Because the liberal use of salicylates imposes an acid load, acetaminophen is probably the preferred antipyretic. Sudden transition to high altitude and exposure to situations likely to cause chilling should be avoided. The high risk of overwhelming pneumococcal disease in children mandates the use of penicillin prophylaxis and pneumococcal vaccination. Preventive measures and early medical intervention for febrile illnesses substantially decrease the incidence of meningitis and reduce mortality ([427]).

BLOOD TRANSFUSION One of the most effective therapeutic measures presently available is the transfusion of normal red cells ([836] , [837]). However, because of the complications of transfusion therapy, it is reserved for selected complications, such as severe anemia, progressive or recurrent organ damage, surgery, and certain severe acute vasoocclusive events ([836] , [837]). Transfusion therapy facilitates improved blood and tissue oxygenation, reduces the propensity for sickling by diluting host cells, and temporarily suppresses the production of red cells containing Hb S. With chronic transfusion support, splenic involution and fibrosis are reversed in some patients ([838] , [839]). The viscosity of deoxygenated sickle cell blood is disproportionately reduced by the addition of normal red cells. A mixture of one-fourth Hb A cells and three-fourths Hb S cells reduces the viscosity of deoxygenated blood by 50% ([162]). Accordingly, the relative number of Hb S–containing cells needs to be reduced only to approximately 40% to prevent most clinically significant vasoocclusive events ([840]). Replacement of patient cells with donor cells is readily accomplished by a limited exchange transfusion, in which patient blood is removed before or during packed cell transfusion ([779] , [841] , [842] and [843]). Repeated partial exchange transfusion, which can be performed through erythrocytapheresis, greatly reduces the net gain of iron ([844] , [845]). However, the long-term central venous access, which is often required, may be associated with an unusually high rate of catheter infection, thrombosis, and premature removal of the central line ([846] , [847]). Repeated simple transfusions are probably equally effective in terminating the consequences of *in vivo* sickling ([848]). Packed red cell transfusions at 3- to 4-week intervals generally are sufficient to maintain the relative number of donor cells in the circulation above 70%, but Hb S is more easily suppressed in some patients than others ([849]). Furthermore, chronic transfusion may result in recurrent splenomegaly and the additional problem of hypersplenism ([850]). Although effective in circumventing the numerous complications of sickle cell anemia ([851] , [852]), chronic transfusion therapy is limited by logistic and toxicologic considerations. The requisite commitment of personnel and blood resources is considerable, and the risks of hepatitis, alloimmunization, and hemosiderosis are cumulative and potentially life-limiting. Of individuals with sickle cell anemia, 18 to 36% become alloimmunized, considerably more than with other forms of anemia ([853] , [854]). The greater risk of alloimmunization in sickle cell anemia is primarily a result of racial differences between the blood donor and recipient populations. The development of multiple antibodies is a relatively common problem ([854]); antibodies against C, E, and Kell (K) antigens account for most of the alloantibodies. The use of racially matched and selected minor blood group antigen-matched blood for chronically transfused patients with sickle cell disease has been recommended to prevent alloimmunization ([854] , [855] and [856]). Hemolytic transfusion reactions are associated with as many as 3% of transfusions. Most occur several days after the transfusion and are accompanied by a falling hematocrit, hemoglobinuria, increased jaundice, and, frequently, a pain episode ([316] , [857]). In some cases, a delayed hemolytic transfusion reaction may lead to a fall in Hb level to a level lower than before transfusion, with a life-threatening or fatal outcome resulting from attempts to provide further transfusions ([856]). Iron overload has been an inevitable result if chronic transfusion is not performed by partial exchange methodology, such as erythrocytapheresis. The severity of iron overload commonly has been monitored with serum ferritin concentration, and there is a strong *intra*patient correlation between ferritin levels and volumes transfused ([858]). However, there is wide *inter*patient variability, indicating a need to assess iron stores directly by liver biopsy to determine the necessity for iron chelation with deferoxamine ([858] , [859]).

Anemia Anemia with Hb levels as low as 5 g/dl generally is well tolerated and requires no therapy. During hematologic crises, however, the Hb concentration may fall precipitously, requiring rapid correction. An aplastic crisis caused by parvovirus infection often requires a single packed red cell transfusion before erythropoiesis eventually returns. A severe splenic sequestration crisis may require an immediate transfusion to restore blood volume and oxygen-carrying capacity. If the patient does not have an elective splenectomy, chronic transfusion therapy to maintain splenic function has been used as an alternative. However, recurrences of sequestration have occurred despite transfusion ([410]). The experimental use of polymerized bovine Hb in adult patients and polymerized human Hb along with erythropoietin in a sickle cell patient with multiple red cell antibodies has been described ([860] , [861]), but overall evidence of the efficacy and safety of this approach is lacking.

Progressive Organ Damage The risks and expense of a long-term transfusion program are justified if progressive or recurrent vasoocclusive events threaten major organ function ([862]). Chronic transfusion therapy minimizes the risk of recurrent or progressive neurologic deterioration in children who have had a stroke ([322] , [332] , [863]). Progressive retinopathy, sickle cell renal disease, and cardiac decompensation may also be arrested with repeated transfusions. Short-term transfusion therapy may be of benefit for a variety of complications, including ACS pain events, priapism, protracted hematuria, and chronic skin ulcerations ([852]).

Surgery Anesthesia, surgery, and postsurgical convalescence expose patients to the formidable consequences of hypoventilation, hypotension, cooling, dehydration, acidosis, and immobilization. Although recommendations regarding the preparation of patients for surgery have varied, simple transfusions before elective procedures ([848] , [864]) and partial exchange transfusions before emergency surgery ([307] , [842]) have been used. The CSSCD noted a perioperative mortality rate over a 10-year period of 1.1% ([865]). A large multicenter prospective trial compared the rates of perioperative complications among patients randomly assigned to receive either an aggressive transfusion regimen (to decrease the Hb S level to <30%) or a conservative regimen (to increase the Hb level to 10 g/dl) ([866]). Perioperative complications, including ACS, were similar in the two groups except for transfusion-associated complications, which were more common in the aggressively treated group. With good perioperative management, it is unnecessary to markedly reduce the Hb S level before surgery ([866]).

Pregnancy Like women who are hematologically normal, women with sickle cell anemia experience a decrease in Hb concentration during pregnancy as a consequence of hemodilution. In general, however, the minor aggravation of anemia is without symptomatic consequence, and no therapy is indicated. However, the final weeks of pregnancy are often complicated by vasoocclusive events that may have devastating consequences for both mother and fetus. In an attempt to prevent progressive placental infarction and premature delivery, some authors advocate the use of transfusion therapy during the third trimester ([702] , [867]). In the only randomized study of its effectiveness, however, prophylactic transfusion therapy did not have a favorable impact on maternal morbidity (other than a reduction in the number of pain crises) or fetal wastage ([868]).

NEW APPROACHES TO THERAPY

Activation of Hemoglobin F Synthesis Reversal of ontogeny with reinstitution of Hb F synthesis ([869]) is a long-standing objective that appears increasingly attainable. This therapeutic strategy is based on the observation that clinical expression of the sickle gene is prevented by Hb F synthesis in the perinatal period, as well as throughout life in individuals with HPFH. Initial attempts to augment ?-globin synthesis were based on the observation that DNA in the vicinity of a wide variety of expressed genes is undermethylated relative to the DNA flanking inactive genes ([870] , [871]). 5-Azacytidine, a cytidine analog that blocks DNA methylation, reactivated dormant genes in cultured cells and increased Hb F synthesis in anemic baboons ([872]). When given to patients with severe sickle cell anemia, 5-azacytidine caused a four- to sixfold increase in net ?-globin synthesis, a marked increase in the proportion of reticulocytes containing Hb F (F reticulocytes), and a precipitous decrease in the number of ISCs and dense red cells ([873] , [874]). Because of the known carcinogenic potential of 5-azacytidine, alternative stimulants of fetal Hb were sought. Hydroxyurea, a cytotoxic drug having no known effect on DNA methylation, also increases Hb F production in anemic primates ([875]) and in patients with severe sickle cell anemia ([876] , [877]). Hydroxyurea preferentially arrests the development of the more mature erythroid precursors, perhaps resulting in the recruitment of earlier erythroid progenitors with a greater capacity for Hb F synthesis ([878]). Alternatively, hydroxyurea may have a direct effect on “reprogramming” globin synthesis by early erythroid progenitors, a suggestion that is supported by the fact that the increase in F-reticulocyte numbers that follows hydroxyurea

administration occurs sooner (within 2 to 3 days) than would be expected if the effect represented recovery from bone marrow suppression ([876], [877], [879]). Alterations in the physical properties of red cells produced under the influence of 5-azacytidine and hydroxyurea appear to be out of proportion to modest changes in the level of Hb F. This disparity is attributed in part to reduced ß ^{S}-globin synthesis and in part to increased formation of a2?ß ^{S} tetramers, which do not participate in polymer formation ([880]). Patients taking hydroxyurea consistently develop macrocytosis, which may occur before any change in Hb F takes place. They also show a rapid correction toward normal of red cell density distribution and improved whole blood viscosity. The density profile is characterized by the disappearance of two red cell populations: the densest, most dehydrated, ISC-enriched fraction and the least dense, most hydrated cells ([691]). The least dense cells tend to adhere most tenaciously to the endothelium, and the most dense cells are the least deformable. It is possible that these changes in red cell density distribution may be unrelated to the increased Hb F induced by hydroxyurea therapy ([881]). Recently, it has been demonstrated that hydroxyurea therapy is associated with the intravascular and intraerythrocytic generation of NO and that this might have a role in the induction of fetal Hb and, possibly, in clinical response that precedes the improvement in fetal Hb level ([882], [883] and [884]). In 1995, a double-blind multiinstitutional trial of hydroxyurea versus placebo in approximately 300 adults with moderate to severe sickle cell disease was concluded with convincing evidence of clinical benefit from the drug ([220]). Patients treated with hydroxyurea had approximately 50% lower rates of pain crises, ACS, hospitalization, and transfusion. There was wide variability in drug tolerance and clinical response, but the primary toxicity and dose-limiting factor was mild neutropenia. Because of the favorable outcome in the majority of treated patients, hydroxyurea has become widely used in the treatment of adult patients who experience frequent vasoocclusive crises ([885]). However, a report of severe complications of sickle cell disease (ACS, fatal cerebral hemorrhage) in two young adults who were on long-term hydroxyurea treatment indicates that the drug may not reverse preexisting pathology ([886]). Studies in pediatric patients are more limited, but several recent studies, including a multicenter phase I-II trial, indicate that school-aged children treated with hydroxyurea have increases in fetal Hb, Hb concentration, and MCV similar to those of adults and suggest that clinical benefit and toxicity may also be similar ([887], [888], [889], [890] and [891]). Recent studies in children 6 to 24 months of age (at onset of treatment) and 2 to 5 years of age have not indicated unusual toxicity from hydroxyurea ([892], [893]). The capacity of this treatment for prevention or reversal of organ dysfunction remains to be determined, but a return of splenic function has occurred in a few patients treated with hydroxyurea ([886], [888], [893], [894]). The drug has led to weight gain and improved exercise performance in adults ([895]) and growth in children ([896]). Recent pilot trials have suggested that hydroxyurea with or without concurrent phlebotomy may be substituted for chronic transfusion in the prevention of recurrent stroke ([339], [897]). Although caution about the long-term carcinogenic and teratogenic potential of hydroxyurea needs to be exercised, to date there is no evidence that the drug leads to an increased cancer risk or to congenital anomalies in offspring of women who inadvertently became pregnant while taking hydroxyurea ([898], [899] and [900]). Prediction of fetal Hb response in patients with sickle cell disease receiving hydroxyurea has been difficult ([901]), but a recent analysis of the multicenter phase I-II trials has indicated that baseline Hb F and Hb concentrations, maximum tolerated dose, compliance, and therapy-related changes in blood count had predictive value ([902]). Increased levels of Hb F during stress erythropoiesis result from premature maturation of early erythroid progenitor cells under the influence of high concentrations of erythropoietin ([903]). In patients with sickle cell anemia, doses of erythropoietin above 1000 units/kg were shown to increase Hb F levels modestly ([904], [905]). Erythropoietin given in combination with hydroxyurea did not show any additional effect on Hb F production ([906]), but another trial in which hydroxyurea was alternated with erythropoietin and supplemental iron did result in a significant further increase in Hb F level ([907]). a-Aminobutyric acid, a fatty acid metabolite in maternal serum, was found to be the likely cause of the delayed ?- to ß-globin switch in infants of mothers with poorly controlled diabetes ([908]). Subsequently, parenteral infusions of butyrate were shown to augment Hb F production in primates ([909], [910]). Short courses of intravenous arginine butyrate administered to children with sickle cell anemia were associated with increases in F reticulocytes and relative rates of ?-globin synthesis ([911]), but administration of the drug over a 10-week period did not demonstrate a hematologic response ([912]). Subsequently, intermittent or pulse dosing of butyrate for 4 days at a time resulted in a sustained increase in Hb F in most patients ([913]). Oral sodium phenylbutyrate has also been shown to increase fetal Hb levels ([914]). The mechanism of action of butyrate compounds is unknown; it has been postulated that they interfere with transcriptional silencing factors and interact with promotor sequences located near the ?-globin gene ([913], [915]). The antiepileptic drug valproic acid also has been reported to stimulate Hb F ([916]), as has the azacytidine analog 5-aza-2prime;-deoxycytidine (decitabine) ([917]).

Antisickling Agents Acting on Hemoglobin or Membrane The definition of the molecular basis of sickling has stimulated an intense search for chemical agents that block Hb polymerization or preserve membrane integrity ([918], [919]). Many agents that inhibit *in vitro* sickling have been identified. Some have appeared promising in initial clinical trials only to be shown ineffective in properly controlled studies. Based on the mechanism of action, these inhibitors of sickling can be grouped into two broad categories. The first category includes compounds that bind Hb S either irreversibly (covalent agents) or reversibly (noncovalent agents). The second category consists of compounds that act on the red cell membrane rather than on Hb. Covalent agents act at different sites of the globin chain to decrease deoxy Hb S gelation, to increase the affinity of Hb for oxygen, or both. Noncovalent agents decrease Hb S gelation by interference with hydrophobic bonds between Hb tetramers. However, *in vitro* behavior does not necessarily predict *in vivo* effectiveness. Inhibition of sickling by an increase in the oxygen affinity of Hb, for example, may be offset *in vivo* by increased blood viscosity imposed by an expanded red cell mass. Of the covalent agents, cyanate has an antisickling effect mediated primarily by an increase in oxygen affinity ([920]). Short-term treatment with cyanate prolongs red cell survival but has little or no effect on the frequency of vasoocclusive crises, and it has unacceptable neurologic toxicity ([921], [922]). The extracorporeal treatment of red cells with cyanate avoids systemic toxicity but is time consuming and costly ([923]). Of the noncovalent inhibitors, only urea has been evaluated clinically. Although it disrupts intermolecular hydrophobic bonds at molar concentrations ([924]), urea is ineffective at concentrations obtainable *in vivo* ([925]). Poloxamer-188, also known as RheothRx, is a nonionic copolymer emulsifying agent that may counteract the tendency of sickle cells to adhere to endothelium by decreasing the interaction between red cells and fibrinogen ([926], [927]).

Reduction of Red Cell Hemoglobin Concentration Therapy designed to reduce the MCHC is based on the fact that small decrements in the MCHC significantly delay the rate of deoxy Hb S polymerization and inhibit red cell sickling. The delay time of gelation of deoxy Hb S is inversely proportional to the thirtieth power of Hb S concentration ([45]). Anecdotal accounts of patients with a low MCHC on the basis of iron deficiency led to the suggestion that symptomatic crises were fewer ([928]) and red cell survival was longer ([929]). One approach to reduction of the MCHC used the long-acting antidiuretic hormone desmopressin, salt restriction, and water loading. When combined, these measures induced sufficient hyponatremia and osmotic swelling of red cells to reduce the MCHC by 2 to 3 g/dl ([930]), but clinical testing uncovered problems related to poor compliance, fluctuating levels of serum sodium, neurologic complications, and lack of efficacy ([931], [932]). The Ca $^{2+}$-activated K $^{+}$ channel (Gardos channel) contributes to the deleterious dehydration of sickle cells. One of the membrane-active agents, cetiedil, appears to inhibit sickling by inducing red cell swelling and decreasing the MCHC as a result of inhibiting the Gardos pathway and increasing passive Na $^{+}$ influx more than K $^{+}$ efflux. In a placebo-controlled study, cetiedil appeared to shorten the duration of pain crises but had no effect on the total analgesic requirement ([303]). Clotrimazole and other imidazole antimycotics also prevent sickle cell dehydration by inhibiting the Gardos pathway ([110]). In a small group of sickle cell patients, clotrimazole resulted in reduced red cell dehydration, increased cell potassium content, and increased Hb levels ([933]), but analogs of the drug may be less toxic. Because the K-Cl cotransporter is a major determinant of sickle cell dehydration and is inhibited by increasing red cell magnesium, phase I and II trials of oral magnesium pidolate in adult sickle cell patients have been conducted ([111], [112]). Biologic effects included a reduction in red cell MCHC and K-Cl cotransport activity and an absence of clinical toxicity except for mild diarrhea. The combination approach of oral hydroxyurea and magnesium treatment has been suggested because the two agents have differing mechanisms of action and different toxicities, and because hydroxyurea by itself may induce magnesium loss ([934]).

Bone Marrow (Stem Cell) Transplantation Bone marrow transplantation has the potential to normalize Hb synthesis in patients with sickle cell anemia. The first transplant was performed in a child with both sickle cell anemia and acute myeloblastic leukemia in 1984; bone marrow from an HLA-identical sibling abolished both diseases ([935]). Subsequent transplant experience has been reported from Belgium, France, and the United States ([936], [937] and [938]). The majority of donors have been HLA-identical relatives, and pretransplant conditioning regimens have generally consisted of busulfan and cyclophosphamide with or without antithymocyte globulin. In the updated American multiinstitutional study ([938]), 50 children younger than 16 years of age received HLA-identical marrow allografts because of a history of stroke, recurrent ACS, or recurrent pain crises. Kaplan-Meier probabilities of survival and event-free survival at a median follow-up of 58 months were 94% and 84%, respectively. Lung function was stable in almost all patients; among patients with prior central nervous system vasculopathy who had engraftment, stabilization of cerebral vascular disease was documented by MRI and magnetic resonance angiography. An adverse effect of busulfan conditioning was seen in five of seven evaluable females. Because four of the first seven patients enrolled had neurologic events ([939]), including two episodes of intracranial hemorrhage, anticonvulsant prophylaxis with dilantin was initiated before transplantation, hypertension was strictly controlled, and platelet counts were maintained above 50,000/mm ^{3}. Among 50 patients transplanted in Belgium, overall and event-free survival were 93% and 85%, respectively, but the group transplanted early in the course of their condition (before developing clinical complications) had better overall and disease-free survival ([936]). The availability and the relative success of bone marrow transplantation worldwide have raised a number of social and ethical questions about its use. For example, how severe must sickle cell disease be to justify a transplant-associated mortality rate of 5 to 10%? In the United States, only 6% of patients with sickle cell anemia met the criteria for transplantation specified in the study protocol; furthermore, a survey of children with sickle cell anemia in the San Francisco area estimated that only 18% would have sibling donors ([940]). Although these criteria would result in approximately 1% of American children with sickle cell anemia being eligible for transplantation, criteria used in Belgium were based on the poor prognosis of children with sickle cell disease who were returning to a setting of limited medical care in central Africa ([936]). Another point of view has been that transplantation is warranted in virtually all patients for whom a suitable donor is available ([941]), particularly before organ dysfunction and transfusion exposure occur. Recently, it has been noted that the transplant enrollment criteria parallel those of studies using hydroxyurea treatment ([942]). When these two modalities are compared, transplantation offers a definitive cure for sickle cell anemia but a significant risk of mortality, whereas hydroxyurea offers amelioration of the clinical symptoms with short-term complications that appear to be reversible and small. When transplantation and periodic prophylactic blood transfusion were compared in a

hypothetical intention-to-treat analysis for sickle cell patients at high risk for ischemic stroke, the number of quality-adjusted life years experienced by both populations was essentially identical ([943]). Another significant issue is the cost of treatment; in the early 1990s, allogeneic bone marrow transplantation in the United States cost $150,000 to $200,000 ([944] , [945]), but the annual cost for the care of a child with stroke requiring chronic transfusion therapy and chelation was approximately $32,000 ([946]). Other approaches to transplantation are rapidly being developed. Cord blood stem cells harvested from HLA-identical newborn sibs, as well as unrelated donors, have been successfully transplanted ([947] , [948]). Directed donor banking of cord blood of a sibling of a child who has a disorder treatable by stem cell transplantation has been shown to be feasible and has made possible cord blood allografts that were successful in 16 of 17 cases ([949]). Another approach is based on the observation that when stable mixed chimerism is established after stem cell transplant, even a minority of donor cells with a selective advantage may overcome a genetic defect. In an analysis of 50 patients with successful allografts from the multiinstitutional sickle cell trial, five had chimerism with a relatively low proportion of donor cells (range, 11 to 74%). These five patients had normal Hb levels and much lower Hb S fractions than the proportion of donor chimerism, suggesting that donor erythroid progenitors or erythrocytes had a survival advantage over recipient sickle cell counterparts ([950]). Because these five patients were also clinically asymptomatic, this observation suggested that full-donor chimerism is not necessary to cure nonmalignant disorders, and reduced intensity regimens that allow mixed chimerism may be effective ([950] , [951]). Stem cell transplantation after reduced intensity conditioning in an adult patient with severe complications of sickle cell disease has been reported ([952]).

SICKLE CELL TRAIT

Sickle cell trait, the heterozygous state for the Hb S gene, is present in approximately 8% of black Americans and in as many as 30% of some African populations. The red cells of such individuals contain both Hb A and Hb S, but there is always more Hb A than Hb S ([27]).

Clinical Features

Sickle cell trait rarely is associated with clinical or hematologic manifestations of significance. Individuals have no anemia, and red cell morphology is normal. Growth and development proceed normally ([953]), infections occur with no greater frequency than in the general population, and no increased frequency of bone and joint disease is observed ([954]). A prospective study of pregnant women with sickle cell trait documented an overall incidence of complications and a distribution of birth weights similar to those of a control group ([955]). Life expectancy and overall mortality rate for persons with sickle cell trait are the same as for the general population ([956]). The prevalence of the trait among professional football players is the same as that in the black population, suggesting that it imposes no limitation in physical capabilities ([957]). Nevertheless, most of the complications associated with sickle cell anemia have been described in individuals with sickle cell trait. In most such reports, the presence of Hb S was likely an incidental finding, unrelated to the observed deficit.

Most reports of sudden death in soldiers and athletes undergoing strenuous physical conditioning lack pertinent information concerning the relative amounts of Hb A and Hb S and the presence of potential but undetected underlying illness ([958] , [959]). Nevertheless, a comprehensive analysis of sudden unexplained deaths among more than 2 million recruits undergoing basic training in the U.S. Armed Forces demonstrated a small but convincing increase of such deaths in association with sickle cell trait ([960]). Because the risk under even the most adverse circumstances is low (1 in 3200 in the Armed Forces study), it is important that the millions of black individuals with sickle cell trait not be labeled as sick.

Other complications of the trait are well documented but relatively rare: hematuria, urinary tract infection, and splenic infarction. The former generally is transient and probably is related to poor perfusion of the renal papillae ([623] , [645] , [961] , [962]). Frank renal papillary necrosis has been described ([641]). Urine-concentrating ability also is impaired, although renal acidification is normal ([963]). A Jamaican study of older adult women showed an increased frequency of bacteriuria in those with sickle cell trait ([964]). During pregnancy, women with sickle cell trait have increases in bacteriuria and pyelonephritis ([965]). There are numerous reports of splenic infarction in individuals with sickle cell trait who are exposed to altitudes of 10,000 feet or more in unpressurized aircraft, but this has not been reported in commercial flights, in which cabin pressure is equivalent to approximately 8000 feet ([966]). Individuals with sickle cell trait, especially whites, have suffered splenic infarction at mountain altitudes ([967]). Most individuals with sickle cell trait, however, tolerate simulated high altitude with impunity ([968]).

Diagnosis

Sickle cell trait is characterized by an electrophoretic pattern containing both Hb A and Hb S, with more Hb A than Hb S. The interaction of a-thalassemia with sickle cell trait is responsible for a trimodal distribution of Hb S with means of approximately 41%, 35%, and 28%, corresponding to the aa/aa, -a/aa, and -a/-a genotypes, respectively ([739] , [969] , [970]). The positive correlation between the proportion of Hb S and the output of a genes indicates the greater affinity of ß ^{A}-chains than of ß ^{S}-chains for a-chains in the formation of Hb tetramers. Excess ß ^{S}-chains presumably are destroyed by proteolysis ([971]). The relative amount of Hb S is also decreased by iron ([972]) and folate ([973]) deficiencies.

Screening Programs

There are two possible reasons to screen groups for the presence of sickle cell trait: (a) to inform affected persons of health risks and (b) to provide information that might affect an individual's reproductive decisions. Most hemoglobinopathy screening is now done to identify sickle cell disease in neonates. Therefore, identification of sickle cell trait occurs at a time when counseling of the affected individual obviously is impossible. Counseling of family members of newborns with sickle cell trait may be of value but is only performed sporadically in most states.

The technique chosen for screening should be genetically diagnostic and should clearly differentiate between sickle cell trait and those disorders of Hb having implications for health. Both conventional Hb electrophoresis ([974]) and thin-layer isoelectric focusing on acrylamide gel ([975]) have been adapted satisfactorily to mass screening. Because solubility tests do not detect ß-thalassemia trait, Hb C, and other Hb variants that interact with Hb S to cause disease, they should not be used for screening.

OTHER SICKLING SYNDROMES

Several of the doubly heterozygous states for Hb S and a second disorder of Hb synthesis are characterized by clinical and hematologic aberrations that to some extent mimic the features of sickle cell anemia. The clinically significant disorders resulting from double heterozygosity for Hb S and a second Hb variant are considered forms of sickle cell disease.

Hemoglobin SC Disease

The sickling disorder known as *hemoglobin SC* disease results from the inheritance of an Hb S gene from one parent and an Hb C gene from the other parent. Red cells contain approximately equal amounts of the two hemoglobins. Hb A is absent, and Hb F is normal or slightly increased. The disorder occurs with an approximate frequency of 1 in 1100 births among black Americans ([793]) and 1 in 1400 births in Jamaica ([744]). In Ghana, the presumed site of origin of the Hb C mutation ([976]), Hb SC disease is as prevalent as sickle cell anemia, and in some regions, it affects as many as 25% of the population ([4]).

The clinical and laboratory features of Hb SC disease cannot be explained by copolymerization of Hb C with Hb S ([977]). The solubility of mixtures of deoxy Hb S and Hb C is no different from that of mixtures of Hb S and Hb A ([978]). Differences in the sickling properties of sickle trait cells and Hb SC cells are related to two factors: a higher proportion of Hb S and a higher concentration of Hb in Hb SC cells compared with Hb AS cells ([977] , [979]). The 10 to 15% greater proportion of Hb S in Hb SC cells is the result of differences in rates of subunit assembly, which, in turn, are determined by the net surface charges of ß ^{A}, ß ^{S}, and ß ^{C} ([979]). The higher MCHC of Hb SC cells relates to the opening of normally dormant membrane channels that allow the loss of K $^{+}$ and water ([980]).

CLINICAL FEATURES The clinical manifestations of Hb SC disease are similar to, but less severe than, those of sickle cell anemia ([2] , [6] , [981]). Growth and sexual development are delayed compared to normal children, but less so than in children with sickle cell anemia ([488]). Symptoms in the first year are rare, and one-fourth of affected individuals remain asymptomatic throughout the first decade of life ([744] , [982]). The most common symptom is episodic abdominal or skeletal pain, qualitatively similar to that caused by vasoocclusive events in sickle cell anemia. The average number of painful episodes/year for Hb SC patients is approximately one-half that

for persons with sickle cell anemia (0.4 vs. 0.8 episodes/year) (278). Moderate enlargement of the spleen is present in approximately two-thirds of children and often persists into adult life. Spleen perfusion is intact, however, and as a result, symptomatic splenic infarction (983, 984 and 985) and acute splenic sequestration (986) may occur in adults as well as in children. Loss of spleen function is more gradual and occurs at a later age than occurs in sickle cell anemia (271, 450). The frequency of infections of patients with Hb SC disease is increased, but fatal pneumococcal septicemia, although well documented (987), is less of a risk than is noted in sickle cell anemia (988). In contrast to the infectious complications of sickle cell anemia, those of Hb SC disease are characteristically associated with a primary focus, tend not to recur, and respond promptly to therapy (989, 990). *S. pneumoniae* is the most common bacterial isolate, and the respiratory tract is the most common focus (989, 990 and 991). The incidence of bacteremia drops abruptly after 2 years of age, a contrasting pattern to sickle cell anemia, in which the incidence declines gradually between 2 and 6 years of age (429). Because bacteremia rarely progresses to septicemia and a fatal outcome in young children with Hb SC disease, prophylactic penicillin is thought to be unnecessary by some investigators (469). However, fatal pneumococcal septicemia has been reported in a series of seven children, six of whom were older than 3 years of age (992). Central nervous system deficits (993), asymptomatic hematuria, ankle ulceration, priapism, and other complications of sickling occur with Hb SC disease but are infrequent events. In the United States, the median lifespan for male and female Hb SC patients is 60 and 68 years of age, respectively (232). Because of the frequency with which they occur, certain complications of Hb SC disease deserve special comment. Proliferative retinopathy is more common and more severe than in sickle cell anemia (176, 674). Progressive loss of vision may have its onset early in the second decade, and patients should be encouraged to have an annual ophthalmologic examination after reaching adolescence. Aseptic necrosis of the femoral head has been reported to have a greater frequency in Hb SC disease than in Hb SS, but a recent report indicates that the age-adjusted prevalence is lower (515). ACS, attributed to fat emboli after bone marrow infarction, occurs most commonly during the final months of pregnancy (994, 995 and 996) in women with Hb SC. The exaggerated vulnerability of individuals with Hb SC disease to certain complications is thought to be a function of the higher viscosity of the blood relative to that in sickle cell anemia. Two recent analyses of adults with Hb SC disease (997, 998) have reemphasized the common clinical features of pain crises, avascular necrosis of the hip, proliferative sickle retinopathy, and splenic infarction/sequestration. In one series, it was noted that comorbidity of obesity, hypertension, and type 2 diabetes mellitus were common (998). In the other, decreased morbidity was noted in patients who had concurrent a-thalassemia 2 (997). Moderately severe complications of *in vivo* sickling occur in Hb SC-Harlem disease (999) and in the Hb SC/a-thalassemia syndrome (1000). Combined Hb SC disease and hereditary spherocytosis was documented as the cause of recurrent splenic sequestration crises (1001).

LABORATORY FEATURES Anemia is mild or nonexistent; 75% of children 2 to 15 years of age have a hematocrit between 28 and 38, and 75% of adults have a hematocrit between 28 and 42 (with males having higher levels than females) (1002). Compared with Hb SS, the MCV may be decreased (10 to 15 fl lower), and the MCHC may be increased owing to cellular dehydration (1002, 1003). Reticulocytes are modestly increased in number. Blood films contain as many as 50% target cells. Although sickled cells are relatively rare, cells containing Hb “crystals” are noted regularly (1004). These hyperchromic, shrunken cells are distorted into pyramidal or elongated contours by condensed aggregates of Hb (Fig. 40.12). The white blood cell count and leukocyte differential are normal (227).

TREATMENT Unlike the extensive investigations of the use of hydroxyurea in adults and children with Hb SS, data in patients with Hb SC disease are lacking. One study involving six adult Hb SC disease patients noted that hydroxyurea resulted in an increase in hematocrit and MCV, improved cell hydration, and no significant difference in Hb F level (1005). In a study of six severely affected children with Hb SC disease, MCV and Hb F increased, and patients improved clinically, but Hb concentration did not change after hydroxyurea treatment (1006). A randomized trial is necessary to determine if hydroxyurea or other drugs that may affect red cell density are of benefit.

Hemoglobin S–ß-Thalassemia

The doubly heterozygous condition of Hb S and ß-thalassemia is designated as Sß ^{0}-thalassemia if there is no ß-globin synthesis from the affected allele and Sß $^+$-thalassemia if ß-globin synthesis is present but reduced. The clinical manifestations are quite variable, and patients may be nearly asymptomatic or have problems similar to those occurring in the worst cases of sickle cell anemia (1007). In general, Hb Sß ^{0}-thalassemia resembles Hb SS in severity, and Hb Sß $^+$-thalassemia is somewhat milder than Hb SC disease. Patients with Hb Sß ^{0}-thalassemia have a slightly higher Hb level, an increased Hb A $_2$ level (4 to 6%), and a smaller MCV (65 to 75 fl) than those with Hb SS. Hb Sß $^+$-thalassemia patients have a higher Hb level and lower reticulocyte count than those with Hb Sß ^{0}-thalassemia (1007, 1008). In children with Hb Sß ^{0}-thalassemia, splenic dysfunction measured by pit cell counts occurs within the first year of life, but only 20% of those with Hb Sß $^+$-thalassemia have elevated pit counts by 20 years of age (451). Patients with Hb Sß-thalassemia, unlike those with sickle cell anemia, often have splenomegaly beyond the first few years of childhood. The use of hydroxyurea in patients with Hb Sß-thalassemia has been reported to be effective in a small series from Greece (1009) and Sicily (1010). (The interaction of Hb S with thalassemia mutations is discussed further in Chapter 42.)

Hemoglobin S/Hereditary Persistence of Fetal Hemoglobin

In HPFH, Hb F levels are elevated relative to the patient's age. Deletional mutations typically involve large segments of DNA and result in a pancellular distribution of Hb F. Approximately 1:1000 African-Americans carry the deletion HPFH gene. Nondeletion mutations result in more variable levels of Hb F (4 to 30%) and heterocellular or pancellular distribution. The doubly heterozygous condition for Hb S and HPFH results in a heterogeneous disorder that is generally extremely mild and associated with a pancellular distribution of Hb F, normal blood counts, microcytosis, target cells, and 20 to 30% Hb F (2, 51, 52). Overall, there is approximately 1 case of Hb S/HPFH for every 100 cases of Hb SS, but it is important to identify this condition because of its extremely good prognosis.

Hemoglobin SE Disease

Hb E is characterized by the substitution of lysine for glutamic acid at position 26 of the ß-chain and results in a mild ß-thalassemia phenotype. Because of the increase in the Asian population in the United States, the doubly heterozygous condition of Hb SE is now occasionally seen. Patients with Hb SE may have mild anemia and microcytosis along with approximately 30% Hb E, but blood smears look relatively normal (except for target cells), and patients are usually asymptomatic (52, 1011).

Hemoglobin SD Disease

Of the 16 variants fulfilling the electrophoretic and solubility criteria for Hb D or Hb G, at least nine have been recognized in association with Hb S (1012). With one exception, the doubly heterozygous states for Hb S and Hb D or Hb G are clinically silent. Hb D-Punjab (Hb D-Los Angeles) interacts with Hb S to produce mild hemolytic anemia and symptoms that mimic those of mild sickle cell anemia. The Hb SD-Punjab syndrome was first detected in a Caucasian man (1013) whose case had been previously reported as an instance of sickle cell anemia in the white race (1014). Subsequently, Hb SD-Punjab disease was recognized in a number of subjects, most of African origin (1015, 1016, 1017, 1018 and 1019). In each of these subjects, the clinical and hematologic features were those of mild sickle cell anemia.

Hemoglobin SO-Arab Disease

Hb O-Arab interacts strongly with Hb S *in vitro*. As would be predicted, the doubly heterozygous state is clinically and hematologically indistinguishable from sickle cell anemia (34, 1020, 1021, 1022, 1023 and 1024). Functional asplenia occurs at an early age and is followed by progressive splenic infarction. The disorder is differentiated readily from Hb SC disease, with which it is confused on electrophoretic grounds, by the greater prominence of symptoms, the severity of the anemia, and the presence of numerous ISCs on blood smears (1023).

Unstable Hemoglobin Disease

In 1890, Heinz described the staining characteristics of the red cell inclusions that now bear his name. For the next 60 years, *Heinz bodies* were considered to be solely a manifestation of exposure to various kinds of toxins. Their relation to primaquine-induced hemolytic anemia was established in the 1950s (see Chapter 34). In 1952, Cathie described a patient with severe congenital hemolytic anemia in which similar inclusions were found in the absence of toxic exposure ([1]). This congenital form of Heinz-body anemia was more fully delineated by Lange and Akeroyd ([2]) and by Schmid et al. ([3]), who reported similar cases and, in addition, noted brown pigment in the urine. The patients described by Schmid et al., being father and son, provided evidence for the genetic basis of the disease.

The first suggestion that an abnormal hemoglobin (Hb) might be implicated in the pathogenesis was made by Scott and co-workers, who found an electrophoretically abnormal Hb component in a patient with congenital Heinz-body hemolytic anemia ([4]). Their suggestion was supported by the discovery that Hb Zürich was associated with an inclusion-body hemolytic anemia, although only after exposure to sulfonamides ([5]). The discovery of Hb Köln and the determination of its molecular abnormality constituted final proof that congenital Heinz-body hemolytic anemia was a hemoglobinopathy ([6]). Other unstable Hbs—Hb Genova ([7]), Hb Sydney ([8]), and Hb Hammersmith ([9])—were soon found to produce a similar picture. Hb Bristol ([10]) was detected in Cathie's original patient, and the family described by Scott et al. was shown to have Hb Santa Ana.

Characterization of the amino acid substitutions in these and other unstable Hbs paved the way for present concepts of the structure–function relationships of Hb variants. More than 200 unstable Hbs have now been identified ([11] , [12]), and a clearer picture of the spectrum of disease they produce has emerged. Fewer than one-half of the unstable variants are of clinical significance, however. Initially, those that were attended by anemia were referred to as *congenital Heinz-body hemolytic anemia*. These disorders are more properly designated *unstable Hb disease*.

PREVALENCE

Despite the large number of unstable variants, unstable Hb disease is rare. By far the most common of the unstable variants is Hb Köln, which has a worldwide distribution ([6] , [13] , [14] , [15] , [16] , [17] and [18]). The independent occurrence of this variant in so many apparently unrelated individuals suggests that the Hb Köln mutation is located at a methylated CpG dinucleotide sequence of the ß-globin gene that can act as a “hotspot” for mutation through the deamination of the methylcytosine nucleotide to form thymine ([19]). Hb Hammersmith has been reported in cases from China and Japan as well as from the United Kingdom ([20]). Most unstable variables have been demonstrated only in single individuals or within single kindreds ([21]).

Unstable Hb disease is expressed fully in the heterozygous state. Thus, the inheritance pattern is autosomal dominant. Rarely, the homozygous state has been reported. Such was the case with a Pakistani child whose parents, both of whom had Hb Bushwick, were first cousins ([22]). Whereas family members who were heterozygous for the variant Hb had a compensated hemolytic disorder, the homozygous child had chronic anemia due to hemolysis and ineffective erythropoiesis. There were severe exacerbations of anemia during febrile illnesses. The apparent spontaneous mutation rate among affected heterozygotes is high. From a compilation of apparent *de novo* mutations, the mutation rate for unstable variants has been calculated to be 5.9×10^{-9} per ß-gene nucleotide per generation ([23]). Of interest is the fact that most variants resulting from apparent *de novo* mutations are characterized by severe hemolysis. The rarity of symptomatic unstable Hb disease suggests that individuals with severe hemolysis are less likely to reproduce than those with mild disease.

MOLECULAR PATHOLOGY AND PATHOPHYSIOLOGY

The mutations responsible for the unstable Hbs produce major conformational changes. The most common causes of instability are amino acid substitutions that alter the steric configuration of the heme pocket or the site of aß-dimer binding. Other variants are made unstable by substitutions that disrupt the a helix of globin or by the insertion of polar amino acids in the interior of the Hb molecule. Each of these mutations eventually leads to an unfolding of the affected globin chain and subsequent denaturation and precipitation ([11] , [24]). Mutations also can be responsible for posttranslational changes that affect either the variant amino acid or nonmutated residues that are exposed by conformational changes of the molecule ([25]).

The most common and most extensively studied of the mutations responsible for Hb instability are those producing defective heme binding. Loss of stability of the heme-globin linkage is caused by amino acid substitutions in the vicinity of the heme pocket. Variants with a substitution at the proximal histidine of the heme pocket are unable to bind heme. These include Hb Istanbul, Hb Mozhaisk, and Hb Newcastle. Amino acid substitutions involving the distal histidine residue (such as occurs in Hb Zürich and Hb Bicetre) open the heme pocket, exposing heme iron to exogenous compounds (e.g., the sulfanilamides) from which it is normally protected ([26]). Substitution of polar for nonpolar residues in or near the heme pocket (Hb Bristol, Hb Böras, Hb Olmsted, and Hb Shepherds Bush) allows water to enter the normally hydrophobic heme pocket, thereby loosening the heme-globin linkage and rendering heme susceptible to oxidation. Hb Bristol is of particular interest in that DNA sequencing data and protein analysis of the Hb are discordant. Whereas the base substitution in DNA predicts a valine to methionine change at ß67, protein analysis of the variant Hb demonstrates a substitution of aspartate for valine. This seeming paradox is explained by the posttranslational oxidation of translated methionine to aspartate ([25]).

Other substitutions in the heme pocket (those producing Hb Köln and Hb Hammersmith) directly disrupt heme binding ([27]). In each of these variants, heme dissociates from the abnormal chain, resulting in a partially heme-deficient molecule a $_2{}^{\text{heme}}ß°_2$ ([28]). Reversible, then irreversible hemichrome formation in the normal chains follows with subsequent denaturation of the molecule. Precipitates of these Hbs tend to be pale, and the pattern found during electrophoresis is characterized by multiple bands unless hemin is added ([29]). It is with these variants that dipyrroluria is seen; an observation suggesting that freed heme is converted to dipyrroles rather than to bilirubin.

Some of the amino acid substitutions involving interchain contact sites weaken dimer and tetramer association. Mutations affecting the $a_1ß_1$ interphase [Hb Khartoum, Hb Philly, Hb Stanmore ([30]), and Hb Tacoma] tend to be more unstable than those affecting the $a_1ß_2$ contact sites. Isolated globin chains and aß-dimers are vulnerable to oxidation and hemichrome formation ([31]). Hemichrome formation is followed by precipitation of Hb and isolated globin chains without loss of heme ([32]).

Disruption of the a helix is caused by mutations substituting proline for another amino acid in all but the first three and final positions of the helix. Disruption of the a helix, in turn, markedly affects tertiary structure and molecular stability. Mutations that interfere with a-helix formation include Hb Atlanta, Hb Bibba, Hb Casper, Hb Duarte, Hb Genova, Hb Madrid, Hb Perth, Hb Sabine, and Hb Santa Ana. To the extent that these substitutions involve the heme pocket, they also produce abnormal heme binding.

The folding of normal globin chains ensures that charged amino acids are on the surface of the Hb molecule in contact with cell water, whereas nonpolar residues are on the interior of the molecule, interacting hydrophobically to stabilize it. This organization is disrupted by the insertion of polar residues into the interior of the molecule. In some Hb variants, such substitutions permit water to enter the molecule, thereby altering tertiary structure. In others, the substituted polar residue is

forced to the surface of the molecule, again distorting molecular structure. Variants characterized by internal polar substitutions include Hb Ann Arbor, Hb Böras, Hb Olmsted, and Hb Riverdale-Bronx.

Shortened red cell survival is mediated by two processes: Heinz body formation and oxidant damage to membrane lipids and proteins ([33]). The sequence of events involved in the oxidative conversion of Hb to hemichromes and the precipitation of hemichromes to form Heinz bodies is outlined in Chapter 32. In addition to denatured globin and hemichromes, Heinz bodies derived from some unstable variants (Hb Köln) contain fluorescent breakdown products of heme ([34]). They attach to red cell membranes by hydrophobic bonds ([29]), limiting cellular deformability and increasing membrane permeability. Heinz bodies are removed selectively by the spleen, a phenomenon that contributes directly to the hemolytic process and also leaves damaged cells with reduced viability.

The role of membrane oxidant damage unrelated to Heinz body formation is less well characterized ([33]). Red cells containing Hb Köln are unusually susceptible to lipid peroxidation ([35]). In addition, membranes prepared from the red cells of patients with Hb Köln disease who have had splenectomies contain aggregates composed of disulfide-linked spectrin, band 3, and globin as well as high-molecular-weight complexes composed in part of denatured spectrin ([35] , [36]). As would be expected, the deformability of cells containing membrane aggregates is limited. The treatment of normal red cell membranes with malondialdehyde, a product of lipid peroxidation, reproduces the protein cross-linking seen in unstable Hb Köln cells ([37]). Oxidative injury of membranes is attributed to superoxide and other reactive oxygen radicals generated in excessive quantities by a physicochemically altered heme moiety ([38] , [39]). The importance of these membrane changes for cell survival is suggested by the fact that they cannot be demonstrated in patients with Hb Köln disease whose spleens are intact ([35]). This concept of splenic removal of oxidant-injured cells is further supported by an animal model involving the use of red cells with diamide-induced membrane aggregates ([40]).

The relative proportion of unstable Hb in heterozygotes generally is considerably less than that of stable variants. The unstable ß-chain variants constitute less than 30% of the total Hb, and the unstable a-chain variants often constitute less than 20%. Although the findings from studies of the synthetic rates of unstable Hbs are difficult to interpret, most evidence suggests that synthesis is appropriate for gene dose ([24]). Low levels of unstable Hbs are most likely explained by posttranslational loss of mutant globin chains. The initial explanation was that this loss occurs through protein denaturation and the selective removal of Heinz bodies. If so, however, the level of the variant Hb should correlate with disease severity, and such is not the case. Although associated with severe hemolysis, Hb Bristol ([10]) and Hb Hammersmith ([9]) constitute 30 to 37% of the Hb in circulating red cells, whereas Hb Christchurch ([41]) and Hb Köln ([18]) are characterized by less severe disease and a relative Hb level of only 12 to 22%. A more likely explanation is that the low levels of unstable Hbs result from proteolysis of abnormal globin chains before their incorporation into Hb tetramers. This concept relates the amount of unstable Hb in mature cells to conformationally abnormal globin chains, and the severity of hemolysis to conformationally abnormal Hb tetramers. Highly unstable globin variants disrupt the balance between a- and ß-chains, producing a thalassemia phenotype ([11] , [42]). An extreme example is Hb Indianapolis, which is so unstable that it can be detected only as newly synthesized protein in reticulocytes and bone marrow normoblasts ([43]).

CLINICAL FEATURES

The unstable Hbs give rise to a broad spectrum of hemolytic syndromes ([11] , [44]). They can be classified on the basis of the severity of symptoms with which they are associated (Table 41.1). Some variants causing severe hemolytic disease are expressed clinically in the first year of life. These include Hb Bibba, Hb Bristol, Hb Castilla, Hb Hammersmith, Hb Indianapolis, Hb Nottingham, Hb Olmsted, Hb Perth, Hb Sabine, Hb Savannah, and Hb Yokohama. Except for Hb Bibba, which is an a-chain variant, signs and symptoms of hemolysis evolve gradually as fetal Hb (HbF) synthesis is phased out. The Hb concentration is less than 7 g/dl, and the reticulocyte count may exceed 30%. Some reported values for reticulocytes may be factitiously high in that cells containing inclusion bodies may be mistaken for reticulocytes ([24]). Splenectomy fails to confer clinical benefit. Except for Hb Bibba and Hb Indianapolis, the variants producing severe disease appear to have arisen as *de novo* mutations.

Other variants give rise to moderately severe hemolytic disease that is benefitted by splenectomy (Table 41.1). Detection of the disorder is often delayed until late childhood or adolescence. Intermittent jaundice, splenomegaly, hemolytic crisis, or symptoms related to cholelithiasis are the usual presenting manifestations. In approximately one-half of cases, a family history of hemolytic disease can be elicited. Before splenectomy, the Hb concentration averages approximately 9 g/dl (range, 7 to 12 g/dl), with 4 to 20% reticulocytes. After splenectomy, anemia is corrected but reticulocytosis persists.

Many unstable Hb variants produce mild hemolytic disease. In the steady state, anemia is mild or absent, and the reticulocyte count ranges between 4 and 10%. Splenomegaly may or may not be present. Most patients with mild disease are first seen during a hemolytic crisis.

More than one-half of the unstable Hb variants are associated with no hematologic abnormality. Most of these variants were detected through screening programs and therefore are characterized by an abnormal electrophoretic pattern. They are of no clinical significance.

Although most differences in clinical phenotypes are explained by the multiplicity of unstable variants, variation in the clinical and hematologic expression of individual unstable Hbs also has been noted ([45]). Investigation of the basis for intrafamilial variation in drug-related hemolysis in Hb Zürich disease led to the surprising recognition that tobacco smoking has an ameliorating effect on the hemolytic process ([46], [47]). This effect is explained by a 65-fold increase in the affinity of Hb Zürich for carbon monoxide ([26]). This ligand stabilizes the Hb molecule, protecting it from denaturing influences. As a result, the rates of *in vitro* Heinz body formation and isopropanol-induced precipitation of Hb Zürich vary inversely with carboxyhemoglobin levels ([46], [47]).

Hemolytic crises characteristically occur during febrile illnesses. Oxidants generated by phagocytic cells involved with microbial killing have been implicated in Hb oxidation ([33]). In addition, fever itself may be responsible for hemichrome formation and precipitation of unstable methemoglobins ([48]). The formation of Heinz bodies has been demonstrated for cells containing Hb Christchurch, Hb Köln, and Hb Volga when incubated at 40°C *in vitro* ([49]). Less frequently, hemolytic crises can be attributed to drugs given for febrile illnesses. Drug-induced hemolytic anemia has been demonstrated in patients with Hb Zürich ([5]), Hb Torino ([50]), Hb Peterborough ([51]), Hb Bushwick ([52]), Hb Shepherds Bush ([53]), Hb Hasharon ([54]), and Hb Leiden ([55]). Sulfonamides are the usual offending agents. Phenazopyridine, a urinary tract analgesic, also has been incriminated ([46]). Nitrates in drinking water are believed to have aggravated the severity of hemolysis in a patient with Hb Perth ([56]). Drug sensitivity is not a feature of Hb Köln ([57]) or Hb Sögn ([58]) diseases. With most other variants, drug sensitivity has not been assessed.

For many of the unstable variants, the clinical symptoms of anemia correlate poorly with the Hb concentration, principally because of differences in the affinity of variant Hbs for oxygen. Although individuals with Hb Caribbean, Hb Hope, and Hb Seattle maintain Hb levels of approximately 10 g/dl, they have no symptoms and no signs of hemolysis. Anemia is likely related to the low oxygen affinity of these Hb variants, permitting more efficient tissue oxygenation ([59]). Other unstable variants are characterized by increased oxygen affinity and little or no anemia, despite chronic hemolysis. Patients having such variants may be thought of as “physiologically anemic” despite normal blood Hb levels ([60]). They are unusually susceptible to tissue hypoxia if they develop diseases that further impair oxygen delivery. Erythrocytosis may be observed after splenectomy ([13]). The importance of oxygen affinity for patient management is well illustrated by the clinical consequences of Hb Hammersmith ([9]) and Hb Nottingham ([61]), both Hbs associated with severe hemolysis. The original patient with Hb Hammersmith, a low-affinity Hb, experienced normal growth and development despite a Hb concentration of 6 to 7 g/dl; whereas the patient with Hb Nottingham, a high-affinity Hb, had anemia of comparable severity but manifested evidence of marrow expansion and a transfusion requirement.

Some of the unstable Hb disorders are associated with the intermittent passage of dark urine, varying from brown to almost black. The pigment is believed to be a dipyrrole related to the mesobilifuscin group and derived from heme released during Heinz body formation ([62]). In general, the degree of discoloration is related to the intensity of hemolysis, although intermittent pigmenturia without clear relation to other signs of hemolysis may be noted ([14]). Some unstable Hbs, including Hb Philly, Hb Riverdale-Bronx, Hb Sydney, and Hb Sabine, retain heme during Heinz body formation and therefore are not associated with pigmenturia.

Dusky cyanosis has been described in patients with unstable Hbs that predispose to methemoglobin formation. These variants include Hb Freiburg, Hb St. Louis, Hb I Toulouse, and Hb Tübingen. Clinical cyanosis may be observed in persons with other variants as well. Approximately one-third of patients are said to be cyanotic, perhaps because of hemichromes or other abnormal heme pigments ([63]).

One example of a symptomatic unstable HbF has been described ([64]). HbF Poole produced hemolytic anemia and hyperbilirubinemia in the newborn period. As HbF was replaced by adult Hb (HbA), hemolysis disappeared and the hematologic status returned to normal.

HEMATOLOGIC FEATURES

As noted previously, anemia, if present, is variable in severity and by itself is a poor index of the severity of hemolysis. Red blood cell indices are normal or indicative of hypochromia. The mean corpuscular Hb concentration may be as low as 25 g/dl, the result of heme loss from the unstable Hb or of Hb loss through Heinz body formation. Red cell morphology is characterized by polychromatophilia, anisopoikilocytosis, stippling, and (possibly) hypochromia. With severe disease and during hemolytic crises, microspherocytes and fragmented cells may be observed. Many of the latter appear to have had “a bite taken from them.” These “bite cells” are thought to result from the phagocytosis of Heinz bodies during passage of the cell through the spleen. Moderate thrombocytopenia, possibly due to splenic sequestration, may occur.

Heinz bodies in circulating red cells usually are found only after splenectomy or during an acute hemolytic episode. Under such circumstances, more than 50% of the cells typically contain one large, spherical inclusion when stained with methyl violet or brilliant cresyl blue. Rhodanile blue may offer some advantages over the classic stains ([48], [65]). Because it has no redox activity, it merely stains rather than induces Heinz bodies. It also is more satisfactory as a stain for permanent mounting and storage of preparations. Heinz bodies seen in unstable Hb disease differ from those associated with toxic exposures in that they are larger and are found in reticulocytes as well as in older cells. The inclusions consist mainly of denatured globin, although other cellular constituents, including porphyrins and nucleic acids, may be adsorbed nonspecifically.

Hb electrophoresis may or may not reveal the abnormality. Hb Köln migrates more slowly than HbA when routine methods are used. Other variants migrate more slowly or faster than HbA or may be inseparable from it. Electrophoretic behavior cannot be predicted from the change in charge induced by the amino acid substitution; the altered tertiary structure exposes some groups normally hidden and conceals others, thereby changing the overall surface charge.

In a number of instances, an inhomogenous streak trailing behind HbA has been described, presumably the result of heme loss occurring during electrophoresis. In such circumstances, a more discrete band may be seen if electrophoresis is performed at 10°C ([14]) or if excess hemin is added ([32]).

The amount of abnormal Hb varies considerably. Unstable ß-chain variants average approximately 25% of the total Hb, whereas a-chain variants average 12%. Only when associated with thalassemia does the amount of an unstable Hb exceed 50%. Hb Duarte ([66]) and Hb Köln ([67]) each constitute 100% of the Hb in individuals who are doubly heterozygous for these Hb variants and ß°-thalassemia. The abnormal Hb constitutes less than 2% of the total in the case of Hb Bushwick and Hb Bryn Mawr, and one Hb, Hb Indianapolis, is present in such small amounts that it is undetectable by usual methods ([43]).

With ß-chain unstable Hbs, free a-chains may be found by electrophoresis; these typically have even slower anodal mobility than HbA_2. In addition, heme-depleted unstable Hb ($a_2{}^{heme}ß°_2$) may be found, usually migrating just in front of HbA_2. HbA_2 proportions may be increased to as high as 5% in association with unstable ß-chain variants, and HbF levels may be increased to as much as 10 to 12%.

Red blood cell survival ranges from a mean lifespan of 6 days in severe disease to one of 20 to 35 days in mild disease ([68]). Because rates of chromium binding and elution from some Hb variants are undoubtedly different from those for HbA, DF ^{32}P is the preferred red cell label. At least for Hb Köln and Hb Hammersmith, however, chromium and DF ^{32}P techniques for measuring cell survival give equivalent results ([68]).

DIAGNOSIS

Both the heat denaturation test and the isopropanol precipitation test reliably detect most unstable Hbs. Because they constitute less than 2% of the total Hb, Hb Bryn Mawr and Hb Indianapolis are not identified by the heat denaturation test. With the quantitative heat denaturation procedure, 8 to 45% of the Hb is precipitated as compared with less than 1 to 2% of normal Hb. In Hb Köln disease, 10 to 15% of the Hb is precipitated. With some variants, modification of incubation time and temperature may be required.

Because of its simplicity and sensitivity, the isopropanol test is probably the preferred screening procedure. False-positive results are common, however, especially if the specimen has been stored or if HbF levels are greater than 4% ([69]). The addition of potassium cyanide greatly reduces the number of false-positive results, and the effects of storage are minimized if specimens are stored as whole blood at a temperature of 4°C rather than as hemolysates.

Electrophoresis may be helpful in characterizing an unstable Hb, although as noted previously, many variants have a normal electrophoretic pattern. The intense fluorescence of cells containing Hb Köln, measured by a hematofluorometer or spectrofluorometer, provides a convenient method for screening patients for this variant ([34]). Precise identification of the abnormal Hb requires peptide analysis. For the clinical hematologist, however, this information may not be necessary, because clinical management generally does not require knowledge of the specific variant.

Synthetic oligonucleotide probes for the nucleotide mutation (G?A) associated with Hb Köln provide a sensitive technique for both the pre- and postnatal diagnosis of Hb Köln disease ([70]).

TREATMENT

Management is dictated by the severity of hemolysis. Patients with mild disease require little or no therapy, except during hemolytic crises. They should be cautioned against the use of sulfonamides and other oxidant drugs listed in Chapter 34 as causing hemolysis in glucose-6-phosphate dehydrogenase deficiency, unless they have a variant (Hb Köln, Hb Sögn) that is not drug sensitive. They should also be apprised of the potential for febrile illnesses to trigger hemolytic crises. To the extent that intercurrent illnesses compromise nutrition, folic acid should be taken prophylactically. Red cell transfusion may be required for symptomatic crises.

Severe unstable Hb disease may require intermittent or chronic transfusion therapy. Because many of the substitutions producing Hb instability also modify the affinity of the molecule for oxygen, the decision to transfuse should be based on patient tolerance of anemia rather than on the Hb concentration alone. Splenectomy reduces or obviates a transfusion requirement in some of the unstable Hb diseases. An informed decision regarding splenectomy is facilitated by precise identification of the variant. Many of the clinically expressed unstable Hbs are classified with respect to response to splenectomy in Table 41.1. However, the best responses tend to occur in patients with only moderately severe disease, whereas those with the most severe illness tend not to benefit from this procedure. Exceptions to this generalization, however, have been noted. Patients with Hb Casper have severe disease yet respond to splenectomy ([71]), and patients with Hb Sabine have moderate disease yet do not improve with the operation. Presumably, splenectomy fails to be beneficial when the most severely damaged erythrocytes are removed as readily by macrophages in the liver as in the spleen. Overwhelming pneumococcal septicemia occurred after splenectomy in a 6-year-old boy with Hb Hammersmith ([44]), and fatal thromboembolic disease was noted in two splenectomized patients with Hb Duarte ([66]). A potentially pertinent fact is that both of the latter patients had postsplenectomy erythrocytosis. These experiences underscore the importance of delaying splenectomy until after the first decade of life, if possible, and of avoiding the procedure in persons with high-affinity Hbs, if possible.

Thalassemias and Related Disorders: Quantitative Disorders of Hemoglobin Synthesis

The thalassemias are a group of congenital anemias that have in common deficient synthesis of one or more of the globin subunits of the normal human hemoglobins (Hbs). The primary feature is a quantitative one, but it is now clear that some of the thalassemias derive from structural hemoglobin variants leading to the production of an unstable globin chain. Therefore, a rigid differentiation from the qualitative changes of hemoglobin structure that characterize the hemoglobinopathies is no longer appropriate. According to the chain whose synthesis is impaired, the thalassemias are designated a-, ß-, ?-, d-,dß-, or e?dß-thalassemia. These subgroups have in common imbalanced globin synthesis, with the consequence that the globin produced in excess is responsible for ineffective erythropoiesis and peripheral destruction of red cells. In the last few years, the application of recombinant DNA technology has permitted the understanding of the basic aspects of gene structure and function and the characterization of the molecular basis for deficient globin synthesis. The thalassemias result from the interaction of a large number of different molecular defects.

PREVALENCE AND GEOGRAPHIC DISTRIBUTION

Thalassemia is considered the most common genetic disorder worldwide. It occurs with a particularly high frequency in a broad belt extending from the Mediterranean basin through the Middle East, Indian subcontinent, Burma and Southeast Asia, and Melanesia and islands of the Pacific. According to recent data collected through the Hereditary Disease Program of the World Health Organization and based on local surveys and reports by visiting experts, the carriers of hemoglobin disorders in the world are estimated to be 269 million ([1]). The only countries where a thalassemia register is maintained for surveillance purposes are Iran and Oman ([2], [3]).

Disease caused by a-thalassemia is encountered commonly in Southeast Asia and China and sporadically in India, Kuwait, the Middle East, Greece, Italy, and Northern Europe ([4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14] and [15]). In the eastern oases of Saudi Arabia, more than 50% of the population appears to have a clinically silent form of a-thalassemia, and HbH disease is recognized with increasing frequency ([16], [17] and [18]). In a random population sample, the gene frequency of deletion-type a-thalassemia-2 (-a) was 0.18 in Sardinians and 0.07 in Greek Cypriots; the occurrence of nondeletion a-thalassemia is estimated to be one-third that of the deletion type ([19], [20] and [21]). In black Americans, a-thalassemia is relatively common, but it is rarely of clinical significance ([22], [23]). Three percent of black infants born in Philadelphia were found to have the electrophoretic and hematologic characteristics, and 5.7% of black military recruits had the ß- to a-chain synthetic ratio of heterozygous a-thalassemia ([24], [25]). Of 211 healthy black Americans in whom the a-globin genotype was characterized, 27.5% lacked a single a-globin gene, and 1.9% lacked two of the four a-globin genes ([26]). With the resettlement of nearly 2 million refugees from Cambodia, Laos, and Vietnam in the 1970s and 1980s, symptomatic a-thalassemia syndromes assumed increasing clinical significance in North America and Europe ([27]).

Approximately 3% of the world's population (150 million people) carry ß-thalassemia genes. In Europe, they are particularly prevalent in inhabitants of Italy and Greece. In Italy, the highest prevalence of the carrier state in descending order has been found in Sardinia (13%), the delta region of the Po River near Ferrara (8%), and Sicily (5.9%, with an almost equal distribution over the entire island) ([28], [29] and [30]). In Greece, the prevalence varies considerably, ranging from less than 5% to nearly 15% in the southern and central areas ([31], [32]). In Cyprus, one individual in seven is a carrier of ß-thalassemia, and 1 individual in 1000 is currently homozygous ([1]). In Sardinia, the incidence of homozygous ß-thalassemia was 1:250 live births in the absence of preventive measures ([28]) and is now 1:4000. There are an estimated 3500 individuals with thalassemia major in Greece and 6500 in Italy ([33]). ß-Thalassemia is encountered less often in the northern and western parts of Africa. In the Maghreb (African countries opening on the Mediterranean), frequencies vary from 3% in Algeria to 7% in Morocco and Libya ([34], [35] and [36]). In Egypt, thalassemia represents a serious health problem, with a predicted 1000 new patients born each year ([37], [38]). In Turkey, the frequency varies from 0.8 to 10.8% ([39]). It has been described in high frequencies (10 to 20%) in Indian and Kurdish Jews ([40], [41]). In Arabs, it averages 2% ([17], [42]). Few data are available for Pakistan ([43]). In Indians, frequencies between 3.5 and 14.9% have been reported ([44], [45] and [46]). In North America, thalassemia used to affect mainly individuals of Mediterranean origin and African-Americans but is, at present, most frequently observed in Asians ([23], [47]). In fact, increases in Asian immigration and births in the United States, particularly in California, have led to a prevalence rate of HbE/ß-thalassemia among Southeast Asians of approximately 1 in 2200 ([48]). In one survey of healthy black men, heterozygous ß-thalassemia was documented in 1.4% ([25]). ß-Thalassemia in Jamaica may have its origin in both the African and Oriental immigrant population ([49]). In sporadic cases, ß-thalassemia has been noted in North Europeans with no apparent Mediterranean or Oriental ancestry ([36]). Although well documented in natives of Southeast Asia and southern China, ß-thalassemia is far less prevalent in these regions than a-thalassemia ([5], [50], [51] and [52]). HbE, the hallmark of Southeast Asia, is most frequently found at the border of Thailand, Laos, and Cambodia, where the frequencies may reach 50 to 60%. The average frequency of HbE is 13%. In Great Britain, which is today a multiethnic society due to substantial migration from Cyprus, the Indian subcontinent, Southeast Asia, and the Middle East, it is estimated that 0.37/1000 fetuses have a major hemoglobin disorder, 20% being thalassemias and 80% being sickle cell disease. A formal patient register was also recently established in Great Britain in 1997 ([53]). At the end of 1999, 807 patients with thalassemia major were alive and residing in the United Kingdom, most of whom were of Pakistani or Cypriot origin ([2]). Detailed information on the frequency of thalassemia in different world regions can be found in Weatherall and Clegg and Angastaniotis and Modell ([1], [36]).

Role of Malaria

In the first description from Italy of children affected by thalassemia, Maccanti observed that all the patients came from malarial areas, and, 20 years later, Vezzoso noted that the distribution of Cooley anemia in Italy coincided with that of malaria ([54], [55]). The hypothesis that malaria had an influence in maintaining the high prevalence of hemoglobinopathies in the world was first suggested in 1948 by Haldane, who also proposed that the small red cells of the carriers of thalassemia could be more resistant to the malaria parasites ([56]). A few years earlier, Neel and Valentine had calculated that, in the absence of some kind of selective pressure, the mutation rate for thalassemia had to be in the order of 1 in 2500 ([47]). Carcassi and Siniscalco in Sardinia obtained suggestive epidemiologic data on the distribution of thalassemia and malaria, but their results were not confirmed in other populations ([57], [58]). Molecular biology studies helped to clarify at least some aspects of the problem. In fact, they revealed the very high number of ß-thalassemia mutations that are, for the most part, regionally specific and the association of particular mutations with specific ß-globin gene haplotypes. The regional specificity of mutations suggests local processes for their elevation to high frequencies, whereas the close association with specific haplotypes suggests a recent cause. These observations point to the conclusion that the selective pressure of malaria has amplified the ß-thalassemia genes to high frequency so recently that migration, recombination, or genetic drift could not have had sufficient time to bring them into spatial or

genetic equilibrium with their background ([59]).

The mechanism by which the thalassemia heterozygote could be protected from malaria is still not clear. Several studies have demonstrated reduced red cell invasion by malaria parasites in the severe forms of thalassemia, but the results in the heterozygous states for a- and ß-thalassemia have been contradictory ([60], [61], [62], [63], [64], [65], [66] and [67]). A provocative study performed in newborns with a-thalassemia revealed an increased susceptibility to infection by *Plasmodium vivax*, a less severe form of malaria, and suggested that this could confer permanent cross-species protection against *Plasmodium falciparum* ([68]). Both parasites preferentially invade young circulating red cells, and early infection in a period of life when maternal antibodies are still present could protect from later severe disease. Also, some form of immunologic mechanism could be involved in protecting carriers of thalassemia from malaria and, possibly, from other diseases as well ([69], [70] and [71]).

GENETIC MECHANISMS AND MOLECULAR PATHOLOGY

Synthesis of hemoglobin, the molecule used for oxygen transport, is directed by two gene clusters: the a locus, which contains the embryonic ? gene and the two adult a genes, and the ß cluster, which contains the embryonic e, the fetal ^{G}? and ^{A}?, and the adult d and ß genes (Fig. 42.1). Different hemoglobins are produced during development, and two globin gene switches take place: the embryonic to fetal switch (e to ? and ? to a), which starts very early in pregnancy and is completed at 10 weeks of gestation, and the fetal to adult switch (? to ß), which occurs during the perinatal period ([72]). The globin gene switches, besides the changes in hemoglobin composition, come with changes in other morphologic and biochemical characteristics of the erythropoietic cell line, including the shift from the nucleated megaloblast to macrocyte and to the definitive normocyte, the shift in the site of erythropoiesis from the yolk sac to liver, spleen, and bone marrow, and changes in the membrane antigenic profile and in the red cell glycolytic activity ([72]).

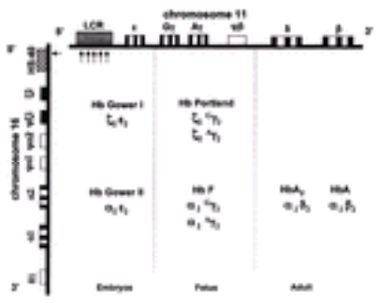

Figure 42.1. a- and ß-globin gene cluster and hemoglobins (Hbs) produced during development. HS, hypersensitive site; LCR, locus control region.

The globin genes are relatively small and are composed of three exons, coding for functional domains of the hemoglobin, and two intervening sequences (introns) ([73]). The different globin gene expression during development is controlled through the action of transcription factors and regulatory elements (promoter, enhancers, and silencers) that flank each globin gene and of more remote sequences important for the regulation of all the loci.

The promoter of each globin gene contains sequences that act as binding sites for erythroid-restricted or ubiquitously expressed transcription factors responsible for tissue-specific and developmental-specific regulation of the globin genes. Particularly relevant promoter sequences are the TATA box, situated 30 base pairs (bp) upstream of the initiation site, and the CAAT and the CACCC boxes at approximately -70 and -110 bp from the initiation site, respectively. Among the transcription factors, some have been studied in detail for their role in the regulation of globin gene expression. GATA-1 is the first of a family of DNA-binding proteins, whose binding sites are present in one or more copies in almost all of the regulatory elements of the globin genes ([74]). Nuclear factor-erythroid 2 and erythroid Kruppel-like factor are transcription factors involved in the expression of the ß-globin gene ([75], [76] and [77]).

Like other genes, globin genes possess a series of motifs critical for their expression: the CAP site, which indicates the start of transcription; the AGT initiation codon, which is the signal for starting translation in mRNA; the donor and acceptor splice sites, which are involved in the processing (splicing) of mRNA; the termination codon, which interrupts translation; and the polyadenylation signal, which is crucial for the addition of a poly (A) tail to the mRNA. Essentially, the process of globin gene expression consists of the following steps: (a) the transcription of DNA into a primary mRNA transcript; (b) the processing of the primary mRNA, involving modifications at both its 5' (capping) and 3' ends (polyadenylation), together with the removal of the introns and joining of the exons (splicing) to produce mature mRNA, the final template for protein synthesis; and (c) the translation of mRNA in the globin protein. Transcription and RNA processing occur in the nucleus, whereas translation occurs in the cytoplasm ([36], [78]).

Thalassemia syndromes result from a large number of molecular defects that alter the expression of one or more of the globin genes.

a-Thalassemia

The a-globin genes are duplicated and located in the telomeric region of chromosome 16 (16p13.3) in a cluster containing an embryonic a-like gene (? $_{2}$) and three pseudogenes (?? $_{1}$, ?a $_{1}$, and ?a $_{2}$) (Fig. 42.1) ([79]). A gene (?) with unknown function—but whose mRNA can be found through all stages of development—is part of the a cluster. Several regions of the cluster contain tandem arrays of short GC-rich sequences (minisatellites), identified as hypervariable regions, and many Alu-family repeats ([80], [81], [82] and [83]). The a complex is arranged in the order in which it is expressed during development: 5'? $_{2}$……a $_{2}$-a $_{1}$. There is a very high homology between a $_{2}$ and a $_{1}$ genes; they only differ in the IVS-2 (two base substitutions and a 7-bp insertion/deletion) and in the 3' noncoding region [18 base substitutions and a single-base deletion in the 3' untranslated region (UTR)] ([84], [85] and [86]). This remarkable homology has been maintained during evolution through repeated rounds of gene conversion ([81], [84], [85] and [86]). The embryonic ? gene shows only 58% homology with the a genes in the coding region.

The level of transcription of the two a genes differs: The a $_{2}$ gene encodes two to three times more a-globin than a $_{1}$ ([87], [88], [89] and [90]). This would imply that the globin structural variants of the a $_{2}$ gene should represent approximately 35% of the total hemoglobin, whereas the a $_{1}$-globin mutants approximately 15%. However, contrasting results have been reported on this point. Shakin and Liebhaber have reported identical translation profiles of a $_{2}$- and a $_{1}$-mRNA and higher percentages of a $_{2}$-globin variants (24 to 40% as compared to 11 to 23% for a $_{1}$-globin variants) ([91]).

Molchanova et al. confirmed the average ratio of 2.6 to 1.0, observed for a $_{2}$- and a $_{1}$-mRNA, but they reported an average percentage of the abnormal hemoglobin in heterozygotes with a2 mutations (23.5%) to be only slightly higher than that in heterozygotes with a1 mutations (19.7%), suggesting a less efficient translation of a $_{2}$-mRNA ([92]). It should be pointed out that, besides the rate of transcription and efficiency of translation, other factors, such as stability of the variant, affinity of the variant for ß-chains, and the number of active a genes, may influence the final level of the abnormal hemoglobin. The issue of different expression of the two a genes is important not only for the a-globin structural variants, but also for the pathophysiology of the deletional and nondeletional forms of a-thalassemia.

The expression of the a-globin genes is regulated by the sequences in and around the structural genes and by a region located 40 kb upstream from the a cluster ([93]). This region, defined as hypersensitive site (HS)-40, contains an erythroid-specific DNAase I HS and a 350-bp core element with multiple binding sites for transacting factors (nuclear factor-erythroid 2, GATA-1), several CACCC motifs, and a YY1 transcription factor binding site. The importance of HS-40 as a regulatory element is suggested by the presence of rare deletions of this region that produce a-thalassemia, although both a genes on the chromosome are intact.

Normal individuals have usually four a-globin genes, but as a result of unequal genetic exchange, some may have five or six a genes, while still being phenotypically normal ([94], [95] and [96]). Multiple arrangements with three to six ?-like embryonic genes have also been reported ([97], [98]).

DELETION a-THALASSEMIA a-Thalassemia is caused most frequently by deletions of DNA that involve one or both a-globin genes. The a-globin genes are embedded within two highly homologous regions extending for approximately 4 kb, whose sequence homology has been maintained by gene conversion and unequal crossover events ([79], [99]). Three homologous subsegments (X, Y, and Z) separated by nonhomologous elements have been defined. Reciprocal recombination between Z boxes, which are 3.7 kb apart, and between X boxes, which are 4.2 kb apart, gives rise to chromosomes with only one a gene. These a-thalassemia

determinants, which are the most common, are referred to as -a *3.7-kb rightward deletion* and -a *4.2-kb leftward deletion*, respectively (Fig. 42.2) ([100]). Based on the exact location within the Z box where the crossover took place, the -a 3.7-kb deletion is further subdivided into -a 3.7 I, -a 3.7 II, and -a 3.7 III ([81]).

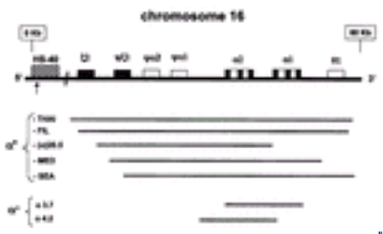

Figure 42.2. Most common deletional a-thalassemia defects. HS, hypersensitive site.

Besides the deletion a-thalassemia determinants, the nonreciprocal crossover produces chromosomes with three a-globin genes: aaa anti-3.7 and aaa anti-4.2 ([94] , [101] , [102]). More complex recombination events result in chromosomes with four a genes (aaaa anti-3.7 and aaaa anti-4.2) ([102]). In addition to the common -a 3.7-kb and -a 4.2-kb deletions, three rare deletion determinants that produce a-thalassemia have been reported. One removes a segment of 3.5 kb containing the whole a $_1$ gene and its flanking DNA (-a 3.5); a second removes the 5'end of the a $_2$ gene, the ?a $_1$ gene, and its flanking region [a(a)5.3]; and the third, described in a Chinese patient with HbH disease, deletes a region containing the a $_1$ gene ([9] , [103] , [104]). The result of a single a-globin gene deletion is a reduced production of a-chains from the affected chromosome (a $^+$-thalassemia). Measurements of a-globin mRNA in patients with -a 4.2 determinants suggest that there is a compensatory increase in expression of the remaining a $_1$ gene, whereas in the chromosome with -a 3.7 deletion, the remaining a gene is expressed roughly halfway between a normal a $_2$ and a $_1$ gene ([105] , [106]). These differences in expression most likely are a consequence of changes in the rate of transcription, due to the new combinations of flanking sequences, to the modification in chromatin structure resulting from the deletion, or to variation in the interaction with the HS-40 regulatory element ([107] , [108]).

Deletions that remove all or part of the a-globin gene cluster, including both a genes (entirely or in part) and sometimes the embryonic ? $_2$ gene, result in a ^{0}-thalassemia. The extent of the deletions, completely removing both a-globin genes, is from 100 kb to more than 250 kb; sometimes, other flanking genes, such as a DNA repair enzyme, a protein disulfide isomerase, and several anonymous housekeeping genes, are removed (Fig. 42.2) ([108]). However, interestingly, in subjects with these large deletions, the only phenotypical manifestation is a-thalassemia. Several molecular mechanisms (illegitimate recombination, reciprocal translocation, truncation of chromosome 16) have been described as responsible for these large deletions ([82] , [83]). Two deletions [-(a) $^{5.2}$ and -(a) $^{20.5}$] remove the a $_2$-globin gene and partially remove the a $_1$-globin gene: The affected chromosome produces no a-chains ([13] , [109]). a ^{0}-Thalassemia may also result from deletions of the a-globin regulatory element HS-40. Twelve different deletions of variable extent, all involving HS-40 but leaving both a genes intact, have been reported [for references see Higgs et al. ([108])]. The associated phenotype is the a ^{0}-thalassemia phenotype.

NONDELETION a-THALASSEMIA Single nucleotide mutations or oligonucleotide deletions/insertions in regions critical for a-globin gene expression produce a-thalassemia. Nondeletional types of a-thalassemia are much less common than deletional a-thalassemia, except the Constant Spring mutation, which is quite common in Southeast Asia. Several molecular mechanisms (mutations affecting RNA splicing, the poly (A) addition signal, the initiation mRNA translation, chain termination mutations, in-frame deletions, and frameshift and nonsense mutations) and 41 well-defined types of nondeletion a-thalassemia have been described [for references see Higgs et al. ([108])]. The majority of nondeletional mutants so far reported occur in the a $_2$ gene and, as expected, have a more severe effect on a-globin gene expression. Hb Constant Spring (a 142 TAA?CAA, Stop?Glu) is the most common of the nine potential chain termination mutants, which change the stop codon to one amino acid, allowing mRNA translation to continue to the next in-phase stop codon located within the polyadenylation signal. The result of this class of mutation is the production of a very low amount (approximately 1%) of an a-chain variant elongated by 31 amino acids. It has been suggested that the reason for the reduced production of the elongated variants is the instability of the mRNA due to disruption of the 3' UTR ([110]). Other extended a-chain variants are Hb Icaria (a 142 Lys), Koya Dora (a 142 Ser), Seal Rock (a 142 Glu), and Paksé (a 142 Tyr). Heterozygotes for a-globin elongated chain, besides the presence of the hemoglobin variant, have the phenotype of a-thalassemia. Mutations of a-globin genes, which result in the production of highly unstable globin variants such as Hb Heraklion (a 137 Pro?0) and Hb Agrinio (a 29 Leu?Pro) and are unable to assemble in stable tetramers and are thus rapidly degraded, are associated with the phenotype of a-thalassemia ([111] , [112]).

ß-Thalassemia

The ß-globin gene is located in the short arm of chromosome 11 in a region containing the d gene, the embryonic e gene, the fetal ^{G}? and ^{A}? genes, and the pseudogene ?ß $_1$ (Fig. 42.1) ([113]). The five functional globin genes are arranged in the order of their developmental expression. The complete sequencing of the ß-globin gene complex has shown interspersed repetitive sequences [microsatellite repeats of (CA)n, an (ATTTT)n repeat, Alu I and Kpn I families of repeat DNA sequences], which may play a role in the generation of the deletions of the ß cluster. The region also contains many polymorphic base substitutions, which produce restriction fragment length polymorphisms, combined in a restricted number of haplotypes in linkage disequilibrium with ß-thalassemia mutations ([114]). Haplotype analysis provides information relevant for population genetics of the hemoglobinopathies. Similar to the a-like globin genes, variations in the number of ß cluster genes, mostly involving the ? genes (which may be present in one to five copies), have been reported ([115] , [116]). Like the a genes, ß-globin genes are subject to a very complex regulatory mechanism, acting at the level of single genes as well as of the entire ß cluster.

The appropriate expression of the different ß-like globin genes in erythroid tissues during development depends on a major regulatory region named the *locus control region* (LCR), located 5 to 25 kb upstream from the e-globin gene ([117]). Five DNAase HSs have been described in the region, and each HS contains one or more binding motifs for erythroid-specific transcriptional activator (GATA-1 and nuclear factor-erythroid 2) and for ubiquitous DNA-binding proteins ([72] , [118]). The importance of LCR for the control of the ß-like globin gene expression has also been suggested by a series of naturally occurring deletions that totally or partially remove the HS sites and result in the inactivation of the intact downstream ß-globin gene ([119] , [120]).

ß-Thalassemia mutations result in either a complete absence of ß-globin chains (ß ^{0}-thalassemia) or a largely variable reduction of ß-globin output (ß $^+$-thalassemia). More than 200 different mutations producing ß-thalassemia have been so far described; the large majority are point mutations in functionally important sequences of the ß-globin gene, whereas in contrast to a-thalassemia, gene deletion is a rare cause of ß-thalassemia (Table 42.1). A complete updated list of ß-thalassemia mutations has been published and is also available through the globin gene server web site (noted at chapter's conclusion in the section Web Sites ([121] , [122]).

TABLE 42.1. Mutations Causing ß-Thalassemia

	Phenotype	Number of Mutations
Transcriptional mutants		
Promoter	Silent	2
	Mild	5
	ß $^+$	12
5'-UTR	Silent	4
	Mild	1
	ß $^+$	1

Nonsense codon	ß ^{0}	14
Frameshift	ß ^{0}	64
Deletions	ß ^{0}	17
Dominant ß-thalassemias		
Missense mutations	ß ^{0}	8
Deletion or insertion of intact codon	ß ^{0}	7
Nonsense mutations	ß ^{0}	2
Frameshift or aberrant splicing	ß ^{0}	14

UTR, untranslated region.

NONDELETION ß-THALASSEMIA Point mutations resulting in ß-thalassemia are single nucleotide substitutions or oligonucleotide insertions/deletions that affect the ß gene expression by a variety of mechanisms (Table 42.1).

Transcription Mutations

Promoter Mutations Several mutations have been described in or around the conserved motifs in the 5'-flanking sequence of ß-globin genes (TATA box and the proximal and distal CACCC box). They reduce binding of RNA polymerase, thereby reducing the rate of mRNA transcription to 20 to 30% of normal. They result in a moderate decrease of ß-globin chain output (ß $^{+}$-thalassemia) and, hence, in a mild phenotype. One mutation, C?T at position -101 to the ß-globin gene (distal CACCC box), is unusually mild and associated with a silent phenotype in carriers and in a very mild thalassemia intermedia clinical picture in genetic compounds with severe ß-thalassemia mutations ([123], [124]). The promoter mutations -28 A? G and -29 A?G are relatively common in Chinese and black populations, whereas -87 C?G and the silent -101 C?T have been described in Mediterraneans. No mutations of the CCAAT box have been identified so far.

5' Untranslated Region Mutations Several mutations (single-base substitution and minor deletions) have been reported in this 50-nucleotide region; all have a mild effect on gene transcription. Heterozygotes have normal or borderline red cell indices and HbA $_{2}$, and compound heterozygotes, with severe ß-thalassemia alleles, usually have a mild phenotype. The only homozygous state for a mutation at ß-globin gene mRNA cap site (Cap + 1 A? C) shows hematologic values of a thalassemia trait ([125]).

Mutations Affecting mRNA Processing RNA processing essentially consists of the removal of intervening sequences and the splicing of the coding regions to produce functional mRNA. The precision of this process relies on critical sequences present at intron/exon boundaries: the invariant dinucleotides -GT- at the 5' (donor) and -AG- at the 3' (acceptor) splice junctions and the flanking sequences (consensus sequences) that are rather well conserved ([126]).

Splice Junction and Consensus Sequence Mutations Mutations of the invariants 5'–GT- and 3'–AG- dinucleotides completely abolish normal splicing and result in ß ^{0}-thalassemia. Twenty-four base substitutions or short deletions involving the invariant dinucleotides have been identified. Other cryptic splice sites present elsewhere in precursor mRNA are used for alternative splicing, but the misspliced mRNA cannot be translated into functional ß-globin ([127], [128]). The efficiency of normal splicing may be decreased by mutations within the consensus sequences immediately adiacent to the splice junctions. The reduction of ß-globin production is quite variable, and the resulting phenotypes range from mild to severe. For example, the mutations at position 5 of IVS-1 (G?C, G?T, G?A) produce a consistent reduction of ß-globin synthesis and, hence, a severe ß $^{+}$-thalassemia phenotype, whereas the IVS–1–6 T?C mutation (Portuguese mutation), quite common in the Mediterranean, only mildly affects normal splicing and results in a mild thalassemia intermedia clinical picture ([129]). Even in the consensus sequence mutations, abnormal alternative splicing using neighboring cryptic sites may occur ([127]).

Cryptic Site Mutations in Introns and Exons Along introns and exons, there are sequences similar to those found at the intron/exon boundaries, which normally are not used for splicing (“cryptic” splice sites). A number of nucleotide substitutions involving these sequences transform a cryptic site into a legitimate one. This new splice signal competes with the normal consensus sequence for splicing and, in some cases, is used preferentially (up to 90% in the IVS-1–110 G?A substitution and almost 100% in the IVS-1–116 T?G substitution), resulting in a severe ß $^{+}$- or ß ^{0}-thalassemia phenotype ([130], [131]). Two cryptic splice site mutations in IVS-1 and four in IVS-2 have been described. In the exons, three cryptic splice sites can be activated by nucleotide substitution: one at codon 10 (C?A), a second at codon 19 (A?G), and a third, by mutation, at codons 24 (T?A), 26 (G?A), or 27 (G?T). The nucleotide substitutions partially activate the cryptic splice sites, resulting in both normally and abnormally spliced ß-mRNA. The cd 24 T?A mutation is translationally silent and associated with a severe ß $^{+}$-thalassemia ([132]). Mutations at codons 19, 26, and 27 result in the production of abnormal hemoglobins [cd 19, Hb Malay (Asn?Ser); cd 26, HbE (Glu?Lys); cd 27, Hb Knossos (Ala?Ser)] and are associated with a mild or silent phenotype because of the preferential use of the normal splice sites ([127], [133], [134] and [135]).

Poly (A) and Other 3' Untranslated Region Mutants Downstream of the mRNA terminal codon, there is a highly conserved AAUAAA sequence, which represents a signal for the cleavage and polyadenylation reaction, as a part of the RNA transcript processing. Because polyadenylation is important in determining the stability of mRNA, mutations at the AAUAAA sequence affect the efficiency of translation, resulting in ß $^{+}$-thalassemia of variable, but usually mild, severity. Four nucleotide substitutions and two oligonucleotide deletions (of two and five bases), involving the polyadenylation signal, have been described. Other mutations in the 3' UTR (+1480 C?G) also produce ß $^{+}$ silent–thalassemia.

Mutations Affecting mRNA Translation A large group of mutations alter the different steps of mRNA translation. Three categories of mRNA translation mutations can be identified: initiation codon mutations, nonsense mutations, and frameshift mutations.

Initiation Codon Mutations The initiator codon ATG, which encodes for methionine, is a critical signal for starting translation. Seven different point mutations of the initiation codon have been reported as causes of ß ^{0}-thalassemia.

Nonsense Mutations Single nucleotide substitutions may change a codon for a given amino acid to one of the three possible chain termination codons: TAA, TAG, or TGA. The result is a premature interruption of mRNA translation, with absence of ß-globin production (ß ^{0}-thalassemia). A very low level of ß-mRNA has been detected in affected erythroid cell mutations in exons 1 and 2 as a consequence of rapid degradation of the mutant ß-mRNA ([136], [137]). This process is referred to as *nonsense-mediated decay* and may be a mechanism to eliminate mRNAs encoding truncated polypeptides with potential harmful effects for the erythroid cell ([138], [139] and [140]). Nonsense mutations in exon 3 are associated with ß-mRNA levels comparable with normal levels. The protective process does not occur, and mutant ß-mRNA is probably translated to produce the abnormal globin (see section Hyperunstable Globins) ([141]). The most common nonsense mutation in the Mediterranean population, particularly in Sardinians in whom it accounts for more than 95% of ß-thalassemia, is the C?T base substitution at codon 39, whereas the nonsense mutation at codon 17 A?T shows a high frequency in the Chinese and Thai populations ([142], [143]).

Frameshift Mutations Insertion or deletion of one or a few nucleotides (other than three or multiples of three) alters the reading frame of the encoded mRNA starting at the site of the mutation. The new reading frame usually results in a novel abnormal amino acid sequence and in a premature termination further downstream. The mutant globin chain is rapidly degraded, and the final result is a ß ^{0}-thalassemia. The frameshift resulting from a single base deletion at codon 6 (-A) is relatively common in Mediterranean populations, whereas the -4-nucleotide deletion at codon 41 and 42 is particularly common in Chinese and Asian Indian populations ([144], [145]). The position of the premature termination (in exon 1, 2, or 3) caused by the frameshift mutation affects the mutant mRNA level and processing as previously reported for nonsense mutations.

ß-GLOBIN GENE DELETIONS Several deletions, affecting only the ß-globin gene and ranging in size from 290 bp to approximately 67 kb, have been reported. Only one, the 619-bp deletion, removing the 3' end of the ß-globin gene, is relatively common in the Sind and Punjab population of India and Pakistan ([146]). All the others are extremely rare and have in common the deletion of the promoter region and at least part of the ß-globin gene. The phenotype is that of ß ^{0}-thalassemia with

unusually high levels of HbA $_2$ and HbF in heterozygotes. This is probably the result of the removal of competition for the upstream LCR, thus allowing an increased interaction between LCR and the ? and d gene *in cis*, with a consequently more efficient expression of these genes ([147]). Other deletions causing ß-thalassemia remove either the whole ß-globin cluster or the LCR. Total deletions of ß cluster result in lack of any globin production and, hence, in (e ^{G}?– ^{A}?dß) ^{0}-thalassemia ([148] , [149] and [150]). Three deletions, removing totally or partially the LCR but leaving the ß gene ([120] , [151] , [152]). These deletions confirm importance of the LCR for the control of expression of the ßglobin genes.

ß-THALASSEMIA HEMOGLOBINOPATHIES This group includes some structurally abnormal hemoglobins associated with a thalassemia phenotype. They can be classified according to the molecular mechanism.

dß Hybrid Genes Unequal crossing over between the homologous d- and ß-globin genes results in the formation of hybrid dß and ßd genes, referred to as *Lepore* and *anti-Lepore genes*. The Lepore hemoglobins contain the *N*-terminal amino acid sequence of the normal d-chain and the *C*-terminal sequence of the normal ß-chain; depending on the point of transition from d to ß sequence, three different variants of Hb Lepore have been described: Boston or Washington (d 87/ß IVS-2–8), Baltimore (d 68/ß 84), and Hollandia (d 22/ß IVS-1–16) ([153] , [154] , [155] and [156]). The rate of production of the Lepore hemoglobins (approximately 10% in the carriers) likely depends on the structure of the hybrid gene, which has the promoter of the d gene (this would explain the lower Hb Lepore amount as compared to normal HbA), and the IVS-2 of the ß gene that probably contains an enhancer (this would explain the higher level of Hb Lepore as compared with HbA $_2$). Moreover, the relative instability of the Lepore mRNA may be responsible for the low level of synthesis. Nonhomologous crossing over between the ß and d genes also results in the production of a hybrid ßd gene in a chromosome containing also the normal ß and d genes. These anti-Lepore genes produce approximately 15 to 20% of the abnormal hemoglobin. Based on the position of the fusion point, several anti-Lepore hemoglobins have been identified (Hb Miyada, P Congo, P Nilotic, and Hb Lincoln Park, which has, in addition, a valine residue deleted at position 137), and carriers have normal hemoglobin levels and normal red cell indices. A similar nonhomologous crossing over involving the ^{A}?- and ß-globin gene produces an abnormal hybrid chain, which contains ? and ß sequences (Hb Kenya). Restriction enzyme analysis in these patients showed a deletion of approximately 22.5 kb and the loss of sequences extending from exon 2 of the ^{A}? gene to exon 2 of the ß gene ([157]).

Activation of Cryptic Splice Sites This group, including the HbE, Hb Malay, and Hb Knossos, has been previously described.

Hyperunstable Globins A singular group of ß-globin gene mutants are characterized by amino acid substitutions, additions, or deletions in the ß-globin chain associated with a thalassemic phenotype in the heterozygous state. For this reason, these forms are also referred to as *dominantly inherited* ß *-thalassemia*. The molecular lesions include missense mutations, small deletions resulting in the loss of intact codons, or frameshift mutations producing elongated or truncated ß-globin chains. Most of these mutations are located in the exon 3 ([158] , [159]). In contrast to the typical recessively inherited forms of ß-thalassemia, which lead to a reduced synthesis of normal ß-globin chains, this group of mutations results in the production of ß-globin variants that are extremely unstable. These hyperunstable globins fail to form functional tetramers and precipitate in the erythroid precursors, leading to ineffective erythropoiesis, which is exacerbated by the concomitant relative excess of a-chains ([159]). Most patients present with the clinical phenotype of thalassemia intermedia; a few have the phenotype of thalassemia trait, and some may even have a severe anemia requiring red blood cell (RBC) transfusions. Laboratory findings consist of varying degrees of hypochromic microcytic anemia, increased HbA $_2$, and an imbalanced a- to ß-globin synthesis ratio. In most of the cases, the hemoglobin variant cannot be detected in the peripheral blood.

Unknown Mechanism In 1981, Adams et al. reported a patient with 8% of an abnormal hemoglobin (Hb Vicksburg ß 75 Leu?0) and the phenotype of thalassemia intermedia ([160]). The reason for the thalassemia intermedia phenotype associated with Hb Vicksburg has not yet been defined. The original patient has been reexamined; despite the use of the new technologies of DNA analysis, the predicted Hb Vicksburg deletion was not present ([161]). Moreover, even the Hb variant was not detected on two occasions, whereas HbA, absent at the beginning, has now been found. DNA analysis showed that the patient was a compound heterozygote for the -88 C?T ß $^{+}$ allele and the IVS-2–849 A?G mutation that causes ß ^{0}-thalassemia ([161]). It has been proposed that Hb Vicksburg arose as a stem cell mutation on the ß $^{+}$-thalassemia chromosome. The variable hemoglobin composition at different ages suggests that over time there were at least two clones of erythroid progenitors contributing to erythropoiesis ([161]). A phenotype of mild heterozygous ß-thalassemia with microcytosis and increased levels of HbA $_2$ has been reported in patients with two hemoglobin variants: Hb North Shore (ß 134 Val?Glu) and Hb Woolwich (ß 132 Lys?Glu) ([162] , [163]). In both cases, a mild deficit of ß-globin chain synthesis has been reported. DNA analysis of these patients has not been performed, and the mechanism responsible for the thalassemic phenotype remains unknown.

d-THALASSEMIA Several mutations of the d-globin gene that result in reduced (d $^{+}$-thalassemia) or absent (d ^{0}-thalassemia) production of d-globin chains have been described. These conditions do not have clinical relevance, but the coinheritance with ß-thalassemia mutations may create problems in ß-carrier identification, because the HbA $_2$ may be normal or borderline. The classes of mutations are similar to those responsible for ß-thalassemia. Some d-thalassemia mutations have been described *in cis* to ß-thalassemia. The d $^{+}$27 C?T, fairly common in the Mediterranean, has been reported *in cis* to ß $^{+}$IVS-2–745 C?G, ß ^{0}39 C?T, and ß $^{+}$ 27 G?T (Hb Knossos) ([164] , [165] and [166]). Even the Corfu deletion (-7.2 kb) has been reported with, isolated to, or associated with the ß $^{+}$IVS-1–5 G?A mutation ([167] , [168]).

dß-THALASSEMIA dß-Thalassemia includes a group of disorders characterized by reduced or absent production of both d- and ß-globin chains and by a variable increase in ?-chain synthesis that only partially balances the d- and ß-chain deficiency. The most common molecular mechanism consists of deletions of variable extent of the ß-like globin cluster, which involve the d- and ß-globin genes. Based on the presence of one (^{G}?-) or both (^{G}?- and ^{A}?-) globin genes and, hence, on the residual synthesis of only ^{G}?- or both ^{G}?- and ^{A}?-globin chains, two groups of dß ^{0}-thalassemia have been identified: ^{G}?(^{A}?dß) ^{0}- and ^{G}? ^{A}?(dß ^{0})-thalassemia. In Table 42.2, the different varieties with the size of the deletion are summarized ([169] , [170] , [171] , [172] , [173] , [174] , [175] , [176] , [177] , [178] , [179] , [180] , [181] , [182] , [183] , [184] , [185] , [186] , [187] , [188] and [189]). Some have been described in single or a few families, whereas others, such as the Sicilian, the Spanish ^{G}? ^{A}?(dß ^{0}), and the black ^{G}?(^{A}?dß) ^{0}, are more common. Homozygotes have been reported as well. For some deletions, the 3' breakpoint has not been defined. The majority of the deletions that result in dß-thalassemia are due to illegitimate recombination. Similar but more complex mechanisms have been invoked to explain other dß ^{0}-thalassemias such as Macedonian/Turkish ^{G}? ^{A}?(dß) ^{0}-thalassemia, which is characterized by a double deletion/inversion rearrangement ([170] , [173]). The reasons for the increased expression of the ? genes in (dß) ^{0}-thalassemia and the difference with hereditary persistence of fetal hemoglobin (HPFH) have not been defined. Juxtaposition to the globin genes of new sequences as a result of the deletion, removal of intergene sequences critical for control of ?-globin gene expression, and the altered spatial relationship between the LCR and the genes of the ß cluster with changes in LCR/globin gene promoter interaction and competition have been postulated to explain the up-regulation of the ?-globin genes and the phenotypic differences between (dß)-thalassemia and deletion HPFH. It is possible that a combination of the above mechanisms plays a role and that a balance between regulatory sequences, with positive or negative effects on the ? gene expression, may finally determine the amount of HbF in the red cells.

SE, southeast.

Corfu dß-thalassemia is characterized by a deletion of 7.2 kb, which removes the d gene associated with the ß IVS 1–5 G?A mutation ([190]). Carriers for this mutation have the unusual hematologic phenotype of heterozygous ß-thalassemia with normal levels of HbA $_{2}$, whereas homozygotes have relatively high levels of HbF and a mild clinical phenotype ([167]). The 7.2-kb deletion has been reported isolated as a deletion form of d-thalassemia not associated with increased HbF ([168]). Two varieties of nondeletion (dß-) thalassemia have also been described. One, relatively common in Sardinia, is of the (dß) ^{0} type and presents two mutations *in cis*: the common ß ^{0} 39 C?T nonsense mutation and a point mutation at position -196 in the A? gene promoter, which is responsible for the Italian/Chinese nondeletion A? HPFH ([188]). The other, reported in two Chinese families and characterized by decreased expression of the ß-globin gene and increased expression of both ^{G}?- and ^{A}?-globin genes [(dß) $^{+}$-thalassemia], showed no deletion in the ß-globin cluster ([189]). In one of these families, the -29 A?G mutation in the promoter of the ß gene (a mild ß $^{+}$ allele) and a nonpolymorphic C?T substitution in the 3 ^{A}? enhancer have been identified ([191] , [192]).

Hereditary Persistence of Fetal Hemoglobin

HPFH is characterized by the presence of increased levels of HbF in the adult life in the absence of relevant hematologic abnormalities. The amount of HbF is quite variable, ranging in the carriers from 2.0 to 30%; this variability reflects a marked molecular heterogeneity. Both deletion and nondeletion defects have been identified. The deletions resulting in HPFH, listed in Table 42.3, extend from 13 kb (HPFH-5 or Sicilian HPFH) to approximately 106 kb (HPFH-1 or black HPFH) ([193] , [194]). They remove d- and ß-globin genes but spare both ^{G}? and ^{A}? genes. As in (dß) ^{0}-thalassemia, the most common mechanism producing deletions is an illegitimate recombination followed by unequal crossing over.

[a] Only described in combination with hemoglobin S.

Nondeletion HPFH usually is the result of mutations in the promoter regions of ^{G}? and ^{A}? genes (Table 42.3) ([195] , [196] , [197] , [198] , [199] , [200] , [201] , [202] , [203] , [204] , [205] , [206] , [207] , [208] , [209] , [210] , [211] , [212] and [213]). Most of these mutations are single nucleotide substitutions in, or very close to, the conserved sequences that bind various regulatory transcription factors. As a consequence, there are changes in the binding of repressor or activator proteins that may modify the balance of the competition between the promoter and LCR, ultimately resulting in increased HbF synthesis in adult life ([214]).

In some families, mostly with interacting ß-thalassemia or sickle cell anemia, it has been shown that HPFH may segregate unlinked to the ß-globin cluster ([215] , [216] , [217] , [218] and [219]). Several patterns of inheritance have been identified: autosomal-dominant, X-linked, and autosomal-recessive. The locus for the X-linked form seems to reside at Xp22.2–22.3 ([220]). Craig et al., by using polymorphic markers covering the whole genome to study a single very large family, localized a putative locus for HPFH at 6q22.3-q24 ([219]). The putative loci may affect the HbF levels coding for trans-acting factors that bind within the ß gene cluster and directly act on gene expression or may alter the kinetics of erythropoiesis, mimicking the increased HbF observed in stress erythropoiesis ([214]).

PATHOPHYSIOLOGY

The pathophysiology of thalassemia syndromes is complex and encompasses intracellular processes as well as their consequences for the organism as a whole. An appreciation for the pathophysiology of the thalassemias is essential for understanding the differences in clinical expression of a- and ß-thalassemia, the high variability of clinical phenotypes, and the principles of treatment.

ß-Thalassemia

The basic defect in ß-thalassemia is a reduced or absent production of ß-globin chains with relative excess of a-chains. The direct consequences are a net decrease in the hemoglobin production and an imbalance of globin chain synthesis. The former is more evident in carriers, leading to a reduction of mean cell hemoglobin (MCH) and mean cell volume (MCV), and is of minor clinical significance. The latter has dramatic effects on the red cell precursors, resulting in their premature destruction in the bone marrow and extramedullary sites. This process is referred to as *ineffective erythropoiesis* and is the hallmark of ß-thalassemia. Using ferrokinetic analysis, it has been shown that in ß-thalassemia patients, only 15% of ^{59}Fe is incorporated in circulating erythrocytes, indicating that ineffective erythropoiesis could account for as much as 60 to 75% of total erythropoiesis ([221], [222]). Hemolysis of the erythrocytes containing inclusions that reach peripheral blood is a minor cause of anemia, particularly in thalassemia major (Fig. 42.3).

Figure 42.3. Pathophysiology of ß-thalassemia. Ig, immunoglobulin.

The excess a-chains may, in minor amounts, combine with residual ß- and ?-chains to undergo proteolysis or, in large part, become associated with the erythroid precursors and red cell membrane with deleterious effects on erythroid maturation and survival. Therefore, the main determinant of the clinical severity is the extent of the relative excess of a-chains in red cell precursors and, hence, the degree of a/non-a gene imbalance. In 1966, Fessas et al. described the presence of inclusion bodies in erythroblasts of thalassemic patients, suggesting that they were precipitated a-chains ([223]). The composition of inclusion bodies in ß-thalassemia, completely consisting of precipitated a-chains, has been recently confirmed by immunoelectron microscopy ([224]). Oxidation of excess a-chains results in the formation of hemichromes, whose basic structure consists of the covalent binding of distal histidine E7 to the sixth coordination site of the heme iron ([225]). Irreversible hemichromes and denatured a-chains precipitate as inclusion bodies early during differentiation and throughout erythroid maturation ([226]). a-Chain precipitation in the red cell membrane causes structural and functional alterations with changes in deformability, stability, and red cell hydration ([222], [227], [228]). Isolated red cell membranes from ß-thalassemia intermedia, particularly from splenectomized patients, are rigid and unstable. Protein 4.1, a major component of the cytoskeleton, undergoes partial oxidation in ß-thalassemia, resulting in its defective capability to mediate the formation of the spectrin–protein 4.1–actin complex, which is critical to maintain cytoskeleton stability ([229], [230]). *In vitro* experiments, using purified a-chains released within normal RBCs, support the role of aggregated a-chains in causing red cell membrane rigidity ([231]). A further consequence of the membrane-bound hemichromes is their association with the cytoplasmic domain of protein band 3, creating a neoantigen that is subjected to opsonization with autologous immunoglobulin G and complement and immune removal of the cell by macrophages ([232], [233]). RBCs in ß-thalassemia lose K^{+}, store Ca^{++}, and are dehydrated, resulting in altered deformability ([222]). Besides oxidation, free a-chains are subjected to degradation, resulting in the formation of denatured a-globin protein, heme, and free iron. These degradation products play a role in damaging erythroid precursors and red cell membranes. The effect of precipitated a-globin on the structure and function of red cell membrane has been discussed above. Free iron, via the “Fenton reaction,” generates reactive oxygen species, which cause lipid and protein peroxidation with consequent damage to red cell membranes and intracellular organelles ([234], [235]). High levels of iron, closely associated with denatured hemoglobin, have been found in the membrane of ß-thalassemic red cells ([236]). *In vitro* and *in vivo* (in humans and animals) experiments have shown that the oral iron chelator deferiprone, which may enter the cells, is able to remove free iron from thalassemic red cells, resulting in an improvement of red cell survival ([237], [238] and [239]). These results confirm the role of free iron in damaging red cell membrane structure. Also, heme and its oxidized form hemin produce oxidative damage to the different components of the red cell membrane with consequent structural and functional alterations ([227], [240], [241]).

These alterations of erythroid precursors result in an enhanced rate of apoptosis ([242]). Apoptosis contributes significantly to ineffective erythropoiesis and occurs primarily at the polychromatophilic erythroblast stage ([243]). There is wide variability of apoptosis in the different forms of thalassemia, and erythroid expansion seems to be important in determining the extent of apoptosis ([244], [245]). It is not clear how a-globin precipitation causes apoptosis, but the apoptotic control and ineffective erythropoiesis are under active investigation ([246], [247] and [248]).

Ineffective erythropoiesis and anemia have several consequences. The first response to anemia is an increased production of erythropoietin, causing a marked erythroid hyperplasia, which may range between 10 to 30 times normal ([221]). Anemia may produce cardiac enlargement and, sometimes, severe cardiac failure. Erythroid expansion produces skeletal deformities, osteoporosis, and, occasionally, extramedullary masses, and it contributes to splenomegaly. Untreated or undertreated individuals with thalassemia major have retarded growth as a result of anemia and an excessive metabolic burden imposed by erythroid expansion. Environmental factors such as poor nutrition and infections may contribute to growth failure. The high vascularization of expanded marrow results in an increase in plasma volume that, associated with splenomegaly, aggravates the anemia. Ineffective erythropoiesis is associated with increased iron absorption that further contributes to the iron burden imposed by blood transfusions ([249]). Iron overload damages several organs, including the myocardium, liver, and endocrine glands. Removal of the abnormal RBCs by the reticuloendothelial elements of the spleen results in splenomegaly and hypersplenism, which, when severe, may exacerbate anemia and cause thrombocytopenia and neutropenia.

A further consequence of the RBC membrane damage is the loss of the normal asymmetric distribution and increased surface exposure of the procoagulants, negatively charged phospholipids phosphatidylserine and phosphatidylethanolamine. The anionic phospholipids increase thrombin generation, which leads to activation of platelets and endothelial cells ([250], [251] and [252]). Evidence of *in vivo* platelet activation is supported by kinetic studies using platelets labeled with indium-111 oxine that have shown a significant reduction of mean platelet lifespan in patients with thalassemia major and intermedia ([253]). Further evidence of the chronic platelet activation has been provided by the increased urinary levels of metabolites of thromboxane A_2 and prostacyclin ([254]). Decreased levels of naturally occurring anticoagulants, such as protein C and protein S, and elevated plasma levels of thrombin–antithrombin III complex have been reported ([255], [256]). It has also been shown that adherence of thalassemic red cells to endothelial cells is markedly enhanced as compared to that of normal red cells, and elevated levels of endothelial adhesion proteins (intracellular adhesion molecule-1, E-selectin, vascular cell adhesion molecule-1, von Willebrand factor) in the serum and plasma of thalassemic patients have been described ([257], [258]). Activated monocytes and granulocytes, found in patients with thalassemia, could contribute to the endothelial damage and the hypercoagulable state ([259], [260]).

a-Thalassemia

As in the case of ß-thalassemia, the primary defect of a-thalassemia is the imbalance of globin biosynthesis, with excess of ß-, ?-, or both globin chains. Unlike a-chains, which are highly unstable and unable to form soluble tetramers, excess ?-chains in fetal life and ß-chains in extrauterine life associate to form partially soluble $?_4$ tetramers (Hb Bart) and $ß_4$ tetramers (HbH), respectively ([261], [262]). These excess non–a-chains damage mostly mature red cells and, to a lesser extent, erythroid precursors, leading mainly to hemolysis and minimally to ineffective erythropoiesis. The different characteristics of the excess chains in a-thalassemia are of great importance in determining its pathophysiology, but also the functional properties of HbH and Hb Bart and the number of a genes contribute to the different severity of a-thalassemia as compared to ß-thalassemia syndromes.

RBCs in a-thalassemia are rigid, as in ß-thalassemia, but, unlike ß-thalassemia, they are hyperhydrated and have red cell membranes that are hyperstable. The reason for hyperhydration has not been clearly defined, but it is likely a consequence of the effect of ß-chain excess on the KCl cotransporter system. Membrane skeletal–bound ß-globins become partially oxidized with consequent membrane damage ([230]). *In vitro* studies have shown that entrapment of ß-chains in normal red cells does not result in any significant change in membrane protein function or thiol concentrations; rather, it produces changes in red cell deformability, as reported *in vivo* in patients with HbH disease ([228], [263], [264]). Interaction of excess ß-globin with the cytoplasmic domain of protein band 3 is abnormal in erythrocytes of patients with HbH disease, because $ß_4$ tetramers tend to adhere tightly to protein band 3 ([229], [265]).

ß-Globin tetramers precipitate as the red cells age, forming inclusions. These inclusions can be induced by vital stains, such as brilliant cresyl blue or new methylene blue, and are more common in splenectomized patients ([266], [267]). Studies using monoclonal antibodies have shown that red cell inclusions in HbH disease are

composed of ß-globin ([224]). Membrane-bound inclusion bodies perturb the flow velocity during transit through the spleen capillaries, ultimately resulting in mechanical trapping and macrophagic phagocytosis ([268]). Hemolysis is the main pathophysiologic mechanism of HbH disease, but ineffective erythropoiesis is a component even if moderate. This has been suggested by morphologic and ferrokinetic studies and by the analysis of plasma levels of transferrin receptor ([244] , [269] , [270] and [271]). Excess ß-chains accumulate and precipitate not only in older red cells, but also in marrow erythroid precursors in which they may cause some intramedullary cell death. ß $_4$ Inclusion bodies alter the normal membrane phospholipid bilayer, exposing phosphatidylserine, which represents a signal for the development of apoptosis and red cell removal by the macrophages in the spleen and other reticuloendothelial organs ([272] , [273]). Programmed cell death is moderately increased in patients with HbH disease ([244]). Red cell membrane deformability and stability are even more affected in patients with HbH/Hb Constant Spring ([274]). As compared with patients with HbH disease, those with HbH/Hb ^{CS} have a higher amount of HbH and a higher percentage of erythrocytes with inclusion bodies and translocated phosphatidylserine ([267] , [272] , [275]). These differences may account for the greater hematologic severity of HbH/Hb ^{CS} disease. ?-Globin tetramers (Hb Bart) are much less prone than ß-globin tetramers to precipitate and form inclusions ([276]).

Besides the characteristics of excess ß- and ?-globin chains discussed above, other functionally abnormal properties are important in determining the pathophysiology of a-thalassemia. HbH and, even more so, Hb Bart have a very high oxygen affinity and show no heme–heme interaction or Bohr effect, hence severely reducing their oxygen-carrying capacity ([277] , [278]).

GENOTYPE-PHENOTYPE CORRELATION

The recent progress in molecular biology and the wide availability of methods for DNA analysis have allowed for the definition of globin gene defects in thalassemia syndromes and the understanding of the mechanisms of globin gene regulation and expression and have partially elucidated the relationship between genotype and phenotype. This knowledge is helpful in clinical practice for planning the management of the patients and in genetic counseling for the prediction of phenotype from genotype in couples at risk.

The differentiation between thalassemia major and intermedia is essential for design of the appropriate treatment. The prediction of a mild phenotype may avoid unnecessary transfusions and their complications, whereas the diagnosis of thalassemia major allows an early start of the transfusion program, thus preventing hypersplenism and the red cell sensitization often associated with a delayed start of red cell administration ([279]).

As reported earlier in this chapter, in ß-thalassemia, the globin chain imbalance is the main determinant of clinical severity. Therefore, the presence of factors able to reduce the globin chain imbalance results in a milder form of thalassemia. These factors are the coinheritance of a-thalassemia or of genetic determinants that increase ?-chain production and the presence of silent or mild ß-thalassemia alleles associated with a high residual output of ß-globin.

Examples of these alleles are the silent -101 C?T and the mild IVS-1–6 T?C mutation in Mediterraneans and the -29 A?G in Africans. Deletion and nondeletion HPFH mutations, associated with a high HbF level in carriers, when in genetic compounds with severe ß-thalassemia alleles, result in mild thalassemia intermedia. The effect of a-thalassemia determinants in ameliorating the disease severity is less consistent, but the coinheritance of the deletion of two a-globin genes with homozygous ß $^+$-thalassemia, and sometimes even with ß ^{0}-thalassemia, produces the clinical picture of thalassemia intermedia ([36] , [280] , [281]). However, because each genetic combination is associated with a wide range of clinical outcomes, the definition of the a-globin genotype in each single patient may not have an absolute value in the prediction of the clinical picture.

The precise definition of the phenotype from the genotype is helpful also in genetic counseling because it may prevent the necessity for prenatal diagnosis in cases of expected very mild thalassemia intermedia in the fetus. Prenatal diagnosis in at-risk couples in whom the -101 C?T mutation is present should not be considered, and the same applies to the coinheritance of the triple a gene arrangement or of the HPFH mutations associated with high levels of HbF. The ameliorating effect that results from the presence of mild ß-thalassemia alleles is less constant. The mild ß-thalassemia allele IVS-1–6 T?C, common in Mediterraneans, shows remarkable phenotypic diversity in some populations, such as the Jewish population ([282]).

In conclusion, despite the progress made in molecular genetics, the accurate prediction of phenotype from the genotype is still not perfect, but a careful analysis of clinical, hematologic, genetic, and molecular data of patient and parents may allow a reasonable aptitude for treatment and for genetic counseling in many cases.

HbH disease has a wide phenotypic diversity. Studies that have correlated hematologic and clinical findings with a-globin genotypes indicate that HbH patients with nondeletion a-thalassemia defects have a more severe clinical expression ([283] , [284] , [285] and [286]).

As reported above, the wide range of phenotypic manifestations of thalassemia results from the heterogeneity of primary mutation and from the coinheritance of other globin gene–associated determinants that may ameliorate or worsen the disease severity ([287]). However, other known or unknown genetic determinants may modify the clinical expression of the thalassemia syndromes. Several secondary genetic modifiers have been identified in the recent years. The presence of (TA) $_7$ polymorphism in the promoter region of the uridine diphosphate–glucuronosyltransferase gene, which, in the homozygous state, is associated with the Gilbert syndrome, is a risk factor for the development of cholelithiasis in thalassemia major and intermedia patients and in patients with HbE/ß-thalassemia ([288] , [289]). Other candidate genes for modification of the thalassemia phenotype are the apolipoprotein E e4 allele, which seems to be a genetic risk factor for left ventricular failure in homozygous ß-thalassemia ([290]). Less consistent data have been reported for genes involved in iron metabolism (C282Y and H63D HFE gene mutations), probably because their effect on iron overload is hidden as a result of treatment (i.e., secondary iron overload from red cell transfusion and iron chelation) ([291] , [292] and [293]).

CLINICAL AND LABORATORY FEATURES

a-Thalassemia: Clinical Forms

Despite the large number of a-thalassemia alleles (approximately 50 associated with a $^+$-thalassemia and 40 associated with a ^{0}-thalassemia), only four hematologic and clinical conditions of increasing severity are recognized: silent carrier, a-thalassemia trait, HbH disease, and Hb Bart hydrops fetalis.

SILENT CARRIER This condition results from the presence of a single a-globin gene defect associated with the 3.7- or 4.2-kb deletion (-a/aa). This genotype is characterized in the newborn period by a very mild increased percentage (1 to 2%) of Hb Bart, a tetramer of four ?-globin chains (? $_4$). However, failure to demonstrate Hb Bart in cord blood does not exclude the silent carrier state ([294] , [295]). Among black Americans, the incidence of the silent carrier state determined by gene mapping is approximately 27%, yet Hb Bart is detected in only 12% of cord samples. Similar trends have been found in Mediterranean and Saudi Arabian populations ([83] , [295]). Adult individuals with three functional a genes may have a completely silent phenotype (normal RBC indices) or present with a moderate thalassemia-like hematologic picture (reduced MCV and MCH and very mild anemia) with normal HbA $_2$ and HbF. Analysis of globin chain synthesis in peripheral blood reticulocytes displays a reduced a to ß ratio in the range of 0.8 to 0.9. Infants with the -a $^{4.2}$ deletion, which removes the a $_2$ gene, have a more severe phenotype than children with the -a $^{3.7}$ deletion, which deletes most of the less productive a $_1$ gene, resulting in a hybrid gene consisting of the 5' part of the a $_2$ gene linked to the 3' part of the a $_1$ gene ([105] , [296]). However, with increasing age, the two genotypic forms become phenotypically indistinguishable, presumably due to up-regulation of a-globin production by the a $_1$ gene in subjects with the -a $^{4.2}$ deletion ([106] , [296] , [297]).

a-THALASSEMIA TRAIT This disorder is characterized in the newborn by higher levels of Hb Bart (5 to 6%) and in the adult by thalassemia-like red cell indices, normal HbA $_2$ and HbF, and a reduced a- to ß-globin chain synthesis ratio in the range of 0.7 to 0.8. Subjects with two residual functional a genes, either *in cis* on the same chromosome (–/aa or a ^{0}-thalassemia carriers) or *in trans* in opposite chromosomes (-a/-a, homozygous a $^+$-thalassemia), clearly show the a-thalassemia carrier state. Carriers of nondeletion defects have quite variable hematologic phenotypes ranging from the a-thalassemia trait to the silent carrier state. Double heterozygotes for -a/ and nondeletion a-thalassemia [-a/(aa) ^{T}] and homozygotes for nondeletion defects [(aa) ^{T}/(aa) ^{T}] have the typical phenotype of the a-thalassemia carrier state. However, homozygotes for some nondeletional forms of a-thalassemia may have a mild HbH disease ([298]). Homozygotes for Hb Constant Spring, the most common nondeletion defect in the Oriental population, have a clinical syndrome similar to that of HbH disease ([299]). The a-thalassemia carrier state should be differentiated from iron deficiency and from d- and ß-thalassemia interaction (see section Carrier Detection). This differentiation has important practical consequences.

HEMOGLOBIN H DISEASE HbH disease is common in Southeast Asia and relatively frequent in Mediterranean countries and parts of the Middle East, but it occurs

rarely in populations of African descent. This clinical condition results from the presence of only one functional a gene, usually as a consequence of the compound heterozygous state for a ^{0}-thalassemia/a $^{+}$-thalassemia (–/-a or -/a ^{T}a). As a consequence of the relative excess of ß-chains, individuals with HbH disease produce a variable amount of this abnormal hemoglobin, a tetramer of ß-globin chains (ß $_{4}$). HbH is unstable and precipitates inside red cells and, to some extent, in erythroid precursors, causing membrane damage and premature erythrocyte destruction. As reported above, both hemolysis and ineffective erythropoiesis contribute to anemia in HbH disease, but the predominant mechanism is hemolysis. HbH has a much higher oxygen affinity than HbA; this may worsen the severity of symptoms produced by anemia ([300]). In the neonatal period, subjects with the HbH disease genotype have consistently elevated Hb Bart (approximately 25%) that may still be detected in small amounts in some adults. The syndrome of HbH disease shows considerable variability in clinical and hematologic severity. The majority of patients have minor disability; few are severely affected, requiring regular blood transfusions; and rare cases have been described with the hydrops fetalis clinical picture ([36] , [285] , [301] , [302]). The most relevant features are microcytic and hypochromic hemolytic anemia, hepatosplenomegaly, jaundice, and moderate thalassemia-like skeletal modifications. The hemoglobin concentration is usually in the range of 7 to 10 g/dl, and the MCV varies with age (approximately 58 fl in childhood and approximately 64 fl in adulthood), whereas the MCH is approximately 18 pg irrespective of age. Reticulocytes range between 5 and 10%, and the a- to ß-globin chain synthesis ratio is markedly reduced, in the order of 0.20 to 0.60. Hemoglobin electrophoresis at alkaline pH shows a fast moving band (HbH) ranging from 1 to 40%. On occasion, HbH may not be detected due to low levels and loss because of instability in preparation of the hemolysate. The most sensitive method for detection of HbH consists of the incubation of peripheral blood cells for 1 to 2 hours at 37°C in the presence of supravital dyes (brilliant cresyl blue or methyl violet), which induce precipitation of the abnormal hemoglobin as inclusion bodies, easily recognizable by the microscope (Fig. 42.4). Determination of the a-globin genotype may be useful for prognosis of HbH disease, being that the nondeletion forms are more severe than the deletion forms.

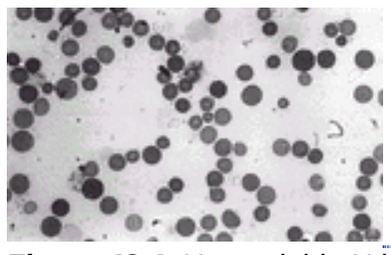

Figure 42.4. Hemoglobin H inclusion bodies. See Color Plate.

Anemia is accentuated during pregnancy and may worsen quite dramatically as a consequence of increased hemolysis with infections and after administration of oxidant drugs ([266] , [285]). A variable spleen enlargement is almost always present, whereas liver enlargement is less common. A mild phenotype of HbH disease may result from the homozygous state for nondeletional a-thalassemia, even if the phenotype in some cases is closer to that of the homozygous state for a $^{+}$-thalassemia, although the degree of anemia and hypochromia may be more severe ([303]). In particular, homozygotes for the elongated a-chain variant Hb Constant Spring are asymptomatic but show mild pallor and jaundice with liver and spleen enlargement in approximately 50% of the cases ([36] , [299] , [304]). The hemoglobin level ranges from 9 to 11 g/dl, and the MCV tends to be normal (88 ±6 fl), whereas the MCH is slightly reduced (26 ±3 pg). The peripheral blood contains HbA $_{2}$, HbA, Hb Constant Spring, and traces of Hb Bart rather than HbH ([36]). The severity of HbH disease shows a good correlation with the degree of a-chain deficiency. Thus, the more severe phenotypes are associated with interactions involving nondeletion a-thalassemia defects that affect the dominant a $_{2}$ gene, including (–/a $^{\text{Constant Spring}}$a), (–/a $^{\text{NcoI}}$a), and (–/a $^{\text{HphI}}$a) ([283] , [284] , [302]). Few patients with HbH disease resulting from the interaction of a $^{+}$-thalassemia (-a) with the deletion of the HS-40 regulatory region have been reported [for references see Higgs ([108])]. A very few cases of unusual severe HbH disease associated with hydrops fetalis due to coinheritance of a ^{0}- and a $^{+}$-thalassemia have been described ([305] , [306] and [307]). In four cases, the a $^{+}$-thalassemia alleles were mutations of the a $_{2}$ gene associated with hyperunstable a-globin variants. In the other patients, the molecular mechanism was less clear. In these families, prenatal diagnosis may be indicated. Subjects with HbH disease may develop complications including hypersplenism, leg ulcers, and gallstones. Hypersplenism has been reported in 10% of Thai patients but seems to be rare elsewhere ([308]). Iron overload is not common and has been reported only in older patients and as a result of repeated blood transfusions ([36] , [309]). In general, patients with HbH disease do not need any treatment. Some clinicians recommend folic acid supplementation as for other hemolytic anemias. Patients should be advised to avoid oxidant drugs because of the risk of hemolytic crisis. Occasional blood transfusions may be required when the hemoglobin level suddenly drops. Pregnant women need careful monitoring of hemoglobin levels. Splenectomy may be indicated in the presence of hypersplenism, but the potential complication of venous thrombosis, reported in some patients with HbH disease after splenectomy, should be considered ([310] , [311]).

HEMOGLOBIN BART HYDROPS FETALIS SYNDROME Hb Bart hydrops fetalis syndrome is the most severe a-thalassemia clinical condition, often associated with the absent function of all four a-globin genes (homozygous a ^{0}-thalassemia or -/–). A few cases of hydrops fetalis have been reported in infants with very low levels of a-chain synthesis, resulting from interaction of common a ^{0}-thalassemia determinants with uncharacterized nondeletion defects ([305] , [306] and [307]). Hb Bart hydrops fetalis syndrome is relatively common in Southeast Asia; however, in Mediterranean populations, it is relatively rare due to the low frequency of a ^{0}-thalassemia ([36] , [312] , [313]). Due to the extreme rarity of the -/aa genotype, this disorder rarely, if ever, affects infants of African descent. A fetus homozygous for a ^{0}-thalassemia produces mainly Hb Bart (? $_{4}$), which is functionally useless for oxygen transport, and survival to late pregnancy is due to the presence of small amounts of embryonic hemoglobins Portland 1 (? $_{2}$? $_{2}$) and Portland 2 (? $_{2}$ß $_{2}$). This condition is usually not compatible with postnatal life, and affected fetuses are either stillborn or die soon after birth ([314]). The clinical features of this syndrome are those of a very severe anemia (Hb level range, 3 to 8 g/dl), with marked hepatosplenomegaly, generalized edema, signs of cardiac failure, and extensive extramedullary erythropoiesis ([36] , [315]). Other congenital abnormalities, particularly of the skeletal, cardiovascular, and urogenital system, have been reported. Complications during pregnancy are common and include severe and mild preeclampsia, polyhydramnios or oligohydramnios, and antepartum hemorrhage. Postpartum complications include placenta retention, eclampsia, hemorrhage, anemia, and sepsis. At present, there is no effective treatment. Early treatment with intrauterine transfusions or *in utero* hematopoietic stem cell transplantation has been unsuccessfully attempted and also may not be justified in view of the unknown future risks for normal development ([276] , [316] , [317] , [318] and [319]). Given the severity of this syndrome and the potential for maternal obstetric complications, early termination of at-risk pregnancies is recommended.

UNUSUAL FORMS OF a-THALASSEMIA There are two unusual forms of a-thalassemia: acquired HbH disease associated with myelodysplasia and a-thalassemia associated with mental retardation syndrome.

a-Thalassemia/Myelodysplasia Syndromes Patients with myelodysplasia may rarely develop an unusual form of HbH disease characterized by the presence of classic HbH inclusion bodies in RBCs, often detectable levels of HbH (1 to 57%), and a severe microcytic and hypochromic anemia with anisopoikilocytosis ([320]). The a- to ß-globin mRNA ratio is reduced (0.06:0.50), as is the a- to ß-globin chain synthesis ratio (0.28) ([321]). The molecular basis of this form of a-thalassemia has not been defined. Structural analysis of the a-globin genes and of their flanking regions has revealed no abnormalities in such patients ([321] , [322]). It seems possible that the a genes are down-regulated by a mutation in trans-acting genes that normally controls a gene expression.

a-Thalassemia and Mental Retardation Syndromes There are two different syndromes in which a-thalassemia is associated with mental retardation ([108] , [323] , [324]). The first is characterized by relatively mild mental retardation and a variety of facial and skeletal abnormalities. These subjects have extended (1 to 2 megabases) deletions resulting from rearrangements of the short arm of chromosome 16. The deletions remove both a-globin genes and other known and unknown genes. Two common patterns of a-thalassemia have been described: One is characterized by parents with normal a-globin genotype (aa/aa) and an affected offspring with the phenotype of severe a-thalassemia trait (genotype -/aa); in the other, one parent has the phenotype of mild thalassemia trait, and the child has the phenotype of HbH disease. This condition is called a *-thalassemia mental retardation-16 syndrome*. The second group of patients has a complex phenotype characterized by severe mental retardation, quite uniform clinical features, similar facial appearance, genital abnormalities, other developmental abnormalities, and defective a-globin synthesis, resulting in a relatively mild form of HbH disease. No structural changes of the a cluster or 16p chromosome have been found in these patients, and the transmission is X-linked. Recently, it has been shown that this syndrome is associated with mutations in an X-encoded gene, the XH2 gene, a member of the DNA helicase family ([325] , [326] , [327] and [328]). Mutations in this gene down-regulate the expression of the a-globin genes and of other unidentified genes producing the complex phenotype. This condition is referred to as a *-thalassemia mental retardation-X syndrome*.

a-Thalassemia Associated with Structural Variants

A number of syndromes result from the interaction of a-thalassemia genes with those producing structurally abnormal hemoglobins. In some disorders, thalassemia genes that otherwise would have gone unnoticed are given clinical expression by the variant hemoglobin; in others, the relative amount of the variant hemoglobin is altered by the thalassemia gene. Features common to all of these syndromes are red cell hypochromia and microcytosis, in addition to the presence of a hemoglobin variant.

Some of the mutations causing a-chain structural variants appear to have occurred in chromosomes with only a single a-globin gene. Thus, HbQ/a ^{0}-thalassemia has a clinical phenotype similar to that of HbH disease ([329]). Affected subjects synthesize no HbA. This disorder has been described in individuals from Thailand, China, Iran, and India ([330] , [331] , [332] , [333] and [334]). The mutation responsible for HbG Philadelphia sometimes occurs on a chromosome with a single a-globin gene and other

times on a chromosome containing both a genes. This variant is encountered primarily in black individuals ([335]). In persons with a normal a-globin gene on the same chromosome containing the HbG mutation, HbG-Philadelphia/a ^{0}-thalassemia (a ^{G}a/–) is characterized clinically by a-thalassemia minor, whereas in individuals with no normal a gene *cis* to the a ^{G} gene (-a ^{G}/–), the doubly heterozygous state resembles HbH disease clinically. The variant hemoglobin constitutes approximately 40% of the total concentration of hemoglobin in the former situation and more than 90% in the latter ([36]). HbI/a-thalassemia has been reported in a black patient ([336]). That the gene for HbI is not linked *in cis* with an a-thalassemia gene is indicated by the presence of 30% HbA. The combination of a-thalassemia with ß-chain variants is associated with a decrease in the relative amount of the variant hemoglobin and a clinical picture similar to that of the heterozygous state for the structural variant ([36]). The lower than usual percentage of the variant hemoglobin is attributed to the preferential binding of a-chains with ßA-chains. The ß-chain variants noted in association with a-thalassemia include HbS, HbC, HbE, and HbJ Bangkok ([36]).

The interaction of a-thalassemia and HbS trait produces a trimodal distribution in the relative amount of HbS. Individuals with a full complement of a-globin genes have more than 35% HbS, compared with 28 to 35% in those with the (-a/aa) genotype, 25 to 30% in those with the (-a/-a) genotype, and no more than 20% in those with the rare (–/-a) genotype ([337] , [338]). Reductions in MCV and MCH are also observed. a-Thalassemia modifies some of the hematologic consequences of homozygous sickle cell anemia. Subjects with the (-a/-a) genotype have a higher hemoglobin concentration, lower red cell indices, fewer irreversibly sickled cells, a lower reticulocyte count, and lower serum bilirubin levels than subjects without concurrent a-thalassemia ([9] , [339] , [340]). The ameliorating effect of a-thalassemia is probably mediated by a decreased red cell concentration of HbS. a-Thalassemia fails, however, to temper significantly the clinical expression of sickle cell anemia.

ß-Thalassemia Major

The designations commonly used to describe the ß-thalassemia syndromes are based on clinical severity. The most severe form is defined ß-thalassemia major and is characterized by transfusion-dependent anemia. *Thalassemia intermedia* is the term used to designate a form of anemia that, independent of the genotype, does not require transfusion. *Thalassemia minor* indicates the heterozygous state that is usually asymptomatic. *Thalassemia minima* was used in the Italian literature to indicate a carrier in whom no hematologic or clinical symptoms were recognizable, but the term should probably be abandoned. Some authors use the term *thalassemia minima* to indicate the condition of silent carrier.

HISTORY Initial descriptions of thalassemia appeared as *anemia splenica infantum*, a term that undoubtedly included several conditions, often not well distinguished from one another. Syphilis was considered a possible cause, as were tuberculosis and leishmaniasis. Affected children appeared normal at birth and grew normally until the second half of the first year, when they were noticed to become pale and to develop an enormous abdomen, containing a spleen that could extend from a few centimeters below the left costal margin to the iliac crest and below. At this time in the disease course, the patients liked to be left alone and to lie down “in a monotonous morbid state” ([54]). Bone deformities, especially of the skull, soon appeared, giving the children a distinctive “mongolian” appearance ([341] , [342] and [343]). The disease was often present in more than one sibling, or, more frequently, other siblings had previously died of the same disease. The first systematic descriptions of what was to be identified as thalassemia major came from Drs. Cooley and Lee, who observed the disease in Italian and Greek children, and from Dr. Maccanti, a pediatrician from Ferrara, Italy, who also noted that the children often came from malarial areas near the Po river ([341]). Anemia, leukocytosis, and normoblastemia were present. Both groups unsuccessfully tried the entire armamentarium of therapies then available, as well as blood transfusions ([54] , [342]). The futility of the latter is not surprising, considering the very limited blood matching available at the time and the already enormous size of the spleen at presentation. Splenectomy and roentgen irradiation of the spleen were also performed without benefit. All children died shortly after presentation. At about the same time, Rietti, also from Ferrara, reported three adult patients, two of whom were father and son, who presented with “primitive hemolytic jaundice” associated with decreased osmotic fragility ([344]). Anemia, microcytosis, anisocytosis, and basophilic stippling were noted. The syndrome was probably a form of thalassemia intermedia, and for a long time, the eponymic title of *Rietti-Greppi-Micheli* was used. In 1932, in consideration of the Mediterranean origin of the patients affected by Cooley anemia, Whipple and Bradford proposed the name *thalassemia*, from the Greek word *thalassa*, meaning sea ([345]). Subsequently, the severe and the mild form of thalassemia were designated *thalassemia major* and *minor*, respectively ([346]). However, the lack of communication between the two sides of the Atlantic delayed further characterization of the disorders ([347] , [348]). In 1940, Wintrobe reported the presence of a familial hemopoietic disorder in adolescents and adults of Italian origin, while in Italy between 1943 and 1947, Silvestroni and Bianco defined the hematologic, clinical, and epidemiologic characteristics of thalassemia minor and its relationship with thalassemia major ([349]). A detailed report of contributions can be found in a recent, comprehensive book on thalassemia by Ida Bianco Silvestroni ([350]). The picture was further clarified by the identification of HbA $_{2}$ and its increase in the parents of patients affected by thalassemia major ([351] , [352]). The patients, on the other hand, were found to be completely devoid of HbA and to have, in addition to HbA $_{2}$, only an alkali-resistant variant usually found in the newborn—HbF ([353]). Erythrokinetic studies documented extensive ineffective erythropoiesis ([354]). Between 1956 and 1961, the chemical structure of hemoglobin was defined, and soon the complete sequences of globin chains were clarified ([355] , [356]). The introduction of techniques for assessment of globin chain synthesis confirmed the suggestion that thalassemia resulted from defective production of adult hemoglobin ([357]). The contributions of molecular biology continue to clarify aspects of this disease.

CLINICAL FEATURES The clinical picture of ß-thalassemia major includes features that are due to the disease itself, as well as others that represent the consequences of therapy and are, in a sense, iatrogenic.

Anemia Symptoms of the disease usually appear in the first year of life, as the synthesis of ?-chains is down-regulated. In an ethnically composite population of transfusion-dependent children diagnosed in the United Kingdom, the mean age at presentation was reported to be 6 months; in a study from Greece, the age was 13.1 months, ranging from 2 to 36 months ([358] , [359]). In Sardinia, the disease was recognized at approximately 8 months of age in patients with transfusion-dependent thalassemia but at 2 years of age in non–transfusion-dependent children ([28]). The age at diagnosis is influenced by the molecular defect and by the degree of suspicion of the treating physician. Pallor is usually the first sign, accompanied by splenomegaly of various severity, fever, and failure to thrive.

Bone Deformities Untransfused or poorly transfused patients develop typical bone abnormalities that are due to extremely increased erythropoiesis, with consequent expansion of the bone marrow to 15 to 30 times normal ([341] , [342] , [360]). The skull is large and deformed by frontal and posterior bossing with the diploë increased in thickness to several times normal. The outer and inner tables are thin, and the trabeculae are arranged in vertical striations, resulting in a “hair-on-end” appearance. A peculiar, stratified appearance of the skull has been reported (Fig. 42.5) ([361]). The zygomatic bones are prominent, the base of the nose appears to be depressed, and pneumatization of the sinuses is delayed. Overgrowth of the maxilla produces severe malocclusion, with a rodentlike appearance ([362]). Metatarsal and metacarpal bones are the first to expand as a consequence of increased erythropoiesis (Fig. 42.6). The measurement of the size of the metacarpal bones has been proposed as an indicator of time for initiating transfusion therapy ([363]). The ribs are broad, often with a “rib-within-rib” appearance, and the vertebral bodies are square. The trabeculation of the medullary space gives the bones a mosaic pattern. Shortening of long bones is frequent as a result of premature fusion of the humeral and femoral epiphyseal lines ([364] , [365]). Extramedullary erythropoiesis gives rise to masses that protrude from bones where red marrow persists ([366]). Overgrowth from the vertebral bodies has been reported to cause cord compression and paraparesis ([365]). Ear impairment due to extramedullary marrow growing in the middle ear and progressive visual loss caused by compressive optic neuropathy have been reported ([367] , [368]). This kind of picture is more often present in patients with thalassemia intermedia, in whom transfusions are avoided at the price of intense autologous marrow hyperactivity. Improvement in the radiologic appearance of bone in patients who have had the benefit of transfusion therapy from early age is striking. However, bone lesions of a different nature may be observed as a consequence of excessive deferoxamine (DFO) therapy.

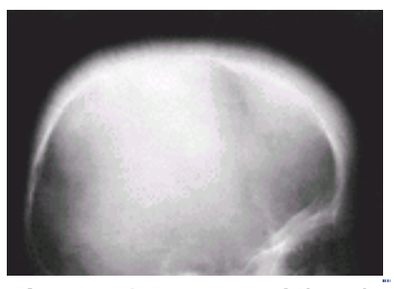

Figure 42.5. X-ray of the skull. In the frontal area, the bone has a lamellated structure, parallel to the inner table of the diploe. In the parietal area, erythroid hyperplasia has perforated the outer table, producing a characteristic “hair-on-end” appearance. (Courtesy of Dr. C. Orzincolo.)

Osteoporosis Reduced bone mineral density and consequent susceptibility to fractures have been observed in thalassemia patients and, in recent years, have been the subject of intense research. Mineral density is usually investigated with dual-energy x-ray absorptiometry at the spinal (L1 to L4) and femoral neck level. *Osteoporosis* is defined as a decrease in bone mineral density greater than or equal to 2.5 standard deviations (SD) below the young adult mean value, whereas a decrease between -1.0 and -2.5 SD is defined as *osteopenia* ([369]). Osteoporosis in thalassemia has been found to affect 51% of the patients, with an additional 45% affected by osteopenia. Male sex, lack of spontaneous puberty, and diabetes seem to represent significant risk factors, whereas transfusion history, chelation, and erythropoietic activity do not ([370]). Analysis of genetic polymorphisms for the collagen type I gene, vitamin D, estrogen, and calcitonin receptors has given conflicting results ([371] , [372]). Bone formation, as evidenced by the levels of serum alkaline phosphatase and osteocalcin, does not appear to be impaired, whereas an increase in bone resorption, evaluated by means of the measurement of the urinary *N*-terminal peptides of collagen type I, has been demonstrated ([373]). Fractures, often secondary to mild or moderate trauma, are more frequent than in the general population ([374] , [375]). Bone pain of varying severity is a common complaint among adult patients, and it has been attributed to expanded bone marrow with consequent pressure on the cortical bone ([376]). Magnetic resonance imaging (MRI) in these cases shows reappearance of hypercellular areas in bones previously replaced by fatty marrow. Reduced and irregular mineralization of the bone has been found using microradiography and x-ray in thalassemic patients with and without clinically evident bone abnormalities ([377]). Therapy should include sex hormone replacement therapy, regular exercise, and a diet rich in calcium and vitamin D. Treatment with bisphosphonates has been tried with encouraging preliminary results ([378] , [379]). Parathormone is another promising alternative ([380]).

Cholelithiasis Gallstones have been reported in 4 to 23% of patients with thalassemia ([381] , [382]). The large variability may be related to differences in transfusion practices and consequent variations in ineffective erythropoiesis and hemolysis, to the time of splenectomy, and, probably more importantly, to the associated presence of the $(TA)_7$ promoter mutation of the uridine diphosphate–glucuronosyltransferase gene, which is associated with Gilbert syndrome ([288]). Ultrasonography of the gallbladder should be checked regularly. If stones are present at the time of splenectomy, cholecystectomy should be performed at the same time. Prophylactic cholecystectomy has been proposed, but it is probably unnecessary for well-transfused patients, especially in view of data suggesting an increased risk of intestinal cancer after cholecystectomy ([383]). It could be considered for patients with persistently elevated indirect bilirubin or for patients who are known to be homozygous for the Gilbert mutation.

Thrombotic Complications In recent years, there have been numerous reports of thromboembolic complications in thalassemia. In a multicenter study, the frequency of thromboembolic events was found to be 4% in patients with thalassemia major and 10% in patients with thalassemia intermedia ([384]). Other groups have reported similar prevalences ([385]). A chronic hypercoagulable state has been observed even in childhood ([256]). It has been demonstrated that procoagulant phospholipids are exposed on the surface of the red cells and that platelets and the hemostatic system are activated in thalassemia major and intermedia. In addition, vascular endothelial cell injury has been proposed as a possible pathogenetic mechanism ([257] , [386]). Concomitant prothrombotic conditions are frequently present in thalassemia patients after the first decade of life: insulin-dependent diabetes, estrogen therapy, atrial fibrillation, and postsplenectomy thrombocytosis, among others. A thorough review of the literature on the mechanisms of the hypercoagulable state present in thalassemia has been recently published ([252]). Prophylactic measures have been proposed ([385]).

Pseudoxanthoma Elasticum The development of clinical and histopathologic manifestations of a diffuse elastic tissue defect, resembling inherited pseudoxanthoma elasticum, has been encountered with a notable frequency in patients with ß-thalassemia. This clinical syndrome, consisting of skin, ocular, and vascular manifestations, has a variable severity and is age dependent, with an onset usually after the second decade of life ([387]). The defect is believed to be acquired, but its progression seems to be similar to that of the inherited form ([388]).

Secondary Gout Hyperuricemia is not unusual in thalassemia patients, but gouty arthritis has been rarely reported ([389]).

LABORATORY FINDINGS AND DIAGNOSIS Laboratory data at presentation are characterized by HbF levels ranging from 10 to 100% and HbA_2 levels that may be normal or increased to 5 to 7%, with HbA constituting the remainder. HbF is heterogeneously distributed among red cells. The reticulocyte count is low, usually below 1%. MCV is typically 60 to 70 fl, and MCH is 12 to 18 pg/cell. In the peripheral blood smear, a great variation in size and shape of the erythrocytes is always evident. Together with large and pale target cells, microcytes, tear drop cells, and nucleated red cells are present (Fig. 42.7). The hemoglobin composition varies according to genotype. Homozygotes for $ß^0$-thalassemia mutations have HbF and HbA_2 but no HbA, whereas homozygotes for $ß^+$-thalassemia mutations and $ß^0/ß^+$ genetic compounds have HbA, HbA_2, and a variable, but always significantly elevated, amount of HbF (10 to 90%). HbA_2 in homozygous ß-thalassemia may be normal or increased and so of no diagnostic value. Hemoglobin separation is accomplished by a number of different methods, including electrophoresis at alkaline or acidic pH, isoelectric focusing, and high-performance liquid chromatography ([36]). In transfused patients, diagnosis can be made by globin chain synthesis analysis from peripheral blood reticulocytes, which shows a severe a/non-a imbalance (usually >2), or by ß-globin gene analysis to identify the DNA mutations ([36] , [390] , [391] , [392] and [393]).

THERAPY

Blood Transfusion For many years after the description of thalassemia major as a clinical entity, therapy was limited to blood transfusion, generally reserved for those with incapacitating symptoms. By today's standards, transfusion therapy was inadequate, failing to arrest progressive hepatosplenomegaly and skeletal changes. In the 1960s, the superiority of regular and methodically repeated transfusions was recognized, first by Orsini in France, and later by Wolman in Philadelphia, and Piomelli in New York, who started a program of chronic transfusion directed at maintaining a baseline hemoglobin level sufficient to eliminate hypoxia ([394] , [395] , [396] and [397]). It was calculated that the amount of iron administered to maintain an Hb of 9.5 g/dl was only 50% greater than that resulting from maintaining a baseline hemoglobin of 6 g/dl. Further, the additional iron intake could be counterbalanced in part by reduction of intestinal iron absorption. This regimen, designed to maintain the hemoglobin above 9.5 to 10 g/dl, was termed *hypertransfusion*. Complete bone marrow suppression, however, is seldom obtained at these hemoglobin levels; therefore, some bone remodeling and expansion of the blood volume persist. To completely correct the effects of anemia, Propper launched what was called a “supertransfusion” regimen, in which the pretransfusion packed cell volume was maintained above 35% ([398]). This approach was based on the hypothesis that the amount of blood needed to maintain a higher baseline would be no greater because of a reduction in blood volume. Experience has shown, however, that patients maintained at a higher baseline hemoglobin level require a larger amount of blood and, therefore, accumulate more iron ([399] , [400] and [401]). In a study of patients kept at a pretransfusion hemoglobin level between 9 and 10 g/dl, the erythroid marrow activity, evaluated through the measurement of serum transferrin receptor, did not exceed two to three times normal levels ([401]). Therefore, as a consequence of these more recent studies, the majority of centers choose to transfuse at an Hb level of 9 to 10 g/dl ([402]). To reduce the volume transfused and to avoid the administration of foreign proteins, packed RBCs must be transfused. In addition, to avoid transfusion reactions resulting from the development of antibodies to white blood cells, the blood product should be rendered leukocyte-free. In the United States, this goal was achieved using frozen blood. This was expensive, however, and required 15% more blood than when using standard packed RBCs ([403]). At present, leukocyte depletion is achieved by filtering donor blood. Transfusion reactions were found to complicate 1% of the transfusional events in 17% of the patients reported by the Cooley Care Programme ([404]). Alloimmunization against red cells varies between 4 and 23%, the lower

percentages being found in patients who received blood matched for the ABO, Rhesus, and Kell systems from their first transfusion ([279]). Extended red cell antigen typing, including at least the Rh antigens, Duffy, Kidd, and Kell, is recommended before the patient is started on a transfusion regimen. Transfusion of young red cells (neocytes) obtained by centrifugation has been proposed in the attempt to reduce the total blood requirement, but the results obtained were not sufficient to justify increased cost and the exposure to a larger number of donors ([398] , [405] , [406]). In general, the amount transfused should not exceed 15 to 20 ml/kg/day, at a maximum rate of 5 ml/kg/hour, to avoid rapid increase of blood volume. Rarely, if ever, do more than two units need to be transfused at a time. In the case of patients with cardiac problems, smaller volumes at a slower rate (no more than 2 ml/kg/hour) should be administered. When cardiac failure or severe anemia is present, the administration of diuretics before transfusion is advisable. The recommended interval between transfusions is usually 2 to 3 weeks, rarely longer.

Complications of Transfusion Although blood transfusions are lifesavers for thalassemia patients, who no longer die of anemia, they are also responsible for the main afflictions now complicating the course of the disease: chronic viral infections and hemosiderosis.

INFECTIONS The risk of transfusion-transmitted viral infection is well known. The hepatotropic viruses include hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis G virus. The prevalence of infection with these viruses in multitransfused patients is very different in different parts of the world, and it is directly related to their frequency in that population. In 1992, serologic evidence of previous HBV infection was found in 19% of French and in 34% of Italian patients but in 56 to 66% of Indian patients ([407] , [408] and [409]). The risk of chronic hepatitis is approximately 5% ([410]). A DNA recombinant vaccine for HBV is available and should be administered to all patients who have not yet been infected. HCV infection is widely diffused among thalassemia patients who were transfused before 1989, when systematic screening of blood units was begun ([411]). Recent data from the Cooley Care Cooperative Group have reported the presence of HCV antibodies in 85% of multitransfused Italian patients, whereas 23% of patients tested positive in 1990 in the United Kingdom, 34% in France, and 21% in India ([407] , [412] , [413]). In the United States, one-third of the transfusion-dependent thalassemia patients were found to have antibodies against HCV. Of these, one-third were RNA positive ([414]). In Italy between 1994 and 1999, the residual risk of transfusion-transmitted infections associated with window period donations has been calculated to be 2.5/million donations for human immunodeficiency virus (HIV), 15.8/million donations for HBV, and 4.5/million for HCV ([415]). HCV hepatitis becomes chronic in 70 to 80% of infected individuals ([416]). HCV-RNA may be detected in patients' serum, and liver histology shows signs of chronic inflammation, fibrosis, and even cirrhosis. The risk of liver fibrosis is highest in patients with HCV infection and elevated iron load ([417]). It has been calculated that 20% of HCV chronically infected patients develop cirrhosis within 10 years and that their risk of developing hepatocellular carcinoma is increased ([418] , [419]). Transaminase levels typically fluctuate between normal and slightly elevated values, with a good correlation being demonstrated between transaminase levels and viral load measured by quantitative polymerase chain reaction (PCR) ([410]). Treatment with interferon-a is effective in inducing sustained viral clearance in 25 to 30% of thalassemia patients ([28] , [420]). Young age, a histologic picture of chronic active hepatitis, and low liver iron content appear to correlate with a better prognosis ([28] , [421]). Patients who do not respond to interferon treatment or relapse after cessation of therapy may benefit from ribavirin in combination with interferon ([422] , [423]). The recently identified member of the Flaviviridae hepatitis G virus, common among multitransfused patients, seems to carry a low risk of chronic liver disease even in long-term follow-up ([424] , [425]). Cytomegalovirus is notoriously widely diffused in most populations and can be transmitted by blood transfusion. A European collaborative study revealed a positive cytomegalovirus immunoglobulin G test in two-thirds of the thalassemia patients examined ([407]). The same study found the disquieting presence of human T-cell leukemia virus type-1 antibodies in a few patients from Sicily. HIV infection was acquired almost exclusively before the systematic screening of blood donation. In 1987, the prevalence of HIV in thalassemia patients from 13 European or Mediterranean countries was found to be 1.56%. Two years later, no HIV seroconversion was observed in the same areas when a total of 2972 patients affected by thalassemia who had received 96,518 blood units were examined ([426]). Malaria can be transmitted by transfusions in endemic areas ([427]).

HEMOSIDEROSIS In patients who undergo transfusion therapy for several years, the accumulation of iron, if untreated, causes considerable morbidity and, ultimately, leads to death. Because each unit of blood contains approximately 200 mg of iron, a patient who receives 25 to 30 units of blood/year, in the absence of chelation, accumulates more than 70 g of iron by the third decade of life ([428]). In addition to the iron administered through blood transfusions, a hyperactive bone marrow favors increased intestinal iron absorption that contributes, although marginally, to the total body load ([429]). Excessive intracellular iron may damage the cell by several mechanisms. In patients who have fully saturated transferrin, a significant fraction of the total iron in plasma circulates in the form of low-molecular-weight complexes not bound to transferrin ([430] , [431]). Although the exact mechanism of tissue damage remains unclear, iron-induced peroxidative injury to the phospholipids of lysosomes and mitochondria, produced by free hydroxyl radicals, is probably the most important pathogenetic factor ([432]). During chelation, non–transferrin bound iron (NTBI) decreases to normal levels; because desferrioxamine causes a dose-related inhibition of iron-dependent lipid peroxidation, a simple method for measuring NTBI, based on the use of a probe fluorescin DFO, termed *deferoxamine-chelatable iron*, has been devised ([433] , [434] and [435]). Ascorbic acid at suboptimal concentration is a prooxidant and enhances the catalytic effect of iron in free radical formation. Excessive iron stores lead to depletion of substances that defend against free radical attack (i.e., ascorbic acid, which is oxidized to oxalate, and vitamin E) ([436] , [437] and [438]). This, in turn, causes sequestration of the iron in the reticuloendothelial system, somehow protecting tissues from siderosis ([439]). In fact, the amount of iron deposited in parenchymal tissues seems to be more dangerous than iron deposited in the reticuloendothelial system. The presence of the genetic hemochromatosis mutations does not seem to influence the degree of iron overload and its consequences in regularly transfused and chelated patients with thalassemia major ([291]).

Assessment of Iron Stores The iron status of multitransfused patients can be inferred by several methods. The use of two or more parameters usually provides a good approximation of the total amount of iron accumulated. Serum iron is always elevated. Transferrin saturation correlates reasonably well with serum ferritin, and before the discovery of the HFE gene mutation, it was used to identify patients with genetic hemochromatosis ([440] , [441]). After only a few years of transfusion, however, transferrin is usually completely saturated, even in well-chelated patients. Serum ferritin has, in general, been found to correlate well with iron stores, as measured by phlebotomy and liver iron, either measured directly by liver biopsy or by magnetic susceptometry ([442] , [443] , [444] and [445]). In one study, however, the 95% prediction intervals in hepatic iron concentrations for a given plasma ferritin were so broad as to make plasma ferritin a poor predictor of body iron burden ([446]). Several variables can interfere with the reliability of ferritin as a marker of iron overload. Being an acute phase reactant, ferritin is increased in chronic disease, malignancy, and inflammatory disorders. A ferritin concentration of 4000 µg/L is considered the maximum level of physiologic synthesis, whereas higher values would represent the release of intracellular ferritin from damaged cells ([447]). Ascorbic acid deficiency can lead to decreased synthesis and release of ferritin. This can, therefore, lead to ferritin levels that are only mildly elevated, even in the presence of massive iron stores ([439] , [448]). Conversely, patients with active liver disease may have high serum ferritin that does not mirror the body iron load. Lack of correlation between serum ferritin and directly measured liver iron in transfusion-dependent thalassemia patients with chronic hepatitis has been demonstrated ([449]). Despite all this, serial measurements of serum ferritin remain a reliable means, as well as the easiest one, to evaluate iron overload and efficacy of chelation therapy. The measurement of iron excretion over 24 hours after an intramuscular injection of 500 mg of desferrioxamine was, in the past, largely used to establish the time to start chelation therapy or to evaluate the iron burden. Unfortunately, the correlation between urinary excretion and body iron is not very good, as many factors, including the dose of chelator administered and vitamin C status, influence iron excretion ([450]). None of these methods provide an estimate of iron accumulation in the various organs, as its distribution is usually not homogeneous. At present, the most accurate way of estimating the iron burden is by direct measurement of iron concentration in the liver. Needle biopsy specimens of 1 mg dry weight are adequate ([451]). The measurement is performed by atomic absorption spectrometry on ashed or lyophylized samples and correlates well with the total amount of blood transfused and with the extent of hepatic fibrosis ([452]). It has been demonstrated through post–bone marrow transplantation (BMT) phlebotomies that total body iron stores (in mg/kg of body weight) is equivalent to 10.6 times the hepatic iron concentration (in mg/g of liver, dry weight). In the absence of cirrhosis, the correlation is linear up to a body iron burden of 250 mg/kg ([417]). Noninvasive alternative methods include computed tomography, nuclear MRI, and magnetic susceptometry ([453] , [454]). MRI, which has the advantage of avoiding radiation exposure to the patient, has been used by several authors to demonstrate the presence of iron in the pituitary gland, the pancreas, the liver, and even the heart ([455] , [456] and [457]). A good correlation between the amount of liver iron evaluated with MRI and liver iron measured in biopsy samples has been found, although the presence of fibrosis makes estimates of hepatic iron, derived from MRI, not completely reliable ([458] , [459]). Liver to muscle signal intensity ratio on spin-echo T1-weighted images was recently found to be of value for estimating liver iron content ([460]). A recent study has demonstrated the value of a new so-called T2-star technique in the evaluation of myocardial and liver iron ([461]). Hopefully, in the not-too-distant future, standardization of the methods will provide a precious tool for obtaining reproducible results. Magnetic susceptometry is based on the magnetic response of ferritin and hemosiderin iron in the liver ([442] , [462] , [463] and [464]). The equipment necessary for this measurement [superconducting *q*uantum *i*nterference *d*evice (SQUID)] is so far available only in two sites in the United States and one in Italy.

Clinical Manifestations of Iron Overload

HEART Although the cardiac complications of thalassemia are multifactorial, the role of iron in the development of cardiac dysfunction is of paramount importance. In the absence of chelation, subclinical dysfunction has its onset in the second decade of life, or when approximately 20 g of iron have been accumulated. Subsequently, cardiomegaly and left ventricular deterioration progress to congestive heart failure. Arrhythmias are a cause of sudden death ([465]). The classic picture of end-stage iron-induced cardiomyopathy is a combination of left ventricular diastolic dysfunction, pulmonary hypertension, and right ventricular dilatation ([466] , [467]). Myocardial iron toxicity is attributed to free radical damage, and the role of NTBI has been demonstrated both *in vitro* and in the experimental animal ([468]). When iron is taken up by the heart fibers, protective antioxidant enzymes decrease, free radical production increases, and cardiac dysfunction ensues. In a series of patients followed prospectively, the frequency of cardiac failure was significantly lower in patients chelated from early childhood. In a study of 97 patients born before 1976 who were treated with regular transfusions and chelation, the prognosis for survival without cardiac disease was best for those in whom fewer than 33% of the serum ferritin values exceeded 2500 ng/ml ([469] , [470]). Nevertheless, heart disease, including cardiac failure, arrhythmias, myocarditis, pericarditis, and myocardial infarction, is the leading cause of death in thalassemia major, accounting for 71% of the deaths ([471]). The measurement of cardiac iron is not easily obtainable. Endomyocardial

biopsies, performed in small series of patients with primary or secondary iron overload, revealed an uneven iron distribution in different biopsy fragments from the same patient and a poor correlation between endomyocardial iron grade and liver iron ([472], [473] and [474]). In other studies of endomyocardial biopsies, good correlation was found between iron loading and the degree of cardiac fibrosis and between cardiac fibrosis and electrophysiologic disturbances ([472], [475]). A poor correlation between myocardial and liver iron was documented with MRI ([461]). Traditional diagnostic tools (i.e., electrocardiography, 24-hour tracings, echocardiography, nuclear studies), although routinely used, are not predictive of subsequent cardiac dysfunction ([466]). The prognosis for patients with heart failure has always been poor. Recently, however, the 5-year survival rate after the onset of heart failure was reported to be 48% ([476]). In the prechelation era, acute episodes of sterile pericarditis were seen in approximately one-half of the patients with massive iron overload but are now quite uncommon ([477]). Impaired cardiac function due to iron deposition may be compounded by coexistent anemia ([478]). Viral infections and pulmonary hypertension have also been suggested as possible concomitant causes ([467], [479], [480]). Management of cardiac complications in patients with thalassemia major has been described in detail ([481]). In asymptomatic thalassemia patients with normal myocardial mass, diastolic dysfunction has been found to be an early event, even while the systolic function is only mild impaired. There are no universally accepted treatments for diastolic abnormalities ([466]). The effect of the angiotensin-converting enzyme inhibitor enalapril was recently reported in asymptomatic or minimally symptomatic patients with left ventricular dysfunction resulting from ß-thalassemia major. Echocardiographically, significant improvement in systolic and diastolic function was demonstrated ([482]). Whether this will have an impact on long-term prognosis and survival remains to be demonstrated. The treatment of arrhythmias is difficult, and the risk of proarrhythmic effects of antiarrhythmic drugs is high. Once electrolyte imbalances have been corrected and the metabolic homeostasis has been monitored, the help of a cardiac electrophysiologist is often necessary. Heart transplantation has been attempted with variable results ([483], [484], [485] and [486]).

LIVER Studies in dogs have shown the liver to be the site of earliest iron deposition. Parenchymal siderosis is present from the very early stages of iron loading and progresses to fibrosis and cirrhosis ([487]). In transfusion-dependent thalassemia, fibrosis of the liver correlates directly with age, number of units transfused, and liver iron concentration ([488]). The degree of liver fibrosis is best evaluated by the Ishak score ([489]). In a study of patients with genetic hemochromatosis, mean hepatic iron concentration in the absence of liver fibrosis was 13 ±6 mg/g dry weight, whereas it was 18 ±9 mg/g when fibrosis was present ([490]). Accordingly, in a group of patients followed after BMT for an average of 100 months, no progression of fibrosis was noted in HCV-negative patients when the iron concentration in the liver was below 16 mg/kg. If HCV infection was present, no threshold for iron could be established (Fig. 42.8 and Fig. 42.9) ([417]). Iron depletion by venesection after BMT has produced regression of cirrhosis in iron overloaded patients, some of whom were HCV positive ([491]). Chelation therapy has been found to be effective in improving liver fibrosis in a proportion of transfusion-dependent patients (Fig. 42.10) ([492], [493]). Viral infections contribute to liver damage, and HCV is believed to account for more than 90% of cases of transfusion-associated hepatitis in most Western countries. Iron influences the natural history of hepatitis C and the response of chronic hepatitis C to treatment. The mechanisms responsible for the effects of iron are not clear, but emerging data suggest that the cellular location of iron within the liver lobule and the subsequent effects on immune function are likely to be critical determinants for these effects ([494]). A larger iron load is present in patients with chronic hepatitis, probably as a consequence of an inflammation-dependent iron deposition ([449]). Cirrhosis of the liver, attributed to the combination of transfusional and alimentary iron, is observed at necropsy in almost 50% of the patients ([495], [496]).

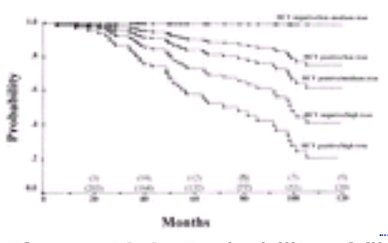

Figure 42.8. Probability of fibrosis progression-free survival according to iron concentration and hepatitis C virus (HCV) status. (Reprinted from Angelucci E, Muretto P, Nicolucci A, et al. Effects of iron overload and hepatitis C virus positivity in determining progression of liver fibrosis in thalassemia following bone marrow transplantation. Blood 2002;100:19. The American Society of Hematology, with permission.)

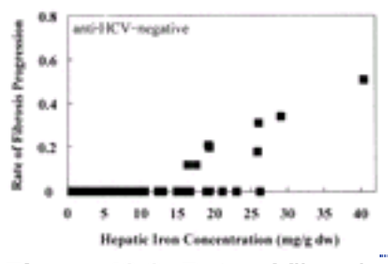

Figure 42.9. Rate of fibrosis progression in hepatitis C virus (HCV)–negative patients according to hepatic iron concentration. Rate of fibrosis progression was determined by dividing the difference between the final fibrosis score and initial fibrosis score by years of follow-up. In the absence of HCV infection, no patient with hepatic iron content lower than 16 mg/g dry weight showed fibrosis progression. (Reprinted from Angelucci E, Muretto P, Nicolucci A, et al. Effects of iron overload and hepatitis C virus positivity in determining progression of liver fibrosis in thalassemia following bone marrow transplantation. Blood 2002;100:19. The American Society of Hematology, with permission.)

Reversibility of cirrhosis in patients cured of thalassemia by bone marrow transplantation. Ann Intern Med 2002;136:669, with permission.)

Liver biopsy represents a precious tool to assess both histology and liver iron concentration. However, it has been suggested, on the basis of autoptic measurements recently confirmed by the MRI technique, that the distribution of iron within the liver is not uniform ([497], [498]). However, these results were based on autoptic measurements that could be influenced by the presence of large amounts of heme iron. Hepatocellular carcinoma is the primary cause of death in patients with genetic hemochromatosis in whom cirrhosis is present at diagnosis, and it frequently complicates the course of cirrhosis due to chronic HCV and HBV hepatitis ([419], [499], [500] and [501]). Despite the numerous risk factors present in multitransfused patients, only one case so far has been reported in thalassemia, possibly because death occurs before the development of the tumor ([502]).

ENDOCRINE GLANDS Iron deposition can damage also the endocrine glands, either directly or through the hypothalamic-pituitary axis. *PUBERTAL DELAY.* Lack of sexual maturation is very common, affecting, in 1997, 55% of patients older than 15 years of age ([471]). The data are very similar to those collected 15 years earlier, when 67% of males and 38% of females between 12 and 18 years of age had no signs of pubertal maturation, suggesting little, if any, improvement in pubertal development in adolescents treated with transfusion and chelation from an earlier age ([503]). Similar percentages have been published elsewhere ([504]). Conversely, Bronspiegel-Weintrob found in a younger group of female patients that beginning chelation before 10 years of age helped to attain normal sexual maturation ([505]). Secondary amenorrhea has been reported in 10 to 20% of the girls who had developed normally ([503], [506]). A proportion of sexually mature men go on to develop impotence. Hypogonadism is hypogonadotropic in origin and is probably due to the free radical oxidative damage caused by iron deposition in the anterior pituitary, in the hypothalamus, or both. Damage to the gonads can sometimes be demonstrated ([507]). Replacement therapy consists of conjugated estrogens and progesterone for females and testosterone enanthate for males ([359]). Hormone replacement, in addition to inducing secondary sexual characteristics, enhances height velocity, contributes to the prevention of osteoporosis, and has enormous psychological benefits ([378]). Fertility is normal in female patients with normal menstrual function, or it can be induced with gonadotropin or follicle-stimulating hormone in those without menses ([508], [509]). Oligospermia and astheno-spermia have been reported in more than 50% of men with thalassemia ([510]). Gonadotropin treatment, using human chorionic gonadotropin plus human follicle-stimulating hormone or gonadotropin-releasing hormone, is given to stimulate spermatogenesis and induce fertility ([511]). *PREGNANCY.* Hundreds of pregnancies have now taken place, and severe obstetric complications have been quite rare ([508], [512], [513] and [514]). During pregnancy, anemia should be avoided to protect the fetus from hypoxia (maintaining hemoglobin >10 g/dl), and desferrioxamine or deferiprone should be discontinued because of concerns regarding teratogenicity ([515], [516]). However, more than 40 cases have been reported in which desferrioxamine was given in various periods of gestation without evidence of a teratogenic effect ([517]). Preexisting cardiomyopathy, expanded plasma volume, increase of the cardiac output, increasing iron deposits in the absence of chelation, and reduced glucose tolerance all pose potential threats to maternal health in the course of pregnancy. Death from cardiac failure has been reported ([508], [518]). Delivery has been performed by elective cesarean section in approximately one-half of the cases reported. Genetic counseling is mandatory before conception. *GROWTH RETARDATION.* Stunted growth is

common in thalassemia and is not correlated with transfusion regimens or iron chelation ([519]). It has been attributed to the disease itself, to delayed puberty, to iron overload, and to desferrioxamine toxicity ([520]). Sitting height is also reduced as a consequence of spinal growth abnormalities. Eight percent of boys 7 to 8 years of age who had been adequately treated were found to be below the third percentile for height. The percentage grew to 12% of boys and 15% of girls 20 to 29 years of age, one-half of whom had spontaneously completed puberty ([521]). The prevalence of short stature was 29% when other endocrinopathies were present, marking an improvement in comparison to data reported in 1982, when 52% of males and 39% of females older than 14 years of age were below the third percentile for height ([503]). Growth hormone deficiency can be detected in 20% of patients, and circulating insulinlike growth factor-1 and insulinlike growth factor–binding protein-3 are low in patients with short stature but increase after the insulinlike growth factor generation test, suggesting intact insulinlike growth factor-1 generation by the liver ([521] , [522] and [523]). Treatment with recombinant human growth hormone improves height velocity, but patients remain below their target height ([521] , [524]). In one report, long-acting androgens administered for 1 year were found to significantly improve growth ([521] , [525]). *HYPOTHYROIDISM.* Hypothyroidism is not uncommon, having been reported in 5.6% to 17.0% of patients ([379] , [526]). The majority of patients have subclinical or mild forms, whereas approximately one-third have overt disease. No difference in the mean level of serum ferritin concentration was found between patients with or without hypothyroidism ([471]). *HYPOPARATHYROIDISM.* Hypoparathyroidism is reported to affect 3% to 7% of patients, and it is attributed to iron deposition in the parathyroids ([28] , [527]). Males seem to be affected more often than females. Extreme hypocalcemia is a frequent late event. Early detection requires periodic estimation of calcium homeostasis. Serum calcium levels below 8 mg/dl (2 mmol/L), phosphorus above 7 mg/dl (2.6 mmol/L), and low 1,25-dihydroxyvitamin D are suggestive of hypoparathyroidism. Symptoms are usually mild and include paresthesias, muscle pain, and, when severe, tetany and even convulsions ([359]). A decrease of parathyroid hormone levels in the absence of symptoms has been reported in more than 12% of the patients examined ([528]). *ADRENAL DYSFUNCTION.* No adrenal insufficiency has been reported ([526] , [529]). *DIABETES MELLITUS.* In 1992, 4.2% of 2535 transfusion-dependent patients were affected by diabetes ([526]). However, the reported prevalence of insulin-dependent diabetes and of impaired glucose tolerance is variable, and it has changed in recent years, probably as a result of chelation therapy ([530] , [531]). Pathologically, iron deposition resulting in excess collagen deposition in the pancreas and defective microcirculation can be demonstrated ([532]). Age at initiation of transfusion therapy, liver iron load measured by the SQUID, poor compliance with chelation, and male sex were found to be significant factors in the development of diabetes, whereas serum ferritin level was not ([531] , [533] , [534]). It has been suggested that liver damage could contribute to the impairment of islet cell function ([535]). Diabetes developing in thalassemic patients differs from the usual form in that there is no association with HLA haplotypes, and islet cell antibodies are negative ([531]). Ketoacidosis is said to be uncommon, and retinopathy develops in one-fourth of patients, a frequency that is approximately one-half that of age- and sex-matched diabetic controls without thalassemia ([359] , [536]). Insulin resistance and increased insulin secretion are thought to antedate the development of overt diabetes ([533] , [537]). Impaired glucose tolerance is often responsive to oral hypoglycemic drugs. Intensive chelation may reverse glucose intolerance and postpone the onset of insulin-dependent diabetes ([538]). Insulin therapy needs to be closely monitored, as glucose control is often difficult.

EXOCRINE GLANDS Reduced serum levels of chymotrypsin have been described in patients with thalassemia and have been attributed to hemosiderosis of the pancreatic acinar tissue ([539]). Low values of lipase and trypsin were also found in a small group of patients in whom ultrasonography showed increased echogenicity of the pancreas ([540]). Sicca syndrome, xerostomia, and xerophthalmia, also attributed to iron overload, have been reported in a patient with genetic hemochromatosis and in one with thalassemia ([541] , [542]). However, it is now known that HCV can also cause sicca syndrome; therefore, the relation of these symptoms to iron overload is not certain.

EYE It has been known for a long time that retinal pigmentary changes may complicate hemochromatosis. Accordingly, retinal hyperpigmentation detected in a group of thalassemia patients was attributed to iron overload. Also reported were abnormal electroretinographic potentials, similar to those observed in experimental siderosis bulbi ([543] , [544]). Their severity was directly correlated with iron overload. Most eye problems in patients with thalassemia major, however, are a consequence of desferrioxamine toxicity and are discussed later.

PULMONARY INSUFFICIENCY Pulmonary problems, mainly due to ventilatory restrictive impairment, have been reported in patients with thalassemia major, and iron deposition in the respiratory system has been proposed as the likely cause. In a recent study, however, no correlation was found between restrictive impairment and iron deposition in the respiratory system evaluated by MRI ([545]). Pulmonary hypertension seems to be more frequent after splenectomy and in patients with thalassemia intermedia.

Chelation To prevent hemosiderosis, iron administered as blood must be chelated and excreted. Iron balance is obtained when the daily excretion is sufficient to eliminate the iron introduced by transfusion. This amount approximates, in most patients, 0.5 mg/kg. The two main sources of chelatable iron are (a) the intracellular labile pool, derived from lysosomal catabolism of ferritin and from transferrin and NTBI, and (b) the iron derived from red cell catabolism in macrophages ([546] , [547] and [548]). The first contributes chiefly to the hepatocellular load and is excreted as fecal iron, whereas the second is the major source of urinary iron. Ferric iron has six coordination sites, which need to be chelated completely if generation of harmful free radicals is to be prevented. Two chelators are presently in use: DFO, which, being hexadentate, forms stable iron-chelate complexes using a single molecule, and deferiprone, which, being bidentate, requires three molecules to coordinate all six sites and tends to dissociate from iron at low concentrations.

Deferoxamine B DFO, a trihydroxamic acid produced by *Streptomyces pilosus*, was first used for the treatment of transfusional hemosiderosis in 1962 ([549]). Because of its large molecular weight, it is not efficiently absorbed from the gut, and it cannot, therefore, be administered orally. Initially, the drug was given by intramuscular injection, but, due to the drug's short half-life and the finite chelatable iron pool available at any given time, negative iron balance was not obtained ([550]). In a fundamental study performed in the United Kingdom, it was found that patients treated with DFO had, after 7 years, lower ferritin levels and lower liver iron concentration than those not chelated ([550] , [551] and [552]). However, it was only with the administration of prolonged parenteral infusions, intravenous at first and then subcutaneous, that negative iron balance was achieved ([549] , [553] , [554] , [555] and [556]). Today, DFO is most frequently administered subcutaneously by means of a portable, battery-operated pump, starting at a dose ranging between 20 and 60 mg/kg/day over 8 to 12 hours at night. The dose can then be adjusted according to ferritin levels and urinary iron excretion. Decreasing growth velocity should be an indication to lower the dose of the chelator. Pharmacokinetic studies have shown that a plateau is reached within 4 and 8 hours after starting the infusion and that plasma levels fall rapidly thereafter ([557]). NTBI is efficiently bound by DFO, so that the effects of free radical formation and lipid peroxidation are prevented ([558]). The efficacy of DFO in reducing the iron burden and in improving organ function and survival has been repeatedly demonstrated ([469] , [471] , [530] , [559] , [560]). To avoid severe effects on growth and bone metabolism, DFO should not be started before a significant amount of chelatable iron is present. It is usually advised that chelation be started when ferritin levels reach 1000 ng/ml, or after 10 to 15 units of blood have been given ([561] , [562]). These recommendations have been corroborated by a study in which serial liver biopsies were performed after inception of transfusion therapy ([563]). The mean liver iron concentration after 1.3 years was found to be 8.5 mg/g, slightly above the limit of 7.0 mg/g that is considered compatible with a normal life expectancy in patients with idiopathic hemochromatosis ([564]). The adequacy of therapy is monitored by serial measurements of serum ferritin and by direct quantification of liver iron when necessary. The main limitation of the drug is the requirement for parenteral administration. Compliance with DFO, therefore, is often erratic, especially during the teenage years. In patients who have accumulated a large iron burden and who show signs of cardiac involvement, continuous intravenous infusion through implantable venous access ports should be considered ([565] , [566]). Improvement of cardiac performance can usually be demonstrated even before the total iron load is significantly reduced, probably as a result of binding of toxic NTBI ([566]). As shown in heart cell culture studies, DFO removes iron directly from iron-loaded heart cells, inhibits lipid peroxidation, and reverses the abnormalities in cellular contractility and rhythmicity induced by iron ([567] , [568]). The dose of DFO should never exceed 100 mg/kg/day. This dose, to be administered only in the presence of symptoms of severe iron overload and in the attempt to improve cardiac function, should be infused slowly, preferably over 24 hours. At these dosages, an acute, often lethal, pulmonary infiltration syndrome can occur ([569] , [570]). The principal catheter-related complications are infection and thromboembolism, reported in one study to occur at a rate of 1.15 and 0.48/1000 catheter days, respectively ([566]). The administration of DFO by twice daily subcutaneous bolus injection has been demonstrated to induce the same urinary iron excretion as the slow, pump-mediated infusion and to be well accepted, especially by older patients ([571] , [572] and [573]).

DEFEROXAMINE B TOXICITY The most common side effects of DFO are represented by local reactions with redness and soreness at the site of infusion. Inflammation, necrosis, and even ulceration can be caused by the intradermal insertion of the needle. If the reaction persists after appropriate needle placement in the subcutaneous tissue, hydrocortisone (5 to 10 mg) can be added in the syringe. The direct and rapid injection of DFO in a vessel can cause brief episodes of nausea, hypotension, and collapse. Systemic allergic reactions and, occasionally, anaphylaxis require desensitization or change of chelator ([574] , [575]). Retinal and optic nerve disturbances, manifesting as loss of central vision, night blindness, and amaurosis, were reported in patients treated with high-dose DFO ([576] , [577]). These disturbances are reversible on discontinuation of therapy, and resumption of treatment is well tolerated. High-frequency sensorineural hearing loss is observed in a large percentage of patients during intensive DFO therapy. The defect is correlated with the total monthly dose of DFO received, and it is more frequent in younger patients with low serum ferritin levels ([578]). Auditory toxicity can be often prevented by keeping a therapeutic index devised for that purpose [mean daily dose of DFO (mg/kg) divided by the serum ferritin (µg/L)] below 0.025 ([579]). The hearing defect should be detected early, performing an audiogram at least yearly, or whenever symptoms, even subtle, are reported. Significant improvement has been observed after reduction of the DFO dose in patients with a mild defect, whereas only little benefit has been gained by those severely affected ([580]). Stunted growth and ricketslike bone abnormalities have been described when treatment was initiated early, at a dosage higher than 40 mg/kg, or when the iron burden was not severe ([520] , [561] , [581] , [582]). Sitting height is more often affected than standing height, as a consequence of vertebral growth retardation or flatness of vertebral bodies (Fig. 42.11). Cupping of the ulnar, radial, and tibial metaphyses, which are poorly ossified and with irregular sclerotic margins, can be demonstrated radiographically and, when more advanced, can produce severe deformity of knees and elbows (Fig. 42.12). Reduction of the DFO dose is sufficient to reestablish normal growth velocity, but orthopedic surgery has sometimes been required for correction of advanced varus and valgus deformities of the knees ([582] , [583]). Pulmonary toxicity has been observed in patients treated intensively with “rescue” doses of DFO (10 to 20 mg

kg/hour) ([569], [570]). Renal failure has also been reported in this context ([584], [585]). Infection with *Yersinia enterocolitica* is a well-known complication of hemosiderosis. The presence of DFO in plasma and tissues further fosters the growth of the organism that uses the drug as a siderophore ([586]). Fever and gastrointestinal symptoms are an indication to temporarily discontinue DFO. Antibiotic therapy is indicated, as *Yersinia* infection can be severe and even life-threatening ([587]).

Figure 42.12. A: Desferrioxamine toxicity. The growth plate of the distal ulna is wide, and the metaphysis exhibits a cuplike deformity with sclerotic and irregular borders. **B:** A similar picture is present in the metaphyses of the femur and fibula. (Courtesy of Dr. C. Orzincolo.)

Deferiprone Deferiprone (L1) is a member of the family of the hydroxypyridin-4-one chelators that have been intensively studied during the past two decades to find an orally active alternative to DFO for the treatment of transfusional iron overload. Because each molecule provides two coordination sites, three molecules of deferiprone are required to fully bind iron. The iron-chelate complex that is formed has a lower stability than that of DFO. Deferiprone is easily absorbed from the gut and a peak concentration is reached in the plasma 45 minutes after ingestion ([588], [589]). The sources of chelatable iron are both parenchymal and reticuloendothelial cells. In addition, iron is mobilized from transferrin, lactoferrin, and hemosiderin. Most iron is excreted in urine, whereas fecal excretion ranges between 5 and 20%. A dose of 75 mg/kg/day has been shown to induce urinary iron excretion equivalent to that achieved with 40 mg/kg/day of DFO ([466]). Greater excretion can be obtained with a dose of 100 mg/kg/day, but it is believed that more toxic effects occur at this dose ([590]). A metaanalytic review of nine clinical trials, including 129 iron-overloaded patients, concluded that deferiprone is effective in achieving negative iron balance and reducing the body iron burden in hemosiderotic patients ([591]). A decrease in NTBI was demonstrated in a small series of patients in whom the decrease of ferritin had not been statistically significant ([592]). No effect of ascorbate has been found on iron excretion in response to deferiprone. Deferiprone has been licensed for clinical use in India and Europe. The recommended dosage is 75 mg/kg/day in three divided doses given 1 hour before meals. In a randomized trial comparing the efficacy of desferrioxamine and deferiprone, no difference between the two groups in reduction of liver and heart iron content was found after 1 year by magnetic resonance ([593]). Recent studies have explored the effectiveness of combining deferiprone and DFO therapy ([594]). Results have usually demonstrated an additive effect of combination therapy, suggesting that the two drugs access different pools of iron ([594]). Deferiprone, being able to pass through membranes, could “shuttle” tissue iron to DFO in the bloodstream and then be reused ([595]). If this is the case, combination therapy could provide better therapeutic strategies for iron-overloaded patients.

DEFERIPRONE TOXICITY The main adverse effects observed with deferiprone are agranulocytosis, reported in 0.5 to 2.0% of patients exposed to the drug, and neutropenia, reported in 4% ([596], [597]). The dose that these patients were receiving ranged from 50 to 105 mg/kg, and the interval from inception of therapy to appearance of the complication ranged between 6 weeks and 21 months ([590], [598], [599] and [600]). Rechallenge with the drug has invariably produced relapse of the agranulocytosis and is contraindicated ([590]). In a prospective multicenter study, the incidence of agranulocytosis was found to be 0.6/100 patient-years, whereas that of neutropenia was 5.4/100 patient-years. Neutropenia occurred more frequently in nonsplenectomized patients ([601]). No deaths were reported as a consequence of low neutrophil counts. Other unwanted effects include nausea or anorexia, zinc deficiency, and fluctuation in liver enzymes, more commonly found in patients with hepatitis ([602]). Arthropathy, particularly of the knees, occurs in 6 to 39% of patients, and it appears to be more frequent in patients who have more severe iron overload ([596], [601], [603]). It has been hypothesized that the formation of 1:1 or 1:2 deferiprone-iron complexes can induce inflammatory changes, possibly mediated by free radicals. Progressive liver fibrosis was reported in 5 out of 14 patients treated with deferiprone for over 2 years ([604]). More recently, however, a large multicenter study, involving 56 patients over 3.5 years, whose liver biopsies were evaluated in blinded fashion, did not confirm an effect of deferiprone on hepatic fibrosis ([605]).

Vitamin Supplementation Hemosiderotic patients are often found to be ascorbate deficient, and a case of frank scurvy has been reported ([436], [439], [448]). DFO-induced iron excretion is enhanced by ascorbic acid supplementation due to the expansion of the chelatable iron pool to which DFO has access ([554]). However, ascorbate, a natural reducing agent, accelerates iron-induced lipid peroxidation in biologic systems at low concentrations, and it has been shown to alter the function of rat myocardial cells in culture ([437], [568]). In addition, echocardiographic observations suggest it may potentiate cardiotoxicity ([606]). Vitamin C supplementation is therefore recommended only in patients not affected by myocardiopathy, who have unsatisfactory iron excretion and demonstrated ascorbate deficiency. When necessary, 50 mg/day of ascorbate in children younger than 10 years of age and 100 mg/day thereafter should be sufficient. Vitamin C should be given when DFO infusion is already under way. a-Tocopherol, a lipid-soluble antioxidant, is able to interrupt the membrane lipid peroxidation process ([568]). Supplementation with vitamin E is therefore often suggested, but data demonstrating its efficacy are lacking. Folic acid deficiency was reported in early studies and, more recently, from Thailand ([607], [608]). Folate supplementation is advised for patients with a hyperactive bone marrow, such as those with thalassemia intermedia, and during pregnancy. Zinc has been found to be low in patients with thalassemia major, even though these patients have a normal zinc-binding capacity. Zinc-binding capacity is generally increased in nutritional zinc deficiency ([609], [610]). Desferrioxamine and deferiprone could, at least in some cases, be responsible for this finding.

Splenectomy Splenectomy together with blood transfusions for many years represented the mainstay of therapy in thalassemia. It was often performed shortly after diagnosis because the spleen soon reached an enormous size and caused profound neutropenia and thrombocytopenia. The introduction of regular transfusions has significantly delayed the appearance of splenomegaly, so that splenectomy is now postponed until the second decade of life or later. Rational criteria for splenectomy were first proposed by Modell ([611]). She suggested that surgery should be performed when the transfusion requirement exceeds 50% above that of the average of the splenectomized population. In practice, this occurs when more than 200 to 250 ml/kg/year of pure red cells are required to maintain a pretransfusional Hb of 9.0 to 9.5 g/dl. Splenectomy reduces the transfusion requirement to approximately 150 ml/kg/year, with some variation from patient to patient, and the effect has been demonstrated to be long lasting ([612]). The use of technetium-99 sulfur colloid or technetium-99 RBC uptake to assess the need for splenectomy has not proven to be of great practical use. Laparoscopic splenectomy, when available, avoids the disfiguring scar created by laparotomy, reduces the hospital stay, and does not have a higher financial cost ([613]). Risks associated with splenectomy include increased susceptibility to infections with encapsulated bacteria and an increase in thromboembolic events. In addition, increased frequency of pulmonary hypertension has recently been reported ([311], [614], [615], [616], [617], [618] and [619]). The role of splenectomy in worsening iron overload is controversial. The problem of postsplenectomy sepsis with encapsulated organisms has been recognized for many years ([611], [620], [621] and [622]). These infections are often abrupt in onset and rapidly fatal. Overwhelming postsplenectomy sepsis results from the removal of a major site of antibody production (in particular, the splenic marginal zone) and, possibly, the long-term decrease of T-cell subsets of functional relevance for primary immune responses ([623], [624]). The most frequently responsible bacteria are *Streptococcus pneumoniae, Haemophilus influenzae*, and *Neisseria meningitidis*, but cases have been reported in which *Escherichia coli* and *Staphylococcus aureus* were the causative agents. Malaria and babesiosis can be particularly severe after splenectomy ([625]). *Capnocytophaga canimorsus*, a gram-negative rod present as a commensal organism in the saliva of cats and dogs, has also caused severe infections in asplenic and splenectomized individuals ([626]). The risk of severe infections is greatest in younger children and in the first years after splenectomy, but it never disappears. It has been suggested that thalassemia patients are exposed to a higher risk than other nonimmunodeficient patients splenectomized for different causes ([627]). From a review of the literature, Singer found that 25% of patients undergoing splenectomy for thalassemia developed postsplenectomy sepsis ([628]). Later, however, in Thai patients, the frequency was found to be 4%, with a mortality of 89% ([629]). Guidelines for the prevention of postsplenectomy infections were published by the British Committee for Standards in Haematology in 1996 and include antibiotic prophylaxis, with penicillin, amoxicillin, or erythromycin, for the first 2 years after surgery and for children until 16 years of age ([630]). The Committee also recommended early antibiotic treatment for fever and malaise, as well as antipneumococcal immunization to be given 2 weeks before the procedure, or as soon as possible after it. A second dose should be repeated after 5 years. The recently developed 7-valent conjugated antipneumococcal vaccine should be administered in young children. Immunization against *H. influenzae* is also recommended ([631]). The antimeningococcal vaccine presently in use, giving only short-lasting protection, should be administered only during epidemics in small

communities. At present, however, a protein-conjugate vaccine producing longer immunologic memory is available for the prevention of infection due to meningococcus type C ([632]). The efficacy of antipneumococcal immunization in conjunction with early antibiotic therapy has been demonstrated in children, but infection by serotypes not included in the vaccine or poorly immunogenic has been reported ([633] , [634]). Compliance with penicillin prophylaxis can be a problem and requires continuous reinforcement ([635] , [636]). The risk, already increased, of thrombotic events can be exacerbated by splenectomy ([252] , [384]). Thrombocytosis, due at least in part to the presence in the circulation of platelets previously marginated in the spleen, develops in 75% of splenectomized patients; in 15%, it reaches 1 million/mm ^{3} or more, peaking between 8 days and 4 months after surgery ([637] , [638]). The value of low-dose aspirin for patients with high platelet counts has not been demonstrated. A correlation between splenectomy and pulmonary hypertension has been suggested on the basis of a high prevalence of asplenia among patients with unexplained pulmonary hypertension and has been confirmed by case series reports ([616] , [618] , [619]). Recurrent lung thromboembolism could be responsible for the phenomenon. In an attempt to avoid these complications of splenectomy, several alternative approaches have been proposed with mixed results. Partial splenectomy and partial dearterialization of the spleen have been reported to have an immediate beneficial effect but are of short duration ([639]). Partial embolization of the spleen has been successfully performed with long-lasting results, but it has sometimes led to complications ([428] , [640] , [641]). It has the advantage of not requiring general anesthesia and not leaving a scar. The theory that a residual portion of spleen protects the patient from infections and thrombotic events is tempting but still unproven. It has been hypothesized that the spleen could represent a reservoir for transfused iron and that splenectomy would, therefore, expose the patient to the risk of more massive siderosis of the liver ([642]). However, the iron content of the spleen, at splenectomy, is low, amounting to no more than one-fifth to one-tenth of the liver iron content ([643]). In addition, no difference has been observed in extent of liver fibrosis between splenectomized and nonsplenectomized patients ([644]).

PROGNOSIS WITH CONVENTIONAL THERAPY Thalassemia used to be a rapidly fatal disease, but prognosis is constantly improving. Between 1949 and 1957, only 9% of patients in Ferrara reached 6 years of age, and at the end of the 1970s, one-half of the Italian patients died before 12 years of age ([350]). Today, at least in developed countries, most patients reach the age of employment and marriage ([560]). A review of patients followed between 1960 and 1976 at Cornell Medical Center reported a median survival of 17.1 years for patients who were conventionally transfused and not chelated, whereas those who were hypertransfused and well chelated had a median survival of 31.0 years ([645]). A large cooperative study involving 1146 uniformly treated patients showed a probability of survival at age 20 of 89% for patients born in the years 1970 to 1974 and 96% for those born between 1975 and 1979. Eighty-two percent of the patients of the cohort 1970 to 1974 were alive at 25 years of age ([471]). The importance of good chelation in improving life expectancy has been repeatedly demonstrated (Fig. 42.13) ([470] , [645]).

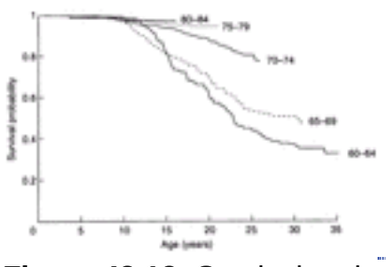

Figure 42.13. Survival probability as of January 1996 of thalassemic patients born in Italy between 1960 and 1984. (Prepared by C. Borgna-Pignatti. Reprinted from Weatherall DJ, Clegg JB. The thalassemia syndromes, 4th ed. London: Blackwell Science Ltd, 2002:639, with permission.)

Complications are still frequent and, together with the burden of therapy, compromise quality of life. Studies of the effects of the illness on psychosocial adjustment report contradictory results. According to a survey from Greece, 42% of the patients examined had psychiatric problems, whereas other authors demonstrate that thalassemic adults have normal psychologic development and better social adjustment and self-esteem than their normal peers ([646] , [647] and [648]). Cultural and economic variables probably influence the acceptance of the chronic problems of thalassemia ([649]). Psychologic support seems appropriate as an adjunct in treating thalassemia, a chronic disease with a considerable role for self-management. However, no randomized controlled trials assessing the effectiveness of specific psychologic interventions have so far been performed ([650]).

BONE MARROW TRANSPLANTATION BMT is an accepted approach to the treatment of thalassemia major and, at this time, the only curative one. The first transplant for thalassemia was performed in Seattle in 1981 ([651]). The patient is now a completely normal young man. Nearly 2000 patients have since been transplanted worldwide. The majority had thalassemia major; a few had thalassemia intermedia, HbE/ß-thalassemia, or HbH disease. Most donors have been chosen among HLA-identical siblings. The conditioning regimen has, in general, included busulfan, 14 mg/kg, and cyclophosphamide, 200 mg/kg. Prophylaxis against graft-versus-host disease (GVHD) has more often been performed with cyclosporine A alone or in combination with methotrexate. High-risk patients were reported to benefit from a conditioning regimen containing a lower dose of cyclophosphamide, with or without the addition of antilymphocyte globulin ([652]). The largest experience has been reported by Lucarelli and his group, who suggest that patients be stratified by risk group based on the presence or absence of portal fibrosis, hepatomegaly, and regular chelation ([653] , [654] , [655] and [656]). The lowest risk group is comprised of patients who have been regularly chelated and who have not had liver fibrosis or hepatomegaly. Patients poorly chelated, with hepatomegaly and portal fibrosis, are believed to have the highest risk, whereas the intermediate risk group includes patients with one or two risk factors. According to this classification, age in itself does not influence prognosis. The reported event-free survival probability is 90% in class 1 patients, 81% in class 2, and only 54% in class 3. Similar data (overall survival, 88%; disease-free survival, 80%) were reported in a review of 80 patients transplanted in Europe, Asia, and South America ([657]). From the United States, the reported probability of survival was 80%, with disease-free survival of 57% and rejection in 24% of the patients ([658]). Several reports of transplants for thalassemia are being published from countries where the disease is common and conventional therapy is not always available ([659] , [660] and [661]). The results reported are as good as those from Western countries, and the procedure has proven to be cost effective. When partially mismatched siblings or parents, phenotypically identical parents, and other relatives were used as marrow donors, sustained engraftment was obtained in only 45% of patients, with a probability of graft failure or rejection of 55% ([662]). For patients who do not have a genotypically identical donor, selection of matched unrelated donors, using modern molecular typing techniques, has been shown to improve prognosis (Fig. 42.14) ([663]). Patients of all ages have been grafted, including several adults ([652] , [664]). The Pesaro group's experience with 86 patients from 17 to 32 years of age includes probabilities of survival, event-free survival, and rejection of 65%, 63%, and 3%, respectively ([652]). Sixteen percent developed chronic GVHD. Rejection can appear in different patterns ([665]). The patients can have no take, develop aplasia, or, more often, have autologous reconstitution of the thalassemic marrow after engraftment. Approximately two-thirds of rejections were observed within the first 100 days after transplant. Second transplants have been performed in those who have rejected their graft. Approximately one-half of the patients survive the second transplant, and one-third reach sustained engraftment. Transient engraftment and autologous reconstitution have been reported in a substantial number of patients from Thailand ([666]). In general, these patients had multiple risk factors, including inadequate transfusion therapy, little or no chelation, hepatosplenomegaly, very active erythropoiesis, and iron-induced organ damage. The most common transplant-related cause of death is infection, especially in patients who remain aplastic after graft rejection. A few splenectomized patients have died after transplant of overwhelming sepsis.

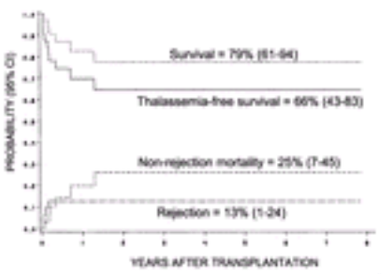

Figure 42.14. Survival of patients from all risk classes treated with bone marrow transplantation from an unrelated identical donor. (Reprinted from La Nasa G, Giardini C, Argiolu F, et al. Unrelated donor bone marrow transplantation for thalassemia: the effect of extended haplotypes. Blood 2002;99:4354. The American Society of Hematology, with permission.)

Persistent mixed chimerism has been observed in 11% of patients ([667] , [668]). Despite the presence of large numbers of residual host cells, these patients no longer required RBC transfusions, producing levels of HbA ranging from 8.3 to 14.7 g/dl. The mechanisms underlying this apparent state of immunologic tolerance or education are not clear. However, these observations may be useful in defining optimal strategies for gene therapy, *in utero* hematopoietic stem cell transplantation, and adoption of less toxic conditioning regimens. The feasibility of “minitransplants” is being explored.

Side Effects of Bone Marrow Transplantation

Chronic Graft-Versus-Host Disease Between 6% and 24% of the patients surviving with a functioning graft for at least 150 days developed moderate or severe chronic GVHD ([658] , [669]). This complication, a multiorgan disorder with features of an autoimmune disorder, is of particular concern for a procedure that is offered for quality of life considerations rather than as therapy for a disorder with impending death.

Growth, Development, and Fertility Short stature is a frequent complication of transplantation. There appears to be a good correlation between age at the time of transplant and final adult height. In one study, patients who were transplanted before 7 years of age reached their genetic target for height, whereas those who were older did not ([670]). This is in contrast with most studies of children transplanted for hematologic malignancies that have demonstrated that the younger the patient

was at the time of BMT, the greater was the loss in height. Probably, the deleterious effects on growth of iron overload and desferrioxamine toxicity are greater than the effects of pretransplant conditioning ([671]). Clinical and hormonal evidence of gonadal dysfunction is frequent in patients transplanted during childhood or in the prepubertal period, and normal puberty occurs in only 40% of them. There is no correlation between pubertal maturation and age at BMT or serum ferritin levels ([672]). Sterility from pretransplant conditioning is also a potential complication. Nevertheless, successful conception and the delivery of healthy infants have been observed in several individuals after BMT in childhood ([673]) (Angelucci E, Borgna-Pignatti C, *personal communication*, November 6, 2002).

Malignancies A few solid tumors and several cases of early and late non-Hodgkin lymphoma have been observed in patients transplanted for thalassemia ([674] , [675] , [676] and [677]).

Iron Depletion After BMT, ferritin increases, reaching a peak around the third month after the procedure, probably as a consequence of bone marrow aplasia and a shift of iron to the storage compartment. Thereafter, ferritin usually returns to pretransplant levels. In the absence of chelation therapy, liver iron concentration remains high, and hepatic fibrosis, often present before transplantation, can progress to cirrhosis. Therefore, phlebotomy is indicated for patients with high ferritin levels, high liver iron concentration, or both. In one study, bimonthly venesections starting at least 18 months after grafting succeeded in decreasing the median ferritin level from 2587 to 417 µg/L and median liver iron concentration from 20.8 to 4.2 mg/g of dry tissue. Also, serum transaminases decreased significantly ([678]). Monthly erythrocytaphereses are equally effective. This technique has the advantage of saving plasma and mononucleated cells, but it is more costly and time consuming ([679]). Cirrhosis of the liver has been shown to be reversible after iron depletion by phlebotomy ([491]). Desferrioxamine can be used to reduce the iron burden in patients who are anemic after transplantation or who have difficult venous access ([680]). Chelation should not be started until well after transplantation, because desferrioxamine has been reported to interfere with grafting.

Cord Blood Transplantation Related cord blood transplantation for hemoglobinopathies appears to have a probability of success comparable to that offered by BMT and, in addition to avoiding general anesthesia for the donor, is associated with lower risks of transplant-related mortality, chronic GVHD, and transmission of viral infections. The main disadvantage is represented by the longer time necessary to reach safe platelet and neutrophil counts. The first successful transplantation of cord blood stem cells in a patient with thalassemia was reported in 1995 from Thailand ([681]). Subsequently, numerous cord blood transplants have been performed ([666] , [682]). In some cases, combined cord blood and bone marrow cells have been infused ([683]). A recent review of 44 cord blood transplants performed in ten countries between 1994 and 2001, in patients having a median age of 5 years (range, 1 to 20 years), reported a survival rate of 100% and an event-free survival of 79%. Forty-one donors were HLA-identical siblings, whereas three were mismatched for one antigen. The risk of chronic GVHD was 6% ([684]).

In Utero Transplantation Early in gestation, the fetus is immunoincompetent and, therefore, unable to reject allogeneic cells. Several attempts at *in utero* stem cell transplantation have been made ([685]). None of those performed for thalassemia has, so far, been successful. In conclusion, BMT offers a chance for cure when an HLA-compatible donor is available. The availability of a donor is related to the size of the sibship, the frequency of certain haplotypes, and the degree of inbreeding in a particular population. In Italy, approximately 30% of patients have an HLA-identical donor ([686]). It is now clear that patients in good general condition and who are well chelated have the highest disease-free survival after BMT ([687]). However, these patients have a good prognosis also with conventional therapy. For older patients in whom hemosiderosis has already produced organ damage, both treatment modalities carry a high risk of death. The high initial cost of bone marrow or cord blood transplantation is easily compensated by the high prices of conventional treatment. In countries where the blood supply is not safe and chelation is not readily available, stem cell transplantation may represent the only opportunity for survival.

HEMOGLOBIN F REACTIVATION For patients with homozygous ß-thalassemia, an increased ?-globin chain production would result in a more balanced a- to non–a-globin ratio and an amelioration of disease severity. ?-Chains neutralize the harmful excess of a-chains and allow a better survival of erythroid precursors in the bone marrow and of the red cells in the peripheral blood. Effective procedures to enhance red cell production could reduce or even eliminate the need for transfusions and would represent a major advance in the treatment of homozygous ß-thalassemia. To this aim, trials with chemotherapeutic agents known to increase ?-chain production *in vitro* and in animals have been conducted in thalassemia patients. 5-Azacytidine is a cytidine analog that, when incorporated into newly synthesized DNA, leads to extensive demethylation and to reactivation of ?-globin synthesis ([688]). 5-Azacytidine was the first drug shown to enhance ?-globin synthesis in patients with ß-thalassemia ([689]). Small clinical trials have been conducted with 5-azacytidine with some apparent clinical benefit, but its use is limited because of concern about its carcinogenic risk ([690] , [691]). An analog of 5-azacytidine, 5-aza-2'-deoxycytidine, which may have fewer adverse effects than the parent drug, is being evaluated in patients with sickle cell anemia ([692]). At present, these drugs are considered investigational. The effect of 5-azacytidine on HbF synthesis may be mediated also by its cytotoxic properties. Like other antimetabolites, 5-azacytidine preferentially kills dividing cells, permitting the emergence of primitive erythroid progenitors more highly committed to HbF synthesis ([693]). Therefore, other cell cycle–specific agents, including hydroxyurea (HU), cytarabine, and vinblastine, have been used with the aim of increasing HbF production ([694] , [695] and [696]). The largest experience has been reported with HU, which has been given with many different regimens and doses, alone or in combination with other drugs including erythropoietin. Only in some patients with thalassemia intermedia has there been a modest effect on hemoglobin concentration and HbF ([697] , [698] and [699]). HU has been used effectively in thalassemia intermedia also to reduce the size of extramedullary erythropoietic masses when these compress vital organs or tissues ([700] , [701] and [702]). In conclusion, the efficacy of HU to increase the hemoglobin level in thalassemia is still controversial, and more controlled and expanded trials are warranted. Butyrate and its analogs have been used to induce HbF production in hemoglobinopathies with variable responses ([703] , [704]). Therefore, their use remains experimental and cannot be recommended outside of clinical trials. Several studies have been performed with recombinant human erythropoietin, mainly on patients with ß-thalassemia intermedia, but the results have been inconsistent ([705] , [706] and [707]). Combinations of HbF inducers, erythropoietin, and other cytokines have been proposed to increase HbF production in an additive or synergistic manner, but these combinations also must be considered investigational ([708]).

GENE THERAPY The b-thalassemias were among the first diseases to be considered for gene therapy. In principle, the tissue to be corrected (i.e., the bone marrow) can be removed, treated, and reinfused into the patient. Moreover, the gene and the molecular lesions responsible for the disease are well known. Therefore, genetically based strategies, aimed at inserting a normal copy of the human ß-globin gene along with key regulatory sequences into autologous hematopoietic stem cells, represent a feasible alternative to BMT for curative intent. However, this approach has been impeded over the last decade by challenging obstacles, including the isolation and the biology of the optimal target cell (i.e., the pluripotent self-renewing hematopoietic stem cell), a safe and efficient method of transduction, and a stable and effective transgene expression ([709]). Encouraging reports of the successful transfer of a human ß-globin gene into the hematopoietic stem cells of mice, using an oncoretroviral vector, appeared in 1988 ([710] , [711]). However, the level of expression was too low (<1% of mouse ß-globin) for a potential therapeutic effect. Recent studies using murine models support the clinical impression that sustained and regulated transgene expression in the range of 10 to 20% of the level of the endogenous globin is required for a therapeutic benefit ([712] , [713]). The discovery that the nuclease HSs of the ß-LCR possess powerful erythroid-specific enhancer activity led to the hope that inclusion in the transgene of relatively small (<1 kb) “core” HS fragments might significantly increase its level of expression. Regrettably, inclusion of HS core elements in retroviral vectors caused genetic instability of the vector genome, with frequent rearrangements and low titers of viral producer cell clones ([714] , [715]). Other major barriers to efficient gene transfer into stem cells are related to low levels of viral receptors on the stem cells of large animal species and the low frequency of cycling stem cells in the bone marrow. To overcome these problems, several strategies have been attempted, such as the use of cytokine-mobilized peripheral blood cells as targets for gene transfer, of different envelope proteins (“pseudotyping”) for vector particles, and of alternative vector systems (adeno-associated virus, lentiviral vectors) ([716] , [717] , [718] , [719] , [720] and [721]). Recent advances in vector construction have overcome this and other problems that limit both gene transfer efficiency and regulation of transgene expression ([722]). Using a lentiviral vector termed TNS9, May et al. (2000) recently succeeded in stably transmitting a vector harboring a large ß-globin gene fragment, including the promoter, from position -618 and the intragenic and 3' enhancers, combined with specific segments spanning the HS2, HS3, and HS4 regions of the human ß-globin LCR ([723] , [724] , [725] and [726]). The human ß-globin expression in transduced hematopoietic stem cells of ß-thalassemic heterozygous mice reached high and sustained levels of expression (17 to 24% of total hemoglobin) ([723]). Long-term (up to 40 weeks) synthesis of chimeric hemoglobin (murine a_2:human $ß_2^A$) has been achieved in mice with ß-thalassemia intermedia after engraftment with bone marrow cells transduced with the same lentiviral vector encoding the human ß-globin gene ([727]). Ineffective and extramedullary erythropoiesis regressed, and hepatic iron accumulation was markedly decreased. Similar results have been obtained in mouse sickle cell disease models ([728]). Experiments in large animals are needed for a full understanding of the real value of these new therapies. Moreover, the promising results with recombinant lentiviruses might have therapeutic applications once safety concerns are fully addressed.

Thalassemia Minor

CLINICAL FEATURES The classic heterozygous carrier of ß-thalassemia is usually asymptomatic. The diagnosis is made through evaluation of a positive family history or during population screening. Several series have been published on the clinical and hematologic features of people with thalassemia minor ([729] , [730] , [731] and [732]). Anemia is mild or absent. In pregnancy, however, anemia may be more severe than in normal women ([733] , [734]). Folate supplementation at the dose of 5 mg daily is recommended ([735] , [736]). Iron absorption is increased, and frank iron overload has been reported. Inappropriate administration of iron has been proposed as a possible cause in some of the patients ([737]). In addition, it has been observed that the ß-thalassemia trait aggravates hemochromatosis in individuals homozygous for the mutations C282Y and H63D, favoring higher rates of iron accumulation and the possible development of iron-related complications ([738]). On the other hand, the H63D mutation has been reported to increase iron overload in ß-thalassemia carriers ([739]). Iron deficiency anemia occurs less frequently in children heterozygous for ß-thalassemia as compared to normal controls, but its clinical expression, at similar levels of iron depletion, is more severe. The hemoglobin nadir at the end of the first trimester of life is also deeper and more prolonged in carriers of the trait ([740]). Serum bilirubin levels present considerable variation. Homozygosity for the

mutation typical of Gilbert syndrome is one of the factors determining hyperbilirubinemia in these individuals ([741]). Increased risk of gallstones has also been observed in women with ß-thalassemia trait as compared to controls ([742]). Data from Sicily suggest that heterozygotes for ß-thalassemia have a longer life expectancy ([743]). Men have a lower risk of myocardial infarction than the general population ([744]). A partially improved cardiovascular risk profile has been observed with respect to a low packed cell volume and low low-density lipoprotein cholesterol and apolipoprotein B in carriers of ß-thalassemia ([745]). The low-density lipoprotein–lowering effect of the thalassemia trait is evident even in patients with familial hypercholesterolemia ([746]).

LABORATORY FEATURES The mean hemoglobin concentration in affected Italian men and women is 12.7 and 10.9 g/dl, respectively; in Greek men, 13.9 g/dl; and in Oriental men and women, 12.1 and 10.8 g/dl, respectively ([731] , [732] , [736] , [747]). A slightly lower hemoglobin concentration was noted in Jamaicans with heterozygous ß ^{0}-thalassemia (11.3 g/dl) compared with those having heterozygous ß $^{+}$-thalassemia (12.5 g/dl) ([748]). Hemoglobin is less markedly decreased in Africans than in Mediterraneans ([748] , [749]). The red cell count is elevated, and the MCV and MCH values are reduced. The mean cell hemoglobin concentration is normal or only slightly decreased. In one series of 244 cases of ß ^{0}-thalassemia carriers, the MCV was 67 ± 4.6 fl (mean, ±1 SD), the MCH was 22.4 ± 1.6 pg, and the mean cell hemoglobin concentration was 32.9 ± 0.8 g/dl RBCs ([732]). The degree of reduction in the MCV is directly related to the degree of reduction in ß-globin production ([750]). The MCVs produced by ß ^{0} mutations are lower than those produced by ß $^{+}$-mutations ([751]). Heterozygotes for mild ß-thalassemia mutations, as a group, have higher MCV and MCH as compared to the severe ß ^{0} and ß $^{+}$ alleles. Microcytosis and hypochromia, associated with variation in size and shape of the erythrocytes, are commonly observed in the peripheral blood smear. Basophilic stippling is frequently found in heterozygous individuals from the Mediterranean, but not in Africans or Orientals ([730] , [752]). Reticulocytes are generally increased to twice the normal numbers and have been found to correlate with the hemoglobin level ([730] , [731]). In children, the MCV is lower than in the adults and normally increases with age; in thalassemia carriers, the correlation with age is less evident ([753]). The evolution of hematologic parameters in children at various ages is summarized in Table 42.4 ([754]). Free erythrocyte protoporphyrin is normal or slightly increased. Osmotic fragility is decreased. Red cell survival, measured by ^{51}Cr, shows mild ineffective erythropoiesis rather than peripheral hemolysis ([755]). HbA $_{2}$ is elevated in heterozygous carriers of ß-thalassemia in all the ethnic groups studied. The values range from 3.5 to 7.0% with a mean of 5% ([36]). This increase appears to be determined by an increased output of d-chains from both loci *in cis* and *in trans* to the thalassemia gene. HbF is increased in one-half of the patients, but the values observed are in general in the range of 1 to 3%. The distribution within the red cells is usually heterogeneous ([756] , [757]). A minority of carriers show unusually high levels of HbA $_{2}$ (>6.5%) associated with a variable increase of HbF. The molecular basis for these forms is large deletions of the ß-globin gene that remove its 5' promoter region. Globin chain synthesis analysis in heterozygous ß-thalassemia shows variable imbalance correlated to the severity of ß-globin chain defect ([36]). The physiologic decline of HbF in the first weeks of life is slower in ß-thalassemia heterozygotes (Table 42.4).

TABLE 42.4. Main Hematologic Parameters of ß-Thalassemia Carriers According to Age

Age	Hb (g/dl)	Mean Cell Volume (fl)	HbA $_{2}$ (%)	HbF (%)
At birth	18.3 ± 2.3	99 ± 8	0.5 ± 0.2	73.8 ± 10.1
4 mo	10.1 ± 1.1	70 ± 6	3.2 ± 0.7	27.0 ± 10.5
7 mo	10.5 ± 0.8	59 ± 4	4.8 ± 0.7	8.2 ± 4.0
9–10 mo	11.1 ± 0.9	59 ± 2	5.1 ± 0.5	4.4 ± 2.1

ATYPICAL CARRIERS The typical phenotype of ß-thalassemia trait, essentially characterized by reduced MCV and MCH and increased HbA $_{2}$, may be modified by several genetic and acquired factors causing problems in carrier identification (Table 42.5). The coinheritance of heterozygous ß-thalassemia with homozygous a $^{+}$-thalassemia (-a/-a) or heterozygous a ^{0}-thalassemia (–/aa) has a substantial effect on MCV and MCH, which may fall within normal ranges (Fig. 42.15) ([758]). However, the HbA $_{2}$ in these double heterozygotes remains in the carrier range, thus allowing their identification. Atypical carriers with reduced MCV and MCH and normal or borderline HbA $_{2}$ include double heterozygotes for d- and ß-thalassemia and carriers of some mild mutation, such as the -87 C?G, the -29 A?G, and IVS-1–6 T?C (Table 42.6). The differential diagnosis includes iron deficiency and a-thalassemia trait. Specific tests and, sometimes, family studies allow correct identification ([759] , [760]).

A third group of atypical ß-thalassemia carriers is represented by heterozygotes for very mild or silent ß-thalassemia mutations (Table 42.6). As a result of minimal deficiency of ß-globin production, these carriers have normal MCV and MCH and normal or borderline HbA_2 ([759], [761]). The a- to ß-globin chain synthesis ratio is normal or slightly higher than 1, confirming that these mutations cause only a very mild reduction in the expression of ß-globin gene. In this group also, the carriers of the triple a-globin gene arrangement (aaa/aa), which for the excess of a-globin chain produced may be considered as a very mild ß-thalassemia allele, should be included ([96], [761]). Identification of these silent carriers is usually retrospective in parents of patients with mild thalassemia intermedia. An extreme, although rare, instance of complex thalassemia gene combination that may lead to an almost silent phenotype is the coinheritance of a-, d-, and ß-thalassemia ([762]). Acquired factors able to modify the typical phenotype of ß-thalassemia trait are iron deficiency and folate deficiency ([763]). When severe, iron deficiency may decrease the high HbA_2 levels typical of heterozygous ß-thalassemia, and folate deficiency may increase the MCV to normal values. When these deficiencies are present, other tests, such as DNA analysis to identify the ß-globin gene mutation or retesting after correction of the anemia, may be necessary for diagnosis.

dß-THALASSEMIA AND HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN CARRIERSdß ^{0}-Thalassemia carriers have RBC changes milder than those observed in ß-thalassemia trait. Overall, MCV and MCH are approximately 70 fl and 24 pg, respectively. HbA_2 is normal or reduced, and HbF is increased (5 to 20%) and heterogeneously distributed among red cells. The degree of globin chain imbalance is mild (a- to non–a ratio approximately 1.5). Heterozygotes for deletional HPFH are characterized mostly by normal MCV, MCH, and HbA_2. Only in some cases is there a mild reduction of red cell indices and HbA_2. HbF ranges from 15 to 30% with pancellular distribution. a-/Non–a-globin synthesis is normal or mildly unbalanced ([214]). Nondeletional HPFH heterozygotes have red cell indices, HbA_2, and a- to non–a ratios similar to those of deletional HPFH carriers, whereas mean HbF levels vary from 2.5 to 27.0% ([214]).

CARRIER DETECTION

ß-Thalassemia and dß-Thalassemia Carrier detection methods should be able to identify typical and atypical heterozygous ß-thalassemia as well as dß-thalassemia and the hemoglobin variants, such as HbS and HbE, which interact with ß-thalassemia to produce clinically significant syndromes. As compared to most genetic diseases, carrier detection in hemoglobinopathies is relatively easy because it may be achieved through hematologic examination rather than DNA analysis. However, DNA analysis is needed for prenatal diagnosis. Basic hematology methods for carrier detection consist of RBC indices determination and hemoglobin pattern analysis. More specialized tests and eventually DNA analysis are required in some cases for definitive diagnosis. High-pressure liquid chromatography (HPLC) provides effective separation of hemoglobins, gives an accurate quantitation of HbA_2 and HbF, and detects the large majority of Hb variants ([764], [765]). Alternatively, cellulose acetate electrophoresis or isoelectric focusing can be used for detecting Hb variants, but quantitation of HbA_2 and HbF should be performed by microchromatography and alkali denaturation, respectively. Elution of HbA_2 and HbF bands after electrophoresis is an accurate, but time-consuming, method. Appropriate tests for iron status determination and globin chain synthesis analysis are supplementary hematologic methods useful in carrier detection procedures. Family studies may be helpful in some atypical cases, particularly in genetic compounds for two different alleles. Carrier detection procedure should be designed so as not to miss any carrier or couple at risk. Based on the frequency and heterogeneity of thalassemia types present in a population, appropriate screening programs are set out. The most used flow chart for Mediterranean populations is provided in Figure 42.16 ([759]). In addition to MCV and MCH, the first set of tests includes HbA_2 quantitation to avoid missing double heterozygotes for a- and ß-thalassemia with normal MCV and MCH. Globin chain synthesis analysis is performed to differentiate a-thalassemia trait from d- + ß-thalassemia or mild ß-thalassemia alleles. With this flow chart, only the truly silent ß-thalassemia carrier and the triple a-globin gene arrangement may be missed. In populations with low frequency of thalassemia, the initial screening can be performed by the evaluation of red cell indices, followed by hemoglobin pattern analysis to confirm the presence of a thalassemic allele. The osmotic fragility test is a simple approach to screening for thalassemia ([766]). However, this test is sensitive but not specific, difficult to standardize, and gives false-negative results. Several mathematic indices derived from red cell parameters have been proposed, discriminating thalassemia trait from iron deficiency (e.g., Mentzer, England and Fraser, Shine and Lal). However, these indices are not accurate, particularly in pregnant women, in children, and in a-thalassemia–ß-thalassemia interaction, predicting the correct diagnosis only in 80 to 90% of the patients ([767]). Therefore, their use is not appropriate, particularly in populations with a high frequency of ß-thalassemia, in which missing a carrier may have serious consequences.

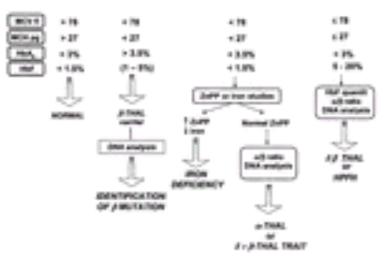

Figure 42.16. Flow chart for the diagnosis of thalassemia syndromes. Hb, hemoglobin; HPFH, hereditary persistence of fetal hemoglobin; MCH, mean cell hemoglobin; MCV, mean cell volume; THAL, thalassemia.

Two common problems in screening for ß-thalassemia are the presence of borderline HbA_2 levels (i.e., HbA_2 of 3.2 to 3.6%) and the differential diagnosis of microcytosis with normal to borderline HbA_2 ([759], [760] and [761]). Borderline values of HbA_2 are associated with molecular defects in the ß-, d-, or a-globin genes. Further investigation using globin chain synthesis, DNA analysis, or both is needed, particularly when one individual with a borderline HbA_2 level has a partner with typical ß-thalassemia trait. A phenotype characterized by microcytosis, hypochromia, normal or borderline HbA_2, and normal HbF may result from iron deficiency, a-thalassemia, d-thalassemia–ß-thalassemia interaction, mild ß-thalassemia, or, very rarely, e?dß-thalassemia. After exclusion of iron deficiency by erythrocyte zinc protoporphyrin determination, evaluation of transferrin saturation, or both, the different thalassemia determinants leading to this phenotype are discriminated by globin chain synthesis analysis and eventually by a-, d-, and ß-globin gene analysis. dß ^{0}-Thalassemia carriers and HPFH heterozygotes, both characterized by increased HbF levels, can be clearly differentiated by globin chain synthesis analysis, showing an a-/non–a-globin imbalance in the former. Identification of the molecular defect by globin gene DNA analysis confirms the diagnosis. Hb Lepore is suspected in the presence of an abnormal, slow Hb band on the electrophoretic pattern associated with reduced MCV, MCH, and HbA_2 and usually a mild increase (approximately 2 to 5%) of HbF. The diagnosis is confirmed by DNA analysis of ß-globin gene cluster. The specific mutation is defined by globin gene DNA analysis using PCR-based methods. There are several PCR-based techniques that can be used to identify the globin gene mutations, including dot-blot and reverse dot-blot analysis, the amplification refractory mutation system, denaturing gradient gel electrophoresis, gap-PCR, restriction endonuclease analysis, d-HPLC, and direct manual or automated DNA sequencing. Details on these methods can be found in specific surveys and laboratory manuals ([36], [390], [391], [392] and [393]). Each method has advantages and disadvantages, and the choice depends not only on the technical expertise of the laboratory, but also on the type and variety of the mutations likely to be encountered in the population group being tested. In fact, despite the marked heterogeneity of thalassemia mutations, a limited number of molecular defects are prevalent in each population (Table 42.7). This information is very useful in practice because the most appropriate probes or primers can be selected according to the carrier's ethnic origin. It is advisable for any diagnostic laboratory to have at least two alternative methods for detecting mutations.

a-Thalassemia a-Thalassemia carriers are more difficult to identify than ß- or dß-thalassemia carriers because they do not have typical changes in HbA_2 or HbF levels. MCV and MCH are always reduced in carriers of -a/-a and -/aa genotypes, whereas -a/aa carriers often have a normal or, sometimes, a mild reduction of MCV and MCH values. The hemoglobin pattern in adult a-thalassemia carriers is normal, although as a group, they have slightly lower levels of HbA_2. In the newborn, the electrophoretic detection of Hb Bart ($?_4$), a fast-moving band, is useful for the diagnosis of a-thalassemia trait. a $^+$-Thalassemia carriers usually show up to 3% of Hb Bart, and a ^{0}-thalassemia carriers (–/aa) and a $^+$-thalassemia homozygotes (-a/-a) may have 3 to 8%. However, in some carriers, Hb Bart may be not detected ([294] , [295]). A simple test for detecting a-thalassemia carriers is the incubation of the peripheral blood with brilliant cresyl blue; the smear examination may show rare RBCs with HbH inclusion bodies, although their absence does not exclude a-thalassemia carrier status ([295]). Globin chain synthesis analysis is used to identify a-thalassemia carriers that show an a to ß ratio lower than 0.9. This test is helpful in the presence of microcytosis with normal HbA_2 to differentiate the a-thalassemia trait from the d-thalassemia–ß-thalassemia interaction. Definitive diagnosis of a-thalassemia carriers can also be achieved with DNA analysis of the a-globin genes. The methods used depend on the type of mutations expected in each population and are divided into those that detect deletions (i.e., gap-PCR and, sometimes, Southern blotting) and those that detect point mutations [i.e., nondeletion a-thalassemia (direct detection by restriction enzyme analysis, allele-specific oligonucleotide hybridization, denaturing gradient gel electrophoresis, and DNA sequencing)] ([768] , [769] , [770] , [771] and [772]). The a ^{0}-thalassemia phenotype can be detected with an anti–?-globin monoclonal antibody, because small amounts of embryonic ?-globin are produced in adult life by chromosomes lacking both a-globin genes ([773]). Detection of a ^{0}-thalassemia carriers is important for prevention of Hb Bart hydrops fetalis syndrome, for which prenatal diagnosis is always indicated. HbH disease is not considered to be among those hemoglobinopathies targeted for prevention.

Hemoglobin E The diagnosis of heterozygous HbE is based on the hemoglobin pattern analysis by electrophoresis or HPLC separation. At alkaline pH (8.4), HbE moves in the same position as HbA_2 and can be distinguished by its high concentration, usually 25 to 30%. HbE has the same elution time as HbA_2 on HPLC ([774]). Lower proportions of HbE in carriers indicate the presence of coinheritance a-thalassemia or of iron deficiency anemia. The blue dye dichlorophenolindophenol can be used as a screening test for HbE, which dissociates and precipitates at the bottom of the tube on incubation at 37°C ([775]).

PRENATAL DIAGNOSIS The availability of prenatal diagnosis added a new option to couples at risk for a major hemoglobinopathy, leading to a significant change in the effectiveness of screening and counseling in hemoglobinopathy prevention ([776]). Prenatal diagnosis of both a- and ß-thalassemia was carried out for the first time in the 1970s using globin chain synthesis analysis in fetal blood, obtained by fetoscopy or placental aspiration around the nineteenth week of gestation ([777]). The advent of DNA analysis and the introduction of chorionic villi sampling resulted in a notable improvement in prenatal diagnosis because it could be performed within the first trimester of pregnancy, generally at 10 to 12 weeks of gestation ([778] , [779]). Fetal DNA can be obtained also from amniocytes at 15 to 17 weeks of pregnancy. Chorionic villi sampling is carried out transcervically or transabdominally. The reported risk of fetal loss with this procedure ranges from 0.5 to 4.5% ([780] , [781] and [782]). However, in experienced hands, the fetal loss rate appears to be 0.5 to 1.0%, similar to natural wastage for pregnancies of this duration ([782] , [783]). After sampling, fetal DNA analysis is performed by the PCR-based methods mentioned for carrier detection procedures. In general, the mutation to be detected in the fetus is first identified in the parents. The results of DNA analysis are very accurate, but misdiagnosis may occur for several reasons (failure to amplify the target DNA fragment, mispaternity, maternal contamination, and sample exchange). However, the risk of misdiagnosis can be significantly reduced using a number of precautionary measures, such as fetal DNA analysis for selected polymorphic markers ([759] , [784] , [785]). Fetal cells, known to be present in the maternal circulation, represent an attractive, noninvasive approach to prenatal diagnosis ([786]). Fetal cells, immunologically isolated for their low purity, can only be used for the prenatal diagnosis of ß-thalassemia in women whose partners carry a different mutation ([787]). Recently, this problem has been overcome by the development of a technique able to isolate single fetal erythroblasts from maternal blood by microscopic micromanipulation, making possible the analysis of both fetal genes in a single cell ([788] , [789]). However, this procedure is associated with several technical and biologic problems, and it is not widely applicable. The discovery of free fetal DNA in maternal plasma provided the basis for developing another method for noninvasive prenatal diagnosis ([790]). However, because free maternal DNA is also present, the application to prenatal diagnosis of thalassemias would be possible only to exclude paternally derived pathologic alleles different from the mother's mutation. The advent of DNA amplification has made it possible to define the genotype of a single cell biopsied from cleaving embryos (preimplantation diagnosis) and to analyze the polar body

obtained during the maturation of the oocyte (preconceptional diagnosis) ([791] , [792]). These procedures avoid the need to terminate affected pregnancies and permit the transfer of only healthy embryos established from *in vitro* fertilization. Successful experiences in many couples with this approach have been reported in hemoglobinopathies ([793] , [794] and [795]). However, preimplantation genetic diagnosis is a technically challenging, intensive procedure, which requires the close collaboration of a team of specialists. To date, programs for ß-thalassemia prevention based on carrier screening, genetic counseling, and prenatal diagnosis are ongoing in several areas at risk in Mediterranean countries, with a marked decline in the incidence of thalassemia major (Fig. 42.17) ([33] , [796] , [797]). Effective preventive programs have also been established in countries such as the United Kingdom, where thalassemia is a rare disorder that affects diverse minority ethnic groups. Special attention should be given in these programs to the different religious and social issues and to the different aptitude toward prenatal diagnosis of the various ethnic minorities ([798]).

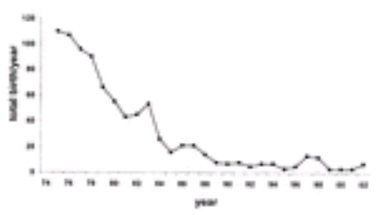

Figure 42.17. Fall in the birth rate of infants with homozygous ß-thalassemia in Sardinia. (Reprinted from Cao A, Rosatelli C, Galanello R. In: Variation of the human genome. Control of beta-thalassaemia by carrier screening, genetic counselling and prenatal diagnosis: the Sardinian experience. Ciba Found Symp 1996;197:137, Wiley, with permission.)

Thalassemia Intermedia

GENETIC DETERMINANTS The remarkable clinical diversity of thalassemia intermedia is related to the great variety of genotypes. Thalassemia intermedia most commonly is associated with homozygous or compound heterozygous state for two ß-thalassemia alleles ([36] , [280] , [799]). However, several patients with this mild clinical picture have only a single ß-globin gene affected and are considered heterozygotes for ß-thalassemia. It has been clearly established that the severity of ß-thalassemias is related to the degree of globin chain imbalance. Therefore, in homozygous ß-thalassemia, any inherited or acquired factor able to reduce the degree of globin imbalance may produce milder clinical forms (Fig. 42.18). On the other hand, in simple ß-thalassemia heterozygotes, the worsening of globin chain imbalance may turn the asymptomatic carrier state into a significant clinical phenotype.

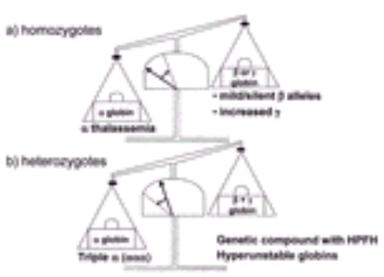

Figure 42.18. Mechanisms of ß-thalassemia intermedia. **A:** Reduced globin chain imbalance. **B:** Increased globin chain imbalance. HPFH, hereditary persistence of fetal hemoglobin.

Homozygotes or compound heterozygotes for mild ß-thalassemia mutations, characterized by a residual high ß-globin chain production, usually have thalassemia intermedia. Examples are the homozygous state for -29 A?G in black patients and the IVS-1–6 T?C in Mediterranean patients ([129] , [800] , [801]). Compound heterozygotes for a mild and a severe mutation may cover a remarkably broad clinical spectrum of severity ([281] , [282]). This variability can be related to the presence of a-thalassemia or of genetic determinants able to increase ?-chain production ([281]). Few homozygotes for silent mutations have been reported (i.e., ß CAP +1 A?C, IVS-2–844 C?G); they have the hematologic and clinical characteristics of ß-thalassemia trait ([125] , [802]). Compound heterozygotes for a silent and a severe mutation usually have very mild thalassemia intermedia, but exceptions with a severe phenotype have been reported ([124] , [282] , [761] , [803] , [804] , [805] and [806]). Coinheritance of a-thalassemia with homozygous ß-thalassemia leads to a reduction in the excess of a-chains (Fig. 42.18). Interacting a-thalassemia has been reported in patients with ß-thalassemia intermedia from the Mediterranean and Southeast Asia ([807] , [808] , [809] and [810]). However, the ameliorating effect depends both on the type of coinherited a-thalassemia (the presence of two a genes deleted being more effective) and on the severity of the ß-thalassemia allele (a-thalassemia being less effective in ameliorating the homozygous ß ^{0}-thalassemia). Genetic determinants maintaining a high ?-chain synthesis after birth result in a reduction of the a-/non–a-chain imbalance, thus producing a mild phenotype when coinherited with homozygous severe ß-thalassemia. Moreover, a high ?-chain synthesis produces a net increase in total hemoglobin synthesis. Several genetic determinants associated with a high ?-chain output have been identified, including ß-thalassemia defects with intrinsic propensity to increase ?-chain production (dß-thalassemia, some deletions causing ß ^{0}-thalassemia, Hb Lepore) and independent genetic determinants, such as mutations in the ^{G}?- or ^{A}?-promoter associated with ß-thalassemia mutations ([280] , [811]). The most common is -158 C?T G? promoter substitution, which is in linkage disequilibrium with several ß ^{0}-thalassemia mutations [cd 6 (-A), cd 8 (-AA), IVS-2–1 G?A] ([280] , [811] , [812]). This mutation leads to enhanced ?-chain production under conditions of erythropoietic stress and partially compensates for the absence of ß-chain synthesis with consequent amelioration of the a-/non-a imbalance and of the clinical phenotype. The -158 G? C?T substitution has been found occasionally in patients with ß $^{+}$ IVS-1–6 T?C and with the severe ß ^{0} 39 C?T mutation ([813]). Other genetic determinants increasing ?-chain production unlinked to the ß-globin cluster have been mapped on chromosome 6q and Xp ([219] , [220]). However, in many patients with thalassemia intermedia and homozygotes or compound heterozygotes for severe ß-thalassemia mutations, even of the ß ^{0} type, the inherited modifying factors able to ameliorate the clinical features are yet unknown. Several patients with thalassemia intermedia have only a single ß-globin gene affected—they are simple ß-thalassemia heterozygotes. The worsening of globin chain imbalance in most of these cases results from the coinheritance of one or two extra a-globin genes due to the heterozygous or homozygous state for the triplicated a gene complex (aaa/aa or aaa/aaa) ([96] , [814] , [815]). The compound heterozygosity for severe ß-thalassemia with both deletion and nondeletion pancellular HPFH results in a mild thalassemia intermedia phenotype. As reported above, hyperunstable hemoglobins are a group of hemoglobin variants able to produce the clinical picture of thalassemia intermedia of variable severity when present in heterozygous state ([158]). Compound heterozygosity for ß-thalassemia and some structural ß-chain variants (HbD-Los Angeles ß 121 Glu?Gln, HbC ß 6 Glu?Lys, HbO-Arab ß 121 Glu?Lys) may produce thalassemia intermedia as a result of globin chain imbalance in combination with the modified structural and functional characteristics of the variant ([816]). Finally, several patients heterozygote for ß-thalassemia with the typical thalassemia intermedia clinical picture have been reported in whom extensive analysis of ß- and a-globin gene cluster and family studies fail to identify any other associated molecular defect ([817] , [818]). Recently, a new protein has been identified that binds to a-globin, preventing its precipitation ([819]). This protein belongs to the group of molecular chaperones and is referred to as a *-hemoglobin–stabilizing protein*. Transgenic mice, lacking functional a-hemoglobin–stabilizing protein, showed RBC changes consistent with damage caused by excess a-chains. Unexplained cases of thalassemia intermedia in ß-thalassemia heterozygotes might result from mutations in a-hemoglobin–stabilizing protein that would cause the a-chain excess to be more detrimental ([819] , [820]).

CLINICAL FEATURES The term *thalassemia intermedia* designates a non–transfusion-dependent thalassemia phenotype. The disorder is heterogeneous, and severity is variable. Conventionally, the condition is considered non–transfusion-dependent if hemoglobin is spontaneously maintained at or above 7.0 to 7.5 f/dl. Age at presentation seems to represent a good indicator of future transfusion independence. In fact, Modell and Berdoukas reported that only 11% of patients with thalassemia intermedia presented in the first year of life, 30% presented in the second year, and 59% presented later in life ([358]). Cao et al., describing a group of 34 patients with thalassemia due to ß ^{0} homozygosity, observed that those who became transfusion dependent were diagnosed at a mean age of 8.5 ± 1.8 months, whereas those who remained transfusion independent were diagnosed at 17.4 ± 11.8 months ([821]). From the experience of many, however, it appears that a steady-state hemoglobin value is reached only several years after diagnosis. In the truly transfusion-independent forms of thalassemia intermedia, anemia of various degree and mild jaundice are present, whereas growth and development remain normal. The spleen is palpable from the beginning in the majority of the patients, and its size increases with time. Hypersplenism is frequently heralded by decreasing hemoglobin levels. Thrombocytopenia and neutropenia may then ensue. Bone abnormalities are common and include frontal bossing, prominence of the zygomatic bones, depression of the base of the nose, shortening of long bones, excessive thinning of cortices, and dilatation of the medullary cavities, as described for thalassemia major. Fractures due to minor trauma are also signs of medullary overgrowth. Bone and joint pains are not infrequent. The skeletal abnormalities are a consequence of increased erythropoiesis and, when severe, indicate that marrow activity is excessive and that transfusion is required. Osteoporosis, an emerging problem in thalassemia major, has been reported also in thalassemia intermedia ([822]). Extramedullary erythropoiesis is frequent in thalassemia intermedia and can produce all sorts of bizarre symptoms ([823] , [824] , [825] and [826]). In a series of adult patients subjected to computed tomography scan, 65% were found to have ectopic erythropoiesis ([827]). A review of radiologic characteristics and MRI findings of extramedullary hemopoiesis has recently been reported ([828] , [829] , [830] and [831]). Spinal cord compression causing paraparesis and cauda equina syndrome

are not rare and require urgent treatment. Transfusion is effective, but regression of the extramedullary masses is slow ([832], [833]). More rapid results can be obtained by x-ray therapy or with the administration of HU ([701], [832], [834], [835]). Iron loading in patients who receive no or few transfusions is mainly a consequence of increased iron absorption from the digestive tract. An increase in ferritin levels with age has been observed, but rarely untransfused patients with thalassemia intermedia accumulate large amounts of iron before 20 years of age ([836], [837], [838] and [839]). In a study of 20 patients with thalassemia intermedia, it was found that 62% of the variation in serum ferritin was explained by age and by changes in soluble transferrin receptor, a reliable measure of erythropoiesis ([840]). An aggravating effect of splenectomy on hemosiderosis has been suggested ([841], [842]). Endocrine function is usually normal, although diabetes mellitus has frequently been reported ([535], [824], [843]). Puberty is normal or delayed, but fertility is usually preserved ([513]). Miscarriages seem to be more frequent than in the normal population, especially if severe anemia is present ([844]). Leg ulcers, appearing above the medial malleolus, are a common and distressing problem that has been attributed to the hypoxia caused by anemia and to the abnormal rheology of the thalassemic red cells ([845], [846]). Treatment is often unsatisfactory. It includes pressure dressing, skin grafting, blood transfusion, HU, arginine butyrate, granulocyte colony-stimulating factor, and platelet growth factor ([847], [848], [849] and [850]).

Thromboembolic Disease A hypercoagulable state has been described in patients with thalassemia major and intermedia ([252]). In an Italian multicenter study, the prevalence of thromboembolic events was found to be 9.6% in patients with thalassemia intermedia as compared to 4.0% in patients with thalassemia major ([384]). In a recent study, Cappellini et al. reported a high prevalence (29%) of thromboembolic events in splenectomized patients with thalassemia intermedia ([851]). These authors found high plasma levels of markers of coagulation and fibrinolysis activation and hypothesized that the abnormal red cells and erythroid precursors of patients affected by thalassemia intermedia act as activated platelets in thrombin generation. Thrombosis of the portal vein after splenectomy has been described ([852]). Heparin therapy followed by long-term oral anticoagulants is indicated after significant thrombotic episodes. Gallstones are a frequent complication, especially in patients homozygous for the Gilbert promoter mutation ([853]). Folic acid deficiency can be present, and it can be at the basis of intervening severe anemia ([358], [824], [843]). Regular folate supplementation should be administered.

Cardiac Disease Limited data were available on the cardiac function of patients with thalassemia intermedia until recently when a large multicenter study from Greece described a worrisome picture ([854]). One hundred and ten patients having a mean age of 32.5 ± 11.4 years with a mean hemoglobin of 9.1 ± 1.1 g/dl and ferritin levels of 1657 ± 1477 ng/ml were included in the study. Overall, 5.4% of the patients had congestive heart failure, and 8.0% had a history of acute pericarditis. In addition, pulmonary hypertension developed in 59% of the patients, making it the leading cause of cardiac failure. A smaller study of left ventricular function by two-dimensional and M-mode echocardiography in 24 asymptomatic young adults affected by ß-thalassemia intermedia demonstrated significant increases in left ventricular volumes, left ventricular mass, and cardiac index, more pronounced than those found in patients affected by thalassemia major ([855]).

TRANSFUSION THERAPY When assessing the need for a transfusion program, in addition to the level of hemoglobin, the general condition must be considered, particularly with respect to growth, skeletal deformities, and size of the spleen. Only if the patient's well-being and activity are preserved, at not too high a cost in terms of medullary and extramedullary hyperplasia, can transfusion be withheld. Thalassemia intermedia, by definition, does not require transfusion therapy except in special circumstances that include infections, hypersplenism, periods of rapid growth, and pregnancy. Aplastic crises complicating the course of thalassemia intermedia (as well as of all other conditions characterized by shortened red cell life) are typically due to parvovirus B19 infection. Small epidemics have been reported ([856]). Reticulocytes disappear from the circulation, and typical giant and bizarre pronormoblasts appear in the marrow ([857]). Sometimes, transient pancytopenia is present ([858]). The crisis typically lasts 1 to 2 weeks, but anemia may be severe enough to require blood transfusion. The development of cardiac disease is also an indication to begin transfusions. Sometimes, adults who have maintained acceptable hemoglobin levels for 20 or more years develop transfusion dependency. The need for transfusion must be evaluated carefully because the risk of alloimmunization and autoimmunization is high in thalassemia patients who have not been transfused in the first years of life. A Greek study reported a frequency of alloimmunization of 20.9% versus 47.5% when patients transfused before and after 3 years of age were compared ([279]). Also, Asian patients seem to be more prone to this complication, both when transfused from different ethnic donors and from donors of the same ethnicity ([859], [860]). When immunization develops, anemia can be life-threatening, but transfusing only aggravates the problem. Immunosuppressive therapy is not always successful. Remission of the hemolytic process has been reported with HU, and one patient has undergone allogeneic BMT from an HLA-matched unrelated donor ([851], [861]). Hypersplenism is an almost inevitable complication of thalassemia intermedia, leading to transfusion dependency that is usually reversed by splenectomy. HU therapy in patients with thalassemia intermedia may increase total HbF levels and improve their sense of well-being. Good results have been reported with different protocols at doses varying between 3.0 to 10.0 mg/kg/day and 1.5 g/day ([862], [863]). Therefore, a trial of HU for thalassemia intermedia patients in whom chronic transfusion therapy is being contemplated is indicated.

IRON OVERLOAD Bone marrow hyperactivity stimulates iron absorption from the gut; however, as mentioned, accumulation of large amounts of iron is an uncommon event in untransfused children with thalassemia intermedia ([836], [837]). Blood transfusions, however, even when occasional, can contribute to iron overload so that some way of eliminating the excess iron becomes necessary. Subcutaneous desferrioxamine by continuous infusion remains the first choice, accompanied by careful assessment of iron stores and regular monitoring for toxicity ([572], [573]). Reduction in tissue iron stores and normalization of serum ferritin concentration have also been reported with the use of deferiprone ([456]). Phlebotomy could be an option for patients with sufficiently high hemoglobin levels ([824], [864]).

Megaloblastic Anemias: Disorders of Impaired DNA Synthesis

HISTORICAL BACKGROUND

The story of megaloblastic anemia, its causes, and how they were decoded is a wonderfully instructive chapter of medicine. The random advances of clinical observation set the stage for a series of insightful clinical investigations that dramatically converted a dreaded “pernicious” condition into one that is now easily treated.

A puzzling illness with idiopathic anemia, debilitation, languor, and, finally, torpor and death was described by Addison ([1]) in 1849. Although possibly similar cases were reported earlier and Addison believed the anemia to be related to adrenal dysfunction, this is generally taken as the first description of pernicious anemia, a colorful, apt name coined by Biermer ([2]). Neuropathy was noted by Osler and Gardner in 1877, and the association with myelopathy was made by Lichtheim 10 years later. In 1880, Ehrlich ([3]) identified megaloblasts and proposed them as the precursors of the “giant blood corpuscles” described in the peripheral blood by Hayem ([4]). The white cell changes were not established until the 1920s.

The clinical breakthrough occurred in 1926 when Minot and Murphy ([5]), using the then new technique of reticulocyte assessment, showed that the disease could be reversed and held in abeyance by eating prodigious amounts of liver; for this, they shared the Nobel Prize. Three years later, Castle ([6]), building on earlier descriptions of achylia gastrica, demonstrated that gastric juice contains an “intrinsic factor” (IF) that combines with an “extrinsic factor” in meat and allows it to be absorbed. Several decades later, the extrinsic factor, vitamin B_{12}, was synthesized by biochemists at two drug companies ([7], [8]), and its structure was demonstrated by Hodgkin ([9]), who was awarded a Nobel Prize for her crystallographic work.

Studies by Wills ([10]), who treated macrocytic anemia with yeast, and by many others defined the need for folate, which was isolated and characterized by 1948 ([11]). The ability of nutritional folate deficiency to cause megaloblastic anemia was proven in a notable self-experiment by Herbert ([12]). The stories of these and other discoveries are available in several highly readable books and articles ([13], [14], [15] and [16]).

Cure is so simple now that the once deadly diseases are considered domesticated. Although that development is a gratifying contrast with the past, the potential for clinical neglect has emerged ([17], [18] and [19]), even as major metabolic and molecular advances continue. With increasingly finer and more accessible biochemical tools, the boundaries of insufficiency are expanding in efforts to define optimal health in addition to treating disease. Still, unsolved questions persist.

NORMAL PHYSIOLOGY AND PATHOPHYSIOLOGY

Megaloblastic anemia is, most often, a product of folic acid or cobalamin (vitamin B_{12}) deficiency. The two vitamins are closely interrelated metabolically, and their disorders are sometimes difficult to differentiate. However, the vitamins, the disorders responsible for their deficiencies, and the approaches to their diagnosis and treatment are very distinct. Folic acid and cobalamin are discussed separately throughout this chapter, reflecting the clinical necessity of always differentiating between the two.

Biochemistry and Metabolism

FOLATE Folate, or pteroylglutamate, consists of a pteridine ring, paraminobenzoate, and one or more glutamate side chains (Fig. 43.1). Polyglutamated folates, with three or more ?-carboxyl–linked glutamate residues, predominate intracellularly; they are better retained in cells than are monoglutamated forms, which traverse cell membranes more easily ([20]). The polyglutamated forms are more effective participants in enzymatic reactions, as reviewed elsewhere ([21]), although 5-methyltetrahydrofolate (methylTHF), the major folate in the body, tends to be a poor substrate for polyglutamation.

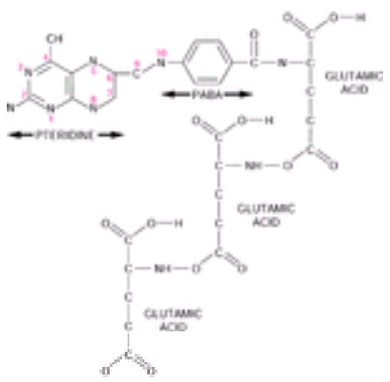

Figure 43.1. Folate structure. The constituents are, from left to right, pteridine and *p*-aminobenzoic acid (PABA), which together make up the pteroyl moiety, and one or more glutamates that are attached by ?-carboxyl linkage (in this diagram, three glutamates are linked). Metabolic activity requires reduction to tetrahydrofolate at positions 5, 6, 7, and 8. Various one-carbon moieties are attached to the nitrogen at positions 5 (5-methyl, 5-formyl, or 5-formimino) or 10 (10-formyl), or bridging 5 and 10 (5,10-methylene or 5,10-methenyl). Each folate takes part in specific reactions by transferring, accepting, or transforming its one-carbon moiety.

Folates, when reduced to the tetrahydrofolate (THF) form, function as one-carbon group donors and acceptors. THFs with one-carbon moieties of varying oxidation states attach to select enzymes and serve as active substrates in cytoplasmic or mitochondrial one-carbon group transfers involving amino acids (Fig. 43.2; reactions

4, 5, and 7), purines (reactions 10 and 11), and pyrimidines (reaction 2). Folate is also indirectly linked to DNA methylation by contributing to *S*-adenosylmethionine (AdoMet) availability for methylation of DNA cytosine (Fig. 43.2; reaction 13). Cellular folate metabolism and its compartments are reviewed elsewhere ([22], [23]).

Figure 43.2. Folate metabolism (*left*) and its linkage with cobalamin (*center*) to homocysteine and methionine metabolism (*right*). Vitamin cofactors are highlighted in boxes. Not all bidirectional reactions are noted as such. The enzymes for the reactions include the following: *(1)* dihydrofolate (DHF) reductase; *(2)* thymidylate synthase; *(3)* methylene tetrahydrofolate (THF) reductase; *(4)* methionine synthase (maintained by a reductive system mediated by methionine synthase reductase); *(5)* serine hydroxymethyltransferase; *(6)* two reactions mediated by two enzymes' activities of one protein (methylene THF dehydrogenase and methenyl THF cyclohydrolase); *(7)* glutamate formiminotransferase; *(8)* formimino THF cyclodeaminase; *(9)* methenyl THF synthase; *(10)* glycinamide ribonucleotide (GAR) transformylase; *(11)* 5(4)-aminoimidazole-4(5)carboxamide ribonucleotide (AICAR) transformylase; *(12)* methionine adenosyltransferase; *(13)* various *S*-adenosylmethionine (AdoMet)–dependent methyltransferases; *(14) S*-adenosylhomocysteine (AdoHcy) hydrolase (kinetics usually favor synthesis of AdoHcy); *(15)* betaine:homocysteine methyltransferase; *(16)* cystathionine ß-synthase; *(17)* cystathionine ?-lyase. dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; FAD, flavin adenine dinucleotide (riboflavin); FAICAR, formylAICAR; FGAR, formylGAR; FIGLU, formiminoglutamic acid; Glu, glutamic acid; MeCbl, methylcobalamin; PLP, pyridoxal 5'-phosphate.

COBALAMIN *Cobalamin*, a member of the corrin family, is a planar tetrapyrrole with a central cobalt atom and a nucleotide (5,6-dimethylbenzimidazole) below and a variable prosthetic moiety above the plane (Fig. 43.3). Specific cobalamins are named according to that prosthetic moiety. A methyl moiety gives rise to methylcobalamin, which predominates in plasma and cytoplasm, and 5'-deoxyadenosyl gives rise to adenosylcobalamin, which predominates intramitochondrially. *Vitamin B* $_{12}$, often used as a general name for cobalamin, was the name given to cyanocobalamin ([7]); the latter is a stable pharmacologic preparation but must be converted to other forms for metabolic utilization. Noncobalamin corrinoids, often with structural deletions, are present in nature but cannot be used by humans. Some of these analogs can nevertheless be bound by the widely distributed cobalamin-binding protein transcobalamin (TC) I ([24], [25]) and are found in blood and tissues ([26]).

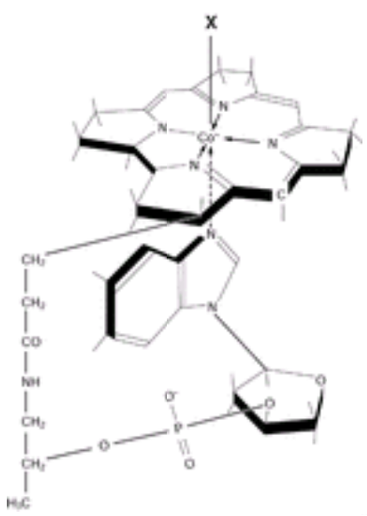

Figure 43.3. Cobalamin structure. Attached to the central cobalt atom of the corrin tetrapyrrole and to one of the pyrrole rings is the a-ligand, the 5,6-dimethylbenzimidazole nucleotide, extending below the corrin's plane. The ß-ligand (marked as X in the diagram) above the plane can be any one of several moieties, such as methyl, 5'-deoxyadenosyl, hydroxyl, or cyanide.

To be active, cobalamin requires reduction of its naturally oxidized, trivalent cobalt [cob(III)alamin] or the divalent cob(II)alamin. Reduced cob(I)alamin has two known roles in humans. Attached to methionine synthase, it accepts the methyl group from 5-methylTHF as methylcobalamin and transfers it to homocysteine (Fig. 43.2; reaction 4). Cobalamin activity for this reaction is maintained by methionine synthase reductase ([27]) and requires AdoMet. In its second role, reduced mitochondrial cobalamin accepts 5'-deoxyadenosyl from adenosine triphosphate and binds to methylmalonyl coenzyme A (CoA) mutase. That enzyme mediates an intramolecular rearrangement of L-methylmalonyl CoA to succinyl CoA in propionate metabolism ([28]). Cobalamin deficiency has a major impact on folate, homocysteine, and methionine metabolism by impairing the methionine synthase reaction. Considerable evidence supports the concept that cobalamin deficiency thereby traps methylTHF, which has no alternative metabolic role or route ([29], [30]). Feedback mechanisms activate methyleneTHF reductase (Fig. 43.2; reaction 3) in a vain effort to mobilize methylTHF for methionine synthesis but only end up diverting even more methyleneTHF from its other roles and into the trap. A general paralysis of folate metabolism ensues as THF and other active forms of folate decrease. An alternative proposal to the trap hypothesis emphasizes that the failure of methionine synthesis ultimately leads to formate “starvation” ([31]), with depletion of formylTHF, methenylTHF, and methyleneTHF.

HOMOCYSTEINE AND METHIONINE Folate and cobalamin are intertwined with the metabolism of homocysteine and methionine, as discussed. The adenosine triphosphate–dependent conversion of methionine to AdoMet (Fig. 43.2; reaction 12) serves several important functions. AdoMet helps regulate the metabolism of folate and disposition of homocysteine by inhibiting methyleneTHF reductase (reaction 3), as well as betaine hydroxymethyltransferase [an alternate remethylator of homocysteine (reaction 15) in liver and perhaps kidney and lens], and by activating cystathionine ß-synthase (reaction 16) ([32]). Even more important, AdoMet is the critical methyl donor for most cellular methylation reactions affecting proteins, nucleic acids, histones, phospholipids, and neurotransmitters—all mediated by various methyltransferases (reaction 13) ([33]). For example, DNA hypomethylation, which has been associated with neoplasia, can result from AdoMet deficiency. In the methylation reactions, *S*-adenosylhomocysteine (AdoHcy) is formed. AdoHcy, which in excess inhibits the methylation activity of AdoMet, can be hydrolyzed to homocysteine; under normal conditions, however, the direction of this reaction favors AdoHcy synthesis (reaction 14). An alternate fate of homocysteine is its transsulfuration to cystathionine and then to cysteine; both of these steps require pyridoxal 5'-phosphate (reactions 16 and 17). This is the major catabolic pathway of homocysteine, which is toxic to cells in concentrations normal for other amino acids. The pathway also produces glutathione, an important reducing agent. Thus, homocysteine has important ultimate influence on redox activity as well as synthesis of important thiols.

Normal Folate Physiology

NUTRITIONAL CHARACTERISTICS Folate, named for green leafy vegetables, is found in nearly all classes of foods. Organ meats (e.g., liver and kidney) and yeast are particularly rich, although not frequently eaten, sources. More common sources are other meats, nuts, beans, orange juice, dairy products, grains, and cereals. However, folate is labile, and large losses occur with some cooking processes and some foods ([34]), especially when water is used that is then discarded ([12]). Fortification of the American food supply with 140 µg folic acid/100 g in grain and cereal products was begun in 1998 to lower the risk of neural tube defect births ([35]). Many food producers have exceeded that amount, thus increasing the average folate intake by an estimated 190 µg/day ([36]). An independent but parallel development has been the growing use of vitamin supplements in Western societies, especially the United States. However, folate intake is often marginal or low in developing countries. The Institute of Medicine ([37]) has revised earlier recommendations for folate intake that had been based on the replacement of daily losses and prevention of evidence of deficiency. The new recommendations also take into account folate bioavailability, which is highest for synthetic folic acid. Food folate tends to be polyglutamated and requires conversion to monoglutamate for optimal absorption, making it less bioavailable than folic acid. Recommended daily intake is therefore expressed in dietary folate equivalents, in which 0.5 µg of synthetic folic acid delivers the dietary equivalent of 1 µg of food folate. The recommended dietary folate equivalent intake is 400 µg daily for adults, 600 µg for pregnant women, 500 µg for lactating women, and lesser amounts scaled for age for children. Women of reproductive age are advised to take 400 µg synthetic folic acid as an additional supplement for prevention of neural tube defect births.

PHYSIOLOGIC CYCLE OF ASSIMILATION

Folate Absorption The absorption of folate combines specific, saturable, carrier-mediated processes that tend to predominate in the upper small intestine and nonsaturable ones that predominate in the ileum ([38]). Luminal binding proteins appear not to be involved. The saturable process allows absorption of all forms of folate, usually after polyglutamated forms are hydrolyzed to monoglutamated ones by glutamate carboxypeptidase, a zinc-dependent enzyme with a pH optimum of 5.5 in the jejunal brush borders. Saturable absorption is mediated largely by the reduced folate carrier (RFC) that has high affinity for reduced folates and is in the brush border membrane of the more mature intestinal cells ([39], [40]). Conversion to methylTHF tends to occur in the intestinal cell, which then exports it into the blood via carrier-mediated basolateral membrane transport. Folate appears in the blood soon after ingestion, with peak levels at 1 hour. The nonsaturable process allows the absorption of large, linearly proportional fractions of the folate presented to the ileum. The mechanism assumes a dominant role whenever more than 200 µg of

folate, which exceeds the capacity of the jejunal process, is ingested. Such absorption probably explains why oral folic acid is effective even when the specific jejunal mechanisms fail in some malabsorptive disorders. The monoglutamic folic acid also does not require hydrolysis and often enters the bloodstream both as a monoglutamate and unreduced.

Folate Binders and Receptors The roles of many of the specific and nonspecific folate binders, which do not appear to be required as facilitators of cellular uptake of folate, are incompletely understood. Specific binding proteins in the blood bind only a small fraction of circulating folate. Secretions, especially milk, also contain specific binding protein whose role is unclear but may withhold folate from bacteria. The previously mentioned RFC is a 58-kd protein whose complementary DNA (cDNA) has been cloned and the gene for which is on chromosome 21q22. RFC transports reduced folates into cells; it also transports the antifol, methotrexate. RFC participates in folate uptake not only in intestinal cells but also in the brain, liver, and heart. Specific, partially homologous folate receptors, folate receptor-a (FR-a) and FR-ß, are found in epithelial cells, hematopoietic cells, renal tubular cells, and placenta ([39], [40] and [41]). Their cDNAs have been cloned, and four related genes and pseudogenes have been localized to chromosome 11q13. These receptors are covalently linked to glycosylphosphatidyl inositol anchors on the membrane, bind and internalize methylTHF by endocytosis via clathrin-coated pits, and are recycled ([42], [43]). The roles of the folate receptor isoforms, which have slightly different affinities for folates, are not known. Folate receptors may also have potential roles in chemotherapy because of their expression in malignant cells and involvement in the uptake of antifols as well as folates. FR-a also serves as a cofactor for entry of Marburg and Ebola viruses into cells ([44]). Some folate receptor is found intracellularly, and some circulating folate-binding proteins appear to derive from folate receptor. The subject of folate binders and receptors has been reviewed ([39], [40]).

Folate Transport and Cellular Utilization Dietary folate and reabsorbed biliary folate enter the bloodstream and are rapidly cleared to tissues ([45]). The flux probably explains why serum folate declines within 3 weeks when intake is reduced ([12]). Most circulating folate is methylTHF. It is bound nonspecifically and with low affinity to proteins such as albumin, approximately one-third circulates unbound, and a tiny fraction is bound specifically by cell membrane–derived folate-binding protein ([46]). None of the circulating proteins play any obvious role in cell uptake of folates. Cellular uptake of monoglutamated folate occurs via either folate receptor or RFC in the cell membrane, the details varying among different cell types and conditions ([39], [40]). Passive diffusion also occurs. Inside the cell, folates are rapidly polyglutamated by cytosolic folylpoly-?-glutamate synthetase, which permits their retention and promotes attachment to enzymes. The folate is transported by poorly understood saturable mechanisms into organelles; 35% of intracellular folate is in mitochondria. The distribution and roles of intracellular folates have been reviewed ([23]).

Folate Stores and Turnover Extrapolations from a depletion study suggest that body stores of folate can be depleted in a few months to levels that do not support normal hematopoiesis ([12]). However, specific numbers are scarce, and the rate of depletion is unlikely to be linear. Old data suggest that normal liver folate content exceeds 7.5 mg ([47]). The liver concentrates much of the body's folate and is a major site of one-carbon metabolism. Several folate pools exist, with different turnover rates ranging up to 100 days ([48]); the exchange among them is not well defined. Enterohepatic recycling occurs on a large scale ([45]). Approximately 200 µg of folate is excreted fecally every day. However, in addition to reflecting loss of body folate via sloughed intestinal cells and nonreabsorbed biliary folate, part of that does not really involve the body folate economy because it is unabsorbed food folate and folate synthesized by intestinal bacteria ([48]). Folate is also filtered in the glomerulus and reabsorbed and conserved in the tubules by a carrier-mediated process, but some is secreted by tubular cells as well. Oxidatively degraded folate ([49]) is also lost, primarily in urine. The relative proportions of urinary and fecal avenues of loss are unclear.

Normal Cobalamin Physiology

NUTRITIONAL CHARACTERISTICS Humans obtain cobalamin third-hand, either by eating animals that have ingested the bacteria that synthesize cobalamin or by eating animal produce, such as milk, cheese, or eggs. The more prodigious bacteria ingestors, such as ruminants and oysters, are rich sources. Plants do not contain cobalamin. Bioavailability varies with different foods. Cereals, fortified with cobalamin, and dairy products appear to be more effectively assimilated than are meats ([50]). Cobalamin supplement use, usually as part of a multivitamin, has grown ([51], [52] and [53]). The daily requirement of cobalamin has been increased recently to 2.4 µg in adults ([54]) and is predicated on normal absorption. A survey in 1995 indicated that typical daily intake of cobalamin in the United States is 4.0 to 6.2 µg ([55]). An informative comparison is that this is only 1% of the amount of folate required daily, even though body stores of the two vitamins are nearly equal.

PHYSIOLOGIC CYCLE OF ASSIMILATION Intestinal absorption and cellular uptake by tissues (Fig. 43.4) are designed to internalize and concentrate available cobalamin while excluding possibly harmful nonfunctional analogs. The process is tightly regulated by a complex system of binding proteins and specific receptors ([56]). Excess cobalamin above the limits of the capacity of IF is poorly absorbed ([57]), unlike free folic acid. IF mediates the absorption of more than 75% of a small cobalamin load in a meal or supplement but can accommodate little more than a total of 1 to 2 µg at a time ([47]).

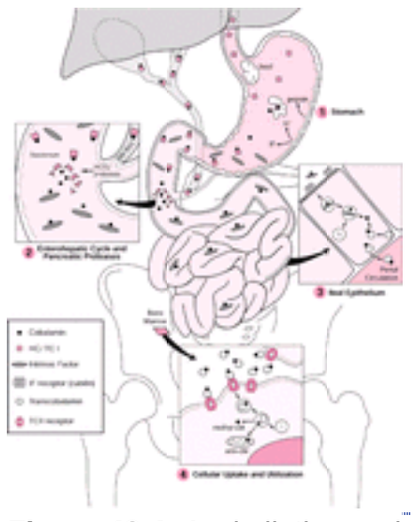

Figure 43.4. Assimilation and utilization of cobalamin. ado-cbl, adenosylcobalamin; HC/TC I, haptocorrin/transcobalamin I; IF, intrinsic factor; methyl-cbl, methylcobalamin. (From Carmel R. Cobalamin deficiency. In: Carmel R, Jacobsen DW, eds. Homocysteine in health and disease. Cambridge, UK: Cambridge University Press, 2001:289–305, with permission.)

Cobalamin-Binding Proteins Three proteins with nonoverlapping roles bind cobalamin ([56], [58], [59]) (Table 43.1). IF and TC II (sometimes called simply *TC*) each have specific cell membrane receptors, via which they transport cobalamin into cells by endocytosis. They have different distributions in the body. Parietal cell–derived IF is localized to the gut, whereas TC II, which is synthesized by endothelial, ileal, and other cells ([60], [61] and [62]), is found in plasma and other fluids. IF is highly specific for cobalamin and does not bind nonfunctional analogs ([24]). The structures of both proteins have been elucidated and their cDNA sequenced ([63], [64]). The two genes show considerable homology ([64], [65]) but are localized to different chromosomes: 11q12-q13 for IF and 22q11.2-qter for TC II ([63], [66]). A single-nucleotide polymorphism of the TC II gene has been identified ([67]), but its functional effect is unclear. Levels of TC II in plasma tend to rise in inflammatory and other disorders, suggesting an acute phase reactant character ([58], [68], [69]), but holo-TC II (TC II that is carrying cobalamin) is also cleared quickly from the plasma ([70]).

TABLE 43.1. Cobalamin-Binding Proteins

	Intrinsic Factor	TC II	Haptocorrin; TC I
Cbl-related role	Promotes ileal uptake	Promotes cell uptake	Unknown (carries Cbl in blood; initial binder of Cbl in stomach)
Cbl binding	Highly specific	Intermediate specificity	Also binds nonfunctional analogs
Receptors	Cubilin (ileal epithelium)	All cells	None identified [a]
Cell of origin	Gastric parietal cell	Endothelial cell; fibroblast; ileal cell; ?hepatocyte	Neutrophil; exocrine epithelium
Distribution	Gastrointestinal tract	Plasma, cerebrospinal fluid, semen	Plasma, secretions
Protein structure	48-kd glycoprotein	43-kd peptide chain	66-kd glycoprotein
Consequence of binder deficiency	Cbl malabsorption	Severe cellular Cbl deficiency	Low serum Cbl level without Cbl deficiency

Cbl, cobalamin; TC, transcobalamin.

[a] Nonspecific clearance of desialylated TC I by asialoglycoprotein receptors may occur in the liver.
Modified from Carmel R. Cobalamin deficiency. In: Carmel R, Jacobsen DW, eds. Homocysteine in health and disease. Cambridge, UK: Cambridge University Press, 2001:289–305.

Haptocorrin (HC) or TC I (also called *R binder* and *cobalophilin*; HC/TC I is the abbreviation used here) refers to a family of immunologically identical glycoproteins ([58]). They vary in carbohydrate residues, however, which gives them slightly different physicochemical characteristics and has led to probably unjustified distinctions between TC I and "TC III" subsets in the blood. The HC/TC I gene, found on chromosome 11p11.11-q11, has limited homology to IF and TC II ([65], [71]). HC/TC I is synthesized in specific granules of late myeloid precursors ([72]) and probably in exocrine gland epithelium. The concentration in plasma approaches that of TC II, but HC/TC I predominates in secretions, such as saliva, bile, and breast milk ([58]). Although its binding of cobalamin is avid and most circulating cobalamin is carried by it, the role of HC/TC I in cobalamin metabolism is unknown. HC/TC I–cobalamin is cleared nonspecifically by hepatic receptors for asialoglycoprotein ([73]). Several minor, unrelated cobalamin-binding proteins have also been described in plasma, but their roles are unknown ([58], [74]).

Cobalamin Absorption Cobalamin is released from binding proteins in food by pepsin at an acid pH in the stomach and is then bound by salivary HC/TC I (Fig. 43.4; panel 1). In the duodenum, pancreatic secretions neutralize the pH and provide proteases that degrade HC/TC I ([75]). The released cobalamin, including biliary cobalamin ([25]), becomes available for binding to IF (panel 2). The IF-cobalamin complex later attaches to cubilin receptors for IF in the ileum (panel 3). Cubilin is a 460-kd glycoprotein that lacks a transmembrane domain but is internalized by association with the 600-kd transmembrane protein, megalin ([76]). As reviewed elsewhere ([77]), cubilin and megalin are widely expressed, especially in renal tubules and yolk sac, which have heavy endocytotic traffic. After endocytosis ([56]), the cubilin-IF-cobalamin complex is split. The cobalamin binds to TC II, and the holo-TC II exits basolaterally from the ileal cell. The emergence of cobalamin into the bloodstream occurs several hours after its ingestion.

Plasma Transport and Cellular Utilization After passing from portal blood to the liver, some of the cobalamin is internalized by hepatocytes via TC II receptors; as a result, the holo-TC II fraction is smaller in hepatic vein and peripheral blood than in portal blood ([25], [78]). Clearance of holo-TC II to tissues continues in the systemic circulation, much of it occurring in the kidney, which is rich in cobalamin. Proximal renal tubules are rich in TC II receptors, one of which appears to be megalin ([79]). Because of the continuous uptake by tissues, the half-life of holo-TC II is brief, estimated at 90 minutes ([70]). The HC/TC I–cobalamin complex is not taken up by tissues and circulates with a half life of 9 to 10 days ([70]). Therefore, 70% or more of cobalamin in the plasma is attached to HC/TC I ([78], [80], [81] and [82]), but this varies widely in different conditions ([78]). Endocytosis of holo-TC II occurs via specific receptors for TC II (Fig. 43.4; panel 4), although there may be more than one class of receptors ([56], [79]). After lysosomal degradation of TC II, cobalamin is released to the cytoplasm for attachment to methionine synthase and conversion to methylcobalamin. Cobalamin also enters mitochondria and is converted to adenosylcobalamin. The cellular uptake of holo-TC II has been reviewed ([83]).

Body Stores and Turnover The total body content of cobalamin approximates 2.5 mg in adults ([84]) and is well conserved. Only approximately 1 µg is lost daily. Some of the loss is by biliary excretion, although most biliary cobalamin is reabsorbed via the IF mechanism ([25]). A small amount escapes renal tubular reabsorption and is lost in urine. The body stores to daily requirement ratio approximates 1000:1, taking into account the recommended excess intake to accommodate the restricted absorption.

CLINICAL AND LABORATORY FEATURES

The hematologic consequences are identical in folate and cobalamin deficiency. Similarities also exist in other clinical expressions of the two vitamin deficiencies, with the notable exception of neurologic dysfunction. Some clinical variance is influenced by the ways in which the deficiencies arise. Folate deficiency has a rapid evolution, measured in weeks or months; its broad dietary origins and association with other deficiencies and with alcohol abuse can also make attribution of some reported findings to the folate deficiency uncertain. Cobalamin deficiency, on the other hand, has a slow onset often measured in years but tends to be a purer deficiency state because of the usual specificity of cobalamin malabsorption.

Megaloblastic Anemia in Cobalamin and Folate Deficiency

BIOCHEMISTRY MethyleneTHF is needed for the methylation of deoxyuridylate to deoxythymidylate (Fig. 43.2; reaction 2). Deficiency of folate compromises this reaction directly, and deficiency of cobalamin does so indirectly, as described earlier. However, impaired *de novo* thymidylate synthesis only partially explains megaloblastic anemia. Observations in nonanemic patients with cobalamin deficiency ([85], [86], [87] and [88]) and animal models ([89]) show that thymidylate synthase impairment need not lead to anemia. Other DNA processes become defective ([90]). Excess uracil from deoxyuridylate is misincorporated into DNA in place of thymine ([91], [92]). Active excision repair produces many single-strand breaks. However, when excision coincides at opposing DNA strand sites, double-stranded breaks result, and this DNA damage may explain the nuclear defects of megaloblastic anemia. The end result appears to be an arrest at various stages of interphase in hematopoietic precursors ([93]). The role of apoptosis is controversial ([93], [94] and [95]). It is noteworthy that an identical anemia is seen in patients with hereditary thiamine-responsive megaloblastic anemia and with antipurine drugs, neither of which reflects cobalamin or folate deficiency.

HEMATOPATHOLOGY Megaloblastic anemia is a panmyelosis, even though the terminology suggests a disorder limited to red cells and erythroid hyperplasia is prominent in the bone marrow. Indeed, the immature appearance of megaloblastic nuclei and occasionally intense myeloid proliferation in the marrow have led to a misdiagnosis of leukemia in rare cases ([96]). The morphologic hallmark is nuclear-cytoplasmic dissociation, which is best appreciated in precursor cells in the bone marrow aspirate (Fig. 43.5). Megaloblastic nuclei are larger than in comparable normoblastic cells, and nuclear chromatin appears abnormally dispersed due to its retarded condensation. Random chromosomal abnormalities are seen, including centromere spreading ([97]), but nonrandom changes may also occur ([98], [99]). Cytoplasmic maturation and appearance are unremarkable.

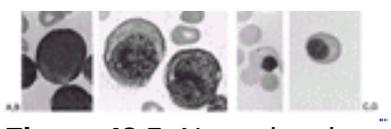

Figure 43.5. Normal and megaloblastic precursor cells in the bone marrow. **A:** Pronormoblast. **B:** Megaloblastic equivalent of cell in **A**. **C:** Late normoblast. **D:** Megaloblastic equivalent of cell in **C**. See Color Plate. (From Lee RG, Foerster J, Lukens J, et al., eds. Wintrobe's clinical hematology, 10th ed. Philadelphia: Lippincott Williams & Wilkins, 1999: 913, with permission.)

Giant band cells and metamyelocytes with unusually large and often misshapen nuclei are typically seen. Neutrophils with hypersegmented nuclei are characteristic in the blood (Fig. 43.6), although they do not arise from the giant metamyelocytes ([90]). The mechanism of hypersegmentation is unknown as is the explanation for its persistence in the blood for a week or longer after therapy ([100]). Although platelets are often functionally impaired ([101], [102]), megakaryocytes do not show definable morphologic changes. Neither do lymphocytes, although biochemical and functional changes have been reported ([103]).

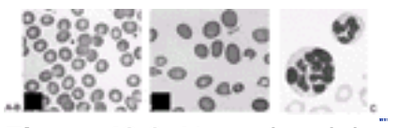

Figure 43.6. Normal peripheral blood cells compared with megaloblastic cells. Normal red blood cells **(A)**; macroovalocytic red blood cells with poikilocytosis **(B)**; and a normal neutrophil with a larger, hypersegmented one below it **(C)**. See Color Plate. (From Lee RG, Foerster J, Lukens J, et al., eds. Wintrobe's clinical hematology, 10th ed. Philadelphia: Lippincott Williams & Wilkins, 1999: 910, 1895, with permission.)

Macrocytosis of red blood cells (Fig. 43.6) occurs early in the peripheral blood and increases progressively. Individual macrocytes appear first, followed by a gradual rise in mean corpuscular volume (MCV) that eventually crosses the line into abnormality (>97 fl), long before the hemoglobin and packed cell volume levels fall ([12]). In the case of cobalamin deficiency, with its slow progression, macrocytosis precedes anemia by months ([17], [18]). Macroovalocytes are especially characteristic of megaloblastic anemia but are not specific ([104]). Early megaloblastic changes in the bone marrow precede the macrocytosis ([12], [105]) but tend to be mild and are easily missed. As anemia advances, poikilocytosis becomes more pronounced with teardrop cells. Eventually, nucleated red cells, Howell-Jolly bodies, and even Cabot rings appear in the blood. Receding macrocytosis has been reported in very severe anemia, presumably caused by increasing poikilocytosis and fragmentation ([106]). As anemia progresses, iron levels, sideroblast counts, and the ferritin content of erythroid precursors and macrophages increase ([47], [107]). Neutrophils develop hypersegmented nuclei very early in the course ([12], [108]). As megaloblastic anemia progresses, neutropenia may develop and, in severe cases, can be striking. This is even more true of thrombocytopenia. As reviewed elsewhere ([47], [90], [93]), the functional pathophysiology of megaloblastic anemia is ineffective hematopoiesis in all three hematopoietic cell lines. Many of the precursor cells are arrested at various stages in interphase but continue to mature. When the process is advanced, most of

the precursors within the hypercellular bone marrow die and are phagocytosed. Whether early cell death is primarily apoptotic or not is controversial ([93], [109], [110]) and may depend on the model studied. Reticulocytosis does not occur. Advanced anemia also has a poorly understood component of intravascular hemolysis, and survival is short for normal red cells transfused into cobalamin-deficient patients ([111]). Low serum glutathione has been reported as the most significant metabolic predictor of anemia in cobalamin deficiency ([112]). Abnormalities of erythrocyte membrane proteins, including spectrin, have also been described ([113]). The evolution of hematologic changes has been detailed elsewhere ([47]). With progressive anemia also come hyper-volemia, cardiovascular symptoms, pallor combined with hyperbilirubinemia that gives a classic lemon yellow skin color, and even retinal hemorrhages and, on occasion, pseudotumor cerebri. Erythropoietin levels correlate with severity of anemia, but variations can be wide ([114]).

Neurologic Dysfunction

COBALAMIN DEFICIENCY

Pathophysiology Demyelination with subsequent axonal disruption and gliosis can affect all parts of the central nervous system. Peripheral nerves, however, tend to show axonal degeneration without demyelination ([115], [116]). The classic myelopathic syndrome is subacute combined degeneration, in which posterior and lateral column damage predominates; dorsal, pyramidal, and spinocerebellar tracts are affected. The earliest changes are in the cervical or thoracic spine and can be detected by magnetic resonance imaging (Fig. 43.7). Larger, more heavily myelinated fibers tend to be affected most often ([117]).

Figure 43.7. Magnetic resonance imaging (T2 weighted) of a sagittal section of the cervical spine of a man with pernicious anemia and severe myelopathy. Note the posterior localization of the high signal intensity lesion (arrow). (From Larner AJ, Zeman AZ, Allen CMC, et al. MRI appearances in subacute combined degeneration of the spinal cord due to vitamin B_{12} deficiency. J Neurol Neurosurg Psychiatry 1997;62:99–101, with permission.)

The biochemical mechanisms are unknown, however. Because neurologic involvement is much more prominent in cobalamin deficiency than in folate deficiency, suspicion fell first on the role of adenosylcobalamin in propionate metabolism, with possible consequences to fatty acids in myelin. Most evidence, reviewed elsewhere ([118], [119]), now points to methio-nine synthase impairment and its effects on methionine metabolism instead. Animal data suggested that methionine ameliorates cobalamin deficiency–induced neurologic dysfunction; preliminary cerebrospinal fluid studies in humans described low AdoMet levels; and high AdoHcy to AdoMet ratios suggested inhibition of AdoMet's methylation activity by AdoHcy. A comparison of serum metabolite levels in patients with pernicious anemia suggests an even more complex picture ([112]). Unexpectedly, AdoMet levels were higher in neurologically impaired patients than in neurologically intact patients. Higher cysteine levels in neurologically affected patients were the most significant of the many differences found in both the transsulfuration and remethylation pathways of homocysteine metabolism. Moreover, neurologically impaired patients had significantly higher serum folate levels than those without neurologic problems ([112], [120], [121]). It is unclear if these changes represent cause or effect.

Clinical Features The frequency of neurologic involvement in cobalamin deficiency is not known. Often regarded as a later development than anemia, neurologic changes can precede anemia ([122], [123] and [124]). Anemia may be absent in as many as 28% of cases of neurologic dysfunction ([123]). However, very mild hematologic changes are often found with careful search. Interestingly, the presence and severity of neurologic and hematologic expressions of cobalamin deficiency tend to be inversely related to each other in patients ([120], [124]). Moreover, patients in whom one manifestation predominates tend to reexpress it if cobalamin deficiency relapses ([124], [125] and [126]). Neuromyelopathic symptoms are the most common neurologic features of cobalamin deficiency ([117], [124], [127], [128] and [129]). Sensory findings include position sense disturbance and dysesthesia; pyramidal tract signs include spasticity and the Babinski reflex; neuropathy is exemplified by loss of tendon reflexes; and gait disturbances are common signs of advanced involvement. A general symmetricalness of manifestations is a hallmark. Neuropathy, which is usually sensory but can be sensorimotor ([130]), and posterior column damage are often hard to differentiate clinically ([124], [127], [131]). Sometimes, the reversal of neuropathy early in therapy unmasks myelopathic findings, which may be mistaken for deterioration. The earliest manifestations are loss of vibratory sense in the feet and numbness, tingling, and loss of fine sensation. Others include loss of proprioception and, depending on the balance between myelopathy and neuropathy, hyperactive or diminished deep tendon reflexes. Involvement ascends up the legs, and, eventually, hands are affected as well. Muscle weakness and tenderness may be seen but are unexplained. Ataxia, spasticity, gait disturbances, positive Babinski reflex, impotence, and loss of bladder and bowel control are found in advanced cases. Cerebral symptoms, notably cognitive and emotional changes, can be severe ([123], [124]), or they can be so mild as to be recognized only in retrospect after therapeutic improvement. As with myelopathy, demyelinative changes in the brain can be detected by magnetic resonance imaging ([132]) (Fig. 43.8). Chronic dementias, such as Alzheimer disease, appear unrelated to cobalamin deficiency and do not improve with cobalamin therapy ([133]), even though cobalamin levels are low in 10 to 20% of affected patients ([87], [134], [135]). In young children, developmental delay, lethargy, cerebral atrophy, and seizures may occur.

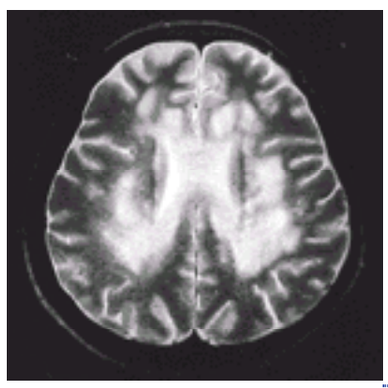

Figure 43.8. Magnetic resonance imaging (T2 weighted) of the brain in a woman with pernicious anemia and cognitive dysfunction. Large confluent and focal areas of increased signal intensities are seen, predominating around the ventricles. The changes improved after therapy. (From Stojsavljevic N, Levic Z, Drulovic J, et al. A 44-month clinical-brain MRI follow-up in a patient with B_{12} deficiency. Neurology 1997;49:878–881, with permission.)

Other manifestations include visual changes ([124], [136]), optic neuritis, which predominates in men ([124]), disturbances of smell or taste, and autonomic dysfunction ([115], [137]). Classic motor dysfunction is rare, other than that caused by spasticity and proprioceptive loss, although abnormal central motor conduction times have been described ([130]). At early or late stages, demyelination can be documented by magnetic resonance imaging ([130], [132], [138], [139]) (Fig. 43.7 and Fig. 43.8) and functional changes by electrophysiologic tests of evoked potentials, nerve conduction, and electroencephalography ([130], [140], [141], [142] and [143]). Changes and their reversal were first identified electrophysiologically in the asymptomatic, preclinical deficiency state in some studies ([88], [133], [144]) but not others ([145]). Unlike anemia, neurologic dysfunction does not always respond to cobalamin therapy. Poor response is not always predictable but tends to be associated with more extensive involvement and longer duration before treatment begins ([127], [128]). Mistaken folate therapy has also been tied to this problem sometimes. The reason is presumed to be the delayed recognition of cobalamin deficiency that can result when its anemia responds to folate. The folate therapy thus allows neurologic abnormalities to appear, progress, and, in occasional reports ([146]), perhaps even to accelerate. Although folate should never be given alone to cobalamin-deficient patients, the events it sets in motion are more ambiguous than usually assumed: transient neurologic responses to folate actually occur in some cases ([147]), and hematologic improvement is usually neither complete nor long lived ([146], [147]).

FOLATE DEFICIENCY Neurologic dysfunction has been reported infrequently in adults with folate deficiency ([148], [149], [150] and [151]) and is rarely as severe as in cobalamin deficiency. Although myelopathy has been reported ([151]), mild mental changes, such as forgetfulness and irritability, and mild neuropathy have been better

accepted. A causative association with depression is controversial ([152], [153]). As noted earlier, attribution of neurologic changes to folate deficiency must be cautious until alternative explanations such as alcohol or thiamine deficiency have been considered. Nevertheless, children with inborn errors of folate metabolism often have severe myelopathy and brain dysfunction ([154], [155], [156] and [157]). The explanations for these neurologic differences between folate and cobalamin deficiency and between acquired and hereditary disorders are unknown.

Other Clinical and Laboratory Manifestations

MISCELLANEOUS CLINICAL FINDINGS Atrophy of tongue papillae is common with cobalamin deficiency and sometimes gives rise to a beefy red tongue that may or may not be symptomatic ([47], [158]). Aphthous stomatitis and oral soreness can be prominent in some patients, including some without anemia. However, oral and tongue changes occur with other deficiency states also. The glossitis of cobalamin deficiency does not respond to folate ([159]). Mucosal changes occur everywhere ([47]). Megaloblastic changes have been shown in buccal epithelium, cervical cells, and intestinal villi ([160], [161] and [162]). Reversible intestinal absorptive defects affecting various nutrients and substances have also been described ([162], [163] and [164]). Reversible weight loss of uncertain cause ([165]) and anorexia occur in pernicious anemia, presumably as a result of cobalamin deficiency. Reversible signs of impaired osteoblastic activity are common in cobalamin deficiency ([166]), but studies of bone density and fractures have not shown consistent clinical findings. Reversible splenomegaly and fever have been reported ([47]) but should be attributed to cobalamin deficiency only after exclusion of other explanations. Sporadic, reversible cases of infertility have been described. Reversible darkening of nails and skin and change of hair color are sometimes seen in blacks, south Asians, and Latin-Americans with cobalamin or folate deficiency ([167], [168] and [169]).

MISCELLANEOUS LABORATORY ABNORMALITIES Platelet function is sometimes impaired, and rebound hyperfunction may occur transiently after therapy ([101], [102]). Neutrophil dysfunction has been variable ([170]). Neutrophil myeloperoxidase and platelet monoamine oxidase contents are increased ([171], [172]). Cobalamin deficiency also produces reversible changes in blood analytes that, unlike lactate dehydrogenase, bilirubin, and iron-related changes, are not directly related to the anemia: Serum alkaline phosphatase is often decreased ([166]); cholesterol falls, whereas triglyceride and free fatty acid levels rise ([47], [173]); immunoglobulin levels sometimes decline ([174], [175]); and hemoglobin A_2 levels tend to rise slightly ([176], [177]). Occasional patients with sickle cell trait have shown striking changes in hemoglobin S and F levels when folate deficient ([178], [179]).

ASYMPTOMATIC (SUBCLINICAL) DEFICIENCY Sensitive metabolic tests have permitted recognition and better understanding of the early stages of vitamin deficiency.

Subclinical Cobalamin Deficiency Many patients and healthy people have low cobalamin levels but are asymptomatic and have normal blood counts. The low cobalamin levels had been thought artifactual, but, as reviewed elsewhere ([180], [181]), mild cellular cobalamin insufficiency exists in 60 to 70% of such people ([88], [182], [183] and [184]) and is reversible with cobalamin therapy ([185]). Such asymptomatic people are said to have subclinical deficiency, although some may also have electrophysiologic abnormalities that improve with therapy ([133], [144]). The number has grown further with the documentation of abnormal homocysteine and methylmalonic acid (MMA) levels in some asymptomatic people with low-normal cobalamin levels ([182]). This massive influx has revolutionized the concept of cobalamin deficiency but also introduced quandaries about cobalamin levels. It is important to remember that 30 to 40% of people with low cobalamin levels (<250 ng/L) and nearly 70% of those with low-normal levels (250 to 350 ng/L) are metabolically normal. A small proportion of people with subclinical deficiency have early pernicious anemia ([186]). They, and others with malabsorption of free cobalamin identifiable by the Schilling test, can be expected to progress to clinical deficiency eventually. However, the course in the many remaining cases is unknown. An older and limited study reported that they remain free of symptoms and anemia for at least 10 years, even though their cobalamin levels remain low ([187]). The elderly are at increased risk for both clinically expressed and subclinical cobalamin deficiency ([180], [188], [189]). Most studies estimate that approximately 10% of the elderly are affected. The frequency of low cobalamin levels increases from 8% of 65- to 75-year-old people to 20% of those 80 years of age or older, whereas low folate levels are found in only 1% of both those age subgroups ([190]).

Subclinical Folate Deficiency Subclinical folate deficiency and its mechanisms have been less explicitly defined than subclinical cobalamin deficiency. The reasons include the fact that folate status is regulated largely by dietary intake variations ([191]) and thus fluctuates more readily. The question has also been subsumed by a focus on the hyperhomocysteinemia that is its identifying metabolic feature. The chief importance of subclinical folate deficiency may reside in its potential influence on the several issues that are discussed next.

Vitamin Status as Risk Factor Folate supplementation reduces a woman's risk of having a child with a neural tube defect ([192], [193]) but must be taken at conception because the neural tube closes at approximately day 18. Doses of 400 µg are effective, with 4 mg recommended for women with risk factors such as a history of previous neural tube defects or anticonvulsant use. Because many women are unaware of their pregnancy in its first few weeks and because compliance with advised supplementation is always spotty, all grain and cereal foods are now fortified with folic acid. The debate continues about potential side effects of the increased folate intake on the elderly and others with unrecognized cobalamin deficiency ([194], [195]). The explanation for the preventive effect of folic acid is unknown, almost certainly variable, and often multifactorial. Neural tube defects are rarely due to acquired folate deficiency. It is likely that genetic susceptibilities to abnormal metabolism of folate, cobalamin, or homocysteine (or all three) underlie the risk. Epidemiologic data have suggested possible associations with folate status in other birth defects also ([196]). Altered folate status may increase the risk of cancer in some people. Proposed mechanisms include folate's direct role in thymidylate synthesis and indirect role in generating AdoMet, which is needed for DNA methylation ([197], [198]). The data are inconsistent, but the most suggestive evidence has been associated with colon cancer ([199]). Interestingly, men with mildly impaired activity of methyleneTHF reductase due to the common 677C>T mutation of its gene have a diminished risk for colon cancer ([200]). Cervical atypia may also be increased in women with limited folate status, perhaps especially those with papillomavirus infection ([201]).

HYPERHOMOCYSTEINEMIA Extrapolation from inborn errors of homocysteine metabolism suggested that severe hyperhomocysteinemia is associated with severe thrombotic manifestations ([202]). Considerable epidemiologic data, reviewed elsewhere ([203]), indicate that even mild elevations of homocysteine carry increased risks for coronary, cerebral, and peripheral vascular complications. Mild homocysteine elevations are often reversible by folate, cobalamin, and sometimes vitamin B_6 ([204]), even if evidence of vitamin deficiency is absent, which suggests pharmacologic or epigenetic effects in many cases. As a result, folate or multivitamins are often prescribed to bring homocysteine levels down. Closer scrutiny showed that the associations were less firm in prospective, rigorously designed studies than in retrospective or less rigorous ones ([203], [205], [206] and [207]). The results of large interventional trials of lowering homocysteine levels are not available yet, but a decreased risk of postangioplasty restenosis was found in a small, randomized supplementation study ([208]). As mentioned earlier, mild hyperhomocysteinemia is also associated with neural tube defects, other birth defects, and fetal loss ([196]). The mechanisms underlying these associations and the benefits of lowering homocysteine levels remain unclear. A role for homocysteine in cognitive dysfunction in the elderly, independent of cobalamin, has also been proposed ([209]) but may reflect increased cerebrovascular events ([210]).

Laboratory Evaluation

Laboratory evaluation has two separate targets. The diagnostic hematologic, metabolic, and clinical chemistry changes in the laboratory assessment of cobalamin and folate deficiency are discussed next. Laboratory testing for the conditions and diseases that cause the vitamin deficiencies are discussed in Laboratory Diagnosis of the Causes of Deficiency.

HEMATOLOGIC ASSESSMENT The classic blood count findings in cobalamin deficiency are anemia, a high MCV and mean corpuscular hemoglobin (MCH), and, in more advanced cases, thrombocytopenia and neutropenia. In folate deficiency, the findings may be admixed with those of coexisting problems such as alcohol abuse. Patients are often identifiable at an early stage in which they have only MCV and MCH elevation; indeed, sometimes they can be identified with an MCV and MCH that are higher than their previous levels but still within the reference range (e.g., an MCV of 90 fl replacing one of 85 fl). An early anisocytosis as new macrocytic cells begin to emerge is occasionally detectable by an elevated red cell distribution width, but a high red cell distribution width is not invariable ([211]). This slow progression can precede anemia by many months in cobalamin deficiency but only by a few weeks in folate deficiency. Red cell counts fall before hemoglobin and packed cell volume levels. Megaloblastic anemia is not the only cause of macrocytic anemia, however, or even the most common (Table 43.2). A recent study found 63.6% of MCV values greater than 100 fl in one hospital to be due to chemotherapy, antiretroviral therapy, or alcohol abuse ([104]). Cobalamin and folate deficiencies accounted for only 6.3% of the high values but accounted for most MCV values above 110 fl. Experience may vary in other hospitals and in outpatients. A survey of MCV values above 90 fl in a pediatric center found no cases of cobalamin or folate deficiency ([212]), but it was not clear how carefully those diagnoses were sought.

TABLE 43.2. Causes of Macrocytosis, Defined as Mean Corpuscular Volume (MCV) Greater Than 97 fl [a]

Causes	Likelihood of Severe Macrocytosis (MCV >110 fl)
Megaloblastic anemia	

Cobalamin or folate deficiency	High
Other metabolic disorders (e.g., thiamine responsive)	High
Cytotoxic drugs	High
Immunosuppressive drugs	High
Alcohol	
Without liver disease	Low
With liver disease	High
Drugs	
Antiviral drugs	High
Anticonvulsant drugs	Low
Disorders of red cell production	
Aplastic anemia; pure red cell aplasia	High
Myelodysplastic syndromes	High
Myeloproliferative disease; leukemia	Low
Sideroblastic anemia (hereditary or acquired)	Low
Reticulocytosis	
Hemolytic anemia	High
Nonhematologic disease	
Liver disease (alcohol unrelated)	High
Hypothyroidism	Low
Physiologic	
Red cells are enlarged in the first 4 wk of life	Low
Idiopathic	
Pregnancy	Low
Chronic lung disease, smoking	Low
Cancer	Low
Multiple myeloma	Low
Artifact of electronic cell sizing	
Cold agglutinins	High
Severe hyperglycemia	High
Hyponatremia	?
Stored blood	?
Warm antibody to red blood cells	?

[a] Macrocytosis can also be diagnosed when an MCV is not yet >97 fl but is higher than usual for the patient. The second column in the table also estimates how often macrocytosis can be severe (>110 fl).

Reticulocyte counts never rise and may fall slightly. The serum lactate dehydrogenase and indirect bilirubin levels begin to rise only as anemia advances, usually when the hemoglobin falls below 10 g/dl (47). The laboratory signs of ineffective erythropoiesis and hemolysis include not only lactate dehydrogenase levels that can eventually reach thousands of units/L and hyperbilirubinemia but also high serum transferrin receptor (213), iron, ferritin, nontransferrin bound iron (214), and methemalbumin levels (215) and low serum haptoglobin levels (215). As anemia progresses, platelet and neutrophil counts start to decline and can become very low in severe megaloblastic anemia. The pancytopenia can ultimately mimic aplastic anemia, which is also usually macrocytic but does not feature the hyperbilirubinemia and lactate dehydrogenase elevation. Most of the variability in the hematologic picture is dictated by the stage at which the patient is discovered (47). However, other influences also affect the pattern. Patients with coexisting iron deficiency display dimorphic red cell patterns. They and patients with thalassemia may have normal or low MCV, which fall further when vitamin therapy is given (216). Iron deficiency sometimes blunts the erythroid megaloblastic changes themselves, both morphologically and by deoxyuridine suppression testing (217 , 218). Iron studies in untreated megaloblastic anemia often do not reveal the coexisting iron deficiency (47). Because those marrow and blood markers of iron status uniformly fall sharply within 24 to 48 hours of vitamin therapy, it may be advisable to wait several days after that for the tests to stabilize and reflect the patient's true iron status. Hypersegmentation of neutrophil nuclei is a constant feature but is variably defined (47). The most serviceable criteria are finding one or more neutrophils with six or more nuclear lobes or showing that at least 4 to 5% of neutrophils have five lobes. Calculating lobe averages is considered the gold standard but cannot rely on published reference ranges because interobserver variation is great. Hypersegmentation often precedes anemia (12 , 108), but it is not found in subclinical deficiency (219). The finding is also not specific for cobalamin or folate deficiency. Hypersegmented neutrophils are found in patients receiving chemotherapeutic drugs such as 5-fluorouracil or hydroxyurea, some patients receiving steroid therapy for immune thrombocytopenic purpura (220), rare patients with myelofibrosis or chronic myelogenous leukemia, and, perhaps, as a benign hereditary condition. Whether hypersegmentation is caused by iron deficiency or reflects a coexisting folate deficiency in such cases is controversial (221 , 222). A higher normal neutrophil segmentation has been reported in blacks than in whites (219). The above events mark most patients with megaloblastic anemia. Nevertheless, not every cobalamin-deficient patient expresses the same level of anemia for his or her level of deficiency. Many patients with severe deficiency have surprisingly mild anemia or even lack it. The explanations for blunted anemia are not always apparent, although there is a tendency for an inverse association of anemia with neurologic dysfunction (122 , 123).

LABORATORY ASSESSMENT OF DEFICIENCY Cobalamin and folate levels can be measured in serum and in cells. The original methods were microbiologic, exploiting the vitamin requirements of various microorganisms and including differential bacterial sensitivity to specific forms of folate (47). Although rarely used today, microbiologic assays provided the basis for our understanding of cobalamin levels (223 , 224) and remain the gold standard. They were replaced by radiodilution binding assays, which are now giving way to automated, chemiluminescence-based immunoassays. Technical ease has improved, but each methodologic changeover has been accompanied by diminishing documentation and validation (225 , 226). Metabolic tests are available to augment and clarify the vitamin levels, as summarized in Table 43.3 and reviewed elsewhere (225). However, these are not necessary in many cases, and no single test is conclusive for either cobalamin or folate deficiency. The metabolic tests are essential in the diagnosis of inborn errors of metabolism, however, in which vitamin levels are often normal. They are also useful in monitoring response of deficiency to therapy when necessary. Unlike vitamin levels, which rise instantly whether vitamin therapy was beneficial or not, metabolite levels do not change in the first few days, thus allowing delayed reassessment of the suspected diagnosis in early posttreatment specimens. More important, metabolite levels do not improve at all unless the therapy was effective.

TABLE 43.3. Biochemical Tests for the Diagnosis and Differentiation of Cobalamin and Folate Deficiencies

Test	Deficiency of		Ability to Discriminate between the Two Deficiencies
	Cobalamin	Folate	
Serum cobalamin [a]	?	N or ?	Fair to good
Serum folate [a]	N or ?	?	Very good
Red cell folate [a]	? or N	?	Poor
Serum methylmalonic acid [a]	?	N	Very good
Serum 2-methyl citric acid [b]	?	N	Good
Plasma homocysteine [a]	?	?	Poor
Plasma cystathionine [b]	?	?	Poor
Deoxyuridine suppression test [b]	Abnormal [c]	Abnormal [c]	Very good [c]

?, increased; ?, decreased; N, normal result.

[a] Test is available in clinical laboratories.

[b] Test is limited to research laboratories.

[c] The diagnostic discriminatory power arises from including testing with various vitamin additives *in vitro*. Folate-deficient cells show normal results after exposure to any form of folate (folic acid, methyltetrahydrofolate, formyltetrahydrofolate, and so forth) but not to cobalamin. Cobalamin-deficient cells respond to cobalamin and those forms of folate that bypass the methyltetrahydrofolate trap, such as folic acid or formyltetrahydrofolate; they do not respond to methyltetrahydrofolate. Modified from Zittoun J, Zittoun R. Modern clinical testing strategies in cobalamin and folate deficiency. Semin Hematol 1999;36:35–46.

Cobalamin Levels In cobalamin deficiency, serum cobalamin levels fall below the generally accepted cutpoint of 200 to 250 ng/L. (Note that publications often express values in pmol/L; 1 ng = 0.738 pmol.) The lower the level, the more likely is clinically noteworthy deficiency with symptoms and signs to exist ([223], [224]). However, not every level below 100 ng/L represents deficiency, whereas some patients with obvious deficiency have only mildly decreased cobalamin levels. Levels of 100 to 200 ng/L were reported in 27% of patients with pernicious anemia and levels of 200 to 250 ng/L in another 9% ([122]). Therefore, despite the poor positive predictive value of serum cobalamin levels when the clinical picture is not taken into account ([227]), all subnormal levels in patients suspected of deficiency require attention. As mentioned earlier, occasional patients with cobalamin deficiency, including a few with frank symptoms and signs of deficiency, have normal serum cobalamin levels for unknown reasons ([182], [228], [229]). Metabolic abnormalities compatible with deficiency are found in 30 to 35% of healthy elderly people with cobalamin levels of 250 to 350 ng/L, as summarized elsewhere ([230]). Raising the serum cobalamin cutpoint for deficiency to 350 ng/L has been suggested so as to encompass those cases ([51]). The controversy centers on the trade-off between identifying that 30 to 35% subset, consisting mostly of asymptomatic people with subclinical deficiency, and mislabeling as deficient the other 65 to 70% who are not deficient at all ([180], [181]). Moreover, neither abnormal homocysteine nor abnormal MMA levels alone are incontrovertible proof of deficiency, especially in patients whose cobalamin levels are normal. Causes of low cobalamin levels, including falsely low levels, are listed in Table 43.4. Serum cobalamin levels frequently fall in folate deficiency, becoming subnormal in approximately 10% of cases, and recover after folate therapy ([47]); such cases must be differentiated from combined deficiency of both vitamins. Cobalamin levels also decline as pregnancy progresses and can reach levels below 100 ng/L, recovering within days after delivery. Low levels occur in 35% of women in the third trimester ([231]). The explanation is unknown, and metabolic studies do not demonstrate evidence of deficiency ([231], [232]). Low cobalamin levels without evidence of deficiency also occur in patients with human immunodeficiency virus (HIV) infection ([233], [234] and [235]), multiple sclerosis ([236]), and multiple myeloma ([237]). Diagnostic dilemmas may be especially acute in HIV infection and multiple sclerosis, in which neurologic defects often resemble those of cobalamin deficiency.

TABLE 43.4. Causes of Low Serum Cobalamin Levels

Most common causes (in approximate descending order of frequency)
Inappropriately high reference range [a]
Subclinical (biochemical) cobalamin deficiency
Latent pernicious anemia or other malabsorptive disorders uncovered at early, presymptomatic stage
Atrophic gastritis
Strict vegetarianism
Other (e.g., elderly with causes not listed above)
Idiopathic
Clinical (symptomatic or anemic, or both) cobalamin deficiency
Pregnancy (second or third trimester)
Mild haptocorrin/transcobalamin I deficiency
Laboratory error or artifact
Other causes of undetermined or low frequency
Folate deficiency
Severe haptocorrin/transcobalamin I deficiency
Human immunodeficiency virus infection [a]
Anticonvulsant therapy [a]
Multiple myeloma [a]
Multiple sclerosis
Hairy cell leukemia
Aplastic anemia
Myelodysplasia
Paroxysmal nocturnal hemoglobinuria
Gaucher disease
Oral contraceptive use

[a] Evidence of true cobalamin deficiency or malabsorption has been found in only some cases in these categories.

Elevated cobalamin levels are more common than low levels in clinical practice ([82]). The most frequently identified association was renal failure ([82]), although low levels have also been reported in patients undergoing chronic high-flux hemodialysis ([238]). Cobalamin therapy must always be considered as a cause of high cobalamin levels. Consistent but infrequent causes include chronic myelogenous leukemia and acute promyelocytic leukemia, both accompanied by markedly increased HC/TC I levels ([58]). Patients with chronic myelogenous leukemia and coexisting pernicious anemia have falsely normal cobalamin levels ([239]). Other associations of high cobalamin and HC/TC I levels include some cases of metastatic cancer, often with leukemoid reactions or hepatic involvement, and hepatoma ([58]). Spontaneous or therapy-acquired autoantibody to TC II is a rare cause of elevated cobalamin levels ([74], [240], [241]). Cobalamin levels, like HC/TC I and TC II levels, tend to be higher in blacks than in whites ([242]).

Serum Folate The traditional definition of folate deficiency, derived from patients with megaloblastic anemia, is a serum folate level below 2.5 µg/L. (Note that publications often express folate in nmol/L; 1 µg = 2.266 nmol.) However, studies in the elderly suggest that homocysteine levels tend to rise in those whose serum folate falls below 4.8 µg/L ([191]) or 6.5 µg/L ([243]). Homocysteine also tends to improve when folate is given to people with folate levels up to 4.5 or 5.0 µg/L ([244]). These findings justify viewing serum folate levels between 2.5 and 5.0 µg/L with suspicion, at least in the elderly. Due to folate instability, levels fall within a few days of sample storage, especially if ascorbate is not added to protect against oxidative damage. Serum folate levels tend to rise with cobalamin deficiency and are high in approximately 30% of cases ([47]). The most common cause of elevated levels is the use of folate supplements, however. Artifactually high levels also occur in hemolyzed blood samples because red cell folate is released into plasma.

Red Blood Cell Folate MethylTHF (60.4%) and formylTHF (26.3%) are the major folates in red cells ([245]). Red cell folate is viewed as a truer indicator of tissue folate than are serum levels, which fluctuate with changes in folate intake. Levels below 160 µg/L red blood cells are usually considered low ([246]), but the reference range varies widely among laboratories and methods. Red cell folate results do not distinguish between folate and cobalamin deficiencies; 63% of patients with cobalamin deficiency have low levels ([246]). This finding is thought to reflect the limited intracellular retention of the increased but less easily polyglutamated methylTHF. Because early cells are richer in folate than older cells, red cell folate levels are higher, and therefore unreliable, in states of intense reticulocytosis such as hemolytic anemia ([246]). Transfusion invalidates red cell folate measurement. Red cell folate, much of it bound to hemoglobin ([247]), is also slightly higher in deoxygenated than oxygenated cells ([248]). The several clinical sources of error, along with methodologic difficulties, have led some to downgrade the usefulness of red cell folate determination ([249]).

Plasma Homocysteine In the past decade, precise measurement of low concentrations of homocysteine has become possible with high-performance liquid chromatography and other techniques. These methods measure “total” homocysteine, which consists of reduced homocysteine and its oxidized forms, homocystine and mixed disulfides. Measuring levels after oral loading with methionine is occasionally useful, especially when vitamin B_6 deficiency is suspected ([250]). Because of methodologic, subject recruitment and conceptual differences, no universally agreed reference range exists. Age and sex further influence normal levels ([251]). Levels

above 12 to 14 nmol/L in women and 14 to 15 in men are generally regarded as elevated. It is essential to use plasma rather than serum and to separate plasma from blood cells within an hour to avoid artificial elevation of homocysteine levels. Because homocysteine and creatinine levels correlate even in patients without renal failure, serum creatinine should be measured whenever a high homocysteine level is found. Homocysteine rises, often very markedly, with either folate or cobalamin deficiency. Although this lack of discrimination limits its diagnostic usefulness, a normal result can help exclude deficiency. Homocysteine levels are elevated in more than 95% of patients with clinically expressed cobalamin deficiency, but sensitivity is only 86% in clinical folate deficiency ([252]). The levels fall several days after appropriate treatment of either vitamin deficiency and become normal within a week, but they do not budge if the wrong vitamin is used ([228], [253]). As reviewed elsewhere ([254]), homocysteine levels rise in many other acquired and genetic conditions (Table 43.5). This further reduces the specificity of elevated levels, despite the observation that folate and cobalamin status accounts for 63 to 66% of the risk for elevated homocysteine levels in the healthy population ([251]). Folate intake and serum creatinine levels are major determinants of homocysteine status in population surveys ([251]). Cobalamin levels, but not intake, assume increased significance in the elderly ([191], [251]). Cystathionine, a product of homocysteine transsulfuration, also rises in cobalamin and folate deficiency but has little clinical application.

TABLE 43.5. Causes of Elevated Homocysteine Levels

Causes	Degree of Homocysteine Elevation [a]
Vitamin deficiency	
Cobalamin deficiency	Mild to severe
Folate deficiency	Mild to severe
Vitamin B_6 deficiency	Mild [b]
Riboflavin deficiency	Mild
Disease	
Renal failure	Mild to moderate
Posttransplantation	Mild to moderate
Hypothyroidism	Mild [c]
Acute lymphocytic leukemia	Mild
Psoriasis	Mild
Drugs and toxins	
Alcohol abuse	Mild to severe
Methotrexate and other antifols	Mild to severe
Trimethoprim; levodopa	Mild
Fenofibrate	Mild [c]
Cyclosporine A	Mild
Drugs affecting vitamin B_6 (e.g., isoniazid)	Mild [b]
Nitrous oxide toxicity	Mild to severe
Genetic disorders	
Cystathionine ß-synthase deficiency	
Homozygous state	Severe
Heterozygous state	Mild [b]
Hereditary disorders of cobalamin metabolism, transport, or absorption	Mild to severe
Hereditary disorders of folate metabolism, transport, or absorption	Mild to severe
Methylene tetrahydrofolate reductase polymorphisms (homozygous C677T or A1298C mutations)	Mild [d]
Physiologic and lifestyle factors [e]	
Male sex	Mild
Aging	Mild
Coffee drinking	Mild
Smoking	Mild
Artifact	
Use of serum; delay in centrifugation	Mild

[a] Homocysteine elevations are categorized arbitrarily as mild (15–25 µmol/L), moderate (25–50 µmol/L), and severe (>50 µmol/L).

[b] Often inapparent unless postmethionine-loading measurement is done.

[c] Homocysteine elevation may be due to change in creatinine level.

[d] Often inapparent unless folate status is compromised.

[e] In these categories, it is not known if other influences are responsible for the differences attributed to the factors.

Methylmalonic Acid MMA, a product of accumulated D-methylmalonyl CoA, increases in serum and urine with cobalamin deficiency but not folate deficiency. MMA is therefore a more specific test for cobalamin deficiency than homocysteine. With the advent of sensitive methods ([253], [255]), serum MMA was shown to be elevated in 98.4% of patients with symptomatic cobalamin deficiency ([252]). Definitions of the reference range are almost as uncertain as with homocysteine. Serum levels are now considered elevated above 280 nmol/L (0.28 µmol/L), but much of the literature has been based on considerably higher cutpoints. MMA levels often exceed 1000 nmol/L in symptomatic cobalamin deficiency, with milder elevations in subclinical deficiency. The levels fall several days after cobalamin therapy and become normal within a week ([228], [253]); folate therapy has no effect. MMA levels rise in renal failure, making it useful to measure serum creatinine in any patient with elevated MMA. Some high levels are unexplained, including those in occasional folate-deficient patients, and have often been attributed to volume contraction ([252]), but other explanations seem possible ([256]). The observation that MMA levels fall after antibiotic therapy ([228]) also suggests bacterial causes for MMA elevation. High MMA levels occur in many newborns ([257], [258]); it is unknown if the elevations reflect hepatic immaturity or transient cobalamin insufficiency. Urine MMA assay ([255], [259]) is less widely used. Serum 2-methylcitric acid also rises with impaired propionate metabolism in cobalamin deficiency but has little clinical use.

Deoxyuridine Suppression Test The ability of deoxyuridine, added *in vitro* to bone marrow cells in short-term culture, to suppress the normal incorporation of thymidine into DNA ([260]) was developed into a test of cobalamin and folate deficiency ([261]). Its mechanism as a reflection of impaired thymidylate synthase has been questioned ([262]). Nevertheless, the test appears at least as sensitive for cobalamin deficiency as homocysteine or MMA assay ([263]) and served to first define subclinical cobalamin deficiency ([87], [88], [185]). Cobalamin and folate deficiencies can usually be differentiated by incubation of cell aliquots with different vitamins *in vitro* ([261], [264]). However, the procedure is labor intensive and requires bone marrow aspiration, and tests using lymphocytes are unreliable ([265]).

Other Tests Formal diagnostic trials of reticulocyte response to a small dose of either folic acid or cobalamin ([266]) are no longer needed. Nevertheless, evaluation of the clinical response is an important part of management. Because most circulating cobalamin is carried by HC/TC I and is thus unavailable for cell uptake, measuring holo-TC II is a theoretically attractive diagnostic tool ([267]). However, the interpretation and clinical value of the results are unproved ([268], [269]).

SPECIFIC DISORDERS CAUSING DEFICIENCY

Diagnostic evaluation requires that the condition responsible for the deficiency is identified. This process helps confirm the diagnosis of deficiency, ascertains the prognosis, and is invaluable for management. The underlying cause also determines the rate at which cobalamin deficiency progresses or relapses. A metabolic or cellular block produces deficiency within days, weeks, or at most a few months, whereas deficiency is delayed for several years when IF-mediated absorption is disrupted and even longer if dietary insufficiency is the cause. These approximate time scales are modified if limited body stores or other compromises coexist.

Causes of Cobalamin Deficiency

The disorders follow the cobalamin assimilation and utilization sequence illustrated in Figure 43.4.

DIETARY INSUFFICIENCY

Adults The circumscribed dietary source for cobalamin and the huge body stores to daily loss ratio protect most adults from becoming frankly deficient on a purely dietary basis. Malnutrition lasting a few weeks or months does not produce cobalamin deficiency, nor does old age or alcohol abuse lead to dietary insufficiency. The only adults at risk are long-term, strict vegetarians, especially vegans who also avoid eggs and dairy products. A study of vegetarian women showed their cobalamin intake was 1.68 ± 1.60 µg/day, one-half that of nonvegetarian controls ([270]). Minimal changes of MCV have been noted in surveys of vegetarians ([271] , [272]), but macrocytic anemia is uncommon. Even long-standing dietary restriction rarely leads to megaloblastic anemia or myelopathy, which tend to be accompanied by MMA levels exceeding 1000 nmol/L ([273]). Consideration of coexisting causes, such as malabsorption, is warranted in patients with symptoms ([274] , [275]). Most often, vegetarians are found only to have mildly low cobalamin levels and mildly elevated MMA and homocysteine levels ([276] , [277] and [278]).

Children The consequences of dietary restriction are often more serious in children, who must simultaneously undergo neurologic development and expansion of cobalamin stores. Children in macrobiotic communities have persistent metabolic abnormalities ([279]), and perhaps impaired cognitive performance ([280]), even years after starting cobalamin supplementation. Diets restricted because of phenylketonuria may also lead to cobalamin deficiency ([281]). The consequences are sometimes catastrophic for babies born to and breast-fed by mothers who are strict vegetarians or have undiagnosed pernicious anemia ([167] , [282] , [283]). Indeed, maternal deficiency is the most common cause of cobalamin deficiency in childhood ([284]). It is very instructive of the cobalamin differences between adults and children that the mothers are themselves mildly deficient and asymptomatic, whereas the children have severe neurologic and developmental abnormalities. Involuntary movements and tremors are also common and may increase just after therapy is begun ([285]). Long-term neurologic deficits may persist ([286]). Dietary and second-hand cobalamin deficiency may have substantive roles in growth and developmental retardation ([284] , [287]).

MALABSORPTION

Pernicious Anemia The central defect of pernicious anemia, as well as its defining characteristic, is not the anemia but the malabsorption of cobalamin due to the loss of IF. Although atrophic gastritis is universal in Addisonian pernicious anemia, it differs from the much more common, nonpernicious anemia form of gastritis in which IF secretion persists long after acid secretion ceases ([288]). In 90% of cases of pernicious anemia, the gastric atrophy affects the fundus but spares the antrum, which is often hypertrophic. The disease, with its loss of parietal cells that synthesize IF, appears autoimmune in nature. The gastric and immune aspects of pernicious anemia have been reviewed ([47] , [289] , [290]). Antibodies to gastric antigens are found in 85% of cases, more often directed against the parietal cell but more telling when directed against IF; the gastric histology suggests an inflammatory disorder; cell-mediated immune abnormalities have been suggested; steroid therapy sometimes restores IF secretion; and other immune disorders often coexist. No consistent association with HLA subtypes has been found, but lymphocytotoxic antibodies and CD4 cells are increased ([291] , [292] and [293]). Gastritis was subdivided presumptively into types A and B ([294]). Type A gastritis is characterized by the presence of parietal cell antibody and sparing of the antrum; although the less common form in the general population, it is found in 80 to 90% of patients with pernicious anemia. Type B gastritis is a pangastritis without antibodies. It predominates in the general population but is found in only a minority of patients with pernicious anemia; it is now known that type B gastritis usually results from *Helicobacter pylori* infection. *H. pylori* infection is infrequent in patients with pernicious anemia ([295]). Pernicious anemia appears to have a familial predisposition ([296] , [297]). Relatives of affected patients have increased frequencies of atrophic gastritis, antibodies to parietal cells, and thyroid disease ([296]). Pernicious anemia occurs most often in people older than 60 years of age ([47]), although the gastritis begins many years earlier ([298]). A survey of the elderly in Los Angeles found that 1.9% had unrecognized pernicious anemia ([186]). Older surveys in Scandinavia found the prevalence to be 0.13 to 0.2% among all ages ([47]). Women are affected almost 50% more often than men in most surveys ([47] , [299]). Although most common in northern Europeans, pernicious anemia occurs throughout the world ([47] , [186] , [242] , [299] , [300] , [301] , [302] and [303]). Indeed, the frequency in African-Americans approaches that in American whites ([186]). The reason why black women develop the disease more often before 50 years of age than do whites and have antibody to IF more often is unknown ([299]); a similar but less significant trend was found in American Hispanics ([242] , [302]). Nevertheless, even in whites, approximately 10% of cases occur at a young age, sometimes in childhood or adolescence ([47]). Called *juvenile pernicious anemia* in children, it is accompanied by especially high rates of antibodies, immune endocrinopathy, and a positive family history. Similar characteristics were noted in young and middle-aged patients in Denmark ([297]). Pernicious anemia carries many disease-specific associations and prognostic implications, besides causing relentless cobalamin deficiency. The most serious one is an increased risk for two gastric tumors, both predominating in the fundus. Gastric carcinoid is found in 7% of patients but metastasizes in only 20% of them ([289] , [304] , [305]). The increased risk for gastric carcinoma has been widely noted ([47] , [289] , [306] , [307] and [308]), although some reports disagree ([309] , [310]). A prospective endoscopic study reported a 4.1% incidence ([307]). Most experts recommend endoscopy at the time of diagnosis in every patient with pernicious anemia ([311]), but routine examinations thereafter are not advised. Other gastroenterologic associations with pernicious anemia include bacterial contamination of the stomach and upper small bowel, perhaps due to achlorhydria ([312]), and gall bladder disease ([313]). Iron deficiency is seen in 21% of patients at diagnosis and in another 23% later ([314]). An independent cause of iron deficiency is not always found, suggesting that iron malabsorption due to gastritis may play a role. Approximately 10% of patients develop clinical or latent thyroid disease, most often hypothyroidism ([315]). Other immune disorders associated with pernicious anemia include vitiligo, hypoparathyroidism, hypoadrenalism, and myasthenia gravis ([47]). A noteworthy syndrome occurs in patients with agammaglobulinemia or common variable immunodeficiency ([316]); the patients are young, have type B gastritis, often have bacterial overgrowth, and are at very high risk for gastric cancer. Associations with pernicious anemia have also been suggested for immune thrombocytopenia, immune hemolytic anemia, transient red cell aplasia, diabetes mellitus, biliary cirrhosis, and renal tubular acidosis ([47] , [317] , [318] , [319] , [320] and [321]). Links have also been suggested with myelodysplasia, leukemia, chronic myelogenous leukemia, and other myeloproliferative diseases ([239] , [308] , [322] , [323] and [324]). An increased rate of tuberculosis was reported in Asian Indians and Chinese ([301] , [303]) but has not been described in Westerners.

Hereditary Intrinsic Factor Deficiency Also called *congenital pernicious anemia*, this autosomal-recessive disorder is characterized by absence of gastric IF ([157] , [325]). Nonfunctional ([326]) and unstable IF ([327]) have also been reported. Gastric status is otherwise normal, although basal hypochlorhydria sometimes occurs ([325]). Hereditary HC/TC I deficiency coexisted in one patient ([328]). Hereditary IF deficiency usually presents with anemia, myelopathy, and, occasionally, developmental delay in the first few years of life. Infrequently, diagnosis is delayed until adolescence or later ([325]).

Food-Cobalamin Malabsorption It was recognized in 1973 that the existing tests of cobalamin absorption, such as the Schilling test, failed to identify defects in the release of food-bound cobalamin because they used free, crystalline cyanocobalamin in the test dose ([329]). Tests using a variety of food vehicles showed that many patients did not absorb food-bound cobalamin while absorbing free cobalamin normally, as reviewed elsewhere ([330]). Most prominent among these were patients with gastric surgery or with gastritis but intact IF secretion. Patients taking acid-suppressive drugs, such as omeprazole, also malabsorb food-cobalamin ([331] , [332]), but cobalamin deficiency has been rare thus far. The crux of food-cobalamin malabsorption appears to be the loss of pepsin and the loss of acid secretion needed for optimal pepsin activity ([333]) (Fig. 43.4; panel 1). However, the gastric defect is more heterogeneous than suspected, and not all patients have severe gastritis and achlorhydria ([334]). An association also exists with *H. pylori* infection, but there are many exceptions ([335]). Malabsorption improves with antibiotic therapy sometimes; improvement was accompanied by disappearance of *H. pylori* in one study ([334]), but anaerobic bacteria were suspected in another ([336]). Food-cobalamin malabsorption is found in 30 to 40% of people with low cobalamin levels. It is usually associated with subclinical cobalamin deficiency and less often with severe deficiency ([88] , [330] , [337] , [338]) but also occurs in 10 to 15% of people with normal cobalamin status ([330]). Progression to pernicious anemia with loss of IF has been reported in several patients ([275] , [337]).

Gastric Surgery Subtotal gastrectomy is associated with eventual cobalamin deficiency in 15 to 30% of patients ([339] , [340]). Some patients develop severe deficiency with megaloblastic anemia and neuropsychiatric problems. However, absorption of free cobalamin (Schilling test) is usually normal ([341]), and most patients have only low cobalamin levels and food-cobalamin malabsorption ([329]). Iron deficiency and folate malabsorption may be seen ([342] , [343]). Food-cobalamin malabsorption and mild cobalamin deficiency also complicate other gastric procedures, such as those performed to promote weight loss ([344] , [345] and [346]).

Pancreatic Insufficiency Pancreatic proteases and bicarbonate degrade HC/TC I and release its cobalamin for transfer to IF ([75]). One-half of patients with chronic pancreatic insufficiency have abnormal Schilling test results, requiring exogenous pancreatic extract for correction. Nevertheless, cobalamin deficiency is rarely seen, perhaps because malabsorption must continue without treatment for several years before deficiency develops.

Bacterial Overgrowth of the Small Bowel As reviewed elsewhere ([347]), bacteria take up cobalamin and may compete with IF for it. Large enough numbers of bacteria in the upper small bowel may accumulate in structural abnormalities (e.g., fistulas, strictures, large diverticula) or motility disorders (e.g., autonomic dysfunction in diabetes). Cobalamin deficiency is sometimes the only obvious clinical manifestation. Folate deficiency does not occur. Antibiotics reverse the malabsorption, but relapse occurs if the cause of bacterial overgrowth is not corrected.

Parasitic Infestation The classic parasite associated with cobalamin deficiency is *Diphyllobothrium latum*, which infests freshwater fish ([348]). The tapeworms in the upper small intestine compete avidly for cobalamin. Most patients are asymptomatic, but cobalamin levels are often low ([349]). It is uncertain whether the worm load or coexisting disorders determine the extent of deficiency. Affected patients often have atrophic gastritis also. The infection is rare in the United States. *Giardia lamblia* has been associated with cobalamin malabsorption in a few cases, particularly children or immunocompromised patients. It is unclear if the association is a causal one. Low cobalamin levels have been reported in heavy *Strongyloides stercoralis* infection. Malabsorption in parasitic infections has been reviewed ([348]).

Gastrinoma The Zollinger-Ellison syndrome has been associated with cobalamin malabsorption. The basis appears to be the low pH in the intestine ([350]). Ileal uptake of the IF-cobalamin complex requires a neutral pH.

Ileal Diseases Acquired diseases involving enough of the ileum impair IF receptor–mediated absorption of cobalamin (Fig. 43.4; panel 3). Diagnosis requires the Schilling test, which shows malabsorption that is not corrected by oral IF, and it is followed by diagnostic pursuit of the specific disease. Tropical sprue is endemic in many regions, such as the Caribbean and South Asia, but manifestations may also appear long after a person has emigrated. Cobalamin deficiency, occurring in chronic cases, is sometimes the sole clinical finding ([351] , [352]). Some patients have folate deficiency instead, especially early in the course, or have both deficiencies. As in all malabsorptive diseases, other nutrients are also at risk. Cobalamin malabsorption can also occur in inflammatory bowel disease and occasionally in celiac disease ([353]). Ileal malabsorption has been associated with acquired immunodeficiency syndrome in some studies but does not explain most of the low cobalamin levels. Few HIV-infected patients have metabolic evidence of deficiency, and the low cobalamin levels may reflect low HC/TC I levels ([233] , [234] and [235]). Ileal resection may lead to cobalamin malabsorption. Jejunoileal bypass for obesity also creates long-term malabsorption ([354] , [355]). Creation of an ileal reservoir for the ureters in bladder cancer has been associated with cobalamin malabsorption and deficiency ([356] , [357]). The risk in all ileal surgery appears proportional to the length of affected ileum. Radiation therapy involving the ileum sometimes causes cobalamin malabsorption.

Imerslund-Gräsbeck Syndrome (Megaloblastic Anemia Type 1) Selective malabsorption of cobalamin due to heterogeneous genetic defects affecting ileal IF receptor function has been described worldwide. Two mutations of the cubilin gene have been identified in Finnish families only ([358] , [359]). The malabsorption is limited to cobalamin and usually produces clinical signs of deficiency in the first few years of life ([360] , [361]). Diagnosis is occasionally delayed. The disorder is often accompanied by mild proteinuria because the cubilin receptor for IF is also distributed in renal tubular cells, where it takes up other proteins also ([76]). The proteinuria is not reversed by cobalamin therapy ([362]).

Drugs, Toxins, and Related Toxicities Many drugs and toxins interfere with cobalamin absorption, usually by unknown mechanisms ([363] , [364] and [365]). Known agents include alcohol, colchicine, metformin, neomycin, cholestyramine, paraaminosalicylic acid, and slow-release potassium. The true list of offending drugs is probably longer, but cobalamin deficiency rarely occurs with any of them. Exposure must be constant for several years to deplete cobalamin stores, and few drugs fulfill that criterion. Cobalamin deficiency itself impairs ileal absorption of cobalamin and other substances ([163] , [164]), which has been attributed to megaloblastic changes in the gut ([160]).

TRANSPORT AND CELLULAR DEFECTS Most disorders of cobalamin transport and utilization are genetic in origin and usually affect children. Table 43.6 summarizes the hereditary disorders. Serum cobalamin levels are almost invariably normal.

TABLE 43.6. Hereditary Disorders of Cobalamin (Cbl) and Cobalamin-Related Metabolism

Disorder	Defect	Cbl	Homocysteine	Methylmalonic Acid	Megaloblastic Anemia	Myeloneuropathy	Diagnostic Findings
Congenital pernicious anemia	IF synthesis	?	?	?	Yes	Often	Absent IF/Abnl Schilling test, corrected with IF
Imerslund-Gräsbeck	IF receptor defect	?	?	?	Yes	Often	Abnl Schilling test not corrected with IF; urine IF receptor assay
TC II deficiency	TC II synthesis	N	?	N-?	Yes	Occasionally	Absent TC II in serum
HC/TC I deficiency	HC/TC I synthesis	?	N	N	No	No	Absent HC/TC I in serum and saliva
CblA defect	Mitochondrial reduction of Cbl	N	N	?	No	No [a]	Complementation study in fibroblasts
CblB defect	Cob(I)alamin adenosyl transferase	N	N	?	No	No [a]	Complementation study in fibroblasts
CblC defect	?Cytoplasmic reduction of Cbl	N	?	?	Yes	Yes [b]	Complementation study in fibroblasts
CblD defect	?Cytoplasmic reduction of Cbl	N	?	?	Mild [c]	No? [d]	Complementation study in fibroblasts
CblE defect	Methionine synthase reductase	N	?	N	Yes	Yes [e]	Complementation study in fibroblasts
CblF defect	Cbl transfer from lysosome?	N	?	?	Mild	No [f]	Complementation study in fibroblasts
CblG defect	Methionine synthase	N	?	N	Yes	Yes [e]	Complementation study in fibroblasts
CblH defect	Mitochondrial reduction of Cbl	N	N	?	No	No [a]	Complementation study in fibroblasts
Mut ^{0} defect	MM-CoA mutase (absent)	N	N	?	No	No [a]	Complementation study; enzyme assay
Mut defect	MM-CoA mutase (decreased)	N	N	?	No	No [a]	Complementation study

?, increased; ?, decreased; Abnl, abnormal; HC, haptocorrin; IF, intrinsic factor; MM-CoA, methylmalonyl-coenzyme A; TC, transcobalamin.

[a] Patients have hypotonia, lethargy, failure to thrive, vomiting, and acidosis.

[b] Patients also have lethargy, poor feeding, seizures, microcephaly, developmental delay, and retinopathy.

[c] Overt megaloblastic anemia did not develop (only mild macrocytosis) in the two brothers, but deoxyuridine suppression test showed cobalamin deficiency in marrow cells.

[d] The two brothers had mental slowness and behavioral abnormalities.

[e] Patients also have developmental delay, cerebral atrophy, seizures, and hypotonia.

[f] Patients have growth retardation and poor feeding.

Nitrous Oxide Toxicity Nitrous oxide oxidizes cob(I)alamin, irreversibly inactivating the methionine synthase to which the cobalamin is bound ([366]). Because exposure during dental and surgical procedures is brief and enzyme is regenerated quickly, clinical problems do not occur despite mild metabolic abnormalities lasting a few days ([367] , [368] and [369]). There are two exceptions to the benign consequences. One is repetitive exposure ([370]), such as recreational abuse of the gas. The other is when someone with unrecognized preexisting cobalamin deficiency undergoes routine intraoperative exposure to nitrous oxide ([371] , [372] , [373] , [374] and [375]). Both situations lead to megaloblastic anemia, but neuropsychiatric dysfunction is especially prominent ([366]). Like nitrous oxide, nitric oxide reacts with cobalamin and inhibits methionine synthase ([376] , [377]), but its clinical impact is unknown.

Cbl Mutations Inborn errors affecting intracellular cobalamin metabolism, designated *cbl* mutations and differentiated by complementation studies, are summarized in Table 43.6. All the *cbl* disorders call for cobalamin therapy, but responses vary. The methylmalonic acidurias (*cblA*, *B*, and *H* defects) affect adenosylcobalamin, which is needed in the methylmalonyl CoA mutase reaction. The *cblB* defect involves the adenosyltransferase needed for adenosylcobalamin synthesis, whereas mitochondrial reduction of cobalamin appears to be defective in *cblA* and *cblH* ([157]). These disorders cause lethargy, vomiting, dehydration, failure to thrive, hypotonia, and acidosis but do not produce megaloblastic anemia ([378]). Presentation is in the first months of life, but the course and response to cobalamin may vary.

The methylmalonic acidurias also include disorders arising from noncobalamin defects in the mutase enzyme itself: *mut* ^{0} , characterized by enzyme deficiency, and *mut* $^{-}$, with abnormal enzyme. These disorders do not respond to cobalamin therapy and are mentioned here for differential diagnosis purposes only. Clinical manifestations may be absent or resemble those of cobalamin-related methylmalonic acidurias. The *cblC*, *cblD*, and *cblF* mutations involve unidentified cellular processes that affect both methylcobalamin and adenosylcobalamin and are characterized by hyperhomocysteinemia and methylmalonic aciduria. Megaloblastic anemia is prominent in *cblC*, often with a microangiopathic and thrombocytopenic process resembling the hemolytic-uremic syndrome ([379]), but megaloblastic anemia is muted in *cbl D* and *cblF* defects ([85]). The course of the child with *cblC* defect is often severe, marked by neurologic dysfunction, acidosis, perimacular degeneration, and thromboses, and has a poor prognosis ([380]). The two brothers with cblD mutation had mild neuropsychiatric problems, minimal megaloblastic anemia, and venous thromboses ([85]). Variable presentations are seen in the *cblF* defect ([381] , [382] and [383]). The *cblE* defect results from methionine synthase

reductase deficiency, and the *cblG* defect results from methionine synthase deficiency. Thus, hyperhomocysteinemia occurs in both, but adenosylcobalamin activity and MMA levels are normal. Megaloblastic anemia and prominent neurologic problems occur, usually in the first few years of life ([384]), although one patient was not diagnosed until adulthood ([385]). Therapy is generally effective, although the neurologic problems are difficult to reverse unless treated early.

Transcobalamin II Deficiency Deficiency of TC II impairs delivery of cobalamin to cells, although some cobalamin enters cells by unknown, presumably nonspecific means. The undelivered HC/TC I–bound cobalamin continues to circulate; serum cobalamin levels are normal, with only rare exceptions ([386]). The children typically have megaloblastic anemia and failure to thrive in the first year of life. Neurologic dysfunction is less frequent but can occur later in the course, especially when the diagnosis is delayed and folate is used ([387]). Some children also have infections suggesting immune hypofunction ([388]). Because of the role of TC II in transporting absorbed cobalamin, most children have abnormal Schilling test results. The diagnosis rests on TC II assay, preferably immunoassay of total TC II ([386]). Several mutations of the TC II gene have been identified ([389] , [390]). Nonfunctional TC II has also been described ([391]). The disorder responds clinically to frequent cobalamin injections. Eventual oral therapy has been used in some cases, but severe complications have also been attributed to undertreatment ([392]).

Haptocorrin (Transcobalamin I) Deficiency This disorder is marked by low serum cobalamin levels, because most circulating cobalamin is carried by HC/TC I. Cellular deficiency, metabolic dysfunction, and megaloblastic anemia do not result ([393] , [394]). HC/TC I deficiency is typically diagnosed accidentally in adults who are investigated for a low cobalamin level, which causes diagnostic confusion with cobalamin deficiency. A few patients have had atypical neurologic dysfunction that was not cobalamin responsive ([393] , [395]). The diagnosis requires demonstration of absent HC/TC I in serum and secretions, such as saliva. A combined deficiency of HC/TC I and lactoferrin, both of which are synthesized in specific granules of myeloid cells and in exocrine gland epithelium, was demonstrated in one family ([395]); there was no predisposition to infection. Another patient had coexisting HC/TC I and IF deficiencies ([328]). A milder HC/TC I deficiency, perhaps the heterozygous state of the severe deficiency ([395]), has been identified in approximately 15% of all patients with low cobalamin levels, all of them asymptomatic ([396]). In these patients, plasma HC/TC I is decreased but not absent; saliva HC/TC I content is normal.

INCREASED REQUIREMENTS High demand for cobalamin in hypermetabolic and increased cell turnover states has been proposed, but its clinical relevance is undefined. Refractoriness to erythropoietin therapy was reported in a patient found to have cobalamin deficiency, but no evidence of cobalamin depletion was detected in 30 other patients receiving erythropoietin while on hemodialysis ([397]).

Causes of Folate Deficiency

Folate deficiency is often multifactorial. Limited intake may not be able to compensate for increased folate demand, or a drug that mildly inhibits folate metabolism can convert borderline folate intake into frank deficiency. In addition, a diet that is insufficient in folate is typically insufficient for other nutrients also. That being said, it also must be noted that the landscape of folate deficiency has changed dramatically as a result of food fortification and supplement use. The incidence of deficiency has decreased sharply in the United States. A large clinical laboratory reported that the incidence of subnormal folate levels declined from 1.3% to 0.3% of submitted samples between 1994 and 1998 ([398]). The literature on folate status in Americans was reviewed in 1995 ([399]), but the applicability of pre-1997 data today is open to question. Nevertheless, subpopulations remain at risk. These include premature infants, adolescents, young women, and some ethnic groups, such as blacks and Mexican-Americans ([184] , [400] , [401]). The prevalence of deficiency in the elderly has declined, however ([402]).

DIETARY INSUFFICIENCY The small ratio of body stores to daily requirement and the lability of food folates make it possible to become folate deficient after several weeks or months of poor intake. As mentioned, the likelihood of deficiency is enhanced when other causes coexist. By far, the most common of these is alcohol abuse ([403]), especially when involving hard liquor, which contains little folate.

Children Delivery of maternal folate to the fetus is efficient, so folate deficiency is rare at birth ([284]). Folate levels decline thereafter, and problems might arise in some children in whom growth demands and limited diet combine. Premature infants have especially high requirements ([404]). The availability of folate from milk is limited. Deficiency can appear in babies whose diet depends heavily on milk and who do not receive folate-fortified foods or supplements. Folate deficiency can also occur in restricted diets, such as those given to patients with phenylketonuria.

MALABSORPTION

Intestinal Malabsorption In tropical sprue, folate deficiency appears early and is often seen in the setting of marked gastrointestinal symptoms and other absorptive defects ([351] , [352]). The intestinal lesion itself often remits with folate therapy, although antibiotic therapy tends to produce more durable remission. Celiac disease also causes folate malabsorption and deficiency in some patients ([405]). Inflammatory bowel disease, such as Crohn's disease, which involves ileum most prominently, produces folate deficiency less often ([406]). Folate malabsorption has been described in patients with dermatitis herpetiformis.

Other Malabsorptive Mechanisms Patients with pancreatic insufficiency have diminished folate absorption when oral pancreatic replacement therapy is given ([407]), perhaps because of its pH-buffering effect. Folate absorption is diminished in the presence of endogenous or iatrogenic achlorhydria and in gas-tropathy ([343] , [408] , [409] , [410] and [411]), although it is not clear how often deficiency results ([410]).

DRUGS AND TOXINS Alcohol abuse is a major contributor to folate deficiency ([403]) and should be suspected even when other causes of deficiency are found. The risk is highest in alcoholics who eat poorly, but alcohol also has direct effects on folate metabolism and transport. The latter include interruption of the enterohepatic recycling of hepatic methylTHF, direct toxicity to enterocytes, formation of aldehyde adducts, and increased degradation of folates ([412] , [413] , [414] and [415]). Drug effects on folate status have been reviewed ([416]). Sulfasalazine interferes with folate absorption and perhaps with folate-related enzymes ([417]). Hydantoins, and to a lesser extent other anticonvulsants, have been associated with macrocytosis and low folate levels, but megaloblastic anemia is uncommon ([47]). The mechanisms remain unclear. Valproic acid inhibits mitochondrial folate metabolism and has fetal effects ([418]). Antifols, such as methotrexate, inhibit dihydrofolate binding to its reductase and thus limit the availability of metabolically active THF. Their effect can be bypassed by administering reduced folates such as 5-formylTHF (leucovorin). Trimetho-prim-sulfamethoxazole and pyrimethamine are potent inhibitors of bacterial dihydrofolate reductase but weak inhibitors of the human enzyme. They have been reported to cause megaloblastic anemia but appear to do so especially in patients with other limitations of folate status ([419]). Oral contraceptive use has been associated with diminished serum folate levels, but deficiency has not been clearly documented ([420]). Cellular depletion of folate has been proposed as an interactive risk factor for cervical dysplasia, especially in women who have papillomavirus infection or use oral contraceptives, or both ([421]).

INBORN ERRORS OF TRANSPORT AND METABOLISM

Methylene Tetrahydrofolate Reductase Deficiency Homozygous deficiency of this enzyme (Fig. 43.2; reaction 3) produces severe neurologic dysfunction, including myelopathy, developmental delay, seizures, and microcephaly ([157]). Thrombosis may also occur. Symptoms usually arise in the first year, but mild cases may be diagnosed in adulthood. Anemia does not develop because methyleneTHF remains available for thymidylate synthesis (reaction 2). The serum folate level is low because methyleneTHF cannot be converted to methylTHF, the main circulating form of folate. The diagnosis is made by measuring enzyme activity in fibroblasts or leukocytes, which correlates with disease severity ([422]). Many mutations of the reductase gene have been identified ([157]). Early treatment, which includes betaine, is essential ([423]).

Hereditary Folate Malabsorption Hereditary folate malabsorption is a rare disorder that is characterized by impaired transport of all folate forms across the intestinal mucosa and the choroid plexus. Transport in other cells and tissues appears adequate. Low serum folate levels, megaloblastic anemia, and severe neurologic dysfunction, including seizures, appear in the first few months of life ([154] , [155] and [156]). Diarrhea, failure to thrive, and oral ulcers also occur. Intensive parenteral and even intrathecal therapy is required, but cerebrospinal fluid folate levels are difficult to maintain.

Miscellaneous Disorders A rare, poorly understood familial syndrome of aplastic anemia and defective cellular uptake of folate has been described ([424]). Hereditary formiminoglutamic aciduria has been associated with deficiency of glutamate formiminotransferase or cyclodeaminase deficiency, or both (Fig. 43.2; reactions 7 and 8), but it is unclear that clinical dysfunction results ([284]).

Enzyme Polymorphisms Two common single nucleotide polymorphisms in the gene for methyleneTHF reductase, 677C>T and 1298A>C, produce mildly diminished enzyme activity ([425]). No symptoms result, but mild hyperhomocysteinemia is seen if folate levels are diminished or borderline.

INCREASED DEMAND OR INCREASED LOSSES

Increased Demand for Folate Fetal needs divert maternal folate via placental receptors. Other settings for increased demand for folate are lactation, chronic hemolytic anemia, and perhaps psoriasis and myeloproliferative diseases. Evidence exists for stress on folate metabolism ([37] , [426] , [427] and [428]). Folate deficiency may result when dietary intake cannot compensate adequately or disorders such as alcohol abuse or malabsorption supervene. Therefore, folic acid is often given routinely to pregnant women and patients with chronic hemolysis. Nevertheless, the only prospective, randomized trial of supplementation in sickle cell anemia did not show any clinical benefits ([429]). Routinely supplemented patients have developed unrecognized pernicious anemia with neurologic deterioration ([430]).

Increased Folate Loss Folate is lost during dialysis, and supplements are now used in chronic dialysis. As reviewed elsewhere ([431]), increased folate catabolism and loss have been proposed with alcohol abuse, anticonvulsants, and oral contraceptives.

Acute Folate Deficiency A syndrome of acute deficiency, megaloblastic changes in bone marrow (but not peripheral blood), and pancytopenia was described in severely ill patients in intensive care units ([432] , [433]). Folate levels are normal. The mechanism, and even the entity itself, is unclear because the patients have many illnesses and receive many drugs.

Causes of Megaloblastic Anemia Other Than Cobalamin or Folate Deficiency

THIAMINE-RESPONSIVE MEGALOBLASTIC ANEMIA A rare familial syndrome of megaloblastic anemia, diabetes mellitus, and sensorineural deafness has been described in the first few years of life ([434], [435]). The megaloblastic anemia and diabetes improve at least partially with thiamine therapy. Neither folate nor cobalamin have any known role. Several mutations of the thiamine transporter-1 gene have been found ([436], [437] and [438]), but the patients have no signs of thiamine deficiency.
HEREDITARY OROTIC ACIDURIA Megaloblastic anemia unrelated to folate or cobalamin accompanies developmental delay and orotic acid crystalluria in affected patients ([439]). There is clinical heterogeneity, with most cases occurring in the first few years of life. Some patients also have congenital malformations and immune deficiency. The biochemical lesion usually involves defects in orotate phosphoribosyltransferase and orotidine 5'-monophosphate decarboxylase. Treatment is with oral uridine.
MISCELLANEOUS CAUSES Chemotherapeutic agents that affect nucleoprotein synthesis, such as hydroxyurea and 5-fluorouracil, cause megaloblastic anemia. More easily distinguishable from megaloblastic anemia are the bizarre nuclear changes in arsenic toxicity. Myelodysplastic syndromes occasionally feature nuclear characteristics that resemble megaloblastic change, but hyposegmentation of neutrophil nuclei ("pseudo–Pelger-Hüet") is more common than hypersegmentation. Erythroleukemia and some cases of acute myelogenous leukemia also show megaloblastic-like nuclear changes in erythroid precursors.

Laboratory Diagnosis of the Causes of Deficiency

COBALAMIN DEFICIENCY Absorption is the first target of diagnostic evaluation because 95% or more of cases of frank cobalamin deficiency in adults arise from gastrointestinal problems ([440]). The situation has been modified by the growing, often accidental identification of patients with subclinical deficiency, which is less often associated with malabsorption and much less so with malabsorption of free cobalamin ([180], [181]). The diagnostic approach is somewhat modified in children, depending on the child's age and other issues. Maternal cobalamin status must be part of the evaluation of very young children. Inborn errors of metabolism tend to present clinically in early childhood but should be considered at any age.
Tests of Free Cobalamin Absorption The classic absorption test is the Schilling test, which measures the urinary excretion of an oral dose of ^{57}Co-labeled crystalline ("free") cyanocobalamin that approximates the amount ingested in a meal ([441]). The patient is tested in the fasted state, at least 3 days removed from a cobalamin injection. To minimize diversion of the absorbed cobalamin to TC II and tissues, the patient is given 1000 µg cyanocobalamin intramuscularly within 2 hours after the oral dose. All urine is collected for 24 hours because the peak of excretion varies. If excreted radioactivity is subnormal, usually defined as less than 8% of the oral dose, then the test is repeated a few days later with an oral dose of IF. Correction of an abnormal result by this maneuver is diagnostic for the absence of IF (i.e., pernicious anemia). If the result remains abnormal, the problem resides in the intestine. However, 40% of patients with pernicious anemia may have abnormal results with IF until they have been treated with cobalamin for several weeks ([163], [164]). Further modifications can be applied to identify bacterial overgrowth in the gut (antibiotic treatment before retesting) or pancreatic insufficiency (incorporating pancreatic extract into the test), when appropriate. The Schilling test's drawbacks are its requirement for normal renal function and complete collection of urine, its inconvenience, and the exposure to radioisotope. It is also subject to occasional unexplained false results. Because the procedure treats the patient with cobalamin, any studies requiring the untreated state must be done beforehand. Various modifications of the Schilling test have been tried. The most popular has been the simultaneous testing of absorption with and without IF, using a commercial double-isotope kit. Besides its greater convenience, the test sometimes allows interpretation of results even if urine collection is incomplete. However, the test is also subject to errors, especially the frequently false normal result in patients with pernicious anemia caused by isotope exchange. Isotopic tests of absorption are becoming less available, in part because of economic and technical considerations. This may create a serious gap in the diagnosis of cobalamin malabsorption, which has been abetted by misperceptions that identifying malabsorption is clinically unimportant.
Food-Bound Cobalamin Absorption Test Impaired release of ingested cobalamin from its binding to food proteins ([329], [330]) is not recognized by the Schilling test, which provides the free cobalamin as the test substance. Several test models were developed, using egg, egg yolk, or chicken serum as the vehicle in a procedure otherwise identical to the Schilling test ([330]). However, the tests are not available commercially. Blood tests of gastric status are unreliable as surrogate diagnostic markers ([335]).
Gastric Autoantibodies Testing serum for antibody to IF permits the diagnosis of pernicious anemia in some cases without having to resort to the Schilling test. Two antibodies to IF have been identified. Blocking or type I antibody, which attaches to the cobalamin-binding site of IF, is found slightly more often. It is also tested more easily than the type II antibody, which is detected as a complex with IF. Antibody to IF is found in 50 to 70% of patients with pernicious anemia, with somewhat higher frequencies if more sensitive assays are used ([442], [443] and [444]). Some subpopulations of patients have higher rates; IF antibody is present in more than 90% of black women, for example. Despite its limited sensitivity, the antibody is very useful because only rare patients without pernicious anemia have it ([445], [446]). Modern data on specificity are not available, but it probably exceeds 95%. However, samples obtained within a day or two after cobalamin injection produce false-positive results ([447]). Parietal cell antibody is directed to the membrane H^{+},K^{+-}adenosine triphosphatase pump subunits preexisting in cytoplasmic tubulovesicles ([290], [448], [449]). The antibody occurs in 80 to 90% of patients with pernicious anemia. However, its diagnostic value is limited because it is specific for immune gastritis ([450]), not for pernicious anemia. Moreover, the antibody is found less frequently than IF antibody in young patients ([443]) and in blacks, Latin-Americans, and Hong Kong Chinese ([303], [443]). The antibody also tends to disappear with time, unlike IF antibody ([451]).
Blood Tests of Gastric Atrophy Serum gastrin levels are elevated in 80 to 90% of patients with pernicious anemia ([452]), reflecting the patients' gastric achlorhydria and frequent antral hypertrophy ([289], [294]). Gastrin levels tend to be very high, often in the thousands, particularly in women ([443], [452]). However, hypergastrinemia has many causes, such as atrophic gastritis without pernicious anemia or with the use of omeprazole. Serum gastrin levels are often mildly elevated in patients with food-cobalamin malabsorption but overlap with control values, which renders them unreliable as a test for this condition ([335]). Serum pepsinogens I (or A) and II (or C) also reflect gastric status. Pepsinogen I, derived from fundic chief cells, is usually decreased in pernicious anemia, whereas pepsinogen II, which derives from fundus and antrum, is normal or elevated because of antral sparing in most patients with pernicious anemia ([453]). A low pepsinogen I to II ratio or low pepsinogen I level, or both, may be the most sensitive blood tests for pernicious anemia ([452]) but have limited specificity.
Direct Gastric Tests Measuring IF content in stimulated gastric juice is considered the best test for pernicious anemia, but IF assay is not widely available. IF fragments are detectable in urine ([454]), but assay problems bar its clinical application ([455]). Measuring gastric acid secretion has diagnostic value only in that the presence of acid in stimulated gastric juice rules out Addisonian pernicious anemia.
Tests of Ileal Function Ileal cobalamin malabsorption is demonstrable only with the Schilling test. The specific disease is identified by the relevant gastroenterologic methods.
Cobalamin-Binding Proteins Serum TC II levels are measured in children with unexplained cobalamin deficiency who have normal cobalamin levels. Measuring HC/TC I levels is useful in patients with unexplained low cobalamin levels who are asymptomatic or have equivocal symptoms ([396]). The radioimmunoassays for HC/TC I and TC II are not widely available. Measurement of unsaturated cobalamin-binding capacity is done in some commercial laboratories but is informative only if the individual TCs are separated and if the patient is not receiving cobalamin by injection. Measurement of TCs is sometimes also helpful in explaining high cobalamin levels (e.g., by identifying HC/TC I elevation in chronic myelogenous leukemia, acute promyelocytic leukemia, cancer, and other disorders) ([58]).
FOLATE DEFICIENCY Because dietary insufficiency, alcohol abuse, drug effects, and high utilization states are frequent contributors to folate deficiency, a careful history is usually the most effective diagnostic test. Malabsorption must be considered when history or other findings suggest it and whenever no dietary cause is apparent. Tests for folate absorption are not in common use. Therefore, the diagnosis of malabsorption rests on general gastroenterologic procedures, such as measuring absorption of other substances, radiographic tests, blood tests for intestinal disorders such as celiac disease, and intestinal biopsies. Acquired causes predominate in children also. Dietary deficiency may occur in specific settings and are often aggravated by the high demands created by growth and development. Hereditary disorders are rare.

MANAGEMENT

Management of cobalamin and folate deficiencies extends beyond giving the patient the right vitamin and can be complex. It is often subject to patient noncompliance ([125]) and physician error. Management goals are to reverse symptoms; to select the appropriate dose, route, and duration of vitamin replacement; to assure that the vitamin deficiency was identified properly and that the patient responded appropriately; to identify the underlying disorder that caused the deficiency and treat it directly, if possible; to define the prognosis and manage the complications of the underlying disorder; and to provide patient education.

Reversal of Presenting Symptoms

COURSE Megaloblastic anemia reverses quickly with the correct vitamin therapy. The patient begins to feel better within a day, before anemia improves. Reticulocytes begin to appear in 2 to 3 days. Ineffective hematopoiesis is replaced by effective hematopoiesis, as lactate dehydrogenase and bilirubin decline while serum transferrin receptor levels rise transiently. Maturation of erythroid precursors becomes more normoblastic. Although neutrophil hypersegmentation persists for 2 weeks or more ([100]), the white blood cell and platelet counts rise in the first week if they were originally decreased. Peak reticulocytosis occurs at 7 to 10 days, and

the hemoglobin level begins to rise. As normocytic cells replace macrocytic ones, the MCV declines. The blood count becomes completely normal before 8 weeks have elapsed. In most cases, neurologic improvement also becomes noticeable in the first few weeks of cobalamin therapy and continues more slowly for several months.

MONITORING THE RESPONSE Homocysteine and MMA levels begin to fall within a few days of therapy and can be used to monitor response ([456], [457]); monitoring vitamin levels has little value. If needed, adequacy of reticulocyte response can be assessed best at the end of the first week. However, it is always useful to determine completeness of response after 8 weeks, when the blood count should be completely normal. An incomplete hematologic response at either time point usually indicates a coexisting cause of anemia; most often, that cause is iron deficiency, which may have been masked before the patient's megaloblastic anemia was treated. A poor response can also indicate that the original diagnosis was incorrect. The extent of neurologic improvement cannot be predicted with full confidence. In general, the likelihood of full reversal after cobalamin therapy is inversely related to the duration of symptoms before therapy was started and to the extensiveness of the dysfunction. Whatever reversal can be expected is usually completed by 6 months, but, occasionally, improvement continues over a year or more. Progression of symptoms despite therapy rules out cobalamin deficiency as its cause.

BLOOD TRANSFUSION Patients with megaloblastic anemia tend to compensate for even severe anemia surprisingly well ([458]) and usually can be managed supportively until therapy takes effect. The temptation to transfuse should be resisted unless worrisome symptoms or signs require immediate intervention. If transfusion is used, care must be taken to avoid aggravating the patient's volume overload.

Dose, Route, Duration, and Toxicity of Vitamin Replacement

Using both folate and cobalamin regardless of the deficiency has unclear benefits and can muddy continuing evaluation and patients' understanding of their condition.

COBALAMIN DEFICIENCY Immediate reversal of megaloblastic anemia or neurologic dysfunction is achieved most reliably with intramuscular cobalamin. A series of 1000-µg injections is often given during the first few weeks. Because nonspecific absorption of cobalamin is very limited, many details of subsequent therapy depend on whether the IF mechanism is intact. When absorption is normal, oral cobalamin can be used. Normal intake is mimicked by using 2 µg twice a day, which does not exceed IF capacity, but one daily dose is also effective and more practical. If free cobalamin cannot be absorbed, as in pernicious anemia, the classic regimen calls for 100 to 1000 µg given intramuscularly once a month. Although most of the dose is excreted rapidly in the urine, the total amount retained is higher with higher doses. Occasional patients seem to require more frequent injections for unexplained reasons. Oral therapy has been resurrected as a suitable alternative in the past decade; however, the most detailed study included many patients who did not have malabsorption ([459]), and not all studies report consistently optimal clinical responses ([460]). Daily oral doses of 1000 µg must be taken. The advantages of oral therapy are its lower cost and avoidance of injections. These must be weighed against the need to take that dose every day, often for life, the need to monitor periodically because so much depends on daily compliance, which may not be as good in daily medical practice as in study volunteers, and the still incompletely proved equivalence of neurologic improvement after oral and parenteral cobalamin. Because of the quicker relapse when oral therapy is discontinued ([126]), replenishing stores by injection before embarking on oral maintenance may be advisable. The optimal treatment of patients with malabsorption that is limited to food-bound cobalamin, such as patients with atrophic gastritis or gastric surgery, is unclear. Oral 6-µg doses are not always effective ([344], [345] and [346]), and daily doses of 25 to 50 µg or more have been recommended ([461], [462] and [463]). Because gastric status is not always known, the higher doses may be advisable in all cases, especially in elderly patients. Treatment of hereditary disorders must be tailored individually because expression and severity vary even in the same disorder. Because of the need to overcome transport and enzymatic blocks, the frequently poor prognosis, and developmental concerns in children, therapy tends to be parenteral, frequent, and with doses of at least 1000 µg. Constant monitoring is required until the patient has been stabilized. Cobalamin replacement must continue for as long as the underlying cause persists. Cyanocobalamin use predominates in the United States, but hydroxocobalamin is more physiologic and has better retention ([464]). The only described side effects of cobalamin are occasional allergic reactions, often to the preservative, and formation of anti-TC II antibodies in some patients treated with depot preparations of hydroxocobalamin ([240]). Earlier reports of frequent sudden death during treatment of severe pernicious anemia, hypothesized to result from the transient hypokalemia that accompanies the early hematologic response to therapy, have not been borne out ([465]). A report that viral load correlates with serum cobalamin levels in hepatitis C–infected patients raised the possibility that cobalamin influences viral replication in the human host ([466]). However, cobalamin also appears to inhibit HIV integrase ([467]).

FOLATE DEFICIENCY Oral synthetic folic acid is cheap and stable, and doses of 1 mg suffice in most patients. As noted earlier, it is better absorbed than food folate by patients with malabsorptive disorders because several effective pathways of specific and nonspecific folate absorption operate throughout the small intestine. Monitoring the response can determine if higher doses or parenteral administration are needed. Treatment of children with inborn errors of folate metabolism calls for larger doses, often given parenterally, and may require specialized regimens. Leucovorin (5-formylTHF) is needed only in patients unable to reduce folic acid, such as those using drugs that inhibit dihydrofolate reductase. Indications for methylTHF therapy are unclear. Therapy is often continued until body stores are repleted, which can be done within a month. The need to continue therapy beyond that is guided by the underlying disorder, its persistence or likelihood of recurrence, and the patient's dietary, medical, and social details. Toxicity of folic acid is minimal ([468]). Seizure disorders have worsened in some patients receiving large doses intravenously ([469]). Massive doses have caused renal failure in rats, presumably due to precipitation in the tubules. By far, the most important risk of folate therapy, however, is its administration to someone with untreated cobalamin deficiency; this was documented in 13% of cobalamin-deficient patients in one survey ([19]). The anemia of cobalamin deficiency usually responds at least partially to folate, although relapse occurs eventually ([146], [147]). In the meantime, unchecked neurologic progression can occur. Related concerns have been raised in the debate about the increased intake of folic acid, much of it by the elderly, as a result of food fortification and supplement use ([470]).

Assurance of Response

The diagnosis of deficiency is often made with varying degrees of certainty. The less compelling the original evidence, the greater is the value of monitoring therapeutic response. The time landmarks of improvement of clinical manifestations and the preference for metabolic over serum vitamin determinations have been mentioned.

Managing Underlying Disorders Causing the Deficiency

The argument that testing for causes is wasteful because cobalamin deficiency is usually due to pernicious anemia is not sound. Only 70% of megaloblastic anemias due to cobalamin deficiency were caused by pernicious anemia ([440]); the remainder included treatable intestinal diseases, such as sprue and bacterial overgrowth that would have been missed without diagnostic assessment. Yet, even establishing the diagnosis of irreversible diseases has benefits. Proving that a patient has pernicious anemia allows the physician to recommend endoscopy to screen for cancer, to be vigilant for early signs of hypothyroidism, and to be confident in recommending lifelong cobalamin therapy.

Folate deficiency often has underlying causes with implications as important for the patient as the deficiency itself. Dietary correction, intervention for alcoholism, and readjustment of medications are some of the potential benefits.

Patient Education

Pernicious anemia is a prototype of the ideal medical encounter, a disease with potentially disastrous consequences that is easily treatable without risk. Yet, relapse due to discontinued therapy is distressingly common ([125]), and patient education is critical to preventing this. Patient noncompliance occurs in other serious but treatable diseases, such as Hodgkin disease and tuberculosis. In many of those diseases, therapy has considerable toxicity and inconvenience. Just the opposite may be operative in pernicious anemia; a byproduct of its simple therapy may be a complacent attitude to “vitamin problems” ([471], [472]).

Preventive and Other Use of Supplements

Nonmedical vitamin use is widespread in the United States, especially in certain subpopulations, such as women, the elderly, and affluent whites. The result has been eradication of folate deficiency as a common clinical problem. Most over-the-counter preparations do not exceed 400 µg of folic acid, which is effectively absorbed. There is concern that intake of more than 1 mg may increase the risk of neurologic complications if cobalamin deficiency is present, although the selection of that cutpoint is imprecise because most reports of adverse effects of folate therapy in cobalamin deficiency involved doses many times higher.

Most multivitamin preparations contain 6 µg of cyanocobalamin, but many contain up to 25 µg or more. Although serum cobalamin levels tend to be higher in supplement users than in nonusers, a subset of supplement users nevertheless continues to have metabolic evidence of cobalamin deficiency ([52], [462]), in some cases even despite supplements of 100 µg ([461], [463]). It seems likely that mild absorptive limitations or other factors sometimes impair responsiveness, and these

need to be better defined.

Acquired and Inherited Aplastic Anemia Syndromes

ACQUIRED APLASTIC ANEMIA

Historical Background

The first known reported case of aplastic anemia was in 1888 when Ehrlich ([1]) described a young woman with bleeding, fever, and severe anemia. Her bone marrow at autopsy was found to be largely devoid of blood-forming elements. The term *aplastic anemia* was introduced by Vaquez and Aubertin in discussions of the Society of the Hospital of Paris in 1904 ([2]). The word *aplastic* is derived from the Greek *a* and *plasso* meaning “without form.” Despite the potentially misleading term *anemia*, patients with aplastic anemia fail to form blood cells of all three lineages. This combination of decreased or absent bone marrow precursor cells and peripheral cytopenias characterizes aplastic anemia.

The paucity at presentation of the organ of interest, the bone marrow, poses a formidable obstacle to investigations into the pathophysiology of aplastic anemia. Nonetheless, ongoing studies continue to yield significant progress in the understanding of the biology and treatment of aplastic anemia.

Aplastic anemia may be acquired or inherited. The causes are numerous, and the clinical histories are diverse. The distinction between inherited and acquired aplastic anemia syndromes carries profound treatment implications, and each entity is discussed separately in this chapter.

Epidemiology

A large, prospective study conducted in Europe and Israel between 1980 and 1984 that required stringent case definition and pathologic confirmation reported an annual incidence of aplastic anemia of 2 new cases per 1 million population per year ([3]). Aplastic anemia occurs much more commonly in the Far East than in the West ([4]). This geographic variation likely stems from environmental rather than genetic risk factors, because the Japanese population in Hawaii manifests similar rates of aplastic anemia as other Americans ([5]). Studies have not been able to attribute the increased risk of aplastic anemia in the Far East to specific agents, such as chloramphenicol, widely used in Asia ([6], [7]).

The incidence of acquired aplastic anemia varies bimodally with age, with one peak between ages 15 to 25 years and another peak at older than 60 years of age ([8], [9]). Aplastic anemia occurs with equal frequency in both genders ([6]).

Clinical Causal Associations

The cause of aplastic anemia is generally difficult to determine in an individual patient. In the vast majority of cases, no causal etiology can be found. Attributions of causality in the literature must be interpreted with caution, as often multiple risk factors can be uncovered for any given patient. The clinical prognosis and management are generally related more to the severity of the disease than to the underlying cause.

IONIZING RADIATION Aplastic anemia has been reported after exposure to ionizing radiation due to nuclear bomb explosion, radioactive fallout, and medical or occupational exposure. Bone marrow cells are affected by both high-energy gamma rays as well as by absorbed lower-energy alpha particles. Acute radiation exposure in large doses leads to dose-related depressed marrow function. Bone marrow hypoplasia is observed at total body exposures between 1.0 and 2.5 Gy. LD_{50} due to marrow failure is observed at a dose of 4.5 Gy, and 100% mortality is observed in the range of 10 Gy ([10]). Chronic radiation-induced aplasia is also dose dependent, and radiation exposures greater than 4.4 Gy are associated with the development of aplasia ([11]). Nuclear reactor accidents, malfunctioning medical equipment, and accidental industrial exposures have resulted in a wide range of injuries, including marrow aplasia. Thermal burns and gastrointestinal toxicity pose early management problems and contribute greatly to mortality in such accidents. The use of the radioactive compound thorium dioxide as a diagnostic aid in the form of Thorotrast was associated many years later with the development of aplastic anemia and leukemia ([12]). Acute radium poisoning, such as that affecting radium dial workers, is accompanied by striking changes in the blood. A high incidence of leukemia and cancer has been observed in people exposed to ionizing radiation, and aplastic anemia has been reported in a few survivors ([13]). The effects of continuous internal irradiation were described many years ago in radium dial workers ([14]). In these people, injured by the ingestion of radium through the habit of wetting their brushes by mouth, severe macrocytic anemia with megaloblasts in the circulating blood, leukopenia, and relative lymphocytosis developed. The bone marrow showed primitive red cells and leukocytic hyperplasia, as well as numerous megakaryocytes. In some of the affected workers, death occurred as late as 4 to 6 years after they left their occupation. Hyperplastic marrow and macrocytic anemia have also been noted in human beings and animals subjected only to external roentgen radiation ([15], [16]). The practice of making regular blood counts in people occupationally exposed to radiation yields little to justify it ([17]). Degrees of radiation exposure 20 times greater than the maximal permissible dose may produce a real drop in neutrophils or lymphocytes, and serious aplastic anemia has been observed to occur without a preceding decrease in blood counts. Regular physical measurement of the doses received by the use of film badges and other methods is a more practical procedure in most situations.
DRUGS AND CHEMICALS Table 44.1 lists many of the drugs and chemicals associated with an increased risk of aplastic anemia. Of note, many drugs and toxins have been implicated by circumstantial evidence and may represent confounding factors associated with other, unrecognized, primary etiologies. For example, if an individual develops an infection and is treated with an antibiotic and an analgesic and then is subsequently found to have pancytopenia, it is impossible to determine whether this is secondary to the infection, the pharmacologic exposures, a synergistic interaction of disease and treatment, or is unrelated. Thus, although the listed agents warrant judicious use, they are by no means prohibited if the clinical indications for their use in a specific patient are strong. Even drugs that carry increased risks of marrow failure account for only a minority of cases ([3]).

TABLE 44.1. Drugs and Chemicals Associated with Aplastic Anemia

Agents that regularly produce marrow depression as major toxicity in commonly used doses or normal exposures
Cytotoxic drugs used in cancer chemotherapy
Benzene (less often benzene-containing chemicals)
Agents probably associated with aplastic anemia but with a relatively low probability relative to their use
Chloramphenicol
Insecticides

Antiprotozoals: quinacrine and chloroquine
Nonsteroidal antiinflammatory drugs: phenylbutazone, indomethacin, ibuprofen, sulindac, and aspirin
Anticonvulsants: hydantoins, carbamazepine, phenacemide
Gold (and possibly other heavy metals such as arsenic, bismuth, mercury)
Sulfonamides as a class: some antibiotics, antithyroid drugs (e.g., methimazole, methylthiouracil, and propylthiouracil), antidiabetes drugs (e.g., tolbutamide and chlorpropamide), carbonic anhydrase inhibitors (e.g., acetazolamide and methazolamide)
D-Penicillamine
Estrogens (in pregnancy and in high doses in animals)

Agents more rarely associated with aplastic anemia
Antibiotics: streptomycin, tetracycline, methicillin, mebendazole, sulfonamides, trimethoprim/sulfamethoxazole, flucytosine
Antihistamines: cimetidine, ranitidine, chlorpheniramine
Sedatives and tranquilizers: chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon
Allopurinol (may potentiate marrow suppression by cytotoxic drugs)
Methyldopa
Quinidine
Lithium
Guanidine
Potassium perchlorate
Thiocyanate
Carbimazole

From Shimamura A, Young NS. Acquired bone marrow failure syndromes. In: Handin RI, Lux SE, Stossel TP, eds. Blood: principles and practice of hematology, 2nd ed. Philadelphia: Lippincott, Williams & Wilkins, 2002, with permission.

The mechanisms whereby drugs might cause aplastic anemia are diverse. Some drugs, such as certain chemotherapeutic agents, may be directly cytotoxic to bone marrow precursor cells. In most cases, however, drug-related aplasia is idiosyncratic and occurs unpredictably in a minority of individuals. A genetic predisposition has been suggested for some cases of idiosyncratic drug-induced aplasia.

Benzene and Its Derivatives Benzene has been known as a cause of fatal aplastic anemia since a description in 1897 of four cases in workers in a bicycle-tire factory ([18]). Benzene (C_6H_6) is a hydrocarbon byproduct of the manufacture of coke. Benzene is used as a solvent for rubber, gum, resins, fats, and alkaloids and in the manufacture of drugs, dyes, and explosives. It has been used in many industries, including the manufacture of artificial leather, natural leather products, enamels, rubber, waterproof fabrics, lacquers, shellac, paint removers, batteries, and bronzing, silvering, and gilding liquids; in electroplating, lithography, photography, dry cleaning, and feather preparation; and in the airplane, linoleum, and celluloid industries. Certain petroleum fractions contain significant quantities of benzene and often are used to clean machinery parts or to remove grease from the hands. Benzene is volatile and consequently is readily absorbed by inhalation in badly ventilated rooms; it is poorly absorbed through the skin ([19]). In industrialized countries, exposure limits have been established, but higher levels are common in the manufacturing sector of developing nations. Even though industrial exposure appears to be declining, benzene remains an important cause of hematopoietic damage. Benzene is found in gasoline, automobile emissions, and cigarette smoke, and a concern of possible benzene exposure in the general population has been raised as the result of surveys using sensitive assays of urinary metabolites of benzene ([20]). Great variations are noted in susceptibility to benzene poisoning ([18]). Evidence of poisoning may appear in a few weeks or only after many years of exposure, or it may not be discovered until the onset of infection, long after exposure has ceased. The classic picture of leukopenia, thrombocytopenia, and severe anemia represents only the severe and fatal spectrum of poisoning by benzene. Among exposed workers, the most common abnormalities reported were anemia (48%), thrombocytopenia (33%), and leukopenia (15%) ([18], [21]). Other manifestations of poisoning are lymphocytopenia, increased reticulocyte counts, eosinophilia, immature marrow elements in the circulating blood, leukocytosis, and pseudo-Pelger-Hüet cells ([18], [22]). Evidence of increased blood destruction also has been reported. In one survey, serum bilirubin values were elevated in one-third of the subjects ([23]). Like the blood abnormalities, which may be of the regenerative or the hemolytic type instead of aplastic, the bone marrow may be hyperplastic rather than acellular. Extramedullary hematopoiesis has been observed ([18]), and the complete picture of myeloid leukemia has been described in a few patients ([24]). More often, when extramedullary hematopoiesis has been present, splenomegaly and a blood picture of myelophthisic anemia have been found.

Chloramphenicol A review of chloramphenicol-associated aplastic anemia can be found in reference [25]. An analysis of 408 cases of chloramphenicol-associated, nonneoplastic depression of one or more blood cell types reported to the registry concluded that people of all ages are affected, with a broad age spectrum ranging from 25 to 65 years old for adults and a childhood peak ([26]). In 75% of the patients reported, all three blood cell types were depressed, and marrow hypoplasia was found. No clear relationship could be established between the development of the dyscrasia and previous exposure to the drug, the dose used, or continuous versus intermittent administration. In 50% of the subjects, evidence of reaction appeared within 38 days of the last dose, in 22% during therapy, and in 10% after 130 days. The overall mortality rate was approximately 50%, with one-half the number of deaths occurring within 50 days of the reaction. The pathogenesis of chloramphenicol-associated blood dyscrasia is unclear despite extensive research efforts. Two types of reactions have been described: a reversible suppression of erythropoiesis ([27]) and an irreversible aplasia ([28], [29]). Reversible bone marrow suppression primarily involving erythropoiesis occurs in approximately 50% of patients to whom chloramphenicol is given in large doses. In such cases, the marrow is not characterized by hypoplasia, and abnormal sideroblasts have been seen in the marrow of some patients. A striking finding in the bone marrow is vacuolization of the nucleus and cytoplasm of the erythroblasts and, less often, the granulocytes ([30]). These toxic effects usually are observed between 11 and 18 days after initiation of antibiotic therapy. If the drug is withdrawn at this point, the reaction is reversible. Severe and often irreversible bone marrow aplasia, often resulting in death, does not manifest any clear clinical or pathogenic relationship to the reversible form of erythropoietic suppression. Individual susceptibility appears more likely. Because in most cases aplastic anemia becomes evident only after drug use has been discontinued and a long period of aplasia follows, some type of damage that lingers long after the last traces of drug have disappeared must be considered. No evidence exists to indicate that monitoring the effects of chloramphenicol by repeated blood counts reduces the incidence of chloramphenicol-associated aplastic anemia.

VIRUSES Patients with bacterial or viral infections frequently develop moderate pancytopenia. Cases of aplastic anemia have been reported in the context of a number of diverse viruses (reviewed in reference [9]). As in the prior example, such patients receive multiple medications, confounding the etiologic factor for the pancytopenia. Furthermore, in some cases, it is unclear whether the infection came before or after the pancytopenia. Several models have been proposed for the mechanism by which viruses induce bone marrow aplasia. Viruses may be directly cytotoxic to bone marrow cells. Alternatively, viral infection of bone marrow progenitor cells may stimulate an immune response against those cells through activation of cytotoxic lymphocytes, cell-surface expression of viral proteins, or shared epitopes leading to an autoimmune reaction. Infection of bone marrow stromal cells has also been postulated to compromise the bone marrow microenvironment and result in diminished hematopoiesis. Acute hepatitis has been associated with the subsequent development of aplastic anemia (reviewed in reference [31]). Antecedent hepatitis has been noted in 2 to 5% of aplastic anemia cases occurring in the West. The converse is less common; less than 0.07% of total pediatric hepatitis cases have been followed by the development of aplastic anemia, and less than 2% of the non-A, non-B hepatitis cases. The association appears to be much higher in patients undergoing liver transplant for hepatic failure after non-A, non-B hepatitis: 28% or 9 of 32 patients in one series. Post-hepatitis aplastic anemia has not been consistently associated with any of the known hepatitis viruses. The clinical features of aplastic anemia after hepatitis have been described. Bone marrow suppression generally occurs during convalescence approximately 2 months after the acute hepatitis episode. Untreated hepatitis-associated aplastic anemia has a particularly poor prognosis. In one early series of 174 cases, more than 90% of patients died within 1 year of diagnosis, and the average duration of survival was only 11 weeks from onset of pancytopenia ([31]). These patients may respond to antithymocyte globulin (ATG) ([32], [33] and [34]) or benefit from early bone marrow transplantation (BMT) ([35], [36] and [37]). Acute infectious mononucleosis caused by Epstein-Barr virus (EBV) can be accompanied by aplastic anemia, albeit rarely. One study found immunologic and molecular evidence of EBV in the bone marrow cells of six aplastic anemia patients ([38]). Serologic evidence of recent infection or reactivation was documented in all six patients, but only two had a previous clinical history of typical infectious mononucleosis, suggesting that the virus may be involved more frequently than recognized from the history alone ([38], [39]). Patients with aplastic anemia and herpes simplex infections may respond to acyclovir therapy ([40], [41]). Suppressor T-cell activation may mediate EBV-associated bone marrow failure ([42]). One patient with EBV-associated aplastic anemia responded to ATG ([43]). Although cytomegalovirus (CMV) infection generally produces only mild clinical symptoms, it may be associated with bone marrow failure, particularly in immunosuppressed patients. In immunodeficient mouse models, CMV infection prevented bone marrow reconstitution in a manner that could be reversed by the presence of cytotoxic $CD8^+$ cells ([44], [45]). CMV inhibition of hematopoiesis may occur through primary infection of bone marrow precursor cells, bone marrow stromal cells, or through reversal of the T helper/T suppressor ratio. Although the pancytopenias associated with human immunodeficiency virus (HIV) infection are generally associated with cellular but dysplastic marrow, aplastic anemia may also occur ([46]). Concomitant infections and myelosuppressive drug therapies can also contribute to marrow hypocellularity in this patient population ([47], [48]). Cytopenias in acquired immunodeficiency syndrome patients may also stem from immune destruction or

from retroviral infection of bone marrow precursor cells ([49], [50]). Recent *in vitro* studies indicate that neither HIV-1 nor HIV-2 infects human CD34 $^{+}$ bone marrow cells ([51]).

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA Paroxysmal nocturnal hemoglobinuria (PNH) is characterized by the clinical triad of intravascular hemolysis, venous thrombosis, and bone marrow failure (Chapter 37). The increased sensitivity of erythrocytes to complement is due to an inability to inactive complement on the cell surface. PNH was found to affect diverse membrane proteins sharing a common structural feature: the glycophosphatidylinositol (GPI) anchor linking these proteins to the cell membrane. GPI covalently binds to specific carboxyl terminal protein sequences and attaches them to cell membrane phosphatidylinositol residues. The genetic defect in PNH was found to reside in the X-linked PIG-A (phosphatidylinositol glycan class A) gene whose product functions in an early step in GPI anchor formation. The PNH defect can be detected by the absence of GPI-anchored cell-surface proteins in flow cytometry. Approximately 20 to 50% of patients presenting with aplastic anemia manifest the PNH cell phenotype on their granulocytes and erythrocytes by this assay ([52], [53]). Detection of the PNH phenotype is more sensitive by flow cytometric analysis than by sucrose hemolysis or acid lysis tests because flow cytometry can detect smaller numbers of abnormal cells and is not affected by prior red cell transfusion if neutrophils are assayed. Aerolysin-based assays may allow detection of even smaller PNH clonal populations. Because the toxin aerolysin must bind to the GPI anchor before forming transmembrane channels that lead to cell lysis, PNH cells do not bind aerolysin and are unaffected by concentrations that lyse normal cells. In one series, PNH clones were detected in 61% (14 of 23) of aplastic anemia patients using the aerolysin-based assays but in only 4% (1 of 23) of these patients by flow cytometry ([54]). The PNH defect may also appear during the course of otherwise typical aplastic anemia. Aplastic anemia-PNH patients can respond to immunosuppressive therapy. Studies of hematopoiesis in PNH patients have not detected any selective proliferative advantage of the GPI-anchored protein-deficient hematopoietic clones ([55]). Severe combined immunodeficiency mice infused with bone marrow from PNH patients showed preferential engraftment with the PNH clones ([56]). An *in vitro* study comparing proliferation of PIG-A(–) and PIG-A(+) CD34 cells from PNH patients found a selective growth deficiency in the PIG-A(+) cell population rather than an advantage for the PIG-A mutant cells ([57]). Fas expression was elevated on the wild type compared with the GPI-deficient cells, suggesting increased resistance to apoptosis as one potential mechanism for these findings. Expansion of the PNH clone has been proposed to be the result of escape from an immune-mediated bone marrow suppressive process ([58]). Another possibility is that the abnormal PNH clone itself might trigger an aberrant immune response, culminating in immune-mediated bone marrow failure ([59], [60]). In support of an immune disorder underlying PNH, abnormal T-cell clonal expansions were noted in PNH patients, as compared with multitransfused hemoglobinopathy patients or age-matched healthy controls ([61]). Arguing against the model of PNH as a form of escape from immune-mediated bone marrow failure is the observation that PNH clone size did not show any consistent change as a result of immunosuppression or relapse. A third possibility is that PNH represents a primary stem cell abnormality. The role of immune, proliferative, and survival mechanisms in marrow aplasia continues to be investigated ([62]).

Pathophysiology

HEMATOPOIETIC STEM CELLS Low numbers of bone marrow hematopoietic progenitor cells have been consistently reported in aplastic anemia. The long-term-culture–initiating cell, which serves as a surrogate measure of hematopoietic stem cells, is markedly reduced in aplastic anemia patients ([63], [64]). CD34 $^{+}$ cell numbers are also greatly diminished ([65], [66]). Several lines of evidence support the hypothesis that abnormalities in the hematopoietic stem cell compartment may contribute to the development of aplastic anemia. Stem cell infusion from an identical twin donor without prior conditioning of the recipient is curative in approximately 50% of cases ([67]). These results are consistent with a primary underlying stem cell deficiency and argue against disorders of the bone marrow microenvironment or global immune dysfunction as the only causes of stem cell destruction, at least in a subset of patients. Although the requirement for prior conditioning in approximately 50% of BMTs between syngeneic twins has been interpreted to indicate an underlying immune process targeted on bone marrow cells, it is also possible that such conditioning is necessary to ablate an abnormal bone marrow precursor with suppressive rather than proliferative qualities. Low stem cell numbers persist even after hematologic recovery with immunosuppressive therapy ([68]). Blood cell parameters, such as macrocytosis, do not return to normal after medical therapy in many cases. The increased incidence of late clonal disorders, such as myelodysplasias (MDSs) or acute leukemia, also suggests an underlying stem cell defect. Ball et al. ([69]) reported significant telomere shortening in the leukocytes of aplastic anemia patients. Because telomeres play an important role in maintaining stable chromosome ends and preventing chromosomal rearrangements, it is possible that chromosomal instability may contribute to progressive marrow aplasia. A second study reported relatively normal telomere lengths in patients who responded to immunosuppression, whereas untreated or unresponsive patients showed significant telomere shortening ([70]). Whether telomere shortening represents a primary versus a secondary event in the genesis of aplastic anemia remains to be ascertained.

HEMATOPOIETIC STROMA AND GROWTH FACTORS Inability of the bone marrow stroma to support hematopoiesis has been proposed as a potential mechanism underlying aplastic anemia ([11]). Abnormal adipocyte proliferation, based on morphologic characteristics of fatty marrow in patients and controls, has even been proposed as the primary lesion in aplastic anemia ([71]). Animal models of stromal cell defects resulting in bone marrow failure have been reported. For example, bone marrow failure due to a stromal defect occurs in the Sl/Sl ^{d} mouse. In this disorder, a genetic defect of the Sl ^{d} allele results in an anemia that is not corrected by stem cell infusion but is cured by splenic transplantation. The product of the Sl allele is stem cell factor, the ligand for the c-kit receptor ([72], [73] and [74]). The presence of normal stem cells in Sl/Sl ^{d} mice is shown by the ability of their spleen or bone marrow to cure W/W ^{v} animals carrying a mutation in the gene for c-kit. Parallel results occur in long-term bone marrow cultures: Stroma of Sl/Sl ^{d} animals does not support hematopoiesis by W/W ^{v} cells, whereas W/W ^{v} stroma supports hematopoiesis from Sl/Sl ^{d} mice ([75]). Evidence to date fails to support a clear role for bone marrow stromal cell defects in the pathogenesis of aplastic anemia. Direct evidence for a microenvironmental defect in aplastic patients has not been found in biochemical analysis of the composition of fat cells ([76]) or in ultrastructural studies of marrow microvasculature ([77]). After marrow transplantation, most stromal cell elements remain of host origin ([78]) and adequately support the donor's stem cells. Bone marrow stromal cells derived from aplastic anemia patients can support hematopoiesis of normal CD34 $^{+}$ cells in culture, whereas CD34 $^{+}$ cells derived from aplastic anemia patients failed to grow on normal stromal control cells ([79], [80]). Hematopoietic growth factor production and plasma levels are usually elevated rather than decreased in aplastic anemia patients (reviewed in reference [81]). Circulating levels of erythropoietin, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), thrombopoietin, and flt-3 ligand are elevated in patients with aplastic anemia. Stem cell factor levels have been reported to be low to normal. Levels of interleukin-1 (IL-1), produced by monocytes, are low in aplastic anemia. Therapeutic trials with these factors have not been consistently successful and have generally resulted in partial rather than complete hematologic improvement ([82]), casting doubt on the pathophysiologic significance of these factor deficiencies.

IMMUNE SUPPRESSION OF HEMATOPOIESIS Aplasia often responds to treatment with antilymphocyte globulin/ATG (ALG/ATG) and/or cyclosporin A (CYA). This response to treatment regimens that suppress immune function has fueled current theories of immune-mediated bone marrow suppression as the mechanism underlying aplastic anemia. The antilymphocyte preparations contain heterogeneous mixtures of antibodies and are clearly immunosuppressive as well as generally cytotoxic. They lead to rapid lymphopenia during and immediately after treatment, and reduced levels of lymphocytes persist for months. Cyclosporin exerts inhibitory effects on T cells and on transcription of genes for cytokines, including IL-2 and ?-interferon ([83]). Nonetheless, the attribution of immune dysregulation as causal in aplastic anemia based on therapy must be tempered with caution because ATG and cyclosporin exert multiple effects in addition to immunosuppression. ATG is a complex mixture of diverse antibodies directed against a wide range of antigens, including signal transduction and adhesion molecules ([84]). The active component(s) of ATG in aplastic anemia has yet to be identified. Therapies with mixtures of monoclonal antibodies specific for human T cells have not been very effective in clinical trials to date (reviewed in reference [85]). Furthermore, ATG can increase colony growth in normal, MDS, and aplastic anemia CD34 $^{+}$ bone marrow cells in culture ([86]). ATG treatment also reduces the expression of Fas-Ag on aplastic anemia bone marrow CD34 $^{+}$ cells ([87]). As cyclosporine is thought to be more specifically immunosuppressive than ATG, its efficacy has been cited as further evidence for T-cell mediation in the pathophysiology of aplastic anemia; however, cyclosporine therapy also has a multitude of additional effects. Recent studies reporting ATG ([88]) or cyclosporin ([89]) to be effective in the treatment of MDS suggest either that these agents act on the bone marrow in addition to modulating immune function or an immune mechanism underlying MDS ([90]). A role for immune dysregulation is supported by several studies of T-cell characteristics in aplastic anemia. T cells were first implicated by *in vitro* studies of an aplastic patient's bone marrow in mixing and depletion experiments. Hematopoietic colony formation occurred only after physical separation of myeloid cells from lymphocytes; colony formation was improved by addition of antilymphocyte serum, and the patient's bone marrow cells inhibited normal bone marrow colony formation. In several larger series, inhibition was detected in most ([91], [92]) or at least some patients ([93], [94]). In contrast, other studies reported that only a minority of cases showed cellular suppression of hematopoiesis ([95], [96]), and others found no evidence of inhibitory cells ([97]). Suppressor cell activity has shown variable responses to therapy ([92], [98], [99]). Because many of these studies were performed in pretreated or transfused patients, lymphocyte function could arguably also represent a secondary phenomenon. Use of T-cell depletion was proposed to distinguish the transfusion effect; marrow burst-forming unit erythrocyte–derived colony formation was increased by this maneuver in 8 of 32 patients ([100]). Studies of heavily transfused patients with diverse hematologic diseases as controls ([91], [101]) or using the T-cell depletion assay continued to support a role for immune-mediated bone marrow suppression in some patients ([92], [93]). Analysis of cell-surface phenotypes further suggests an immune-mediated pathogenesis for aplastic anemia. Lymphocytes with immunoglobulin G receptors and T? $^{+}$-activated cytotoxic lymphocytes were reported in aplastic but not in normal bone marrow ([102]). Cell clones of this phenotype have been isolated from patients, and *in vitro* they overproduce inhibitory cytokines and inhibit hematopoiesis ([103], [104] and [105]). Altered T-helper and T-cytotoxic cell profiles have been reported in patients with aplastic anemia ([106], [107] and [108]). Identification of a T-cell clone showing HLA-DRB1 0405–restricted cytotoxicity for hematopoietic cells was seen in one patient with aplastic anemia ([109]). Studies of V $_{\beta}$ T-cell receptors have not found any general restriction of T-cell clonality or of dominant lymphocyte clones ([110]). Skewing of the CDR3 (complementarity-determining region 3) of the V $_{\beta}$ region of the

T-cell receptor, suggestive of clonal predominance, has been noted in a small group of cyclosporin-dependent patients ([111]). Furthermore, analysis of the CDR3 region of CD4 cells derived from five patients with aplastic anemia and an HLA-DR2 haplotype showed a high frequency of clones bearing identical CDR3 DNA sequences that were not found in normal controls ([112]). Skewing of the CDR3 V_{β} size distribution was increased in newly diagnosed aplastic anemia patients, as compared with age-matched healthy controls or multiply transfused control patients; however, the degree of V_{β} skewing showed either no change after ATG treatment or increased after CYA treatment, calling into question the etiologic significance of this correlation ([113]). It remains to be determined whether these oligoclonal T-cell expansions represent either a cause or an effect of the aplastic bone marrow process.

Clinical Features

The presenting symptoms of aplastic anemia generally reflect the underlying anemia, neutropenia, or thrombocytopenia. Bleeding or bruising secondary to thrombocytopenia is common and typically presents as easy bruising and petechiae, usually over dependent surfaces, bleeding gums, and epistaxis. In a study of 22 aplastic anemia patients, the most common oral manifestations were petechiae and spontaneous gingival bleeding ([114]). Heavy menstrual flow or menorrhagia is common in menstruating women. In classic cases of PNH, dark red urine is reported, but visible bleeding from the genitourinary and gastrointestinal tracts is otherwise rare on presentation in patients with aplastic anemia. Major hemorrhage from any organ can occur in aplastic anemia but is usually not seen until late in the course of the disease and is generally associated with infections (especially invasive fungi), drug therapy (e.g., ulcerogenic corticosteroids), or traumatic therapeutic procedures (e.g., intravenous line placements). Patients also present with nonspecific symptoms of fatigue, lack of energy, shortness of breath, or even angina secondary to anemia, although its gradual onset allows physiologic compensation even at alarmingly low hematocrits. Young children may present with poor feeding, lack of interest in playing, or excessive sleep. Patients can also present with a fever in the setting of neutropenia. Most patients appear clinically well on initial presentation.

A careful history should be obtained regarding exposures to drugs or chemicals or any preceding infections. Any family history of blood diseases, early onset cancers, or congenital anomalies should be ascertained to assess for a potential inherited bone marrow failure syndrome.

The physical examination is generally unremarkable except for bruising and petechiae, as noted above. Hepatosplenomegaly and lymphadenopathy are usually absent. The presence of short stature; congenital anomalies, such as abnormal thumbs or forearms; café au lait spots; rashes; or nail abnormalities suggests a possible underlying inherited bone marrow failure disorder such as Fanconi anemia (FA) or dyskeratosis congenita (DKC) (see sections Fanconi Anemia and Dyskeratosis Congenita).

Laboratory

PERIPHERAL BLOOD Peripheral blood cytopenias and bone marrow hypocellularity constitute the key diagnostic features of aplastic anemia. The severity of aplastic anemia was classified by Camitta et al. ([115]) in an effort to make possible the comparison of diverse groups of patients and different therapeutic approaches. Diagnosis of severe aplastic anemia requires that the patient have at least two of the following: a granulocyte count below 500/µl, a platelet count below 20,000/µl, and an absolute reticulocyte count = 40×10^{9}/L. In addition, the bone marrow biopsy must contain less than 25% of the normal cellularity. Very severe aplastic anemia is further defined by a granulocyte count <200/µl ([116]). Mild or moderate aplastic anemia is distinguished from the severe form by the presence of mild or moderate cytopenias and more variable, but still deficient, bone marrow cellularity. These distinctions are more than semantic; they are critical for the prediction of outcome and the choice of therapy. The workup of the patient with peripheral blood pancytopenia should be focused on eliminating diagnoses for which alternative curative therapies are available or for which treatments for aplastic anemia would be inappropriate. Although a complete workup is important, it also behooves the clinician to draw the minimal volume of blood necessary, particularly from small pediatric patients. Table 44.2 lists the differential diagnosis of pancytopenia. *Pancytopenia* is a descriptive term referring to a reduction in all three blood cell lineages: erythrocytes, leukocytes, and platelets. Pancytopenia can result from diverse mechanisms. For example, pancytopenia can be associated with a decrease in hematopoietic cell production in the bone marrow secondary to toxins, medications, or infections. In such cases, the bone marrow appears hypoplastic. Replacement of normal marrow by malignant cells, granulomas, or storage cells points to other etiologies for pancytopenia. In other situations, the marrow may appear normocellular or even hypercellular. Such a marrow might be seen in cases of ineffective hematopoiesis, formation of defective cells that are rapidly removed from the circulation, peripheral sequestration of normal cells in a hypertrophied or overactive reticuloendothelial system, or immune-mediated destruction.

TABLE 44.2. Differential Diagnosis of Pancytopenia

Hypocellular bone marrow
Acquired aplastic anemia
Inherited bone marrow failure syndrome (e.g., Fanconi anemia, dyskeratosis congenita, amegakaryocytic thrombocytopenia, and Shwachman-Diamond syndrome)
Hypoplastic myelodysplastic syndrome
Virus-associated aplastic anemia
Cellular bone marrow
Primary bone marrow disease
Malignant/clonal
Myelodysplasia
Myelofibrosis
Paroxysmal nocturnal hemoglobinuria
Acute myelogenous leukemia
Acute lymphoblastic leukemia
Hemophagocytic lymphohistiocytosis
Osteopetrosis
Secondary to systemic disease
Metastatic solid tumors
Autoimmune
Systemic lupus erythematosus
Sjögren syndrome
Nutritional/toxic
Vitamin B_{12} deficiency
Folate deficiency
Alcoholism
Infections
Overwhelming infection/sepsis
Virus
Brucellosis
Ehrlichiosis
Mycobacteria
Storage disease
Gaucher
Niemann-Pick
Sarcoidosis
Anatomic
Hypersplenism

A suggested laboratory evaluation for aplastic anemia is outlined in Table 44.3. The red cell morphology is normal other than the frequent finding of macrocytosis. Fetal hemoglobin concentration and erythrocyte i antigen expression may be increased. The absolute reticulocyte count is low. Neutrophils may show toxic granulations. Decreases in monocyte and lymphocyte counts are variably seen. Platelet size is most often normal. Folate and vitamin B_{12} levels are normal. Erythropoietin levels are usually increased. Serum transaminase elevation, if present, suggests hepatitis-associated aplastic anemia. Elevated serum creatinine points to underlying renal disease. Because aplastic anemia can be the first presenting symptom of FA, chromosome breakage studies should be performed in all patients (see Fanconi Anemia). Peripheral blood should be sent for flow cytometry tests to rule out PNH. Once the diagnosis of aplastic anemia is confirmed, HLA typing should be performed on all patients and potential related donors (e.g., siblings and parents).

TABLE 44.3. Laboratory Evaluation for Aplastic Anemia

Test	Rationale
Complete blood cell count and differential	Define severity of aplasia
Morphology	Define abnormal cells (e.g., blasts or storage cells)
	Vitamin B_{12} deficiency
Reticulocyte count	Define severity
	Differentiate production vs. destruction
Bone marrow biopsy	To assess cellularity
	To assess architecture (e.g., granuloma, fibrosis, hemophagocytosis, and infiltrative or metastatic disease)
Bone marrow aspirate	
Morphology	Malignant vs. benign disease
	Storage disease
	Hemophagocytosis
	Congenital disorder
Cytogenetics	Myelodysplasia
Culture	Infectious agent (e.g., tuberculosis or virus)
Other	DNA/antigen-based viral tests
Peripheral blood studies	
Aspartate aminotransferase, alanine aminotransferase, ?-glutamyltransferase, bilirubin	To evaluate for hepatitis
Blood urea nitrogen, creatinine	To assess for chronic renal failure
Serologic testing	To evaluate for human immunodeficiency virus, Epstein-Barr virus, hepatitis, other virus
Ham test/fluorescence-activated cell sorter	To evaluate for paroxysmal nocturnal hemoglobinuria
Chromosomal breakage studies (diepoxybutane/mitomycin C)	To assess for fanconi anemia
Autoimmune disease evaluation	Evidence of collagen vascular disease
Histocompatibility testing	To establish potential transplant donor pool

BONE MARROW Both a bone marrow aspirate to assess cell morphology, and a bone marrow biopsy to assess cellularity and architecture are required for diagnosis (Fig. 44.1). Biopsy point counting (determination of numbers of cells in small grids) is the most accurate method of determining cellularity, but visual estimation is more frequently used ([117]). The lower limit of normal marrow cellularity decreases with age, but in the typical adult, it is approximately 30%. Although aplastic anemia patients have decreased myeloid cellularity by definition, significant residual cellularity is present in some patients because of lymphocytosis. A few patients may manifest patchy areas of hematopoiesis ([118]). Cellularity often diminishes rapidly, and a discordant relationship between cellularity and peripheral blood findings should prompt a repeat evaluation after a short interval.

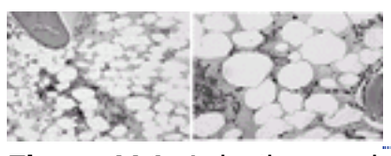

Figure 44.1. Aplastic anemia bone marrow histology. A bone marrow biopsy obtained from a child with aplastic anemia shows the characteristic hypocellularity. Note the abundance of fat. The few cellular elements are comprised primarily of lymphocytes. See Color Plate.

Individual cell morphology is best appreciated on Wright-Giemsa stain of the aspirate smear. The predominant cells usually are lymphocytes. Increased numbers of mast cells can also be associated with bone marrow failure. Dyserythropoiesis is common, with the “megaloblastoid” features of macrocytosis and some nuclear-cytoplasmic maturation asynchrony. An increase in myeloblast count is not seen in patients with aplastic anemia and may herald the evolution of leukemia from pancytopenia ([119]). The biopsy usually shows almost complete replacement of the marrow with fat. Reticulin stains do not show increased marrow fibrosis. The presence of ring sideroblasts in iron-stained marrow should point to alternative diagnoses such as MDS. Intramedullary granulomas suggest other infectious or autoimmune diagnoses. Bone marrow cytogenetics are typically normal for patients initially presenting with aplastic anemia. In contrast, cytogenetic abnormalities are frequently found in myelodysplastic bone marrows and may be helpful in distinguishing aplastic anemia from hypoplastic MDS. The subsequent development of clonal cytogenetic abnormalities represents a serious complication of aplastic anemia and is discussed in the section Complications of Immunosuppressive Therapy.

Treatment

Severe aplastic anemia is a medical emergency and warrants an expeditious workup and prompt institution of treatment. The management of patients with aplastic anemia entails both corrective treatment of the bone marrow failure and the institution of aggressive supportive care.

HEMATOPOIETIC STEM CELL TRANSPLANT The earliest successful treatments for aplastic anemia involved BMT ([120], [121]). As noted above, stem cell transplant (SCT) between identical twins in the absence of any conditioning regimen is curative in approximately 50% of cases. A recent study showed that long-term survival for identical twin transplants was highest using an algorithm of initial transplant without conditioning followed by a subsequent transplant with conditioning for any patients failing to engraft with the first transplant ([67]). None of the patients who failed the first transplant died before receiving a second transplant, and mortality was similar to that of patients who received conditioning upfront. In the absence of an identical twin donor, conditioning for transplant is necessary, although less intensive than that used for most other diseases.

Allogeneic Donors Outcomes for several large studies of HLA-matched allogeneic SCT are summarized in Table 44.4. The improvement in survival rates over time has been attributed in large part to improvements in graft-versus-host disease (GVHD) prevention and graft rejection rates ([122]). From the most recent data reported to the International Bone Marrow Transplant Registry (IBMTR), among 1699 patients receiving HLA-identical sibling transplants for aplastic anemia between 1991 and 1997, the 5-year probabilities of survival (95% confidence intervals) by age were: up to 20 years of age, 75% ± 3%; between 21 to 39 years of age, 68% ± 4%; older than 40 years of age, 35% ± 18%. Survival data from single centers showed more variability but overlapped with the 95% confidence intervals reported by the IBMTR ([123]). Patient age, duration of aplasia before transplant, prior transfusion history, and clinical status all affected survival rates. Survival after SCT was not affected by severity of aplasia.

TABLE 44.4. Allogeneic Stem Cell Transplant for Aplastic Anemia

Study (Reference)	Survival (%)	Chronic Graft-Versus-Host Disease (%)	Rejection/Failure (%)
Gluckman et al. ([336])	68 + 10 (5 yr)	35	3
Champlin et al. ([337])	78 ± 10 (5 yr)	12	17
May et al. ([338])	79 ± 8	0	29
Storb et al. ([132], [339])	89 (8 yr)	34	5

Passweg et al. (122)	66 ± 6 (5 yr)	32	16
Reiter et al. (340)	95 (15 yr)	53	0

An unexpectedly high rate of engraftment failure was noted early on (124, 125) even in syngeneic transplants with (126) or without (127) conditioning. Graft rejection rates have been increased in aplastic patients undergoing SCT, compared to those with leukemia. The more intensive conditioning regimens used to eradicate malignant disease may also more effectively ablate the host immune system. Mixed hematologic chimerism occurs commonly after transplantation in aplastic anemia, and persistence of donor lymphocytes is highly associated with graft rejection (30% vs. 5% in complete chimeras) (128). Increased intensity of pretransplant conditioning regimens has been accompanied by significant decreases in graft rejection (116, 129). The rate of successful second transplants in response to graft rejection has also improved (129). Transfusion sensitization poses a significant risk for graft failure. In general, risk of graft rejection increases with higher numbers of units transfused, although this relationship does not appear strictly linear. In the IBMTR analysis, untransfused patients had a risk of rejection of approximately 5%, heavily transfused patients (more than 40 units) had a risk of more than 25%, and patients who received 1 to 40 units had an intermediate risk of approximately 15% (130). In the Seattle retrospective analysis, increased graft rejection was observed in patients who had received more than 10 units of erythrocytes or 40 or more units of platelets (131). Studies of allogeneic transplantation of multiply transfused patients with severe aplastic anemia using a conditioning regimen combining cyclophosphamide with ATG (132) reported sustained engraftment in 96% of patients and 88% survival with a median follow-up time of 6 years (133). Increased survival in patients without transfusions could also reflect the influence of other variables, especially the absence of hemorrhage and infection in the patient who receives a transplant soon after diagnosis (134). Nonetheless, a plateau of graft rejection in the range of 5 to 10% persists. Improvements in stem cell engraftment accompanying intensification of conditioning regimens are counterbalanced by increased risks of GVHD and other end-organ toxicity syndromes. The IBMTR compared the efficacy over time of 1305 HLA-identical sibling BMTs performed between 1976 and 1992 and found that changes in GVHD prophylaxis accounted for much of the improvement in 5-year survival. Mortality from severe GVHD has not improved substantially over time, although the proportion of patients developing severe GVHD has declined (135).

Alternative Donors Approximately 70% of aplastic anemia patients do not have histocompatible sibling donors. Alternative potential donors include phenotypically matched relatives, partially matched (mismatched) relatives, and histocompatible but unrelated volunteers. Haplotype sharing between parents occasionally has allowed successful transplantation between phenotypically matched (but genotypically mismatched) family members. Survival after alternative donor transplants, although improving, has continued to be significantly lower than that achieved with matched HLA-identical sibling transplants for aplastic anemia (reviewed in reference 136). Transplantation with matched unrelated or mismatched donors is discussed in Chapter 25. Retrospective analysis of patients undergoing unrelated donor transplant in the 1990s has resulted in disease-free survival rates of 56% at 5 years and confirms prior suggestions that earlier transplantation results in better outcomes (137). Also, age younger than 20 years again was associated with better outcomes. Umbilical cord blood has been used successfully as a source of hematopoietic stem cells for unrelated, often mismatched, transplantation (138, 139, 140, 141 and 142).

IMMUNOSUPPRESSIVE THERAPY

Antilymphocyte Sera ATG or ALG, particularly in combination with additional agents, is an effective therapy for many aplastic anemia patients who do not receive SCTs. This has been particularly important for older patients who may not be candidates for SCT. Both horse ATG (ATGAM, Upjohn, Kalamazoo, MI) and rabbit ATG (Thymoglobulin, SangStat Medical Corp., Fremont, CA) are approved for use in the United States. ATG is derived from animals immunized with normal human thymocytes, whereas the immunogen for ALG is human thoracic duct lymphocytes. Studies have shown superior response rates in patients treated with ATG/ALG as compared with androgens (70% vs. 18%) as well as superior 1-year survival rates (76% vs. 22%) (143). A randomized trial also reported higher response rates to ATG as compared with supportive care only (144). However, variability in patient populations, differences in the definition of hematologic response, differences in the time at which a response is measured, and duplication of case material in the literature make an overall response rate to ATG difficult to approximate. Specific criteria used to measure improvement in aplastic anemia can include independence of need for transfusions (which may be subjective and does not measure neutrophil improvement), improvement in blood counts (which are altered by transfusion and affected by error at the low range of reticulocyte and platelet determinations), and clinical assessments of improvement (145). Although the average time to improvement in neutrophil number (the only objective measure unaffected by transfusion) is 1 to 2 months (145) and to transfusion independence is approximately 2 to 3 months (146, 147), continued improvement without further therapy commonly occurs beyond 3 months. A small fraction of patients are late responders, with responses observed as far out as 9 months (147). ATG-induced remission rates vary between studies from a low of approximately 24% in severe disease (146) to high rates of approximately 85% (148, 149). The true rate likely lies in the mid-range of 40 to 60%. Variations in ATG or ALG lots do not appear to account for differences in clinical response (150). In contrast to SCT, the likelihood of response to ALG has been correlated with disease severity (151), with the lowest responses in patients with absolute neutrophil counts less than 200/µl (152). Atgam is often given to a total dose of 100 to 160 mg/kg divided over 4 to 10 days. A comparison of ATG administered over 10 days versus 28 days showed no statistical difference in response rates (32). Lower frequency and severity of serum sickness is associated with shorter courses of ATG/ALG. The heterologous horse serum proteins trigger an immune response, leading to rapid clearance of ATG with resultant compromise of any benefit of prolonged administration of ATG (153). Patients who fail to respond within 2 to 3 months after the initial round of ATG/ALG may respond after a repeated course of treatment, with reported response rates varying from 22 to 64% (154). The three major side effects associated with antilymphocyte serum treatment are immediate allergic reactions, serum sickness, and transient blood count depression. Fever, rigors, and urticaria are common on the first day or two of therapy and respond to antihistamines, steroids, and meperidine. Anaphylaxis is rare but can occur. Patients treated with a second course of ATG of the same animal species have not shown any significant increase in side effects, although the side effects were seen sooner during the subsequent administration (154). Serum sickness, caused by the patient's antibody response to the horse/rabbit proteins, is a common occurrence. Serum sickness usually begins 5 to 11 days after the first dose of horse/rabbit immunoglobulin. Although the symptoms are generally brief, they can persist for weeks. Clinical manifestations are variable and include symptoms of fever, malaise, a cutaneous maculopapular rash, arthralgia, and myalgia. Gastrointestinal and neurologic symptoms may also be seen. A serpiginous rash on the volardorsal border of the hands and feet is an early pathognomonic sign. Urinalysis and creatinine clearance may be transiently abnormal, but frank renal failure is uncommon. In severe cases, rhabdomyolysis and myocarditis may be seen. There is no correlation between hematologic recovery and serum sickness (155). Corticosteroids are usually administered in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to minimize the symptoms of serum sickness. In addition to lymphocytes, ATG reacts with cell-surface antigens on granulocytes, platelets, and red cells, and decreased blood cell counts are common during the immediate period of ATG use. No direct comparisons between ATG and ALG, or even between ATG preparations derived from horses versus rabbits for the treatment of aplastic anemia, are available. A comparison between horse versus rabbit ATG on *in vitro* T-cell priming effects showed similar levels of tumor necrosis factor-a, interferon-?, and GM-CSF in T-cell supernatants as well as similar effects of T-cell supernatants on colony formation. It is important to be aware that ATG/ALG consists of crude mixtures of antibodies against a myriad of targets and that their active components have yet to be identified. Monoclonal antibodies directed against T cells have not been effective in the treatment of aplastic anemia either as single agents or in combination. Thus, it remains to be demonstrated whether the lymphocytotoxic and immunosuppressive effects of ATG/ALG are responsible for their therapeutic effects. Pleiotropic effects of ATG/ALG have been identified. ATG can increase colony growth of cultured bone marrow cells (86) and reduce the expression of Fas-Ag on aplastic anemia bone marrow CD34 $^{+}$ cells (87). ATG also includes antibodies against a variety of signal transduction and cell adhesion molecules (84). In a mouse model, ATG increased circulating levels of colony-stimulating activity (156). ATG also binds directly to bone marrow precursor (157) and progenitor (158) cells. In the absence of complement-mediated lysis, ATG/ALG can also stimulate lymphocyte function (159, 160).

Cyclosporin CYA is an effective immunosuppressive drug that has been successfully used to treat many autoimmune diseases (161). Although it has highly specific inhibitory effects on T-lymphocyte function, the mechanism of action responsible for its therapeutic effect in aplastic anemia has yet to be conclusively demonstrated. CYA inhibits inducible gene transcription and affects production of IL-2 and ?-interferon but not colony-stimulating factors. Cytotoxic T-cell activation of IL-2 receptors in response to lectins and alloantigens is prevented by cyclosporine. Multiple studies of aplastic anemia patients report responses to CYA (162, 163), although the success rates were highly variable (164, 165). A cooperative group study comparing patients with severe aplastic anemia randomly assigned to receive either ALG or CYA as initial therapy found equivalent remission rates and survival in the two groups (166, 167). As with ATG, clinical response cannot be predicted by *in vitro* tests. For many patients, remissions have been sustained even after discontinuation of CYA, although some patients relapse once CYA is discontinued. A proportion of patients who relapse respond to a second course of treatment. Some patients are unable to be weaned off CYA and require maintenance CYA treatment (165). Oral cyclosporin is generally administered twice daily at a dose that maintains blood trough levels between 100 and 250 ng/ml, as measured by radioimmunoassay (161). Hematologic responses can take weeks to months, and an initial trial period of 3 to 6 months is generally recommended. Periodic measurements of blood levels of CYA are necessary to ensure adequate immunosuppression and to avoid toxicity. Variability in cyclosporine metabolism, especially in children, may require serum levels to be determined frequently for dose adjustments (168). Cyclosporine toxicities include hypertension, azotemia, hirsutism, and gingival hypertrophy. Increasing serum creatinine levels are an indication to lower the dose (161). Chronic, irreversible nephrotoxicity can occur with long-term exposure. Cyclosporine, especially in combination with other agents, results in temporary immunodeficiency and new susceptibility to opportunistic infections.

Combination Immunosuppressive Therapy A striking increase in the response rate to immunosuppression was achieved using combination therapy with ALG and CYA: an 85% hematologic remission rate at 6 months, compared with 50% in those treated with ALG alone (169). Furthermore, CYA appeared to increase the tempo and extent of the responses. Subsequent trials have supported the improved effect of combined treatment with response rates of approximately 70 to 80% and 5-year survival rates of 90% in responders. Intensive immunosuppressive therapy has particularly improved the results in patient populations generally refractory to ALG or

ATG alone such as patients with very severe disease or children ([170]). A study enrolling both children and adults observed response rates of 67% at 43 months and a 5-year survival of 86% in those responding to treatment ([171]). The Gruppo Italiano Trapianti di Midolio Osseo/European Group for Blood and Marrow Transplantation study of 100 patients with severe aplastic anemia, including children (median age, 16 years) treated with ALG, CYA, prednisolone, and G-CSF, found trilineage hematopoietic responses in 77% after one or more courses of ALG ([172]). ATG is typically given over a 4-day course followed by a 6- to 12-month course of cyclosporin. When cyclosporin is discontinued, blood counts should be closely monitored. Some patients require continuous cyclosporin, and they should be maintained on the lowest effective dose. A review of ongoing trials revealed that 14 to 29% of initial responders have required continuous treatment ([171]). The reoccurrence of frank pancytopenia generally requires a second course of ATG followed by full-dose cyclosporin. Patients treated with immunosuppressive therapy often continue to have subnormal counts, although levels are functionally adequate. Thus, the goal of treatment is to maintain blood counts in a range that is adequate to minimize the risks of bleeding and infection and to prevent excessive fatigue. The addition of high-dose methylprednisolone to ALG has been associated with high response rates in some trials ([148], [149]) but not in other studies ([173]). Survival was the same for low- and high-dose methylprednisolone ([152]). A retrospective analysis of published series failed to find any advantage for the high-dose regimen ([174]). Because very high doses of corticosteroids can be associated with serious toxicity, this regimen is not currently recommended as first-line therapy.

Relapse Relapse is common after immunosuppressive therapy, with a 1993 report estimating relapse risk at 35% at 14 years ([175]). An ongoing National Institutes of Health trial noted a higher relapse rate, with an apparent plateau at 64% between 7 and 10 years, possibly an offsetting result of the higher initial response rates noted with cyclosporine-containing combination regimens ([171]). Disease severity, age, sex, and etiology were not predictive of relapse. A short interval to response after initiation of therapy and a long interval from diagnosis to treatment correlated with an increased risk of relapse ([175]). The definition of relapse varies between studies and physicians and can range from a decrease below a specified blood count(s) or the development of symptomatic cytopenia(s). Relapse has not significantly compromised survival in those patients who continue to respond to additional courses of immunosuppression. Tichelli et al. ([154]) studied the efficacy of repeated treatment with ALG for patients with severe aplastic anemia who either failed to respond to an initial course of ALG or who experienced hematologic relapse. Transfusion independence was achieved in 63% of patients, and survival probability was 52% ± 8% at 10 years. No differences were noted between patients retreated for nonresponse versus relapse. No increases in acute toxicity were noted with additional courses of ALG, although the timing of serum sickness tended to occur earlier after repeat ALG administration.

Complications of Immunosuppressive Therapy Patients treated for aplastic anemia with immunosuppressive therapy have an increased risk of developing clonal hematopoietic disorders (reviewed in references [176] and [177]). This increased malignant risk does not appear to be due to any direct carcinogenic effect of the immunosuppressive medications but likely arises from either the persistent alterations in immune surveillance or the continued presence of the underlying abnormal marrow. In an analysis of 860 patients treated with immunosuppression, there were 11 cases of MDS, 15 cases of acute leukemia, seven cases of solid tumors, and one case of non-Hodgkin lymphoma ([178]). Of 748 patients treated with transplantation, nine malignancies were reported: two acute leukemias and seven solid tumors. The cumulative incidence of developing a malignant tumor at 10 years was 18.8% after immunosuppression and 3.1% after transplantation. A recent series of 122 National Institutes of Health patients treated with immunosuppression reported a 33% risk of developing a clonal hematopoietic disorder at 10 years ([9]). A cohort of 30 aplastic anemia patients who developed clonal bone marrow abnormalities was followed prospectively ([179]). Abnormalities of chromosome 7 were seen in 40% of cases, and these accounted for most of the deaths related to leukemic transformation. The 23% of patients with trisomy 8 did not develop leukemias and had an excellent prognosis. The cytogenetic abnormalities were transient in only two patients, both of whom had manifested only 20 to 25% cytogenetically abnormal metaphases at the time the clonality was noted.

IMMUNOSUPPRESSION VERSUS BONE MARROW TRANSPLANTATION Immunosuppressive therapy and BMT are both effective therapies for aplastic anemia. For the 25% of patients for whom a suitable HLA-identical sibling donor is available, the decision to treat with immunosuppression versus HLA-identical sibling SCT is based on a consideration of risks and benefits that vary depending primarily on patient age and neutrophil count. Both short-term and long-term efficacy and side effects for each treatment must be carefully weighed. BMT is more expensive and riskier in the short term, but it is capable of permanently restoring normal hematopoiesis. Immunosuppression is cheaper, much less toxic, but more often results in partial remission ([174]) or in gradual recovery ([180]) rather than prompt reconstitution of entirely normal blood counts. As discussed above, late complications after immunosuppressive therapy include relapse and the development of late clonal hematologic disorders and malignancies in surviving patients. Immunosuppressive drugs have also been associated with end-organ toxicities such as cataracts, avascular necrosis, or renal failure. BMT is also not without its late problems. A small number of transplant patients may show late graft loss ([181]). Chronic thrombocytopenia occurred in 23% of patients who underwent transplants for diverse hematologic diseases ([182]). Acute leukemia has been reported to occur shortly after BMT for aplastic anemia ([183]). Moreover, the conditioning drugs and radiation of the transplantation procedure produce their own delayed complications, including pulmonary disease, endocrine dysfunction and infertility, leukoencephalopathy, cataracts, and secondary malignancies ([181], [184]). A recent European Group for Blood and Marrow Transplantation study in adult patients from ages 20 and older showed that response to immunosuppression (62% at 12 months) was independent of age, but mortality increased with increasing age ([185]). Studies comparing BMT and immunosuppression in children have generally significantly favored SCT. A comparison of immunosuppression versus BMT in patients stratified by age and neutrophil count showed superior failure-free survival with BMT for children regardless of their neutrophil count ([186]). The advantage of BMT increased with increasing follow-up time, most likely due to the ongoing risks of late relapse and evolution to MDS and leukemia in the immunosuppression group. Children have a lower mortality with SCT, and a longer posttreatment life expectancy places them at higher risk for late complications of immunosuppressive therapy than older adults. Thus, it has been recommended to treat young patients (= 10 years) with HLA-identical sibling SCT when a suitable donor is available. Patients younger than 40 years of age with neutrophil counts <300/µl also did better with BMT. Patients older than 40 years of age generally did better with immunosuppressive therapy. No clear advantage was apparent for either therapeutic option in patients between the ages of 20 and 40 years with neutrophil counts >300/µl. Studies comparing SCT to immunosuppressive therapy for the treatment of aplastic anemia are summarized in Table 44.5.

TABLE 44.5. Stem Cell Transplant vs. Immunosuppressive Therapy for Aplastic Anemia

	Survival (%)		
Study (Reference)	**Stem Cell Transplant**	**Immunosuppressive Therapy**	***p* Value**
Speck et al. (147)	44	69	NS

Locasciulli et al. (343)	63	48	.002
Speck et al. (344)	50	71	NS
Paquette et al. (345)	72	45	NS
Lawlor et al. (346)	75	92	NS
Doney et al. (347)	69	38	<.001
Fuhrer et al. (348)	84	87	NS
Kojima et al. (349)	97	55	<.001

NS, not statistically significant.

It is important to note that many studies of long-term outcomes were performed before the development of current immunosuppressive regimens containing both ATG and cyclosporin. Any differential long-term effects of these more intensive immunosuppressive regimens remains to be ascertained.

ANDROGENS Androgens no longer have a primary role in the management of aplastic anemia and are generally reserved for patients who have failed immunosuppressive therapy. In the past, early reports of responses to androgens ([187], [188]) were not supported by subsequent studies that found low rates of remission and no improvement in survival ([189], [190] and [191]). When the effects of androgens are compared in patients with severe and moderate aplastic anemia, the response rate (8% vs. 56%) ([192]) and subsequent survival (20% vs. 58%) ([193]) have generally been lower in those patients with severe disease. Selection bias for patients with moderate or chronic disease who could tolerate and survive a 3-month+ treatment regimen may account for a significant fraction of patient responses reported in many of the early studies. The greatest response to androgens is seen in the hematocrit, although improvements in granulocytes and in platelets may also occur ([193], [194]). Three to 6 months of treatment may be required before an adequate response is seen. Androgen therapy has multiple side effects such as virilization, hirsutism and acne, fluid retention, and psychological alterations. Hepatotoxicity can occur with all preparations but is less frequent with parenteral preparations ([195]). Liver function test abnormalities are usually reversible when androgens are discontinued, but the rare syndrome peliosis hepatis has been associated with androgen therapy ([196]). Children can tolerate high doses of androgens for more than a year without lasting effects on growth or maturation ([197]). The mechanism of action has

been reviewed extensively by Gardner and Besa ([198]). Androgens have a wide variety of biologic effects ([199] , [200]), including several actions on hematopoiesis ([201] , [202] and [203]). The effect of androgens on stimulating erythropoietin production by the kidney is unlikely to be important in aplastic patients, who produce abundant amounts of erythropoietin. Androgens have direct effects on hematopoietic cells. Androgens also have diverse, generally suppressive effects on the immune system ([201]).

HEMATOPOIETIC GROWTH FACTORS Although patients with aplastic anemia do not have a deficiency of most hematopoietic growth factors (see Hematopoietic Stroma and Growth Factors), it was hypothesized that supraphysiologic levels might stimulate hematopoiesis of one or more cell lines (reviewed in reference [82]). Trials of GM-CSF ([204] , [205] and [206]), G-CSF ([207] , [208]), IL-3 ([209] , [210]), IL-1 ([211]), IL-6 ([212]), SCF ([213]), and IL-11 ([214]) in aplastic anemia have been reported. Although the total number of patients treated in these protocols is not large, these studies do not support the use of growth factors as primary treatment for aplastic anemia. No consistent benefit in terms of response rate or survival after the adjunctive use of growth factors in immunosuppressive regimens has been observed. A recent pediatric prospective, randomized trial of G-CSF for aplastic anemia patients with neutrophil counts greater than 200/μl found no difference in the incidence of fever or infection with or without G-CSF ([215]). A few refractory patients have had responses to single or combined growth factors. A major concern with G-CSF treatment of aplastic anemia patients is the potential risk of promoting the development or propagation of a dysplastic or malignant clone (reviewed in reference [216]). A retrospective study of children with severe acquired aplastic anemia in Japan found that 11 out of a total of 167 patients developed MDS/acute myeloid leukemia (AML). Ten of the 11 cases showed monosomy 7. All 11 cases had received combination therapy with cyclosporin and G-CSF ([217]). It has been difficult to distinguish whether growth factor treatment is causally related to MDS/AML or whether MDS/AML develops in those patients selected for growth factor therapy because of the severity of the underlying bone marrow premalignant state. A recent study comparing 144 aplastic anemia patients on immunosuppressive therapy with or without G-CSF found that the risk of developing MDS/AML was similar between the two groups ([218]). In eight aplastic anemia patients who had developed MDS/AML, no mutations were detected in the cytoplasmic domain of the G-CSF receptor ([219]). Toxicities of recombinant human growth factors vary. G-CSF and GM-CSF are associated with flulike symptoms, bone pain, and splenomegaly. Symptoms of “cytokine flu”—fever, rash, hives, headache, and myalgia—are common but do respond to acetaminophen or resolve with the passage of time. Bone pain may be a symptom of increased marrow activity, although this is more commonly seen with G-CSF. At higher doses, the severity of symptoms increases, and there may be evidence of visceral engorgement and fluid retention. The toxic effects of IL-3 are similar, usually including fever, chills, and headache. Hypotension is the dose-limiting toxicity of IL-1. Anaphylactic responses have been associated with the use of SCF, also known as *mast cell factor*.

OTHER THERAPIES New therapeutic regimens aimed at improving rates of hematologic response and minimizing acute and long-term complications of therapy are under investigation ([85]). Administration of high doses of cyclophosphamide is an effective nonmyeloablative immunosuppressive therapy. An early study of treatment with this drug without transplant indicated a complete response in seven of ten patients treated with 45 mg/kg per day for 4 days ([220]). A subsequent phase III prospective, randomized trial compared high-dose cyclophosphamide plus cyclosporin to ATG plus cyclosporin as first-line therapy ([221]). The trial was terminated prematurely due to invasive fungal infections and three early deaths in the cyclophosphamide group (none in the ATG group). Responses at 6 months follow-up were seen in 6 of 13 (46%) patients treated with cyclophosphamide versus 9 of 12 (75%) patients treated with ATG. Other immunosuppressive agents currently under investigation include an anti–IL-2 receptor monoclonal antibody (Daclizumab), mycophenolate mofetil (MMF; Cell-Cept), FK506, and rapamycin.

Supportive Care of Bone Marrow Failure Patients

To avoid sensitization of the aplastic anemia patient, blood product support should be used sparingly, and donors should never be from the patient's family. All blood products should be leukofiltered and irradiated.

THROMBOCYTOPENIA Platelet (and red cell) support has probably had the greatest impact on survival in bone marrow failure by greatly reducing the mortality from bleeding. Few studies of platelet therapy in bone marrow failure patients are available, and treatment has generally been extrapolated from studies in acute leukemia patients. Significant characteristics of the bone marrow failure patients, such as the chronicity of the cytopenias, the absence of intensive chemotherapy, and differences in immune system function, dictate caution in applying studies of leukemia patients to this population. Platelets can be obtained from several individual units of blood or by plateletpheresis from a single donor. One platelet unit from a single unit of blood contains at least 5.5×10^{10} platelets, whereas a single donor apheresis pack contains 3 to 6×10^{11} platelets. Because the donor exposure is markedly diminished using apheresis platelets, the risk of allosensitization and of blood-borne infection transmission would, in theory, be lower using this approach. Although a recent multiinstitutional, randomized, blinded study in patients receiving induction chemotherapy for acute myeloid leukemia found similar low rates of allosensitization between patients receiving leukoreduced apheresis platelets or pooled platelet concentrates ([222]), the intensive immunosuppressive effects of induction chemotherapy compromises the generalizability of these findings to other immunocompetent bone marrow failure states. Refractoriness to platelet transfusions can be a devastating consequence of allosensitization, and management once this occurs is difficult ([223] , [224]). Nonimmune causes of platelet refractoriness should also be considered and include disseminated intravascular coagulation, amphotericin B treatment, antibiotics, splenomegaly, ongoing bleeding, and fever. The main role of prophylactic platelet support is reduction of the risk of intracranial hemorrhage, which is a rare but devastating event. Intracranial hemorrhage must be considered in thrombocytopenic patients presenting with headache, particularly when accompanied by additional symptoms of increased intracranial pressure, such as vomiting, or focal neurologic signs. Evaluation of such patients typically includes neuroradiologic imaging studies to assess for an intracranial bleed. Of note, in the setting of anemia, blood may generate a less intense signal on computed tomography scan, rendering acute bleeds more difficult to detect, and magnetic resonance imaging scans may be advantageous in certain cases. Although it is generally accepted that prophylactic platelet transfusions can reduce the risk of hemorrhage, the guidelines for such treatments remain an area of controversy ([225]). Multicenter, randomized trials in newly diagnosed AML patients found no significant difference in risk of major bleeding between patients randomized to receive prophylactic platelet transfusions at threshold platelet counts of 20,000/μl versus 10,000/μl ([226] , [227]). Use of the lower platelet threshold significantly reduced platelet use. Patients with fevers, active bleeding, or invasive procedures were transfused at platelet counts between 10,000 and 20,000/μl. Platelet transfusions at platelet counts below 5000 to 10,000/μl in stable outpatients with chronic severe aplastic anemia were feasible and safe in a recent study ([228]). This decision should be individualized for each patient, taking into consideration whether the patient has manifested a tendency to bleed reproducibly at any given platelet level. Chronic platelet transfusions for aplastic anemia are not used as frequently as they are in leukemia, and they are usually given when there are symptoms of bleeding or if the patient is at increased bleeding risk (e.g., toddlers learning to walk, patients with hypertension while on cyclosporin, and patients with fever and infection). Other measures to reduce bleeding include maintenance of good dental hygiene ([229]), use of a soft toothbrush, stool softeners, and avoidance of trauma. Drugs that may interfere with platelet function, such as aspirin or nonsteroidal antiinflammatory drugs, should be avoided. Antifibrinolytic agents, such as aminocaproic acid, may decrease bleeding, particularly from the gums and nasal mucosa ([230] , [231]). Management of menstrual prophylaxis should be initiated as appropriate for the degree of thrombocytopenia.

ANEMIA Red cells should be provided as clinically indicated. When possible, extended panel red cell antigen typing to minimize the risk of allosensitization seems reasonable, although studies to support the efficacy of this approach are currently lacking. Chronic anemia can be well tolerated, particularly in children. Anemia in the setting of concurrent thrombocytopenia is a potentially dangerous combination, and the threshold for transfusion may be higher in this situation. Long-term transfusions lead to iron overload, with accumulation in critical organs. Permanent damage to heart, liver, and endocrine glands can be prevented by iron chelation therapy ([232]). This may be difficult in thrombocytopenic patients, who may not tolerate subcutaneous infusions. Guidelines for the institution of iron chelation therapy in bone marrow failure patients are based on those established for thalassemia patients who are undergoing accelerated, albeit ineffective, erythropoiesis and often have concomitant increases in iron absorption. Total red blood cell volumes transfused, particularly for infants and small children, as well as total body iron status as reflected in serum ferritin and liver iron levels must be carefully monitored.

INFECTIONS There are few reported studies of infection management in bone marrow failure patients ([233] , [234]), and therapy is based largely on studies in cancer patients. Important differences from cancer patients should be noted. Whereas severe granulocytopenia may last for years, the cellular immune functions of aplastic anemia patients (before SCT or immunosuppressive therapy) remain intact. In addition, mucositis with subsequent compromise of mucosal barriers that can accompany chemotherapy is absent. Neutropenia (and perhaps monocytopenia) increases the risk of bacterial infection in aplastic anemia. Because neutropenia precludes the development of an inflammatory response, signs and symptoms of infection can be deceptively minimal. Bacterial infections may involve gram-negative bacilli, such as *Escherichia coli, Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*, as well as gram-positive cocci such as *Staphylococcus aureus*, *Staphylococcus epidermidis*, and streptococci. Immunosuppression due to preparation for BMT or as primary therapy for aplastic anemia may lead to unusual bacterial, fungal, viral, and protozoan infections. Treatment regimens are changing rapidly as new generations of treatments are developed and are beyond the scope of this chapter. The use of prophylactic antibiotics has no demonstrated role in the otherwise well patient with aplastic anemia. Although specific studies of the bone marrow failure population are lacking, patients undergoing immunosuppressive therapy should receive prophylaxis for *Pneumocystis carinii*. In the context of fever and neutropenia, complete evaluation and cultures of all possible sites should generally be followed by the administration of broad-spectrum parenteral antibiotics until the fever abates and all cultures are negative. Fungal infections occur with increased frequency in patients who have received repeated or extended courses of antibiotics; candidiasis and, especially, aspergillosis, which lead to sinusitis, lung disease, or disseminated infection, were frequent causes of death in a retrospective study of aplastic anemia patients between 1978 to 1990 ([233]). Antecedent or concurrent administration of steroids is expected to increase this risk. Aggressive initiation of ampho-tericin B treatment is indicated in the persistently febrile patient who is unresponsive to antibiotics or in the appropriate clinical setting.

INHERITED APLASTIC ANEMIA SYNDROMES

Fanconi Anemia

HISTORICAL BACKGROUND FA is an inherited syndrome with a variable clinical presentation that includes congenital anomalies, progressive pancytopenia, and cancer susceptibility. Guido Fanconi reported a familial syndrome of pancytopenia and congenital physical abnormalities in 1927 ([235], [236]). The diagnostic hallmark of FA is increased chromosomal breakage in response to DNA-damaging agents such as mitomycin C (MMC) or diepoxybutane (DEB). Remarkable advances in the last few years have elucidated a biochemical pathway that is disrupted in FA cells and carry potential implications for the diagnosis and treatment of FA patients.
EPIDEMIOLOGY FA follows an autosomal-recessive pattern of inheritance ([237], [238]). FA is found with similar frequencies in both genders and has no known ethnic restriction. The heterozygote carrier state has been estimated at 1 in 300 in the United States and in Europe ([237]) but may be higher in South Africa ([239]). The mean age at diagnosis is generally reported to be between 7 to 9 years, with 75% of cases diagnosed between the ages of 4 and 14 years; however, FA has been diagnosed in neonates as well as in adults in their 40s ([240]).
CLINICAL FEATURES FA should be considered in patients with congenital anomalies, aplastic anemia, or a family history of bone marrow failure or cancer susceptibility. The International Fanconi Anemia Registry analysis of 370 patients found that nearly 40% had no reported physical findings ([241]). Aplastic anemia or malignancy may be the presenting sign of the underlying diagnosis of FA in the absence of physical anomalies or prior family history. The manifestations of FA can vary between affected members of the same family, suggesting that additional genetic or environmental factors likely influence the disease course. A wide range of congenital anomalies has been reported in FA patients (reviewed in reference [240]) (Table 44.6). Skin pigmentary changes, short stature, and upper limb and thumb abnormalities are the most common manifestations associated with FA, although these characterize some of the other inherited bone marrow failure syndromes as well. Abnormalities of the skeletal, ocular, renal, genital, aural, gastrointestinal, cardiac, and central nervous systems have also been reported.

TABLE 44.6. Physical Findings Associated with Fanconi Anemia

Skeletal
Short stature
Radial anomalies (e.g., thumbs, hands, and forearms)
Microcephaly
Hip and spine anomalies
Skin
Hyperpigmentation (e.g., café au lait spots)
Hypopigmentation (e.g., vitiligo)
Genitourinary
Renal anomalies
Hypogonadism
Craniofacial
Ophthalmic anomalies (e.g., microphthalmia and epicanthal folds)
Otic anomalies (e.g., external and internal ear anomalies and deafness)
Gastrointestinal malformations
Cardiac malformations

The hematologic complications of FA typically present within the first decade of life, most often as moderate single or bilineage cytopenia. Patients with FA have an increased risk of developing MDS or AML. The overall incidence of MDS is estimated at 5%, and the incidence of AML is estimated at 10% ([242]). The cumulative risk of developing MDS or AML increases with increasing age, with an actuarial risk of 52% by 40 years of age ([243]). Patients with FA are also at increased risk of developing solid tumors, particularly squamous cell carcinomas of the head and neck, skin, gastrointestinal tract, and genital tract ([242]). All patients, and perhaps particularly those receiving androgen treatment, are at increased risk of liver tumors. The majority of tumors associated with FA develop in patients in their second or third decade of life. These malignancies may be difficult to treat because patients with FA are sensitive to chemotherapy and radiation. Regular and frequent surveillance for cancers is particularly important in this population and is discussed further in the section Supportive Care. Growth hormone deficiency has been observed in some FA patients ([244]), and treatment with growth hormone improved growth in a subset of these patients ([245]). Additional endocrine disorders associated with FA include hypothyroidism with or without thyroid hormone–binding globulin deficiency, abnormal glucose tolerance, and diabetes mellitus ([244]).
DIFFERENTIAL DIAGNOSIS FA is the most common known genetic cause of aplastic anemia and one of the most common genetic causes of hematologic malignancy. Cells derived from patients with other chromosomal breakage syndromes or syndromes with similar constitutional findings, such as Bloom syndrome or ataxia-telangiectasia, may also exhibit high rates of spontaneous chromosomal breakage; however, only FA cells exhibit increased chromosomal breakage in response to DEB.
LABORATORY Cell morphology on peripheral blood smear is typically unremarkable except for red cell macrocytosis and mild anisocytosis, although these are variably present. Thrombocytopenia or leukopenia typically precede anemia. Pancytopenia generally worsens over time. Erythrocyte macrocytosis and increased hemoglobin F levels may be present even in the absence of cytopenias. Bone marrow biopsy findings vary from normal cellularity to frank aplasia. Morphologic examination of the bone marrow aspirate may show dysplastic features, with nuclear-cytoplasmic maturation dysynchrony. Dyserythropoiesis with multinucleate forms or nuclear fragmentation may be seen. Bone marrow aspirates should be sent for cytogenetic analysis, as FA patients are at high risk for malignant transformation.
The diagnosis of FA is based on the demonstration of increased chromosomal breakage in the presence of DNA cross-linking agents such as MMC or DEB ([246], [247]) (Fig. 44.2). DEB is preferred in some centers because it is associated with less variability in chromosomal breakage among normal controls. The chromosomal breakage test is usually performed on metaphase spreads of peripheral blood lymphocytes treated with MMC or DEB. A total of 50 cells in metaphase are analyzed for chromosomal breakage, including the formation of radials—a hallmark of this disease. Results are compared to a normal and a positive control that have been run in parallel. Results are reported as aberrations per cell and the number of cells with radial forms. Increased spontaneous chromosomal breakage may be observed in some FA patients; nonetheless, the rate of breakage is markedly enhanced by exposure to MMC or DEB regardless of patient phenotype or severity of disease. Chromosomal breakage in response to MMC/DEB can also be assessed in fetal cells obtained by amniocentesis or chorionic villus sampling for prenatal diagnosis ([248], [249]). If the disease-causing mutation is known for a given family, these assays can be used for preimplantation genetic diagnosis ([250]). FA patient cells also exhibit cell cycle abnormalities, with G_2 phase prolongation and arrest by flow cytometry ([251], [252]). Studies comparing results of DEB chromosomal breakage with cell cycle analyses of patients referred for FA testing showed close correlation between the results of these two tests ([253]). Constitutive elevation of serum alpha-fetoprotein has been reported in FA patients ([254]), although variations in alpha-fetoprotein levels determined by different methodologies and the lack of specificity has limited the diagnostic utility of this test so far ([255]). FA heterozygous carriers cannot be reliably detected by cytogenetic testing for chromosomal breakage.

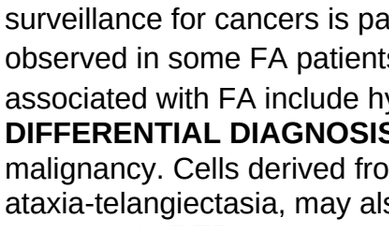

Figure 44.2. Chromosomal breakage in Fanconi anemia. Peripheral blood lymphocytes from a Fanconi anemia patient were cultured without **(A)** or with **(B)** mitomycin C. The black arrows indicate chromosomal breaks. The red arrows indicate radial chromosomal fusions characteristic of Fanconi anemia. (Courtesy of Lisa A. Moreau, Dana Farber Cancer Institute, Boston, MA.)

Somatic reversion to wild type has been observed in a subset of lymphocytes from some FA patients. Increased chromosomal breakage may only be seen in a subpopulation of lymphocytes in such patients. The reversion to normal cellular phenotype has been attributed to recombination or gene conversion events leading to selective advantage of the reverted lymphocytes ([256], [257]), although somatic reversion has also been reported in earlier hematopoietic lineages ([258]). Patients with a high degree of wild-type lymphocyte mosaicism may be difficult to diagnose. In such cases with a high degree of suspicion for FA, the MMC/DEB test should be performed on skin fibroblasts derived from a punch biopsy because somatic mosaicism has not been observed in fibroblasts.
PATHOPHYSIOLOGY Several mechanisms for the underlying defect in FA have been postulated, and data are available to support each theory. Models of the FA

biochemical pathway have emerged from molecular studies of the cloned FA gene products. At least eight different FA complementation groups (A, B, C, D1, D2, E, F, G) have been identified, and the corresponding genes have been identified ([259], [260]) (Table 44.7). The proteins FANCA, FANCC, FANCD2, FANCE, FANCF, and FANCG do not share homology to known proteins, and their function is not known. The gene for Fanconi subtype D1, and possibly also subtype B, is the previously identified tumor suppressor gene, BRCA2 ([260]). These complementation groups were first identified through cell fusion studies looking for correction of MMC sensitivity ([261]). Subtyping analysis has been facilitated by the use of retroviral vectors to introduce different wild-type Fanconi complementary DNAs to assess for correction of MMC sensitivity in cultured patient cells ([262], [263]). The most common FA subtype is FA-A (60 to 70%), followed by FA-C (10%), and FA-G (10%). The other FA subtypes are rare. The mutations associated with FA are highly variable.

TABLE 44.7. Complementation Groups of Fanconi Anemia (FA)

Subtype	FA Patients (Estimated)	Chromosome Location	Protein Products (kd)
A	70%	16q24.3	163
B (BRCA2?)	Rare	(13q12.3?)	(380?)
C	10%	9q22.3	63
D1/BRCA2	Rare	13q12.3	380
D2	Rare	3p25.3	155,162
E	Rare	6p21-22	60
F	Rare	11p15	42
G	10%	9p13	68(XRCC9)

A model (Fig. 44.3) has emerged whereby DNA damage by agents, such as MMC, ionizing radiation, or ultraviolet radiation, leads to activation of the Fanconi proteins A, B, C, E, F, and G to culminate in the covalent attachment of a ubiquitin protein (monoubiquitination) to FANCD2 ([264]). After monoubiquitination, FANCD2 colocalizes in nuclear foci with BRCA1, a known cancer susceptibility gene implicated in DNA repair. Additional DNA repair proteins, such as rad 51, MRE11, and NBS1, also localize in BRCA1-containing foci ([265], [266]) to further implicate FANCD2 in DNA repair. Monoubiquitination of FANCD2 is required for MMC resistance and is dependent on the functional integrity of the upstream Fanconi proteins. FANCD2 monoubiquitination remains intact in bone marrow failure syndromes other than FA ([267]). The role of FANCD2 monoubiquitination is a subject of intensive investigation. FANCD2 monoubiquitination can be assessed on a Western blot and serves as a potentially useful biochemical diagnostic screen for FA.

Figure 44.3. Model of the Fanconi anemia biochemical pathway. After activation by DNA damage, the upstream Fanconi proteins A, B/BRCA2, C, E, F, and G function coordinately to culminate in monoubiquitination of the Fanconi D2 protein. Monoubiquitinated FANCD2 interacts with the tumor suppressor BRCA1 protein and translocates to discrete nuclear foci together with additional DNA repair proteins. The Fanconi D1/BRCA2 protein is not required for FANCD2 monoubiquitination.

Elucidation of the Fanconi biochemical pathway in turn led to the identification of interactions between the Fanconi proteins and other known tumor suppressor pathways. These findings provide biochemical support for a role of the Fanconi pathway in tumorigenesis. FANCD2 was subsequently shown to be phosphorylated at a serine residue at amino acid position 222 ([268]). FANCD2 serine 222 phosphorylation is dependent on ATM kinase and is required for the cell cycle S-phase checkpoint in response to radiation ([268]). ATM function is disrupted in the chromosomal instability syndrome ataxia-telangiectasia. Thus, FANCD2 links two DNA repair pathways, the Fanconi pathway and the ataxia-telangiectasia pathway. Dysfunction of the Fanconi pathway or the ATM pathway is associated with increased cancer susceptibility. The Fanconi biochemical pathway was further implicated in DNA repair by the identification of the gene for FANCD1, and possibly also FANCB, as the tumor suppressor gene, BRCA2 ([260]). Given the compelling biochemical data linking the Fanconi pathway to other known DNA repair pathways functioning in tumor suppression, the question of whether asymptomatic FA heterozygotes carry an increased risk of developing malignancies is a subject of active investigation. Previous studies of cancer risk in FA heterozygotes by Swift et al. ([269], [270]) were performed before the development of diagnostic tests for FA, and the diagnosis of the study population is not clear because other syndromes may also manifest with low blood counts and congenital anomalies. In addition to a nuclear role in DNA repair, numerous studies suggest additional potential functions for the FA proteins. FA cells are sensitive to many different extracellular apoptotic signal, such as ?-interferon, tumor necrosis factor-a, and double-stranded RNA ([271], [272], [273] and [274]). Furthermore, Fanconi proteins, such as FANCC, may have additional roles in other signaling pathways ([275]). Studies also suggest a role for the FA proteins in mediating oxidative stress ([276], [277]). DEB, a clastogen to which Fanconi cells are especially susceptible, can cause oxidative DNA damage. FA cells can exhibit increased susceptibility to oxidative damage, and reactive oxygen species can damage DNA and can lead to DNA cross-links and double-stranded breaks.

SUPPORTIVE CARE The guidelines discussed above for supportive care of the aplastic anemia patient also are generally applicable to FA patients with marrow failure. Choice of therapies should be guided by an understanding of the underlying pathophysiology and after careful consideration of concomitant treatments. Cancer surveillance and education play an important role in the management of FA patients. Physicians should counsel patients regarding established behavioral and environmental risk factors associated with increased cancer risk. Because FA patients have a defect in DNA repair, imaging studies should minimize exposure to ionizing radiation. For example, when clinically indicated, it is reasonable to use magnetic resonance imaging scans rather than computed tomography scans for FA patients. Complete blood cell counts to monitor for MDS or leukemia are recommended. Given the increased risk of MDS and leukemias in bone marrow failure patients, annual bone marrow aspirates and biopsies with cytogenetic analysis are recommended. For patients on androgen therapy, regular physical examinations for liver size, liver ultrasound for masses or abnormalities every 6 to 12 months, and frequent liver enzyme tests are recommended. Annual examinations for leukoplakia or other signs of squamous cell carcinoma of the oral cavity and oropharynx by an otolaryngologist are important for patients with FA, DKC, and those FA patients previously treated with BMT. Annual endoscopy can be considered in older FA and DKC patients. Regular dental examinations are important both for maintenance of oral hygiene and for detecting leukoplakia. Patients should be evaluated immediately for symptoms of pain in the mouth or throat, difficulty swallowing, changes in voice, anorexia, or weight loss. Suspicious lesions should be biopsied immediately because early surgical excision is the mainstay of cancer therapy in FA patients. Annual gynecologic examinations, including Pap smears and human papillomavirus examination, are recommended at puberty or after the age of 16 years. Counseling regarding sexual activity should be provided as this possesses an increased risk for neutropenic and thrombocytopenic patients. Barrier methods of contraception may be particularly pertinent for the FA patients who are already at risk for cervical and vulvar malignancies. Regular breast examinations are also recommended, although it is not clear what role mammography should play in cancer screening of these patients. Regular endocrinology evaluations are important, particularly in the pediatric population if the patient exhibits poor growth or delayed puberty. Gastrointestinal symptoms may present in FA patients, necessitating prompt referral to a gastroenterologist.

TREATMENT Hematopoietic SCT is the only curative therapy for the hematologic manifestations of FA. Because patients with FA are exquisitely sensitive to the toxicity of the usual chemotherapy and radiation regimens used in preparation for BMT, reduced doses are typically used. An appropriate conditioning regimen combined with use of a matched sibling donor has resulted in survivorship in 65 to 80% of patients ([278], [279] and [280]). The long-term effects of transplantation, both with respect to immune suppression and end-organ toxicity, in this population remain unclear. Some patients have experienced post-SCT malignancies, especially squamous cell carcinomas of the head and neck. Risk factors for posttransplant malignancies have included the use of radiation and chronic GVHD. In an attempt to reduce the long-term risk for malignancies, clinical trials replacing radiation with fludarabine and ATG are in progress. Initial results show engraftment rates comparable to those with radiation-containing regimens. Long-term outcomes on malignancy risk remain to be determined. Global effects of SCT on growth, endocrine disturbance, and other end-organ function are poorly characterized. Alternative donor SCT has been limited by high rates of graft failure and toxicities from the more rigorous conditioning regimens required for these transplants ([281], [282]). Encouraging preliminary results have been reported in studies investigating the addition of fludarabine to the conditioning regimens, including either total body irradiation or busulfan. Improvements in engraftment and GVHD have been seen with fludarabine-conditioning regimens; however, fatal opportunistic infections remain a major source of mortality. Multiple other therapies are also available to FA patients. Androgens can improve the blood counts in approximately 50% of patients with FA. Suggested treatment guidelines have been proposed by a consensus committee of the Fanconi Anemia Research Foundation, though these guidelines must be individualized for each patient and undergo continuous modification as new data emerge. The suggestion of the committee is to consider an allogeneic SCT or androgen therapy if the hemoglobin falls below 8 g/dl, if anemia is symptomatic, if

the platelet count falls below 30,000/mm ^{3}, or the neutrophil count falls below 500/mm ^{3}. The earliest and most frequent response to androgens is seen in red cells, with reticulocytosis and increase in hemoglobin generally occurring within the first 1 to 2 months of treatment. Responses in the white blood cell count and platelet count are variable and may not be seen until 6 to 12 months of therapy. Resistance to therapy often develops over time (generally years). A common androgen regimen consists of oxymetholone, 2 to 5 mg/kg/day given orally. Androgen doses may be slowly tapered to the minimal effective dose with careful monitoring of the blood counts. Side effects of androgen administration include liver toxicity such as elevated liver enzymes, cholestasis, peliosis hepatis, and increased propensity to develop hepatic tumors. Other side effects of androgens include acne, oily skin, enlarged penis/clitoris, hoarseness/voice deepening, hair growth or hair loss, behavioral changes, hot flashes, breast enlargement or tenderness, amenorrhea, fluid retention, and secondary hypertension. Hematopoietic growth factors, such as G-CSF or GM-CSF, have been shown to improve the neutrophil count in the majority of treated patients ([283], [284]). In a few patients, platelet or red cell counts have also improved after treatment with G-CSF ([284]). Growth factor treatment is generally not recommended for patients with MDS and is generally avoided for those with a clonal cytogenetic abnormality of the bone marrow, although there are no available data that address these issues. It is reasonable to perform a bone marrow aspirate and biopsy before the initiation of growth factor therapy and monitor regularly throughout therapy. Results of a gene therapy trial for FA-C patients have been reported ([285]). Three FA-C patients underwent three to four cycles of retroviral transduction of G-CSF–mobilized peripheral blood CD34 $^+$ mononuclear cells, whereas a fourth patient received a single infusion of transduced cells. The transduced wild-type FANC-C gene was detected in peripheral blood and bone marrow mononuclear cells in association with increased hematopoietic colony growth *in vitro*. Transient improvement in bone marrow cellularity accompanied these findings, and two patients experienced a transient improvement in blood counts, suggesting that correction of the underlying FANCC gene defect may be sufficient to improve hematopoietic function. However, these findings were transient, indicating that hematopoietic stem cell transduction had not been achieved.

Dyskeratosis Congenita

DKC is an inherited disorder characterized by abnormalities of skin pigmentation, nail dystrophy, and leukoplakia. X-linked–recessive, autosomal-dominant, and autosomal-recessive inheritance patterns have been reported. Patients exhibit a predisposition to bone marrow failure, malignancy, and pulmonary dysfunction.

CLINICAL FEATURES A comprehensive study of the clinical features associated with DKC was undertaken by the DKC registry established in 1995 ([286]). By 1999, the registry included 92 families from 20 countries. There were 148 DKC patients of whom 127 were male and 21 were female. Twenty-five families showed an X-linked–recessive pattern of inheritance, whereas 51 families had sporadic affected males. Sixteen families included one or more affected females representing both autosomal-dominant and autosomal-recessive forms of the disease. The severity of the clinical phenotype can vary widely in affected members of the same family. In addition to the classic triad of skin, nail, and oral findings, a variety of other clinical features have been described in patients with DKC (Table 44.8). The range of physical findings in female patients is similar to those reported in male patients, though the phenotype in females is highly variable ([286]). Most of the somatic abnormalities are not present early in life but develop progressively with age. The skin rash is typically reticular and mottled in appearance and may be localized or widespread. The classic triad of abnormal skin pigmentation, nail dystrophy, and leukoplakia generally appears between the ages of 5 and 10 years, with a median age of onset between 6 and 8 years (range, 0.5 to 26.0 years) ([286]). Both the tempo of symptom progression as well as symptom severity are highly variable between patients. For example, nail dystrophy can range from minimal nail irregularities to progressive atrophy and even complete nail loss.

TABLE 44.8. Clinical Features Associated with Dyskeratosis Congenita

Skin pigmentary abnormalities	Hyperhidrosis
Nail dystrophy	Malignancy
Bone marrow failure	Intrauterine growth retardation
Leukoplakia	Gastrointestinal disorders
Epiphora	Ataxia
Cognitive/developmental delay	Hypogonadism/undescended testes
Pulmonary disease	Microcephaly
Short stature	Urethral stricture/phimosis
Dental caries/tooth loss	Osteoporosis/aseptic necrosis/scoliosis
Esophageal stricture	
Hair loss/gray hair/sparse eyelashes	Deafness

From Dokal I. Dyskeratosis congenita in all its forms. Br J Haematol 2000;110:768–779, with permission.

Peripheral cytopenias of at least one lineage developed in 85.5% of patients, and two or more peripheral lineages were affected in the majority of registry patients. The median age of onset of pancytopenia was 8 years, with 50% developing pancytopenia younger than the age of 10 years ([286]). The bone marrow is typically hypocellular, though cellularity may be normal or even increased early in the disease. Bone marrow failure or its associated complications accounted for the majority of deaths (67%). Approximately 20% of patients develop pulmonary disease with reduced diffusion capacity and/or restrictive pulmonary disease ([286], [287] and [288]). Pulmonary complications account for nearly 10% of deaths ([286]). Postmortem studies reveal pulmonary fibrosis and abnormalities in the pulmonary microvasculature. Similarly, a high incidence of early and late fatal BMT-associated pulmonary complications has also been reported in DKC patients ([289]). Immunologic abnormalities, including low or high immunoglobulins, reduced numbers of B or T cells, and reduced stimulation by phytohemagglutinin, have been described in some DKC patients ([286], [290]). Opportunistic infections, such as *P. carinii* pneumonia, have been reported ([291], [292]). Malignancies were noted in 13 out of 148 patients (8.8%) in the DKC registry ([286]). Malignancies developed in older patients, generally after the second decade of life. It is possible that a higher incidence of malignancies might have been observed had not many patients succumbed to aplastic anemia at an earlier age. An increased incidence of MDS and acute myeloid leukemia has also been observed ([286]). Eight cases of carcinomas were reported in patients aged 20 to 56 years.

DIFFERENTIAL DIAGNOSIS Although DKC shares many clinical features with FA (e.g., aplastic anemia, oral leukoplakia, and cancer predisposition), cells from DKC patients do not manifest increased chromosomal breakage in response to MMC or DEB ([309]). Literature reports differ over whether cells from DKC patient cells exhibit increased chromosomal breakage in response to other agents ([310], [311], [312], [313] and [314]). Because DKC patients may develop aplastic anemia in the first decade of life before the manifestation of skin or nail abnormalities, they may be misdiagnosed as having severe aplastic anemia. With the identification of two of the genes involved in DKC, DNA sequence analysis of skin fibroblasts or buccal swabs will be useful in directly identifying DKC.

LABORATORY FINDINGS In addition to peripheral cytopenias, red cell macrocytosis and elevated fetal hemoglobin may be seen in patients with DKC ([315]). As noted above, immunologic abnormalities have also been described in some patients ([286], [290]). Primary DKC skin fibroblasts grow slowly in culture and exhibit abnormal morphology. X-chromosome inactivation patterns in female obligate carriers showed complete skewing, consistent with a growth or survival disadvantage for cells expressing only the defective X-chromosome allele ([316], [317] and [318]). Spontaneous unbalanced chromosomal translocations have been observed ([306], [319]).

PATHOPHYSIOLOGY Reduced hematopoietic progenitor cell colonies have been described for all three hematopoietic lineages, compared with controls ([293], [294], [295] and [296]). DKC patients show a reduction in the proliferative capacity of myeloid progenitors, as measured by secondary colony formation after replating ([297]). Bone marrow cells from DKC patients show poor growth in long-term bone marrow culture assays. The defect is intrinsic to the hematopoietic stem cells because DKC stromal cells are able to support hematopoietic cells from normal controls, whereas DKC hematopoietic cells grow poorly on normal control stroma ([296]). The X-linked–recessive form of DKC was linked to Xq28, and the gene was identified by positional cloning and named *DKC1* ([298]). *DKC1* encodes a ubiquitously expressed protein, dyskerin, that exhibits strong homology to two previously characterized proteins: *Saccharomyces cerevisiae* Cbf5p ([299], [300]) and rat NAP57 ([301]). Like Cbf5p and NAP57, dyskerin is localized primarily in the nucleolus and shares some homology with RNA pseudouridine synthases. Pseudouridine synthases together with small nucleolar RNAs isomerize uridine bases in ribosomal RNAs (rRNAs) to pseudouridine. In the absence of Cbf5p, yeast rRNA processing is defective ([300]). The hypothesis that dyskerin mutations might lead to misprocessing of rRNA and defective ribosomal function is not supported by studies of pseudouridylation or rRNA processing in affected cells ([302]). It was subsequently shown that dyskerin interacts with human telomerase as well as with other small nucleolar RNAs ([303]). Telomere length is abnormally short, and levels of human telomerase RNA and of telomerase activity are reduced in cells from X-linked DKC patients with two different dyskerin point mutations ([302]). Because dyskerin mutations described to date consist of missense mutations or small deletions, it is possible that these result in partial loss of telomerase function and that null mutations might be lethal. In further support of a telomerase defect in DKC, the mutations responsible for the autosomal-dominant form of DKC in three affected families were found to reside in human telomerase RNA itself ([304]). *Telomerase* is an enzyme that adds DNA sequences to the ends of chromosomes (the telomeres) to prevent loss of terminal repeats during DNA replication (reviewed in reference [305]). Telomeres are important for the prevention of chromosomal fusions and rearrangements. Spontaneous unbalanced chromosomal rearrangements have been described in fibroblasts and bone marrow cells from DKC patients ([306]). Telomerase consists of a catalytic reverse transcriptase component as well and an RNA

component. Although telomerase activity is abundant early in development, it is later detectable only in a subset of tissues, including the progenitor cells of the hematopoietic system, the basal layer of the epidermis, intestinal cells, and hair follicles. These tissues mirror those most severely affected in DKC patients. Telomere loss has also been implicated in contributing to the process of aging, and DKC may represent a form of premature aging of tissues with a high replicative requirement ([307], [308]). With the identification of two of the genes responsible for DKC, a relationship between the genotype and phenotype of extended kindreds can be established. It is possible that the full syndrome of DKC might represent only the most severe form of the disease and that previously unrecognized milder forms exhibiting only isolated symptoms might also exist.

SUPPORTIVE CARE Supportive care for DKC patients is similar to that outlined for aplastic anemia and FA patients. In addition, annual pulmonary function testing is recommended. Regular endocrinology visits are particularly important as DKC patients are at increased risk of osteoporosis, and their diet, vitamin D, and parathyroid hormone levels and calcium status should be monitored.

TREATMENT The only curative treatment for bone marrow failure in DKC remains allogeneic SCT ([289], [320], [321], [322], [323], [324], [325] and [326]). Although long-term survivors have been reported, early and late fatal pulmonary and vascular complications after SCT remain a significant problem ([289], [320], [323], [324], [327]). The avoidance of drugs associated with pulmonary toxicity and the use of radiation-sparing conditioning regimens may provide useful avenues for future study. DKC may be mistaken for chronic GVHD in patients transplanted for aplastic anemia ([328], [329]). Improvement in peripheral blood counts has been described in response to oxymetholone ([330]). Improved neutrophil counts in response to GM-CSF ([331], [332]) or G-CSF ([333], [334]) have been reported. Combined treatment with G-CSF and erythropoietin led to improved neutrophil and red cell counts in one case report ([335]).

Red Cell Aplasia

ADULT PURE RED CELL APLASIA

Pure red cell aplasia (PRCA) is a syndrome characterized by normochromic normocytic anemia, reticulocytopenia (reticulocyte count <1%), and almost a complete absence of erythroblasts from the bone marrow (erythroblasts <0.5%) ([1]). PRCA is a rare disorder that affects any age group and both males and females equally.

In contrast to aplastic anemia, in which the aplasia involves all three cell lines, in PRCA, the aplasia is selective for the erythroid cell line, resulting in severe anemia with normal leukocyte and platelet counts. This disorder was described for the first time in 1922 ([2]) and later appeared in the literature under different names, including *pure aplastic anemia*, *erythrophthisis*, *chronic hypoplastic anemia*, *aplastic crisis*, *erythroblastopenia*, *erythrogenesis imperfecta*, *Blackfan-Diamond syndrome*, *pure red cell agenesis*, and *primary red cell anemia* ([1]). Today, the term *PRCA* is used to describe this disorder in adults, whereas the terms *Diamond-Blackfan anemia* (DBA) and *transient erythroblastopenia of childhood* (TEC) are used for the congenital and acquired forms that occur in infants and children.

Etiology and Pathogenesis

PRCA is an acquired anemia that may be primary or secondary to a variety of neoplastic, autoimmune, or infectious diseases ([1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31], [32], [33], [34], [35], [36], [37], [38], [39], [40], [41], [42], [43], [44], [45], [46], [47], [48], [49], [50], [51], [52], [53], [54], [55], [56], [57], [58], [59], [60], [61], [62], [63], [64], [65], [66], [67], [68], [69], [70], [71], [72], [73], [74], [75], [76], [77], [78], [79], [80], [81], [82], [83], [84], [85], [86], [87], [88], [89], [90], [91], [92], [93], [94], [95], [96], [97], [98], [99] and [100]) (Table 45.1).

TABLE 45.1. Classification of Pure Red Cell Aplasia

- Congenital hypoplastic anemia (Diamond-Blackfan syndrome) ([3])
- Acquired pure red cell aplasia
  - Primary
    - Autoimmune (includes transient erythroblastopenia of childhood)
    - Preleukemic
    - Idiopathic
  - Secondary, associated with
    - Thymoma ([1], [4], [5])
    - Hematologic malignancies
      - Chronic lymphocytic leukemia
        - B-cell type ([1], [6], [7] and [8])
        - T-cell type ([1], [9], [10] and [11])
        - Large granular lymphocyte leukemia ([1], [12])
      - Hodgkin disease ([13], [14], [15] and [16])
      - Non-Hodgkin lymphomas ([17], [18], [19], [20] and [21])
      - Multiple myeloma ([22], [23])
      - Waldenström macroglobulinemia ([24])
      - Chronic myelocytic leukemia ([25], [26] and [27])
      - Myelofibrosis with myeloid metaplasia ([1], [27], [28] and [29])
      - Essential thrombocythemia ([30])
      - Acute lymphoblastic leukemia ([31], [32] and [33])
    - Solid tumors
      - Carcinoma of the stomach ([34])
      - Adenocarcinoma of the breast ([35], [36])
      - Adenocarcinoma of the bile duct ([37])
      - Squamous cell carcinoma of the lung ([38], [39] and [40])
      - Epidermoid carcinoma of the skin ([41])
      - Carcinoma of the thyroid ([42])
      - Renal cell carcinoma ([43])
      - Carcinoma of unknown primary site ([44])
      - Kaposi sarcoma ([6], [45], [46])
  - Infections
    - Human B19 parvovirus ([47], [48], [49], [50], [51], [52], [53], [54], [55], [56] and [57])
    - Human immunodeficiency virus ([58], [59])
    - T-cell leukemia-lymphoma virus ([60])
    - Infectious mononucleosis ([61], [62], [63] and [64])
    - Viral hepatitis ([65], [66] and [67])
    - Mumps ([1], [68], [69])
    - Cytomegalovirus ([70])
    - Atypical pneumonia ([1], [68], [69])
    - Meningococcemia ([1], [68], [69])
    - Staphylococcemia ([1], [68], [69])
    - Leishmaniasis ([70], [71] and [72])

Chronic hemolytic anemias (1, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56 and 57)
Collagen vascular diseases
  Systemic lupus erythematosus (73, 74)
  Rheumatoid arthritis (75, 76)
  Mixed connective tissue disease (77)
  Sjögren syndrome (78, 79)
Drugs and chemicals (see Table 45.2)
Pregnancy (80, 81, 82 and 83)
Severe renal failure (84)
Severe nutritional deficiencies (85, 86, 87 and 88)
Miscellaneous
  Post–ABO-incompatible bone marrow transplantation (89, 90)
  Angioimmunoblastic lymphadenopathy (91, 92)
  Autoimmune multiple endocrine gland insufficiency (93, 94)
    Autoimmune hypothyroidism (95, 96)
    Autoimmune chronic hepatitis (97, 98)
  Anti-EPO antibodies after treatment with EPO (99, 100)

EPO, erythropoietin.

Primary acquired PRCA affects individuals of any age in the absence of any underlying disorder. It may run an acute and usually self-limited course or may persist chronically as a form of refractory anemia. In children, this condition is referred to as *TEC*, which is usually of limited duration ([1], [69], [70], [101], [102]). In contrast, the acute form of primary PRCA is very rare in adults, and the chronic form of this disorder predominates. Acute PRCA in adults escapes diagnosis because acute arrest of erythropoiesis of short duration does not lead to symptoms of anemia due to the long lifespan of the red cells. Many cases of PRCA have been shown to have an immune pathogenesis and are classified as autoimmune. However, there are cases in which no immune pathogenic mechanism can be established by *in vitro* assays, and these are classified as idiopathic. Failure to demonstrate an immune mechanism does not exclude an immune pathogenesis because the outcome of treatment seems to be the same in autoimmune and idiopathic cases ([1]). A small percentage of cases of idiopathic PRCA, usually refractory to treatment, may evolve into acute leukemia, and these cases are classified as preleukemic or myelodysplastic ([1], [103]).

PRCA may develop as a hematologic complication in the course of a variety of diseases. Of these, thymic neoplasms were the first to be associated with erythroid aplasia ([1], [5], [6]). The incidence of PRCA among patients with thymoma was initially estimated to be as high as 15%; however, in more recent series, the incidence was found to be close to 4% ([1], [5]). The presence of a thymoma among patients presenting with PRCA was initially reported to be as high as 50%, but in more recent series, it was estimated to be close to 9% ([1], [5], [6], [104]). PRCA may precede the development of thymoma, coexist with thymoma, or even develop years after the surgical removal of a thymoma.

Various hematologic malignancies have been associated with severe erythroid aplasia ([7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31], [32] and [33]) with chronic lymphocytic leukemia (CLL) of B-cell or T-cell type, or of the large granular lymphocyte (LGL) type, being the most frequent ([6], [12]). The incidence of severe erythroid aplasia among patients with CLL may be as high as 6%, with many cases missed because severe normochromic anemia and reticulocytopenia are frequent manifestations of advanced stage CLL and are usually attributed to the myelophthisic process in the marrow. The development of erythroid aplasia may depend on the stage of CLL ([104]); however, it does not affect its prognosis and, in the majority of cases, does not seem to be related to previous cytotoxic chemotherapy ([1], [6]). PRCA has also been described in association with Hodgkin and non-Hodgkin lymphomas ([13], [14], [15], [16], [17], [18], [19], [20] and [21]), multiple myeloma, Waldenström macroglobulinemia ([22], [23] and [24]), chronic myelocytic leukemia, idiopathic myelofibrosis, essential thrombocythemia ([25], [26], [27], [28], [29] and [30]), and acute lymphoblastic leukemia ([31], [32] and [33]).

PRCA may develop in the course of a variety of nonhematopoietic, nonthymic neoplasms ([34], [35], [36], [37], [38], [39], [40], [41], [42], [43], [44], [45] and [46]). Considering the frequency of reports of PRCA associated with solid tumors and the high incidence of malignant neoplasms, it becomes clear that such an association is very rare. On the other hand, it may be that PRCA is underdiagnosed in patients with advanced cancer, in whom anemia is such a frequent finding that bone marrow examination is not routinely performed. In both hematopoietic malignancies and solid tumors, PRCA may appear before or after the diagnosis of malignancy and follows a chronic course independent of the evolution of the underlying disease ([1]). In those cases in which a real association exists, successful treatment of the underlying malignant disease leads to remission of PRCA.

Acute, self-limited PRCA may develop in the course of various infections ([47], [48], [49], [50], [51], [52], [53], [54], [55], [56], [57], [58], [59], [60], [61], [62], [63], [64], [65], [66], [67], [68], [69], [70], [71] and [72]). Human B19 parvovirus is responsible for the aplastic crisis seen in children and young adults with chronic hemolytic anemia ([47], [48], [49], [50], [51], [52], [53], [54], [55], [56] and [57]) and for chronic PRCA in immunocompromised patients (e.g., with acquired immune deficiency syndrome, posttransplantation, on chemotherapy, or on immunosuppressive treatment) ([56], [57], [58] and [59]). Viral hepatitis and infectious mononucleosis are two other viral infections that have been reported many times in association with PRCA ([61], [62], [63], [64], [65], [66] and [67]). In general, PRCA remits with treatment or with the resolution of the underlying infection.

It is not surprising that PRCA is a hematologic complication of various autoimmune diseases, including collagen vascular diseases such as systemic lupus erythematosus ([73], [74]), rheumatoid arthritis ([75], [76]), mixed connective tissue disease ([77]), and Sjögren syndrome ([78], [79]), and autoimmune hemolytic anemia ([1]), multiple endocrine gland insufficiency ([93], [94]), autoimmune hypothyroidism ([95], [96]), ulcerative colitis ([97]), autoimmune hepatitis ([97], [98]), angioimmunoblastic lymphadenopathy ([91], [92]), post–ABO-incompatible bone marrow transplantation ([89], [90]), and in very rare cases of patients with end-stage renal disease or other conditions treated with recombinant erythropoietin who develop antibodies to the hormone ([99], [100]). In many of these autoimmune conditions, PRCA may be the first manifestation of the underlying disease.

An ever-increasing number of drugs and chemicals have been reported as causes of PRCA ([106], [107], [108], [109], [110], [111], [112], [113], [114], [115], [116], [117], [118], [119], [120], [121], [122], [123] and [124]) (Table 45.2). Drug-induced PRCA is usually an acute form of erythroblastopenia that remits soon after discontinuation of the drug or cessation of exposure to the chemical. It may appear after the first exposure to the drug or a significant time after drug exposure begins. In most instances, the association of a drug with PRCA is circumstantial and is based on the evidence that PRCA remits after discontinuation of the drug ([1], [107]). Diphenylhydantoin, azathioprine, chlorpropamide, and isoniazid have been repeatedly implicated as causes of PRCA, and, in certain instances, their association to PRCA has been proven by recurrence of anemia on reinstitution of therapy ([1]).

TABLE 45.2. Drugs and Chemicals Associated with Pure Red Cell Aplasia

Allopurinol	Leuprolide
a-Methyldopa	Linezolid
Aminopyrine	Maloprim (dapsone and pyrimethamine)
Anagyrine	
Arsphenamine	Mepacrine
Azathioprine	Methazolamide
Benzene hexachloride	Mycophenolate mofetil
Calomel	D-Penicillamine

Carbamazepine	Penicillin
Cephalothin	Pentachlorophenol
Chenopodium	Phenobarbital
Chloramphenicol	Phenylbutazone
Chlormadinone	Procainamide
Chlorpropamide	Rifampicin
Cladribine	Salicylazosulfapyridine
Cotrimoxazole	Santonin
Diphenylhydantoin	Sodium dipropylacetate
Estrogens	Sodium valproate
Fenbufen	Sulfasalazine
Fenoprofen	Sulfathiazole
FK506	Sulfobromophthalein sodium
Fludarabine	Sulindac
Gold	Tacrolimus
Halothane	Thiamphenicol
Interferon-a	Tolbutamide
Isoniazid	Zidovudine
Lamivudine	

Pregnancy has been associated with PRCA that usually remits after delivery ([80], [81], [82] and [83]). Development of PRCA during pregnancy does not necessarily predict recurrence of the disease in subsequent pregnancies. In a unique case, PRCA developed in three successive pregnancies in the same individual, and two of the fetuses were born with hydrops fetalis and found to have erythroid aplasia on autopsy, whereas the third fetus was treated with intrauterine red cell transfusions and was born with red cell aplasia that remitted after 3 months ([83]).

In rare cases, PRCA has been associated with renal failure ([84]), severe malnutrition such as marasmus and kwashiorkor ([85]), and riboflavin ([85], [125]) B_{12} ([86], [87] and [88]), and folic acid deficiency ([86]).

The failure of erythropoiesis in red cell aplasia is characterized by absence of mature erythroid precursor cells despite the presence in the bone marrow of normal or nearly normal numbers of erythroid progenitor cells. The failure of the erythroid progenitors to mature, differentiate, and give rise to erythroblasts may be due to an intrinsic defect in these cells, to the presence of humoral or cellular inhibitors of erythropoiesis, or to an abnormal bone marrow microenvironment. Different mechanisms seem to operate in each of the various forms of PRCA.

PRIMARY ACQUIRED PURE RED CELL APLASIA In primary acquired PRCA and TEC, multiple studies have indicated that the arrest of erythropoiesis is caused by the presence of an erythropoietic inhibitor in the patient's plasma. Early studies in mice have shown that injection of PRCA patients' plasma leads to a significant suppression of *in vivo* erythropoiesis as measured by ^{59}Fe incorporation into newly formed red cells ([1], [126], [127], [128] and [129]). Evaluation of the response of a patient's marrow cells to erythropoietin by measuring heme synthesis *in vitro* shows that, in the presence of normal plasma, PRCA marrow responds normally to erythropoietin, but in the presence of the patient's autologous plasma, a significant decline in heme synthesis is observed. This suggests the presence of an inhibitor acting on erythroid cells in the patient's plasma ([130], [131]). In approximately 60% of cases, patients' marrow cells respond to erythropoietin in a normal way by increasing the rate of heme synthesis by two- to ninefold, and in approximately 40% of cases, an inhibitor of erythropoiesis can be detected in the plasma. This inhibitor has been localized to the immunoglobulin (Ig) G fraction, and it disappears from the plasma after remission of PRCA ([130], [131], [132] and [133]). The stage of erythropoiesis at which the arrest occurs has been studied by assaying PRCA marrow cells in semisolid media for erythroid progenitors. Despite a conspicuous absence of erythroblasts from the PRCA marrow, normal numbers of early [burst-forming unit, erythroid (BFU-E)] and late [colony-forming unit, erythroid (CFU-E)] erythroid progenitors can be detected in at least 60% of patients, indicating that the arrest occurs at any level between CFU-E and basophilic erythroblasts. In the remaining patients, the erythroid cell compartment is affected at a stage earlier than the CFU-E, so that the CFU-E and/or BFU-E marrow pools are significantly reduced ([1], [27], [134], [135]). The presence of normal numbers of erythroid progenitors has been associated with a favorable outcome of immunosuppressive therapy ([27], [135]). The patient's serum IgG inhibits maturation and differentiation of erythroid progenitors into erythroblasts *in vitro*. The inhibition is dose dependent and is no longer present in the IgG fraction of a patient's plasma collected after remission. The inhibitory effect of the IgG is specific to erythroid cells because no effect on myeloid progenitor cell growth has been detected ([134], [135], [136] and [137]). The mode of action of the PRCA IgG inhibitor of erythropoiesis has been investigated in a number of cases of primary PRCA as well as in cases of TEC. In some cases, the IgG seems to be cytotoxic to CFU-E in the presence of complement; in others, its inhibitory activity is independent of the presence of complement, but IgG's presence is continuously required during the 7-day period of maturation of CFU-E to erythroblasts ([1], [136], [137]). In another cohort of patients, the IgG is cytotoxic to mature recognizable erythroblasts ([132], [138], [139], [140] and [141]), and, in rare cases, the inhibitory IgG has the properties of an antierythropoietin antibody ([100], [142], [143] and [144]). In the majority of cases, the target for the IgG antibody is an erythroid cell at a stage of differentiation between BFU-E and mature erythroblast. The nature of the molecule(s) on the erythroid cell membrane with which the PRCA IgG inhibitor interacts has not yet been defined.

SECONDARY PURE RED CELL APLASIA

Thymoma and Red Cell Aplasia Many studies have shown the presence of an inhibitor of erythroid cell development in the plasma of patients with thymoma and PRCA ([1], [14], [45], [126], [127] and [128]); however, these studies were performed on either mice *in vivo* or allogeneic human marrow cells *in vitro*, and the significance of these findings is unknown because the possibility of detection of heterophile antibodies or antibodies developed from alloimmunization secondary to multiple red cell transfusions cannot be excluded ([1]). A possible role for T-cell–mediated suppression of erythropoiesis has been suggested by more recent studies ([145], [146] and [147]). The exact incidence of antibody- or T-cell–induced erythropoietic arrest in PRCA associated with thymoma remains unknown.

Chronic Lymphocytic Leukemia and Red Cell Aplasia In B-cell CLL, the frequency of PRCA is 6%, and in T-cell CLL and in LGL types, it may be even higher ([6], [7], [8], [9], [10], [11] and [12]). All attempts to detect an inhibitor in the plasma of these patients have provided negative results ([1], [7], [9], [148]). Various studies have demonstrated that, in T-cell CLL (including the LGL type), the T lymphocytes are responsible for the suppression of erythropoiesis ([9], [10] and [11], [60]). The suppression is mediated by direct cell-to-cell interaction, mainly between a subset of T cells expressing receptors for the gamma chain of IgG (T? cells) and erythroid progenitors, and it is HLA-DR restricted ([11]). The suppression is selective for the erythroid cells and is not detectable after remission of the PRCA ([10], [11]). Similar findings have been reported in B-cell CLL in which there seems to be a progressive increase of T? cells in the marrow. These T? cells suppress erythropoiesis and cause red cell aplasia when they reach a critical concentration ([7], [105], [148], [149]). More recently, clonal expansion of LGLs of the gamma/delta type expressing killer cell inhibitory receptors for class I HLA antigens has been shown to be responsible for lysis of erythroblasts, which is most likely related to the declining density and eventual disappearance of HLA-I antigens in late marrow erythroid cells. The role of killer cell inhibitory receptors in the pathogenesis of PRCA in large granular lymphocytosis remains unclear because such receptors are frequently detectable in large granular lymphocytosis CLL cases without PRCA ([150], [151]).

Viral Infections and Red Cell Aplasia Human B19 parvovirus, the cause of erythema infectiosum (fifth disease), is responsible for the acute PRCA (aplastic crisis) in children and young adults with chronic hemolytic anemias ([47], [48], [49], [50], [51], [52], [53], [54], [55] and [56]) and for the chronic PRCA in immunocompromised patients ([56], [57], [152], [153], [154] and [155]). Human B19 parvovirus infection is not associated with TEC, which affects hematologically normal children ([49], [156], [157]). This DNA virus infects erythroid cells by binding to the P antigen on erythroid cell membrane ([158]), is cytotoxic to erythroid progenitors, and inhibits preferentially normal CFU-E growth and development, whereas it has no significant effects on myeloid cells ([49], [50]). The cytotoxic effects of the virus on erythroid cells *in vitro* can be blocked by antibodies to the virus ([49]). In normal individuals, infection by B19 parvovirus does not lead to symptomatic anemia because the arrest of erythropoiesis is transient and the survival of the red cells is normal. However, in the presence of hemolysis, even transient arrest of erythropoiesis leads to acute and precipitous decline of the hemoglobin concentration, resulting in clinically symptomatic anemia. Erythropoiesis is restored usually within 10 to 15 days with development of immunity to the virus and elimination of the viral infection. In immunocompromised patients unable to clear the virus, the infection with B19 parvovirus becomes chronic, and the arrest of erythropoiesis persists for as long as the infection is active, leading to a chronic form of PRCA ([56], [57], [152], [153], [154], [155] and [156]). Administration of high-dose, pooled, human IgG provides adequate amounts of specific antibodies to eliminate the chronic infection, thus allowing the restoration of erythropoiesis. In view of the primary therapeutic role of human IgG in chronic parvovirus infection, all immunocompromised patients with PRCA should be tested for evidence of active parvovirus infection. Studies on the pathogenesis of PRCA in the course of viral hepatitis, infectious mononucleosis, and human T-cell leukemia virus type 1 infection have suggested that

the suppression of erythropoiesis is mediated by cytotoxic T lymphocytes ([60], [64], [67]).

Autoimmune Hemolytic Anemia and Red Cell Aplasia Antibodies directed against red cells may in certain cases attack the erythroid precursors, the progenitors leading to erythroid aplasia, or both ([159]). Such a mechanism was confirmed in two cases of autoimmune hemolytic anemia and PRCA in which the IgG antibody eluted from the red cells inhibited *in vitro* normal and autologous CFU-E growth ([1], [73]). In another two cases, two separate autoantibodies, one directed against the erythrocytes and another inhibiting autologous CFU-E growth *in vitro*, were detected ([160], [161]).

Collagen Vascular Diseases and Red Cell Aplasia A serum IgG inhibitor of autologous erythroid progenitor cell growth *in vitro* has been demonstrated in a case of systemic lupus erythematosus and in a case of rheumatoid arthritis ([74], [75]).

Drug-Induced Red Cell Aplasia Limited numbers of studies have addressed the pathogenesis of drug-induced PRCA. A serum IgG inhibitor was detected in a case of diphenylhydantoin-induced PRCA that inhibited erythroid, but not myeloid, cell growth *in vitro* in the presence, but not in the absence, of subtherapeutic concentrations of diphenylhydantoin. Diphenylhydantoin alone in the same concentration had no effect on autologous erythroid progenitor cell growth *in vitro* ([106]). A similar mechanism was shown in a case of rifampicin-induced PRCA ([161], [162]). In both cases, the plasma inhibitor disappeared from the patients' plasma after remission of PRCA. However, studies performed in cases of isoniazid- and procainamide-induced PRCA failed to demonstrate a similar mechanism ([110], [112], [163]). It seems that various drugs can cause erythroid aplasia through different mechanisms. Studies on direct drug effects on erythroid cell growth *in vitro* should be interpreted with caution because a large number of drugs may affect hematopoietic colony formation *in vitro* in a nonspecific way.

Clinical Manifestations

Adult patients present with symptoms of anemia that may be quite severe at the time of diagnosis. Complete arrest of erythropoiesis leads to the decline of red cell count by approximately 1% per day, so the development of anemia is slow and progressive, allowing for physiologic compensatory changes. Physical examination in primary PRCA is usually negative except for pallor and signs of anemia. Hepatosplenomegaly and lymphadenopathy are not findings consistent with primary PRCA. In secondary cases, physical findings related to the underlying disease may be present. Patients with chronic red cell aplasia who have been supported with red cell transfusions may develop chronic hepatitis or transfusion-acquired hemosiderosis with physical findings secondary to iron overload.

Laboratory Evaluation

In acquired PRCA, the erythrocytes are normochromic and normocytic. There is a complete absence of polychromatophilic red cells on the smear, and the reticulocyte count is between 0 and 1%. A reticulocyte count greater than 2% should raise serious doubt about the correctness of the diagnosis. The white cell count and the differential count are normal. Occasionally, mild leukopenia, lymphocytosis, or eosinophilia may be present. The platelet count is usually normal. Mild thrombocytopenia of 100,000 to 150,000 platelets per µl is occasionally seen, and a number of patients may have a thrombocytosis reactive to anemia.

The hallmark of PRCA is the absence of erythroblasts from an otherwise normal marrow. The cellularity of the marrow is normal or slightly increased. High cellularity with elimination of fat spaces should lead away from the diagnosis of PRCA. In typical cases, the erythroblasts are either totally absent or constitute less than 1% on the marrow differential count. In a small number of cases, a few proerythroblasts, basophilic erythroblasts, or both may be seen, not exceeding 5% of the differential count ([1], [101], [144], [159]). The presence of a small number of proerythroblasts with vacuolated cytoplasm and pseudopodia formation may raise the suspicion of an active B19 parvovirus infection or of severe malnutrition ([50], [85]).

In certain cases, a period of ineffective erythropoiesis characterized by erythroid hyperplasia with maturation arrest at the stage of proerythroblasts or basophilic erythroblasts in the marrow and reticulocytopenia in the blood may precede the development of PRCA, develop during the course of PRCA, or develop after partial response to treatment and before the return of erythropoiesis to normal ([164], [165] and [166]). Although this picture is not diagnostic of PRCA, it is a phase within the natural course of this disease, and, in the absence of any bone marrow karyotypic abnormality or dysplastic features in any one of the three marrow cell lines, it should raise the suspicion of developing PRCA. Under these circumstances, the marrow should be reevaluated at a later time, or the patient should be treated for PRCA.

The myeloid cells and the megakaryocytes in the marrow are normal and exhibit full maturation. An increased number of lymphocytes on marrow smear or an increased number of lymphoid aggregates in marrow biopsy and a mild increase in plasma cells, eosinophils, or mast cells may be seen ([1]). Iron stores are increased and normally distributed, but during recovery or the phase of ineffective erythropoiesis, a few ring sideroblasts may be seen ([1]).

Cytogenetic studies on marrow cells in PRCA reveal a normal karyotype with the exception of preleukemic/myelodysplastic cases, in which chromosomal abnormalities may be detected ([13], [102], [148]). An abnormal karyotype carries a poor prognosis regarding response to treatment and may be a harbinger of leukemic transformation ([12], [103], [133]). Vitamin B_{12}, folic acid, ferritin, serum iron, and saturation of transferrin are normal or elevated. Serum erythropoietin levels are increased in proportion to the severity of the anemia ([132], [139]). Ferrokinetic studies show a prolonged clearance of ^{59}Fe, no accumulation of iron in the sacral bone, and almost undetectable incorporation into red cells—findings consistent with an almost complete arrest of erythropoiesis. Ferrokinetic parameters return to normal after full hematologic recovery except in adult patients in partial remission, in whom ineffective erythropoiesis may be present ([166]). Bone marrow imaging by the use of ^{59}Fe or ^{111}In shows little or no uptake, which returns to normal on remission. In both children and adults with PRCA, ^{51}Cr red cell survival is mildly shortened to a degree that is inadequate to explain the severity of the anemia ([164], [166], [167]). Patients refractory to treatment who are supported by regular red cell transfusions may develop a significant hemolytic component after alloimmunization or development of hypersplenism ([1]).

Various abnormalities of the immune system have been reported in patients with chronic PRCA ([1]), including hypogam-maglobulinemia, monoclonal gammopathies, pyroproteins, decreased complement, antinuclear antibodies, decreased or increased B cells, and impaired phytohemagglutinin-induced lymphocyte cytotoxicity ([1], [139], [168], [169], [170] and [171]). More recently, the presence of lymphocytes with ? or d T-cell receptor gene rearrangement has been described in a number of patients ([172], [173], [174], [175] and [176]); however, it is not yet clear whether these were cases associated with T-cell CLL or lymphoproliferative syndrome, which frequently have very subtle morphologic abnormalities ([12]), or cases of primary acquired PRCA.

Differential Diagnosis

The peripheral blood smear is examined first for the presence of red cells with abnormal morphology, monocytosis, shift to the left, bilobed granulocytes, and lymphocytosis with increase of LGLs. The clinical history may provide evidence for the presence of a disease with which PRCA may be associated. If symptoms are present suggesting an autoimmune disorder, appropriate testing is performed to confirm or rule out such a possibility. In all patients diagnosed with primary acquired PRCA, computed tomography of the chest is obtained to rule out the presence of thymoma. In patients considered to be potentially immunocompromised, active B19 parvovirus infection should be excluded by obtaining IgM and IgG antibody titers for B19 parvovirus or by polymerase chain reaction.

PRCA in adults can be easily diagnosed when isolated anemia with normal white cell and platelet counts is associated with a marrow of normal cellularity in which there is an almost complete absence of erythroblasts but normal myeloid cells and megakaryocytes. It can be easily differentiated from aplastic anemia, in which pancytopenia is present and the marrow cellularity is severely decreased with hypoplasia or aplasia of all three cell lines. High or low cellularity on bone marrow biopsy, presence of a small number of erythroblastic islands, and focal infiltration by lymphoid or immature cells are considered findings against the diagnosis of primary acquired PRCA. If there is a suspicion of a B- or T-cell lymphoid malignancy (B, T, or LGL CLL), the blood is submitted for immunophenotyping of lymphocytes by flow cytometry or for T-cell receptor gene rearrangement. The LGL type of CLL may be difficult to diagnose in its early phases when PRCA is the only predominant hematologic abnormality. The presence of a small number of large, vacuolated proerythroblasts frequently indicates active infection by B19 parvovirus. The most frequent hematologic disorder from which PRCA must be differentiated is refractory anemia or myelodysplastic syndromes.

In myelodysplastic syndromes presenting with isolated anemia, the reticulocyte count is rarely less than 1%, the red cells tend to be slightly macrocytic, and features of dysplasia of white cells may exist. Careful examination of the blood smear may reveal the presence of monocytosis, Pelger-Huët anomaly, or both. In addition, the marrow is hypercellular with dysplastic myelopoiesis, a shift of the myeloid cells to the left with an increase of blasts, and mononuclear megakaryocytes. Erythroblasts may be present in small numbers, but only rarely are they absent or less than 5%, and they usually exhibit megaloblastoid features. Cytogenetic abnormalities are frequent, and their presence is helpful in differentiating preleukemic or myelodysplastic erythroid hypoplasia from primary autoimmune PRCA ([1], [13], [102], [148]).

Treatment

After the diagnosis is confirmed by bone marrow examination, all drugs should be discontinued, and any infection should be treated appropriately. An active or recent B19 parvovirus infection should be treated by administration of normal pooled serum IgG that provides specific antibodies that can clear the viral infection and allow the recovery of erythropoiesis ([55], [56], [152], [153], [154], [155] and [156]). B_{12} or folate deficiency should be treated. In the presence of a malignant tumor, appropriate treatment should be instituted. PRCA associated with drugs or infection usually remits within 1 to 3 weeks after elimination of the responsible drug or treatment of the infection ([1]).

In the presence of a thymoma, thymectomy should be performed before the initiation of any immunosuppressive treatment. In 30 to 40% of patients with thymoma, erythropoiesis returns to normal within 4 to 8 weeks after thymectomy ([4], [5], [177]). Patients not responding to thymectomy should be treated as having primary acquired PRCA. Removal of the thymoma seems to increase the effectiveness of immunosuppressive therapy ([5]). Chemotherapy, radiation, or both ([177], [178]) may benefit patients with severe contraindications for surgery or with malignant thymomas. Thymectomy in the absence of thymoma is not recommended ([1]).

For primary or secondary PRCA not responding to treatment of the underlying disease, the therapeutic plan should focus on sequential use of various immunosuppressive therapies until remission is obtained. Corticosteroids are the immunosuppressive drugs of choice and should be tried before any other form of immunosuppressive treatment. Prednisone is given orally at a dose of 1 mg/kg/day until remission is induced. In approximately 40% of patients, remission usually occurs within 4 weeks, so continuation of a trial with prednisone longer than 12 weeks is not recommended ([133], [179]). The effect of treatment can be assessed by weekly reticulocyte count and measurement of hemoglobin concentration. A rising reticulocyte count, stabilization of the hematocrit, or both are the first laboratory findings indicating response to treatment. Once the hematocrit reaches a level of 35%, the dose of prednisone can be tapered very slowly, and the drug can eventually be discontinued, preferably after 3 to 4 months. Rapid tapering of prednisone may lead to recurrence of anemia. A number of responders may be prednisone dependent, requiring small doses of the drug to maintain a normal hematocrit ([179], [180] and [181]). The patient's dependence of the response on low-dose prednisone can be assessed during the period of slow tapering, and the minimum dose required can be easily determined.

If the patient does not respond to prednisone within 2 to 3 months, the dose should be rapidly decreased to 20 to 30 mg daily, because responses seen after this period of treatment are extremely rare ([179]). Patients who do not respond to prednisone should be treated with an alternate immunosuppressive agent, such as cyclophosphamide or azathioprine, cyclosporine (CsA), antithymocyte g-globulin (ATG), high-dose ?-globulin, humanized anti-CD20, or anti-CD52 (Campath-1H) monoclonal antibodies. No data exist favoring one type of treatment over another. The physician should take into consideration any coexisting disease, the age of the patient, the potential short- and long-term side effects, and the cost of treatment. The advantage of cytotoxic agents is their low cost, but they have long-term potential leukemogenic and carcinogenic effects ([182], [183], [184] and [185]). CsA therapy is more expensive and requires monitoring of the renal function, but it seems that the average time to induce remission is shorter than with cytotoxic drugs. In most cases, ATG administration requires hospitalization that increases its cost significantly, but it lacks the leukemogenic potential of cytostatic agents. High-dose intravenous ?-globulin is an expensive form of therapy but is without significant side effects. Experience with monoclonal antibodies is thus far limited.

Cyclophosphamide or azathioprine is given alone or, preferably, with small doses of prednisone, which seems to increase the effectiveness of treatment. The initial dose is 50 mg by mouth daily. If the white blood and platelet counts allow, it is increased by 50 mg weekly or biweekly to a maximum of 150 mg daily until remission occurs or bone marrow suppression develops. The mean time to response is approximately 11 to 12 weeks, with a broad range of 2 to 26 weeks and an overall response rate of 40 to 60% ([1], [12], [132], [133], [179], [186], [187]). If response occurs, the dose of prednisone is tapered, and then the dose of cytostatic agent is progressively decreased and eventually discontinued. If bone marrow toxicity develops, the drug is discontinued and the marrow is allowed to recover. If after 3 months of treatment, no response or marrow toxicity is seen, the dose can be increased progressively (by 50 mg biweekly) to the maximum tolerable or 250 mg daily under close monitoring of the blood counts. If reticulocytosis or stabilization of the hematocrit is noticed, the dose is gradually reduced. If the absolute neutrophil count decreases to below 1000 per µl or the platelet count drops below 100,000 per µl, the cytotoxic drug is discontinued. In a number of patients, a reticulocytosis is seen with the return of granulocytes and platelets to normal, followed by a return of erythropoiesis to normal. If no response occurs, another type of immunosuppressive treatment should be initiated.

CsA is given at a dose of 10 to 12 mg/kg daily in two divided doses, preferably with 20 to 30 mg of prednisone daily, under monitoring of renal function until remission occurs, usually within an average time of 2 to 4 weeks. A response to CsA is seen in 65 to 80% of patients who receive this drug as a second- or third-line treatment ([1], [12], [137], [188], [189], [190], [191], [192], [193] and [194]). After remission, the dose of prednisone is tapered, followed by tapering of the dose of CsA. If no remission occurs after 3 to 4 months of treatment with CsA, the drug should be discontinued, and an alternate mode of immunosuppression should be instituted.

ATG is used in patients who have not responded to other means of immunosuppression. It is given intravenously as an infusion at a dose of 20 mg of horse IgG per kg of body weight daily for 7 days, preferably in combination with 20 to 30 mg of prednisone orally per day that is rapidly tapered within 2 to 3 weeks after completion of ATG therapy. The overall response rate to ATG seems to be around 50% ([12], [45], [133], [195], [196] and [197]).

High-dose intravenous ?-globulin is the treatment of choice for immunosuppressed patients with PRCA that may be caused by the B19 parvovirus ([55], [56], [152], [153], [154], [155] and [156]). Responses have been reported, however, in nonimmunosuppressed patients with primary or secondary PRCA ([8], [198], [199]).

Humanized monoclonal antibodies directed against specific epitopes on lymphocytes, such as anti-CD20 (rituximab) or anti-CD52 (Campath-1H) have recently been used successfully in the treatment of primary or secondary PRCA refractory to other therapies. The experience with these agents in PRCA is, thus far, limited, and the overall response to such a treatment is unknown ([200], [201], [202], [203] and [204]).

Plasmapheresis is considered in patients who have not responded to any of the above immunosuppressive therapies ([139], [206], [207], [208] and [209]). It is performed at least three times weekly for a minimum of 2 to 3 weeks, and occasionally much longer, until a response is noted. Because IgG is distributed in both intravascular and extravascular space, plasmapheresis should be performed intensively and for a long period of time before any response is seen.

Splenectomy is considered as a final therapeutic maneuver in patients whose disease is refractory to all other forms of treatment. Responses to splenectomy have been reported in approximately 17% of such recalcitrant cases within the first 2 to 3 postoperative months ([1], [69], [159], [210]). Nonresponders to splenectomy should receive another trial of immunosuppression following the same approach as for initial therapy of PRCA. A number of refractory cases have been reported to respond to immunosuppressive therapy after splenectomy ([69], [124], [159], [210], [211] and [212]). Sequential, prolonged immunosuppressive therapy should be administered carefully because, although it induces remission in two-thirds of patients, it is associated with a high frequency of infections, occurring in 30% of cases ([179]).

Patients unresponsive to all forms of treatment should be maintained on regular red cell transfusions. They usually require approximately 1 unit of packed red cells per week. Due to the frequency of red cell transfusions, after a period of time, they develop iron overload, which has detrimental effects on various organs. Thus, in this patient population, institution of iron chelation by deferoxamine should be considered within the first 6 months after the disease is declared refractory to treatment ([1], [213]).

Evaluation of the effectiveness of immunosuppressive treatment of PRCA is very difficult because of the infrequency of the disease and its unpredictable clinical course, with spontaneous remissions occurring in approximately 5 to 10% of cases of primary PRCA within 4 months to 14 years after the diagnosis ([1], [132], [133], [179]). In addition, there is no clinical or laboratory criterion to differentiate between chronic and acute disease other than observation. A number of cases treated immediately after diagnosis may represent acute and self-limited PRCA secondary to a viral infection or drugs that the patient did not mention. Comparative studies between different immunosuppressive modalities are not available. Table 45.3 summarizes the experience with various forms of treatment in 133 patients at three different institutions.

TABLE 45.3. Response of Pure Red Cell Aplasia (PRCA) to Various Immunosuppressive Therapies

Study	Dessypris (1)	Lacy et al. (12)	Charles et al. (135)	Total

Patients (no.)	49	47	37	133
Primary PRCA	32	25	18	75
Secondary PRCA	17	22	19	58
Therapy (no. patients responding/no. patients treated)				
Corticosteroids	18/41	9/29	9/36	36/106 (34%)
Cytotoxic agents [a]	24/54	14/29	8/27	46/110 (42%)
Antithymocyte ?-globulin	2/6	0/1	8/12	10/19 (53%)
Cyclosporine	3/4	4/5	2/3	9/12 (75%)
Intravenous immunoglobulin G	—	1/2	2/8	3/10 (30%)
Plasmapheresis	—	—	0/2	—
Splenectomy	4/23	0/1	0/1	4/25 (16%)
Multiple treatments	35/49	28/47	28/37	91/133 (68%)

NOTE: Many patients did not respond to treatment or suffered relapses, so one patient may be included in more than one treatment modality.

[a] Including cyclophosphamide, azathioprine, or methotrexate given alone or in combination with prednisone.

Prognosis

Sequential immunosuppressive therapy leads to a remission in approximately 68% of patients. Approximately 5 to 10% of patients may remit spontaneously. Relapses are not uncommon, and in one study, 80% of patients relapsed during the 24 months after remission ([179]). However, relapses are treated as successfully as the initial disease ([133] , [179]). A number of patients may require low-dose maintenance immunosuppressive therapy, which, if deemed necessary, should be continued for 1 to 2 years ([1] , [179]). Even after repeated relapses, approximately 60% of patients become transfusion-independent for many years. The median survival of patients with primary acquired PRCA has been estimated to be approximately 14 years ([179]). Overall, patients with bone marrow cytogenetic abnormalities or low growth of erythroid progenitor cells *in vitro* have a much worse prognosis due to very low or no response to immunosuppressive agents, and in these patients, the persistent use of sequential immunosuppressive therapies is not indicated ([1] , [12] , [27] , [179]). Evolution of PRCA into aplastic anemia has been described but is exceedingly rare ([5] , [214]). Approximately 3 to 5% of patients with refractory disease develop acute nonlymphocytic leukemia ([1] , [103] , [179]). The prognosis of patients with secondary PRCA depends on the nature of their primary disease.

RED CELL APLASIA IN CHILDREN

The two major causes of red cell aplasia in children are TEC and DBA.

Transient Erythroblastopenia of Childhood

TEC, a self-limited red cell aplasia, must be considered and ruled out when the diagnosis of DBA is considered lest unnecessary treatment and parental and patient anxiety ensue. The disorder presents in previously well children lacking the physical stigmata of DBA, often follows a viral illness, and resolves spontaneously. Before the report of Cherrick and colleagues (214a), TEC was believed to be restricted to red cells. These authors, however, identified neutropenia in 64% of 50 consecutive patients evaluated prospectively over an 8-year period at a single institution. In the majority of cases studied, TEC was caused, as described earlier in the chapter, by an erythroid-restricted IgG ([136]). This observation suggests that neutropenia may arise as a nonspecific effect of a particular viral infection. Table 45.4 provides a useful guide to differentiating DBA from TEC. However, neither disorder is uniformly restricted to red cells, not all DBA patients have physical anomalies, there is significant age overlap, fetal red cell characteristics are not observed in all patients with DBA (especially at diagnosis), and TEC red cells in recovery will exhibit fetal-like erythropoiesis. TEC is described in more detail below in the sections Differential Diagnosis and Treatment.

TABLE 45.4. Differential Diagnosis of Diamond-Blackfan Anemia (DBA) versus Transient Erythroblastopenia of Childhood (TEC)

	DBA	TEC
Pure red cell aplasia	Present	Present
Age	Younger than 1 yr	Older than 1 yr
Inheritance	Sporadic and dominant or possibly recessive inheritance; mutation analysis available for DBA1 (RPS19)	Not inherited
Congenital anomalies	Present	Absent
Mean corpuscular volume	Elevated	Normal
Fetal hemoglobin	Elevated	Normal
Red blood cell antigen	Present	Absent
Erythrocyte adenosine deaminase activity	Elevated	Normal

NOTE: All red blood cell characteristics except adenosine deaminase activity are helpful only when tested in a reticulocytopenic child. During recovery from TEC, a transient wave of fetallike erythropoiesis may be detected.

Diamond-Blackfan Anemia

DBA, first recognized as a discrete clinical entity in 1938 ([3]), is a rare aregenerative anemia of childhood. The accepted diagnostic criteria are (a) normochromic, usually macrocytic, and occasionally normocytic anemia developing in early childhood; (b) reticulocytopenia; (c) normocellular bone marrow with selective deficiency of erythroid precursors; (d) normal or only slightly decreased granulocyte count; and (e) normal or slightly increased platelet count. DBA is frequently associated with a variety of somatic malformations and, rarely, with developmental delay. The majority of patients (over 80%) respond to corticosteroids with an improvement in or complete remission of their anemia ([215] , [216] and [217]). However, prolonged corticosteroid treatment has been problematic for many patients with DBA ([216]). Since the first description of this syndrome over 60 years ago, a number of theories have been put forth regarding its etiology. The myriad explanations have included humoral ([217]) or cellular ([218] , [219]) suppression of erythropoiesis, a microenvironmental defect ([220]), a block in the erythroid maturation pathway ([221]), accessory cell failure ([222]), and an intrinsic progenitor cell defect ([223] , [224] and [225]). Recent data suggest that there is a defective pathway from the multipotent bone marrow progenitor to the mature CFU-E through terminal differentiation to the proerythroblast and beyond ([224] , [225]), in which an intrinsic defect in erythroid progenitors and precursors render them highly sensitive to death by apoptosis ([226] , [227]).

ETIOLOGY AND PATHOGENESIS Normal erythropoiesis is dependent on the interaction between erythroid progenitors, accessory cells, and the bone marrow stroma ([228]). Thus, the erythroid failure in DBA could potentially arise from an absence of one of these elements or from failure of any one of the elements to act or respond appropriately. Studies performed over the past decade suggested multiple etiologies for this condition. Some early investigators described a marrow microenvironmental defect ([220]) or implicated accessory cell dysfunction ([227]). Others seemingly found evidence that the red cell failure in DBA was due to the presence of cytotoxic or autoreactive T cells ([218] , [219]) or humoral inhibitors of erythropoiesis ([217]). These findings have not been substantiated in the vast majority of patients ([221] , [223] , [224] and [225] , [229] , [230] and [231]). It is now accepted that DBA results from an intrinsic progenitor defect ([221] , [223] , [224] and [225] , [231] , [232] and [233]). Freedman et al. ([223]) first suggested that some patients had decreased numbers of CFU-E, whereas studies by Nathan et al. ([221]), using chronically affected, multiply-transfused

or steroid-dependent patients, suggested a block in maturation between the earliest committed multipotent myeloid progenitor and the immature BFU-E. In addition, these investigators found that the progenitors expressed in culture were relatively insensitive to erythropoietin. Chan et al. ([232], [233]) reiterated the concept of progenitor hyporesponsiveness to erythropoietin and suggested that this abnormality could be corrected, in part, by the addition of glucocorticoids *in vitro*, implying a relationship between clinical response to corticosteroids and *in vitro* progenitor response. A series of studies by Lipton and colleagues confirmed these observations. In these studies, some patients expressed normal or nearly normal numbers of BFU-E–derived colonies but had decreased numbers of CFU-E–derived colonies in the presence of exogenous cytokines and erythropoietin, whereas other patients demonstrated normal numbers of, albeit small and poorly differentiated, colonies from both progenitors ([224]). These data suggested that DBA is a heterogeneous disorder in which erythropoiesis may be blocked at different stages of erythroid differentiation. This observation was later confirmed in studies by McGuckin and colleagues ([234]). Additional studies from this group and others clearly demonstrate that DBA is due to an intrinsic disorder of the erythroid progenitor, which involves its inability to respond normally to inducer(s) of erythroid proliferation and differentiation ([225]), resulting in accelerated apoptosis ([226]), and that the effect could be ameliorated by corticosteroids ([227]). These findings were not associated with any abnormalities in erythropoietin or its receptor in any of the DBA patients studied ([235], [236]). In addition, the defect is likely not confined to erythroid cell differentiation. A mildly decreased leukocyte count and the development of pancytopenia, bone marrow hypoplasia, and reduced clonogenic cell output in long-term culture-initiating cell assays ([237]) as well as hypogammaglobulinemia and T-cell abnormalities ([222], [238]) support this contention. Furthermore, recent studies show that, in addition to erythroid progenitors, a defect in colony-forming unit granulocyte-monocyte can be found in a subset of patients ([234]). These *in vitro* studies are consistent with the observation of neutropenia and even aplastic anemia in some DBA patients. The responses of erythroid cell growth and differentiation to a variety of cytokines in addition to erythropoietin, such as stem cell factor and interleukin-3, have been evaluated with no abnormalities of the cytokines or their receptors being identified ([239], [240], [241], [242] and [243]). The first DBA gene, DBA1, has been cloned and is identified as *RPS19*, a gene that encodes for a ribosomal protein located at chromosome 19q13.2 ([244], [245]). Our knowledge of the activity of RPS19, other than that it is an integral part of the ribosomal machinery, is limited. However, this observation firmly establishes DBA as an intrinsic progenitor cell disorder. The genetics of DBA are discussed in more detail below.

CLINICAL PRESENTATION DBA usually presents in infancy. Severe anemia is recognized at birth in 25% of patients, with 65% diagnosed by 6 months of age and 90% within the first year of life ([246]). DBA presenting as hydrops fetalis has been reported ([247]). Rarely, the disease may present in older children and adults ([246], [248]). The incidence in men equals that in women. The majority of cases are reported in whites, but the disorder has been reported in virtually all ethnic groups ([246]). An unusually high proportion of mothers of patients have a prior history of fetal loss, either by miscarriage or stillbirth ([246]). Other parental problems include premature low birth weight and small for gestational age babies ([246]). Josephs in 1936 ([249]) and Diamond and Blackfan in 1938 ([3]) were the first to describe red cell failure in infants. The variety of descriptive names for what is now preferably called *DBA* includes *congenital pure red cell hypoplastic anemia* (the name preferred by Dr. Diamond), *congenital red cell aregenerative anemia*, *erythrogenesis imperfecta*, *chronic erythroblastopenia*, *primary red cell aplasia*, and *Josephs-Diamond-Blackfan anemia* ([215], [246]) and reflects the historic lack of a precise clinical definition as well as the uncertainty regarding the pathophysiology of the disorder. The diagnostic criteria for DBA reflect the careful clinical analysis performed by Diamond and colleagues ([215]) and, more recently, by Alter ([246], [250], [251]). For an exhaustive compilation of the clinical syndrome of DBA that is beyond the scope of this chapter, interested readers are referred to Young and Alter ([251]). The Diamond-Blackfan Anemia Registry of North America (DBAR), a database of over 350 patients, was established in 1993 and has been described in detail ([216]). The DBAR has provided important information regarding the epidemiology and biology of DBA ([252], [253], [254] and [255]). The male to female ratio of cases is 1:1.04. The median age at presentation is 8 weeks with a median age at diagnosis of 12 weeks. More than 90% of the reported cases presented by 1 year of age. The mainstays of therapy, as described below, remain red cell transfusions and corticosteroids. Physical anomalies, excluding short stature, are found in nearly 50% of patients. The constellation of physical findings in the 47% of affected patients with typical hematologic manifestations includes a high percentage of craniofacial anomalies (50%) and upper limb and hand abnormalities, in particular thumbs (38%), as well as genitourinary (39%) and cardiac abnormalities (30%). Table 45.5 enumerates the congenital anomalies collected in a series by Alter ([256]). Thus, efforts to define genotype-phenotype correlations on the basis of any particular physical findings will require careful mutation analysis as the “DBA genes” are cloned ([257], [258]). The relationship of abnormal thumbs to hematopoietic failure in DBA as well as Fanconi anemia ([258]) and the radial abnormalities in patients with thrombocytopenia and absent radii (TAR syndrome) are particularly fascinating ([259]). Figure 45.1 illustrates typical thumb abnormalities in a patient with DBA. Despite the detailed cataloging of these anomalies, their relationship to the pathogenesis of DBA and other syndromes remains obscure. An understanding of these observations awaits a more complete understanding of the function of the proteins mutated in these disorders.

Figure 45.1. Typical displaced and “trigger” thumbs in a patient with Diamond-Blackfan anemia.

TABLE 45.5. Physical Abnormalities in Patients with Diamond-Blackfan Anemia

Low birth weight	Neck
Short stature, no steroids	Short
Head and face	Webbed
“Cathie” facies	Thumb
Other facies	Triphalangeal
Small head	Duplicated or bifid
Large head	Subluxed
Jaw and mouth	Hypoplastic
Small jaw alone	Renal
Small jaw and cleft palate (e.g., Pierre Robin syndrome)	Dysplastic
	Absent
	Horseshoe
Cleft palate alone	Duplicated ureters
Cleft palate and lip	Caliectasis
Cleft lip alone	Congenital heart disease
Macroglossia	Ventricular septal defect
Flat nasal bridge	Atrial septal defect
Abnormal ears	Coarctation of aorta
Abnormal eyes	Other
Hypertelorism	Mental retardation
Epicanthal folds	Hypogonadism
Ptosis	Asplenia
Strabismus	
Blue sclerae	
Congenital cataracts	
Microphthalmia	
Glaucoma	

Modified from Alter BP. The bone marrow failure syndromes. In: Nathan DG, Oski FA, eds. Hematology of infancy and childhood, 3rd ed. Philadelphia: WB Saunders, 1987:159.

LABORATORY EVALUATION As previously described, DBA is characterized by severe anemia, with hemoglobins in typical patients ranging from 2.8 to 8.5 g per dl ([224]). There is a marked reticulocytopenia, frequently as low as zero. There are usually no significant abnormalities in other cell lines. Occasionally, there is mild neutropenia ([215] , [246] , [256]) or thrombocytopenia ([260]). However, thrombocytosis in the range of 400,000 to 700,000 is more common ([215] , [246] , [256] , [260]). There is no evidence of platelet dysfunction ([260]). Although originally described as a normochromic, normocytic anemia, macrocytosis was noted in approximately 30% of cases reviewed by Alter ([246]) when data at presentation was available. The percentage of patients with macrocytosis increases with the age of the patients as the disease becomes chronic and the normal red cell mean corpuscular volume (MCV) decreases. Indeed, the persistence of “fetallike” red cells with macrocytosis, i antigen, an increased fetal hemoglobin (HbF), and red cell glycolytic and hexose-monophosphate shunt enzyme activities characteristic of fetal cells is a consistent finding. The HbF is typical of fetal cells ([246] , [261]) with an elevated glycine to alanine ratio at position 136 of the gamma chain (Gly:1 ^{136}). Of note is that the fetallike characteristics are not concordant; cells with high HbF are not necessarily those with the i antigen. Although red cells contain significant HbF, as determined by hemoglobin electrophoresis, the distribution is uneven as evaluated by the Kleihauer-Betke method. Alter points out that red cells contain both HbF and adult hemoglobin and that the “re-expression of fetal erythropoiesis is thus incomplete, and not clonal” ([246]). Although glycolytic and hexose-monophosphate shunt enzymes have a fetal pattern, erythrocyte adenosine deaminase (eADA), a purine salvage pathway enzyme, is increased in activity in DBA patients but not in fetal or cord blood erythrocytes ([262]). When compared to controls with normal eADA activity obtained from normals, cord blood, patients with hemolytic anemia, Fanconi anemia, and those with steroid-dependent nephrosis, as well as virtually all patients with TEC, approximately 85% of the patients with typical DBA have an elevated eADA activity ([262] , [263] and [264]). In some DBA patients with normal eADA activity, there is markedly elevated orotidine decarboxylase activity ([263] , [265]). Although abnormalities in purine or pyrimidine biosynthesis are consistent findings in most DBA patients, this observation has not yet been helpful in understanding the pathophysiology of DBA. Red cells of some patients with acute leukemia, adult-type chronic myelogenous leukemia, myeloproliferative disorder with Down syndrome, dyskeratosis congenita with pancytopenia, and megaloblastic anemia were also found to have increased eADA activity ([264]). This may suggest an association of elevated eADA activity with abnormal progenitor function consistent with the concept that DBA is the consequence of an intrinsic progenitor cell defect. Also of interest is the observation that W/W ^{v} and S1/S1 ^{d} mice with genetically determined red cell failure have elevated erythrocyte nucleoside deaminase activity ([266]). Further advances in this area must await a detailed understanding of the biochemistry of hematopoiesis. However, from a practical perspective, eADA activity determinations provide a reasonably useful means for distinguishing approximately 85% of DBA from TEC (see Differential Diagnosis). To date, none of the described abnormalities is linked to a specific pathophysiology, and they have no predictive value in distinguishing steroid responders from nonresponder patients. Vitamin B_{12}, folate, serum iron, and transferrin saturation are elevated or normal in patients with DBA ([215] , [263]). Erythropoietin levels seem to reflect the degree of anemia or may be elevated for the degree of anemia and remain elevated even in steroid-responsive patients ([215] , [246]). Approximately one-third of patients evaluated by Alter had hypogammaglobulinemia consistent with the finding of *in vitro* immunologic abnormalities in some DBA patients ([222] , [246] , [267]). Examination of the bone marrow biopsy and aspirate usually reveals normal cellularity with a paucity of erythroid precursors. Myeloid and megakaryocyte lineages appear normal. Myeloid to erythroid ratios at diagnosis are usually around 10:1 and, with time, may become as high as 100:1 ([215]). This progression of erythroid failure (with time) seems to parallel the more severe abnormalities in *in vitro* progenitor differentiation observed in older chronically affected patients as compared to those newly diagnosed ([225]). The heterogeneity of the disorder is reflected in the marrow. In one series of nine patients, all had marked erythroid hypoplasia: Four had virtually no erythroid precursors, two had erythroid maturation up to the polychromatophilic or orthochromatic normoblast stage, and three had a maturation arrest at the proerythroblast stage with 2 to 7% of the total nucleated cells being proerythroblasts ([224]). In Alter's review, 28 of 29 DBA patients had erythroid hypoplasia ([256]). One had erythroid hyperplasia with a maturation arrest. Several of Alter's patients had normal numbers of proerythroblasts but no differentiation beyond that stage. In a series of patients from Bernard et al., 90% had erythroid hypoplasia, 5% had normal erythroid precursors, and 5% had erythroid hyperplasia ([268]). Although all patients have a profound reticulocytopenia, the erythroid arrest in DBA has been demonstrated, by progenitor assays or morphologically, to occur at all stages of maturation from the multipotent myeloid progenitor to the late normoblast. These and other observations ([237]) suggest that the defect may become more profound with age and that the arrest of erythropoiesis moves to an earlier stage as patients get older. This is, however, somewhat confounding in light of the presence of spontaneous remissions ([216]). Imaging studies are useful to help delineate congenital abnormalities that may be present in patients with DBA. Skeletal surveys are not usually warranted, but selected radiographs may define suspected bony anomalies. Abdominal and cardiac ultrasonography may detect or diagnose suspected and perhaps significant renal or cardiac anomalies.

GENETICS Alter originally estimated that there is more than one affected family member in approximately 10% of the cases ([256]). Data from the DBAR reveal comparable information ([216]). Early case reports are representative of the genetics of DBA. In these families, there are reports of affected same- and opposite-sex siblings ([257] , [269] , [270] and [271]), including identical twins ([272]) and maternal or paternal half-siblings ([273] , [274] , [275] and [276]). There are also instances of parental transmission ([275] , [277] , [278] and [279]). Striking evidence of autosomal-dominant inheritance is illustrated in one case report of DBA in a male infant who had an affected mother and maternal grandfather ([280]). In support of an autosomal-recessive mode, parental consanguinity has been observed ([281] , [282]). Thus, there was early evidence for both autosomal-recessive and -dominant modes of inheritance. The genetics of DBA were more firmly established when, in 1997, after studying a patient with a 19:X translocation, Gustavsson and colleagues ([244] , [245] , [283]) used linkage analysis to show that DBA mapped to chromosome 19q13.2. That observation led to the cloning of a gene that encodes a ribosomal protein, RPS19, the function of which remains unclear. Studies have shown that the RPS19 or DBA1 mutation accounts for only approximately 20 to 25% of familial as well as sporadic cases. More recently, Gazda et al. used linkage to suggest the presence of a second locus, DBA2 at 8p23-22, in approximately 40% of cases studied ([255]). As a significant minority of cases linked to neither 19q nor 8p, it is clear that additional DBA genes exist. These data indicate that the majority of familial cases are of dominant inheritance, with sporadic cases representing new dominant mutations. Within the identified pedigrees, there is marked heterogeneity in the expression of the DBA phenotype. This heterogeneity exists for both the hematologic and nonhematologic manifestations of DBA. Thus, the DBA phenotype appears to be the result of complex interactions between DBA and non-DBA genes. A family with discordant hematologic manifestations, including a nonhematologically affected phenotype and discordance of craniofacial anomalies in affected family members, has been reported ([284]). The incidence of genetically determined cases is no doubt underestimated due to the apparent variable penetrance of the autosomal-dominant cases, in which an elevated HbF, MCV, or eADA activity may be the only abnormality in a parent or sibling of a child with typical DBA ([215] , [245] , [251] , [260] , [261] and [262] , [266]). Indeed, in the case described, the mothers of affected cousins had none of these hematologic abnormalities ([234]). Therefore, pending the availability of a molecular diagnosis for all DBA genotypes, families of affected individuals should be evaluated to determine HbF levels, MCV, and eADA activity. A number of cases currently believed to be sporadic or autosomal recessive in nature will no doubt be recategorized. The absence of a phenotype is a particularly distressing finding, as the use of such potential hematopoietic stem cell transplantation (HSCT) donors with such a “silent phenotype” may result in transplant failure ([285]). The vast majority of DBA patients have a normal karyotype, but the few reported abnormal cases, two of which involve chromosome 1, are of interest ([286] , [287]). These findings have not been corroborated in other patients using more modern banding techniques, but in light of recent discoveries, these will no doubt be revisited.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of DBA includes the normochromic normocytic (or macrocytic) anemias that present from birth through the first year of life. These anemias are pathophysiologically distinct from the majority of PRCA cases seen in adults, which are frequently associated with an underlying disorder. Table 45.4 describes the differential diagnosis of red cell aplasia, with TEC representing the vast majority of cases of autoimmune red cell aplasia in children. The differential almost always consists of DBA versus TEC. For example, the association of PRCA with thymoma, as described in adults, has not been described in infancy, although it has been observed in a 5-year-old girl ([288]). A careful history, physical examination, and examination of the peripheral blood smear can usually rule out hemorrhage, myelosuppression due to infection, renal failure, infiltrative disease, severe protein malnutrition, or drug-related red cell failure, as well as the aplastic crisis of a chronic hemolytic anemia (such as sickle cell anemia or hereditary spherocytosis). Because folate deficiency is prevented as a cause of the hypoplastic crises associated with chronic hemolytic anemia by prophylactic administration of the vitamin, acquired hypoplastic anemia in these patients is now most frequently a consequence of human parvovirus B19 infection. Evidence of human parvovirus B19 infection (see the section Viral Infections and Red Cell Aplasia) has been found in patients with a variety of sickle cell syndromes, hereditary spherocytosis, pyruvate kinase deficiency, and thalassemia after an aplastic crisis ([47] , [48] , [49] , [50] , [51] , [52] , [53] and [54]). Red cell aplasia in otherwise normal neonates (resulting in fetal hydrops) and in a patient on treatment for acute lymphoblastic leukemia has also been described, apparently due to parvovirus infection ([289]). Chronic red cell aplasia due to parvovirus B19 after 10 years of transfusion-dependent anemia has been eradicated by the use of intravenous Ig ([55]). Thus, parvovirus infection should be ruled out in all atypical instances of red cell failure in children. This can best be accomplished by polymerase chain reaction analysis, as IgM and IgG antibody evidence are lacking in the presence of significant immunodeficiency (see Viral Infections and Red Cell Aplasia). A bone marrow examination revealing red cell aplasia or severe hypoplasia with no abnormalities in myeloid or megakaryocyte lineages and no evidence of infiltrative disease or congenital dyserythropoietic anemia in an infant or young child suggests either DBA or TEC. Table 45.4 outlines the important features that distinguish TEC, a temporary suppression of erythropoiesis that frequently follows a viral infection, from DBA. There is a moderate to severe anemia with reticulocytopenia. TEC is not familial, and there are no associated anomalies. The age of onset is usually a bit older than for congenital PRCA. One key point in differentiating between DBA and TEC is the presence of fetal characteristics in the erythrocytes of many patients with DBA (see Laboratory Evaluation). As previously described, these characteristics include an elevated MCV for age, elevated levels of HbF and i antigen, and a fetal erythrocyte glycolytic and hexose-monophosphate shunt enzyme pattern ([290]). These fetal characteristics are probably the consequence of “stress erythropoiesis” associated with chronic DBA. The presence of “fetallike” cells is much less reliable in differentiating DBA from TEC in very young infants, in whom red cells normally possess fetal characteristics. Thus, as more children with TEC who are younger than 1 year of age are being described, the differential diagnosis is becoming more difficult. In addition, adolescents with TEC have been reported ([291]). Even in typical DBA, only 30% of patients will have “fetallike” erythrocytes at diagnosis. In addition, the recovery from TEC is characterized by “stress erythropoiesis giving rise to erythrocytes with fetal characteristics” ([292]). Making a diagnosis of TEC retrospectively after a long course of corticosteroids subjects the child to needless toxicity. As previously described, recent studies by Glader and co-workers ([262] , [263] and [264]) have demonstrated

that elevated eADA activity can be used to distinguish DBA from TEC. However, many patients are transfused before consideration of the diagnosis, making an accurate eADA activity determination impossible. A molecular diagnosis can be made by mutation analysis in approximately 25% of patients mutated at DBA1 (RPS19). Based on the differences listed in Table 45.4, a high index of suspicion of TEC should prompt avoidance of steroids, minimal red cell transfusions, and alleviation of parental concern.

TREATMENT If the diagnosis of DBA versus TEC is in doubt, and the patient has symptomatic anemia, they should be only modestly transfused to a hemoglobin level of 7 to 8 g per dl so that erythropoiesis is not suppressed, delaying recovery in those patients who have TEC. In 1951, corticosteroid treatment in the form of adrenocorticotropic hormone was first shown to be effective in DBA ([293], [294]). The current approach is to start all patients on prednisone, 2 mg/kg/day orally in three to four divided doses. A reticulocyte response usually occurs within 1 to 2 weeks. If there is no response within 2 weeks, the dose may be increased to 3 mg/kg/day. The clinical response to prednisone is variable. Data from the DBAR reveal that 82% of patients were initially responsive to corticosteroids, 16% were nonresponsive, and 1.6% were never treated with steroids ([216]). At the time of the analysis, only 44% of patients were using corticosteroids. Steroid-related side effects were observed in most patients, at least transiently, with 40%, 12%, and nearly 7% manifesting cushingoid features, pathologic fractures, and cataracts, respectively. Thirty-six percent of the patients were receiving red cell transfusions. Some patients respond rapidly and can be tapered off prednisone, remaining in remission for extended periods of time; others respond but require continued therapy, with erythropoiesis ceasing rapidly if steroids are discontinued. Thus, the ability of responders to achieve an effective every-other-day dose schedule is variable. Of the transfused patients, 32% were never steroid-responsive, 17% became steroid-refractory, and 49% could not be weaned to an acceptable dose. A small number never received steroids or were transfused for unspecified reasons. Some patients may be tapered off steroids even after many years. Indeed, the actuarial likelihood of remission is 20% by age 25 years, with 77% entering remission during the first decade of life. Patients appear to remit equally from steroid and transfusion therapy. Almost 75% of these patients have what appears to be a sustained remission. Although high-dose corticosteroid pulses may evoke an erythroid response in some patients ([295], [296]), the potential side effects, the need for repeat pulses, and the failure of this modality in subsequent studies ([297]) have limited its utility. Likewise, trials of CsA, despite anecdotal reports in DBA, have not been particularly encouraging ([298]). Furthermore, the potential toxicity of this agent makes it less preferable than red cell transfusions for those patients who cannot be weaned to an acceptable corticosteroid dose. In some patients who do not respond to prednisone, there may be a response when oxymetholone (2.0 to 5.0 mg/kg/day) is added ([215], [256]). However, most clinicians do not advocate the use of androgens in infants and young children. If there is no response within 1 month, prednisone is discontinued in favor of transfusion and chelation regimens following the established guidelines (see Chapter 42). These patients may receive periodic prednisone trials because they may respond at a later date. For patients who respond to steroids, their hemoglobin levels are followed until a level of 10 gm per dl is achieved. The steroid dose is then tapered until the patient is on the smallest possible alternate-day dose. A Monday-Wednesday-Friday dose schedule is usually effective and easier to comply with than a strict every-other-day regimen. The dosage in a Monday-Wednesday-Friday schedule may range from a few milligrams, even in adolescents, to as much as 40 to 50 mg. Another approach uses 1 week of daily prednisone during a 3-week to monthly cycle ([299]). This regimen may reduce side effects, such as growth retardation, but some patients may not maintain a desirable hemoglobin level. Arbitrary discontinuation of therapy should be discouraged because reestablishment of erythropoiesis after discontinuation of an effective every-other-day course of prednisone requires reinstitution of the original daily dose. For patients who are steroid-refractory or in whom the dose cannot be tapered to an alternate-day regimen and who thus require high daily doses that cause toxicity, chronic transfusion is instituted. Data from the DBAR and accumulated international experience demonstrate that more patients than originally anticipated have significant steroid-related side effects even on a low-dose every-other-day schedule. These occur in addition to pathologic fractures and cataracts, include poor growth, osteoporosis, and osteonecrosis, and may require the discontinuation of corticosteroids in favor of chronic transfusion therapy. There are virtually no pediatric disorders for which corticosteroids are initiated in infancy and may be continued into adulthood. Thus, many experienced clinicians are foregoing steroid treatment in favor of chronic red cell transfusions during infancy. Patients must be carefully monitored and steroid therapy discontinued when morbid side effects ensue. As preparative regimens and infection control have improved and graft-versus-host disease has become more amenable to treatment and prevention, reducing morbidity and mortality, HSCT has been used in DBA patients with good results. The first successful transplant for DBA was performed by August and colleagues in 1976 ([300]). In a 1998 review of stem cell transplantation in DBA by Alter that analyzed 35 of the 37 cases reported to date in the literature, the actuarial survival for predominantly allogeneic HLA-matched donor transplants was 66% ([301]). Two more recent studies suggest that the actuarial survival is in the range of 90% for matched related HSCT in young, otherwise healthy patients ([254], [302]). On the other hand, the still substantial risks associated with alternative donor bone marrow transplantation favor transfusion and chelation in those patients unable to achieve an every-other-day steroid schedule. Modern chelation regimens seem to be very effective in reducing the consequences of iron overload in chronically transfused patients, but the long-term results of these programs are not currently known. This uncertainty and the other risks of transfusion (i.e., sensitization and infection) make the decision regarding bone marrow transplantation (when a suitable alternative donor exists) versus chelation therapy for DBA patients who are steroid-refractory or steroid-intolerant one that must be individualized and constantly reevaluated. Studies indicate that recombinant human interleukin-3 may increase the *in vitro* clonogenicity of DBA progenitors when unfractionated cell preparations are cultured ([303]). The mixed response and, ultimately, the toxicity of interleukin-3, the most promising of the cytokines, have precluded its use in DBA ([304], [305], [306], [307], [308], [309], [310] and [311]).

PROGNOSIS Due to advances in therapy, the published mortality rates are not particularly helpful for determining the prognosis of patients diagnosed today ([251]). Deaths due to infection in splenectomized patients with DBA are now dramatically reduced through the use of pneumococcal and *Haemophilus influenzae* vaccines, prophylactic penicillin, and careful follow-up and management. In addition, splenectomy is only performed for hypersplenism and an increased transfusion requirement, not as specific therapy for DBA. Modern chelation schemes seem to be able to dramatically postpone, if not eliminate, clinically significant transfusion-related hemosiderosis. There have been 23 deaths recorded by the DBAR as of the last published report: one from severe aplastic anemia, two from *Pneumocystis carinii* pneumonia, one from varicella pneumonia, one from *Pseudomonas* pneumonia and sepsis, two from complications of iron overload, one from cardiac tamponade secondary to a vascular access device complication, six from malignancy, and nine from HSCT complications ([216]). Thus, cancer and complications of alternative donor HSCT are the leading causes of death in DBA. Although the major indication for HSCT was steroid nonresponsiveness or intolerance resulting in transfusion dependence, two of the cases recorded by the DBAR were those of patients who were transplanted (one by the HLA-matched related HSCT and one by alternative donor HSCT) for the indication of severe aplastic anemia. The overall actuarial survival rates at approximately 40 years of age are 77.9% ± 5.6%, 100% for those with sustained remissions, 87.4% ± 6.9% for corticosteroid-maintainable patients, and 57.5% ± 12.9% for transfusion-dependent patients. There is a trend toward increased survival in patients with sustained remission and a statistically significant survival advantage for steroid-maintainable patients compared to transfusion-dependent patients. With regard to cancer, 29 cases of cancer in DBA patients have been reported in the literature ([252]). There appears to be no doubt that DBA is a syndrome predisposing to cancer. Both hematopoietic and nonhematopoietic malignancies have been documented. An analysis from the DBAR was performed in an effort to determine the cancer risk in DBA patients. Seven of 354 registered patients had malignancies. Four had osteogenic sarcoma, one had myelodysplastic syndrome, one had colon cancer, and one a soft-tissue sarcoma ([216], [252]). Three additional patients, who were not registered in the DBAR but were DBA-affected relatives of registered patients with documented DBA, were identified. Of these, there was one case each of colon cancer, melanoma, and myelodysplasia. Young age at presentation is a feature of DBA-associated osteogenic sarcoma and perhaps other malignancies. These observations strongly support the need for a genotypic analysis of patients with DBA-associated cancer and their families.

FUTURE DIRECTIONS Advances in cellular and molecular biology have begun to increase our understanding of the pathophysiology of DBA. DBA has been shown to be the consequence of an intrinsic progenitor cell defect. One of the genes responsible for the disease has been cloned, and genetic linkage analysis supports the existence of at least two other genes. Careful clinical investigation has defined the syndrome, and the study of the cellular biology of the disorder has borrowed from and contributed to the understanding of the mechanism of hematopoietic progenitor cell differentiation. Using the DBAR, important epidemiologic, clinical, and laboratory observations have been made with regard to the clinical presentation and inheritance of DBA. The database has yielded other important observations on the genetics of congenital malformations in DBA, the therapeutic outcomes including the efficacy of HSCT, and the recognition of DBA as a cancer-predisposing syndrome. In particular, the DBAR has provided the essential substrate of multiple well-characterized families for gene discovery ([216]). The final description of DBA at the molecular level would be a most extraordinary tribute to Dr. Louis Diamond, whose career spanned over 60 years and who has been a teacher to many and an inspiration to the rest ([250]).

Congenital Dyserythropoietic Anemias

OVERVIEW OF CONGENITAL DYSERYTHROPOIETIC ANEMIA

The *congenital dyserythropoietic anemias* (CDAs) are a group of genetic disorders characterized by ineffective erythropoiesis and dyserythropoiesis ([1], [2]). *Ineffective erythropoiesis* is a kinetic term indicating increased marrow erythroid activity, intramedullary red cell destruction, and decreased release of red blood cells (RBCs) into the circulation. *Dyserythropoiesis* is a descriptive term indicating the presence of morphologically abnormal erythroblasts with multinuclearity, karyorrhexis, or megaloblastic changes. Overt abnormalities in other hematopoietic lineages are uncommon in CDA and have only been reported in association with a few cases ([3], [4]).

Three major types of CDA have been distinguished on the basis of morphologic and serologic classification ([5], [6] and [7]). These have been designated CDA types I, II, and III. In aggregate, a few hundred cases have been described in the literature, and CDA II accounts for approximately two-thirds of all cases reported. A significant number of additional cases have been published that do not fit precisely into the established classification scheme ([8], [9] and [10]). Whether some of these represent distinct entities or represent variants on the three major types is controversial.

The abnormalities associated with all three types of CDA are intrinsic to the erythroid stem cell and are not due to a defect in the cell environment. *In vitro* cultures of erythroid precursors from each of the CDAs reveal the typical morphologic abnormalities seen *in vivo* ([11]). In addition, such studies have revealed that even in a given individual the morphologic manifestations of the disorder may be variable, with a single progenitor cell producing both morphologically normal and abnormal progeny ([12]). The chromosomal locations of the genes for CDA I, II, and III have now been mapped ([13], [14] and [15]). The eventual identification of the actual genes responsible for these disorders should provide insight into normal RBC development.

Clinically, the degree of anemia encountered in the CDAs varies considerably. It may range from a mild to moderate anemia that is only discovered or diagnosed later in life to a severe anemia apparent in infancy, occasionally associated with hydrops fetalis and requiring antenatal intrauterine red cell transfusions ([16], [17], [18], [19] and [20]). Morphologically, the anemia is generally mildly macrocytic in CDA I and is normocytic to mildly macrocytic in CDA II and CDA III. In all of the disorders, the bone marrow findings are consistent with ineffective erythropoiesis: There is erythroid hyperplasia along with morphologically abnormal precursors. An elevation in serum lactate dehydrogenase and indirect bilirubin levels may be observed. Iron absorption and transport are increased, but the use of iron in erythropoiesis is decreased. Thus, patients with CDAs may develop secondary hemochromatosis, although in some cases, a component of intravascular hemolysis has been reported to prevent this complication or even cause iron deficiency ([21]).

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II (HEMPAS)

Type II CDA was first categorized as such by Heimpe and Wendt in 1968 ([1]). It is the most common clinical type of CDA, and more than 150 patients have been described ([22]). The mode of inheritance is autosomal recessive, and the CDAN2 gene has been localized to a 5-cM interval on chromosome 20q11.2 ([14]). This CDA is distinguished by the fact that it can be defined by accompanying serologic abnormalities.

When tested against a panel of acidified sera (pH 6.8) from normal individuals, approximately 30% of the normal sera lyse CDA II red cells. Unlike the situation in paroxysmal nocturnal hemoglobinuria (PNH), there is very rarely lysis of the patient's red cells by his or her own serum under this condition. In addition, CDA II cells do not lyse in isotonic sucrose, as is the case in PNH. The lysis in acidified heterologous sera is due to a naturally occurring immunoglobulin M antibody against a unique antigenic determinant on the cells that binds complement. The combination of the morphologic abnormalities and the above pathognomonic serologic finding led Crookston et al. to propose the acronym for CDA II: HEMPAS (*h*ereditary *e*rythroblastic *m*ultinuclearity with *p*ositive *a*cidified *s*erum test) ([2]).

An additional serologic finding in CDA II is that the red cells of patients have increased expression of the fetal i antigen and are, therefore, strongly agglutinated by both anti-i and anti-I sera ([23]). This is in distinction to other conditions, such as Diamond-Blackfan anemia and sickle cell anemia, in which both antigens may be present but expressed on different erythrocytes, reflecting that a fraction of RBCs are a product of fetal-like erythropoiesis.

Pathogenesis

As might be hinted by the defining serologic abnormalities, the underlying genetic defect in CDA II leads to defective enzymatic glycosylation of membrane proteins ([24]). Normally, a series of enzymatic steps leads to the synthesis of lactosaminoglycans that constitute the carbohydrate moieties of proteins such as band 3 and glycophorin A. Erythrocytes from patients with CDA II contain partially glycosylated proteins with a different structure than normal ([25], [26]). In particular, the abnormal band 3 protein (easily detectable by sodium dodecyl sulfate-polyacrylamide gel electrophoresis analysis) is particularly hydrophobic and tends to cluster, causing disruption of the cytoskeleton ([27]). Such disruption may in part account for the abnormal membrane architecture that is observed in this disorder. In addition, the unused polylactosamines that would normally be conjugated to protein accumulate as glycolipids and may be involved in formation of the antigenic determinant (the HEMPAS antigen) on the surface of cells that leads to complement-mediated lysis with heterologous sera ([28]). Abnormal glycosylation also leads to persistence of the i antigen on the red cell surface.

Initially, abnormalities in two Golgi enzymes were implicated in the pathogenesis of CDA II: *N*-acetylglucosaminyl-transferase II and a-mannosidase II ([29], [30]). In fact, an a-mannosidase II knock-out mouse reproduces a phenotype similar to CDA II ([31]). However, further familial studies have excluded linkage of CDA II to the *N*-acetyl-glucosaminotransferase and a-mannosidase II genes ([32]). Eventual cloning of the CDAN2 gene may reveal that it plays a more fundamental role in glycosylation, and a variety of mutations in this single gene may explain the phenotypic heterogeneity observed ([33]).

Clinical Description and Hematologic Findings

CDA II presents as a normocytic anemia with evidence of ineffective erythropoiesis and premature peripheral RBC destruction, including jaundice and hepatosplenomegaly. In very mild cases, the anemia may be so mild as to remain undiscovered until late in adult life. However, in the majority of patients, the hemoglobin level is less than 11 g/dl, and in 10 to 25% of patients, it is severe enough to require regular transfusions ([16]). As in other disorders in which ineffective erythropoiesis is a prominent feature, abnormal facies and extramedullary hematopoiesis may occur, particularly in severely affected individuals ([34], [35]). Cholelithiasis and secondary hemochromatosis are complications frequently associated with CDA II. In fact, iron overload may be the presenting manifestation in some cases ([36]).

The abnormalities observed on the peripheral blood smear include anisocytosis, poikilocytosis, and basophilic stippling (Fig. 46.1). Phase contrast microscopy of red cell ghosts demonstrates irregular regions of thickened membrane (Fig. 46.2). These regions of apparent doubling of the plasma membrane in a continuous or

discontinuous fashion are derived from endoplasmic reticulum ([37]).

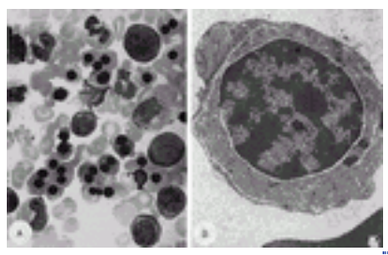

Figure 46.2. A: Binucleate cells in late normoblasts of patient with congenital dyserythropoietic anemia (CDA) type II. **B:** Electron micrograph, CDA II. Note doubling of plasma membrane. (Courtesy of SM Lewis, London.)

Bone marrow examination reveals marked erythroid hyperplasia. Precursors appear normal until after the basophilic erythroblast stage, after which point up to 30% of erythroblasts contain two nuclei (Fig. 46.2). Each of the nuclei contains a normal DNA content, but DNA synthesis in the binucleate cells is markedly reduced or absent. In addition, ineffective erythropoiesis in the marrow may be accompanied by erythrophagocytosis and Gaucher-like histiocytes in some individuals ([38]). Megaloblastic changes are generally not observed.

CDA II often follows an indolent course. However, transfusion-dependent individuals may benefit from splenectomy ([16]). Whether exogenous administration of erythropoietin would be of benefit in this disorder has yet to be formally studied. In one case, allogeneic bone marrow transplant was reported to be curative ([39]). Most important, patients should be monitored closely for secondary hemochromatosis, which can occur even in the absence of regular transfusion therapy ([21]). Iron chelation therapy may be indicated, or alternatively, phlebotomy may be considered in patients with mild anemia.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I

CDA I is the second most common of these disorders, with nearly 100 cases reported in the literature. The mode of inheritance is autosomal recessive, and the CDAN1 gene has been localized to a 0.5-cM interval on chromosome 15, 15q15.1-15.3 ([13]). In contrast to CDA II, there is no defining serologic abnormality (the acidified serum lysis test is negative), and the diagnosis currently is made on a morphologic basis.

Little is known about the exact nature of the pathogenesis of CDA I. It has been suggested that there is an abnormality of nucleoprotein synthesis leading to abnormal mitosis, and it has been suggested that abnormal nuclear histones may be responsible ([40] , [41]). Alternatively, other investigators have suggested a plasma membrane defect, and abnormalities in plasma membrane proteins have recently been described ([42]).

Studies on the natural history of CDA I have been facilitated in part by a clustering of cases in several Israeli Bedouin families ([20] , [43] , [44]). The anemia varies from mild to severe, with the most severe cases presenting in infancy and the milder cases presenting in adolescence or later in life. Jaundice and splenomegaly are common physical findings. In addition, skeletal abnormalities, such as distal limb malformations, have been reported in association with CDA I ([45]).

The anemia is usually macrocytic with a mean corpuscular volume of 90 to 115 fl. Anisocytosis, poikilocytosis, basophilic stippling, and Cabot rings are features of the peripheral blood smear, regardless of whether a splenectomy has been performed (Fig. 46.3). Lactate dehydrogenase and bilirubin levels may be elevated, reflecting ineffective erythropoiesis. Although increased hemoglobin A2 levels have been reported, other evidence for thalassemia is absent ([46]).

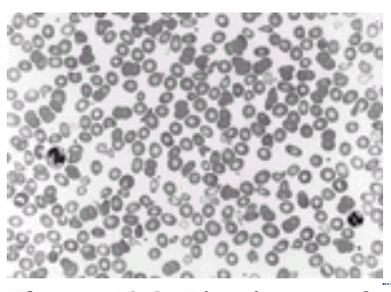

Figure 46.3. Blood smear from a patient with congenital dyserythropoietic anemia type I (×600). (Courtesy of SM Lewis, London.)

The most prominent defining features of CDA I are in the bone marrow. The nuclear chromatin is spongy and has a megaloblastic appearance. Thin, Feulgen test–positive intranuclear chromatin bridges between erythroblasts may be observed in a minority of cells (Fig. 46.4A, Fig. 46.4B and Fig. 46.4C). Electron microscopy of erythroblasts reveals unevenly condensed nuclear chromatin that has a spongy appearance ([47]). Some nuclei may have a characteristic Swiss cheese appearance (Fig. 46.4D) with electron-lucent areas with cytoplasmic components that seem to be located within the nucleus. Studies have demonstrated that marked invagination and evagination of the nuclear envelope are responsible for this phenomenon rather than abnormally located cytoplasmic components ([48]).

Morphologic studies of congenital dyserythropoietic anemia (CDA) type I. **A–C:** An intranuclear chromatin bridge in CDA type I. **A:** With light microscopy. **B:** With transmission electron microscopy. **C:** With scanning electron microscopy. **D:** Abnormal nucleus in CDA type I with Swiss cheese appearance and nuclear invagination. (Courtesy of E Conde, Santander, Spain.)

CDA I often follows an indolent course, although some patients require periodic red cell transfusions. From the limited reports to date, the benefit of splenectomy in this disorder is not clear, although this procedure may be considered in transfusion-dependent patients ([18]). Erythropoietin administration has been examined in CDA I and does not appear to be effective in the management of this disorder ([49]). More recently, on the basis of the fortuitous observation that treatment of a CDA I patient with hepatitis C with interferon-a2a led to hematologic improvement, a few additional patients, including a severely affected infant, have been treated with this therapy and have also experienced hematologic improvement ([50], [51]). This suggests that interferon-a2a may have a role in management. As for CDA II, careful monitoring for secondary hemochromatosis is important, and effective treatment of a CDA I patient with deferoxamine has been reported ([52]).

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE III

CDA III was likely the first of the CDAs to be described. In 1951, Wolfe and von Hofe described familial erythroid multinuclearity, which was also reported in 1962 by Bergström and Jacobsson as hereditary benign erythroreticulosis ([53], [54]). Approximately 50 patients with this disorder have been reported in the literature, and most of these have been members of a single large Swedish family. Although the mode of inheritance of sporadic cases has yet to be determined, the inheritance pattern in the Swedish family is autosomal dominant. Linkage analysis reveals that the CDAN3 gene is localized to an 11-cM interval on chromosome 15, 15q21-q25 ([15]). Little is known about the pathogenesis of CDA III, although minor alterations in the glycosylation of band 3 of erythrocytes similar to those seen in CDA II have been reported ([55]). The diagnosis of CDA III is currently made on a morphologic basis. Although the red cells may be agglutinated by both anti-i and anti-I sera, the acidified serum lysis test is negative with heterologous sera.

The macrocytic anemia is generally of mild to moderate severity, and a few large erythrocytes may be seen on peripheral blood smear (Fig. 46.5). Individuals may experience periods of fatigue and jaundice and episodes of intravascular hemolysis. Hemosiderinuria may be present.

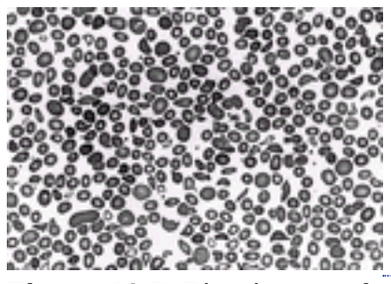

Figure 46.5. Blood smear from a patient with congenital dyserythropoietic anemia type III (×600). (Courtesy of SM Lewis, London.)

Bone marrow examination is remarkable for the finding of marked multinuclearity, with as many as 12 nuclei per cell, which occurs in giant erythrocyte precursors that may reach 50 to 60 µm in diameter (Fig. 46.6A). As many as 30% of the erythroblasts may be multinucleated, and their DNA content is highly variable ([56]). Electron microscopy reveals a variety of features that are similar to CDA I, but CDA III is distinguished by the lack of spongy-appearing chromatin and the preservation of the nuclear envelope (Fig. 46.6B). Time-lapse phase contrast microscopy has demonstrated that the erythroblasts grow to the size at which division is expected but do not divide ([57]). In doing so, they also acquire morphologic abnormalities. Abnormalities in megakaryocytes have been reported in two cases of CDA III ([4]). An association of CDA III with monoclonal gammopathy, macular degeneration, and angioid streaks has also been reported ([58]). Management of CDA III is supportive.

OTHER VARIANTS

Numerous cases of CDA are reported in the literature that could not be classified into one of the three major types. A proposed category of CDA IV used to describe cases with features of CDA II, but a negative acidified serum lysis test with heterologous sera is controversial. Some of these cases may simply represent CDA II in which an insufficiently large panel of heterologous sera was used initially. Examples exist in the literature of cases that have been classified as CDA II when retested ([59], [60]). Aside from these, there are a number of reports of CDA with atypical features, as well as others that presented with severe manifestations such as hydrops fetalis ([8], [9], [61]). Whether these reports represent distinct syndromes or more severe variants of the known CDAs is unknown.

DIAGNOSIS OF CONGENITAL DYSERYTHROPOIETIC ANEMIA

CDA should be suspected in any individual with a chronic anemia that manifests as ineffective erythropoiesis, as well as in individuals with evidence of secondary hemochromatosis. Review of previous complete blood counts may be helpful in determining whether the anemia is congenital, although in some individuals, the anemia is so mild that it goes undetected until late in adulthood.

Bone marrow examination is usually the most helpful procedure in making the diagnosis of a CDA. The finding of erythroid hyperplasia and dyserythropoiesis, along with other signs specific to each of the CDAs, is apparent. However, some care must be taken to thoughtfully rule out other disorders on the differential diagnosis that can have a somewhat similar appearance, including vitamin B_{12} or folate deficiency, ß-thalassemia, sideroblastic anemias, and myelodysplasia.

Serologic studies, such as the acidified serum lysis test with heterologous serum and electron microscopy of bone marrow, are useful for the categorization of the

CDA. If CDA II is suspected, a reasonably large panel of normal sera (=30 samples) should be used in the acidified serum lysis test before deciding that the test is negative. The acidified serum lysis test, also known as the *Ham test*, has been the classic test used to diagnose PNH. Nowadays, however, flow cytometry to look for the presence of CD55 and CD59 has replaced this test for establishing the diagnosis of PNH and has led to decreased availability of the acidified serum lysis test in clinical laboratories. This may present a problem in evaluating patients for CDA. Such limited availability of specialized testing may necessitate referral of clinical specimens to academic centers with an interest in these disorders.

Anemias Secondary to Chronic Disease and Systemic Disorders

ANEMIA OF CHRONIC DISEASE

The anemia that is often observed in patients with infectious, inflammatory, or neoplastic diseases that persist for more than 1 or 2 months is called *anemia of chronic disease*. The characteristic feature of this syndrome is the occurrence of hypoferremia in the presence of ample reticuloendothelial iron stores. Anemia of chronic disease is defined by the presence of this unique combination of findings ([1], [2] and [3]). As so defined, the syndrome does not include anemias caused by marrow replacement, blood loss, hemolysis, renal insufficiency, hepatic disease, or endocrinopathy, even when these disorders are chronic. These other syndromes are discussed in the sections Anemia of Chronic Renal Insufficiency, Anemia in Cirrhosis and Other Liver Diseases, and Anemias Associated with Endocrine Disorders.

As the discussion above suggests, the designation *anemia of chronic disease* is far from perfect ([4]). The most commonly proposed alternative, *anemia of inflammation* ([4]), also has significant deficiencies, and the more pathophysiologically correct term *cytokine-mediated anemia* ([5]) is not commonly used. Highly specific descriptive designations, such as *anemia of defective iron reuse* ([6]), *hypoferremic anemia with reticuloendothelial siderosis*, and *thesauric hypoferremic anemia* ([7]), are also rarely used.

Associated Syndromes

Anemia of chronic disease is extremely common and, overall, is probably more common than any anemia syndrome other than blood loss with consequent iron deficiency. Cash and Sears evaluated all the anemic individuals admitted to the medical service of a busy municipal hospital during two 2-month periods in 1985 to 1986 ([8]). After patients with active bleeding, hemolysis, or known hematologic malignancy were excluded, 52% of anemic patients met laboratory criteria for anemia of chronic disease ([8]). The syndrome is also observed in 27% of outpatients with rheumatoid arthritis ([9]) and in 58% of new admissions to inpatient rheumatology units ([10]). Clinical disorders commonly associated with anemia of chronic disease are listed in Table 47.1. However, it should be remembered that 40% of patients in the series reported by Cash and Sears lacked one of the traditional chronic associated disorders ([8]). Approximately one-third of this latter group had renal insufficiency, in which pathophysiologic mechanisms implicated in anemia of chronic disease are active ([28]).

TABLE 47.1. Conditions Associated with Anemia of Chronic Disease

Chronic infections (8, 13)
Pulmonary infections: abscesses, emphysema, tuberculosis, pneumonia
Subacute bacterial endocarditis
Pelvic inflammatory disease
Osteomyelitis
Chronic urinary tract infections
Chronic fungal disease
Meningitis
Human immunodeficiency virus
Chronic, noninfectious inflammations
Rheumatoid arthritis (14, 15, 16 and 17)
Rheumatic fever (18)
Systemic lupus erythematosus (19)
Severe trauma (20)
Thermal injury (21)
Vasculitis
Malignant diseases (22, 23, 24 and 25)
Carcinoma
Hodgkin disease
Lymphosarcoma

Leukemia
Multiple myeloma
Miscellaneous
Alcoholic liver disease
Congestive heart failure
Thrombophlebitis
Ischemic heart disease
Idiopathic

Clinical and Laboratory Description

Because this type of anemia occurs in association with so many diseases, the clinical manifestations necessarily vary widely. Usually, the signs and symptoms of the underlying disorder overshadow those of the anemia, but on rare occasions, reduction of the hemoglobin level provides the first evidence of the existence of the primary condition. This situation may be observed particularly in difficult-to-diagnose clinical syndromes, such as temporal arteritis ([29]).

Anemia

DEVELOPMENT AND SEVERITY Typically, anemia develops during the first 1 to 2 months of illness and thereafter does not progress ([2]). The hematocrit usually is maintained between 0.25 and 0.40 ([2], [11], [30]), but significantly lower values are observed in 20 to 30% of patients ([8], [9]). The hemoglobin concentration and hematocrit generally provide an accurate reflection of the extent to which the circulating red cell mass is reduced, although in certain cases, expansion of the total blood volume would mean that the reduction in red cell mass is less than the hemoglobin or hematocrit indicates ([11]). This is particularly likely in syndromes associated with increased levels of interleukin (IL)-6. IL-6 produces a dilutional anemia: Expansion of the plasma volume results in a reduced hematocrit or hemoglobin concentration without changes in the circulating red cell mass ([31]). A general correlation exists between the degree of anemia and the severity of the underlying disease ([2]). For example, infections accompanied by pronounced fever, chills, and suppuration are associated with more severe anemia than those with fewer systemic manifestations ([32]). In infected wounds, the degree of anemia is related to the number of organisms present ([32]). Correlation has also been observed between the severity of the anemia and the activity of rheumatoid arthritis, judged by fever, severity of joint swelling and inflammation, and the erythrocyte sedimentation rate ([16], [33]). In patients with malignant disease, anemia is more severe when metastases are widespread than when the disease is localized; however, the development of anemia does not require neoplastic invasion of the bone marrow ([27], [34]). Typically, the percentage of reticulocytes is normal or reduced ([2]), although on rare occasions, it may be slightly increased ([32]).
MORPHOLOGIC FEATURES The erythrocytes usually are normocytic and normochromic; however, hypochromia and microcytosis may be observed. In older series, microcytosis [mean corpuscular volume (MCV) <80 fl] was observed in 2 to 8% of patients with anemia of chronic disease ([16], [35], [36]); however, other more recent studies report a frequency of 20 to 40% ([8], [30]). Hypochromia (mean corpuscular hemoglobin concentration, 26 to 32 g/dl) is more common than microcytosis. In various series, hypochromia was observed in 23 to 50% of patients with chronic infection, 50 to 100% of patients with rheumatoid arthritis, and 44 to 64% of patients with cancer ([2], [30]). Overall, it is observed in 40 to 70% of patients with the anemia of chronic disease ([8], [9], [16], [35], [36]). Hypochromia may be observed even though the hematocrit remains within normal limits ([12]). Microcytosis in anemia of chronic disease is usually not as striking as that commonly associated with iron deficiency anemia; values for MCV below 72 fl are rare ([2], [30]). Another distinction from iron deficiency is that hypochromia typically precedes microcytosis in anemia of chronic disease but typically follows the development of microcytosis in iron deficiency ([2]). Slight anisocytosis and poikilocytosis may be detected, but such changes tend to be less prominent than in iron-deficient subjects. Routine examination of the blood smear rarely reveals specific morphologic abnormalities. The width of the erythrocyte size distribution curve (red cell distribution width) is typically elevated to a moderate degree.
IRON METABOLISM Characteristically, serum iron concentration is decreased, total iron-binding capacity (or serum transferrin concentration) is reduced, and transferrin saturation is subnormal ([2], [36]). In patients with infection, hypoferremia develops early in the course of the illness, often within 24 hours, and is observed even in acute, self-limited febrile diseases or after experimentally induced fever in humans or animals ([7], [11], [37], [38]). When the infection is of short duration, the serum iron returns to normal, and anemia does not develop; in prolonged illnesses, the serum iron level remains low as long as the disease is active. When the disorder subsides, anemia often is relieved before the serum iron level returns to normal. The degree of hypoferremia is related to the severity of the underlying illness ([15], [16], [36]). In bone marrow aspirates stained for iron, the number of sideroblasts is reduced to 5 to 20% of the total quantity of normoblasts (normal, 30 to 50%). In contrast, the amount of hemosiderin within macrophages usually is increased; exceptions probably represent cases complicated by iron deficiency ([2]). Serum ferritin levels are useful indicators of iron status in patients without underlying chronic disorders. In patients with anemia of chronic disease, however, the serum ferritin level indicative of adequate reticuloendothelial iron stores requires upward adjustment. Serum ferritin values usually increase in patients with inflammatory diseases ([39]), and extreme elevations of serum ferritin may be a nonspecific indicator of significant underlying disease ([40]). When iron deficiency coexists, the serum ferritin level falls but may not reach values as low as those found in uncomplicated iron deficiency. Values of 60 to 100 µg/L previously suggested as the appropriate lower limit of normal for serum ferritin in chronic inflammation are almost certainly too low ([41], [42] and [43]). In a recent single institution experience, all patients with serum ferritin levels below 30 µg/L were iron deficient by marrow examination, as were the majority of hospitalized patients with serum ferritin levels 30 to 100 µg/L and approximately one-third of hospitalized patients with serum ferritin levels between 100 and 200 µg/L (Fig. 47.1) ([44]). Combining the serum ferritin level with other parameters, such as erythrocyte sedimentation rate and C-reactive protein, did not improve its predictive value ([45]), although it has been suggested that the combination of serum ferritin with red cell ferritin may be more predictive ([46]). The recognition of iron deficiency in patients with chronic inflammatory states is not a trivial issue: Iron deficiency contributes to anemia in up to 27% of anemic rheumatoid arthritis patients ([9]) and probably accounts for periodic reports of successful treatment of “the anemia of chronic disease” with iron preparations ([47]). A patient with chronic inflammatory disease and a serum ferritin less than 30 µg/L is certainly iron deficient, and a patient with a serum ferritin greater than 200 µg/L is certainly not iron deficient; in other circumstances, certainty can be provided only by examination of a Prussian blue–stained marrow specimen. An elevated serum concentration of soluble transferrin receptors (sTfR) may be able to identify iron-deficient individuals with normal serum ferritin concentrations ([48]).

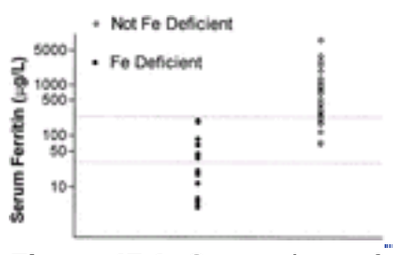

Figure 47.1. Comparison of serum ferritin levels from iron-deficient and non–iron-deficient patients as identified by bone marrow examination during 1994 to 1995 at the University of Cincinnati Medical Center. Dashed lines indicate the range of normal for the laboratory.

Other Biochemical Findings

The concentration of free protoporphyrin in the erythrocytes (FEP) tends to be elevated in patients with anemia of chronic disease ([11], [49], [50]). However, FEP increases more slowly in anemia of chronic disorders than it does in iron deficiency, and it does not become clearly abnormal until significant anemia has developed. It is a test that separates groups of patients with anemia of chronic disease from groups of patients with iron deficiency, but it is not particularly useful in the evaluation of individuals.

A variety of other biochemical changes often are detected in patients with chronic diseases. Many of these changes reflect alteration of levels of particular plasma proteins, often called *acute phase reactants* ([51], [52], [53], [54] and [55]). The concentrations of certain plasma proteins, such as fibrinogen, ceruloplasmin, haptoglobin, C-reactive protein, orosomucoid, C3, and amyloid A protein, increase ([56], [57] and [58]), whereas the concentrations of albumin and transferrin characteristically decrease ([59]). The increase in ceruloplasmin accounts for the increase in serum copper levels often noted in association with chronic diseases ([2], [11]). An elevated

fibrinogen level is probably the most important factor in the increased sedimentation rate ([60]).

Patients with chronic illness develop accelerated protein catabolism and negative nitrogen balance associated with muscle proteolysis ([61], [62] and [63]). Over time, this phenomenon can result in muscle wasting, increased urea excretion, weight loss, and growth impairment in children. However, protein catabolism generates amino acids that can be used by the patient as alternative energy sources or to supply substrates for biosynthetic processes related to host response. In this context, it is perhaps relevant that elevated serum levels of tumor necrosis factor (TNF), a cytokine implicated in the pathogenesis of anemia of chronic disease, are noted in patients with significant malnutrition ([64], [65]).

Kinetic Characteristics

Erythrocyte survival is modestly but significantly reduced in patients with anemia of chronic disease. In two studies comparing red cell survival in anemic patients with rheumatoid arthritis to red cell survival in normal individuals, the mean red cell survivals noted were 81 days versus 98 days and 90 days versus 114 days, respectively ([14], [62]). In a similar study comparing red cell survivals in ten anemic patients with a variety of chronic inflammatory states to ten normal individuals, the mean values observed were 80 days versus 88 days, respectively ([63]). The usual manifestations of increased blood destruction, such as increases in serum bilirubin values and urobilinogen excretion, are not typically observed ([2], [64]).

There is little evidence of a compensatory erythropoietic response to this reduction in red cell survival. The reticulocyte count usually is normal or decreased, and little or no erythroid hyperplasia of the marrow is observed. The pathogenetic significance of these findings is discussed in the following section. Kinetic data indicate that anemia develops because the bone marrow fails to increase red cell production sufficiently to compensate for a mild decrease in the lifespan of the red cells ([2], [7], [63]). Ferrokinetic studies involving patients with chronic infections ([65], [66]), rheumatoid arthritis ([67]), and various malignant diseases ([26], [27], [33]) reveal that the rate of disappearance of iron from the plasma is rapid, the plasma iron transport rate is normal or slightly increased, the uptake of iron into erythrocytes and the amount of iron turning over through red cells daily are normal or increased, and the fraction of red cells renewed daily is increased ([2]). When techniques that allow the division of marrow iron turnover (a measure of total erythropoiesis) into red cell iron turnover and ineffective iron turnover were used, marrow iron turnover was normal in patients with anemia of chronic disease ([14], [62], [63], [68]). Ineffective iron turnover was also normal, or even less than normal, indicating a lack of ineffective erythropoiesis ([14]). In iron-deficient subjects, ineffective iron turnover is increased, perhaps because of greater stimulation of the marrow.

Pathogenesis

Efforts to clarify the pathogenesis of anemia of chronic disease have focused on three principal abnormalities: shortened erythrocyte survival, impaired marrow response, and disturbance in iron metabolism. The modest shortening of the erythrocyte survival creates an increased demand for red cell production on the marrow. Normally, the marrow could easily accommodate this demand, but in the setting of anemia of chronic disease, the marrow is unable to respond fully because of a combination of a blunted erythropoietin response, an inadequate progenitor response to erythropoietin, and limited iron availability.

Cytokines

Anemia of chronic disease is one manifestation of the systemic response to immunologic or inflammatory stress, which results in the production of various cytokines ([3], [69]): The ability to trigger this cytokine response appears to be the common pathogenetic factor shared by the various conditions associated with this anemia syndrome. The central role of these molecules suggests that anemia of chronic disease may be best understood as a cytokine-mediated process ([5]). The cytokines most often implicated in the pathogenesis of the anemia of chronic disease are TNF ([70], [71] and [72]), IL-1 ([73], [74]), and the interferons ([75], [76] and [77]), concentrations of which have been reported to be increased in the serum or plasma of patients with disorders associated with anemia of chronic disease ([75], [77], [78], [79] and [80]). Therapeutic administration of TNF or interferon may induce anemia ([81], [82]). IL-6, another cytokine implicated in the inflammatory and immune response ([83], [84]), is a special case. Although increased serum IL-6 is observed in anemic patients with rheumatoid arthritis ([85]), IL-6 does not suppress erythropoiesis but rather is associated with increased plasma volume; the anemia is therefore dilutional ([31]). The association of IL-6 with hepatocyte activation may thus explain the dilutional component of the anemia observed in liver disease ([86], [87] and [88]).

Shortened Erythrocyte Survival

The rate of survival of cells from patients with arthritis, when transfused into normal subjects, is normal, and the survival of red cells from normal individuals in the circulation of patients with arthritis is less than the normal rate ([2], [35]). Therefore, shortened red cell survival in patients with chronic inflammatory disorders is attributed to an extracorpuscular mechanism ([15]). IL-1 levels and shortened red cell survival are correlated in anemic patients with rheumatoid arthritis ([89]), and mice that become anemic after exposure to TNF *in vivo* also exhibit a shortened red cell survival ([90]). The precise mechanism by which this shortened red cell survival is produced remains unclear. Peroxynitrite, derived from the reaction of the cytokine second messenger nitric oxide ([91]) and superoxide, may contribute to red cell rigidity and thus to decreased survival ([92]). Neocytolysis, a selective hemolysis of newly formed erythrocytes induced by activated macrophages ([93], [94]), may also play a role in the abnormal red cell survival observed in anemia of chronic disease.

Impaired Marrow Response

Normal bone marrow, capable of a six- to eightfold increase in the red cell production rate, should easily compensate for such a modest reduction in erythrocyte survival. Its failure to do so in anemia of chronic disease suggests that impaired production capacity is of fundamental importance in the pathogenesis of this condition. The possible defects in erythropoiesis fall into three categories: inappropriately low erythropoietin secretion, diminished marrow response to erythropoietin, and iron-limited erythropoiesis.

An inverse relationship between serum or plasma erythropoietin levels and hemoglobin normally exists: As the hemoglobin decreases, the erythropoietin level rises ([95]). A similar inverse relationship between hemoglobin and erythropoietin level exists in anemic individuals with rheumatoid arthritis, cancer, and human immunodeficiency virus infection ([96], [97], [98] and [99]); however, for any given anemic patient in these disease categories, the erythropoietin level was lower than that found in equally anemic individuals with iron deficiency, indicating that the erythropoietin response to anemia was blunted (Fig. 47.2). This impaired erythropoietin response is cytokine-mediated. IL-1, TNF-a, and transforming growth factor-ß inhibit production of erythropoietin by various hepatoma cell lines and by isolated perfused rat kidneys *in vitro* ([100], [101]). This effect occurs at the messenger RNA level ([100]). It has been proposed that this inadequate erythropoietin secretion is adaptive; that is, it reflects reduced tissue oxygen use so that normal oxygenation is maintained despite reduced hemoglobin levels. One colorful description of this process is that the “hematologic thermostat has been turned down a bit” ([7]), perhaps to allow diversion of substrates normally used in erythropoiesis to more immediately critical activities. A model that supports this explanation is the “euthyroid sick syndrome,” in which serum triiodothyronine levels are reduced without evidence of clinical hypothyroidism because of decreased conversion of thyroxine to triiodothyronine in peripheral tissues ([102], [103] and [104]). These findings provide a basis for reduced oxygen consumption at the tissue level. However, changes that ordinarily signify erythrocyte adaptation to tissue hypoxia such as increased erythrocyte 2,3-diphosphoglycerate levels are observed in anemia of chronic disease ([105]). Hemoglobin oxygen affinity is also slightly decreased in these patients but overlaps the range observed in normal subjects ([105]).

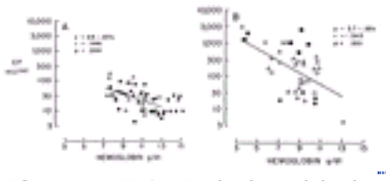

Figure 47.2. Relationship between the logarithm of serum immunoreactive erythropoietin (EP) and the hemoglobin concentration in 54 patients with rheumatoid arthritis **(A)** and in 41 anemic patients without rheumatoid arthritis **(B)**. In **(A)**, anemic patients with deficient or replete marrow iron stores are indicated by open triangles and solid triangles, respectively. In **(B)**, the 25 patients with simple iron deficiency anemia are indicated by open triangles. The nine patients with anemia and an associated malignancy or chronic inflammatory disease are indicated by circles—solid for those who were iron replete and open for those who had concomitant

iron deficiency. (From Baer AN, Dessypris EN, Goldwasser E, et al. Blunted erythropoietin response to anaemia in rheumatoid arthritis. Br J Haematol 1987;66:559–564, with permission.)

Although the erythropoietin levels of patients with anemia of chronic disease are lower than those observed in equally anemic iron-deficient individuals, they are still higher than are observed in normal individuals who are not anemic. This implies that inhibition of erythropoietin production cannot entirely account for the impaired erythropoiesis associated with anemia of chronic disease, and that the erythroid progenitors themselves exhibit an abnormal response to erythropoietin. Studies of anemic cancer patients support this concept ([106], [107]).

TNF, IL-1, and interferon have all been reported to inhibit erythropoiesis *in vivo* and *in vitro* ([80], [82], [108], [109], [110], [111], [112], [113], [114], [115] and [116]). TNF inhibits *in vitro* colony formation by human erythroid colony-forming units (CFU-E) indirectly, through soluble factors released from marrow accessory cells in response to TNF. The identity of the required accessory cells is unknown at present; cell-mixing studies imply that it is neither a lymphocyte nor a monocyte ([117]). Inhibition of CFU-E colony formation by TNF was ablated by neutralizing antibodies to interferon-ß, which itself has direct inhibitory effects; however, insufficient quantities of interferon-ß were produced in response to TNF to entirely account for the inhibition observed ([118]). The inhibitory effect of rhIL-1 on human CFU-E colony formation was also indirect and dependent on marrow accessory cells; however, the responsible accessory cells in this case were T lymphocytes, and the mediator was interferon-?, which also exhibits a direct inhibitory effect on human CFU-E ([119]). Although interferon-a and interferon-ß share a common receptor, interferon-a does not exert a direct inhibitory effect on human CFU-E colony formation. Instead, its effect is mediated through an unidentified soluble factor released by T lymphocytes ([120]). The inhibitory effects of interferon-a and interferon-ß exhibit synergy with interferon-? ([120]). An important point to consider in reviewing the various models for cytokine effects on erythropoiesis is that none of the systems described operates in isolation *in vivo*. Thus, TNF induces IL-1 production by macrophages, IL-1 induces interferon-? production by T lymphocytes, and interferon-? can exhibit positive or negative feedback on production of IL-1 and TNF.

Treatment with recombinant human erythropoietin can correct anemia of chronic disease in many cases. Inhibition of *in vitro* erythroid colony formation by interferon-?, but not interferon-a and interferon-ß, can be corrected by exposure to high concentrations of erythropoietin ([120], [121]).

Abnormal Iron Metabolism

It has been proposed that lack of iron for erythropoiesis contributes to the inadequate marrow response in anemia of chronic disease. Evidence of a functional iron deficiency in this syndrome includes erythrocyte microcytosis, increased FEP ([11], [50]), reduced transferrin saturation ([36]), and decreased marrow sideroblasts ([36]).

Ferrokinetic studies have proved confusing. It has been reported that erythroid iron turnover correlated with serum iron levels, permitting a conclusion that marrow proliferation was limited by availability of iron in anemia of chronic disease ([106]). Other studies found no correlation between marrow iron turnover and serum iron concentration ([14], [62], [63], [122]).

The major contributor to hypoferremia in patients with anemia of chronic disease is probably a shift of iron from a transferrin-bound, available state to a ferritin-incorporated storage state. Iron absorption appears to be normal, but iron tends to remain in the mucosal cell and in hepatocytes ([123], [124]). Macrophages, the major site from which iron is obtained for erythropoiesis, also exhibit increased iron storage. Macrophage iron becomes available for erythropoiesis through two mobilization pathways: a rapid pathway, associated with almost immediate return of the iron retrieved from senescent red cells, and a slower pathway, consisting of iron mobilized from storage ([125], [126]). In anemia of chronic disease, the slower pathway predominates, and iron tends to accumulate. This phenomenon probably explains previous studies that demonstrated defective reuse of erythrocyte iron in patients with inflammatory conditions and in animal models of such conditions ([127], [128] and [129]).

Apoferritin is normally synthesized in response to increased intracellular iron concentration ([130]). One possibility is that, like acute phase proteins, excess apoferritin is made in inflammatory and malignant conditions, and the surplus binds a larger than usual amount of iron entering the cell ([131], [132]). In effect, such a mechanism would divert iron from the rapid to the slow pathway of iron release. Studies of cytokine effects on iron mobilization support this hypothesis. A correlation between the immune activation marker neopterin and increasing ferritin levels in patients with malignancies has been demonstrated, implying that immune activation can alter iron metabolism ([133]). Rodents injected with recombinant TNF developed a hypoferremic anemia associated with impaired storage iron release and incorporation into erythrocytes ([90], [134]). It has also been reported that IL-1 increases translation of ferritin messenger RNA and that this additional ferritin could act as a trap for iron that might otherwise be available for erythropoiesis ([135]). Nitric oxide, which is a common mediator of cytokine effects, has similar effects on ferritin expression ([136], [137]).

The lactoferrin hypothesis ([138]) is another approach to explaining iron abnormalities in anemia of chronic disease. *Lactoferrin* is a transferrin-like protein found in neutrophil-specific granules ([139], [140]). It is released from the neutrophil during phagocytosis or stimulation by IL-1 ([141]). At low pH, lactoferrin binds iron more avidly than does transferrin ([142]). Lactoferrin-bound iron is not immediately available for erythropoiesis ([143]); rather, it binds to specific receptors on macrophages (particularly in the liver and spleen) and is endocytosed and subsequently incorporated into ferritin ([23], [144]). Thus, lactoferrin transfers iron from its transferrin-bound, circulating state to a storage state, from which it cannot be rapidly mobilized ([138]). Definitive experimental confirmation of the lactoferrin hypothesis is not available. One group of investigators found that reducing the available lactoferrin by inducing neutropenia in rats blunted the hypoferremic response to IL-1 ([145]), but another group found that administration of recombinant IL-1 induced hypoferremia in mice, even in the face of severe neutropenia ([146]).

Hepcidin, an acute-phase reactant antimicrobial protein produced in the liver, appears to be a key regulator of iron storage and transport and has been proposed as a mediator of the anemia of chronic disease ([146a], [146b] and [146c]). Urinary hepcidin excretion is strongly correlated with serum ferritin concentration and is markedly elevated in patients with the anemia of inflammation (defined as anemia with a characteristic clinical setting and an elevated serum ferritin) compared to iron deficient patients ([146c]). Serum hepcidin concentration is also strongly correlated with serum ferritin concentration, but does not differ when iron deficient patients are compared to those with the anemia of chronic disease (defined as hypoferremia with adequate iron stores) ([146d]). The apparent discrepancy most likely reflects the different definitions used.

In addition to decreased availability of iron, erythroid progenitors may also be unable to fully use the iron available to them. Erythroblasts from anemic patients with rheumatoid arthritis express fewer surface TfR than do erythroblasts from normal individuals. These TfR also exhibit lower binding affinity for transferrin ([147]). Furthermore, acute phase reactants, such as a $_1$-antitrypsin, impair transferrin binding to erythroblasts and also inhibit transferrin internalization ([148]). Recombinant human erythropoietin appears to induce a greater level of TfR expression on erythroid cells ([149]). Circulating sTfR in anemia of chronic disease are most likely of nonerythroid origin ([150]).

Figure 47.3 summarizes the pathogenetic mechanisms involved in anemia of chronic disease and the role of cytokines in this syndrome ([151]).

Figure 47.3. Schematic diagram representing cytokine effects in the pathogenesis of anemia of chronic disease. Positive regulatory effects are represented by solid lines, and negative regulatory effects are represented by broken lines. IFN, interferon; IL-1, interleukin 1; TNF, tumor necrosis factor. (Modified from Means RT Jr, Krantz SB. Progress in understanding the pathogenesis of the anemia of chronic disease. Blood 1992;80:1639–1647.)

Anemia in Patients with Cancer

Much of the anemia commonly observed in patients with cancer can be attributed to the mechanisms involved in the anemia of chronic disease; however, certain processes unique to malignancy may also contribute. Erythroid precursors may be displaced from marrow by metastatic tumor ([152]), tumor-induced fibrosis ([153]), or tumor-associated marrow necrosis ([154]). The treatment of cancer can also produce or exacerbate anemia by a variety of mechanisms, including impaired erythropoietin production ([155]) and cytotoxic effects of therapy on erythroid progenitors ([156]).

Diagnosis

Recent studies suggest that diagnosis of anemia of moderate degree, as is commonly observed in anemia of chronic disease, is often missed ([157]). Anemia of chronic disease should be considered in anemic patients with associated inflammatory, infectious, or neoplastic states. As described in Table 47.1 ([8]), not all cases are associated with a classic chronic disease, but virtually all cases are associated with states of cytokine or immune activation. The diagnosis is confirmed by demonstrating hypoferremia with adequate reticuloendothelial iron stores in a patient with an appropriate clinical syndrome. Typically, the serum transferrin is either low or low normal. The major differential diagnosis is iron deficiency anemia. This is not a trivial distinction. The diagnosis of iron deficiency mandates identification of a source of blood loss. Incorrectly labeling a patient with anemia of chronic disease as iron deficient exposes that patient to intrusive and expensive (although fairly safe) diagnostic procedures and to ineffective therapy. Mislabeling an iron-deficient patient as having anemia of chronic disease may result in failure to diagnose an underlying gastrointestinal malignancy at a curable stage and in failure to offer inexpensive and effective therapy. The diagnosis of iron deficiency is discussed in detail in Chapter 28 and in the section Abnormal Iron Metabolism.

Treatment

The focus of therapy should be on the underlying disorder. The anemia itself is rarely an important clinical problem. Thus, direct approaches to correction of the anemia are rarely necessary. Less than 30% of patients have hematocrits sufficiently low to necessitate transfusion, and assessment of the symptomatic state should always be considered before administration of blood products. Recombinant erythropoietin is effective and safe but expensive (Fig. 47.4) ([158] , [159] and [160]). Because most patients were not symptomatic from their anemia, symptomatic benefit was rarely reported in the initial studies ([158] , [159]). Subsequent studies using more sophisticated evaluation instruments have reported increased quality of life in anemic patients with rheumatoid arthritis ([161]) or cancer ([162]) treated with erythropoietin, suggesting that more frequent use may be indicated in anemia of chronic disease. It can also be used for patients who wish to donate blood for autologous transfusion at elective surgery but are too anemic to do so ([163]) or to permit autologous blood donation by a patient with anemia of chronic disease and multiple alloantibodies ([164]).

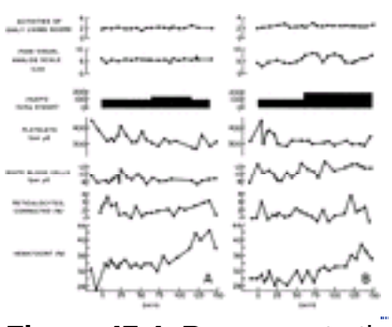

Figure 47.4. Response to therapy with recombinant human erythropoietin (rHuEPO), as observed in changes in hematocrit value, reticulocyte count, white blood cell count, arthritis-associated pain, and activities of daily living scores in patient 1 **(A)** and patient 2 **(B)**. (Reproduced from Means RT, Olsen NJ, Krantz SB, et al. Treatment of the anemia of rheumatoid arthritis with recombinant human erythropoietin: clinical and in vitro studies. Arthritis Rheum 1989;32:638–642, with permission.)

It is debated whether or not to routinely administer iron to patients receiving erythropoietin therapy. It is this author's practice to do so. In one study of anemic patients with rheumatoid arthritis, the concurrent use of iron supplementation was a powerful predictor of response to erythropoietin ([165]); however, many of the patients in this study may have been iron deficient. Although there are reports of correction of anemia of chronic disease by intravenous iron without erythropoietin ([47] , [166]), normalization of hemoglobin was only described in patients who were clearly iron deficient ([47]). Iron therapy by itself is likely to be useful only in patients who have concurrent iron deficiency ([9]), and then only for the component of anemia caused by iron deficiency. There is no convincing evidence that iron alone corrects anemia of chronic disease per se.

Darbepoetin (also called *novel erythropoiesis stimulating protein*) is an erythropoietin analog with modified glycosylation permitting a longer half-life. It has been shown to be effective in anemic patients with cancer (whether receiving chemotherapy or not) and in a cytokine-mediated anemia animal model ([167] , [168]). The optimal dosing schedule is not yet established.

ANEMIA OF CHRONIC RENAL INSUFFICIENCY

Anemia is an almost invariable manifestation of chronic renal failure, often contributing substantially to the morbidity of the condition. It may be considered as typical of the disease as azotemia ([169]). In the era before the availability of recombinant human erythropoietin, 98% of patients on hemodialysis were anemic ([170]); even now, 28% of dialysis patients have hematocrit values less than 0.30 ([171]). The term *anemia of chronic renal insufficiency* refers to that anemia resulting directly from failure of the endocrine and filtering functions of the kidney. The kidney is the major source of erythropoietin, and the ability to secrete this hormone is lost as the kidney fails. In addition, renal failure is associated with other pathologic processes, including some that may inhibit erythropoiesis and others that may shorten erythrocyte survival. Lack of sufficient erythropoietin is by far the most important of these anemia-causing factors; consequently, the hypoproliferative features of the anemia tend to predominate ([172]).

In clinical settings associated with chronic renal failure, additional factors may also contribute to the development of anemia, but these should be considered complications rather than fundamental components of the anemia of renal insufficiency itself. In the presence of infection or inflammation, anemia of chronic disease is likely to be observed. Iron deficiency anemia (see Chapter 35) may develop because of blood loss from the gastrointestinal tract or (less frequently) hematuria or from retention of blood in the hemodialysis apparatus tubing ([172] , [173]). The megaloblastic anemia of folate deficiency also may occur in patients on dialysis ([174] , [175]) but is otherwise uncommon ([176]). Certain types of renal disease, including the hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura, are associated with microangiopathic hemolytic anemia (see Chapter 54). Finally, aluminum intoxication can cause microcytic anemia in dialysis patients ([177]).

Clinical Description

Chronic renal failure occurs during the final stages of several renal diseases. As a rule, the nature of the underlying disease bears little relation to the degree of anemia, although anemia may be less severe in patients with hypertensive renal disease ([178]) and is considerably less severe in patients with polycystic disease ([179] , [180]). In one series, the mean hematocrit in 12 subjects with polycystic disease was 0.297 as compared with 0.212 in 24 subjects with other types of chronic renal failure ([179]). Apparently, the erythropoietin-secreting function of the kidney is preserved in polycystic disease—even when filtering function is lost ([180] , [181]). Erythropoietic activity can be found in the cystic fluid and may arise from single interstitial cells juxtaposed to proximal tubular cysts ([180]).

In most instances, the patient seeks medical attention because of symptoms related to the underlying renal disease, and anemia is an incidental finding. Occasionally, however, the renal symptoms are so subtle and so slowly progressive that the patient cites only symptoms of pallor, exertional dyspnea, or other signs of the cardiovascular adjustment to anemia. The severity of the anemia bears a rough relationship to the degree of renal insufficiency. Anemia is not routinely observed until the creatinine clearance falls below 40 ml/minute, which corresponds roughly to a serum creatinine of 2.0 to 2.5 mg/ml in an average-sized adult. At creatinine clearance rates below that, a statistically significant correlation between creatinine clearance and hematocrit has been reported ([181] , [182]). However, the variation in

the results of these studies is so great that one cannot reliably predict the hemoglobin level in an individual patient on the basis of renal function.

Laboratory Findings

Anemia tends to become more severe as renal failure worsens, but in most patients, the hematocrit ultimately stabilizes between 0.15 and 0.30 ([2]). Because regulation of body water and electrolyte balance is impaired in renal disease, the apparent degree of anemia may be exaggerated or minimized by alterations in plasma volume.

The erythrocytes usually are normocytic and normochromic, but slight macrocytosis is occasionally observed ([184]). The majority of red cells appear normal on blood smears. Occasionally, however, “burr” cells (Fig. 47.5) are observed along with some triangular, helmet-shaped, or fragmented cells. The reticulocyte count often is within normal limits ([185]), but it may be moderately increased ([184] , [186]). In one study, the numbers of reticulocytes were normal when the blood urea nitrogen (BUN) value was less than 130 mg/dl; at higher BUN levels, however, their number often was increased ([187]). The highest values (average, 6%) were observed with extreme azotemia (BUN, 300 to 350 mg/dl).

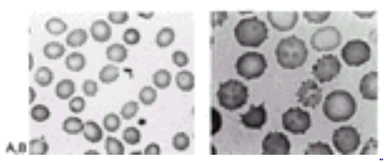

Figure 47.5. A: Crenated cells in renal disease (×1500). **B:** Burr cells in renal disease (×3000). See Color Plate.

The leukocyte count typically is normal, but slight neutrophilic leukocytosis may be observed. In one series, the leukocyte count averaged 10.7 × 10^{9}/L ([185]). The platelet count is either normal or slightly increased ([185]), but platelet function may be severely impaired, resulting in defective hemostasis (see Chapter 58).

The bone marrow tends to be moderately hypercellular, and slight erythroid hyperplasia may be observed. The myeloid to erythroid ratio averaged 2.5:1.0 in one study ([185]). Erythroid maturation appears morphologically normal. In some instances, especially when renal failure is relatively acute, hypoplasia of erythroid elements is noted ([188] , [189]).

The serum bilirubin level was within normal limits in all of the 26 patients in one series ([184]). The hemolytic index, a measure of urobilinogen excretion in relation to total circulating hemoglobin, was increased in approximately 40% of patients evaluated ([184] , [190]).

Values for serum iron vary considerably in renal disease ([184] , [190]). As a rule, the value is normal when renal impairment is mild. With more severe disease, some investigators observe a decrease in serum iron levels ([191]), whereas others note hyperferremia ([190] , [192]). Whether a characteristic disturbance of serum iron concentration is associated with “uncomplicated” renal failure remains to be determined. One group of investigators has reported that the gastrointestinal absorption of iron is reduced in patients with chronic renal failure ([193]). Other researchers, using a different method, found iron absorption was related to disturbances in iron balance and was unrelated to the degree of anemia, the rate of erythropoiesis, or the degree of azotemia ([194]). FEP may be normal or moderately increased ([184]), but the increased values seem to occur only in patients with hypoferremia ([195]). The erythrocyte lactate dehydrogenase level is within normal limits ([196]).

The glycated fraction (A_1) of hemoglobin (the best known component of which is hemoglobin A_{1c}) tends to increase in chronic renal failure. In uremic patients who have not undergone dialysis, the hemoglobin A_1 value averaged 10.8% of the total hemoglobin as compared with 7.1% in nonuremic individuals ([197]). In uremic patients treated with dialysis, the value averaged 8.8%. The increase is thought to result from carbamylation of the hemoglobin molecule by urea-derived cyanate; it can be detected by using column chromatography but not by using certain chemical methods designed for hemoglobin A_{1c}. The magnitude of the increase usually correlates with the average value for BUN over the preceding 2 to 3 months. The increase in the A_1 fraction may continue after successful renal transplantation has brought the azotemia under control; in this case, the increase might reflect disturbed carbohydrate metabolism ([198]) and probably reflects hemoglobin A_{1c}.

Pathogenesis

It has been known for many years that there are three factors involved in the pathogenesis of anemia of chronic renal failure. These factors are erythropoietin deficiency, suppression of marrow erythropoiesis, and shortened red cell survival ([199] , [200] and [201]). When anemia is severe, ferrokinetic studies typically demonstrate that the plasma iron transport rate is normal, but red cell iron utilization and erythrocyte iron turnover are decreased ([172] , [184]). With milder degrees of anemia, ferrokinetic measurements tend to be near normal. In anemic patients, however, such “normal” values indicate an insufficient marrow response to the stimulus of anemia. The success of recombinant erythropoietin in the treatment of anemia of renal failure has caused the other two factors to receive short shrift in recent years.

As renal function deteriorates, renal erythropoietin secretion decreases ([183] , [202]). Measured erythropoietin values may be lower than normal, higher than normal, or normal ([182] , [183] , [202] , [203]). However, it is important to remember that even the “increased” erythropoietin concentrations observed in this syndrome are still strikingly low for the degree of anemia ([204]). Overall, the usual relationship between erythropoietin and hemoglobin concentrations is lost, indicating a loss of customary feedback mechanisms ([181]). Some capacity to induce erythropoietin secretion is preserved, however, because even the very low levels of erythropoietin secretion in renal disease change in response to hemorrhage or transfusion ([205]). Certain extrarenal sources of erythropoietic hormone account for some of the activity found in serum, especially that found in anephric subjects ([204] , [206]). This extrarenal erythropoietin secretion does not, however, appear to increase sufficiently in response to anemia to compensate for deficiencies at the renal source ([207]). Elegant studies in sheep ([208]) and subsequent confirmatory studies in patients ([209] , [210]) have established the primacy of erythropoietin deficiency in the pathogenesis of anemia of chronic renal failure.

There is also a significant body of data suggesting that the inadequate marrow response to anemia is not solely due to erythropoietin deficiency. The observation that the rate of erythropoiesis improved in patients treated with dialysis even though erythropoietin levels were unchanged ([186] , [211]) suggested that retained uremic toxins depress erythropoiesis directly. This field of research has been quite confusing, because not all investigators have been able to confirm the presence of inhibitors or to demonstrate their specificity. Several groups of investigators have shown that plasma from uremic patients can depress heme synthesis ([212]) or inhibit growth of erythroid colonies *in vitro*, or both ([213] , [214] , [215] and [216]). The polyamine spermine and other molecules that accumulate in renal failure have been proposed as candidates ([214] , [215] , [217] , [218] and [219]). Inhibitors of multipotential stem cell (colony-forming unit granulocyte-erythroid-macrophage-megakaryocyte) growth have also been detected in uremic plasma ([220]), but they are of uncertain pathophysiologic importance ([214]). Parathyroid hormone, associated with secondary hyperparathyroidism in renal failure patients, may also contribute to marrow suppression ([221]). The hematocrit increases in approximately one-half of the patients with renal failure who undergo parathyroidectomy, although only to a modest degree ([222] , [223] and [224]). Some, but not all, investigators suggest that levels of parathyroid hormone similar to those found in the serum of uremic patients depress the growth of erythroid colonies *in vitro* ([221] , [225] , [226] and [227]). Hyperparathyroidism may also exert its effects by causing marrow fibrosis ([222] , [224]).

In recent studies, Allen and colleagues have demonstrated that inhibition of erythroid colony formation by uremic serum can be abrogated by neutralizing antibodies to TNF and interferon-? ([28]). These data suggest that cytokine-mediated anemia mechanisms typically associated with anemia of chronic disease may be active in renal failure ([228]). It is also possible that the excellent response of anemia of renal failure to erythropoietin does not indicate a lack of contributing inhibitors but rather reflects the ability of erythropoietin to overcome an inhibitor, as has been reported for interferon-? ([120]).

A third pathogenetic factor is hemolysis. Erythrocyte survival, although often within normal limits, may be slightly to moderately reduced ([229]). Depending on the evaluation technique used, 20 to 70% of uremic patients show shortened red cell survival ([169] , [184] , [186] , [191]). The extent to which red cell survival is decreased is somewhat related to the degree of azotemia ([172]). Cross-transfusion studies suggest that the hemolytic factor, when present, is extracorpuscular. Survival of normal

cells transfused into patients is shortened, whereas patients' cells survive normally in normal recipients ([169], [184], [191]). Less commonly, shortened survival of uremic patients' cells is observed even in normal subjects ([191]). In some patients, splenic sequestration of red cells may be a contributory factor ([230]).

The hemolytic factor(s) is presumed to be a toxic substance (or substances) normally excreted or metabolized by the kidney. Guanidine and its derivatives appear to be a subset of the many retained metabolites that adversely affect erythrocyte survival ([231], [232]). The hypothetical factor(s) is apparently not dialyzable ([199]). Peroxidation of membrane lipids by free radicals may also contribute to the shortened survival observed ([233]).

In approximately 20% of uremic patients not treated with dialysis, the red cell pentose phosphate pathway is impaired as a result of a poorly defined substance in the plasma ([234], [235]). This defect is best detected by using the ascorbate-cyanide test; other tests of pentose phosphate pathway function may yield normal results ([236]). Administration of glutathione returns the ascorbate-cyanide test to normal ([233]). Oxidant drugs, such as primaquine or sulfonamides, produce a Heinz body hemolytic anemia in patients with the pentose phosphate pathway defect. Even in the absence of drug exposure, Heinz bodies may be observed in the red cells of uremic patients if they have undergone splenectomy ([234]). Contamination of dialysate water by chloramines, which inhibit phosphoglyceromutase and thus cause accumulation of glycolytic intermediates, may worsen this defect ([235], [237]).

Cation transport may be impaired in uremic red cells: The defect reverts toward normal after dialysis ([238], [239]). When sensitive measures are used, nearly all patients can be shown to have such an abnormality ([239]); in those most severely affected, the erythrocyte sodium concentration is increased ([238]). Considerable disagreement surrounds the nature of the defect, with various investigators reporting abnormalities in cation pump site number or function ([238], [239]) and others reporting the presence (or absence) of soluble, dialyzable inhibitors of pump function ([240], [241] and [242]).

Evidence of impaired erythrocyte glycolysis has been found in uremic patients ([243]); however, in most studies, the overall glycolytic rate is increased ([244], [245]), probably because of the elevation in plasma levels of inorganic phosphorus ([244]). The increase in the glycolytic rate probably accounts for the observed increase in red cell adenosine triphosphate levels ([244], [245]). Hemoglobin oxygen affinity is reduced ([246]), presumably because of increased erythrocyte adenosine triphosphate and 2,3-DPG levels. Such abnormalities would not be expected to cause reduced red cell survival.

Neocytolysis, the selective hemolysis of newly formed red cells, has been reported after erythropoietin withdrawal in dialysis patients and may contribute to shortened red cell survival in dialysis patients ([93]).

Management and Course

RECOMBINANT ERYTHROPOIETIN Recombinant human erythropoietin has been available for treatment of anemia of renal disease since 1989 and has revolutionized the approach to this disorder. Therapy with this agent is safe and effective, and it substantially improves quality of life and cognitive function ([247], [248]). It is the treatment of choice for anemia in renal insufficiency, being effective in patients receiving peritoneal or hemodialysis ([209], [210], [249]). It is equally efficacious in anemia due to renal insufficiency not sufficiently advanced to require dialysis, but in which the creatinine clearance is less than 40 ml/minute or the serum creatinine is greater than 2.5 mg/ml ([182], [183], [250], [251]). Erythropoietin can be administered intravenously or subcutaneously: The latter route may allow lower total weekly doses ([252]). Although erythropoietin was originally given three times weekly (to coincide with dialysis schedules), single weekly doses are similarly efficacious if the total weekly dose is increased appropriately ([253]). A standard starting dose would be 150 U/kg/week, given as a single or divided dose. Higher doses generally result in faster correction of anemia; target hemoglobin is typically attained within 6 to 8 weeks ([249]). Iron supplementation is necessary, particularly in patients on hemodialysis (discussed in section Dialysis). The target hemoglobin/hematocrit range is usually 12 g/dl/0.360; some data suggest that higher levels may have an adverse clinical impact ([254]).

Side Effects/Adverse Reactions As noted earlier, erythropoietin is generally safe. When used for anemia in renal disease, increased blood pressure is an important complication, experienced by up to 35% of patients ([255], [256]). Occasionally, the hypertension is abrupt and severe with encephalopathy and seizures ([257]). The occurrence of hypertension appears to be more closely related to the rate of increase in the blood hemoglobin level than the dose of recombinant erythropoietin ([258]). It tends to be a transient phenomenon confined to the first 3 to 6 months of treatment. The pathogenesis is incompletely understood and probably multifactorial ([258]). Because heart rate, stroke volume, and cardiac output decrease as anemia is corrected, an increase in peripheral vascular resistance may be responsible. Daytime vasoconstriction may be a consequence of reduced plasma volume ([255]). Left ventricular hypertrophy, an important predictor of cardiac morbidity and mortality in renal patients, tends to decrease by approximately 18% within a year of correction of anemia; this beneficial effect may be diminished by hypertension ([256]). However, erythropoietin can also contribute to hypertension through direct vasopressor effects, which appear most active in renal insufficiency ([259], [260]). In early studies, prolonged or less effective dialysis ([261], [262]) and increased thrombotic events were thought to be problems associated with erythropoietin treatment, but these concerns were not borne out in a large study ([249]). Anaphylaxis in response to erythropoietin has been described but is extremely rare ([263]).

Erythropoietin Resistance As mentioned earlier, more than one-fourth of hemodialysis patients have a hematocrit less than 0.30. The failure of patients to respond optimally to erythropoietin therapy or a requirement for unusually high doses is referred to as *erythropoietin resistance*. The possible causes of erythropoietin resistance are listed in Table 47.2.

TABLE 47.2. Causes of Erythropoietin Resistance

Iron deficiency
Blood loss (in dialysis apparatus, gastrointestinal, genitourinary)
Insufficient iron supplementation
Concurrent cytokine activation
Infection
Inflammation
Neoplasm
Insufficient dialysis intensity
Aluminum toxicity
Secondary hyperparathyroidism
Folate deficiency
Angiotensin-converting enzyme inhibitors
Renal allograft failure
Antierythropoietin antibody-mediated resistance
Pure red cell aplasia
Other
Splenomegaly

Iron deficiency is the most common cause ([264], [265]). Loss of blood in the dialysis apparatus is an important source of iron depletion ([266]). Most patients require iron supplementation at some time during their course ([267]). In general, those with serum ferritin levels below 100 to 200 µg/L or with transferrin saturation values less than 20 to 25% ([265], [268], [269]) require iron supplementation, but such values may not appear until resistance to recombinant erythropoietin becomes apparent. In another study, patients with serum ferritin values between 100 and 400 µg/ml were as likely to respond to iron replacement as those with serum ferritin less than 100 µg/ml ([270]). Other investigators found that a low MCV, but not a low serum ferritin, predicted response to iron replacement ([271]). The best early predictors of erythropoietin response are serum TfRs and serum fibrinogen ([272]). Response rate approaches 100% when both are low and 29% when both are high, reflecting both the patient's iron status and the presence or absence of inflammation. Some authors recommend routine oral iron supplementation for all patients. However, oral iron administration can be limited by intolerance, so that compliance is relatively poor ([267]). Consequently, intravenous iron replacement, particularly with iron dextran, is recommended for dialysis patients ([273], [274]). Studies comparing oral versus intravenous iron supplementation generally find that the intravenous replacement group achieves higher hemoglobin levels with less erythropoietin use ([271], [275]). Inadequate hemodialysis is associated with erythropoietin resistance ([276]). As a general rule, the intensity of dialysis must be sufficient to reduce the BUN by 65% or more to ensure optimal erythropoietin response. Such factors as the frequency and

duration of dialysis and characteristics of the dialyzer may need to be adjusted to achieve this goal ([277]). Mortality is also reduced by attention to dialysis intensity. Rates of reimbursement for dialysis in the United States have discouraged optimal intensity, with the result that mortality is higher there than in Western Europe and Japan. As discussed earlier, secondary hyperparathyroidism often accompanies renal failure, and the associated marrow fibrosis may contribute to the anemia ([221] , [222] , [224]) and to erythropoietin resistance. Treatment with vitamin D_3 can decrease recombinant erythropoietin requirements and improve hemoglobin values ([278]). Aluminum toxicity may also occur ([177]) and tends to respond to chelation therapy ([279]). If erythropoietin resistance is associated with an increased MCV, folate supplementation is warranted ([174]). Serum folate levels may not be helpful in this situation. In some cases, iron replacement may unmask folate deficiency in dialysis patients ([271]). Associated infections or inflammatory states, as in anemia of chronic disease, may provoke cytokine-mediated anemia mechanisms. In addition, there are a number of minor etiologies of erythropoietin resistance. The use of angiotensin-converting enzyme inhibitors in renal failure patients (particularly those undergoing transplantation) may exacerbate erythropoietin resistance ([280] , [281]). Splenomegaly may create a requirement for higher erythropoietin dosing: This is resolved by splenectomy ([230]). Infrequent cases of erythropoietin resistance due to antierythropoietin antibodies, including production of pure red cell aplasia, have been reported ([282] , [283]).

Darbepoetin (Novel Erythropoiesis Stimulating Protein) The long-acting erythropoietin analog darbepoetin (novel erythropoiesis stimulating protein) appears to be safe and effective in the anemia of renal failure ([284]). The recommended starting dose is 0.45 µg/kg/week.

RENAL REPLACEMENT THERAPY Renal replacement approaches (transplantation and dialysis) aim to restore or substitute for lost renal function. As such, they may have some effects on anemia associated with renal failure.

Renal Transplantation In many ways, renal transplantation is the most complete and satisfactory treatment for renal insufficiency. With a successful graft, the hematologic response is often striking. Anemia is usually corrected over an 8- to 10-week period ([285] , [286] and [287]). For the most part, the improvement results from erythropoietin secretion by the grafted kidney. Two peaks of erythropoietin secretion have been documented: an early peak, in which serum erythropoietin levels increase approximately ninefold and then return to normal after approximately 7 days, and a second smaller, more sustained increase in erythropoietin levels, which begins on approximately day 8 and is accompanied by reticulocytosis and a gradual increase in hemoglobin levels. Erythropoietin values return to normal when the hematocrit reaches 0.32. The early peak is seen only in patients with delayed graft function and is not associated with hematologic improvement ([285] , [287]). The second peak is associated with recovery of the graft excretory function and is presumed to be the important factor in the hematologic response. Approximately 80% of patients experience an increase in blood hemoglobin concentration after renal allograft ([286]). Failure to respond usually can be explained on the basis of hemorrhage, vigorous immunosuppression, or graft rejection. The rejection phenomenon often is accompanied transiently by increased erythropoietin levels ([288] , [289]), but this is followed by a profound reduction in erythropoietin levels and reticulocyte counts ([290]). Improvement in erythropoiesis occurs earlier when cyclosporin is used for immunosuppression rather than with antilymphocyte globulin. With the latter, the reticulocyte peak is delayed approximately 2 days. Cyclosporin immunosuppression, however, may be associated with slower correction of the anemia ([290]). In approximately 20% of transplant patients, erythrocytosis follows correction of the anemia ([285]). This complication is discussed in Chapter 49 and can sometimes be avoided by pretransplant use of erythropoietin ([290]).

Dialysis Most patients with end-stage renal disease are maintained on dialysis. As a modality for managing anemia, dialysis has been essentially eclipsed by the availability of erythropoietin and is primarily of interest because the mild increment observed in hemoglobin concentration provides circumstantial evidence for the role of circulating inhibitors. Red cell production increases slightly in patients on hemodialysis, with attendant small increases in hematocrit and decreases in transfusion requirement ([291]). As a general rule, anemia is less severe in patients receiving peritoneal dialysis, with consequently lower erythropoietin and transfusion requirements ([292] , [293] , [294] , [295] , [296] and [297]). Increments in hemoglobin in the absence of erythropoietin are gradual and of modest extent: They are accompanied by an increase in red cell mass and a reduction in plasma volume ([295]). The reasons for the beneficial effects of peritoneal dialysis on erythropoiesis are not firmly established. An increase in erythropoietin production has been reported ([294]), whereas other data suggest that removal of inhibitors in the “middle molecule” range (500 to 1500 daltons) is the important mechanism ([298]). In the erythropoietin era, the importance of other treatments for anemia of renal disease, such as androgens or the use of transfusion only, has become of primarily historical interest. Certainly, the risks of bloodborne infections and of iron overload are significantly increased by the use of transfusion ([291]).

ANEMIA IN CIRRHOSIS AND OTHER LIVER DISEASES

Some degree of anemia is commonly observed in patients with liver disease. Although it has been studied most extensively in patients with alcohol-induced cirrhosis (Laënnec cirrhosis), changes in red cell morphology and other contributors to anemia have been observed in various other liver diseases, including biliary cirrhosis ([299]), hemochromatosis ([88]), postnecrotic cirrhosis, and acute hepatitis ([300]). When the term *anemia of liver disease* is used, it refers to the mild to moderate anemia associated with liver disease in the absence of any complicating factors such as blood loss, marrow suppression by exogenous agents, or nutritional deficiency. This syndrome apparently results from a combination of intravascular dilution due to hypervolemia, shortened red cell survival, and impaired ability of the marrow to respond optimally to the anemia. In addition, some patients develop a severe hemolytic anemia associated with morphologically abnormal erythrocytes (spur cells). Hemolytic anemia associated with Wilson disease is discussed in Chapter 38.

The anemia actually observed in patients with liver disease reflects both the “uncomplicated” anemia discussed above and the consequences of factors extrinsic to the liver itself. Alcohol abusers can develop a characteristic sideroblastic anemia, often accompanied by impaired folate metabolism or overt folate deficiency (see Chapter 43), or may have direct suppression of hematopoiesis by alcohol ([301]). Individuals with cirrhosis of any etiology are at increased risk for hemorrhage. Blood loss occurs in 24 to 70% of patients with alcoholic cirrhosis ([88]). The upper gastrointestinal tract is the major site of bleeding, but loss of blood from the nose, hemorrhoids, and uterus often occurs in association with coagulopathy of hepatic origins.

Prevalence and Clinical Manifestations

Approximately 75% of patients with chronic liver disease develop anemia as defined by a reduction in the hematocrit or hemoglobin level ([87] , [88] , [302]). The whole blood volume in liver disease (especially cirrhosis) averages 10 to 15% greater than normal; thus, hemodilution tends to exaggerate the prevalence and degree of anemia ([87] , [88] , [303]). For the same reason, the hematocrit may be decreased despite a normal red cell mass. The majority of cirrhotic patients are described as anemic, but in only 30 to 40% is the red cell mass reduced ([87] , [303]). Patients with more severe liver disease and bleeding tend to have reduced red cell mass ([88]). The magnitude of the hypervolemia in cirrhosis appears to be related to the degree of portal hypertension, but not to the presence or absence of ascites (Table 47.3).

TABLE 47.3. Changes in Blood Volume in Patients with Cirrhosis

Measurement	Normal Subjects	Patients with Cirrhosis	
		Without Ascites	With Ascites
Hematocrit	0.42	0.35	0.34
Red cell mass (ml/kg)	23	20	19
Plasma volume (ml/kg)	42	57	55
Whole blood volume (ml/kg)	65	74	74

NOTE: Values are means of 24 normal subjects, 63 patients with cirrhosis and no ascites, and 34 patients with cirrhosis and ascites. All groups included approximately twice as many men as women.
Data from Lieberman FL, Reynolds TB. Plasma volume in cirrhosis of the liver. J Clin Invest 1967;46:1297–1308, with permission.

The anemia is usually mild to moderate. In cirrhotic patients, the hemoglobin level averages around 12 g/dl or the hematocrit around 0.36 ([88] , [303]). The hemoglobin level rarely falls below 10 g/dl in the absence of bleeding or severe hemolysis. Approximately 5% of liver disease patients, all of whom have relatively severe hepatocellular disease, develop spur cell hemolytic anemia and hemoglobin concentrations less than 10 g/dl ([304]). Spur cell anemia may be seen chronically with cirrhosis, or it may develop rapidly in association with fulminant hepatic failure. Morphologic and hemolytic abnormalities may resolve or diminish if liver function

improves. Spur cell anemia can also occur in infants with cholestatic liver disease ([305]).

Episodic hemolysis can occur in association with alcoholic liver disease even before cirrhosis ([306], [307]). These episodes are typically related to binge drinking, are usually mild to moderate in severity, and tend to resolve in 2 to 4 weeks if the patient abstains. Splenomegaly is not a major finding in these patients. When accompanied by jaundice and hyperlipidemia, the condition is known as *Zieve syndrome* ([308], [309]). It is unclear whether this transient form of hemolysis in liver disease is a syndrome of discrete and characteristic pathogenesis or simply a coincident constellation of abnormalities to which patients with liver disease are prone anyway. The clinical diagnosis of hemolysis in alcoholic liver disease is problematic in any event, because interruption of alcohol intake is frequently accompanied by reticulocytosis, and liver disease of any etiology may be associated with jaundice.

Hematologic Findings

More often than not, anemia of liver disease is mildly macrocytic: The MCV rarely exceeds 115 fl in the absence of megaloblastic changes in the bone marrow ([86], [87]). When macrocytosis (particularly with very elevated MCVs) is found in patients with liver disease, complicating folate deficiency or stimulated erythropoiesis must be suspected, but such findings may not explain the macrocytosis observed in patients with milder forms of the disease ([310]). The reported proportion of patients with liver disease who have increased MCV varies from 33 to 65% ([88], [302], [311], [312]). Even more common is “thin” macrocytosis—an increase in mean cell diameter with a normal mean cell volume. In one study of 222 patients with various kinds of liver disease, the mean cell diameter was increased in 137 (62%) ([313]). The patients were classified into three groups: thin macrocytosis (81 patients), target macrocytosis (39 patients), and thick macrocytosis (17 patients). The MCV was increased only in the last group. In a sense, thin macrocytes and target macrocytes are the mirror image of the microspherocytes observed in autoimmune hemolysis. The latter result from a decreased membrane pulled more tightly over a constant volume; the former result from a membrane that is more abundant.

The reticulocyte count often is increased, but this depends on the point in the natural history of disease at which it is measured. In one series, the mean reticulocyte percent of all anemic cirrhotic patients was only 2.8 ([87]). However, erythropoiesis can be transiently suppressed by alcohol, and after acute alcohol withdrawal, reticulocyte percentages in the 8 to 10% range are not uncommon ([301], [311], [314]). Sustained reticulocytosis of 15% or more is unusual in the absence of hemorrhage, spur cell anemia, or other complicating conditions.

Target cells and cells with increased diameters are evident on blood smear (Fig. 47.6). The cells appear hypochromic, but the appearance is related to the thinness of the cell rather than to reduced hemoglobin concentration. These morphologic changes are accompanied by increased resistance to hemolysis in osmotic fragility tests ([313], [315]). When spur cell hemolytic anemia supervenes, characteristic acanthocytes—erythrocytes covered with five to ten spikelike projections—are evident. The acanthocytes are morphologically indistinguishable from the distorted erythrocytes found in patients with abetalipoproteinemia. Stomatocytes are sometimes observed in association with the transient hemolytic episodes associated with acute fatty liver disease ([316]), but they are also noted in alcoholics who display no evidence of hemolysis ([307]).

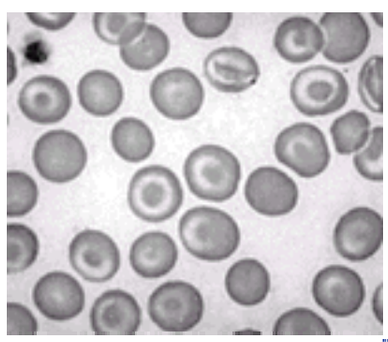

Figure 47.6. Macrocytes and target cells in liver disease (×1500). See Color Plate.

Approximately 50% of patients with cirrhosis have mild thrombocytopenia, but values less than 50 × 10^9/L are uncommon ([87], [302]). A variety of leukocyte abnormalities may be observed; in a study of 25 patients, 16 had lymphopenia, 4 had neutropenia, and 12 had neutrophilia ([302]). Severe pancytopenia associated with splenomegaly in liver disease (Banti syndrome) is discussed in the following section.

Bone marrow cellularity is normal or increased ([88], [302], [312]). Often, erythroid hyperplasia is observed. Red cell precursors at times have been described as *macronormoblasts*, a term that implies their size is increased, but their nuclear chromatin appears normal ([302], [312], [317]). Frank megaloblastosis is seen in less than 20% of patients.

Pathogenesis

SHORTENED ERYTHROCYTE SURVIVAL Red cell survival is decreased in approximately two-thirds of patients with alcoholic liver disease. The precise extent to which this occurs varies depending on the technique used to measure survival, but it is usually of only moderate degree ([87], [88], [300]). Shorter survival tends to be observed in more anemic patients. When indirect bilirubinemia is observed in a liver disease patient (elevated total bilirubin with >70% indirect), erythrocyte survival is particularly likely to be reduced ([319]). Erythrocyte survival also was significantly shortened in patients with biliary cirrhosis ([299]), obstructive jaundice, and infectious hepatitis ([300], [319]), even in the absence of anemia. The mechanism for the observed decrease in red cell lifespan is not fully understood; it is most probably multifactorial. Results of cross-transfusion studies demonstrate improved survival when patients' cells are transfused to normal recipients, suggesting that the hemolytic mechanism is extracorpuscular (i.e., not intrinsic to the erythrocyte) ([318]). Congestive splenomegaly and splenic sequestration are major suspects in this category ([88], [306], [311], [320], [321]), although it cannot always be demonstrated ([88]). In a few patients, correction of the hemolytic process was noted after splenectomy ([322]). Abnormal erythrocyte metabolism is a possible intracorpuscular factor leading to reduced erythrocyte survival in liver disease. Activity of the methylene blue–stimulated pentose phosphate shunt is decreased, with consequent glutathione instability and a tendency to form Heinz bodies ([323], [324]). This metabolic abnormality renders the cell sensitive to oxidant hemolysis, but whether this form of hemolysis is an important mechanism of shortened erythrocyte survival in liver disease is uncertain, because a comparable shunt defect in most patients with glucose-6-phosphate dehydrogenase deficiency does not lead to hemolysis unless oxidant drugs are encountered. However, oxidant drugs can produce hemolysis in liver disease, as when patients with hepatitis C are treated with ribavirin ([325]). Another metabolic abnormality encountered occasionally in liver disease is hypophosphatemia, with reduced erythrocyte adenosine triphosphate levels and consequent hemolysis ([326]). Characteristic alterations in red cell membrane lipids are found in patients with hepatitis, cirrhosis, and obstructive jaundice and may also be another contributor to shortened red cell survival ([306], [315], [327], [328] and [329]). In the usual uncomplicated case, a 25 to 50% increase in both cholesterol and lecithin is noted in the membrane. These changes result in an increased cell-surface area associated with the target cells or thin macrocytes that are so characteristic of liver disease. The loss of sialic acid from the red cell surface may contribute to impaired viability of the cell ([330]). Bile duct obstruction leads to an increase in the activity of neuraminidases, enzymes that remove sialic acid. However, it is not proven that such abnormalities shorten red cell survival ([306]). In spur cell hemolytic anemia, the erythrocyte membrane accumulates excess cholesterol without a corresponding increase in lecithin, resulting in the characteristic morphologic abnormality. This change is accompanied by pronounced reduction in erythrocyte survival, probably because the distorted cells are less deformable than normal and thus become trapped by splenic macrophages. Passage through the spleen causes loss of cell surface with transformation of echinocytes to acanthocytes ([320], [331]), but in fact, the spleen is not required for development of spur cells ([332]). Splenectomy may ameliorate severe hemolysis ([320]). The mechanism whereby the red cell lipid pattern becomes altered is not well understood. One possible factor is an alteration in the cholesterol to phospholipid ratio in high-density plasma lipoproteins, because mature erythrocytes are unable to synthesize lipids and depend largely on plasma lipids for replenishment ([333]). In addition, the process of red cell phospholipid repair appears to be defective in spur cell anemia ([334]). Phospholipid biosynthesis is inhibited and therefore cannot compensate for the increased membrane cholesterol characteristic of liver disease. Other potential contributors to altered erythrocyte membrane lipids in liver disease are changes in plasma lecithin-cholesterol acyltransferase activity, retention of lytic bile acids ([306]), and an increase in the intrinsic proteolytic activity of the membrane ([335]). Zieve syndrome has been mentioned in the section Prevalence and Clinical Manifestations. It has been proposed that the transient hemolytic anemia in this syndrome is caused by the lytic action of certain plasma lipids ([308]). However, hypertriglyceridemia by itself does not cause hemolysis ([329], [336]); erythrocyte lipids in these patients are similar to those described in patients with only a modest hemolytic component ([329]); and hemolytic anemia may occur in patients with acute fatty liver

disease even if plasma triglyceride levels are not increased ([307]). Alcohol-induced vitamin E deficiency with decreased polyunsaturated fatty acids in membrane lipids may play a role in some patients ([336]); similar findings have been reported in vitamin E–deficient children ([337]).
ERYTHROPOIESIS In addition to the shortened erythrocyte survival, the marrow response to the anemia in patients with liver disease may be inadequate. Plasma iron turnover, red cell iron utilization, and erythrocyte iron turnover were normal or reduced in the majority of patients in one series, whereas these parameters were increased two- to threefold in another ([88] , [338]). The presence or absence of complications may explain such discrepancies. Alcohol, in particular, depresses erythropoiesis, and if the patient is studied before the effects of alcohol ingestion subside, marrow function appears depressed ([314]). Serum from cirrhotic patients can suppress hematopoietic colony formation *in vitro* ([339]), and cytokines implicated in inhibition of erythropoiesis have been found to be increased in patients with liver disease ([340]). Dyserythropoiesis with morphologic abnormalities and intramedullary hemolysis has also been reported in severe liver disease ([341]). It has been suggested that extrarenal erythropoietin by the liver is abnormal in patients with liver disease, but in fact, the expected inverse relationship between hemoglobin and erythropoietin production has been found to be preserved in liver disease and to result in levels appropriate for the degree of anemia ([342] , [343]).

ANEMIAS ASSOCIATED WITH ENDOCRINE DISORDERS

A mild to moderate anemia commonly accompanies disorders affecting the thyroid, adrenals, parathyroids, gonads, or pituitary. It is usually not associated with symptomatology (other than that associated with the underlying endocrinopathy) and in fact may reflect a physiologically appropriate hemoglobin concentration because the hormone deficiency often results in reduced oxygen requirements. The anemia is therefore “adaptive” ([344]). In consultative hematology practice, these individuals present as referrals for evaluation of moderate anemia with normal iron, B_{12}, and folate studies, generally with a question from the referring doctor of whether marrow examination is required. The endocrine disorder is typically undiagnosed at time of referral.

Hypothyroidism

Anemia is observed in 21 to 60% of hypothyroid patients and is more common in hypothyroid men than in hypothyroid women ([345]). The anemia observed may be normocytic and normochromic, hypochromic and microcytic, or macrocytic. The last category comprises roughly one-third of anemic patients in most reported series; the frequency of the other two morphologic types varies considerably in different reports (Table 47.4; [344] , [346] , [347] , [348] and [349]).

TABLE 47.4. Incidence of Various Types of Anemia Morphologies in Patients with Myxedema

Type of Anemia	Reference 348 (%)	Reference 345 (%)
Normocytic, normochromic	4	13.5
Hypochromic, microcytic	14	4.5
Macrocytic	13	8
All anemias	31	26

The uncomplicated anemia of hypothyroidism is either normocytic or slightly macrocytic, as is suggested by the predominance of these findings in most series ([345] , [347] , [348]). Hypochromic microcytic anemia found in association with hypothyroidism should be considered iron deficiency until proven otherwise ([344] , [345] , [348]). Biochemical markers of iron deficiency are present: The anemia responds (at least in part) to iron therapy, even if thyroid hormone is not administered, but does not typically respond to thyroid hormone without iron ([345]). Iron deficiency in hypothyroidism may be normocytic, so an important step is to determine the serum iron, transferrin, and ferritin concentrations. Hypothyroid individuals are more likely to become iron deficient because of predisposition to menorrhagia ([349]) and achlorhydria ([348]) and because thyroid hormone itself may be essential for normal iron absorption ([345]). Severely macrocytic anemia usually results from complicating deficiency of vitamin B_{12} ([348]) or folate ([347]).

When patients with iron, folate, or vitamin B_{12} deficiency are excluded, the remaining individuals should be considered to have so-called uncomplicated anemia of hypothyroidism, which is a manifestation of the hormone deficiency itself ([347] , [348]). All or nearly all children with anemia and hypothyroidism have the uncomplicated form of the syndrome ([350]). Anemia usually affects children whose height is below the third percentile. The anemia usually is mild, with the hematocrit rarely falling below 0.35. The plasma volume often is decreased, which tends to make the reduction in hematocrit less than might be expected for a given decrease in red cell mass ([348] , [351]). The degree of anemia is related to both the severity and the duration of the hypothyroidism ([352]). The hematocrit declines for as long as 6 months after thyroidectomy in previously euthyroid subjects, even though the basal metabolic rate remains at a stable reduced level.

The MCV may be increased in hypothyroid patients, even in the absence of anemia ([345]). Anisocytosis, poikilocytosis, and other red cell morphologic abnormalities are uncommon, but acanthocytes are apparent in approximately 20% of patients ([344]). Usually, the leukocyte and platelet counts are within the normal range, although both may be slightly reduced ([352]). The bone marrow may be mildly hypoplastic, but the myeloid to erythroid ratio is not significantly altered ([353] , [354]). Hemoglobin A_2 levels are reduced slightly ([355]).

PATHOGENESIS The anemia of hypothyroidism results from decreased red cell production. Erythrocyte survival is normal or even slightly prolonged in humans ([348] , [356]), but plasma iron transport and erythrocyte iron turnover rates are reduced, indicating subnormal red cell production ([192] , [356]). As noted earlier, the anemia of hypothyroidism is considered “adaptive”—that is, a physiologic adjustment to the reduced needs of the organism for oxygen ([344]). Erythropoietin secretion is reduced in hypothyroid patients ([357]), and 2,3-DPG levels are not increased ([358]) as occurs in most anemias and hypoxic states. Thyroid hormones can enhance erythropoiesis *in vitro* and presumably *in vivo* as well ([359]). The observation that the noncalorigenic d-isomer of triiodothyronine can stimulate erythropoiesis without altering oxygen consumption has been cited as evidence of a hormonal effect that is not oxygen dependent ([360]). The response of anemia of hypothyroidism to thyroid hormone is gradual. No striking reticulocytosis occurs, and the hematocrit returns to a normal value only gradually over approximately a 6-month period (range, 3 to 12 months) ([345] , [348]). The MCV almost always decreases, regardless of its initial value or the presence or degree of anemia, and stabilizes after 4 to 6 months or more ([345]).

Hyperthyroidism

A mild anemia with no other apparent etiology occurs in 10 to 25% of patients with hyperthyroidism ([361] , [362]). Anemia is primarily observed in individuals with severe or prolonged hyperthyroidism ([362]). More typically, the hemoglobin value falls somewhat but remains within normal limits ([361]). The anemia of hyperthyroidism is in many ways the mirror image of that observed in hypothyroidism. MCV is either normal or modestly decreased and, consistent with the comparison to hypothyroidism, may be decreased even in the absence of anemia ([361]). Hemoglobin A_2 levels are slightly increased but not as much as in thalassemia ([355]). Both the anemia and the microcytosis are corrected when the hyperthyroidism is successfully treated; on average, the hemoglobin increases 0.5 g/dl, and the MCV increases 6 fl.

The pathogenesis of anemia and microcytosis of hyperthyroidism is not well understood. Plasma volume may be increased, suggesting dilution ([351]). Erythropoiesis usually is accelerated but ineffective ([362] , [363]). Some (but not all) investigators report increased levels of erythrocyte 2,3-DPG ([358] , [364] , [365]). Such a change would reduce oxygen affinity and improve oxygen delivery, thereby compensating for the reduced hemoglobin level. Increased plasma erythropoietin levels have been reported ([366])—the opposite of what has been described for hypothyroidism.

Adrenal Insufficiency

Although anemia (in the sense of a decreased red cell mass) is common and probably nearly universal in adrenal insufficiency, it may be masked by the dehydration characteristic of this syndrome ([367] , [368]). In a series of patients with untreated Addison disease, the average blood hemoglobin level was 13.2 g/dl (range, 9.4 to 18.0

g/dl) ([369]). The red cells were normocytic and normochromic. After institution of hormone replacement, the average hemoglobin fell to 10.7 g/dl and the hematocrit from 0.42 to 0.33, presumably reflecting the expansion of plasma volume associated with clinical improvement. Later in the course of the disease, reticulocytosis and a return to normal hemoglobin levels occurred ([369]). Pernicious anemia is observed in 3 to 16% of cases of nontuberculous adrenal insufficiency and may complicate 13% of adrenal insufficiency cases associated with the polyglandular autoimmune syndrome type I ([370] , [371]).

Androgen Deficiency

After puberty, values for the hematocrit, blood hemoglobin concentration, and red cell count average approximately 10 to 13% higher in men than in women (see Appendix A). In castrated men, these values fall to within the normal female range ([372] , [373]). This is almost certainly due to a difference in erythropoietin production ([374]), although the relationship between hemoglobin and erythropoietin concentration does not differ between the sexes. After the sixth decade, male hemoglobin values fall back toward those observed in women ([375]). The anemia in these patients is corrected by androgen replacement.

The differences in red cell parameters between the sexes are accounted for chiefly by the stimulating effect of androgens on erythropoiesis. In addition, some observers suggest that estrogens exert a suppressive effect. Thus, castration of male rats precipitates a decrease in hemoglobin, whereas castration of female rats brings about an increase ([376] , [377] and [378]). The administration of androgens to castrated males restores male values for hemoglobin concentration. Androgens can also stimulate erythropoiesis in normal subjects (see Chapter 50). In normal men, testosterone enanthate induced an average red cell mass increase of 1.7 to 2.3 ([379]). The increase in hematocrit was of smaller magnitude (from 0.456 to 0.494), probably because the plasma volume also increased. Androgens act by increasing renal synthesis of erythropoietin ([372] , [380]). Estrogens produce anemia when given in large amounts to rats ([381] , [382]). It has been suggested that this effect results from suppression of hepatic synthesis of erythropoietin, but it may also simply represent opposition to androgen effects in general.

Hypopituitarism

Moderately severe anemia is a well-recognized feature of pituitary insufficiency, regardless of cause. In an extensive review of cases of Simmonds disease in the first half of the twentieth century, the average blood hemoglobin concentration was approximately 10 g/dl, with similar values reported in patients with hypopituitarism that arose from neoplasms ([383] , [384] and [385]). Anemia is also evident in prepubertal pituitary dwarfs but tends to be underappreciated because of contracted plasma volume ([386] , [387]). The anemia usually is normocytic and normochromic, and the red cells appear normal morphologically. In some patients, slight hypochromia or macrocytosis has been observed ([384] , [388]); however, complicating deficiencies of iron or folate were not excluded. Results of kinetic studies demonstrate reduced red cell production ([386] , [389]).

The anemia of hypopituitarism results chiefly from deficiencies of the hormones of target glands controlled by the pituitary, especially the thyroid and adrenal hormones, but also from deficiency of androgens. In addition, lack of other pituitary factors, such as growth hormone ([386] , [387] , [390]), prolactin ([391]), or factors characterized less clearly ([392]), may be of importance. The interrelations of these various hormones have been studied experimentally in animals, especially the rat. In this species, hypophysectomy results in a moderately severe, slightly hypochromic and microcytic anemia ([390] , [393]) associated with a pronounced decrease in erythroid elements in the bone marrow ([394]). No hemolysis has been reported. Combined adrenalectomy and thyroidectomy results in an anemia that is similar, but not identical, to that noted after hypophysectomy ([390] , [395]).

As suggested for the anemia of hypothyroidism, panhypopituitarism probably produces its effects on erythropoiesis chiefly by reducing tissue oxygen consumption ([390]). The organism reacts to this decreased need for oxygen by secreting less erythropoietin, and the red cell mass diminishes until a new equilibrium between oxygen supply and demand is established. This hypothesis is supported by the observations that (a) tissue oxygen consumption is low in the hypophysectomized rat, even if the red cell mass is restored to normal levels ([390]); (b) once equilibrium is established, the marrow of the hypophysectomized animal responds to hypoxia, bleeding, or cobalt administration ([390] , [396]); (c) correlation between oxygen consumption and rate of erythropoiesis is apparent in hypophysectomized animals given thyroxine or 2,4-dinitrophenol ([391]); and (d) erythrocyte 2,3-DPG levels, which increase when tissue oxygen delivery is compromised, are normal in patients with panhypopituitarism ([387]).

Treatment with a combination of thyroxine, cortisone, and growth hormone corrects both the anemia and the marrow hypoplasia ([390]) and is more effective than any single hormone by itself. In one reported case of panhypopituitarism secondary to craniopharyngioma, anemia persisted and progressed despite replacement hormone therapy. Administration of recombinant human erythropoietin (6000 IU/day) was followed by correction of the anemia, with the blood hemoglobin level rising from 6 g/dl to normal over a 3-month period ([397]).

Hyperparathyroidism

Secondary hyperparathyroidism as a contributor to anemia of renal failure has been discussed earlier. Anemia is a rare complication of primary hyperparathyroidism ([398]). At one institution, 17 of 332 patients (5.1%) with primary hyperparathyroidism were anemic, with hematocrit values ranging from 0.23 to 0.37 ([399]). None had leukopenia or thrombocytopenia. The anemia was normocytic and normochromic, and no reticulocytosis was evident. Five patients had bone marrow examinations. Four of these patients had 25% or more of their marrow replaced by fibrosis. Anemic patients appeared to have relatively severe hyperparathyroidism as judged by the presence of bone cysts, subperiosteal bone resorption, and particularly high values for serum calcium, alkaline phosphatase, and parathyroid hormone. The hematocrit increased in all seven patients who underwent parathyroidectomy; in six patients, it became normal ([399]).

The cause of the anemia in these patients remains obscure. Although renal failure and gastrointestinal bleeding occur in association with hyperparathyroidism, they could not be implicated as an etiologic factor in this group of anemic patients, nor was incidental iron deficiency evident. Some authors conclude that parathyroid hormone decreases proliferation of erythroid precursors in culture ([221]). Marrow fibrosis may also be a result of excess hormone levels ([222] , [224]). Myelofibrosis is a common finding in bone marrow biopsy specimens, but the usual morphologic signs of myelophthisis are lacking ([398]).

When hyperparathyroidism is secondary to renal disease, it is difficult to ascertain the relative importance of the hormone excess versus the erythropoietin deficit characteristic of renal failure as a contributor to the observed anemia. Of note, however, is that medical treatment of hyperparathyroidism with vitamin D_3 can bring about improvement in anemia and decreased requirement for erythropoietin in some patients ([278]).

Anorexia Nervosa

Anemia is observed in as many as 84% of patients with anorexia nervosa admitted to the hospital ([400] , [401]). A moderate degree of leukopenia or thrombocytopenia may also be observed. The peripheral blood smear shows a striking campsite process, and bone marrow examination shows gelatinous transformation with necrosis, as well as decreased cellularity in most cases ([400] , [401] and [402]). These are essentially the findings observed in starvation, and they return to normal with improved nutrition ([400] , [401]).
